Macmillan Learning

In 1946, William Freeman founded W. H. Freeman and Company and published Linus Pauling's *General Chemistry*, which revolutionized the chemistry curriculum and established the prototype for a Freeman text. W. H. Freeman quickly became a publishing house where leading researchers can make significant contributions to mathematics and science. In 1996, W. H. Freeman joined Macmillan and we have since

proudly continued the legacy of providing revolutionary, quality educational tools for teaching and learning in STEM.

To my parents, Rush and Amanda Pierce; my children, Sarah Pierce Dumas and Michael Pierce; and my genetic partner, friend, and soul mate for 39 years, Marlene Tyrrell

Contents in Brief

1 Introduction to Genetics

2 Chromosomes and Cellular Reproduction

3 Basic Principles of Heredity

4 Sex Determination and Sex-Linked Characteristics

5 Extensions and Modifications of Basic Principles

6 Pedigree Analysis, Applications, and Genetic Testing

7 Linkage, Recombination, and Eukaryotic Gene Mapping

8 Chromosome Variation

9 Bacterial and Viral Genetic Systems

10 DNA: The Chemical Nature of the Gene

11 Chromosome Structure and Organelle DNA

12 DNA Replication and Recombination

13 Transcription

14 RNA Molecules and RNA Processing

15 The Genetic Code and Translation

16 Control of Gene Expression in Bacteria

17 Control of Gene Expression in Eukaryotes

18 Gene Mutations and DNA Repair

19 Molecular Genetic Analysis and Biotechnology

20 Genomics and Proteomics

21 Epigenetics

22 Developmental Genetics and Immunogenetics

23 Cancer Genetics

24 Quantitative Genetics

25 Population Genetics

26 Evolutionary Genetics

Reference Guide to Model Genetic Organisms

Working with Fractions: A Review

Glossary

Answers to Selected Problems

Index

Contents

Letter from the Author

Preface

Chapter 1 Introduction to Genetics

Albinism in the Hopis

1.1 Genetics Is Important to Us Individually, to Society, and to the Study of Biology

- The Role of Genetics in Biology
- Genetic Diversity and Evolution
- DNA in the Biosphere
- Divisions of Genetics
- Model Genetic Organisms

1.2 Humans Have Been Using Genetic Techniques for Thousands of Years

- The Early Use and Understanding of Heredity
- The Rise of the Science of Genetics
- The Cutting Edge of Genetics

1.3 A Few Fundamental Concepts Are Important for the Start of Our Journey into Genetics

Chapter 2 Chromosomes and Cellular Reproduction

The Blind Men's Riddle

2.1 Prokaryotic and Eukaryotic Cells Differ in a Number of Genetic Characteristics

2.2 Cell Reproduction Requires the Copying of the Genetic Material, Separation of the Copies, and Cell Division

- Prokaryotic Cell Reproduction by Binary Fission
- Eukaryotic Cell Reproduction
- The Cell Cycle and Mitosis
- Genetic Consequences of the Cell Cycle

CONNECTING CONCEPTS **Counting Chromosomes and DNA Molecules**

2.3 Sexual Reproduction Produces Genetic Variation Through the Process of Meiosis

- Meiosis
- Sources of Genetic Variation in Meiosis

CONNECTING CONCEPTS **Mitosis and Meiosis Compared**

- The Separation of Sister Chromatids and Homologous Chromosomes
- Meiosis in the Life Cycles of Animals and Plants

Chapter 3 Basic Principles of Heredity

The Genetics of Blond Hair in the South Pacific

3.1 Gregor Mendel Discovered the Basic Principles of Heredity

- Mendel's Success
- Genetic Terminology

3.2 Monohybrid Crosses Reveal the Principle of Segregation and the Concept of Dominance

What Monohybrid Crosses Reveal

The Molecular Nature of Alleles

CONNECTING CONCEPTS **Relating Genetic Crosses to Meiosis**

Predicting the Outcomes of Genetic Crosses

The Testcross

Genetic Symbols

CONNECTING CONCEPTS **Ratios in Simple Crosses**

3.3 Dihybrid Crosses Reveal the Principle of Independent Assortment

Dihybrid Crosses

The Principle of Independent Assortment

Relating the Principle of Independent Assortment to Meiosis

Applying Probability and the Branch Diagram to Dihybrid Crosses

The Dihybrid Testcross

3.4 Observed Ratios of Progeny May Deviate from Expected Ratios by Chance

The Chi-Square (χ^2) Goodness-of-Fit Test

Chapter 4 Sex Determination and Sex-Linked Characteristics

The Sex of a Dragon

4.1 Sex Is Determined by a Number of Different Mechanisms

Chromosomal Sex-Determining Systems

Genic Sex Determination

Environmental Sex Determination

Sex Determination in *Drosophila melanogaster*

Sex Determination in Humans

4.2 Sex-Linked Characteristics Are Determined by Genes on the Sex Chromosomes

X-Linked White Eyes in *Drosophila*

Nondisjunction and the Chromosome Theory of Inheritance

X-Linked Color Blindness in Humans

Symbols for X-Linked Genes

Z-Linked Characteristics

Y-Linked Characteristics

CONNECTING CONCEPTS **Recognizing Sex-Linked Inheritance**

4.3 Dosage Compensation Equalizes the Amount of Protein Produced by X-Linked and Autosomal Genes in Some Animals

The Lyon Hypothesis

Mechanism of Random X Inactivation

Chapter 5 Extensions and Modifications of Basic Principles

The Odd Genetics of Left-Handed Snails

5.1 Additional Factors at a Single Locus Can Affect the Results of Genetic Crosses

Types of Dominance

Penetrance and Expressivity

Lethal Alleles

Multiple Alleles

5.2 Gene Interaction Takes Place When Genes at Multiple Loci Determine a Single Phenotype

Gene Interaction That Produces Novel Phenotypes

Gene Interaction with Epistasis

CONNECTING CONCEPTS **Interpreting Phenotypic Ratios Produced by Gene Interaction**

Complementation: Determining Whether Mutations Are at the Same Locus or at Different Loci

The Complex Genetics of Coat Color in Dogs

5.3 Sex Influences the Inheritance and Expression of Genes in a Variety of Ways

Sex-Influenced and Sex-Limited Characteristics

Cytoplasmic Inheritance

Genetic Maternal Effect

Genomic Imprinting

5.4 Anticipation Is the Stronger or Earlier Expression of Traits in Succeeding Generations

5.5 Phenotypes May Be Influenced by Environmental Factors and Multiple Genes

Environmental Effects on the Phenotype

The Inheritance of Continuous Characteristics

Chapter 6 Pedigree Analysis, Applications, and Genetic Testing

The Mystery of the Missing Fingerprints

6.1 The Study of Genetics in Humans Is Constrained by Special Features of Human Biology and Culture

6.2 Geneticists Often Use Pedigrees to Study the Inheritance of Characteristics in Humans

- Symbols Used in Pedigrees
- Analysis of Pedigrees
- Autosomal Recessive Traits
- Autosomal Dominant Traits
- X-Linked Recessive Traits
- X-Linked Dominant Traits
- Y-Linked Traits
- Genetic Mosaicism

6.3 Studying Twins and Adoptions Can Help Assess the Importance of Genes and Environment

- Types of Twins
- Concordance in Twins
- A Twin Study of Asthma
- Adoption Studies

6.4 Genetic Counseling and Genetic Testing Provide Information to Those Concerned about Genetic Diseases and Traits

- Genetic Counseling

Genetic Testing

Interpreting Genetic Tests

Direct-to-Consumer Genetic Testing

Genealogies and Genetic Testing for Ancestry

Genetic Discrimination and Privacy

Chapter 7 Linkage, Recombination, and Eukaryotic Gene Mapping

Mapping Fear and Aggression in Dogs

7.1 Linked Genes Do Not Assort Independently

7.2 Linked Genes Segregate Together While Crossing Over Produces Recombination Between Them

Notation for Crosses with Linkage

Complete Linkage Compared with Independent Assortment

Crossing Over Between Linked Genes

Calculating Recombination Frequency

Coupling and Repulsion

CONNECTING CONCEPTS **Relating Independent Assortment, Linkage, and Crossing Over**

Evidence for the Physical Basis of Recombination

Predicting the Outcomes of Crosses with Linked Genes

Testing for Independent Assortment

Gene Mapping with Recombination Frequencies

Constructing a Genetic Map with a Two-Point Testcross

7.3 A Three-Point Testcross Can Be Used to Map Three Linked Genes

Constructing a Genetic Map with a Three-Point Testcross

CONNECTING CONCEPTS **Stepping Through the Three-Point Cross**

Effects of Multiple Crossovers

Mapping Human Genes

Mapping with Molecular Markers

Locating Genes with Genome-Wide Association Studies

7.4 Physical-Mapping Methods Are Used to Determine the Physical Positions of Genes on Particular Chromosomes

Somatic-Cell Hybridization

Deletion Mapping

Physical Chromosome Mapping Through Molecular Analysis

7.5 Recombination Rates Exhibit Extensive Variation

Chapter 8 Chromosome Variation

The Complex Genome of Wheat

8.1 Chromosome Mutations Include Rearrangements, Aneuploidy, and Polyploidy

Chromosome Morphology

Types of Chromosome Mutations

8.2 Chromosome Rearrangements Alter Chromosome Structure

Duplications

Deletions

Inversions

Translocations

Fragile Sites

Copy-Number Variations

8.3 Aneuploidy Is an Increase or Decrease in the Number of Individual Chromosomes

Types of Aneuploidy

Effects of Aneuploidy

Aneuploidy in Humans

Uniparental Disomy

Genetic Mosaicism

8.4 Polyploidy Is the Presence of More Than Two Sets of Chromosomes

Autopolyploidy

Allopolyploidy

The Significance of Polyploidy

Chapter 9 Bacterial and Viral Genetic Systems

The Genetics of Medieval Leprosy

9.1 Bacteria and Viruses Have Important Roles in Human Society and the World Ecosystem

Life in a Bacterial World

Bacterial Diversity

9.2 Genetic Analysis of Bacteria Requires Special Methods

Techniques for the Study of Bacteria

The Bacterial Genome

Plasmids

9.3 Bacteria Exchange Genes Through Conjugation, Transformation, and Transduction

Conjugation

Natural Gene Transfer and Antibiotic Resistance

Transformation in Bacteria

Bacterial Genome Sequences

Horizontal Gene Transfer

9.4 Bacterial Defense Mechanisms

Restriction-Modification Systems

CRISPR-Cas Systems

An Evolutionary Arms Race Between Bacteria and Viruses

9.5 Viruses Are Simple Replicating Systems Amenable to Genetic Analysis

Techniques for the Study of Bacteriophages

Transduction

Gene Mapping in Phages

Plant and Animal Viruses

Human Immunodeficiency Virus and AIDS

Influenza

Rhinoviruses

Zika Virus

Chapter 10 DNA: The Chemical Nature of the Gene

Hominin History in Ancient DNA

10.1 Genetic Material Possesses Several Key Characteristics

10.2 All Genetic Information Is Encoded in the Structure of DNA or RNA

- Early Studies of DNA
- DNA as the Source of Genetic Information
- Watson and Crick's Discovery of the Three-Dimensional Structure of DNA
- RNA as Genetic Material

10.3 DNA Consists of Two Complementary and Antiparallel Nucleotide Strands That Form a Double Helix

- The Primary Structure of DNA
- Secondary Structures of DNA

CONNECTING CONCEPTS **Genetic Implications of DNA Structure**

Chapter 11 Chromosome Structure and Organelle DNA

Telomeres and Childhood Adversity

11.1 Large Amounts of DNA Are Packed into a Cell

- Supercoiling
- The Bacterial Chromosome
- Eukaryotic Chromosomes
- Changes in Chromatin Structure

11.2 Eukaryotic Chromosomes Possess Centromeres and Telomeres

Centromere Structure

Telomere Structure

11.3 Eukaryotic DNA Contains Several Classes of Sequence Variation

The Denaturation and Renaturation of DNA

Types of DNA Sequences in Eukaryotes

Organization of Genetic Information in Eukaryotes

11.4 Organelle DNA Has Unique Characteristics

Mitochondrion and Chloroplast Structure

The Endosymbiotic Theory

Uniparental Inheritance of Organelle-Encoded Traits

The Mitochondrial Genome

The Evolution of Mitochondrial DNA

Damage to Mitochondrial DNA Associated with Aging

Mitochondrial Replacement Therapy

The Chloroplast Genome

Movement of Genetic Information Between Nuclear, Mitochondrial, and Chloroplast Genomes

Chapter 12 DNA Replication and Recombination

The Importance of a Good Start

12.1 Genetic Information Must Be Accurately Copied Every Time a Cell Divides

12.2 All DNA Replication Takes Place in a Semiconservative Manner

Meselson and Stahl's Experiment

Modes of Replication

Requirements of Replication

Direction of Replication

CONNECTING CONCEPTS **The Direction of Synthesis in Different Modes of Replication**

12.3 Bacterial Replication Requires a Large Number of Enzymes and Proteins

Initiation

Unwinding

Elongation

Termination

The Fidelity of DNA Replication

CONNECTING CONCEPTS **The Basic Rules of Replication**

12.4 Eukaryotic DNA Replication Is Similar to Bacterial Replication but Differs in Several Aspects

Eukaryotic Origins of Replication

DNA Synthesis and the Cell Cycle

The Licensing of DNA Replication

Unwinding

Eukaryotic DNA Polymerases

Nucleosome Assembly

The Location of Replication Within the Nucleus

Replication at the Ends of Chromosomes

Replication in Archaea

12.5 Recombination Takes Place Through the Alignment, Breakage, and Repair of DNA Strands

Models of Recombination

Enzymes Required for Recombination

Chapter 13 Transcription

Wrecks on the DNA Highway

13.1 RNA, Consisting of a Single Strand of Ribonucleotides, Participates in a Variety of Cellular Functions

An Early RNA World

The Structure of RNA

Classes of RNA

13.2 Transcription Is the Synthesis of an RNA Molecule from a DNA Template

The Template

The Substrate for Transcription

The Transcription Apparatus

13.3 Bacterial Transcription Consists of Initiation, Elongation, and Termination

Initiation

Elongation

Termination

CONNECTING CONCEPTS **The Basic Rules of Transcription**

13.4 Eukaryotic Transcription Is Similar to Bacterial Transcription but Has Some Important Differences

- Transcription and Nucleosome Structure
- Promoters
- Initiation
- Elongation
- Termination

13.5 Transcription in Archaea Is More Similar to Transcription in Eukaryotes Than to Transcription in Bacteria

Chapter 14 RNA Molecules and RNA Processing

A Royal Disease

14.1 Many Genes Have Complex Structures

- Gene Organization
- Introns
- The Concept of the Gene Revisited

14.2 Messenger RNAs, Which Encode Proteins, Are Modified after Transcription in Eukaryotes

- The Structure of Messenger RNA
- Pre-mRNA Processing
- RNA Splicing
- Alternative Processing Pathways
- RNA Editing

CONNECTING CONCEPTS **Eukaryotic Gene Structure and Pre-mRNA Processing**

14.3 Transfer RNAs, Which Attach to Amino Acids, Are Modified after Transcription in Bacterial and Eukaryotic Cells

The Structure of Transfer RNA

Transfer RNA Gene Structure and Processing

14.4 Ribosomal RNA, a Component of the Ribosome, Is Also Processed after Transcription

The Structure of the Ribosome

Ribosomal RNA Gene Structure and Processing

14.5 Small RNA Molecules Participate in a Variety of Functions

RNA Interference

Small Interfering RNAs and MicroRNAs

Piwi-Interacting RNAs

CRISPR RNA

14.6 Long Noncoding RNAs Regulate Gene Expression

Chapter 15 The Genetic Code and Translation

A Child Without a Spleen

15.1 Many Genes Encode Proteins

The One Gene, One Enzyme Hypothesis

The Structure and Function of Proteins

15.2 The Genetic Code Determines How the Nucleotide Sequence Specifies the Amino Acid Sequence of a Protein

Breaking the Genetic Code

The Degeneracy of the Code

The Reading Frame and Initiation Codons

Termination Codons

The Universality of the Code

CONNECTING CONCEPTS **Characteristics of the Genetic Code**

15.3 Amino Acids Are Assembled into a Protein Through Translation

The Binding of Amino Acids to Transfer RNAs

The Initiation of Translation

Elongation

Termination

CONNECTING CONCEPTS **A Comparison of Bacterial and Eukaryotic Translation**

15.4 Additional Properties of RNA and Ribosomes Affect Protein Synthesis

The Three-Dimensional Structure of the Ribosome

Polyribosomes

Messenger RNA Surveillance

Folding and Posttranslational Modifications of Proteins

Translation and Antibiotics

Chapter 16 Control of Gene Expression in Bacteria

Operons and the Noisy Cell

16.1 The Regulation of Gene Expression Is Critical for All Organisms

Genes and Regulatory Elements

Levels of Gene Regulation

DNA-Binding Proteins

16.2 Transcription in Bacterial Cells Is Regulated by Operons

Operon Structure

Negative and Positive Control: Inducible and Repressible Operons

The *lac* Operon of *E. coli*

lac Mutations

Positive Control and Catabolite Repression

The *trp* Operon of *E. coli*

16.3 Some Operons Regulate Transcription Through Attenuation, the Premature Termination of Transcription

Attenuation in the *trp* Operon of *E. coli*

Why Does Attenuation Take Place in the *trp* Operon?

16.4 Other Sequences Control the Expression of Some Bacterial Genes

Bacterial Enhancers

Antisense RNA

Riboswitches

RNA-Mediated Repression Through Ribozymes

Chapter 17 Control of Gene Expression in Eukaryotes

Genetic Differences That Make Us Human

17.1 Eukaryotic Cells and Bacteria Share Many Features of Gene Regulation but Differ in Several Important Ways

17.2 Changes in Chromatin Structure Affect the Expression of Eukaryotic Genes

- DNase I Hypersensitivity
- Chromatin Remodeling
- Histone Modification
- DNA Methylation

17.3 Transcription Is Regulated by Transcription Factors

- Transcription Factors
- Enhancers and Silencers
- Insulators and Regulatory Neighborhoods
- Regulation of Transcriptional Stalling and Elongation
- Coordinated Gene Regulation

17.4 Eukaryotic Genes Are Regulated by RNA Processing and Degradation

- Gene Regulation Through RNA Splicing
- The Degradation of RNA

17.5 RNA Interference Is an Important Mechanism of Gene Regulation

- Small Interfering RNAs and MicroRNAs
- Mechanisms of Gene Regulation by RNA Interference
- The Control of Development by RNA Interference
- RNA Crosstalk

17.6 The Expression of Some Genes Is Regulated by Processes That Affect Translation or by Modifications of Proteins

CONNECTING CONCEPTS **A Comparison of Bacterial and Eukaryotic Gene Control**

Chapter 18 Gene Mutations and DNA Repair

Lou Gehrig and Expanding Nucleotide Repeats

18.1 Mutations Are Inherited Alterations in the DNA Sequence

- The Importance of Mutations
- Categories of Mutations
- Types of Gene Mutations
- Functional Effects of Mutations
- Suppressor Mutations
- Mutation Rates

18.2 Mutations May Be Caused by a Number of Different Factors

- Spontaneous Replication Errors
- Spontaneous Chemical Changes
- Chemically Induced Mutations
- Radiation

18.3 Mutations Are the Focus of Intense Study by Geneticists

- Detecting Mutagens with the Ames Test
- Effects of Radiation Exposure in Humans

18.4 Transposable Elements Can Cause Mutations

- General Characteristics of Transposable Elements
- The Process of Transposition
- The Mutagenic Effects of Transposition

Transposable Elements in Bacteria

Transposable Elements in Eukaryotes

CONNECTING CONCEPTS **Types of Transposable Elements**

Transposable Elements in Genome Evolution

18.5 A Number of Pathways Can Repair DNA

Mismatch Repair

Direct Repair

Base-Excision Repair

Nucleotide-Excision Repair

CONNECTING CONCEPTS **The Basic Pathway of DNA Repair**

Repair of Double-Strand Breaks

Translesion DNA Polymerases

Genetic Diseases and Faulty DNA Repair

Chapter 19 Molecular Genetic Analysis and Biotechnology

Editing the Genome with CRISPR-Cas9

19.1 Genetics Has Been Transformed by the Development of Molecular Techniques

Key Innovations in Molecular Genetics

Working at the Molecular Level

19.2 Molecular Techniques Are Used to Cut and Visualize DNA Sequences

Recombinant DNA Technology

Restriction Enzymes

Engineered Nucleases

CRISPR-Cas Genome Editing

Separating and Viewing DNA Fragments

Locating DNA Fragments with Probes

19.3 Specific DNA Fragments Can Be Amplified

The Polymerase Chain Reaction

Gene Cloning

19.4 Molecular Techniques Can Be Used to Find Genes of Interest

DNA Libraries

In Situ Hybridization

Positional Cloning

19.5 DNA Sequences Can Be Determined and Analyzed

Dideoxy Sequencing

Next-Generation Sequencing Technologies

DNA Fingerprinting

19.6 Molecular Techniques Are Increasingly Used to Analyze Gene Function

Forward and Reverse Genetics

Creating Random Mutations

Targeted Mutagenesis

Transgenic Animals

Knockout Mice

Silencing Genes with RNAi

Using RNAi to Treat Human Disease

19.7 Biotechnology Harnesses the Power of Molecular Genetics

Pharmaceutical Products

Specialized Bacteria

Agricultural Products

Genetic Testing

Gene Therapy

Chapter 20 Genomics and Proteomics

Sequencing Earth's Biodiversity

20.1 Structural Genomics Determines the DNA Sequences and Organization of Entire Genomes

Genetic Maps

Physical Maps

Sequencing an Entire Genome

The Human Genome Project

What Exactly Is the Human Genome?

Single-Nucleotide Polymorphisms

Bioinformatics

Metagenomics

Synthetic Biology

20.2 Functional Genomics Determines the Functions of Genes by Using Genomic Approaches

Predicting Function from Sequence

Gene Expression

Gene Expression and Reporter Sequences

Genome-Wide Mutagenesis

20.3 Comparative Genomics Studies How Genomes Evolve

Prokaryotic Genomes

Eukaryotic Genomes

The Human Genome

20.4 Proteomics Analyzes the Complete Set of Proteins Found in a Cell

Determination of Cellular Proteins

Affinity Capture

Protein Microarrays

Structural Proteomics

Chapter 21 Epigenetics

Epigenetics and the Dutch Hunger Winter

21.1 What Is Epigenetics?

21.2 Several Molecular Processes Lead to Epigenetic Changes

DNA Methylation

Histone Modifications

Epigenetic Effects of RNA Molecules

21.3 Epigenetic Processes Affect Development

Epigenetic Changes Associated with Cell Differentiation

Transgenerational Effects Through Paramutation

X Inactivation

Genomic Imprinting

Epigenetic Effects in Monozygotic Twins

21.4 Epigenetic Alterations Bring about Changes in Behavior, Reproduction, and Metabolism

Behavioral Epigenetics

Epigenetic Effects of Environmental Chemicals

Epigenetic Effects on Metabolism

21.5 The Epigenome

Chapter 22 Developmental Genetics and Immunogenetics

The Origin of Spineless Sticklebacks

22.1 Development Takes Place Through Cell Determination

Cloning Experiments on Plants

Cloning Experiments on Animals

22.2 Pattern Formation in *Drosophila* Serves as a Model for the Genetic Control of Development

The Development of the Fruit Fly

Egg-Polarity Genes

Segmentation Genes

Homeotic Genes in *Drosophila*

Homeobox Genes in Other Organisms

CONNECTING CONCEPTS **The Control of Development**

Epigenetic Changes in Development

Mapping Gene Expression in *Drosophila* Embryos

22.3 Genes Control the Development of Flowers in Plants

Flower Anatomy

Genetic Control of Flower Development

CONNECTING CONCEPTS **Comparison of Development in Drosophila and Flowers**

22.4 Programmed Cell Death Is an Integral Part of Development

22.5 The Study of Development Reveals Patterns and Processes of Evolution

22.6 The Development of Immunity Occurs Through Genetic Rearrangement

The Organization of the Immune System

Immunoglobulin Structure

The Generation of Antibody Diversity

T-Cell-Receptor Diversity

Major Histocompatibility Complex Genes

Genes and Organ Transplants

Chapter 23 Cancer Genetics

Four Families and the Guardian of the Genome

23.1 Cancer Is a Group of Diseases Characterized by Cell Proliferation

Tumor Formation

Cancer as a Genetic Disease

The Role of Environmental Factors in Cancer

23.2 Mutations in Several Types of Genes Contribute to Cancer

Oncogenes and Tumor-Suppressor Genes

Genes That Control the Cell Cycle

DNA-Repair Genes

Genes That Regulate Telomerase

Genes That Promote Vascularization and the Spread of Tumors

MicroRNAs and Cancer

Cancer Genome Projects

23.3 Epigenetic Changes Are Often Associated with Cancer

23.4 Colorectal Cancer Arises Through the Sequential Mutation of a Number of Genes

23.5 Changes in Chromosome Number and Structure Are Often Associated with Cancer

23.6 Viruses Are Associated with Some Cancers

Retroviruses and Cancer

Human Papillomavirus and Cervical Cancer

Chapter 24 Quantitative Genetics

Corn Oil and Quantitative Genetics

24.1 Quantitative Characteristics Are Influenced by Alleles at Multiple Loci

The Relation Between Genotype and Phenotype

Types of Quantitative Characteristics

Polygenic Inheritance

Kernel Color in Wheat

Determining Gene Number for a Polygenic Characteristic

24.2 Statistical Methods Are Required for Analyzing Quantitative Characteristics

Distributions

Samples and Populations

The Mean

The Variance and Standard Deviation

Correlation

Regression

Applying Statistics to the Study of a Polygenic Characteristic

24.3 Heritability Is Used to Estimate the Proportion of Variation in a Trait That Is Genetic

Phenotypic Variance

Types of Heritability

Calculating Heritability

The Limitations of Heritability

Locating Genes That Affect Quantitative Characteristics

24.4 Genetically Variable Traits Change in Response to Selection

Predicting the Response to Selection

Limits to the Response to Selection

Correlated Responses to Selection

Chapter 25 Population Genetics

The Wolves of Isle Royale

25.1 Genotypic and Allelic Frequencies Are Used to Describe the Gene Pool of a Population

Mathematical Models for Understanding Genetic Variation

Calculating Genotypic Frequencies

Calculating Allelic Frequencies

25.2 The Hardy–Weinberg Law Describes the Effect of Reproduction on Genotypic and Allelic Frequencies

Genotypic Frequencies at Hardy–Weinberg Equilibrium

Closer Examination of the Hardy–Weinberg Law

Implications of the Hardy–Weinberg Law

Extensions of the Hardy–Weinberg Law

Testing for Hardy–Weinberg Proportions

Estimating Allelic Frequencies with the Hardy–Weinberg Law

25.3 Nonrandom Mating Affects the Genotypic Frequencies of a Population

25.4 Several Evolutionary Forces Can Change Allelic Frequencies

Mutation

Migration

Genetic Drift

Natural Selection

CONNECTING CONCEPTS **The General Effects of Forces That Change Allelic Frequencies**

Chapter 26 Evolutionary Genetics

Chimpanzees, Bonobos, and the Question of Species

26.1 Evolution Occurs Through Genetic Change Within Populations

Biological Evolution

Evolution as a Two-Step Process

Evolution in Bighorn Sheep

26.2 Many Natural Populations Contain High Levels of Genetic Variation

Molecular Variation

26.3 New Species Arise Through the Evolution of Reproductive Isolation

The Biological Species Concept

Reproductive Isolating Mechanisms

Modes of Speciation

Genetic Differentiation Associated with Speciation

26.4 The Evolutionary History of a Group of Organisms Can Be Reconstructed by Studying Changes in Homologous Characteristics

Interpreting Phylogenetic Trees

The Alignment of Homologous Sequences

The Construction of Phylogenetic Trees

26.5 Patterns of Evolution Are Revealed by Molecular Changes

Rates of Molecular Evolution

The Molecular Clock

Evolution Through Changes in Gene Regulation

Genome Evolution

Reference Guide to Model Genetic Organisms

The Fruit Fly *Drosophila melanogaster*

The Bacterium *Escherichia coli*

The Nematode Worm *Caenorhabditis elegans*

The Plant *Arabidopsis thaliana*

The Mouse *Mus musculus*

The Yeast *Saccharomyces cerevisiae*

Letter from the Author

Marlene Tyrrell

I still remember the excitement I felt when I was in your place, taking my first genetics course. I was intrigued by the principles of heredity, which allow one to predict what offspring will look like even before they are born; I was fascinated to learn that these principles have their foundation in the chemistry of an elegant molecule called DNA; and I was captivated to find that genetics underlies evolution, the process responsible for life's endless diversity and beauty. These elements of genetics still impress and excite me today. One of the great things about teaching genetics is the chance to convey that excitement to students.

This book has been written in different places: in my office at Southwestern University, on the back porch of my home overlooking the hills of central Texas, in the mountains of northern New Mexico, and in airports and hotel rooms around the country. Regardless of location, whenever I write, I try to imagine that I'm sitting with a small group of students, having a conversation about genetics. My goal as the author of *Genetics: A Conceptual Approach* is to have that conversation with you. I want to become a trusted guide on your journey through introductory genetics. In this book, I've tried to share some of what I've learned in my years of teaching genetics. I provide advice and encouragement at places where students often have difficulty, and I tell stories of the people, places, and experiments of genetics—past and present—to keep the subject relevant, interesting, and alive. My goal is to help you learn the necessary details, concepts, and problem-solving skills while

encouraging you to see the elegance and beauty of the larger landscape.

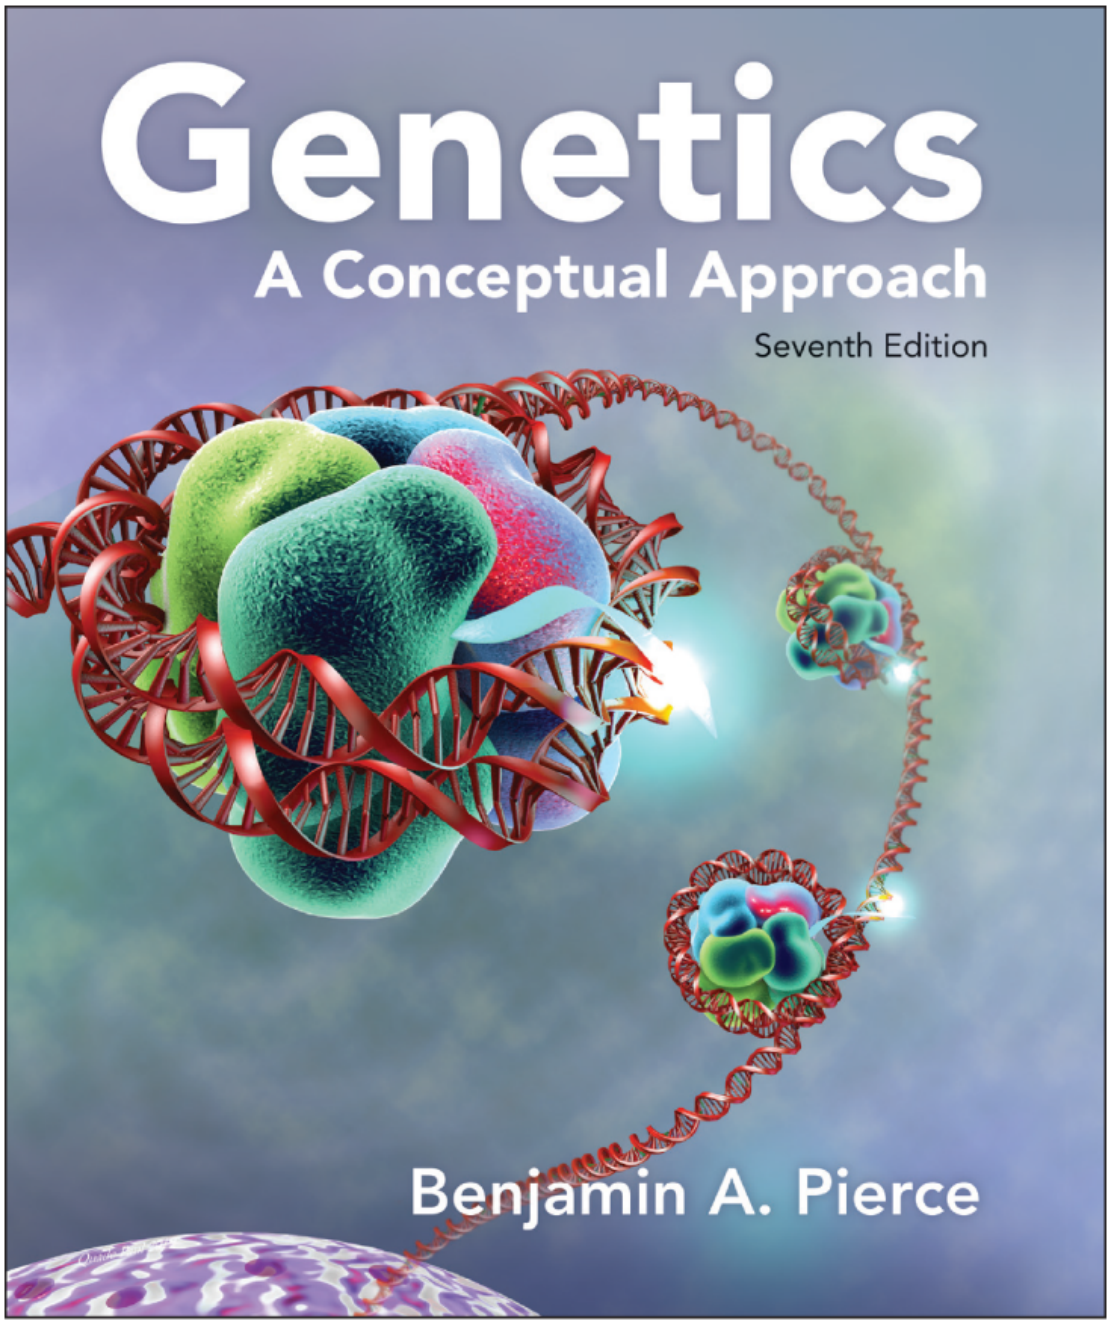
Educational research demonstrates that students learn best when they are actively engaged with their subject, and this has been my own experience in teaching and learning. In this seventh edition of *Genetics: A Conceptual Approach,* I wanted to share some active learning tools that I use in my own classroom: think-pair-share and concept mapping questions—exercises designed for small group work—as well as extensive problem sets at the end of each chapter. Additional group learning exercises and digital learning tools are provided on the SaplingPlus web site. I encourage you to take advantage of these resources and work with other students in learning genetics.

At Southwestern University, my office door is always open, and my students often drop by to share their experiences, concerns, and triumphs. I learn as much from my students as they learn from me, and I would love to learn from you—by email (pierceb@southwestern.edu), by telephone (512-863-1974), or in person (Southwestern University, Georgetown, Texas).

Ben Pierce
Professor of Biology
and Holder of the Lillian Nelson Pratt Chair
Southwestern University

A conceptual approach to success in genetics

With ***Genetics: A Conceptual Approach,*** Ben Pierce brings a master teacher's experience to his introductory genetics textbook, clarifying this complex subject by focusing on the big picture of genetics concepts and how they connect to one another.



Cover and Title Page Illustration: Echo Medical Media

Description

The book cover shows a string of helical D N A wrapped around nucleosomes. Text at the bottom left reads, Benjamin A. Pierce.

The new seventh edition continues this mission by expanding upon the powerful pedagogy and tools that have made this title so successful. New question types, more learning guidelines for students, and an updated art program round out a powerful text. Improvements to the online resources in SaplingPlus give students the conceptual and problem solving understanding they need for success.

New to the seventh edition:

CONNECTING PROBLEMS allow students to connect concepts across chapters. These questions ask students to integrate what they have learned over several chapters, and to apply what they learned to problem solving or data analysis.

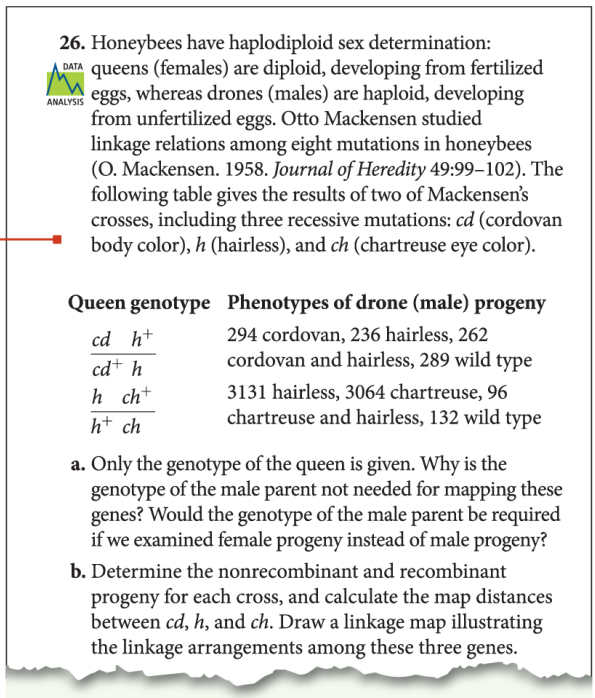
CONCEPT MAPPING EXERCISES help students conceptually map out topics within a chapter by including key terms and describing how they are connected. Creating connections between concepts and ideas is critically important for effective learning. These new concept mapping exercises are designed to help students build an understanding of the relationships among important concepts and terms by creating a visual map that depicts these relationships. These problems can be assigned as homework, or students can work on them in groups, allowing them to discuss how to organize the concepts in a map.

END-OF-CHAPTER LEARNING OBJECTIVES help frame the concepts covered in each section. A set of Learning Objectives, one for each major section of the chapter (followed by key concepts for that section), helps students identify the main learning goals for each chapter.

Powerful tools for problem solving

> ***Genetics: A Conceptual Approach*** features powerful tools, both in the text and online in SaplingPlus, to teach and reinforce the problem-solving skills students need for success in genetics.

DATA ANALYSIS PROBLEMS draw on examples from published research articles and ask students to apply the concepts they learned to analyze real data.



26. Honeybees have haplodiploid sex determination: queens (females) are diploid, developing from fertilized eggs, whereas drones (males) are haploid, developing from unfertilized eggs. Otto Mackensen studied linkage relations among eight mutations in honeybees (O. Mackensen. 1958. *Journal of Heredity* 49:99–102). The following table gives the results of two of Mackensen's crosses, including three recessive mutations: *cd* (cordovan body color), *h* (hairless), and *ch* (chartreuse eye color).

Queen genotype	Phenotypes of drone (male) progeny
$\frac{cd \quad h^+}{cd^+ \quad h}$	294 cordovan, 236 hairless, 262 cordovan and hairless, 289 wild type
$\frac{h \quad ch^+}{h^+ \quad ch}$	3131 hairless, 3064 chartreuse, 96 chartreuse and hairless, 132 wild type

a. Only the genotype of the queen is given. Why is the genotype of the male parent not needed for mapping these genes? Would the genotype of the male parent be required if we examined female progeny instead of male progeny?

b. Determine the nonrecombinant and recombinant progeny for each cross, and calculate the map distances between *cd*, *h*, and *ch*. Draw a linkage map illustrating the linkage arrangements among these three genes.

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

The sample text shows a portion of a page with the following text, Honeybees have haplodiploid sex determination: queens (females) are diploid, developing from fertilized eggs, whereas drones (males) are haploid, developing from unfertilized eggs. Otto Mackensen studied linkage relations among eight mutations in honeybees (O. Mackensen. 1958. Journal of Heredity 49: 99 to 102). The following table gives the results of two of Mackensen's crosses, including three recessive mutations: small C small D (cordovan body color), small H (hairless), and small C small H (chartreuse eye color). A table with two rows and two columns is present below. The column headers are as follows: Queen genotype and Phenotypes of drone (male) progeny. The row entries are as follows:

Row 1: small C small D small H superscript positive on upper chromosome and small C small D superscript positive small H on bottom chromosome; 294 cordovan, 236 hairless, 262 cordovan and hairless, 289 wild type.

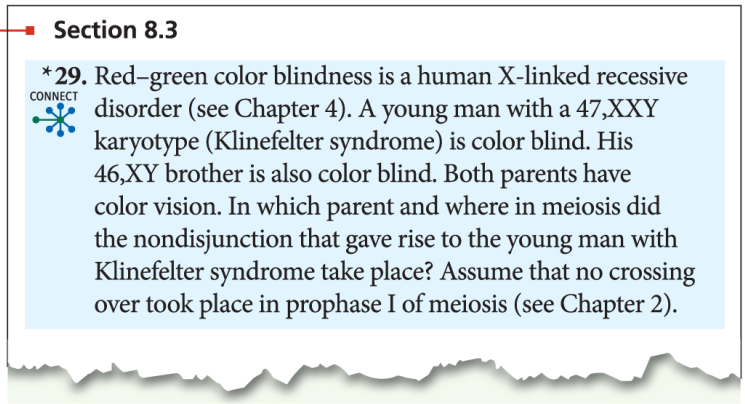
Row 2: small H small C small H superscript positive on upper chromosome and small H superscript positive small C small H on bottom chromosome; 3131 hairless, 3064 chartreuse, 96 chartreuse and hairless, 132 wild type.

Text below reads, a. Only the genotype of the queen is given. Why is the genotype of the male parent not needed for mapping these genes? Would the genotype of the male parent

be required if we examined female progeny instead of male progeny?

b. Determine the nonrecombinant and recombinant progeny for each cross, and calculate the map distances between small C small D, small H, and small C small H. Draw a linkage map illustrating the linkage arrangements among these three genes. Text points to the sample text and reads, DATA ANALYSIS PROBLEMS draw on examples from published research articles and ask students to apply the concepts they learned to analyze real data.

NEW! CONNECTING QUESTIONS help students synthesize concepts from different chapters to understand the big picture. The new questions ensure that students get the bigger picture of the science of genetics and, much like real geneticists, learn to use information from different fields within genetics in problem solving.



Section 8.3

CONNECT

***29.** Red–green color blindness is a human X-linked recessive disorder (see Chapter 4). A young man with a 47,XXY karyotype (Klinefelter syndrome) is color blind. His 46,XY brother is also color blind. Both parents have color vision. In which parent and where in meiosis did the nondisjunction that gave rise to the young man with Klinefelter syndrome take place? Assume that no crossing over took place in prophase I of meiosis (see Chapter 2).

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

Text on the left pointing to the sample text reads, NEW! CONNECTING QUESTIONS help students synthesize concepts from different chapters to understand the big picture. The new questions ensure that students get the bigger picture of the science of genetics and, much like real geneticists, learn to use information from different fields within genetics in problem solving. The sample text reads, Section 8 point 3 29. A logo is present below with text that reads, connect. The body text reads as follows, Red–green color blindness is a human X- linked recessive disorder (see Chapter 4). A young man with a 47, X X Y karyotype (Klinefelter syndrome) is color blind. His 46, X Y brother is also color blind. Both parents have color vision. In which parent and where in meiosis did the nondisjunction that gave rise to the young man with Klinefelter syndrome take place? Assume that no crossing over took place in prophase 1 of meiosis (see Chapter 2).

NEW! CONCEPT MAPPING QUESTIONS, available in the book and in SaplingPlus, ask students to build a visual representation of a topic.

Section 2.3

3. Create a concept map that outlines the role of cohesin in the separation of sister chromatids and homologous chromosomes in mitosis and meiosis.

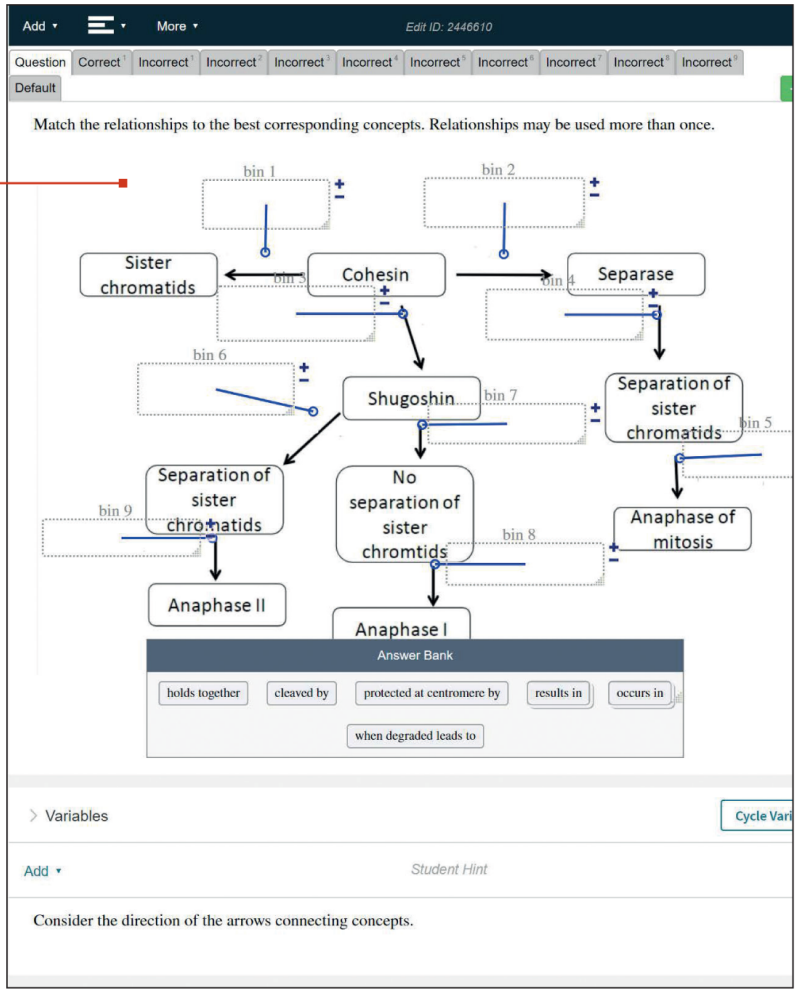
Description

Text on the left pointing to the sample text reads, NEW! CONCEPT MAPPING QUESTIONS, available in the book and in SaplingPlus, ask students to build a visual representation of a topic. The sample text reads, Section 2 point 3, 3. Create a concept map that outlines the role of cohesion in the separation of sister chromatids and homologous chromosomes in mitosis and meiosis.

Concept mapping problems available in SaplingPlus allow students to test their skill through automatically graded exercises.



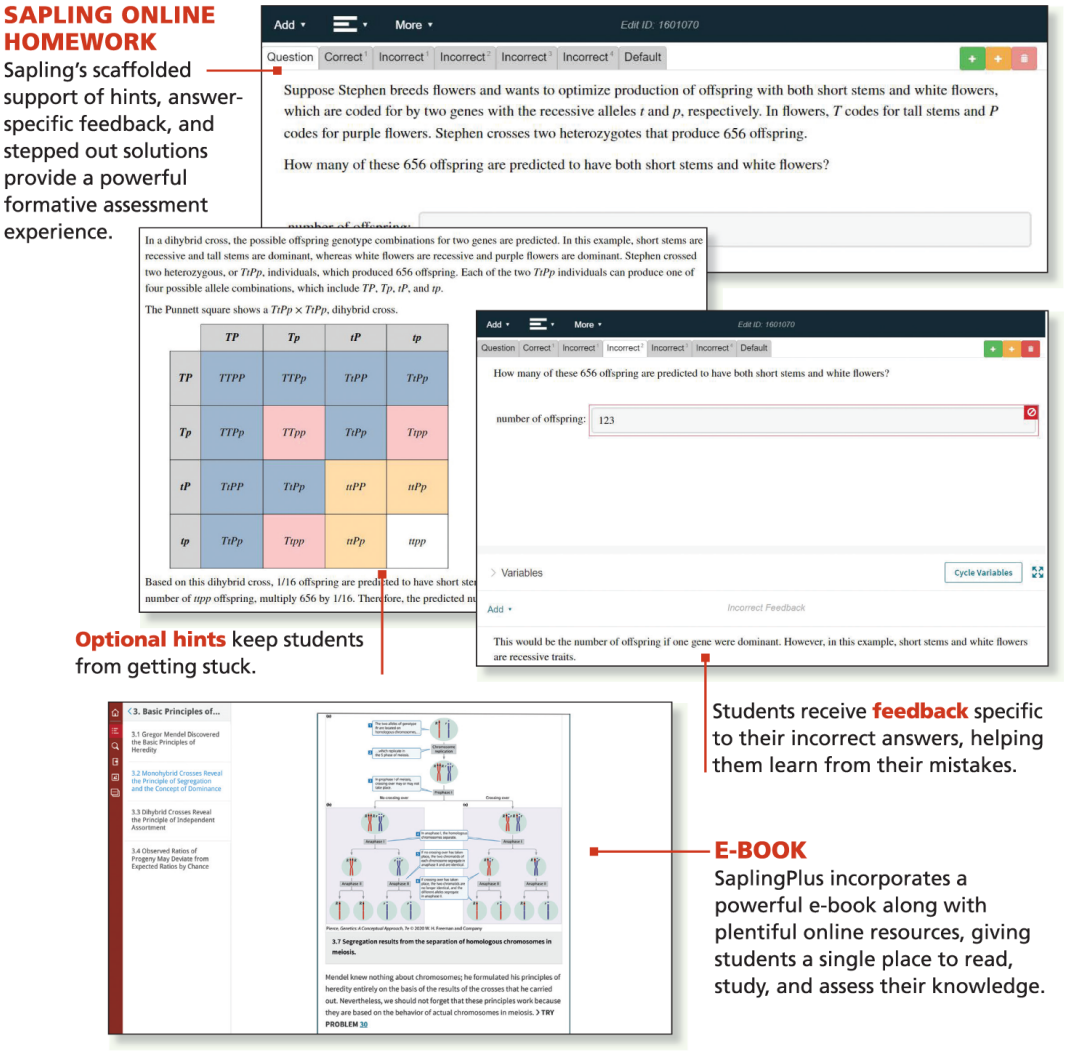
Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description
Text on the left pointing to the sample reads, Concept mapping problems available in SaplingPlus allow students to test their skill¬ through automatically graded exercises. It points to a screenshot on the right that shows blank bins (rectangular boxes) labeled 1 through 9 and arrows that link one box to other. Text at the top of example mapping problem reads, Match the relationship to best corresponding concepts. Relationships may be used more than once. Bin 1 corresponds to the arrow from Cohesin to Sister chromatids. Bin 2 corresponds to the arrow from Cohesin to Separase. A third arrow from Cohesin, corresponding to bin 5, points to Shugoshin. An arrow from Separase to Serparation of syster chromatids corresponds to bin 4. An arrow from Separation of sister chromatids to Anaphase of mitosis corresponds to bin 5. An arrow from Shugoshin to Separation of sister chromatids corresponds to bin 6. An arrow from Separation of sister chromatids to corresponds to bin 7. A second arrow from Shugoshin to Anaphase 2 corresponds to bin 9. An arrow from No separation of sister chromatids to Anaphase 1 corresponds to bin 8. The text boxes in an answer bank below read, holds together, cleaved by, protected at centromere by, results in, occurs in, and when degraded leads to. Text at the bottom reads, consider the direction of the arrows connecting concepts. All the bins have a positive and a negative sign button on their top right corners.

SaplingPlus: Tools for Success

SaplingPlus is the online companion to ***Genetics: A Conceptual Approach*** and combines Sapling's acclaimed automatically graded online homework with a powerful e-book and an extensive suite of engaging multimedia learning resources. Problems feature hints for when students get stuck, answer-specific feedback to help

them learn from their mistakes, and solutions to reinforce what they've learned.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

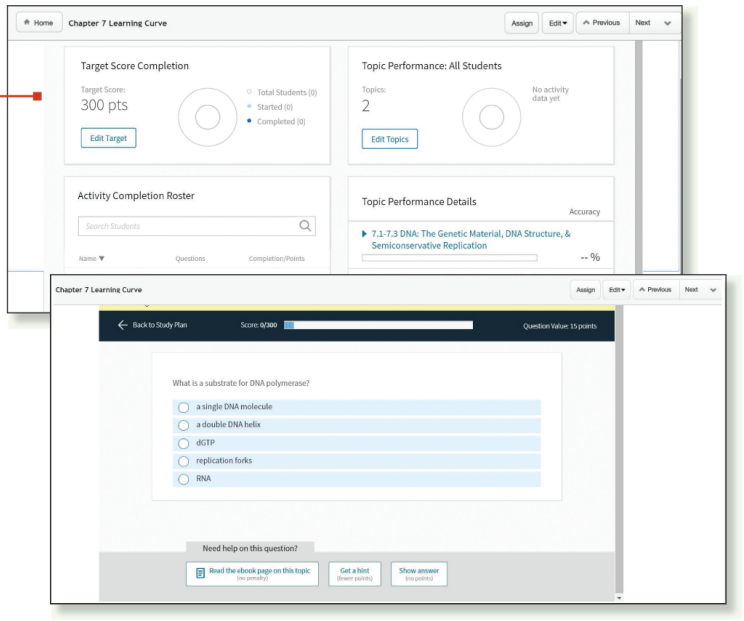
Description

The sample shows a screenshot at the top with a question asking information regarding offspring upon breeding of flowers. Text to its left pointing to the sample reads, SAPLING ONLINE HOMEWORK Sapling's scaffolded support of hints, answer specific feedback, and stepped out solutions provide a powerful formative assessment experience. A screenshot below shows a 4 cross 4 punnett square. Text below reads, Optional hints keep students from getting stuck. A screenshot on the right shows a box to fill the answer.

Text below shows feedback. Text corresponding to this screenshot reads, Students receive feedback specific to their incorrect answers, helping them learn from their mistakes. A screenshot below shows a diagram showing eventual formation of daughter cells. Text corresponding to this screenshot at the right reads, E-BOOK SaplingPlus incorporates a powerful e-book along with plentiful online resources, giving students a single place to read, study, and assess their knowledge.

SaplingPlus also includes tools to help students prepare for class and study for their exams. LearningCurve adaptive quizzing ties back to the e-book and is a great tool to help students learn basic concepts and do assigned readings before coming to lecture. SaplingPlus also includes a wealth of multimedia and problem solving resources to help students make the most of their study time.

LEARNINGCURVE
Put "testing to learn" into action. Based on research, LearningCurve really works: Game-like quizzing motivates students and adapts to their needs based on their performance. It is the perfect tool to get them to engage before class and review after! Additional reporting tools and metrics help teachers get a handle on what their class knows and doesn't know.

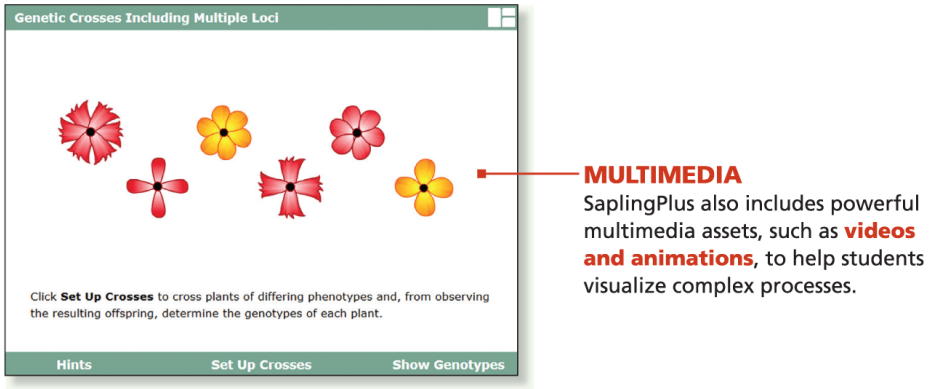


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

A screenshot shows two columns. The first column below on the left shows target score completion and activity completion roster along with activity data. The second column on the right shows topic performance: all students. It shows number of topics done and topic performance details. Text to the left corresponding to the sample reads, LEARNING CURVE Put “testing to learn” into action. Based on research, LearningCurve really works: Game-like quizzing motivates students and adapts to their needs based on their performance. It is the perfect tool to get them to engage before class and review after! Additional reporting tools and metrics help teachers get a handle on what their class knows and doesn’t know.

A screenshot below shows a question that reads, what is a substrate for D N A polymerase. Below are 5 options preceded by a circular space to click. Text below reads, Need help on this question? Read e book page on this topic, get a hint, and show answer.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

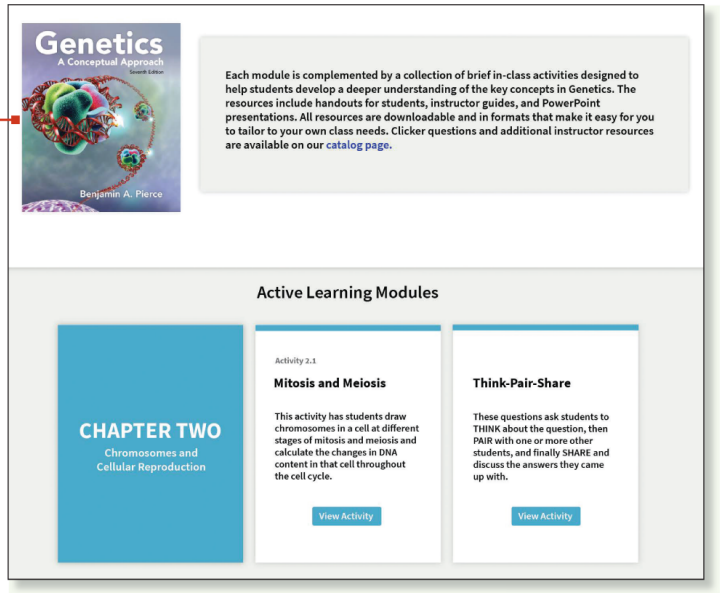
Description

A screenshot shows a heading that reads, genetic crosses including multiple loci. 6 different followers are present below. All the flowers have different shape, different number of petals and different colors. Text below reads, click set up crosses to cross plants of differing phenotypes and, from observing the resulting offspring, determine the genotype of each plant. Buttons on the bottom read, Hints, set up crosses, and show genotypes. Text on the right of the screenshot reads, MULTIMEDIA SaplingPlus also includes powerful multimedia assets, such as videos and animations, to help students visualize complex processes.

Tools for active learning

Genetics: A Conceptual Approach includes support for professors to implement more active learning in the classroom.

NEW! ACTIVE LEARNING HUB with in-class activities is now in SaplingPlus. It contains PowerPoints and worksheets to help you easily implement more active learning in your classroom.



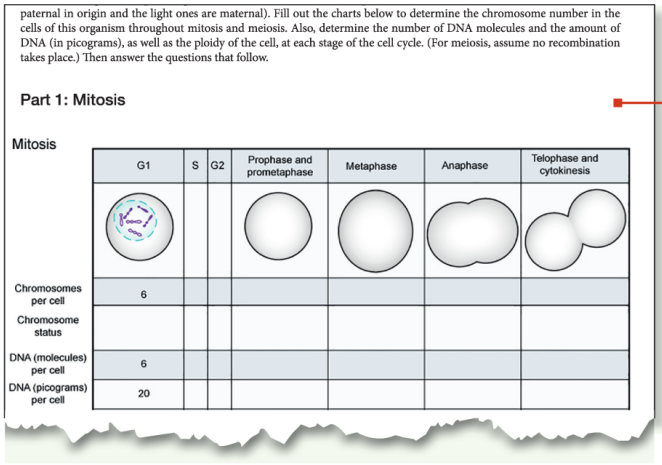
Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

A screenshot on the right shows cover page of a book named Genetics, A Conceptual Approach, Seventh Edition by Benjamin A. Pierce. Text to its right reads, each module is complemented by a collection of brief in class activities designed to help students develop a deeper understanding of the key concepts in genetics. The resources include handouts for students, instructor guides, and PowerPoint presentations. All resources are downloadable and in formats that make it easy for you to tailor to your class needs. Clicker questions and additional instructor resources are available on our catalog page. The screenshot shows active learning modules below. Text on the left of the screenshot reads,

NEW! ACTIVE LEARNING HUB with in-class activities is now in SaplingPlus. It contains PowerPoints and worksheets to help you easily implement more active learning in your classroom.

A panel below shows the heading, chapter 2 chromosomes and cellular reproduction. A panel to its right reads activity 2 point 1 mitosis and meiosis with a view activity button at the bottom. A third panel to the right reads think pair share with a view activity button at the bottom.



paternal in origin and the light ones are maternal). Fill out the charts below to determine the chromosome number in the cells of this organism throughout mitosis and meiosis. Also, determine the number of DNA molecules and the amount of DNA (in picograms), as well as the ploidy of the cell, at each stage of the cell cycle. (For meiosis, assume no recombination takes place.) Then answer the questions that follow.

Part 1: Mitosis

Mitosis

	G1	S	G2	Prophase and prometaphase	Metaphase	Anaphase	Telophase and cytokinesis
Chromosomes per cell	6						
Chromosome status							
DNA (molecules) per cell	6						
DNA (picograms) per cell	20						

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

A screenshot shows text at the top that reads, paternal in origin and the light ones are maternal). Fill out the charts below to determine the chromosome number in the cells of this organism throughout mitosis and meiosis. Also, determine the number of D N A molecules and the amount of D N A (in picograms), as well as the ploidy of the cell, at each stage of the cell cycle. (For meiosis, assume no recombination take place). Answer the question below.

Part 1: Mitosis. A table below shows 6 columns and 5 rows. The columns headers show different stages of mitosis. The first row contains a cell dividing into two daughter cells gradually from column 1 to column 6. All other rows with different headers are blank.

Text to the right of the screenshot reads, IN-CLASS ACTIVITIES encourage students to apply the concepts that they learn and work, and learn, in groups.

New and Reorganized Content

The seventh edition addresses recent discoveries in genetics corresponding to our ever-changing understanding of inheritance, the molecular nature of genetic information, epigenetics, and genetic evolution. This edition also focuses on updating the new research techniques that have become available to geneticists in the past few years. For example, this edition provides expanded coverage of CRISPR-Cas systems and reorganized and updated content in the chapters on molecular genetic analysis and epigenetics.

New and updated content includes:

- Eight new chapter-opening stories, including "Mapping Fear and Aggression in Dogs" (Chapter 4), "Hominin History in Ancient DNA" (Chapter 12), "Wrecks on the DNA Highway" (Chapter 13), and "Sequencing Earth's Biodiversity" (Chapter 20)
- New Concept Mapping exercises
- New Connecting Concepts problems
- New Learning Objectives in chapter summaries
- Revised section on the cutting edge of genetics (Chapter 1)
- Revised section on binary fission in prokaryotes (Chapter 2)

- Revised and updated coverage of mandatory genetic screening of newborns; updated information on noninvasive prenatal screening; and a new section on genealogies and genetic testing for ancestry (Chapter 6)
- Updated discussion of aneuploidy in humans (Chapter 8)
- Updated discussion of bacterial and archaeal diversity; revised discussion of gene mapping in bacteria; a new section called "Bacterial Defense Mechanisms" and expanded coverage of CRISPR-Cas in bacteria; a new section called "Zika virus"; and an updated discussion of the microbiome (Chapter 9)
- New discussion of topologically associated domains in chromatin structure (Chapter 11)
- Revised and updated discussion of eukaryotic origins of replication (Chapter 12)
- New section on internal mRNA modifications (Chapter 14)
- Updated discussion of variation in translation initiation sites (Chapter 15)
- Revised discussion of transcription factors; new discussion of super enhancers, as well as updated discussion of insulators and regulatory neighborhoods (Chapter 17)
- New discussion of single-cell genomic sequencing to estimate rates of somatic mutations, as well as updated discussion of tautomeric shifts (Chapter 18)
- Extensively updated CRISPR-Cas coverage; new discussion of environmental DNA (eDNA); revised discussion of gene libraries; updated discussion of next-generation and third-generation DNA sequencing methods; updated information on

the CODIS system for DNA fingerprinting; and updated information on gene therapy currently in use (Chapter 19)

- New information on DNA and protein databases; expanded discussion of heat maps; new information on applications of RNA sequencing; and added discussion of the interactome (Chapter 20)
- Extensively reorganized and updated epigenetics content; new discussion of epigenome-wide association studies (Chapter 21)
- New section on mapping gene expression in *Drosophila* embryos; updated information on epigenetic modifications affecting eye development in blind cave fish (Chapter 22)
- Updated cancer statistics; a new discussion of autophagy; and an expanded discussion of the factors that contribute to metastasis (Chapter 23)
- Updated information on the wolves of Isle Royale (Chapter 25)
- A new section called “Interpreting Phylogenetic Trees” (Chapter 26)

Acknowledgments

I am indebted to many people for help with this and previous editions of *Genetics: A Conceptual Approach*. I learned much from my genetics teachers: Ray Canham, who first exposed me to genetics and instilled in me a lifelong love for the subject, and Jeff Mitton, who taught me the art of genetic research. I've learned from the thousands of genetics students who have filled my classes over the past 39 years, first at Connecticut College, then at Baylor University, and now at Southwestern University. Their intelligence, enthusiasm, curiosity, and humor have been a source of motivation and pleasure throughout my professional life. I have also learned from students worldwide who have used earlier editions of this book and kindly shared with me, through emails and phone calls, their thoughts about the book and how it could be improved.

I am grateful for the wonderful colleagues who surround me daily at Southwestern University and whose friendship, advice, and good humor sustain my work. The small classes, close interaction of students and faculty, and integration of teaching and research have made working at Southwestern University personally and professionally rewarding. I thank Edward Burger, President of Southwestern University, and Alisa Gaunder, Dean of the Faculty, for sustaining this supportive academic environment, for their

creativity and inspiration, and for their continued friendship and collegiality.

Writing a modern science textbook requires a team effort, and I have been blessed with an outstanding team at W. H. Freeman and Macmillan Learning. General Manager Susan Winslow has been a champion of this book for a number of years; I value her support, strategic vision, and commitment to education. Sandy Lindelof, Executive Program Director, has been an outstanding leader of the project. Her encouragement, attention to detail, creativity, and great sense of perspective have been tremendous assets. Throughout the revision process, I interacted daily with Senior Development Editor Maria Lokshin, who has been instrumental in shaping this edition. Maria's hard work, passion for excellence, superior knowledge of genetics, great organizational skills, and good humor made working on this edition both rewarding and fun, in spite of a demanding schedule.

Senior Project Manager Vanavan Jayaraman expertly managed the production of this seventh edition. During the production phase of the book, we communicated daily, often late at night. His dedication to excellence in all phases of the production process has been a major factor in making the book a success. I thank Dragonfly Media Group for creating the book's illustrations. Quade Paul (Echo Medical Media) designed the cover image from a concept by Emiko Paul. Thanks to Susan Wein and Lawrence Guerra for coordinating the composition and manufacturing phases of production. Natasha

Wolfe developed the book's design. I thank Jennifer MacMillan and Richard Fox for photo research. Cassandra Korsvik provided excellent advice on many aspects of the book, including organization, content, and pedagogy. Amy Thorne, Cassandra Korsvik, Amber Jonker, Heather Held, and Emiko Paul developed the outstanding media and supplements that accompany the book. Keith Smith, Alexis Cowan, Jared Hale, Amy Terry, Juwen DuBois, Jessica Dade, April Williams, Alyssa Jordan, Kate DeRosa, Heather Khanna developed and reviewed assessment questions. Brenda Grewe and Jared Hale reviewed the Solutions Manual for accuracy.

I am grateful to the Faculty Advisory Board for their invaluable input on the new features of the textbook and new Sapling content. The board includes Eugenia Ribeiro-Hurley (Fordham University), David Kass (Eastern Michigan University), Brian Kreiser (University of Southern Mississippi), Karly Ackermann (South Dakota State University), Kari Loomis (University of Massachusetts), Agata Becalska (MacEwan University), and Amanda Moehring (Western University).

As always, I am grateful to the Macmillan Learning sales representatives, regional managers, and STEM specialists who introduce my book to genetic instructors throughout the world. I have greatly enjoyed working with this sales staff; their expertise, hard work, and great service are responsible for the success of Macmillan books.

A number of colleagues served as reviewers of this book, kindly lending me their technical expertise and teaching experience. Their assistance is gratefully acknowledged. Any remaining errors are entirely my own.

Marlene Tyrrell (my spouse and best friend for 39 years), our children and their spouses (Sarah, Matt, Michael, and Amber), and now my F_2 progeny (Ellie, Beckett, and Caroline) provide love, support, and inspiration for everything I do.

My gratitude goes to the reviewers of this new edition of *Genetics: A Conceptual Approach*:

Genetics

A Conceptual Approach

CHAPTER 1

Introduction to Genetics

Ansel Adams/National Park Archives at College Park, MD.

A Hopi pueblo on Black Mesa. Albinism, a genetic condition, arises with high frequency among the Hopi people and occupies a special place in the Hopi culture.

Albinism in the Hopis

Rising a thousand feet above the desert floor, Black Mesa dominates the horizon of the Enchanted Desert and provides a familiar

landmark for travelers passing through northeastern Arizona. Black Mesa is not only a prominent geological feature but also, more significantly, the ancestral home of the Hopi Native Americans. Fingers of the mesa reach out into the desert, and alongside or on top of each finger is a Hopi village. Most of the villages are quite small, having only a few dozen inhabitants, but they are incredibly old. One village, Oraibi, has existed on Black Mesa since 1150 C.E. and is the oldest continuously occupied settlement in North America.

In 1900, Aleš Hrdlička, an anthropologist and physician working for the American Museum of Natural History, visited the Hopi villages of Black Mesa and reported a startling discovery. Among the Hopis were 11 white people—not Caucasians but white Hopi Native Americans. These Hopis had a genetic condition known as albinism (**Figure 1.1**).

© The Field Museum, #CSA118. Charles Carpenter.

1.1 Albinism among the Hopi Native Americans. The Hopi girl in the center of this photograph, taken around 1900, displays albinism.

Albinism is caused by a defect in one of the enzymes required to produce melanin, the pigment that darkens our skin, hair, and eyes. People with albinism either don't produce melanin or produce only small amounts of it and, consequently, have white hair, light skin, and no pigment in the irises of their eyes. Melanin normally protects the DNA of skin cells from the damaging effects of ultraviolet radiation in sunlight, and melanin's presence in the developing eye is essential for proper eyesight.

The genetic basis of albinism was first described by the English physician Archibald Garrod, who recognized in 1908 that the condition was inherited as an autosomal recessive trait, meaning that a person must receive two copies of an albino mutation—one

from each parent—to have albinism. In recent years, the molecular nature of the mutations that lead to albinism has been elucidated. Albinism in humans is caused by a mutation in any one of several different genes that control the synthesis and storage of melanin; many different types of mutations can occur at each gene, any one of which may lead to albinism. The form of albinism found among the Hopis is most likely oculocutaneous albinism (albinism affecting the eyes and skin) type 2, caused by a defect in the *OCA2* gene on chromosome 15.

The Hopis are not unique in having people with albinism among the members of their tribe. Albinism is found in almost all human ethnic groups. It is described in ancient writings and has probably been present since humankind's beginnings. What is unique about the Hopis is the high frequency of albinism in their population. In most human groups, albinism is rare, present in only about 1 in 20,000 individuals. In the villages on Black Mesa, it reaches a frequency of 1 in 200, a hundred times higher than in many other populations.

Why is albinism so frequent among the Hopis? The answer to this question is not completely known, but geneticists who have studied albinism in the Hopis speculate that the high frequency of the albino mutation is related to the special place that albinism occupied in the Hopi culture. For much of their history, the Hopis considered members of their tribe with albinism to be important

and special. Having a number of people with albinism in one's village was considered a good sign, a symbol that the people of the village contained particularly pure Hopi blood. Members of the tribe with albinism performed in Hopi ceremonies and held positions of leadership, often as chiefs, healers, and religious leaders.

Hopis with albinism were also given special treatment in everyday activities. The Hopis have farmed small garden plots at the foot of Black Mesa for centuries. Every day throughout the growing season, the men of the tribe trekked to the base of Black Mesa and spent much of the day in the bright southwestern sunlight tending gardens of corn and vegetables. With little or no melanin pigment in their skin, people with albinism are extremely susceptible to sunburn and have an increased incidence of skin cancer when exposed to the sun. Furthermore, many don't see well in bright sunlight. Therefore, the male Hopis with albinism were excused from farming and allowed to remain behind in the village with the women of the tribe, performing other duties.

Throughout the growing season, the men with albinism were the only male members of the tribe in the village with the women during the day, and thus they may have enjoyed a mating advantage, which helped pass on their albino genes. In addition, the special considerations given to Hopis with albinism allowed them to avoid the detrimental effects of albinism—increased skin cancer and poor eyesight. The small size of the Hopi tribe probably also played a

role by allowing chance to increase the frequency of the albino mutation. Regardless of the factors that led to the high frequency of albinism, the Hopis clearly respected and valued the members of their tribe who possessed this particular trait. Unfortunately, people with genetic conditions in many societies are often subject to discrimination and prejudice. **› TRY PROBLEMS 1 AND 26**

THINK-PAIR-SHARE

- Albinism occupied a special place in the Hopi culture; individuals who possessed this trait were valued by members of the tribe. What are some examples of genetic traits that, in contrast, sometimes result in discrimination and prejudice?
- Albinism in humans can be caused by mutations in any one of several different genes. This situation, in which the same phenotype may result from variation in several different genes, is referred to as genetic heterogeneity. Is genetic heterogeneity common? Are most genetic traits in humans the result of variation in a single gene, or are there many genetic traits that result from variation in several genes, as albinism does?

Genetics is the study of heredity, how inherited variation is encoded, replicated, and expressed, and how it evolves over time. This definition encompasses the three major subdivisions of genetics: transmission genetics, molecular genetics, and population genetics. The study of heredity and inherited variation is one of the most rapidly advancing areas of science, with important new discoveries reported every month. Look at almost any major news source, and chances are that you will see articles related to genetics: on the sequencing of new genomes, such as those of the sunflower, barley, the axolotl, and Darwin's finches; on the discovery

of genes that affect major diseases, including amyotrophic lateral sclerosis (ALS), depression, and cancer; on analyses of DNA from long-extinct organisms, such as a 700,000-year-old Pleistocene horse; or on the identification of genes that affect birth weight, skin pigmentation, height, and learning ability in humans. Even among advertisements, you are likely to see ads for genetic testing to determine a person's ancestry or the pedigree of your dog. These new findings and applications of genetics often have significant economic and ethical implications, making the study of genetics relevant, timely, and interesting.

This chapter introduces you to genetics and reviews some concepts that you may have encountered in your general biology course. We begin by considering the importance of genetics to each of us, to society, and to students of biology. We then turn to the history of genetics and how the field as a whole developed. The final part of the chapter presents some fundamental terms and principles of genetics that are used throughout the book.

1.1 Genetics Is Important to Us Individually, to Society, and to the Study of Biology

Albinism among the Hopis illustrates the important role that genes play in our lives. This one genetic alteration, among the 20,000 genes that humans possess, completely changes the life of a Hopi who possesses it. It alters his or her occupation, role in Hopi society, and relations with other members of the tribe. We all possess genes that influence our lives in significant ways. Genes affect our height, weight, hair color, and skin pigmentation. They affect our susceptibility to many diseases and disorders (Figure 1.2) and even contribute to our intelligence and personality. Genes are fundamental to who and what we are, but they alone do not define us. Many factors—genetic and environmental—help determine our traits. A fundamental problem in genetics is separating the genetic and environmental influences on individual variation.

1.2 Genes influence susceptibility to many diseases and disorders. (a) An X-ray of the hand of a person suffering from diastrophic dysplasia (bottom), a hereditary growth disorder that results in curved bones, short limbs, and hand deformities, compared with an X-ray of a normal hand (top). (b) Diastrophic dysplasia is due to a defect in the *SLC26A2* gene on chromosome 5.

Description

The x-ray pictures on the left show a normal hand with straight fingers on the top. The x-ray below shows the hand of a person with diastrophic dysplasia. This hand has curvy fingers. The drawing “b” on the right shows chromosome 5. The diastrophic dysplasia

gene is located on the long arm of this. The chromosome has multiple bands of varying thickness all throughout.

Although the science of genetics is relatively new compared with sciences such as astronomy and chemistry, people have understood the hereditary nature of traits and practiced genetics for thousands of years. The rise of agriculture began when people started to apply genetic principles to the domestication of plants and animals. Today, the major crops and animals used in agriculture are quite different from their wild progenitors, having undergone extensive genetic alteration that increased their yields and provided many desirable traits, such as disease and pest resistance, special nutritional qualities, and characteristics that facilitate harvest. The Green Revolution, which expanded food production throughout the world in the 1950s and 1960s, relied heavily on the application of genetic methods and principles (**Figure 1.3**). Today, genetically engineered corn, soybeans, canola (rapeseed), squash, sugar beets, and other crops constitute a significant proportion of all the food produced worldwide.

Left: Bettmann/Getty Images. right: IRRI.

1.3 In the Green Revolution, genetic techniques were used to develop new high-yielding strains of crops. (Left) Norman Borlaug, a leader in the development of new varieties of wheat, which led to the Green Revolution. Borlaug was awarded the Nobel Peace Prize in 1970. (Right) Modern, high-yielding rice plant (left) and traditional rice plant (right).

Description
The first photo shows Norman Borlaug writing in a notebook while standing in a rice field. The second photo shows a small, traditional rice plant with tightly packed, shorter stems and spikelets next to the tall, high-yielding modern rice plant with longer stems and spikelets.

The pharmaceutical industry is another area in which genetics plays an important role. Numerous drugs and food additives are synthesized by fungi and bacteria that have been genetically manipulated to make them efficient producers of these substances. The biotechnology industry employs molecular genetic techniques

to develop and mass-produce substances of commercial value. Antimalarial drugs, growth hormone, insulin, clotting factor, antiviral drugs, enzymes, antibiotics, vaccines, and many other compounds are now produced commercially by genetically engineered bacteria and other organisms (Figure 1.4). Genetics has also been used to generate bacterial strains that remove minerals from ore, break down toxic chemicals, and help produce biofuels.

Traimak_Ivan/Getty Images.

1.4 The biotechnology industry uses molecular genetic methods to produce substances of economic value.

Genetics also plays a critical role in medicine. Physicians recognize that many diseases and disorders have a hereditary component, including rare genetic disorders such as sickle-cell anemia and Huntington disease, as well as many common diseases such as asthma, diabetes, and hypertension. Advances in genetics have resulted in important insights into the nature of diseases such as cancer and in the development of diagnostic tests, including tests

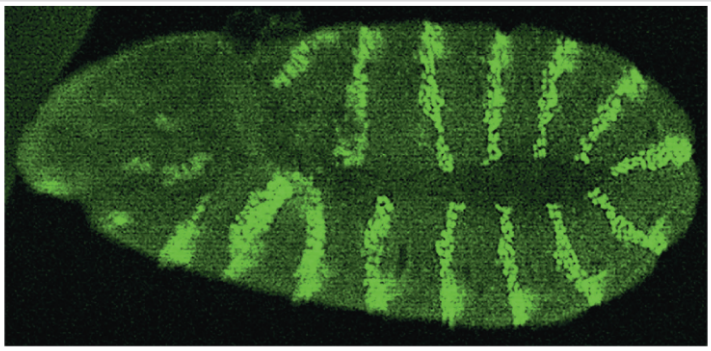
that identify disease-causing mutations as well as pathogens. Genomic data are helping to usher in the era of personalized medicine. Rapid, low-cost sequencing methods now allow us to obtain a person's complete genome sequence, which provides important information about that person's susceptibilities to diseases and likely responses to particular treatments. And gene therapy—the direct alteration of genes to treat human diseases—has now been administered to thousands of patients, although its use is still experimental and limited.

THINK-PAIR-SHARE Question 1

The Role of Genetics in Biology

Although an understanding of genetics is important to all people, it is critical to the student of biology. Genetics provides one of biology's unifying principles: all organisms use genetic systems that have a number of features in common. Genetics also undergirds the study of many other biological disciplines. Evolution, for example, is genetic change taking place over time, so the study of evolution requires an understanding of genetics. Developmental biology relies heavily on genetics: tissues and organs develop through the regulated expression of genes (**Figure 1.5**). Even such fields as taxonomy, ecology, and animal behavior are making increasing use of genetic methods. The study of almost any field of biology or

medicine is incomplete without a thorough understanding of genes and genetic methods.



Steven Paddock.

1.5 The key to development lies in the regulation of gene expression. This early fruit-fly embryo illustrates the localized expression of the *engrailed* gene, which helps determine the development of body segments in the adult fly.

Genetic Diversity and Evolution

Life on Earth exists in a tremendous array of forms and features, occupying almost every conceivable environment. Life is also characterized by adaptation: many organisms are exquisitely suited to the environment in which they are found. The history of life is a chronicle of new forms of life emerging, old forms disappearing, and existing forms changing.

Despite their tremendous diversity, living organisms have an important feature in common: all use similar genetic systems. The complete set of genetic instructions for any organism is its **genome**, and all genomes are encoded in nucleic acids—either DNA or RNA.

The coding system for genomic information is also common to all life: genetic instructions are in the same format and, with rare exceptions, the code words are identical. Likewise, the process by which genetic information is copied and decoded is remarkably similar for all forms of life. These common features suggest that all life on Earth evolved from the same primordial ancestor, which arose between 3.5 billion and 4 billion years ago. Biologist Richard Dawkins describes life as a river of DNA that runs through time, connecting all organisms past and present.

That all organisms have similar genetic systems means that the study of one organism's genes reveals principles that apply to other organisms. Investigations of how bacterial DNA is replicated (copied), for example, provide information that applies to the replication of human DNA. It also means that genes can often function in foreign cells, which makes genetic engineering possible. Unfortunately, the similarity of genetic systems is also the basis for diseases such as AIDS (acquired immune deficiency syndrome), in which viral genes are able to function—sometimes with alarming efficiency—in human cells.

Life's diversity and adaptations are products of evolution, which is simply genetic change over time. Evolution is a two-step process: first, inherited differences arise randomly, and then the proportion of individuals with particular differences increases or decreases. Genetic variation is therefore the foundation of all evolutionary change and is ultimately the basis of all life as we know it.

Techniques of molecular genetics are now routinely used to decipher evolutionary relationships among organisms; for example, analysis of DNA isolated from Neanderthal fossils has yielded new information concerning the relationship between Neanderthals and modern humans, demonstrating that Neanderthals and the ancestors of modern humans interbred some 30,000 to 40,000 years ago. Genetics and the study of genetic variation are critical to understanding the past, present, and future of life. **› TRY PROBLEM 17**

THINK-PAIR-SHARE Question 2

CONCEPTS

Our genes affect many of our physical features as well as our susceptibility to many diseases and disorders. Genetics contributes to advances in agriculture, pharmaceuticals, and medicine and is fundamental to modern biology. All organisms use similar genetic systems, and genetic variation is the foundation of the diversity of all life.

✔ CONCEPT CHECK 1

What are some of the implications of all organisms having similar genetic systems?

a. That all life forms are genetically related
b. That research findings on one organism's gene function can often be applied to other organisms
c. That genes from one organism can often function in another organism
d. All of the above

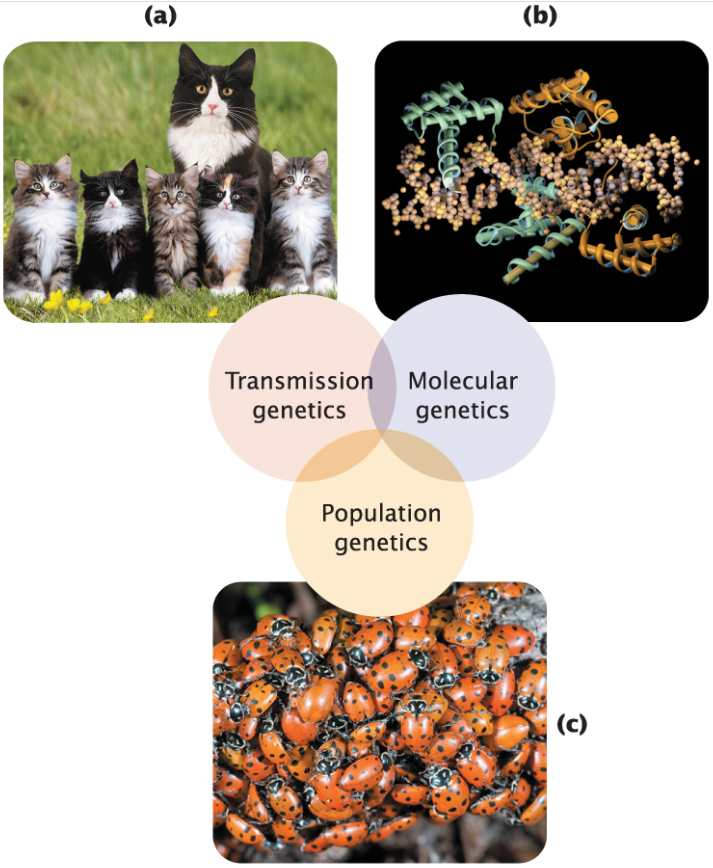
DNA in the Biosphere

Each DNA molecule is very small, but because all cells contain genetic information, there is a tremendous amount of DNA in the world. Scientists estimate that the total amount of DNA in the biosphere is 5.3×10^{31} megabase pairs (millions of base pairs), altogether weighing some 50 billion tons. Storing the information content of the world's DNA would require 10^{21} computers, each with the average storage capacity of the world's four most powerful supercomputers.

Scientists are now cataloging and measuring the world's biodiversity through analysis of DNA. For example, researchers aboard the ship *Tara* surveyed the world's oceans for organisms by isolating DNA from seawater during a three-and-a-half-year voyage. They collected 35,000 seawater samples and extracted DNA from each. The DNA was then sequenced and analyzed, revealing the presence of 150,000 genetically distinct types of eukaryotes. Most of these eukaryotes were newly discovered single-celled organisms. The researchers also detected 5000 viruses, only 39 of which were previously known to science. In an effort named the Earth BioGenome Project (EBP), scientists have recently proposed sequencing the genomes of 1.5 million known eukaryotic species on Earth. (See the Suggested Readings for this chapter in your SaplingPlus for the reference to these studies and many others mentioned in the book.)

Divisions of Genetics

The study of genetics consists of three major subdisciplines: transmission genetics, molecular genetics, and population genetics (Figure 1.6). Also known as classical genetics, **transmission genetics** encompasses the basic principles of heredity and how traits are passed from one generation to the next. This subdiscipline addresses the relation between chromosomes and heredity, the arrangement of genes on chromosomes, and gene mapping. Here, the focus is on the individual organism—how an individual inherits its genetic makeup and how it passes its genes to the next generation.



Part a: Juniors Bildarchiv/Alamy Stock Photo. Part b: Martin McCarthy/Getty Images. Part c: Stuart Wilson/Science Source.

1.6 Genetics can be divided into three major subdisciplines.

Description
The photo “a” on the top left representing transmission genetics shows an adult tuxedo cat with 5 kittens, 2 looking like tuxedo cats and 3 looking like tabbies. The photo “b” on the top right representing molecular genetics shows a 3-D ribbon model of a biomolecule with helical D N A at the center surrounded by ribbons of green and yellow color. The photo “c” below representing population genetics shows a flock of ladybugs. A Venn diagram at the center shows overlapping between transmission genetics, molecular genetics, and population genetics.

Molecular genetics concerns the chemical nature of the gene itself: how genetic information is encoded, replicated, and expressed. It includes the cellular processes of replication, transcription, and translation (by which genetic information is transferred from one molecule to another) and gene regulation (the processes that control the expression of genetic information). The focus in molecular genetics is the gene and its structure, organization, and function.

Population genetics explores the genetic composition of populations (groups of individuals of the same species) and how that composition changes geographically and with the passage of time. Because evolution is genetic change, population genetics is fundamentally the study of evolution. The focus of population genetics is the group of genes found in a population.

Division of the study of genetics into these three subdisciplines is convenient and traditional, but we should recognize not only that

they overlap but also that each one can be further divided into a number of more specialized fields, such as chromosomal genetics, biochemical genetics, and quantitative genetics. Alternatively, genetic studies can be subdivided by organism (fruit fly, corn, or bacterial genetics), and each of these organisms may be studied at the levels of transmission, molecular, and population genetics. Modern genetics is an extremely broad field, encompassing many interrelated subdisciplines and specializations. › **TRY** PROBLEM 18

Model Genetic Organisms

Through the years, genetic studies have been conducted on thousands of different species, including almost all major groups of bacteria, fungi, protists, plants, and animals. Nevertheless, a few species have emerged as **model genetic organisms**—organisms that are widely used in genetic research and that can serve as models for the genetic systems of other organisms, like humans, which, for various reasons, may be more difficult to study. Genetic models typically have characteristics that make them particularly useful for genetic analysis and about which a tremendous amount of genetic information has accumulated. Six model organisms that have been the subject of intensive genetic study are *Drosophila melanogaster*, a species of fruit fly; *Escherichia coli*, a bacterium present in the gut of humans and other mammals; *Caenorhabditis elegans*, a soil-dwelling nematode (roundworm); *Arabidopsis thaliana*, the thale-cress plant;

Mus musculus, the house mouse; and *Saccharomyces cerevisiae*, baker's yeast (Figure 1.7). The life cycles and genetic characteristics of these model genetic organisms are described in more detail in the Reference Guide to Model Genetic Organisms located at the end of this book (pp. A1–A13). This Reference Guide will be a useful resource as you encounter these organisms throughout the book.

1.7 Model genetic organisms are species with features that make them useful for genetic analysis.

Description

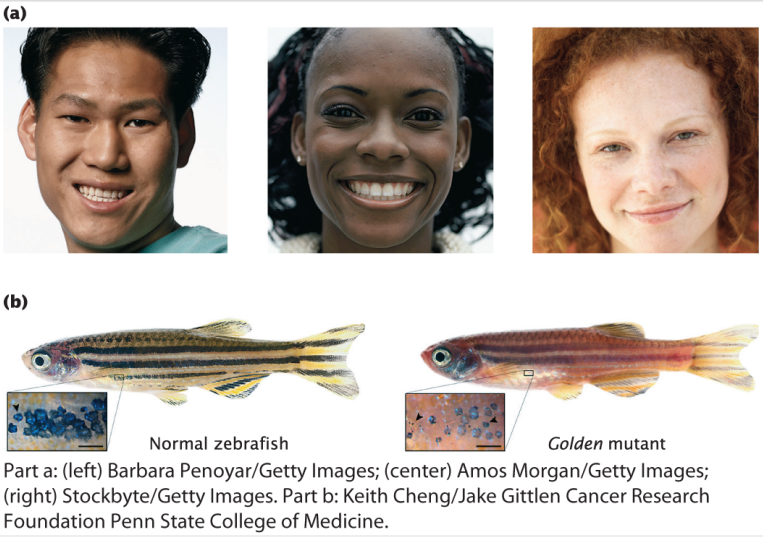
Photo "a" on top left shows Drosophila melanogaster (Fruit fly) sitting over a leaf. Photo "b" in top center shows several rod shaped Escherichia coli Bacterium. Photo "c" in top right shows thin tube shaped Caenorhabditis elegans (Nematode). Photo "d" on bottom left shows Arabidopsis thaliana (Thale-cress plant). Photo "e" on the bottom center shows Mus musculus (House mouse). Photo "f" on bottom right shows Saccharomyces

cerevisiae (Baker's yeast), which has two oval shaped cells attached. The one on the right is smaller as compared to the one on the left.

At first glance, these lowly and sometimes unappreciated creatures might seem unlikely candidates for model genetic organisms. However, all possess life cycles and traits that make them particularly suitable for genetic study, including a short generation time, large but manageable numbers of progeny, adaptability to a laboratory environment, and the ability to be housed and propagated inexpensively. Other species that are frequently the subjects of genetic research and considered genetic models include *Neurospora crassa* (bread mold), *Zea mays* (corn), *Danio rerio* (zebrafish), and *Xenopus laevis* (clawed frog). Although not generally considered a model genetic organism, *Homo sapiens* has also been subjected to intensive genetic scrutiny; special techniques for the genetic analysis of humans are discussed in Chapter 6.

The value of model genetic organisms is illustrated by the use of zebrafish to identify genes that affect skin pigmentation in humans. For many years, geneticists recognized that differences in pigmentation among human ethnic groups were genetic (**Figure 1.8a**), but the genes causing these differences were largely unknown. The zebrafish has become an important model in genetic studies because it is a small vertebrate that produces many offspring and is easy to rear in the laboratory. The mutant zebrafish called *golden* has light pigmentation due to the presence of fewer, smaller, and less

dense pigment-containing structures called melanosomes in its cells (Figure 1.8b).



Part a: (left) Barbara Penoyar/Getty Images; (center) Amos Morgan/Getty Images; (right) Stockbyte/Getty Images. Part b: Keith Cheng/Jake Gittlen Cancer Research Foundation Penn State College of Medicine.

1.8 The zebrafish, a model genetic organism, has been instrumental in helping identify genes encoding pigmentation differences among humans. (a) Humans differ in degree of skin pigmentation. (b) The zebrafish *golden* mutation is caused by a gene that controls the amount of melanin in melanosomes.

Description

Photo a shows an Asian man with a moderate skin tone and dark hair, an African girl with dark skin and hair, and a Scotch-Irish woman with fair skin and freckles. Photo b shows a normal zebra fish and a golden mutant zebra fish; both vary in color. A magnified view of the fish scales show the normal zebra fish with tightly clustered dark scales and an underlying yellow skin tone and the golden mutant with loosely clustered scales and an underlying orange skin tone.

Keith Cheng and his colleagues hypothesized that light skin in humans might result from a mutation that is similar to the *golden* mutation in zebrafish. Taking advantage of the ease with which zebrafish can be manipulated in the laboratory, they isolated and

sequenced the gene responsible for the *golden* mutation and found that it encodes a protein that takes part in calcium uptake by melanosomes. They then searched a database of all known human genes and found a similar gene called *SLC24A5*, which encodes a protein that has the same function in human cells. When they examined human populations, they found that light-skinned Europeans often possess one form of this gene, whereas darker-skinned Africans, East Asians, and Native Americans usually possess a different form. Many other genes also affect pigmentation in humans, as illustrated by the mutations in the *OCA2* gene that produce albinism among the Hopis (discussed in the introduction to this chapter). Nevertheless, *SLC24A5* appears to be responsible for 24% to 38% of the differences in pigmentation between Africans and Europeans.

This example illustrates the power of model organisms in genetic research. However, we should not forget that all organisms possess unique characteristics and that the genetics of model organisms do not always accurately reflect the genetic systems of other organisms.

CONCEPTS

The three major divisions of genetics are transmission genetics, molecular genetics, and population genetics. Transmission genetics examines the principles of heredity; molecular genetics deals with the gene and the cellular processes by which genetic information is transferred and expressed; population genetics concerns the genetic composition of groups of organisms and how that composition changes geographically and over time. Model genetic

organisms are species that have received special emphasis in genetic research; they have characteristics that make them useful for genetic analysis.

✔ CONCEPT CHECK 2

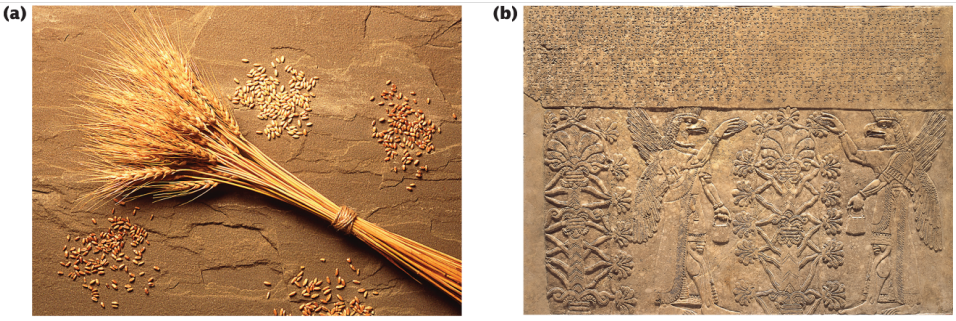
Would the horse make a good model genetic organism? Why or why not?

1.2 Humans Have Been Using Genetic Techniques for Thousands of Years

Although the science of genetics is young—almost entirely a product of the past 120 years or so—people have been using genetic principles for thousands of years.

The Early Use and Understanding of Heredity

The first evidence that people understood and applied the principles of heredity in earlier times is found in the domestication of plants and animals, which began between approximately 10,000 and 12,000 years ago; early farming villages appeared in the Middle East between 11,000 and 11,500 years ago. The first domesticated organisms included wheat, peas, lentils, barley, dogs, goats, and sheep (Figure 1.9a). By 4000 years ago, genetic techniques of selective breeding were already in use in the Middle East. The Assyrians and Babylonians developed several hundred varieties of date palms that differed in fruit size, color, taste, and time of ripening (Figure 1.9b). Other crops and domesticated animals were developed by cultures in Asia, Africa, and the Americas in the same period.



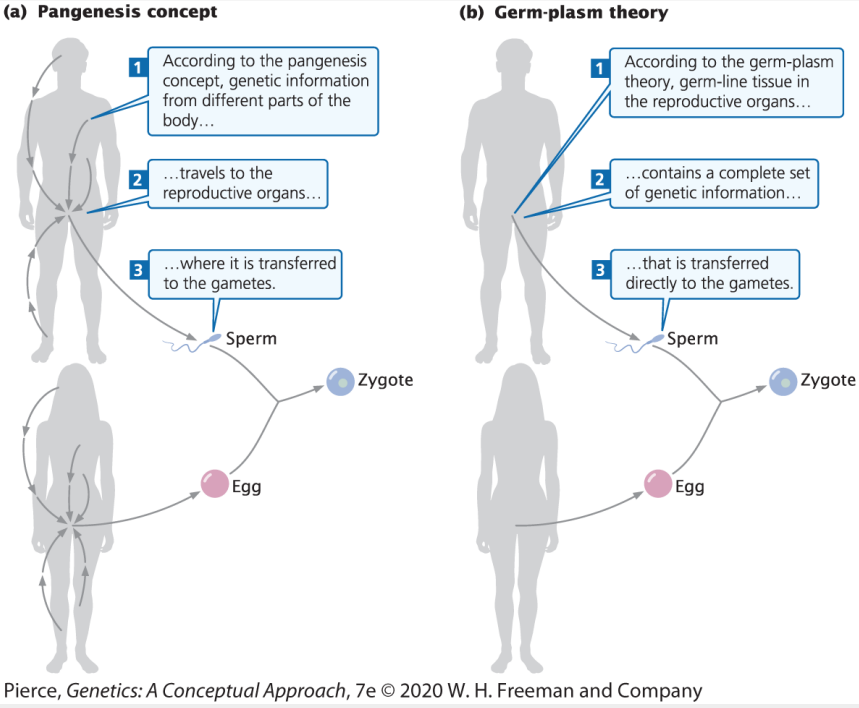
Part a: Scott Bauer/ARS/USDA. Part b: Lower register: Image copyright © The Metropolitan Museum of Art. Image source: Art Resource, NY.

1.9 Ancient peoples practiced genetic techniques in agriculture. (a) Modern wheat, with larger and more numerous seeds that do not scatter before harvest, was produced by interbreeding at least three different wild species. (b) Assyrian bas-relief sculpture showing artificial pollination of date palms at the time of King Ashurnasirpal II, who reigned from 883 to 859 B.C.E.

Description
The photo shows a small sheaf of wheat with grains alongside. The sculpture depicts two mystical figures facilitating artificial pollination of date palms.

Ancient writings demonstrate that early humans were also aware of their own heredity. Hindu sacred writings dating to 2000 years ago suggest that many traits are inherited from the father and that differences between siblings are produced by the mother. The Talmud—the Jewish book of religious laws based on oral traditions dating back thousands of—years, presents an uncannily accurate understanding of the inheritance of hemophilia. It directs that if a woman bears two sons who die of bleeding after circumcision any additional sons that she bears should not be circumcised, nor should the sons of her sisters be circumcised. This advice accurately corresponds to the X-linked pattern of inheritance of hemophilia (discussed further in Chapter 6).

Some early concepts of heredity were incorrect but reflect human interest in heredity and our attempts to explain the inheritance of traits. The ancient Greeks gave careful consideration to human reproduction and heredity. Greek philosophers developed the concept of **pangenesis**, in which each part of the body contains genetic information for that particular part. Specific particles, later called gemmules, carry information from various parts of the body to the reproductive organs, from which they are passed to the embryo at the moment of conception (Figure 1.10a). Although incorrect, the concept of pangenesis was highly influential and persisted until the late 1800s.



1.10 Pangenesis, an early concept of inheritance, compared with the modern germ-plasm theory.

Description

Diagram “a” on the left shows the pangenesis concept. Four arrows from different body parts are marked towards the reproductive organs in man and five arrows from different parts are marked towards reproductive organs in woman. An arrow extends from both man and woman’s reproductive organs points to sperm and egg, respectively. Then, zygote is formed. Three captions read, according to the pangenesis concept, genetic information from different parts of the body, indicated by arrows showing movement from different parts of the body, travels to the reproductive organs, where the information is transferred to the sperm or egg.

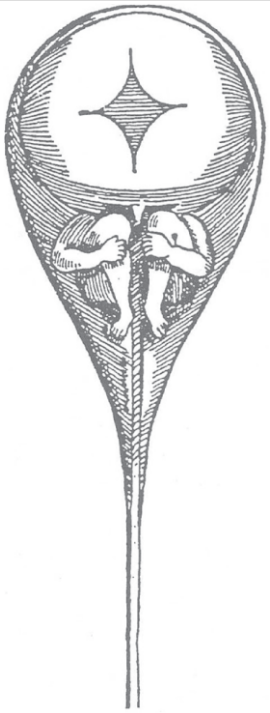
Diagram “b” on the right shows the germplasm concept. An arrow extends from both man and woman’s reproductive organs to sperm and egg, respectively. Then, zygote is formed. Three captions read, according to the germplasm theory, germ-line tissue in the reproductive organs contain a complete set of genetic information that is transferred directly to the sperm and egg.

The concept of pangenesis led the ancient Greeks to propose the notion of the **inheritance of acquired characteristics**, according to which traits acquired in a person’s lifetime become incorporated into that person’s hereditary information and are passed on to offspring; for example, they proposed that people who developed musical ability through diligent study would produce children who were innately endowed with musical ability. Jean-Baptiste Lamarck (1744–1829) was a proponent of this idea and incorporated it into his theory of biological change. The notion of the inheritance of acquired characteristics is also no longer accepted, but it remained popular through the twentieth century.

Although the ancient Romans contributed little to an understanding of human heredity, they successfully developed a number of techniques for animal and plant breeding; their techniques were

based on trial and error rather than any general concept of heredity. Little new information was added to the understanding of genetics in the next thousand years.

Additional developments in our understanding of heredity occurred during the seventeenth century. Dutch eyeglass makers began to put together simple microscopes in the late 1500s, enabling Robert Hooke (1635–1703) to discover cells in 1665. Microscopes provided naturalists with new and exciting vistas on life. Perhaps it was excessive enthusiasm for this new world of the very small that gave rise to the idea of **preformationism**: that inside the egg or sperm there exists a fully formed miniature adult, a *homunculus*, which simply enlarges in the course of development (**Figure 1.11**). Preformationism meant that all traits were inherited from only one parent—from the father if the homunculus was in the sperm or from the mother if it was in the egg. Although many observations suggested that offspring possess a mixture of traits from both parents, preformationism remained a popular concept throughout much of the seventeenth and eighteenth centuries.



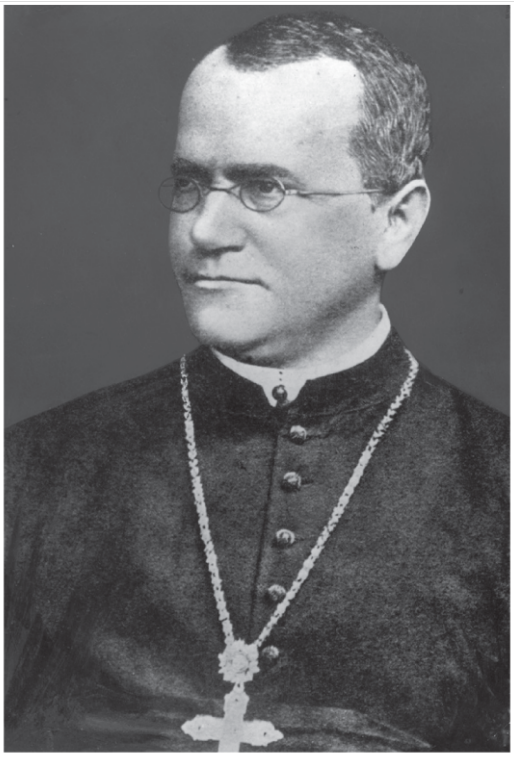
Science Source.

1.11 Preformationists in the seventeenth and eighteenth centuries believed that sperm or eggs contained a fully formed human (the homunculus). Shown here is a drawing of a homunculus inside a sperm.

Another early notion of heredity was **blending inheritance**, which proposed that the traits of offspring are a blend, or mixture, of parental traits. This idea suggested that the genetic material itself blends, much as blue and yellow pigments blend to make green paint; it also suggested that after having been blended, genetic differences could not be separated in future generations, just as green paint cannot be separated into blue and yellow pigments. Some traits do *appear* to exhibit blending inheritance; however, we realize today that individual genes do not blend.

The Rise of the Science of Genetics

In 1676, Nehemiah Grew (1641–1712) reported that plants reproduce sexually. With this information, a number of botanists began to experiment with crossing plants and creating hybrids, including Gregor Mendel (1822–1884; Figure 1.12), who went on to discover the basic principles of heredity. Mendel's conclusions, which were not widely known in the scientific community until 35 years after their publication, laid the foundation for our modern understanding of heredity, and he is generally recognized today as the father of genetics.



Hulton Archive/Getty Images.

1.12 Gregor Mendel is the father of modern genetics. Mendel first discovered the principles of heredity by crossing different varieties of pea plants and analyzing

the transmission of traits in subsequent generations.

Developments in cytology (the study of cells) in the 1800s had a strong influence on genetics. Robert Brown (1773–1858) described the cell nucleus in 1833. Building on the work of others, Matthias Jacob Schleiden (1804–1881) and Theodor Schwann (1810–1882) proposed the concept that came to be known as the **cell theory** in 1839. According to this theory, all life is composed of cells, cells arise only from preexisting cells, and the cell is the fundamental unit of structure and function in living organisms. Biologists interested in heredity began to examine cells to see what took place in the course of cell reproduction. Walther Flemming (1843–1905) observed the division of chromosomes in 1879 and published a superb description of mitosis. By 1885, biologists generally recognized that the cell nucleus contains the hereditary information.

Charles Darwin (1809–1882), one of the most influential biologists of the nineteenth century, put forth the theory of evolution through natural selection and published his ideas in *On the Origin of Species* in 1859. Darwin recognized that heredity was fundamental to evolution, and he conducted extensive genetic crosses with pigeons and other organisms. He never understood the nature of inheritance, however, and this lack of understanding was a major omission in his theory of evolution.

In the last half of the nineteenth century, cytologists demonstrated that the nucleus had a role in fertilization. Near the close of that

century, August Weismann (1834–1914) finally laid to rest the notion of the inheritance of acquired characteristics. He cut off the tails of mice for 22 consecutive generations and showed that the tail length in descendants remained stubbornly long. Weismann proposed the **germ-plasm theory**, which holds that the cells in the reproductive organs carry a complete set of genetic information that is passed to the egg and sperm (**Figure 1.10b**).

The year 1900 was a watershed in the history of genetics. Gregor Mendel's pivotal 1866 publication on experiments with pea plants, which revealed the principles of heredity (considered in more detail in Chapter 3), was rediscovered. Once the significance of his conclusions was recognized, other biologists immediately began to conduct similar genetic studies on mice, chickens, and other organisms. The results of these investigations showed that many traits indeed follow Mendel's rules. Some of the early concepts of heredity are summarized in **Table 1.1**.

TABLE 1.1 Early concepts of heredity

Concept	Proposed	Correct or Incorrect
Pangenesis	Genetic information travels from different parts of the body to reproductive organs.	Incorrect
Inheritance of acquired characteristics	Acquired traits become incorporated into hereditary information.	Incorrect
Preformationism	Miniature organism resides in sex cells, and all traits are inherited from one parent.	Incorrect
Blending inheritance	Genes blend and mix.	Incorrect

Germ-plasm theory	All cells contain a complete set of genetic information.	Correct
Cell theory	All life is composed of cells, and cells arise only from cells.	Correct
Mendelian inheritance	Traits are inherited in accord with defined principles.	Correct

In 1902, after the acceptance of Mendel's theory of heredity, Walter Sutton (1877–1916) proposed that genes, the units of inheritance, are located on chromosomes. Thomas Hunt Morgan (1866–1945) discovered the first mutant fruit fly in 1910 and used fruit flies to unravel many details of transmission genetics. Ronald A. Fisher (1890–1962), John B. S. Haldane (1892–1964), and Sewall Wright (1889–1988) laid the foundation for population genetics in the 1930s by integrating Mendelian genetics and evolutionary theory.

Geneticists began to use bacteria and viruses in the 1940s; the rapid reproduction and simple genetic systems of these organisms allowed detailed study of the organization and structure of their genes. At about this same time, evidence accumulated that DNA was the repository of genetic information. James Watson (b. 1928) and Francis Crick (1916–2004), along with Rosalind Franklin (1920–1958) and Maurice Wilkins (1916–2004), described the three-dimensional structure of DNA in 1953, ushering in the era of molecular genetics (see Chapter 10).

By 1966, the chemical structure of DNA and the system by which it determines the amino acid sequence of proteins had been worked out. Advances in molecular genetics led to the first recombinant

DNA experiments in 1973, which provided techniques for combining genetic material from different sources and touched off another revolution in genetic research. Walter Gilbert (b. 1932) and Frederick Sanger (1918–2013) developed methods for sequencing DNA in 1977. The polymerase chain reaction (PCR), a technique for quickly amplifying tiny amounts of DNA, was developed by Kary Mullis (1944–2019) and others in 1983. PCR has subsequently become one of the most widely used tools in molecular biology.

In 1990, gene therapy was used for the first time to treat human genetic disease in the United States, and the Human Genome Project was launched. By 1995, the first complete DNA sequence of a free-living organism—the bacterium *Haemophilus influenzae*—had been determined, and the first complete sequence of a eukaryotic organism (yeast) was reported a year later. A rough draft of the human genome sequence was reported in 2000 (see Chapter 20), and the sequence was essentially completed in 2003, bringing in another new era in genetics. Building on prior research by several groups, Jennifer Doudna and Emmanuelle Charpentier in 2012 modified the CRISPR-Cas system found in bacteria to develop a powerful new technology for editing the genome. › **TRY PROBLEM 23**

The Cutting Edge of Genetics

With exciting advances being made every year, genetics remains at the forefront of biological research. Rapid methods for sequencing

DNA are being used to sequence the genomes of numerous species, from cockroaches to orangutans to hot peppers to roses. New DNA sequencing techniques are capable of sequencing single DNA molecules, allowing longer and longer sequence reads that facilitate assembling of whole genomes.

Genetics continues to play a major role in agriculture. For example, many people complain about the bland taste of store-bought tomatoes. Geneticists are now using modern genetic techniques to locate genes that are responsible for loss of flavor in commercial tomatoes. In one study, researchers quantified natural compounds that enhance flavor in 400 varieties of tomatoes and identified compounds that were missing or low in poor-tasting commercial varieties. They then used genome sequencing to identify genes that affect the missing flavors, and this information is being used to breed back into commercial varieties compounds that enhance flavor, producing better-tasting tomatoes. Other plant scientists are studying the genetics of volatile organic compounds in flowers, with the goal of engineering fragrance. There is currently a project underway to completely sequence the genomes of 10,000 plant species.

Today, genomic studies provide key insights into evolution. For example, how many types of giraffes are there? Previously, biologists thought there was a single species, but analysis of DNA sequences has now revealed the presence of four distinct species. In 2016, researchers identified the gene responsible for the evolution of

industrial melanism in peppered moths of Britain, where dark moths became more frequent during times of pollution. They discovered that the mutation that produced the dark (*carbonaria*) form of the moths was a large transposable element (a mobile genetic sequence) which inserted into a gene that normally controls cell division and wing development in moths. Whereas archaeologists previously studied fossils, ancient pottery, and tools to understand human ancestry, researchers are now isolating DNA from ancient remains to reconstruct human history. Genome sequences have been analyzed from more than 1000 ancient humans and are being used to answer important questions about the spread of agriculture, the development of languages, and human migration. Genome sequencing of ancient DNA has demonstrated that early *Homo sapiens* interbred with other hominins, including Neanderthals and Denisovans.

Other researchers are unraveling genetic underpinnings of development. Snakes evolved from four-legged ancestors but began to lose their limbs about 150 million years ago. Today, most snakes have lost all vestiges of their limbs (although a few species such as pythons have vestigial pelvises and leg bones). Geneticists have now isolated genes that control the absence of limbs in snakes. When genetic engineers inserted a snake version of an enhancer (a genetic element that controls gene expression) into mice, these mice developed truncated limbs instead of legs.

New research has made CRISPR-Cas9—the powerful genome editing technology that is now widely used in genetic research—more accurate and flexible than ever. New developments have harnessed the ability of CRISPR-Cas9 to provide additional functions, including detection of DNA molecules, editing of RNA, activation of gene expression, and changing of specific base pairs of DNA. CRISPR-Cas was recently used to successfully repair defective genes that cause heart disease in human embryos.

Genetic research continues to provide important information and tools for medicine. Researchers are developing blood tests that detect DNA and proteins shed by tumors, providing the potential for early detection of cancer. Genetics information is being used to develop vaccines to combat infectious diseases such as HIV, Zika, and Ebola. And human gene therapy is being harnessed to treat a number of diseases and disorders, including leukemia, blindness, deafness, blood disorders, cancer, and metabolic disorders. Recently researchers have identified genes that allow Tibetans to live in high altitudes and other genes that allow traditional divers in Southeast Asia to stay underwater for longer periods of time.

As sequencing becomes more affordable, the focus of DNA-sequencing efforts is shifting from the genomes of different species to individual differences within species. In the not-too-distant future, many people will possess a copy of their entire genome sequence, which can be used to help assess the risk of acquiring various diseases and to tailor their treatment should they arise. This

ever-widening scope of genetics raises significant ethical, social, and economic issues.

This brief overview of the history of genetics, from the first domestication of crops to present-day whole-genome sequencing, is not intended to be comprehensive; rather, it is designed to provide a sense of the accelerating pace of advances in genetics. In the chapters to come, we will learn more about the experiments and the scientists who helped shape the discipline of genetics.

THINK-PAIR-SHARE Question 3

CONCEPTS

Humans first applied genetic methods to the domestication of plants and animals between approximately 10,000 and 12,000 years ago. Developments in plant hybridization and cytology in the eighteenth and nineteenth centuries laid the foundation for the field of genetics today. After Mendel's work was rediscovered in 1900, the science of genetics developed rapidly, and today it is one of the most active areas of science.

✔ CONCEPT CHECK 3

How did developments in cytology in the nineteenth century contribute to our modern understanding of genetics?

1.3 A Few Fundamental Concepts Are Important for the Start of Our Journey into Genetics

Undoubtedly, you learned some genetic principles in other biology classes. Let's take a few moments to review some fundamental genetic concepts.

CELLS ARE OF TWO BASIC TYPES: EUKARYOTIC AND PROKARYOTIC

Structurally, cells consist of two basic types, although evolutionarily, the story is more complex (see Chapter 2). Prokaryotic cells lack a nuclear membrane and do not generally possess membrane-bounded organelles, whereas eukaryotic cells are more complex, possessing a nucleus and membrane-bounded organelles such as chloroplasts and mitochondria.

THE GENE IS THE FUNDAMENTAL UNIT OF HEREDITY

The precise way in which a gene is defined often varies depending on the biological context. At the simplest level, we can think of a gene as a unit of information that encodes a genetic characteristic. We

will expand this definition as we learn more about what genes are and how they function.

GENES COME IN MULTIPLE FORMS CALLED ALLELES

A gene that specifies a characteristic may exist in several forms, called alleles. For example, a gene for coat color in cats may exist as an allele that encodes black fur or as an allele that encodes orange fur.

GENES CONFER PHENOTYPES

One of the most important concepts in genetics is the distinction between traits and genes. Traits are not inherited directly. Rather, genes are inherited, and genes, along with environmental factors, determine the expression of traits. The genetic information that an individual organism possesses is its genotype; the trait is its phenotype. For example, the albinism seen in some Hopis is a phenotype, and the information in *OCA2* genes that causes albinism is a genotype.

GENETIC INFORMATION IS CARRIED IN DNA AND RNA

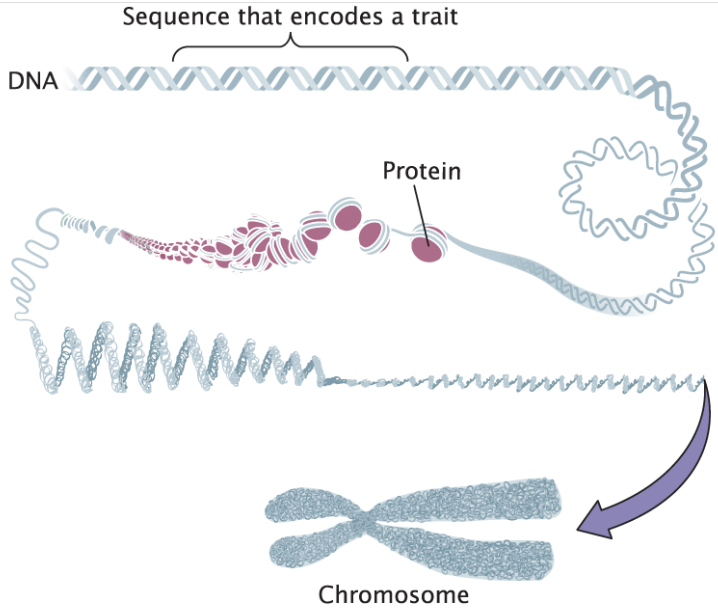
Genetic information is encoded in the molecular structure of nucleic acids, which come in two types: deoxyribonucleic acid (DNA) and

ribonucleic acid (RNA). Nucleic acids are polymers consisting of repeating units called nucleotides; each nucleotide consists of a sugar, a phosphate, and a nitrogenous base. The nitrogenous bases in DNA are of four types: adenine (A), cytosine (C), guanine (G), and thymine (T). The sequence of these bases encodes genetic information. DNA consists of two complementary nucleotide strands. Most organisms carry their genetic information in DNA, but a few viruses carry it in RNA. The four nitrogenous bases of RNA are adenine, cytosine, guanine, and uracil (U).

THINK-PAIR-SHARE Question 4

GENES ARE LOCATED ON CHROMOSOMES

The vehicles of genetic information within a cell are chromosomes (Figure 1.13), which consist of DNA and associated proteins. The cells of each species have a characteristic number of chromosomes; for example, bacterial cells normally possess a single chromosome, human cells possess 46, and pigeon cells possess 80. Genes are located on chromosomes; each chromosome carries a large number of genes.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

1.13 Genes are carried on chromosomes, which consist of highly compacted DNA and proteins. Represented here is a typical eukaryotic chromosome.

Description
The illustration shows a long double helix D N A strand. A region on the D N A is labeled “sequence that encodes a trait”. As it proceeds, a turns and forms coils. On further proceeding, spherical proteins are being wrapped up within D N A coils. Then, D N A strand condenses and takes shape of a wire structure. The wire shaped D N A strand continues and finally leads to super-condensed X-shaped chromosome.

CHROMOSOMES SEPARATE THROUGH THE PROCESSES OF MITOSIS AND MEIOSIS

The processes of mitosis and meiosis ensure that a complete set of an organism’s chromosomes exists in each cell that results from cell division. Mitosis is the separation of chromosomes in the division of

somatic (nonsex) cells. Meiosis is the pairing and separation of chromosomes in the division of sex cells to produce gametes (reproductive cells).

GENETIC INFORMATION IS TRANSFERRED FROM DNA TO RNA TO PROTEIN

Many genes encode characteristics by specifying the structure of proteins. Genetic information is first transcribed from DNA into RNA, and then RNA is translated into the amino acid sequence of a protein.

MUTATIONS ARE PERMANENT CHANGES IN GENETIC INFORMATION THAT CAN BE PASSED FROM CELL TO CELL OR FROM PARENT TO OFFSPRING

Gene mutations affect the genetic information of a single gene; chromosome mutations alter the number or the structure of chromosomes and therefore usually affect many genes.

MANY TRAITS ARE AFFECTED BY MULTIPLE FACTORS

Many traits are affected by multiple genes that interact in complex ways with one another and with environmental factors. Human

height, for example, is affected by many genes as well as by environmental factors such as nutrition.

EVOLUTION IS GENETIC CHANGE

Evolution can be viewed as a two-step process: first, genetic variation arises, and second, some genetic variants increase in frequency, whereas other variants decrease in frequency. **› TRY PROBLEM 25**

Chapter 1 Review

CHAPTER SUMMARY

Section 1.1 Learning Objective: Be able to explain the importance of genetics.

- Genetics is central to the life of every person: it influences a person's physical features, personality, intelligence, and susceptibility to numerous diseases.
- Genetics plays important roles in agriculture, the pharmaceutical industry, and medicine. It is central to the study of biology.
- All organisms use similar genetic systems. Genetic variation is the foundation of evolution and is critical to understanding all life.
- A tremendous amount of DNA exists in the biosphere. Scientists use environmental DNA to study and analyze biodiversity.
- The study of genetics can be broadly divided into transmission genetics, molecular genetics, and population genetics.
- Model genetic organisms are species about which much genetic information exists because they have characteristics that make them particularly amenable to genetic analysis.

Section 1.2 Learning Objective: Be able to describe the history of genetics.

- The use of genetics by humans began with the domestication of plants and animals.
- Ancient Greeks developed the concepts of pangenesis and the inheritance of acquired characteristics, both of which were later disproved. Ancient Romans developed practical measures for the breeding of plants and animals.
- Preformationism suggested that a person inherits all of his or her traits from one parent. Blending inheritance proposed that offspring possess a mixture of the parental traits. These ideas were later shown to be incorrect.
- By studying the offspring of crosses between varieties of peas, Gregor Mendel discovered the principles of heredity. Developments in cytology in the nineteenth century led to the understanding that the cell nucleus is the site of heredity.
- In 1900, Mendel's principles of heredity were rediscovered. Population genetics was established in the early 1930s, followed by bacterial and viral genetics. The structure of DNA was discovered in 1953, stimulating the rise of molecular genetics.
- The first human whole-genome sequence was completed in 2003.

Section 1.3 Learning Objective: Be able to explain basic concepts of heredity.

- There are two basic types of cells: prokaryotic and eukaryotic.
- The set of alleles that determines a trait is termed the genotype; the trait that they produce is the phenotype.

- Genes are located on chromosomes, which are made up of nucleic acids and proteins and are partitioned into daughter cells through the process of mitosis or meiosis.
- Genetic information is expressed through the transfer of information from DNA to RNA to proteins.
- Evolution requires genetic change in populations.

IMPORTANT TERMS

genetics
genome
transmission genetics
molecular genetics
population genetics
model genetic organism
pangenesis
inheritance of acquired characteristics
preformationism
blending inheritance
cell theory
germ-plasm theory

ANSWERS TO CONCEPT CHECKS

1. d

2. No, because horses are expensive to house, feed, and propagate; they have too few progeny; and their generation time is too long.
3. Developments in cytology in the 1800s led to the identification of parts of the cell, including the cell nucleus and chromosomes. The cell theory focused biologists' attention on the cell, eventually leading to the conclusion that the nucleus contains the hereditary information.

Chapter 1 Assessment

COMPREHENSION QUESTIONS

Answers to questions and problems preceded by an asterisk can be found at the end of the book.

Section 1.1

1. *How did Hopi culture contribute to the high incidence of albinism among members of the Hopi tribe?
2. Outline some of the ways in which genetics is important to all of us.
3. Give at least three examples of the role of genetics in society today.
4. Briefly explain why genetics is crucial to modern biology.
5. List the three traditional subdisciplines of genetics and summarize what each covers.
6. What are some characteristics of model genetic organisms that make them useful for genetic studies?

Section 1.2

7. *When and where did agriculture first arise?

8. Outline the concept of pangenesis and explain how it differs from the present-day germ-plasm theory.

9. What does the concept of the inheritance of acquired characteristics propose and how is it related to the concept of pangenesis?

10. What is preformationism? What did it have to say about how traits are inherited?

11. Define blending inheritance and contrast it with preformationism.

12. How did developments in botany in the seventeenth and eighteenth centuries contribute to the rise of modern genetics?

13. List some advances in genetics made in the twentieth century.

14. Briefly explain the contribution that each of the following people made to the study of genetics.

    a. Matthias Schleiden and Theodor Schwann

    b. August Weismann

    c. Gregor Mendel

d. James Watson, Francis Crick, Rosalind Franklin, and Maurice Wilkins

e. Kary Mullis

Section 1.3

15. *What are the two basic cell types (from a structural perspective) and how do they differ?

16. Summarize the relations between genes, DNA, and chromosomes.

APPLICATION QUESTIONS AND PROBLEMS

Section 1.1

17. *How are genetics and evolution related?

18. *For each of the following genetic topics, indicate whether it focuses on transmission genetics, molecular genetics, or population genetics.

    a. Analysis of pedigrees to determine the probability of someone inheriting a trait

b. Study of people on a small island to determine why a genetic form of asthma is prevalent on the island

c. Effect of nonrandom mating on the distribution of genotypes among a group of animals

d. Examination of the nucleotide sequences found at the ends of chromosomes

e. Mechanisms that ensure a high degree of accuracy in DNA replication

f. Study of how the inheritance of traits encoded by genes on sex chromosomes (sex-linked traits) differs from the inheritance of traits encoded by genes on nonsex chromosomes (autosomal traits)

19. How does the picture in **Figure 1.6a** illustrate transmission genetics?

20. Describe some of the ways in which your own genetic makeup affects you as a person. Be as specific as you can.

21. Describe at least one trait that appears to run in your family (appears in multiple members of the family). Does this trait run in your family because it is an inherited trait or because it is caused by environmental factors that are common to family members? How might you distinguish between these possibilities?

Section 1.2

22. *Genetics is said to be both a very old science and a very young science. Explain what is meant by this statement.

23. *Match each of the descriptions (*a* through *d*) with the appropriate theory or concept that follows.

    Preformationism

    Pangenesis

    Germ-plasm theory

    Inheritance of acquired characteristics

    a. Each reproductive cell contains a complete set of genetic information.

    b. All traits are inherited from one parent.

    c. Genetic information may be altered by the use of a characteristic.

    d. Cells of different tissues contain different genetic information.

24. Briefly explain why each of the following theories is incorrect:

    a. Pangenesis

    b. Preformationism

c. Blending inheritance

d. Inheritance of acquired characteristics

Section 1.3

25. *Compare and contrast the following terms:

a. Eukaryotic and prokaryotic cells

b. Gene and allele

c. Genotype and phenotype

d. DNA and RNA

e. DNA and chromosome

CHALLENGE QUESTIONS

Introduction

26. *The type of albinism that arises with high frequency among Hopi Native Americans (discussed in the introduction to this chapter) is most likely oculocutaneous albinism type 2, due to a defect in the *OCA2* gene on chromosome 15. Visit the Online Mendelian Inheritance in Man Website (http://www.ncbi.nlm.nih.gov/omim/) and search the database for albinism. Based on this information, how does the

phenotype of oculocutaneous albinism type 2 differ from the phenotypes of other forms of albinism in humans? What genes are mutated in other types of albinism?

Section 1.1

27. We now know a great deal about the genetics of humans, and humans are the focus of many genetic studies. What are some of the reasons humans have been the focus of intensive genetic study?

28. Use Google Scholar (https://scholar.google.com/) or another appropriate search engine to find research articles published in the past five years that focus on (a) transmission genetics, (b) molecular genetics, and (c) population genetics. Give an example of each.

Section 1.3

29. *Suppose that life exists elsewhere in the universe. All life must contain some type of genetic information, but alien genomes might not consist of nucleic acids and have the same features as those found in the genomes of life on Earth. What might be the common features of all genomes, no matter where they exist?

30. Choose one of the ethical or social issues in parts *a* through *e* and give your opinion on the issue. For background information, you might read one of the articles on ethics

marked with an asterisk in the Suggested Readings section for Chapter 1 in your Sapling Plus.

a. Should a person's genetic makeup be used in determining his or her eligibility for life insurance?

b. Should biotechnology companies be able to patent newly sequenced genes?

c. Should gene therapy be used in people?

d. Should genetic testing be made available for inherited disorders for which there is no treatment or cure?

31. A 45-year-old woman undergoes genetic testing and discovers that she is at high risk for developing colon cancer and Alzheimer disease. Because her children have 50% of her genes, they may also be at an increased risk for these diseases. Does she have a moral or legal obligation to tell her children and other close relatives about the results of her genetic testing?

32. Suppose that you could undergo genetic testing at age 18 for susceptibility to a genetic disease that would not appear until middle age and has no available treatment.

    a. What would be some of the possible reasons for having such a genetic test and some of the possible reasons for not having the test?

    b. Would you personally want to be tested? Explain your reasoning.

💬 ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Think-Pair-Share questions are designed to be worked in collaboration with other students. First THINK about the question, then PAIR up with one or more other students, and finally SHARE your answers and work together to arrive at a solution.

Section 1.1

1. Bob says that he is healthy and has no genetic diseases such as hemophilia or Down syndrome. Therefore, he says, genetics plays little role in his life. Do you think Bob is correct in his conclusion? Why or why not?

2. Are mutations good or bad? Explain your answer.

Section 1.2

3. Propose some arguments for and against the development of genetically engineered foods (genetically modified organisms, or GMOs)? Think about the economic and environmental benefits, health risks, ecological effects, and social impact of their use. List some reasons for and against genetically engineering the foods we eat and the types of evidence that would be needed to support these arguments.

Section 1.3

4. Why do you think all organisms use nucleic acids for encoding genetic information? Why not use proteins or carbohydrates? What advantages might DNA have as the source of genetic information?

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

A concept map, often organized around a question, is designed to help you think about the relationships between concepts. First think of concepts and terms that address the question and the relationships among them. Then create a diagram to show these relationships. In the diagram, draw a circle or box around each concept or term. Represent the relationships between concepts with lines that connect the concepts. Each line should have an arrow, showing the direction of the relationship. For each connecting line, add a label consisting of a few words that explains the relationship between the concepts. Include as many connections as you can.

It is important to recognize that there is not one, single correct map for a set of concepts; the same concepts may be organized in different ways.

Introduction

1. Explain the relationship between genetics and albinism in the Hopi Native Americans by creating a concept map that links the following terms and phrases: albinism, reduced melanin, autosomal recessive, oculocutaneous albinism type II, *OCA2* gene, Hopi Native Americans, mating advantage, small size of the tribe, reduced selection against, light skin, sunburn, skin cancer, visual impairment.

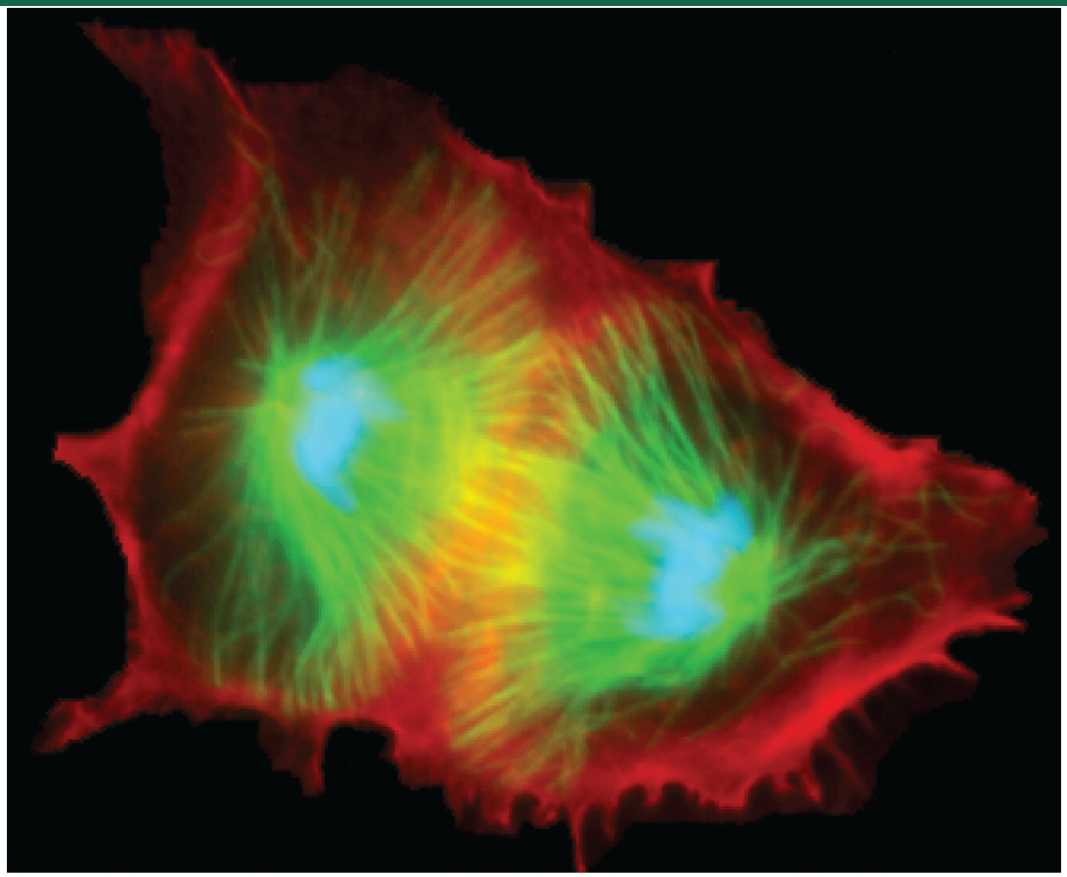
Section 1.3

2. Outline the organization of genetic information within a cell by creating a concept map that links the following terms: DNA, genes, alleles, genotype, phenotype, chromosomes, proteins, environmental factors, genome.

SaplingPlus Self-study tools that will help you practice what you've learned and reinforce this chapter's concepts are available online. Go to www.saplinglearning.com.

CHAPTER 2

Chromosomes and Cellular Reproduction



Courtesy of Julie Canman and Ted Salman.

A rat kangaroo kidney cell undergoing mitosis, the process through which each new cell receives a complete copy of the genetic material. Chromosomes are shown in blue.

The Blind Men's Riddle

In a well-known riddle, two blind men by chance enter a department store at the same time, go to the same counter, and both order five pairs of socks, each pair a different color. The salesclerk is so befuddled by this strange coincidence that he places all ten pairs (two black pairs, two blue pairs, two gray pairs, two brown pairs, and two green pairs) into a single shopping bag, gives the bag of socks to one blind man, and gives an empty bag to the other. The two blind men happen to meet on the street outside, where they discover that one of their bags contains all ten pairs of socks. How do the blind men, without seeing and without any outside help, sort out the socks so that each man goes home with exactly five pairs of different colored socks? Can you come up with a solution to the riddle?

By an interesting coincidence, cells face the same challenge as that of the blind men. Most organisms possess two sets of genetic information, one set inherited from each parent. Before cell division, the DNA in each chromosome replicates; after replication, there are two copies—called sister chromatids—of each chromosome. At the end of cell division, it is critical that each of the two new cells receives a complete copy of the genetic material, just as each blind man needs to go home with a complete set of socks.

The solution to the riddle is simple. Socks are sold as pairs; the two socks of a pair are typically connected by a thread. As a pair is removed from the bag, the men each grasp a different sock of the

pair and pull in opposite directions. When the socks are pulled tight, one of the men can take a pocket knife and cut the thread connecting the pair. Each man then deposits his single sock in his own bag. At the end of the process, each man's bag will contain exactly two black socks, two blue socks, two gray socks, two brown socks, and two green socks.[1]

Remarkably, cells employ a similar solution for separating their chromosomes into new daughter cells. As we learn in this chapter, the replicated chromosomes line up at the center of a cell undergoing division, and like the socks in the riddle, the sister chromatids of each chromosome are pulled in opposite directions. Like the thread connecting two socks of a pair, a molecule called cohesin holds the sister chromatids together until it is severed by a molecular knife called separase. The two resulting chromosomes separate, and the cell divides. This process ensures that a complete set of chromosomes is deposited in each cell.

In this analogy, the blind men and cells differ in one critical regard: if the blind men make a mistake, one man ends up with an extra sock and the other is a sock short, but no great harm results. The same cannot be said for human cells. Errors in chromosome separation, producing cells with too many or too few chromosomes, are frequently catastrophic, leading to cancer, miscarriage, or—in some cases—a child with severe disabilities.

THINK-PAIR-SHARE

- In the blind men's riddle, two blind men must sort out ten pairs of socks so that each man gets exactly five pairs of different colored socks. In the analogy, is it important that the men are blind? In a cell, what does the blindness represent?

This chapter explores the process of cell reproduction and explains how a complete set of genetic information is transmitted to new cells. In prokaryotic cells, reproduction is relatively simple because prokaryotic cells tend to possess only one chromosome per cell. In eukaryotic cells, multiple chromosomes must be copied and distributed to each of the new cells, making cell reproduction more complex. Cell division in eukaryotes takes place through mitosis or meiosis, processes that serve as the foundation for much of eukaryotic genetics.

Grasping the processes of mitosis and meiosis requires more than simply memorizing the sequences of events that take place in each stage, although these events are important. The key is to understand how genetic information is apportioned in the course of cell reproduction through the dynamic interplay of DNA synthesis, chromosome movement, and cell division. These processes also underlie the transmission of genetic information from parent to progeny and are the basis of the similarities and differences between parents and their offspring.

2.1 Prokaryotic and Eukaryotic Cells Differ in a Number of Genetic Characteristics

Biologists have traditionally classified all living organisms into two major groups, the prokaryotes and the eukaryotes (Figure 2.1). A **prokaryote** is a unicellular organism with a relatively simple cell structure. A **eukaryote** has a compartmentalized cell structure with components bounded by intracellular membranes; eukaryotes may be either unicellular or multicellular.

	Prokaryotic cells	Eukaryotic cells
Nucleus	Absent	Present
Cell diameter	Relatively small, from 1 to 10 μm	Relatively large, from 10 to 100 μm
Genome	Usually one circular DNA molecule	Multiple linear DNA molecules
DNA	Not complexed with histones in bacteria; some histones in archaea	Complexed with histones
Amount of DNA	Relatively small	Relatively large
Membrane-bounded organelles	Absent	Present

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company
Photographs (left to right): Dr. Gary D. Gaugler/Newscom; Dr. Kari Lounatmaa/Science Source; Dr. Gopal Murti/ Medicalimages.com; Biophoto Associates/Science Source.

2.1 Prokaryotic and eukaryotic cells differ in structure.

Description

The illustration on the left shows a diagram of a prokaryotic cell and two micrographs. The illustration on the right shows a diagram of a eukaryotic animal cell and plant cell and two micrographs. A table present below compares the differences between prokaryotic and eukaryotic cells.

In the first illustration, a diagram shows cross-section of a rod-shaped prokaryotic cell. The cell has an outer cell wall with various thread-like structures and the plasma membrane underneath. Tiny spheres inside the cell are labeled as ribosomes and an intertwined stranded material is labeled as D N A. Two micrographs show a bacterium and Archaea which are both rod-shaped.

In the second illustration, a diagram shows components of a eukaryotic animal and plant cell. The nucleus, a spherical structure with several wavy layers outside, is located in center of both the cells. The folded layers extending out from the nuclei are components of the endoplasmic reticulum. The inside of the nucleus contains a sphere and D N A. The nucleus is enclosed in a nuclear envelope. Both cell diagrams also consist of ribosomes, mitochondria, Golgi apparatus, and a plasma membrane. The ribosomes are represented by tiny spheres. Mitochondria, oblong enveloped structures with the internal portion of the envelope membrane extending inwards into a number of stacked folds, appears in both cells. The Golgi apparatus, thin stacked cluster of ovular-shaped layers, is present in both the cells. Organelles that are only present in the plant cell are the vacuole, chloroplasts, and cell wall. The vacuole is large and is ovular-shaped which occupies about 50 percent of the inside of the plant cell. The chloroplasts, green-colored ovular membrane-bound objects with multiple spherical structures inside, are only present in the plant cell. Two micrographs below show a eukaryotic animal and plant cell, respectively.

A table below highlights the structural differences between a eukaryotic and prokaryotic cell. The table has 6 rows and 3 columns. The information present in the table is as follows:

Nucleus: Prokaryotic cells, Absent. Eukaryotic cells, present.

Cell diameter: Prokaryotic cells, relatively small from 1 to 10 micrometers. Eukaryotic cells, relatively large from 10 to 100 micrometers.

Genome: Prokaryotic cells, usually one circular D N A molecule. Eukaryotic cells, multiple linear D N A molecules.

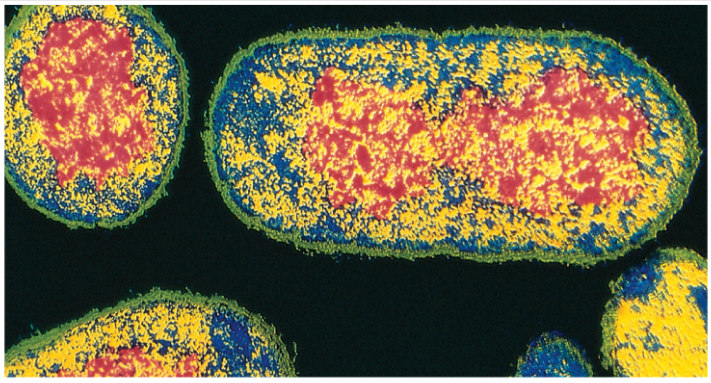
D N A: Prokaryotic cells, not complexed with histones in bacteria; some histones in archaea. Eukaryotic cells, complexed with histones.

Amount of D N A: Prokaryotic cells, relatively small. Eukaryotic cells, relatively large.

Membrane-bounded organelles: Prokaryotic cells, absent. Eukaryotic cells, present.

Research indicates, however, that the division of life is not so simple. Although all prokaryotes are similar in cell structure, they include at least two fundamentally distinct types: the **bacteria** (also called eubacteria or "true bacteria") and the **archaea** ("ancient bacteria"). An examination of equivalent DNA sequences reveals that bacteria and archaea are as distantly related to each other as they are to the eukaryotes. Thus, from an evolutionary perspective, there are three major groups of organisms: bacteria, archaea, and eukaryotes. Although bacteria and archaea are similar in cell structure, some genetic processes in archaea (such as transcription) are more similar to those in eukaryotes, and the archaea may be closer evolutionarily to eukaryotes than to bacteria. Some researchers propose that eukaryotes arose within the archaea and thus that there are two primary domains of life: the bacteria and another domain that includes the archaea and the eukaryotes. The evolutionary relationships among bacteria, archaea, and eukaryotes remain uncertain, however, and are the focus of current research. In this book, the prokaryotic–eukaryotic distinction will be made frequently, but important bacterial–archaeal differences will also be noted.

From the perspective of genetics, a major difference between prokaryotic and eukaryotic cells is that a eukaryotic cell has a nuclear membrane, which surrounds the genetic material to form a **nucleus** and separates the DNA from the other cellular contents. In prokaryotic cells, the genetic material is in close contact with other components of the cell—a property that has important consequences for the way in which gene expression is controlled (**Figure 2.2**).



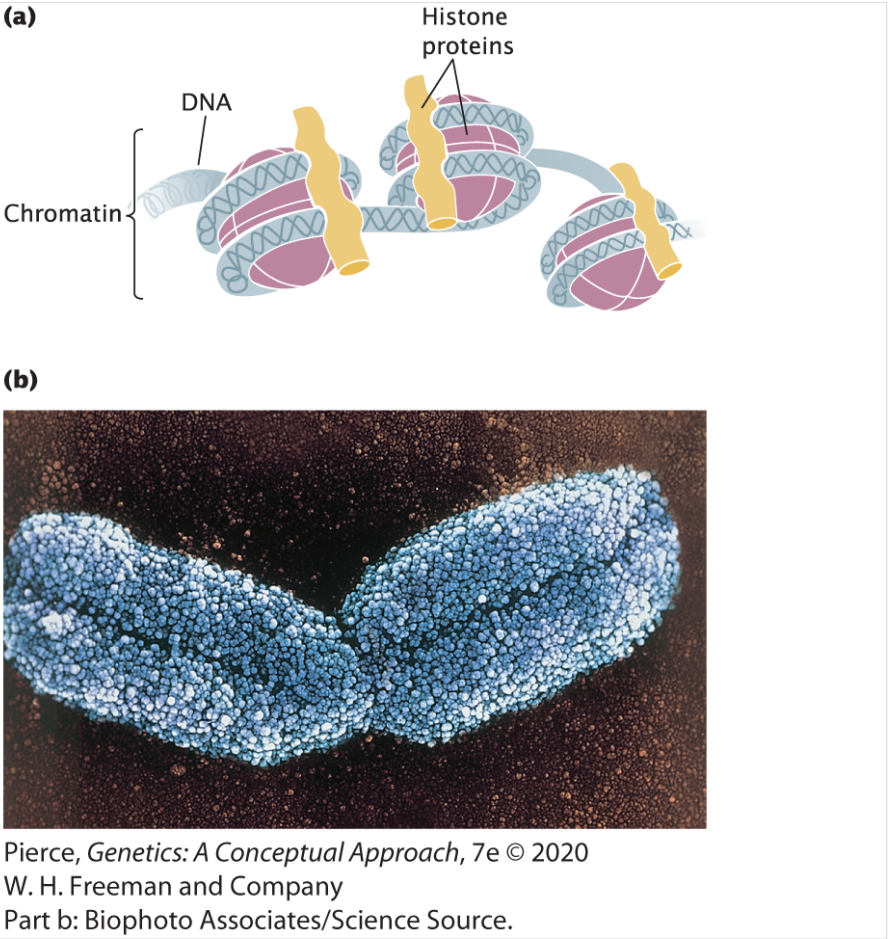
A. Barry Dowsett/Science Source.

2.2 Prokaryotic DNA (shown in red) is neither surrounded by a nuclear membrane nor complexed with histone proteins.

Description
The prokaryotic D N A is not surrounded by a nuclear membrane and is also not complexed with histone proteins.

Another fundamental difference between prokaryotes and eukaryotes lies in the packaging of their DNA. In eukaryotes, DNA associates closely with a special class of proteins, the **histones**, to form tightly packed chromosomes (**Figure 2.3**). This complex of

DNA and histone proteins, called **chromatin**, is the stuff of eukaryotic chromosomes. Histone proteins help regulate the accessibility of DNA to enzymes and other proteins that copy and read the DNA (see Chapter 17), and they also enable the DNA to fit into the nucleus of a eukaryotic cell (Chapter 11). Archaea also have some histone proteins that complex with DNA. The histones found in archaea are related to but distinct from those found in eukaryotes, and the structure of archaeal chromatin is different from that found in eukaryotes. Bacteria do not possess histones, and their DNA does not exist in the highly ordered, tightly packed arrangement found in eukaryotic cells. The copying and reading of DNA are therefore simpler processes in bacteria.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company
Part b: Biophoto Associates/Science Source.

2.3 Eukaryotic chromosomes consist of DNA and histone proteins. (a) DNA wraps around the histone proteins to form chromatin, the material that makes up chromosomes. (b) A eukaryotic chromosome.

Description

Illustration “a” at the top shows a chromatin formed by a D N A duplex wrapped around clusters of histone proteins. The D N A duplex strand wraps twice around each nucleosome. Another histone protein, thin and cylindrical shaped, is attached outside each of the condensed balls formed by D N A wrapped histones.

The micrograph “b” at the bottom shows a eukaryotic chromosome which is X-shaped. It has two lobes on each side with tiny spherical bodies on its surface.

The genes of prokaryotic cells are generally located on a single circular molecule of double-stranded DNA—the chromosome of a prokaryotic cell. In eukaryotic cells, genes are located on multiple, usually linear DNA molecules (multiple chromosomes). Eukaryotic cells therefore require mechanisms to ensure that a copy of each chromosome is faithfully transmitted to each new cell. However, this generalization—a single circular chromosome in prokaryotes and multiple linear chromosomes in eukaryotes—is not always true. A few bacteria have more than one chromosome, and important bacterial and archaeal genes are frequently found on other DNA molecules called *plasmids* (see Chapter 9). Furthermore, in some eukaryotes, a few genes are located on circular DNA molecules found in certain organelles, such as mitochondria and chloroplasts (see Chapter 11).

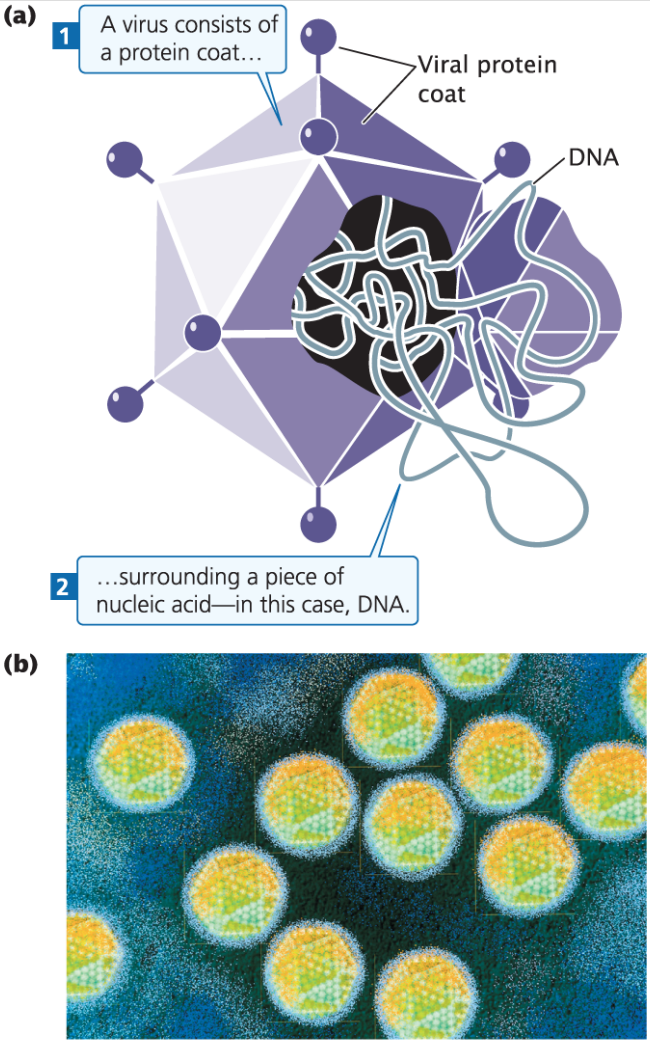
CONCEPTS

Organisms are classified as prokaryotes or eukaryotes, and the prokaryotes consist of archaea and bacteria. A prokaryote is a unicellular organism that lacks a nucleus, and its genome is usually a single chromosome. Eukaryotes may be either unicellular or multicellular, their cells possess a nucleus, their DNA is complexed with histone proteins, and their genomes consist of multiple chromosomes.

✔ CONCEPT CHECK 1

List several characteristics that bacteria and archaea have in common and that distinguish them from eukaryotes.

Viruses are neither prokaryotic nor eukaryotic because they do not possess the structure of a cell. Viruses are actually simple structures composed of an outer protein coat surrounding nucleic acid (either DNA or RNA; **Figure 2.4**). All known viruses can reproduce only within host cells, and their evolutionary relationship to cellular organisms is uncertain. Their simplicity and small genomes make viruses useful for studying some molecular processes and for some types of genetic analyses. For example, bacteriophages—viruses that infect bacteria—have been used to study the control of gene expression, recombination, and molecular evolution.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company
Part b: BSIP/Science Source.

2.4 A virus is a simple replicative structure consisting of protein and nucleic acid. (a) Structure of an adenovirus. (b) A micrograph of adenoviruses.

Description

The diagram “a” shows a purple colored icosahedral-shaped virus, the outside layer is labeled as the protein coat, which is surrounding the virus’s D N A. Each edge of the protein coat has a protruding thin rod with a round structure at its end. The viral D N A is like a long thin grey thread inside the coat. A caption reads, “A virus consists of a protein coat surrounding a piece of nucleic acid—in this case, D N A.” The micrograph “b” shows a number of circular greenish yellow colored viruses over a blue colored background.

2.2 Cell Reproduction Requires the Copying of the Genetic Material, Separation of the Copies, and Cell Division

For any cell to reproduce successfully, three fundamental events must take place: (1) its genetic information must be copied, (2) the copies must be separated from each other, and (3) the cell must divide. All cellular reproduction includes these three events, but the processes that lead to these events differ in prokaryotic and eukaryotic cells because of their structural differences.

Prokaryotic Cell Reproduction by Binary Fission

When a prokaryotic cell reproduces, its circular chromosome replicates, and the cell divides in a process called *binary fission* (Figure 2.5). Replication usually begins at a specific place on the circular chromosome, called the origin of replication. The origins of the two newly replicated chromosomes move away from each other and toward opposite ends of the cell. Proteins called structural maintenance of chromosomes (SMC) complexes encircle the DNA and help keep the two newly synthesized chromosomes from getting

tangled as they are replicated. Finally, a new cell wall forms between the two chromosomes, producing two cells, each with an identical copy of the chromosome. Under optimal conditions, some bacterial cells divide every 20 minutes. At this rate, a single bacterial cell could produce a billion descendants in a mere 10 hours.

2.5 Prokaryotic cells reproduce by binary fission. (a) The process of binary fission. (b) A bacterial cell undergoing binary fission.

Description

The illustration “a” at the top shows a bacterium with a circular D N A double strand. The illustration shows the steps from top to bottom. A caption reads, prokaryotic cell contains a single circular chromosome made up of double-stranded D N A with a yellow-colored spherical origin of replication. This stage progresses to the next stage where the chromosome replicates. A caption reads, as the chromosome replicates, the origins segregate to opposite sides. The resultant cell has replicated D N A where the origins of replication are anchored to opposite sides of the cell. This progresses to the next stage where two cells are distinct with a furrow between them. Each cell shows one circular D N A double strand. A caption reads, the cell divides. Each new cell has an identical copy of the original chromosome. This leads to formation of two daughter cells.

The micrograph “b” at the bottom shows a bacterial cell undergoing binary fission with a furrow forming at its center.

Eukaryotic Cell Reproduction

Like prokaryotic cell reproduction, eukaryotic cell reproduction requires the processes of DNA replication, copy separation, and division of the cytoplasm. However, the presence of multiple DNA molecules requires a more complex mechanism to ensure that exactly one copy of each DNA molecule ends up in each of the new cells.

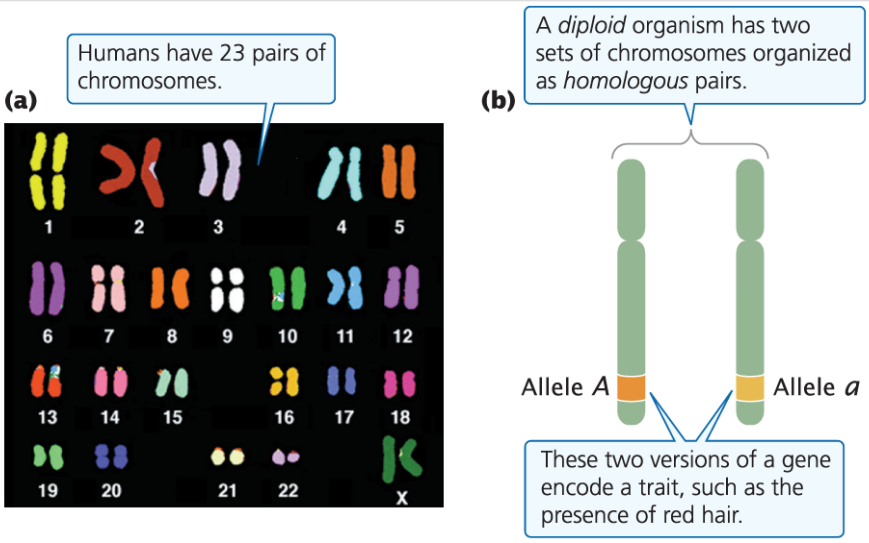
Eukaryotic chromosomes are separated from the cytoplasm by the nuclear membrane. The nucleus has a highly organized internal scaffolding, called the nuclear matrix, which consists of a network of protein fibers. The nuclear matrix maintains precise spatial relations among the components of the nucleus and takes part in DNA replication, the expression of genes, and the modification of gene products before they leave the nucleus.

EUKARYOTIC CHROMOSOMES

Each eukaryotic species has a characteristic number of chromosomes per cell: potatoes have 48 chromosomes, fruit flies have 8, and humans have 46. There appears to be no special relation between the complexity of an organism and its number of chromosomes per cell.

In most eukaryotic cells, there are two sets of chromosomes. The presence of two sets is a consequence of sexual reproduction: one set is inherited from the male parent and the other, from the female parent. Each chromosome in one set has a corresponding

chromosome in the other set; together, the two chromosomes constitute a **homologous pair** (Figure 2.6). Human cells, for example, have 46 chromosomes: in females, there are 23 homologous pairs; in males, 22 pairs are homologous, and the last pair (X and Y chromosomes) is only partially homologous (see Chapter 4).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company
Part a: Courtesy of Dr. Thomas Ried and Dr. Evelin Schrock.

2.6 Diploid eukaryotic cells have two sets of chromosomes. (a) A set of chromosomes from a female human cell. Each pair of chromosomes has been hybridized to a uniquely colored probe, giving it a distinct color. (b) The chromosomes are present in homologous pairs. Each pair consists of two chromosomes that are alike in size and structure and carry information for the same characteristics.

Description
The Karyotype “a” on the left shows 23 sets of human chromosomes that vary in color, shape and size. The chromosomes are not attached into an X shaped formation, but are present as separate entities. The twenty third pair is labeled as X. A caption reads, humans have 23 pairs of chromosomes.

The illustration “b” on the right shows two non-conjoined chromosomes. A caption reads, a diploid organism has two sets of chromosomes organized as homologous pairs. The chromosome on the left has a band at the bottom chromatid, labeled allele big A. The chromosome on the right has a band at the bottom chromatid labeled as allele small a. A caption reads, these two versions of a gene encode a trait, such as the presence of red hair.

The two chromosomes of a homologous pair are usually alike in structure and size, and each carries genetic information for the same set of hereditary characteristics (the sex chromosomes are an exception and will be discussed in Chapter 4). For example, if a gene on a particular chromosome encodes a characteristic such as hair color, another copy of the gene (each copy is called an *allele*) at the same position on that chromosome’s homolog *also* encodes hair color. However, these two alleles need not be identical: one might encode brown hair and the other might encode blond hair.

Cells that carry two sets of genetic information are **diploid**. In general, the ploidy of the cell indicates how many sets of genetic information it possesses. The reproductive cells of eukaryotes (such as eggs, sperm, and spores), and even the nonreproductive cells of some eukaryotic organisms, contain a single set of chromosomes and are **haploid**. The cells of some other eukaryotes contain more than two sets of genetic information and are therefore called **polyploid** (see Chapter 8).

CONCEPTS

Cells reproduce by copying their genetic information, separating the copies, and then dividing. Because eukaryotic cells possess multiple chromosomes, mechanisms exist to ensure that each new cell receives one copy of each chromosome. Most eukaryotic cells are diploid, and their two chromosome sets can be arranged in homologous pairs. Haploid cells contain a single set of chromosomes.

✔ CONCEPT CHECK 2

Diploid cells have

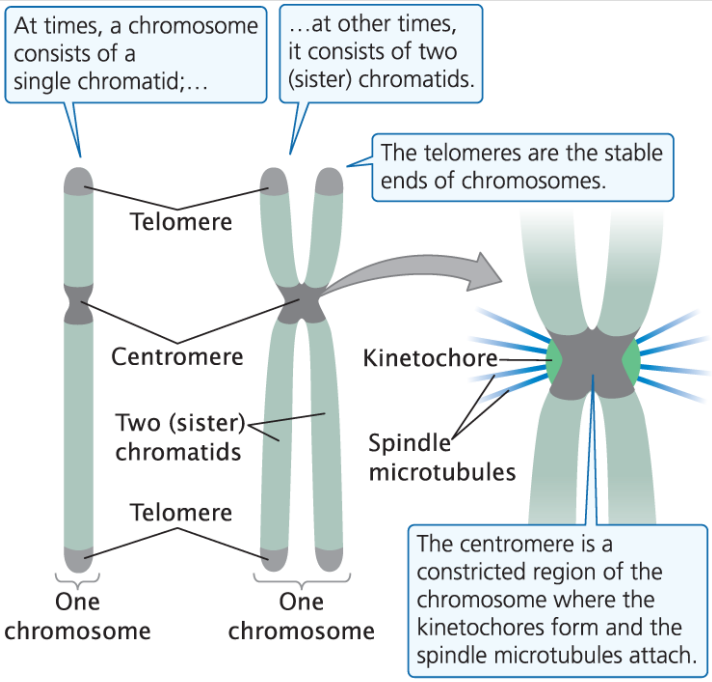
a. two chromosomes.
b. two sets of chromosomes.
c. one set of chromosomes.
d. two pairs of homologous chromosomes.

CHROMOSOME STRUCTURE

The chromosomes of eukaryotic cells are larger and more complex than those found in prokaryotes, but each unreplicated chromosome nevertheless consists of a single molecule of DNA. Although linear, the DNA molecules in eukaryotic chromosomes are highly folded and condensed; if stretched out, some human chromosomes would be several centimeters long—thousands of times as long as the span of a typical nucleus. To package such a tremendous length of DNA into the small volume of the nucleus, each DNA molecule is coiled around histone proteins and tightly packed, forming a rod-shaped chromosome. Most of the time, the chromosomes are thin and difficult to observe, but before cell

division, they condense further into thick, readily observed structures; it is at this stage that chromosomes are usually studied.

A functional chromosome has three essential elements: a centromere, a pair of telomeres, and origins of replication. The **centromere** appears as a constricted region on the chromosome (**Figure 2.7**). It serves as the attachment point for spindle microtubules—the filaments responsible for moving chromosomes in cell division. Before cell division, a multiprotein complex called the kinetochore assembles on the centromere; later, spindle microtubules attach to the kinetochore (see Figure 2.7). Chromosomes lacking a centromere cannot be drawn into the newly formed nuclei; such chromosomes are lost, often with catastrophic consequences for the cell. On the basis of the location of the centromere, chromosomes are classified into four types: metacentric, submetacentric, acrocentric, and telocentric (**Figure 2.8**).

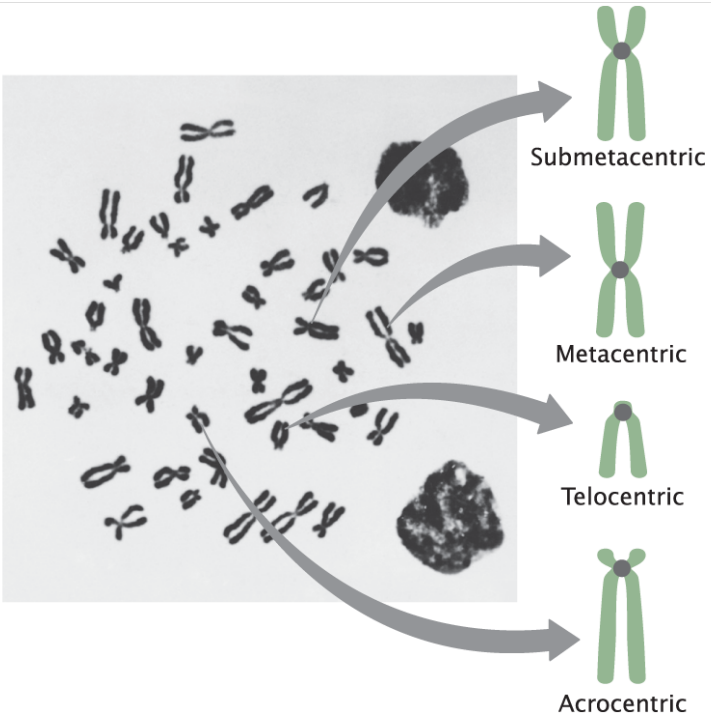


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

2.7 Each eukaryotic chromosome has a centromere and telomeres.

Description

The diagram on the left shows a single rod-shaped chromatid and the diagram in the middle shows 2 sister chromatids conjoined near the middle at the centromere thereby forming an X-shaped chromosome. At the ends of short arms of the chromatids in both diagrams are the telomeres, or the stable ends of the chromosomes. Three captions read, at times, a chromosome consists of a single chromatid at other times, it consists of two (sister) chromatids. The telomeres are the stable ends of chromosomes. The diagram on the right is an up-close picture of the centromere. The kinetochore appears in the diagram as a structure overlaying the entire outside of the centromere, and the spindle microtubules are straight lines touching the kinetochore and extending outward. A caption reads, the centromere is a constricted region of the chromosome where the kinetochores form and the spindle microtubules attach.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company
Don W. Fawcett/Science Source.

2.8 Eukaryotic chromosomes can be divided into four major types based on the position of the centromere.

Description

A magnified view of each type of condensed X-shaped chromosomes is presented in the right side. In a submetacentric chromosome, the centromere is located a little above the center. In a metacentric chromosome, the centromere is located at the center. In a telocentric chromosome, the centromere is located at the terminal end of the chromosome. In an acrocentric chromosome, the centromere is located almost near one end of the chromosome.

Telomeres are the specific DNA sequences and associated proteins located at the tips of whole linear chromosomes (see Figure 2.7). Just as plastic tips protect the ends of a shoelace, telomeres protect and stabilize the chromosome ends. If a chromosome breaks, producing

new ends, the chromosome is degraded at the newly broken ends. Telomeres provide chromosome stability. Research shows that telomeres also participate in limiting cell division and may play important roles in aging and cancer (discussed in Chapter 12).

Origins of replication are the sites where DNA synthesis begins; unlike centromeres and telomeres, they are not easily observed by microscopy. Their structure and function will be discussed in more detail in Chapter 12.

In preparation for cell division, each chromosome replicates, making a copy of itself, as already mentioned. These two initially identical copies, called **sister chromatids**, are held together at the centromere (see Figure 2.7). Each sister chromatid consists of a single molecule of DNA.

THINK-PAIR-SHARE Question 1

CONCEPTS

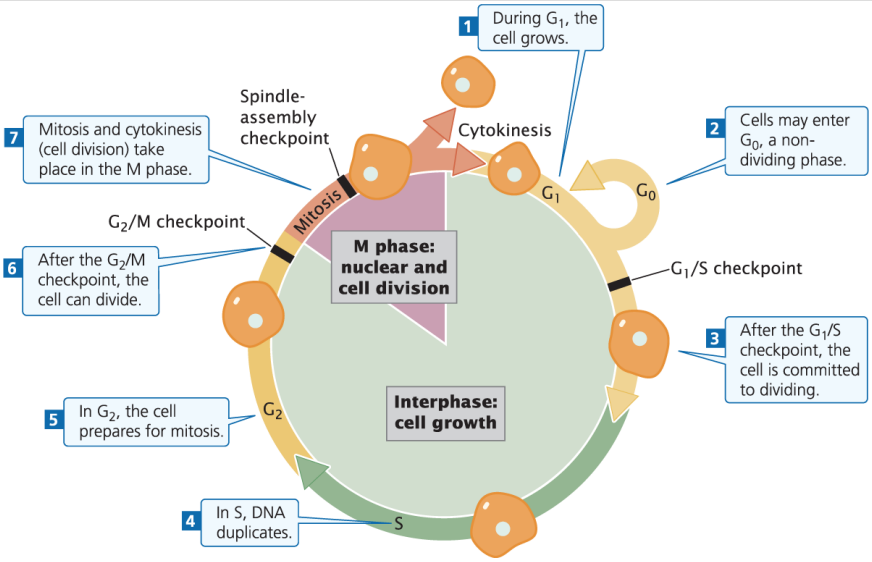
Functional chromosomes contain a centromere, telomeres, and origins of replication. The kinetochore is the multiprotein point of attachment for the spindle microtubules. Telomeres are the stabilizing ends of a chromosome. Origins of replication are sites where DNA synthesis begins. Sister chromatids are copies of a chromosome held together at the centromere.

✔ CONCEPT CHECK 3

What would be the result if a chromosome did not have a kinetochore?

The Cell Cycle and Mitosis

The **cell cycle** is the series of stages through which a cell passes from one division to the next (Figure 2.9). It is through the cell cycle that the genetic instructions for all characteristics are accurately passed from parent to daughter cells.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

2.9 The cell cycle consists of interphase (divided into three stages: G_1, S, and G_2) and the M phase.

Description

The flow chart depicts the different phases of a cell cycle in a clockwise manner. It shows a cell that is represented as a nearly circular structure with a smaller circle representing the nucleus within it. This cell enters the G subscript 1 phase. A caption reads, 1: During G subscript 1, the cell grows. A curved arrow emerges out from G subscript 1 and represents G subscript 0 stage. This arrow again bends to point towards G subscript 1

stage. A caption reads, 2: Cells may enter G subscript 0, a non-dividing phase. The cell now crosses the G subscript 1 over S checkpoint and is relatively larger in size. A caption reads, 3: after the G subscript 1 over S checkpoint, the cell is committed to dividing. The cell now enters the S phase that is represented curved forward pointing arrow. A caption emerging from this stage reads, 4: in S, D N A duplicates. The cell now enters G subscript 2 stage. A caption emerging out from G subscript 2 stage reads, 5: in G subscript 2, the cell prepares for mitosis. The cell then crosses the G subscript 2 over M checkpoint marked as a thin band over the arrow representing G subscript 2 stage. A caption reads, after the G subscript 2 over M checkpoint, the cell can divide. This major section of the circle represents the interphase. A caption reads, Interphase: Cell growth. The cell then enters the M phase which makes up the minor section of the circle. A caption reads, M phase: nuclear and cell division. The cell undergoes mitosis. A caption reads, mitosis and cytokinesis (cell division) take place in the M phase. A thin band represents spindle-assembly checkpoint. The cell crosses this checkpoint and eventually two daughter cells are produced. One of these daughter cell enters the cycle again.

The cell cycle takes place in cells that are actively dividing. A new cycle begins after a cell has divided and produced two new cells. Each new cell grows, develops, and carries out the functions specific to its cell type. At the end of the cycle, the cell divides to produce two cells, which can then undergo additional cell cycles. Progression through the cell cycle is regulated at key transition points called **checkpoints**, which allow or prohibit the cell's progression to the next stage. Checkpoints are necessary to ensure that all cellular components are present and in good working order, and to prevent cells with damaged or missing chromosomes from proliferating. Defects in checkpoints can lead to unregulated cell growth, as is seen in some cancers. The molecular basis of these checkpoints will be discussed in Chapter 23.

The cell cycle consists of two major phases. The first is **interphase**, the period between cell divisions in which the cell grows, develops, and functions. In interphase, critical events necessary for cell division also take place. The second major phase is the **M (mitotic) phase**, the period of active cell division. The M phase includes **mitosis**, the process of nuclear division, and **cytokinesis**, or cytoplasmic division. Let's take a closer look at the details of interphase and the M phase.

INTERPHASE

Interphase is the extended period of growth and development between cell divisions. Although little activity can be observed with a light microscope, the cell is quite busy: DNA is being synthesized, RNA and proteins are being produced, and hundreds of biochemical reactions necessary for cellular functions are taking place. In addition to growth and development, interphase includes several checkpoints.

By convention, interphase is divided into three stages: G_1, S, and G_2 (see Figure 2.9). Interphase begins with G_1 (for gap 1). In G_1, the cell grows and proteins necessary for cell division are synthesized; this stage typically lasts several hours. Near the end of G_1, a critical checkpoint, termed the G_1/S checkpoint, holds the cell in G_1 until the cell has all the enzymes and proteins necessary for the replication of DNA. After this checkpoint has been passed, the cell is committed to divide.

Before reaching the G_1/S checkpoint, cells may exit the active cell cycle in response to regulatory signals and pass into a nondividing phase called G_0, a stable state during which cells usually maintain a constant size. They can remain in G_0 for an extended time, even indefinitely, or they can reenter G_1 and the active cell cycle. Many cells never enter G_0; rather, they cycle continuously. On the other hand, many cells spend most of their life span in G_0.

After G_1, the cell enters the S phase (for DNA synthesis), in which each chromosome is duplicated. Although the cell is committed to divide after the G_1/S checkpoint has been passed, DNA synthesis must take place before the cell can proceed to mitosis. If DNA synthesis is blocked (by drugs or by a mutation), the cell will not normally be able to undergo mitosis. Before the S phase, each chromosome is unreplicated; after the S phase, each chromosome is composed of two sister chromatids (see Figure 2.7).

After the S phase, the cell enters G_2 (gap 2). In this stage, several additional biochemical events necessary for cell division take place. The G_2/M checkpoint is reached near the end of G_2. This checkpoint is passed only if the cell's DNA is completely replicated and undamaged. Unreplicated or damaged DNA can inhibit the activation of some proteins that are necessary for mitosis to take place. After the G_2/M checkpoint has been passed, the cell is ready to divide and enters the M phase. Although the length of interphase varies from cell type to cell type, a typical dividing mammalian cell spends about 10 hours in G_1, 9 hours in S, and 4 hours in G_2 (see Figure 2.9).

Throughout interphase, the chromosomes are in a relaxed but by no means uncoiled state, and individual chromosomes cannot be seen with a microscope. This condition changes dramatically when interphase draws to a close and the cell enters the M phase.

THE M PHASE

The M phase is the part of the cell cycle in which the copies of the cell's chromosomes (sister chromatids) separate and the cell undergoes division. The separation of sister chromatids in the M phase is a critical process that results in a complete set of genetic information for each of the resulting cells. Biologists usually divide the M phase into six stages: the five stages of mitosis (prophase, prometaphase, metaphase, anaphase, and telophase), illustrated in **Figure 2.10**, and cytokinesis. It's important to keep in mind that the M phase is a continuous process and that its separation into these six stages is somewhat arbitrary.

2.10 The cell cycle is divided into interphase and five stages of mitosis.

Description

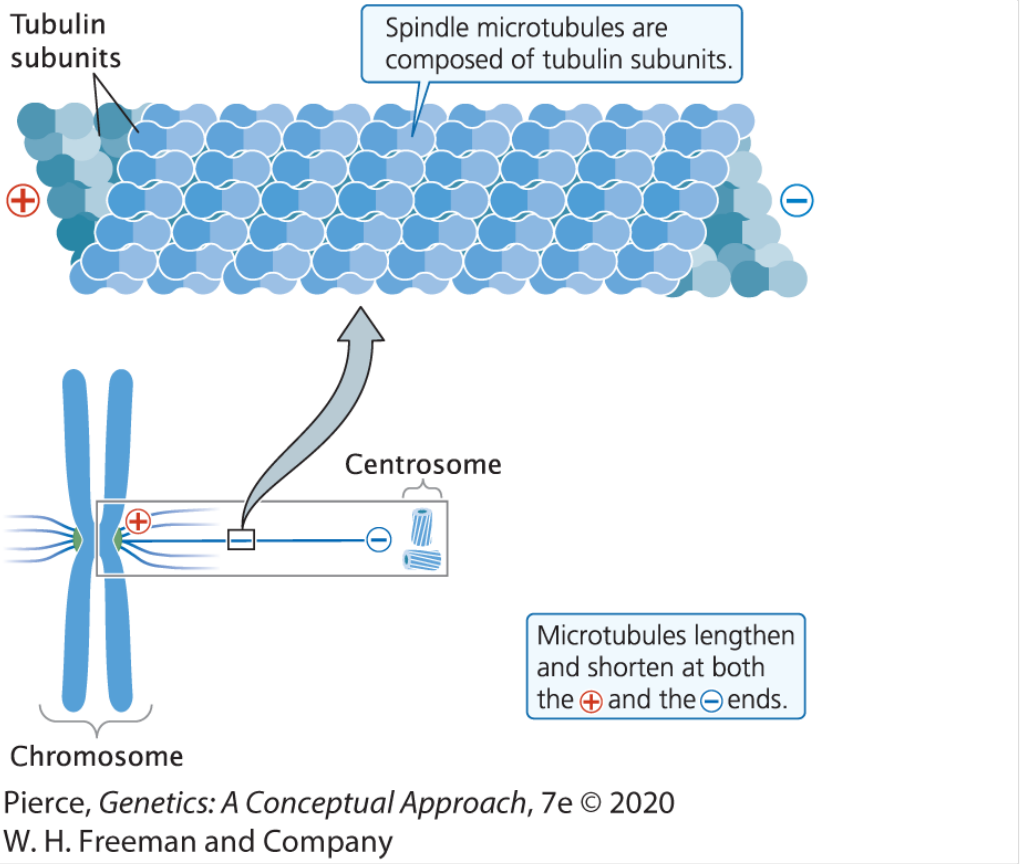
The top left box shows interphase. The nucleus with thread-like nuclear material is surrounded by a nuclear envelope and 4 small rectangular structures called centrosomes lie beside the nucleus. In the florescent image, a blue colored almost round nucleus is present with green webbed fibers around. A caption reads, the nuclear membrane is present and chromosomes are relaxed. This stage leads to prophase. The top center box shows prophase where chromosomes condense as coiled red and blue thread like structures which appear in the nucleus. The spindle fibers form as the centrosomes drift a little apart. This leads to formation of 4 X-shaped chromosomes where two are red chromosome and 2 are blue and each has 2 chromatids. A red and a blue chromosome are larger than its corresponding chromosome. The mitotic spindle elongates as the centrosomes further migrate to opposite sides of the cell. In the fluorescent image, the cell appears to have a larger nucleus (in fluorescent blue) than during interphase and the ends of the cells have spikey green material appear to be extending outwards. A caption reads, Chromosomes condense. Each chromosome possesses two chromatids. The mitotic spindle forms. This stage leads to prometaphase. Top right box shows prometaphase where the nuclear membrane disintegrates. The spindle microtubules attach to the chromatids from left and right ends and the centrosomes appear to be at opposite polar ends of the cell. The red chromosomes are at the top, attached to spindle fiber and blue ones are at bottom, as the spindle fibers now run horizontally from one cell pole to other. In the fluorescent image, a circular nucleus is not present, but blue stings project outward and all of the microtubules (in green) appear concentrated in the center of the image. A caption reads, the nuclear membrane disintegrates. Spindle microtubules attach to chromatids. This leads to next stage metaphase. The bottom right box shows metaphase where the chromosomes line up one below the other on the metaphase plate along the center of the cell. The blue one is at the top, followed by a red, blue and a red chromosome. In the fluorescent image, the blue strings that were once projecting outward, are now aligned in the middle of the green microtubules. A caption reads, chromsomes line up on the metaphase plate. This leads to next stage Anapahse. The bottom centre box shows anaphase where the sister chromatids separate as V shaped and move toward opposite poles. In the fluorescent picture, we see 2 blue and green spiky masses next to each other. A caption reads, sister chromatids separate and move toward opposite poles. This stage finally leads to next stage Telophase. The bottom right box shows telophase where the rod-shaped chromosomes arrive at spindle poles. The nuclear membrane re-forms and the chromosomes relax. Each nucleus now has 2 red(one small, one large) and 2 blue (one small, one large) rod shaped chromosomes. A vertical furrow is formed in the cell as it almost divides into two cells. One centrosome is present in each cell as tiny

spindle fibers still are attached to them. In the fluorescent image, there are 2 circular objects each touching each other, both of which contain a blue circular masses on the opposite ends and a mass of green lines, which are less green in the middle, and thus must be in the process of separating from each other. A caption reads, Chromosomes arrive at spindle poles. The nuclear membrane re-forms and the chromosomes relax.

Prophase. As a cell enters prophase, the chromosomes condense, becoming more compact and visible under a light microscope. A group of proteins called **condensins** bind to the DNA within chromosomes and bring about condensation; condensins are a type of structural maintenance of chromosomes complex, which, as previously discussed, also plays a role in chromosome segregation in bacteria. Because the chromosomes were duplicated in the preceding S phase, each chromosome consists of two sister chromatids attached at the centromere. The mitotic spindle—an organized array of microtubules that move the chromosomes in mitosis—forms. In animal cells, the spindle grows out from a pair of centrosomes that migrate to the opposite sides of the cell. Within each centrosome is a special organelle, the centriole, which is also composed of microtubules. Some plant cells do not have centrosomes or centrioles, but they do have mitotic spindles.

Prometaphase. Disintegration of the nuclear membrane marks the start of prometaphase. Spindle microtubules, which until now have been outside the nucleus, enter the nuclear region. The spindle microtubules are composed of subunits of a protein called tubulin (**Figure 2.11**). During prometaphase, tubulin molecules are added to and removed from the microtubules, causing them to undergo

repeated cycles of growth and shrinkage. When the end of a microtubule encounters a kinetochore, the microtubule becomes stabilized. Eventually, each chromosome becomes attached to microtubules from opposite spindle poles: for each chromosome, a microtubule from one of the centrosomes anchors to the kinetochore of *one* of the sister chromatids; a microtubule from the opposite centrosome then attaches to the *other* sister chromatid, anchoring the chromosome to both of the centrosomes. This arrangement is known as chromosome bi-orientation.



2.11 Microtubules are composed of tubulin subunits. Each microtubule has its plus (+) end at the kinetochore and its minus (−) end at the centrosome.

Description
At the bottom, there is a drawing of an X-shaped chromosome with 1 microtubule attached. The positive end of the microtubule is attached to the kinetochore side and the negative end is near the centrosome. The picture on top shows the tubulin subunits drawn as balls that attach in a spiral manner to form a tube-like structure. The captions read: spindle microtubules are composed of tubulin subunits. Microtubules lengthen and shorten at both the positive and the negative ends.

Metaphase. During metaphase, the chromosomes become arranged in a single plane, called the metaphase plate, between the two centrosomes. The centrosomes, now at opposite ends of the cell, with microtubules radiating outward from each one and meeting in the middle of the cell, center at the spindle poles. A spindle-assembly checkpoint ensures that each chromosome is aligned on the metaphase plate and attached to spindle microtubules from opposite poles.

Tension is generated at the kinetochore as the two conjoined chromatids are pulled in opposite directions by the spindle microtubules. This tension is required for the cell to pass through the spindle-assembly checkpoint. If one chromatid is attached to a microtubule but the other is not, no tension is generated, and the cell is unable to progress to the next stage of mitosis. The spindle-assembly checkpoint is able to detect even a single pair of chromosomes that are not properly attached to microtubules. The importance of this checkpoint is illustrated by cells that are defective in their spindle-assembly checkpoint; these cells often end up with abnormal numbers of chromosomes.

Anaphase. After the spindle-assembly checkpoint has been passed, the connection between sister chromatids breaks down and the sister chromatids separate. This separation marks the beginning of anaphase, during which the chromosomes move toward opposite spindle poles. Chromosome movement is due to the disassembly of tubulin molecules at both the kinetochore end (called the + end) and the spindle-pole end (called the − end) of the spindle microtubule (see Figure 2.11). Special proteins called molecular motors disassemble tubulin molecules and generate forces that pull the chromosome toward the spindle pole.

Telophase. After the sister chromatids have separated, each is considered a separate chromosome. Telophase is marked by the arrival of the chromosomes at the spindle poles. The nuclear membrane re-forms around each set of chromosomes, producing two separate nuclei within the cell. The chromosomes relax and lengthen, becoming indistinguishable under the light microscope. In many cells, division of the cytoplasm (cytokinesis) is simultaneous with telophase.

The major features of the cell cycle are summarized in Table 2.1. You can watch the cell cycle in motion by viewing (A) **Animation 2.1**. This interactive animation allows you to determine what happens when different processes in the cycle fail. ❯ **TRY** PROBLEM 24

TABLE 2.1 Features of the cell cycle

Stage	Major Features
G_0 phase	Stable, nondividing period of variable length.
Interphase	
G_1 phase	Growth and development of the cell; G_1/S checkpoint.
S phase	Synthesis of DNA.
G_2 phase	Preparation for division; G_2/M checkpoint.
M phase	
Prophase	Chromosomes condense and mitotic spindle forms.
Prometaphase	Nuclear membrane disintegrates, and spindle microtubules anchor to kinetochores.
Metaphase	Chromosomes align on the metaphase plate; spindle-assembly checkpoint.
Anaphase	Sister chromatids separate, becoming individual chromosomes that migrate toward spindle poles.

Telophase	Chromosomes arrive at spindle poles, the nuclear membrane re-forms, and the condensed chromosomes relax.
Cytokinesis	Cytoplasm divides; cell wall forms in plant cells.

Genetic Consequences of the Cell Cycle

What are the genetically important results of the cell cycle? From a single cell, the cell cycle produces two cells that contain the same genetic instructions. The resulting daughter cells are genetically identical with each other and with their parent cell because DNA synthesis in the S phase creates an exact copy of each DNA molecule, giving rise to two genetically identical sister chromatids. Mitosis then ensures that one of the two sister chromatids from each replicated chromosome passes into each new cell.

Another genetically important result of the cell cycle is that each of the cells produced contains a full complement of chromosomes: there is no net reduction or increase in chromosome number. Each cell also contains approximately half the cytoplasm and organelle content of the original parent cell, but no precise mechanism analogous to mitosis ensures that organelles are evenly divided.

Consequently, not all cells resulting from the cell cycle are identical in their cytoplasmic content.

THINK-PAIR-SHARE Question 2

CONCEPTS

The active cell cycle phases are interphase and the M phase. Interphase consists of G_1, S, and G_2. In G_1, the cell grows and prepares for cell division; in the S phase, DNA synthesis takes place; in G_2, other biochemical events necessary for cell division take place. Some cells enter a quiescent phase called G_0. The M phase includes mitosis and cytokinesis and is divided into prophase, prometaphase, metaphase, anaphase, and telophase. The cell cycle produces two genetically identical cells, each of which possesses a full complement of chromosomes.

✔ CONCEPT CHECK 4

Which is the correct order of stages in the cell cycle?

a. G_1, S, G_2, prophase, metaphase, anaphase
b. S, G_1, G_2, prophase, metaphase, anaphase
c. Prophase, S, G_1, G_2, metaphase, anaphase
d. S, G_1, G_2, anaphase, prophase, metaphase

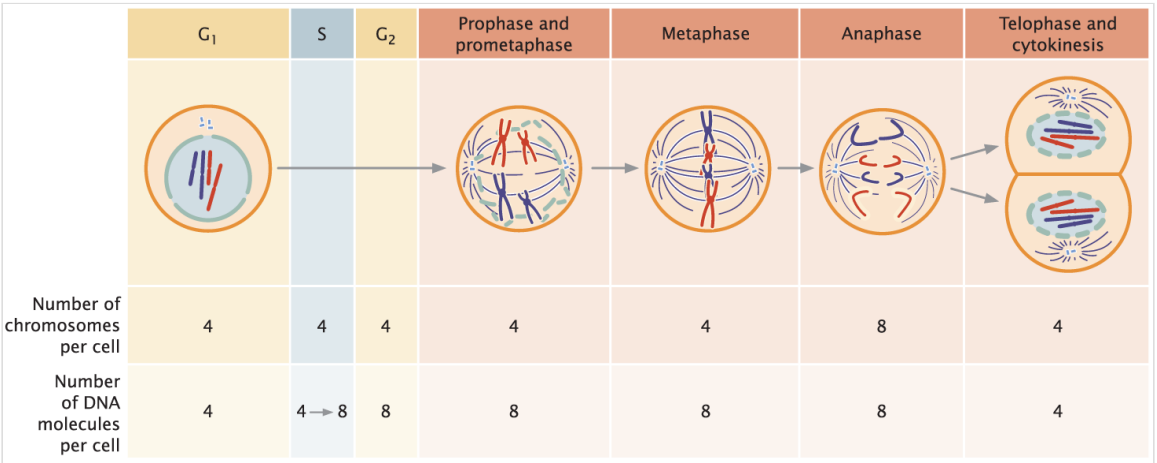
CONNECTING CONCEPTS CONNECT

Counting Chromosomes and DNA Molecules

The relations among chromosomes, chromatids, and DNA molecules frequently cause confusion. At certain times, chromosomes are unreplicated; at other times, each has undergone replication and possesses two chromatids (see Figure 2.7). Chromosomes sometimes consist of a single DNA molecule; at other times, they consist of two DNA molecules. How can we keep track of the number of these structures in the cell cycle?

There are two simple rules for counting chromosomes and DNA molecules: (1) to determine the number of chromosomes, count the number of functional centromeres; (2) to determine the number of DNA molecules, first determine if sister chromatids are present. If sister chromatids are present, the chromosome has replicated, and the number of DNA molecules is twice the number of chromosomes. If sister chromatids are not present, the chromosome has not replicated, and the number of DNA molecules is the same as the number of chromosomes.

Let's examine a hypothetical cell as it passes through the cell cycle (**Figure 2.12**). At the beginning of G_1, this diploid cell has two complete sets of chromosomes, for a total of four chromosomes. Each chromosome is unreplicated and consists of a single molecule of DNA, so there are four DNA molecules in the cell during G_1. In the S phase, each DNA molecule is copied. The two resulting DNA molecules combine with histones and other proteins to form sister chromatids. Although the amount of DNA doubles in the S phase, the number of chromosomes remains the same because the sister chromatids are tethered together and share a single functional centromere. At the end of the S phase, this cell still contains four chromosomes, each with two sister chromatids; so $4 \times 2 = 8$ DNA molecules are present.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

2.12 The number of chromosomes and the number of DNA molecules change in the course of the cell cycle. The number of chromosomes per cell equals the number of functional centromeres. The number of DNA molecules per cell equals the number of chromosomes when the chromosomes are unreplicated (no sister chromatids are present) and twice the number of chromosomes when sister chromatids *are* present.

Description

The table has 4 rows and 7 columns. The column headers from left to right are as follows: G subscript 1; S; G subscript 2; Prophase and prometaphase; Metaphase; Anaphase; and Telophase and cytokinesis. The row entries from top to bottom are as follows:

Row 1: In G subscript 1, the cell has nucleus with two pairs of rod-shaped chromosomes; one is red and the other is blue; that are not attached at the centromere. The cell then progresses directly to the fourth column representing prophase and prometaphase, skipping S and G subscript 2 column. In, prophase and prometaphase stage, the nuclear membrane disintegrates and radially arranged spindle fibers are formed from the two poles of the cell. Four X-shaped chromosomes, 2 red and 2 blue, appear at the center of the cell that are attached to their respective sister chromatid through centromere. In metaphase, these four chromosomes align in a straight line forming the metaphase plate. The spindle fibers from poles are attached to centromeres of the four chromosomes. In anaphase, sister chromatids separate thereby becoming individual chromosomes that migrate toward spindle poles. The diagram shows laterally placed V-shaped chromosomes attached to spindle fibers. In telophase and cytokinesis, the cell divides into two daughter cells wherein chromosomes arrive at spindle poles, the nuclear membrane re-forms, and the condensed chromosomes relax.

Row 2 (Number of chromosomes per cell): G subscript 1, 4; S, 4; G subscript 2, 4; Prophase and Prometaphase, 4; Metaphase, 4; Anaphase, 8; Telophase and cytokinesis, 4.

Row 3 (Number of D N A molecules per cell): G subscript 1, 4; S, 4 becomes 8; G subscript 2, 8; Prophase and Prometaphase, 8; Metaphase, 8; Anaphase, 8; Telophase and cytokinesis, 4.

Through prophase, prometaphase, and metaphase, the cell has four chromosomes and eight DNA molecules. At anaphase, however, the sister chromatids separate. Each now has its own functional centromere, so each is considered a separate chromosome. Until cytokinesis, the cell contains eight unreplicated chromosomes; thus, there are still eight DNA molecules present. After cytokinesis, the eight chromosomes (and eight DNA molecules) are distributed equally between two daughter cells, so each daughter cell contains four chromosomes and four DNA molecules—the number present at the beginning of the cell cycle.

In summary, the number of chromosomes increases only in anaphase, when the two chromatids of a chromosome separate and become distinct chromosomes. The number of chromosomes decreases only through cytokinesis. The number of DNA molecules increases only in the S phase and decreases only through cytokinesis.

2.3 Sexual Reproduction Produces Genetic Variation Through the Process of Meiosis

If all reproduction were accomplished through mitosis, life would be quite dull because mitosis produces only genetically identical progeny. With only mitosis, you, your children, your parents, your brothers and sisters, your cousins, and many people whom you don't even know would be clones—copies of one another. Only the occasional mutation would introduce any genetic variation. All organisms reproduced in this way for the first 2 billion years of Earth's existence (and some organisms still do today). Then, about 1.5 billion to 2 billion years ago, something remarkable evolved: cells that produce genetically variable offspring through sexual reproduction.

The evolution of sexual reproduction is among the most significant events in the history of life. As will be discussed in Chapters 24 and 25, the pace of evolution depends on the amount of genetic variation present. By shuffling the genetic information from two parents, sexual reproduction greatly increases the amount of genetic variation and allows for accelerated evolution. Most of the tremendous diversity of life on Earth is a direct result of sexual reproduction.

Sexual reproduction consists of two processes. The first is **meiosis**, which leads to gametes in which the number of chromosomes is reduced by half. The second process is **fertilization**, in which two haploid gametes fuse and restore the number of chromosomes to its original diploid value.

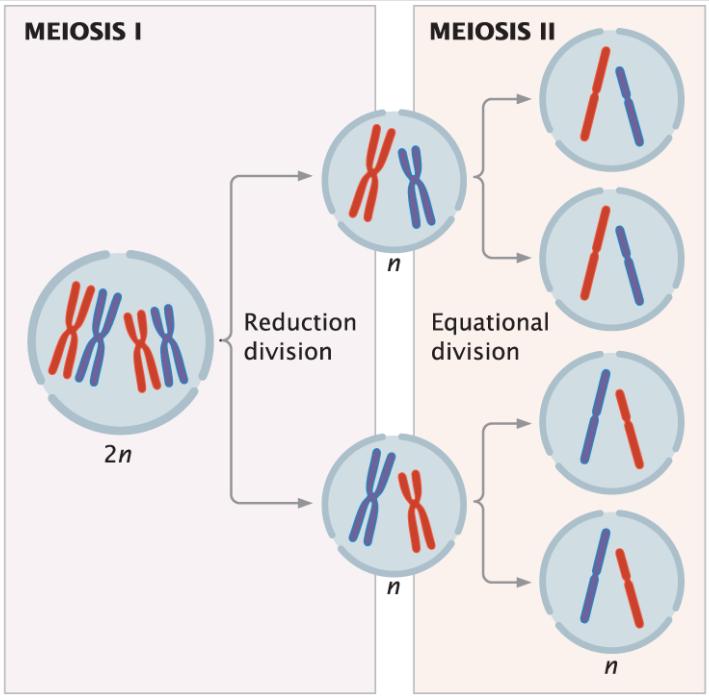
Meiosis

The words *mitosis* and *meiosis* are sometimes confused. They sound a bit alike and may appear superficially similar. But don't be deceived. The outcomes of mitosis and meiosis are radically different, and several unique events that have important genetic consequences take place only in meiosis.

How does meiosis differ from mitosis? Mitosis consists of a single nuclear division and is usually accompanied by a single cell division. Meiosis, on the other hand, consists of two divisions. After mitosis, the chromosome number in the newly formed cells is the same as that in the original cell, whereas meiosis causes the chromosome number in the newly formed cells to be reduced by half. Finally, mitosis produces genetically identical cells, whereas meiosis produces genetically variable cells. Let's see how these differences arise.

Like mitosis, meiosis is preceded by an interphase that includes G_1, S, and G_2 stages. Meiosis consists of two distinct processes: meiosis I

and meiosis II, each of which includes a cell division. The first division, which comes at the end of meiosis I, is termed the reduction division because the number of chromosomes per cell is reduced by half (**Figure 2.13**). The second division, which comes at the end of meiosis II, is sometimes termed the equational division. The events of meiosis II are similar to those of mitosis. However, meiosis II differs from mitosis in that chromosome number has already been halved in meiosis I, so the cell does not begin with the same number of chromosomes as it does in mitosis (see Figure 2.13).

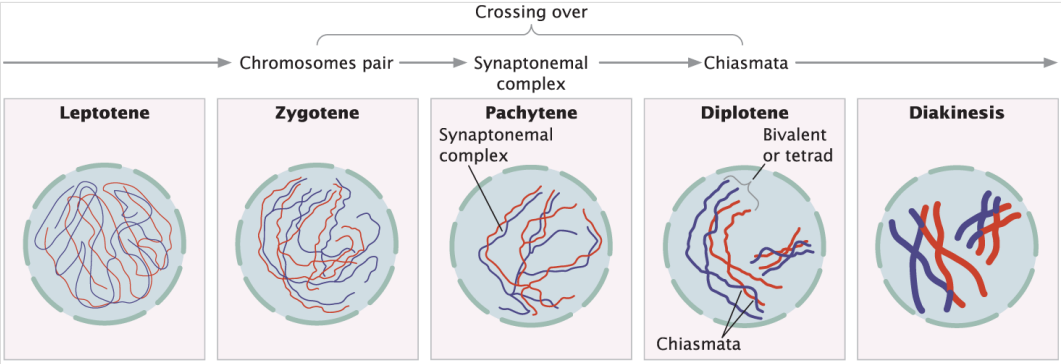


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

2.13 Meiosis includes two cell divisions. In this illustration, the original cell is diploid (2*n*) with four chromosomes. After two meiotic divisions, each resulting cell is haploid (1*n*) with two chromosomes.

MEIOSIS I

During interphase, the chromosomes are relaxed and indistinguishable as diffuse chromatin. **Prophase I** is a lengthy stage, divided into five substages (**Figure 2.14**). In leptotene, the chromosomes condense and become visible. In zygotene, the chromosomes continue to condense; homologous chromosomes pair up and begin **synapsis**, a very close pairing association. Each homologous pair of synapsed chromosomes, called a **bivalent** or **tetrad**, consists of four chromatids. In pachytene, the chromosomes become shorter and thicker, and a three-part synaptonemal complex develops between homologous chromosomes. The function of the synaptonemal complex is unclear, but the chromosomes of many cells deficient in this complex do not separate properly.

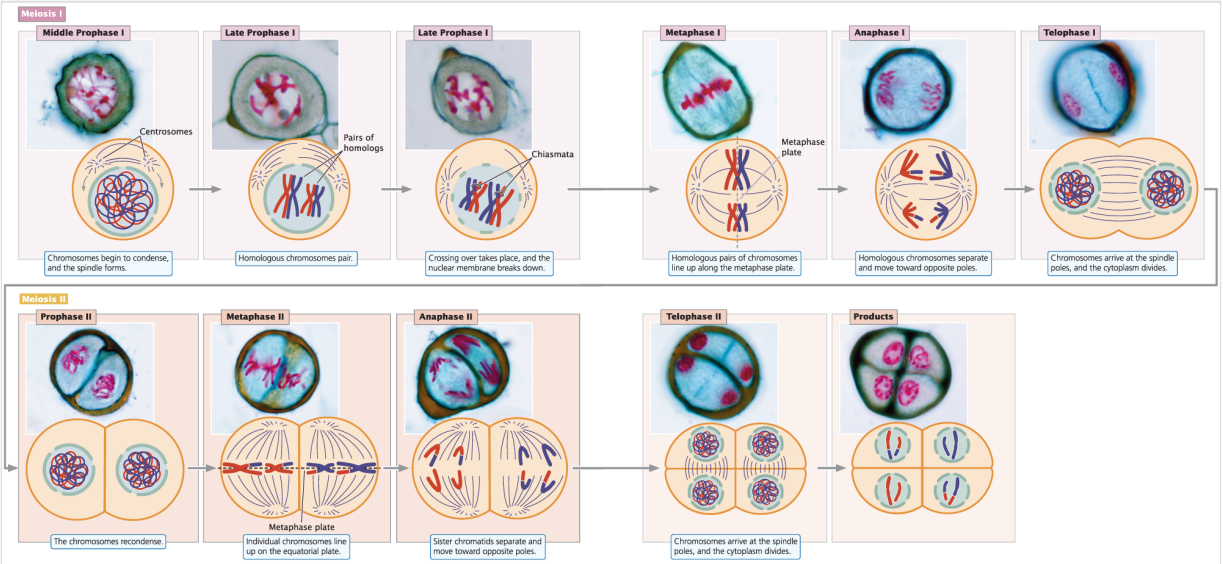


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

2.14 Substages of prophase I. Crossing over takes place during prophase I.

Crossing over, in which homologous chromosomes exchange genetic information, takes place in prophase I. Crossing over generates genetic variation (as we will see shortly) and is essential

for the proper alignment and separation of homologous chromosomes. Each location where two chromosomes cross is called a *chiasma* (plural, *chiasmata*). In diplotene, the centromeres of the paired chromosomes move apart, but the two homologs remain attached at each chiasma. During diakinesis, the final substage of prophase I, chromosome condensation continues, the nuclear membrane breaks down and the spindle forms, setting the stage for metaphase I. The stages of meiosis are outlined in Figure 2.15.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company
University of Wisconsin Plant Teaching Collection, photographs by Michael Clayton.

2.15 Meiosis is divided into stages.

Description

In the first panel at top left with the heading metaphase 1, the homologous pairs of X-shaped chromosomes line up along the metaphase plate one below the other. A large red chromosome with blue part is paired with large blue chromosome with a red part. Below this, a small red X shaped chromosome is paired with small blue X shaped chromosome. The spindle fibers run radially from one cell pole to other. In the corresponding cell staining, the D N A is condensed and located in the middle of the cell. A caption reads, “Homologous pairs of chromosomes line up along the metaphase plate.”

In second panel at top center with the heading anaphase 1, the homologous chromosomes, which have crossed-over and contain a different combination of genes, indicated by different patterns of red and blue, separate and move toward the opposite poles. The red colored chromosomes with blue part move towards left and the blue chromosomes with red part move towards right. In the stained cell image, we see squiggly lines of D N A located at opposite ends of the cell. A caption reads, “Homologous chromosomes separate and move toward opposite poles.”

In the third panel at top right with the heading telophase 1, the chromosomes arrive at the spindle poles and the cytoplasm divides as a furrow forms in between. Both the halves have a nucleus with red and blue thin strings coiled. The spindle fibers run from one nucleus to the other. In the cell staining, a cell divided into two cells with each having nuclei located on opposite ends and a blue ridge forming in the center. A caption reads, “Chromosomes arrive at the spindle poles and the cytoplasm divides.”

Fourth panel at bottom left depicts the beginning of telophase 2 where the chromosomes arrive at the spindle poles and the cytoplasm divides into 4 almost equal halves. Each half has a nucleus with blue and red thin string like coiled chromosome material. Spindle fibers run vertically from one cell to other from top to bottom. In the stained cell image, one cell has 2 circular sections, each having two condensed nuclei at opposite ends of the cell. A blue ridge appears to be forming in the middle of the cell. A caption reads, “Chromosomes arrive at the spindle poles and the cytoplasm divides.”

In the last panel at bottom center, the cell divisions occur and 4 cells are formed as products. One cell has all red rod shaped D N A, one has all blue rod shaped D N A, and two cells have hybrids: one cell has a large and a small red rod shaped D N A both with a blue part and the other cell has a large and a small blue rod shaped D N A both with a red part. In the cell staining diagram, a cell is divided into 4 halves with nearly circular red D N A in all four parts.

For meiosis 1: In panel 1 at the top left, middle prophase 1 is depicted. At this stage, the chromosomes begin to condense which are depicted as coiled red and blue strings. The spindle fibers form outside the nucleus, with the centrosomes migrating to opposite ends of the cell. In the cell staining, the nucleus appears to contain D N A (stained in red) distributed throughout the nucleus (colored green). A caption reads, “Chromosomes begin to condense, and the spindle forms.” This leads to next stage, late prophase 1.

In panel 2 at top center with the heading late prophase 1, the homologous chromosomes pair up. A large red X shaped chromosome pairs up with large blue X shaped chromosome and a small red X-shaped chromosome pairs up with a small blue X-shaped chromosome. The spindle fibers elongate as the centrosomes drift farther away. In the cell staining, the red masses start to clump in the nucleus. A caption reads, “Homologous chromosomes pair.”

In panel 3 at top right with the heading late prophase 1, crossing over takes place, shown by the legs of a blue and a red X-shaped chromosome touching at the chiasmata and the colors of the legs switching. The nuclear membrane also starts to break down. In the cell staining, the red masses almost are distributed throughout the nucleus. A caption reads, crossing over takes place, and the nuclear membrane breaks down.

For meiosis 2: In panel 1 at bottom left with the heading prophase 2, the chromosomes recondense. The cell is divided into two vertical halves. Both the cells have individual nucleus with red and blue coiled string like chromosome material within them. In the cell staining, the cell is divided into two halves and both have red colored D N A condensed and centrally localized. A caption reads, “The chromosomes recondense.”

In panel 2 at bottom center with the heading metaphase 2, the individual chromosomes line up horizontally on the metaphase plate. The X-shaped chromosomes are hybrid in color, containing different amounts of red and blue. The spindle fibers run vertically from one end to other end. In the cell staining, a cell shows 2 almost equals regions, each having red, thick string shaped D N A aligned in the center. A caption reads, individual chromosomes line up on the equatorial plate.

In panel 3 at bottom right with the heading anaphase 2, the sister chromatids containing hybrid D N A separate and move toward opposite poles. In the left half, hybrid red chromatids with blue parts are pulled upwards and red chromatids are pulled downwards. In the right half, hybrid blue chromatids with red parts are pulled downwards and blue chromatids are pulled upwards. In the cell staining, there are 2 circular regions inside the cell, each having a mass of red D N A on opposite ends of the nuclei. A caption reads, sister chromatids separate and move toward opposite poles.

Metaphase I is initiated when homologous pairs of chromosomes align along the metaphase plate (see Figure 2.15). A microtubule

from one spindle pole attaches to one chromosome of a homologous pair, and a microtubule from the other pole attaches to the other member of the pair. **Anaphase I** is marked by the separation of homologous chromosomes. The two chromosomes of a homologous pair are pulled toward opposite poles. Although the homologous chromosomes separate, the sister chromatids remain attached and travel together. In **telophase I**, the chromosomes arrive at the spindle poles, and the cytoplasm divides.

MEIOSIS II

The period between meiosis I and meiosis II is **interkinesis**, in which the nuclear membrane re-forms around the chromosomes clustered at each pole, the spindle breaks down, and the chromosomes relax. The cells then pass through **prophase II**, in which the events of interkinesis are reversed: the chromosomes recondense, the spindle re-forms, and the nuclear membrane once again breaks down. In interkinesis in some types of cells, the chromosomes remain condensed and the spindle does not break down. These cells move directly from cytokinesis into **metaphase II**, which is similar to metaphase of mitosis: the replicated chromosomes line up on the metaphase plate, with the sister chromatids facing opposite poles.

In **anaphase II**, the sister chromatids separate, and the chromatids are pulled to opposite poles. Each chromatid is now a distinct chromosome. In **telophase II**, the chromosomes arrive at the spindle

poles, a nuclear membrane re-forms around the chromosomes, and the cytoplasm divides. The chromosomes relax and are no longer visible. ❯ **TRY** PROBLEM 29

THINK-PAIR-SHARE Questions 3, 4

CONCEPTS

Meiosis consists of two distinct processes: meiosis I and meiosis II. Meiosis I includes the reduction division, in which homologous chromosomes separate and chromosome number is reduced by half. In meiosis II (the equational division), sister chromatids separate.

✔ CONCEPT CHECK 5

Which of the following events takes place in metaphase I?

a. Crossing over occurs.
b. Chromosomes condense.
c. Homologous pairs of chromosomes line up on the metaphase plate.
d. Individual chromosomes line up on the metaphase plate.

The major events of meiosis are summarized in Table 2.2. To examine the details of meiosis and the consequences of its failure, take a look at (A) **Animation 2.2.**

TABLE 2.2 Major events in each stage of meiosis

Stage	Major Features
Meiosis I	

Prophase I	Chromosomes condense, homologous chromosomes synapse, crossing over takes place, the nuclear membrane breaks down, and the mitotic spindle forms.
Metaphase I	Homologous pairs of chromosomes line up on the metaphase plate.
Anaphase I	The two chromosomes (each with two chromatids) of a homologous pair separate and move toward opposite poles.
Telophase I	Chromosomes arrive at the spindle poles.
Cytokinesis	The cytoplasm divides to produce two cells, each having half the original number of chromosomes.
Interkinesis	In some types of cells, the spindle breaks down, chromosomes relax, and a nuclear membrane re-forms, but no DNA synthesis takes place.
Meiosis II	
Prophase II*	Chromosomes condense, the spindle forms, and the nuclear membrane disintegrates.
Metaphase II	Individual chromosomes line up on the

	metaphase plate.
Anaphase II	Sister chromatids separate and move as individual chromosomes toward opposite spindle poles.
Telophase II	Chromosomes arrive at the spindle poles; the spindle breaks down and a nuclear envelope re-forms.
Cytokinesis	The cytoplasm divides.

*Only in cells in which the spindle has broken down, chromosomes have relaxed, and the nuclear membrane has re-formed in telophase I. Other types of cells proceed directly to metaphase II after cytokinesis.

Sources of Genetic Variation in Meiosis

What are the overall consequences of meiosis? First, meiosis comprises two divisions, so each original cell produces four cells (although there are exceptions to this generalization, as, for example, in many female animals; see Figure 2.20b). Second, chromosome number is reduced by half, so cells produced by meiosis are haploid. Third, cells produced by meiosis are genetically different from one another and from the parent cell. These genetic differences result from two processes that are unique to meiosis: crossing over and the random separation of homologous chromosomes.

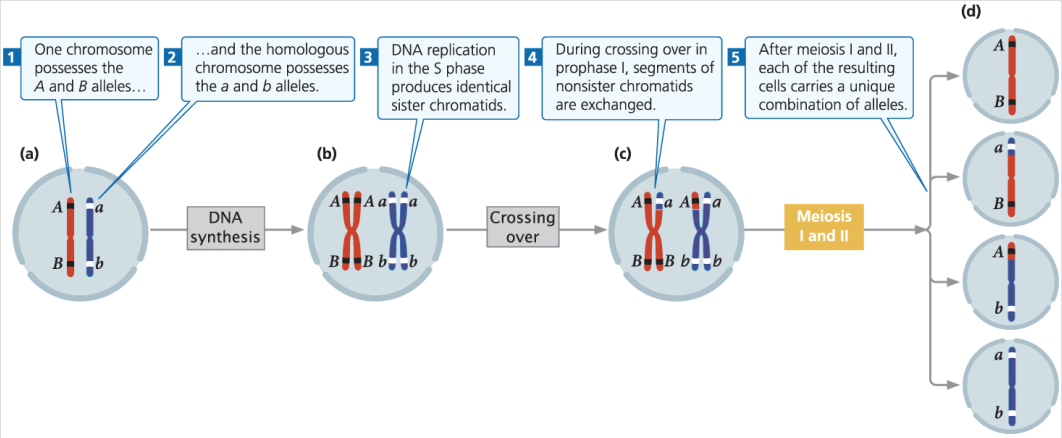
CROSSING OVER

Crossing over, which takes place in prophase I, refers to the exchange of genetic material between nonsister chromatids (chromatids from different homologous chromosomes). Evidence from yeast suggests that crossing over is initiated in zygotene, before the synaptonemal complex develops, and is not completed until near the end of prophase I (see Figure 2.14). In other organisms, crossing over is initiated after the formation of the synaptonemal complex; in still others, there is no synaptonemal complex.

After crossing over has taken place, the sister chromatids are no longer identical. Crossing over is the basis for intrachromosomal **recombination**, the creation of new combinations of alleles on a chromatid. To see how crossing over produces genetic variation, consider two pairs of alleles, which we will abbreviate *Aa* and *Bb*. Assume that one chromosome possesses the *A* and *B* alleles and its homolog possesses the *a* and *b* alleles (**Figure 2.16a**). When DNA is replicated in the S phase, each chromosome duplicates, and so the resulting sister chromatids are identical (**Figure 2.16b**).

In the process of crossing over, there are breaks in the DNA strands, and those breaks are repaired in such a way that segments of nonsister chromatids are exchanged (**Figure 2.16c**). The molecular basis of this process will be described in more detail in Chapter 12. The important thing here is that after crossing over has taken place, the two sister chromatids are no longer identical: one chromatid has

alleles *A* and *B*, whereas its sister chromatid (the chromatid that underwent crossing over) has alleles *a* and *B*. Likewise, one chromatid of the other chromosome has alleles *a* and *b*, and the other chromatid has alleles *A* and *b*. Each of the four chromatids now carries a unique combination of alleles: *A B*, *a B*, *A b*, and *a b*. Eventually, the two homologous chromosomes separate, each going into a different cell. In meiosis II, the two chromatids of each chromosome separate, and thus each of the four cells resulting from meiosis carries a different combination of alleles (Figure 2.16d). You can see how crossing over affects genetic variation by viewing **Animation 2.3**.



2.16 Crossing over produces genetic variation.

Description

The illustration “a” on the left shows a nucleus wherein one rod-shaped chromosome (in red) possesses the big A and big B alleles, and its homologous rod-shaped chromosome (in blue) possesses the small A and small B alleles. A caption reads, one chromosome possesses the big A and big B alleles and the homologous chromosome possesses the small A and small B alleles. D N A synthesis occurs and illustration “b” shows identical

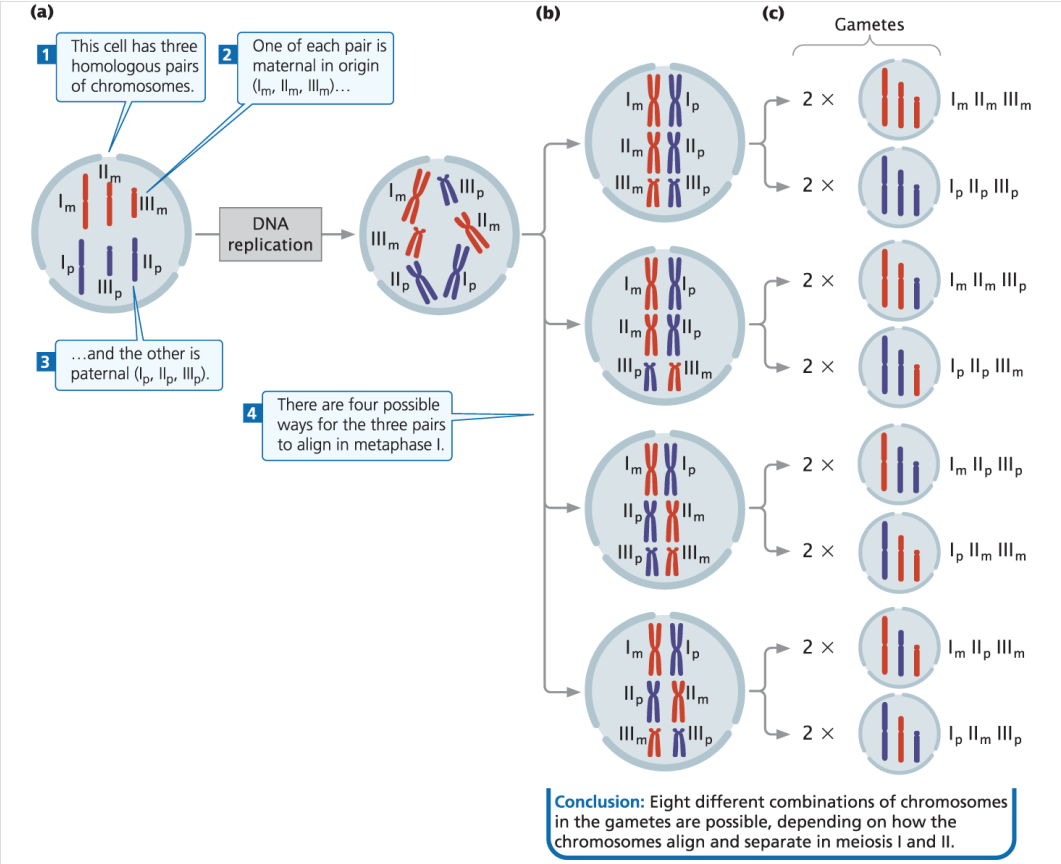
sister chromatids are produced. Now, two X-shaped chromosomes are produced where one is blue and other is red. A caption reads, D N A replication in the S phase produces identical sister chromatids. Crossing over occurs and illustration “c” shows exchange of segments between non-sister chromatids. X-shaped chromosome in red has exchanged a small part of the end of one of its chromatids and is now partially blue containing the small A gene. The blue chromosome now has a small part of red chromosome with gene big A. A caption reads, during crossing over in prophase 1, segments of nonsister chromatids are exchanged. Meiosis 1 and 2 occur, and illustration “d” shows 4 resulting cells that carry a unique combination of alleles: one is red rod shaped having genes big A and big B, one is blue rod shaped having small A and small B genes, one is mostly red rod shaped with a blue end having big B and small A genes, and one is mostly blue rod shaped with a red end, having big A and small B genes.

RANDOM SEPARATION OF HOMOLOGOUS CHROMOSOMES

The second process of meiosis that contributes to genetic variation is the random distribution of chromosomes in anaphase I after their random alignment in metaphase I. To illustrate this process, consider a cell with three pairs of chromosomes, I, II, and III (Figure 2.17a). One chromosome of each pair is maternal in origin (I_m, II_m, and III_m); the other is paternal in origin (I_p, II_p, and III_p). The chromosome pairs line up in the center of the cell in metaphase I, and in anaphase I, the chromosomes of each homologous pair separate. Note that each cell gets one chromosome from each of the three pairs (I, II, and III).

How each pair of homologs aligns and separates is random and independent of how other pairs align and separate (Figure 2.17b). By

chance, all the maternal chromosomes might migrate to one side and all the paternal chromosomes to the other. After division, one cell would contain chromosomes I_m, II_m, and III_m, and the other, I_p, II_p, and III_p. Alternatively, the I_m, II_m, and III_p chromosomes might move to one side and the I_p, II_p, and III_m chromosomes to the other. These different migration patterns would produce different combinations of chromosomes in the resulting cells (**Figure 2.17c**). There are four ways in which the chromosomes in a diploid cell with three homologous pairs can migrate, producing a total of eight different combinations of chromosomes in the gametes. In general, the number of possible combinations is 2^n, where n equals the number of homologous pairs. As the number of chromosome pairs increases, the number of combinations quickly becomes very large. In humans, who have 23 pairs of chromosomes, 2^{23}, or 8,388,608, different combinations of chromosomes are made possible by the random separation of homologous chromosomes. You can explore the random distribution of chromosomes by viewing **Animation 2.3**. The genetic consequences of this process, termed independent assortment, will be explored in more detail in Chapter 3.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

2.17 The random distribution of chromosomes in meiosis produces genetic variation. In this example, the cell possesses three homologous pairs of chromosomes.

Description

Illustration ‘a’ on the extreme left shows a cell with three rod-shaped homologous pairs of chromosomes named 1 subscript m, 1 subscript p; 2 subscript m, 2 subscript p; and 3 subscript m, 3 subscript p. Length of the chromosomes shortens from 1 through 3 in both the colors. The chromosomes with labeling 1 subscript m through 3 subscript m are red, and with labeling 1 subscript p through 3 subscript p are blue in color. First caption reads, 1: this cell has three homologous pairs of chromosomes. Second caption reads, 2: one of each pair is maternal in origin (1 subscript m, 2 subscript m, and 3 subscript m). The maternal origin chromosomes are represented in red. Third caption reads, 3: and the other is paternal (1 subscript p, 2 subscript p, and 3 subscript p). The paternal origin chromosomes are represented in blue. D N A replication occurs and the cell now has six

X-shaped chromosomes namely: 1 subscript m, 3 subscript p, 3 subscript m, 2 subscript m, 2 subscript p, and 1 subscript p. An arrow from this cell leads to illustration “b”.

Illustration b in the center shows four possible ways in which the three chromosome pairs can align in metaphase. 1, Illustration c on the extreme right shows eight different possible combinations of chromosomes in the gametes, depending on how the chromosomes align and separate in meiosis 1 and 2, in the first case, 1 subscript m and 1 subscript p are aligned at the top, 2 subscript m and 2 subscript p are aligned at the center, 3 subscript m and 3 subscript p are aligned at the bottom. This can lead to 2 gametes with 1 subscript m, 2 subscript m, and 3 subscript m and 2 gametes with 1 subscript p, 2 subscript p, and 3 subscript p. In the second case, 1 subscript m and 1 subscript p are aligned at the top, 2 subscript m and 2 subscript m at the center; and 3 subscript p and 3 subscript m aligned at the bottom. This can lead to 2 gametes with 1 subscript m, 2 subscript m, and 3 subscript p and 2 gametes with 1 subscript p, 2 subscript p, and 3 subscript m. In the third case, 1 subscript m, 1 subscript p are aligned at the top, 2 subscript p and 2 subscript m are aligned at the centre, and 3 subscript p and 3 subscript m are aligned at the bottom. This can lead to 2 gametes with 1 subscript m, 2 subscript p, and 2 subscript p and 2 gametes with 1 subscript p, 2 subscript m, and 2 subscript m. In the fourth case, 1 subscript m and 1 subscript p are aligned at the top, 2 subscript p and 2 subscript m are at the center, and 3 subscript m and 3 subscript p are aligned at the bottom. This may lead to 2 gametes with 1 subscript m, 2 subscript p, and 3 subscript m and 2 gametes with 1 subscript p, 2 subscript m, and 3 subscript p. The conclusion states that eight different combinations of chromosomes in the gametes are possible, depending on how the chromosomes align and separate in meiosis 1 and 2.

In summary, crossing over shuffles alleles on the *same* chromosome into new combinations, whereas the random distribution of maternal and paternal chromosomes shuffles alleles on *different* chromosomes into new combinations. Together, these two processes are capable of producing tremendous amounts of genetic variation among the cells resulting from meiosis. **› TRY PROBLEMS 37 AND 38**

THINK-PAIR-SHARE Question 5

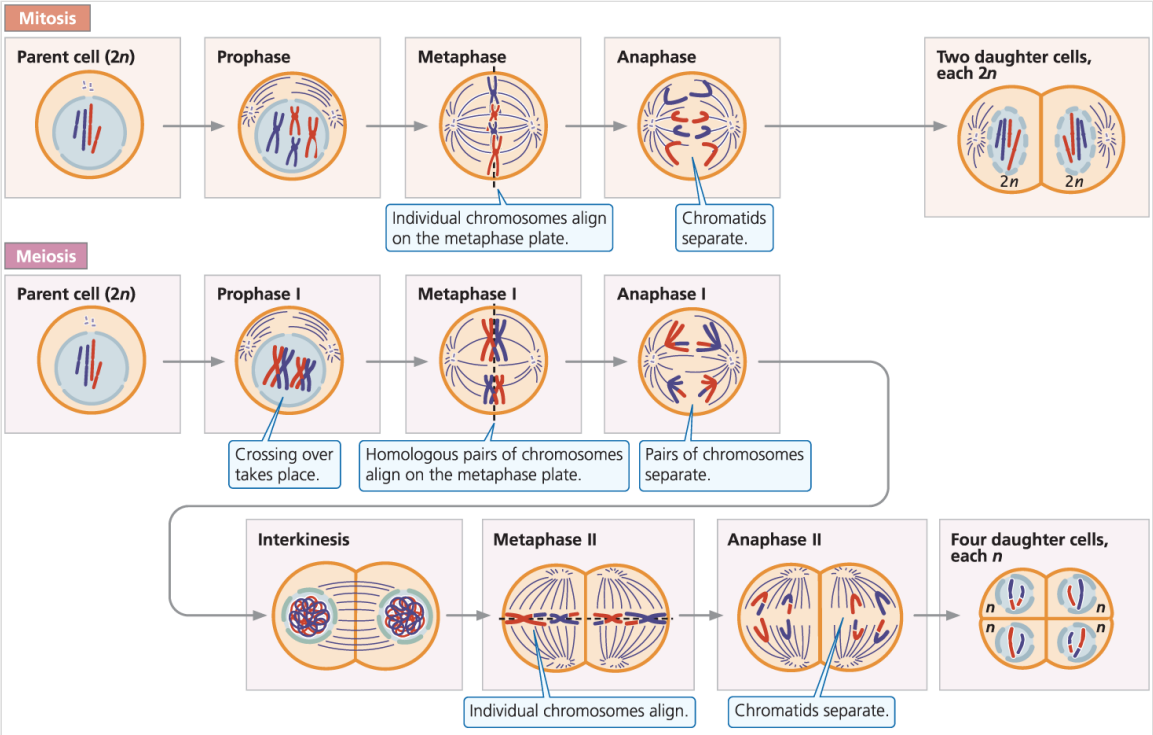
CONCEPTS

The two mechanisms that produce genetic variation in meiosis are crossing over and the random separation of maternal and paternal chromosomes into gametes.

CONNECTING CONCEPTS CONNECT

Mitosis and Meiosis Compared

Now that we have examined the details of mitosis and meiosis, let's compare the two processes (**Figure 2.18** and **Table 2.3**). In both mitosis and meiosis, the chromosomes condense and become visible; both processes include the movement of chromosomes toward the spindle poles, and both are accompanied by cell division. Beyond these similarities, the processes are quite different.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

2.18 Mitosis and meiosis compared.

Description

The first picture in both mitosis and meiosis shows a parent cell with a 2 n nucleus. The nucleus has 4 rod shaped chromosomes where 2 are red (1 small, 1 large) and 2 are blue (1 small, 1 large). The second picture shows the cell in prophase in mitosis and prophase 1 in meiosis, when there are 2 sets of intact X-shaped chromosomes (two red chromosomes where one chromosome is smaller than other and two blue chromosomes where one chromosome is smaller than other). Spindle fibers are produced over the nucleus as the centrosomes drift apart. No crossing over takes place in mitosis and 4 chromosomes are arranged randomly. In the picture below for meiosis, crossing over is occurring at this stage as larger blue and larger red chromosomes overlap and smaller red and smaller blue chromosomes overlap. A caption reads, crossing over takes place.

In the metaphase set of pictures, the X-shaped chromosomes align individually in the middle of the cell one below the other; attached to the spindle fibers running from one cell pole to other during mitosis. The large blue chromosome is at top followed by small red, small blue and finally large red. A caption reads, individual chromosomes align on the metaphase plate. In the picture below, during meiosis they align in groups. The large red and large blue attach together at top followed by small blue and small red at the bottom. A caption reads, homologous pairs of chromosomes align on the metaphase plate.

In the anaphase set of pictures, in mitosis, single chromatids are being pulled to opposite ends of the cell as V-shaped chromatids. A caption reads, chromatids separate. During meiosis, the X-shaped chromosomes wholly move to opposite sides and also have a part of other colored chromosome due to crossing over. A caption reads, pairs of chromosomes separate.

The next set of pictures, starting with interkinesis, only occurs in meiosis. During interkinesis, the cell almost divides into two halves but is still attached together. Both have chromosome material inside individual nuclear envelopes. Spindle fibers are attached between both these cells while a clear vertical division appears between both the cells.

In the metaphase 2 and anaphase 2 pictures during meiosis, the arrangements in the nucleus in meiosis are more similar to metaphase and anaphase of mitosis but here the X-shaped chromosomes align horizontally in the middle of the cell and the individual chromatids are pulled apart respectively. The spindle fibers are now aligned from top to bottom and not horizontally as in case of mitosis.

Two captions read, Individual chromosomes align. Chromatids separate.

The final pictures show the results of mitosis and meiosis. For mitosis, there are 2 daughter cells, each with the same type of nucleus, 2 n, and same combination of genes: 2 red (one small, one large) rod shaped chromatids and 2 blue (one small, one large) rod shaped chromatids. The cell is divided vertically into two halves and one centrosome with tiny spindle fibers appear in each cell.

The results for meiosis are 4 daughter cells, each with an n nucleus. The cell is divided into 4 almost equal halves. Two daughter cells have hybrid chromatids while two have normal copies.

TABLE 2.3 Comparison of mitosis, meiosis I, and meiosis II

Event	Mitosis	Meiosis I	Meiosis II
Cell division	Yes	Yes	Yes
Reduction in chromosome number	No	Yes	No
Genetic variation produced	No	Yes	No
Crossing over	No	Yes	No
Random distribution of maternal and paternal chromosomes	No	Yes	No
Metaphase	Individual	Homologous	Individual

	chromosomes line up	pairs line up	chromosomes line up
Anaphase	Chromatids separate	Homologous chromosomes separate	Chromatids separate

Mitosis results in a single cell division and usually produces two daughter cells. Meiosis, in contrast, comprises two cell divisions and usually produces four cells. In diploid cells, homologous chromosomes are present before both meiosis and mitosis, but the pairing of homologs takes place only in meiosis.

Another difference is that in meiosis, chromosome number is reduced by half as a consequence of the separation of homologous pairs of chromosomes in anaphase I, but no chromosome reduction takes place in mitosis. Furthermore, meiosis is characterized by two processes that produce genetic variation: crossing over (in prophase I) and the random distribution of maternal and paternal chromosomes (in anaphase I). There are normally no equivalent processes in mitosis.

Mitosis and meiosis I also differ in the behavior of chromosomes in metaphase and anaphase and their outcomes. In metaphase I of meiosis, *homologous pairs* of chromosomes line up on the metaphase plate, whereas *individual chromosomes* line up on the metaphase plate in metaphase of mitosis (and in metaphase II of meiosis). In anaphase I of meiosis, *paired chromosomes* separate and migrate toward opposite spindle poles, each chromosome possessing two chromatids attached at the centromere. In contrast, in anaphase of mitosis (and in anaphase II of meiosis), *sister chromatids* separate, and each chromosome that moves toward a spindle pole is unreplicated. Therefore, in contrast with both mitosis and meiosis II, meiosis I produces nonidentical daughter cells. **› TRY PROBLEMS 31 AND 32**

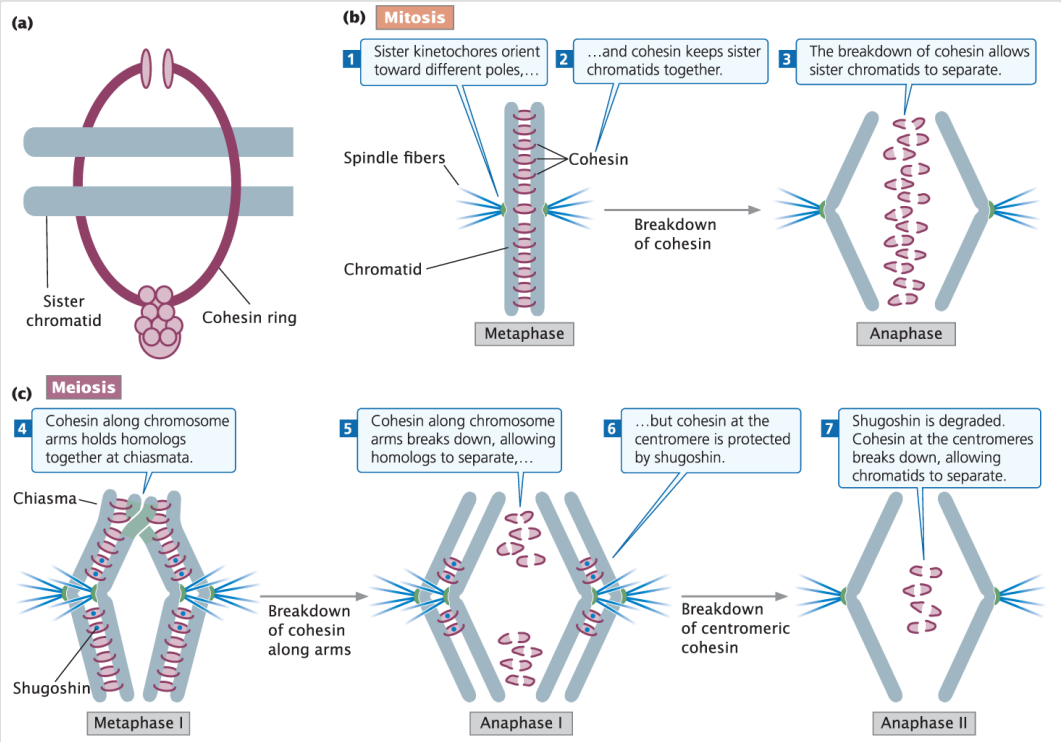
THINK-PAIR-SHARE Questions 6 and 7

The Separation of Sister Chromatids and Homologous Chromosomes

Some of the molecules required for the joining and separation of chromatids and homologous chromosomes have been identified. **Cohesin**, a protein that holds chromatids together, is key to the behavior of chromosomes in mitosis and meiosis (**Figure 2.19a**). Cohesin is another type of structural maintenance of chromosomes (SMC) complex, related to condensins and SMCs that help bring about chromosome condensation in eukaryotes and chromosome segregation in bacteria. Cohesin has a ring-like structure that encircles and holds together the sister chromatids (**Figure 2.19a**). It is loaded onto the chromosome in the S phase and persists through G_2 and early mitosis. In anaphase of mitosis, cohesin along the entire length of the chromosome is broken down by an enzyme called separase, allowing the sister chromatids to separate **(Figure 2.19b**).

As we have seen, mitosis and meiosis differ fundamentally in the behavior of chromosomes in anaphase (see Figure 2.18). Why do homologs separate in anaphase I of meiosis, whereas chromatids separate in anaphase of mitosis and anaphase II of meiosis? It is important to note that the forms of cohesin used in mitosis and meiosis differ. At the beginning of meiosis, the meiosis-specific cohesin is found along the entire length of a chromosome's arms (**Figure 2.19c**). The cohesin also acts on the chromosome arms of

homologs at the chiasmata—the crossover points between homologous chromosomes—tethering two homologs together at their ends.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

2.19 Cohesin controls the separation of chromatids and chromosomes in mitosis and meiosis. (a) Structure of a cohesin ring around a segment of a pair of chromatids. (b) In mitosis, cohesin keeps sister chromatids together until anaphase, when its breakdown allows chromatids to separate. (c) In meiosis, cohesin along the chromosome arms breaks down in anaphase I, but cohesin remains at the centromere, keeping sister chromatids together until anaphase II. (In parts b and c, the cohesin ring structure is simplified.)

Description

In a: The diagram of cohesion shows two horizontal sister chromatids inside a circular loop labeled as cohesion ring having a bunch of circular structures hanging at the bottom. At the top end of the ring, two circular discs appear and an opening is present between them.

In b: The first diagram shows two rod shaped sister chromatids during metaphase. The sister kinetochores are drawn as dots on the middle of the chromatids and originate from a grey structure at the center of the chromatids. The spindle fibers emerge out from these grey structures. The cohesion, represented by pink circles in between the chromatids, holds the sister chromatids together. A caption reads, “Sister kinetochores orient toward different poles, and cohesin keeps sister chromatids together.” This leads to next stage metaphase where breakdown of cohesin occurs. The breakdown in cohesin is shown by the pink circles breaking in half. As a result, the sister chromatids separate. A caption reads, “The breakdown of cohesin allows sister chromatids to separate.” The chromatids separate as lateral V shaped with their open ends close and tips farther.

In c: The first diagram shows 2 V shaped chromosomes together during metaphase 1. Cohesin, represented by pink circles, are located along the chromosome arms. Cohesin also holds the homologs together at the chiasmata. A blue tiny dot is present in the cohesin structure in two molecules above and two below the center and one of them is labeled as shugoshin. The spindle fibers are emerging from green structures present at around center of the chromosomes. A caption reads, “Cohesin along chromosome arms holds homologs together at chiasmata.” Breakdown of cohesin along arms occurs and this leads to next stage anaphase 1.

In the second diagram, the breakdown in cohesin is shown by the pink circles breaking in half. With the breakdown of cohesin, the almost V shaped chromosome homologs separate from each other and migrate to opposite sides. The spindle fibers emerge out from green structures. A caption reads, “Cohesin along chromosome arms breaks down, allowing homologs to separate but cohesin at the centromere is protected by shugoshin.” Breakdown of centromeric cohesion occurs and this leads to next stage anaphase 2. The third diagram shows anaphase 2. The shugoshin is degrade as the blue dots have disappeared. The spindle fibers emerge out from green structures and almost V shaped chromatids are pulled away from each other. A caption reads, “Shugoshin is degraded. Cohesin at the centromeres breaks down, allowing chromatids to separate.”

In anaphase I, cohesin along the chromosome arms is broken, allowing the two homologs to separate. However, cohesin at the centromere is protected by a protein called shugoshin, which means

"guardian spirit" in Japanese. Because of the protective action of shugoshin, the centromeric cohesin remains intact and prevents the separation of the two sister chromatids during anaphase I. Shugoshin is subsequently degraded. At the end of metaphase II, the centromeric cohesin—no longer protected by shugoshin—breaks down, allowing the sister chromatids to separate in anaphase II, just as they do in mitosis (see Figure 2.19c). ❯ **TRY PROBLEM 34**

THINK-PAIR-SHARE Question 8

CONCEPTS

Cohesin holds sister chromatids together during the early part of mitosis. In anaphase, cohesin breaks down, allowing sister chromatids to separate. In meiosis, cohesin is protected at the centromeres during anaphase I, so homologous chromosomes, but not sister chromatids, separate in meiosis I. The breakdown of centromeric cohesin allows sister chromatids to separate in anaphase II of meiosis.

✔ CONCEPT CHECK 6

How does shugoshin affect sister chromatids in meiosis I and meiosis II?

Meiosis in the Life Cycles of Animals and Plants

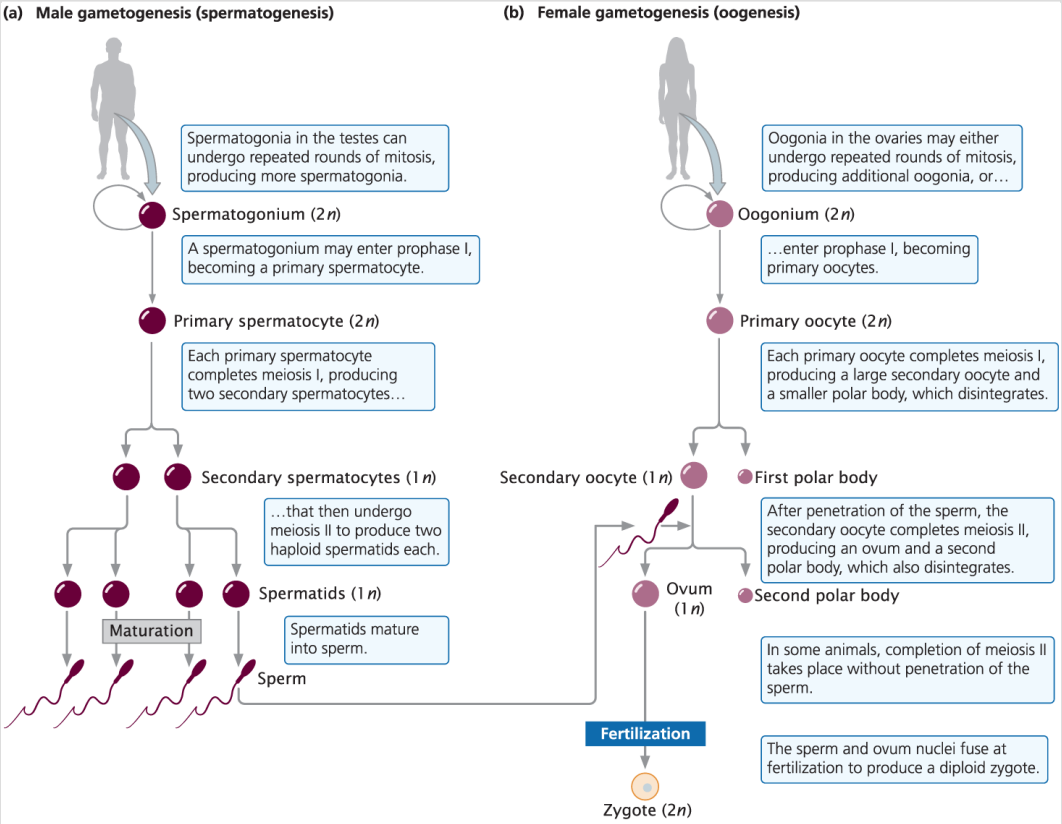
The overall result of meiosis is four haploid cells that are genetically variable. Let's see where meiosis fits into the life cycles of a multicellular animal and a multicellular plant.

MEIOSIS IN ANIMALS

The production of gametes in a male animal, a process called **spermatogenesis**, takes place in the testes. There, diploid primordial germ cells divide mitotically to produce diploid cells called **spermatogonia** (**Figure 2.20a**). Each spermatogonium can undergo repeated rounds of mitosis, giving rise to numerous additional spermatogonia. Alternatively, a spermatogonium can initiate meiosis and enter prophase I. Now called a **primary spermatocyte**, the cell is still diploid because the homologous chromosomes have not yet separated. Each primary spermatocyte completes meiosis I, giving rise to two haploid **secondary spermatocytes** that then undergo meiosis II, with each producing two haploid **spermatids**. Thus, each primary spermatocyte produces a total of four haploid spermatids, which mature and develop into sperm.

The production of gametes in a female animal, a process called **oogenesis**, begins much as spermatogenesis does. Within the ovaries, diploid primordial germ cells divide mitotically to produce **oogonia** (**Figure 2.20b**). Like spermatogonia, oogonia can undergo repeated rounds of mitosis or they can enter meiosis. When they

enter prophase I, these still-diploid cells are called primary oocytes. Each primary oocyte completes meiosis I and divides.



2.20 Gamete formation in animals.

Description

The first flow chart “a” is on the left and shows the outline of a man at the top. All of the cells responsible for forming the sperm are depicted as circles. At the bottom of the flow chart are the outlines of sperm. Male gametogenesis or spermatogenesis is described in the flow chart as follows: Spermatogonium are 2 n. They may also change back to spermatogonium. A caption reads, spermatogonia in the testes can undergo repeated rounds of mitosis, producing more spermatogonia. Spermatogonium then changes to primary spermocyte. A caption reads, a spermatogonium may enter prophase 1, becoming a primary spermatocyte. Primary spermocyte further changes to 2 secondary spermocytes (1 n). A caption reads, each primary spermatocyte completes meiosis 1, producing two secondary spermatocytes. Each secondary spermocyte then leads to the

formation of 2 spermatids (1 n). A total of 4 spermatids is formed. A caption reads, that then undergo meiosis 2 to produce two haploid spermatids each. Each spermatid matures into a sperm and a total of 4 sperms are produced. A caption reads, spermatids mature into sperm.

The second flow chart “b” on the right shows the outline of a woman. The flow chart describes female gametogenesis or oogenesis as follows: Oogonium is 2 n and may also change back to oogonium. A caption reads, oogonia in the ovaries may either undergo repeated rounds of mitosis, producing additional oogonia. Oogonium then changes to Primary oocyte (2 n). A caption reads, enter prophase 1, becoming primary oocytes. The primary oocyte then leads to formation of a larger secondary oocyte (1 n) and a smaller first polar body. A caption reads, Each primary oocyte completes meiosis1, producing a large secondary oocyte and a smaller polar body, which disintegrates. A sperm from male interacts with the secondary oocyte formed and then a larger ovum (1 n) and a smaller second polar body. A caption reads, after penetration of the sperm, the secondary oocyte completes meiosis 2, producing an ovum and a second polar body, which also disintegrates. Fertilization occurs and a zygote (2 n) is produced. A caption reads, the sperm and ovum nuclei fuse at fertilization to produce a diploid zygote. In some animals, completion of meiosis 2 takes place without penetration of the sperm.

At this point, oogenesis begins to differ from spermatogenesis. In oogenesis, cytokinesis is unequal: most of the cytoplasm is allocated to one of the two haploid cells, the **secondary oocyte**. The smaller cell, which contains half of the chromosomes but only a small part of the cytoplasm, is called the **first polar body**; it may or may not divide further. The secondary oocyte completes meiosis II, and again, cytokinesis is unequal—most of the cytoplasm passes into one of the cells. The larger cell, which acquires most of the cytoplasm, is the **ovum**, the mature female gamete. The smaller cell is the **second polar body**. Only the ovum is capable of being fertilized, and the

polar bodies usually disintegrate. Oogenesis, then, produces a single mature gamete from each primary oocyte.

In mammals, oogenesis differs from spermatogenesis in another way. The formation of sperm takes place continuously in a male throughout his adult reproductive life. The formation of female gametes, however, is often a discontinuous process and may take place over a period of years. Oogenesis begins before birth; at this time, oogonia initiate meiosis and give rise to primary oocytes. Meiosis is then arrested, stalled in prophase I. Thus, a female is born with primary oocytes arrested in prophase I. In humans, this period of suspended animation may last 30 or 40 years, until rising hormone levels stimulate one or more of the primary oocytes to recommence meiosis. The first division of meiosis is completed, and a secondary oocyte is ovulated from the ovary (a process called ovulation). In humans and many other species, the second division of meiosis is then delayed until contact with the sperm. When a sperm penetrates the outer layer of the secondary oocyte, the second meiotic division takes place, the second polar body is extruded from the ovum, and the nuclei of the sperm and newly formed ovum fuse, giving rise to the zygote.

CONCEPTS

In the testes, a diploid spermatogonium undergoes meiosis, producing a total of four haploid sperm cells. In the ovary, a diploid oogonium undergoes meiosis to produce a single large ovum and smaller polar bodies that normally disintegrate.

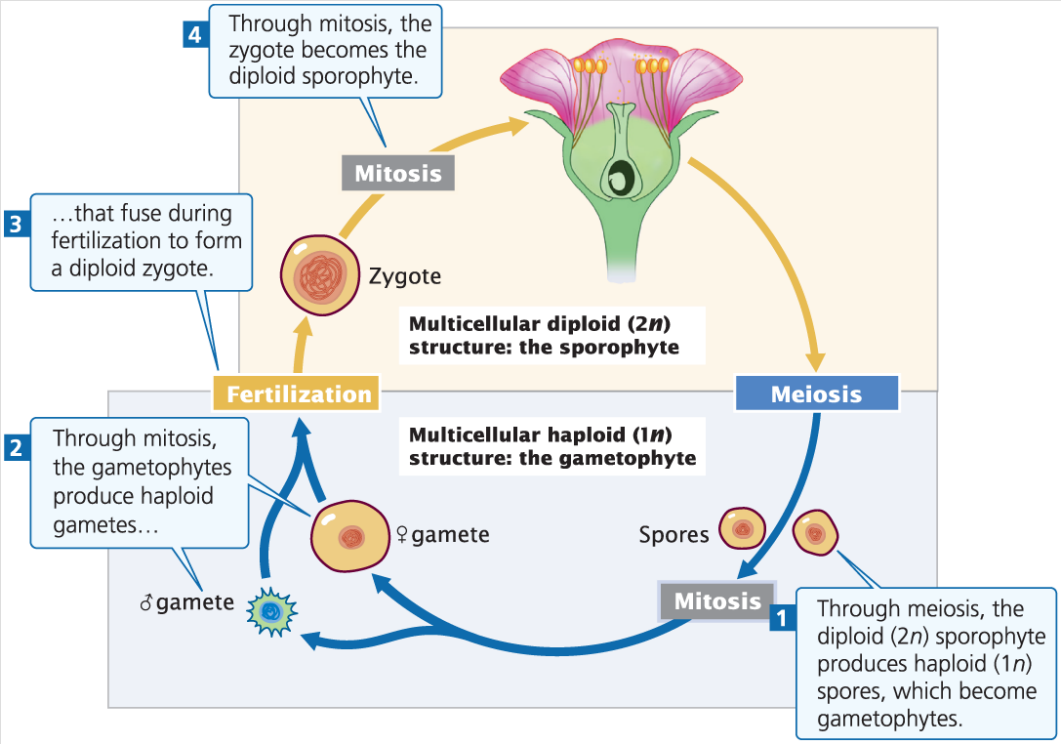
✔ CONCEPT CHECK 7

A secondary spermatocyte has 12 chromosomes. How many chromosomes will be found in the primary spermatocyte that gave rise to it?

a. 6
b. 12
c. 18
d. 24

MEIOSIS IN PLANTS

Most multicellular plants and algae have a complex life cycle that includes two distinct structures (generations): a multicellular diploid sporophyte and a multicellular haploid gametophyte. These two generations alternate; the sporophyte produces haploid spores through meiosis, and the gametophyte produces haploid gametes through mitosis (Figure 2.21). This type of life cycle is sometimes called alternation of generations. In this cycle, the immediate products of meiosis are called spores, not gametes; the spores undergo one or more mitotic divisions to produce gametes. Although the terms used to describe the plant life cycle are somewhat different from those commonly used for animals (and from some of those employed so far in this chapter), the processes in plants and animals are basically the same: in both, meiosis leads to a reduction in chromosome number, producing haploid cells.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

2.21 Plants alternate between diploid and haploid life stages. (Female, ♀; male, ♂).

Description

The upper half of the flowchart is labeled “multicellular diploid (2 n) structure: the sporophyte”, while the lower half is labeled “multicellular haploid (1 n) structure: the gametophyte”. The flowchart starts with a flower having stamen and carpel in the sporophyte stage. Meiosis occurs and two circular shaped spores are formed in the gametophyte stage. A caption reads, “Through meiosis, the diploid (2 n) sporophyte produces haploid (1 n) spores, which become gametophytes.” Mitosis occurs and a larger, circular female gamete and a smaller, circular spiky male gamete are formed in the gametophyte stage. A caption reads, “

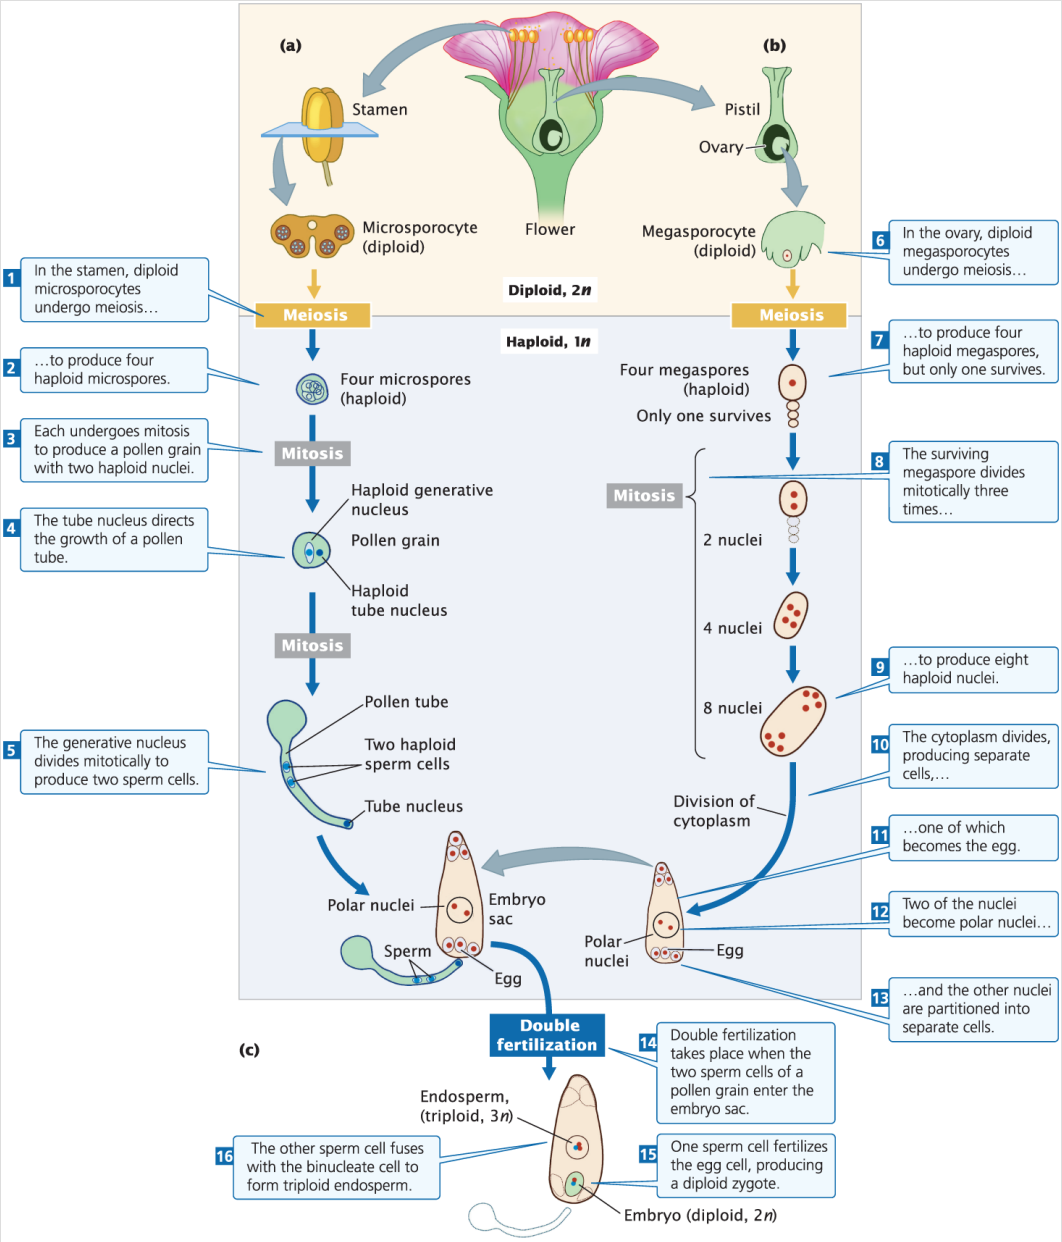
Through mitosis, the gametophytes produce haploid gametes that fuse during fertilization to form a diploid zygote.” Both these gametes undergo fertilization. . A large circular zygote is formed in the sporophyte stage. Mitosis occurs and this again leads to the same flower. A caption reads, “Through mitosis, the zygote becomes the diploid sporophyte.”

In flowering plants, the sporophyte is the obvious, vegetative part of the plant; the gametophyte consists of only a few haploid cells within the sporophyte. The flower, which is part of the sporophyte, contains the reproductive structures. In some species, both male and female reproductive structures are found in the same flower; in other species, they exist in different flowers. In either case, the male part of the flower, the stamen, contains diploid reproductive cells called **microsporocytes**, each of which undergoes meiosis to produce four haploid **microspores** (**Figure 2.22a**). Each microspore divides mitotically, producing an immature pollen grain consisting of two haploid nuclei. One of these nuclei, called the tube nucleus, directs the growth of a pollen tube. The other, termed the generative nucleus, divides mitotically to produce two sperm cells. The pollen grain, with its two haploid nuclei, is the male gametophyte.

The female part of the flower, the ovary, contains diploid cells called **megasporocytes**, each of which undergoes meiosis to produce four haploid **megaspores** (**Figure 2.22b**), only one of which survives. The nucleus of the surviving megaspore divides mitotically three times, producing a total of eight haploid nuclei that make up the female gametophyte, otherwise known as the embryo sac. Division of the cytoplasm then produces separate cells, one of which becomes the egg.

When the plant flowers, the stamens open and release pollen grains. Pollen lands on a flower's stigma—a sticky platform that sits on top of a long stalk called the style. At the base of the style is the ovary. If

a pollen grain germinates, it grows a tube down the style into the ovary. The two sperm cells pass down this tube and enter the embryo sac (**Figure 2.22c**). One of the sperm cells fertilizes the egg cell, producing a diploid zygote, which develops into an embryo. The other sperm cell fuses with two nuclei enclosed in a single cell, giving rise to a 3n (triploid) endosperm, which stores food that will be used later by the embryonic plant. These two fertilization events are collectively termed double fertilization.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

2.22 Sexual reproduction in flowering plants.

Description

At the top center of the illustration is a flower. Both the flowcharts arise from this flower. On the left side is male reproduction labeled as “a” and on the right is female reproduction labeled as “b”. The flowchart “a” starts at the top and progresses downward and arrows are drawn between each stage. Diploid microsporocytes in the stamen undergo meiosis and produce four haploid microspores. A caption reads, “In the stamen, diploid

microsporocytes undergo meiosis to produce four haploid microspores." These microspores undergo mitosis to produce a circular pollen grain with two nuclei: one is a tiny round shaped labeled as haploid

tube nucleus and other is almost rod shaped labeled as haploid generative nucleus. A caption reads, "Each undergoes mitosis to produce a pollen grain with two haploid nuclei. The tube nucleus directs

the growth of a pollen tube." Mitosis occurs and a pollen tube is produced. This pollen tube has a bulge at one end and a long tube. Two haploid sperm cells are marked as bands in its tube part. The end of pollen tube is labeled as tube nucleus. A caption reads, "The generative nucleus divides mitotically to produce two sperm cells." The flowchart "b" shows female reproduction. The ovary in pistil, a diploid megasporocyte, undergoes meiosis to produce 4 haploid megaspores where 1 is a large oval shaped and other three are tiny oval shaped. Out of these 4, only 1 survives. A caption reads, "In the ovary, diploid megasporocytes undergo meiosis to produce four haploid megaspores, but only one survives." The large surviving megaspore undergoes mitosis three times such that after first it has 2 tiny circular nuclei, after second mitosis it has 4 nuclei, and after third mitosis it has 8 nuclei. The megaspore with 8 nuclei has four clustered on each end. A caption reads, "The surviving megaspore divides mitotically three times to produce eight haploid nuclei." The cytoplasm divides. A large spore is produced with three cells arranged at one end, circular polar nuclei with 2 nuclei, and three cells at bottom where one cell in the middle is egg. A caption reads, "The cytoplasm divides, producing separate cells one of which becomes the egg. Two of the nuclei become polar nuclei and the other nuclei are partitioned into separate cells." This spore with egg from flowchart "b" and the pollen tube from male from flowchart "a" interacts. The outer covering of spore is labeled as embryo sac. Double fertilization occurs and part "c" at the bottom shows formation of a spore with an endosperm, (triploid, 3 n) and an embryo (diploid, 2 n). A caption reads, "double fertilization takes place when the two sperm cells of a pollen grain enter the embryo sac. One sperm cell fertilizes the egg cell, producing a diploid zygote. The other sperm cell fuses with the binucleate cell to form triploid endosperm."

We have now examined the place of meiosis in the sexual cycles of two organisms: a typical multicellular animal and a flowering plant. These cycles are just two of the many variations found among

eukaryotic organisms. Although the cellular processes that produce reproductive cells in plants and animals differ in the number of cell divisions, the number of haploid gametes produced, and the relative sizes of the final products, the overall result is the same: meiosis gives rise to haploid, genetically variable cells that fuse during fertilization to produce diploid progeny. **› TRY PROBLEMS 40 AND 42**

CONCEPTS

In the stamen of a flowering plant, meiosis produces haploid microspores that divide mitotically to produce haploid sperm in a pollen grain. Within the ovary, meiosis produces four haploid megaspores, only one of which divides mitotically three times to produce the eight haploid nuclei that make up the embryo sac. After pollination, one sperm fertilizes the egg cell, producing a diploid zygote; the other fuses with two nuclei to form the endosperm.

✔ CONCEPT CHECK 8

Which of the following structures is diploid?

a. Microspore
b. Egg
c. Megaspore
d. Microsporocyte

Chapter 2 Review

CHAPTER SUMMARY

Section 2.1 Learning Objective: Be able to list genetic differences between eukaryotic cells and prokaryotic cells.

- A prokaryotic cell possesses a simple structure, with no nuclear membrane and usually a single circular chromosome. A eukaryotic cell possesses a more complex structure, with a nucleus and multiple linear chromosomes consisting of DNA complexed with histone proteins.

Section 2.2 Learning Objective: Be able to compare cell division in bacteria and eukaryotes.

- Cell reproduction requires the copying of genetic material, separation of the copies, and cell division.
- In a prokaryotic cell, the single chromosome replicates, the two copies move toward opposite sides of the cell, and the cell divides. In eukaryotic cells, reproduction is more complex than in prokaryotic cells, requiring mitosis to ensure that a complete set of genetic information is transferred to each new cell, or meiosis to generate gametes that contain a copy of each chromosome.

- In eukaryotic cells, chromosomes are typically found in homologous pairs. Each functional chromosome consists of a centromere, telomeres, and multiple origins of replication. After a chromosome has been copied, the two copies remain attached at the centromere, forming sister chromatids.
- The cell cycle consists of the stages through which a eukaryotic cell passes between cell divisions. It consists of (1) interphase, in which the cell grows and prepares for division, and (2) the M phase, in which nuclear and cell division take place. The M phase consists of (1) mitosis, the process of nuclear division, and (2) cytokinesis, the division of the cytoplasm.
- Progression through the cell cycle is regulated at checkpoints that allow or prohibit the cell's progression to the next stage.
- Mitosis usually results in the production of two genetically identical cells.

Section 2.3 Learning Objective: Be able to explain how the process of meiosis produces genetic variation during sexual reproduction.

- Sexual reproduction produces genetically variable progeny. It includes meiosis, in which haploid sex cells are produced, and fertilization, the fusion of sex cells. Meiosis includes two cell divisions. In meiosis I, crossing over takes place, and homologous chromosomes separate. In meiosis II, sister chromatids separate.
- The usual result of meiosis is the production of four haploid cells that are genetically variable. Genetic variation in meiosis

is produced by crossing over and by the random distribution of maternal and paternal chromosomes.

- Cohesin holds sister chromatids together. In metaphase of mitosis and in metaphase II of meiosis, the breakdown of cohesin allows sister chromatids to separate. In meiosis I, centromeric cohesin remains intact and keeps sister chromatids together so that homologous chromosomes, but not sister chromatids, separate in anaphase I.
- In animals, a diploid spermatogonium undergoes meiosis to produce four haploid sperm cells. A diploid oogonium undergoes meiosis to produce one large haploid ovum and one or more smaller polar bodies.
- In plants, a diploid microsporocyte in the stamen undergoes meiosis to produce four pollen grains, each with two haploid sperm cells. In the ovary, a diploid megasporocyte undergoes meiosis to produce four haploid megaspores. One of these megaspores divides mitotically three times to produce eight haploid nuclei, one of which forms the egg cell. During pollination, one sperm fertilizes the egg cell and the other fuses with two haploid nuclei to form a triploid endosperm.

WORKED PROBLEMS

Problem 1

A student examines a thin section of an onion-root tip and records the number of cells that are in each stage of the cell cycle. She

observes 94 cells in interphase, 14 cells in prophase, 3 cells in prometaphase, 3 cells in metaphase, 5 cells in anaphase, and 1 cell in telophase. If the complete cell cycle in an onion-root tip requires 22 hours, what is the average duration of each stage in the cycle? Assume that all cells are in the active cell cycle (not G_0).

» Solution Strategy

What information is required in your answer to the problem?

The average duration of each stage of the cell cycle.

What information is provided to solve the problem?

- The numbers of cells in different stages of the cell cycle.
- A complete cell cycle requires 22 hours.

For help with this problem, review:

The Cell Cycle and Mitosis in Section 2.2.

» Solution Steps

This problem is solved in two steps. First, we calculate the proportions of cells in each stage of the cell cycle, which correspond to the amount of time that an average cell spends in each stage. For example, if cells spend 90% of their time in

interphase, then at any given moment, 90% of the cells will be in interphase. The second step is to convert the proportions into lengths of time, which is done by multiplying the proportions by the total time of the cell cycle (22 hours).

The proportion of cells at each stage is equal to the number of cells found in that stage divided by the total number of cells examined:

Interphase	$^{94}/_{120} = 0.783$
Prophase	$^{14}/_{120} = 0.117$
Prometaphase	$^{3}/_{120} = 0.025$
Metaphase	$^{3}/_{120} = 0.025$
Anaphase	$^{5}/_{120} = 0.042$
Telophase	$^{1}/_{120} = 0.008$

Hint: The total of all the proportions should equal 1.0.

To determine the average duration of each stage, multiply the proportion of cells in each stage by the time required for the entire cell cycle:

Interphase	$0.783 \times 22 \text{ hours} = 17.23 \text{ hours}$
Prophase	$0.117 \times 22 \text{ hours} = 2.57 \text{ hours}$
Prometaphase	$0.025 \times 22 \text{ hours} = 0.55 \text{ hour}$
Metaphase	$0.025 \times 22 \text{ hours} = 0.55 \text{ hour}$
Anaphase	$0.042 \times 22 \text{ hours} = 0.92 \text{ hour}$
Telophase	$0.008 \times 22 \text{ hours} = 0.18 \text{ hour}$

Hint: The total time for all stages should equal 22 hours.

Problem 2

A cell in G_1 of interphase has 8 chromosomes. How many chromosomes and how many DNA molecules will be found per cell as this cell progresses through the following stages: G_2, metaphase of mitosis, anaphase of mitosis, after cytokinesis following mitosis, metaphase I of meiosis, metaphase II of meiosis, and after cytokinesis following meiosis II?

» Solution Strategy

What information is required in your answer to the problem?

The number of chromosomes and the number of DNA molecules present per cell at different stages of the cell cycle and meiosis.

What information is provided to solve the problem?

The number of chromosomes in the cell in G_1.

For help with this problem, review:

Connecting Concepts: Counting Chromosomes and DNA Molecules in Section 2.2.

» Solution Steps

Remember the rules about counting chromosomes and DNA molecules: (1) to determine the number of chromosomes, count the functional centromeres; (2) to determine the number of DNA molecules, determine whether sister chromatids exist. If sister chromatids are present, the number of DNA molecules is two times the number of chromosomes. If the chromosomes are unreplicated (don't contain sister chromatids), the number of DNA molecules equals the number of chromosomes. Think carefully about when and how the numbers of chromosomes and DNA molecules change in the course of mitosis and meiosis.

Hint: These two rules are important for answering the question.

The number of DNA molecules increases only in the S phase, when DNA replicates; the number of DNA molecules decreases only when the cell divides. Chromosome number increases only when sister chromatids separate in anaphase of mitosis and in anaphase II of meiosis (homologous chromosomes, not chromatids, separate in anaphase I of meiosis). Like the number of DNA molecules, chromosome number is reduced only by cell division.

Recall: Chromosome number increases only when chromatids separate. The number of DNA molecules increases only in the S phase.

Let's now apply these principles to the problem. A cell in G_1 has 8 chromosomes, and sister chromatids are not present, so 8 DNA molecules are present per cell in G_1. DNA replicates in the S phase, and now each chromosome consists of two chromatids, so in G_2, $2 \times 8 = 16$ DNA molecules are present per cell. However, the two copies of each DNA molecule remain attached at the centromere, so there are still only 8 chromosomes present. As the cell passes through prophase and metaphase of the cell cycle, the number of chromosomes and the number of DNA molecules remain the same, so at metaphase, there are 16 DNA molecules and 8 chromosomes. In anaphase, the sister chromatids separate, and each becomes an independent chromosome; at this point, the number of chromosomes increases from 8 to 16. This increase is temporary, lasting only until the cell divides in telophase or subsequent to it. The number of DNA molecules remains at 16 in anaphase. The

number of DNA molecules and chromosomes per cell is reduced by cytokinesis after telophase because the 16 chromosomes and DNA molecules are now distributed between two cells. Therefore, after cytokinesis, each cell has 8 DNA molecules and 8 chromosomes, the same numbers that were present at the beginning of the cell cycle.

Now, let's trace the numbers of DNA molecules and chromosomes through meiosis. At G_1, there are 8 chromosomes and 8 DNA molecules. The number of DNA molecules increases to 16 in the S phase, but the number of chromosomes remains at 8 (each chromosome has two chromatids). The cell therefore enters metaphase I having 16 DNA molecules and 8 chromosomes. In anaphase I of meiosis, homologous chromosomes separate, but the number of chromosomes remains at 8. After cytokinesis, the original 8 chromosomes are distributed between two cells, so the number of chromosomes per cell falls to 4 (each with two chromatids). The original 16 DNA molecules are also distributed between two cells, so the number of DNA molecules per cell is 8. There is no DNA synthesis in interkinesis, and each cell still maintains 4 chromosomes and 8 DNA molecules through metaphase II. In anaphase II, the two sister chromatids of each chromosome separate, temporarily raising the number of chromosomes per cell to 8, whereas the number of DNA molecules per cell remains at 8. After cytokinesis, the chromosomes and DNA molecules are again distributed between two cells, providing 4 chromosomes and 4 DNA molecules per cell. These results are summarized in the following table:

Stage	Number of chromosomes per cell	Number of DNA molecules per cell
G_1	8	8
G_2	8	16
Metaphase of mitosis	8	16
Anaphase of mitosis	16	16
After cytokinesis following mitosis	8	8
Metaphase I of meiosis	8	16
Metaphase II of meiosis	4	8
After cytokinesis following meiosis II	4	4

ANSWERS TO CONCEPT CHECKS

1. Bacteria and archaea are prokaryotes. They differ from eukaryotes in possessing no nucleus, a genome that usually consists of a single circular chromosome, and a smaller amount of DNA.
2. b
3. The kinetochore is the point at which spindle microtubules attach to the chromosome during cell division. If the kinetochore were missing, spindle microtubules would not attach to the chromosome, the chromosome would not be drawn into a newly formed nucleus, and the resulting daughter cells would be missing a chromosome.
4. a
5. c
6. During anaphase I, shugoshin protects cohesin at the centromere from the action of separase, so centromeric cohesin remains intact, and the sister chromatids remain

together. Subsequently, shugoshin breaks down, so centromeric cohesin is cleaved by separase in anaphase II, and the sister chromatids separate.

Chapter 2 Assessment

COMPREHENSION QUESTIONS

Section 2.1

1. What are some genetic differences between prokaryotic and eukaryotic cells?
2. Why are viruses often used in the study of genetics?

Section 2.2

3. List three fundamental events that must take place in cell reproduction.
4. Outline the process by which prokaryotic cells reproduce.
5. Name three essential structural elements of a functional eukaryotic chromosome, and describe their functions.
6. Sketch and identify four different types of chromosomes based on the position of the centromere.
7. List the stages of interphase and the major events that take place in each stage.
8. What are checkpoints? List some of the important checkpoints in the cell cycle.
9. List the stages of mitosis and the major events that take place in each stage.
10. Briefly describe how the chromosomes move toward the spindle poles during anaphase.
11. What are the genetically important results of the cell cycle and mitosis?
12. Why are the two cells produced by the cell cycle genetically identical?

Section 2.3

13. What are the stages of meiosis, and what major events take place in each stage?
14. What are the major results of meiosis?
15. What two processes unique to meiosis are responsible for genetic variation? At what point in meiosis do these processes take place?
16. How does anaphase I of meiosis differ from anaphase of mitosis?
17. Briefly explain why sister chromatids remain together in anaphase I but separate in anaphase II of meiosis.
18. Outline the processes of spermatogenesis and oogenesis in animals.
19. Outline the processes of male gamete formation and female gamete formation in plants.

APPLICATION QUESTIONS AND PROBLEMS

Introduction

20. *Answer the following questions about the blind men's riddle, presented in the introduction to this chapter.
    a. What do the two socks of a pair represent in the cell cycle?
    b. In the riddle, each blind man buys his own pairs of socks, but the clerk places all the pairs in one bag. Thus, there are two pairs of socks of each color in the bag (two black pairs, two blue pairs, two gray pairs, etc.). What do the two pairs (four socks in all) of each color represent?
    c. What is the thread that connects the two socks of a pair?
    d. What is the molecular knife that cuts the thread holding the two socks of a pair together?
    e. What in the riddle performs the same function as spindle microtubules?
    f. What would happen if one man failed to grasp his sock of a particular pair? How does that outcome relate to events in the cell cycle?

Section 2.1

21. A cell has a circular chromosome and no nuclear membrane. Its DNA is complexed with some histone proteins. Does this cell belong to a bacterium, an archaean, or a eukaryote? Explain your reasoning.

Section 2.2

22. A certain species has three pairs of chromosomes: an acrocentric pair, a metacentric pair, and a submetacentric pair. Draw a cell of this species as it would appear in metaphase of mitosis.

23. Examine **Figure 2.6a**. What type of chromosome (metacentric, submetacentric, acrocentric, or telocentric) is chromosome 1? What about chromosome 4?

24. *A biologist examines a series of cells and counts 160 cells in interphase, 20 cells in prophase, 6 cells in prometaphase, 2 cells in metaphase, 7 cells in anaphase, and 5 cells in telophase. If the complete cell cycle requires 24 hours, what is the average duration of the M phase in these cells? Of metaphase?

25. In what stage of mitosis is the cell illustrated in the chapter opening figure (p. 17)?

Section 2.3

26.

What role would mitosis and/or meiosis play in human reproduction under the theory of preformationism (see Chapter 1)?

27. A certain species has three pairs of chromosomes: one acrocentric pair and two metacentric pairs. Draw a cell of this species as it would appear in the following stages of meiosis:
    a. Metaphase I
    b. Anaphase I
    c. Metaphase II
    d. Anaphase II

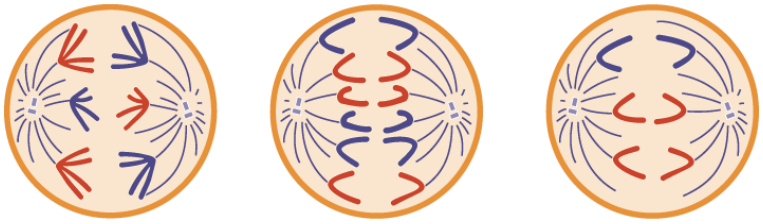
28. Construct a table similar to that in **Figure 2.12** for the different stages of meiosis, giving the number of chromosomes per cell and the number of DNA molecules

per cell for a cell that begins with 4 chromosomes (two homologous pairs) in G_1. Include the following stages in your table: G_1, S, G_2, prophase I, metaphase I, anaphase I, telophase I (after cytokinesis), prophase II, metaphase II, anaphase II, and telophase II (after cytokinesis).

29. *A cell in G_1 of interphase has 12 chromosomes ($2n = 12$). How many chromosomes and DNA molecules will be found per cell when this original cell progresses to the following stages?
    a. G_2 of interphase
    b. Metaphase I of meiosis
    c. Prophase of mitosis
    d. Anaphase I of meiosis
    e. Anaphase II of meiosis
    f. Prophase II of meiosis
    g. After cytokinesis following mitosis
    h. After cytokinesis following meiosis II

30. How are the events that take place in spermatogenesis and oogenesis similar? How are they different?

31. *All of the following cells, shown in various stages of mitosis and meiosis, come from the same rare species of plant.
    a. What is the diploid number of chromosomes in this plant?
    b. Give the names of each stage of mitosis or meiosis shown.
    c. Give the number of chromosomes and number of DNA molecules per cell present at each stage.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The first cell on the left shows three X-shaped chromosomes being pulled to the left and three being pulled to the right with the help of spindle fibers attached to their centromeres. On the left side, the top and bottom

chromosomes are red and the middle one is blue while on the right, top and bottom are blue and middle one is red.

The second cell in the center shows six lateral V-shaped sister chromatids pulled to the left and six pulled to the right. On both the sides, blue chromatids are at first, fourth, and fifth positions while red chromatids are at second, third and sixth positions.

The third cell on the right has three chromatids being pulled to the left and three chromatids are being pulled to the right. On both the sides, the blue chromatids are at the top and rest are red.

32. *The amount of DNA per cell of a particular species is measured in cells found at various stages of meiosis, and the following amounts are obtained:

Amount of DNA per cell in picograms (pg)		
_____ 3.7 pg	_____ 7.3 pg	_____ 14.6 pg

Match the amounts of DNA above with the corresponding stages of meiosis (*a* through *f*, below). You may use more than one stage for each amount of DNA.

Stage of meiosis

a. G_1
b. Prophase I
c. G_2
d. Following telophase II and cytokinesis
e. Anaphase I
f. Metaphase II

33. CONNECT Tawa has oculocutaneous type 2 albinism (see introduction to Chapter 1). How many copies of the DNA sequence that causes albinism will be present in Tawa's cells during the following stages?
    a. Anaphase of mitosis
    b. G_1 of interphase
    c. Prophase of mitosis
    d. Anaphase II of meiosis
    e. Metaphase I of meiosis

f. After cytokinesis following meiosis II
g. After cytokinesis following mitosis

34. *How would each of the following events affect the outcome of mitosis or meiosis?
    a. Mitotic cohesin fails to form early in mitosis.
    b. Shugoshin is absent during meiosis.
    c. Shugoshin does not break down after anaphase I of meiosis.
    d. Separase is defective.

35. *A cell in prophase II of meiosis contains 12 chromosomes. How many chromosomes would be present in a cell from the same organism if it were in prophase of mitosis? Prophase I of meiosis?

36. A cell has 8 chromosomes in G_1 of interphase. Draw a picture of this cell with its chromosomes at the following stages. Indicate how many DNA molecules are present at each stage.
    a. Metaphase of mitosis
    b. Anaphase of mitosis
    c. Anaphase II of meiosis
    d. Diplotene of meiosis I

37. *The fruit fly *Drosophila melanogaster* (left) has four pairs of chromosomes, whereas the house fly *Musca domestica* (right) has six pairs of chromosomes. In which species would you expect to see more genetic variation among the progeny of a cross? Explain your answer.

Left: © Graphic Science/Alamy Stock Photo; right: © Debug/ iStock Photo.

38. *A cell has two pairs of submetacentric chromosomes, which we will call chromosomes I_a, I_b, II_a, and II_b (chromosomes I_a and I_b are homologs, and

chromosomes II_a and II_b are homologs). Allele *M* is located on the long arm of chromosome I_a, and allele *m* is located at the same position on chromosome I_b. Allele *P* is located on the short arm of chromosome I_a, and allele *p* is located at the same position on chromosome I_b. Allele *R* is located on chromosome II_a and allele *r* is located at the same position on chromosome II_b.

a. Draw these chromosomes, identifying genes *M*, *m*, *P*, *p*, *R*, and *r* as they might appear in metaphase I of meiosis. Assume that there is no crossing over.

b. Taking into consideration the random separation of chromosomes in anaphase I, draw the chromosomes (with genes identified) present in all possible types of gametes that might result from this cell's undergoing meiosis. Assume that there is no crossing over.

39. A horse has 64 chromosomes and a donkey has 62 chromosomes. A cross between a female horse and a male donkey produces a mule, which is usually sterile. How many chromosomes does a mule have? Can you think of any reasons for the fact that most mules are sterile?

40. *Normal somatic cells of horses have 64 chromosomes ($2n = 64$). How many chromosomes and DNA molecules will be present in the following types of horse cells?

Cell type	Number of chromosomes	Number of DNA molecules
a. Spermatogonium	_____	_____
b. First polar body	_____	_____
c. Primary oocyte	_____	_____
d. Secondary spermatocyte	_____	_____

© Dozornaya/iStock Photo.

41. Indicate whether each of the following cells is haploid or diploid.

Cell type	Haploid or diploid?
Microspore	_____
Primary spermatocyte	_____
Microsporocyte	_____
First polar body	_____
Oogonium	_____
Spermatid	_____
Megaspore	_____
Ovum	_____
Secondary oocyte	_____
Spermatogonium	_____

42. *A primary oocyte divides to give rise to a secondary oocyte and a first polar body. The secondary oocyte then divides to give rise to an ovum and a second polar body.
    a. Is the genetic information found in the first polar body identical to that found in the secondary oocyte? Explain your answer.

b. Is the genetic information found in the second polar body identical to that in the ovum? Explain your answer.

CHALLENGE QUESTIONS

Section 2.3

43. CONNECT An autotriploid (3*n*; see Chapter 8) has three sets of homologous chromosomes in each cell instead of the usual pairs of homologous chromosomes present in diploid individuals (2*n*). How would mitosis and meiosis be different in an autotriploid? (Hint: See Figure 8.26.)

44. From 80% to 90% of the most common human chromosome abnormalities arise because the chromosomes fail to divide properly in oogenesis. Can you think of a reason why failure of chromosome division might be more common in female gametogenesis than in male gametogenesis?

45. On average, what proportion of the genome in the following pairs of humans would be exactly the same if no crossing over took place? (For the purposes of this question only, we will ignore the special case of the X and Y sex chromosomes and assume that all genes are located on nonsex chromosomes.)
    a. Father and child
    b. Mother and child
    c. Two full siblings (offspring that have the same two biological parents)
    d. Half siblings (offspring that have only one biological parent in common)
    e. Uncle and niece
    f. Grandparent and grandchild

46. *Female bees are diploid, and male bees are haploid. The haploid males produce sperm and can successfully mate with diploid females. Fertilized eggs develop into females and unfertilized eggs develop into males. How do you think the process of sperm production in male bees differs from sperm production in other animals?

💬 ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Section 2.2

1. A chromosome consists of two sister chromatids. Does the genetic information on the two sister chromatids come from only one parent or from both parents? Explain your reasoning.

2. Are homologous pairs of chromosomes present in mitosis? Explain your reasoning.

Section 2.3

3. A species has two pairs of chromosomes: one metacentric and one submetacentric. Draw pictures of a cell of this species as it would appear in the following stages:
   a. Metaphase of mitosis
   b. Anaphase of mitosis
   c. Metaphase I of meiosis
   d. Anaphase I of meiosis
   e. Anaphase II of meiosis

4. A cell has 8 chromosomes in metaphase II of meiosis. How many chromosomes and DNA molecules will be present per cell in this same organism at the following stages?
   a. Prophase of mitosis
   b. Metaphase I of meiosis
   c. Anaphase of mitosis
   d. Anaphase II of meiosis
   e. Anaphase I of meiosis
   f. After cytokinesis following mitosis
   g. After cytokinesis following meiosis II

5. What is the difference between sister chromatids and homologous chromosomes?

6. List as many similarities and differences between mitosis and meiosis as you can. Which differences do you think are most important, and why?

7. Describe how and where each of the following terms applies to mitosis, meiosis, or both: (1) replication; (2) pairing; (3) separation.

8. Do you know of any genetic diseases or disorders that result from errors in mitosis or meiosis? How do errors in mitosis or meiosis bring about these diseases or disorders?

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Section 2.1

1. Create a concept map that compares the characteristics and relationships of archaea, bacteria, eukaryotes, and viruses. Your map should have a minimum of 12 concepts and links.

Section 2.2

2. Summarize the structures of eukaryotic chromosomes by creating a concept map that links the following terms: chromosome, origin of replication, DNA molecule, kinetochore, homologous pair, sister chromatids, telomere, and centromere.

Section 2.3

3. Create a concept map that outlines the role of cohesin in the separation of sister chromatids and homologous chromosomes in mitosis and meiosis.

SaplingPlus Self-study tools that will help you practice what you've learned and reinforce this chapter's concepts are available online. Go to www.saplinglearning.com.

CHAPTER 3

Basic Principles of Heredity

© Anthony Asael/Danita Delimont/Alamy.

Blond hair occurs in 5%–10% of dark-skinned Solomon Islanders. Research demonstrates that blond hair in this group is a recessive trait and has a different genetic basis from blond hair in Europeans.

The Genetics of Blond Hair in the South Pacific

A thousand miles northeast of Australia lies an ancient chain of volcanic and coral islands known as the Solomons (Figure 3.1). The Solomon Islands were first inhabited some 30,000 years ago, when Neanderthals still roamed northern Europe. Today, the people of the Solomons are culturally diverse but consist largely of Melanesians, a group that also inhabits other South Pacific islands. Most people from the Solomon Islands have dark skin. Remarkably, 5%–10% also have strikingly blond hair; in fact, people of the Solomon Islands have the highest frequency of blond hair outside Europe.

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

3.1 Map of the Solomon Islands.

Description

The illustration shows an earth with a black square highlighting the Solomon Island. The map which is zoomed out of the illustration shows the Solomon Islands in the Solomon Sea. The Islands are to the east of Papua New Guinea. Australia is south-west to the Solomon Islands. Vanuatu and New Caledonia are south-east to the islands and South Pacific Sea is in north-east. Coral Sea is to the south of these islands, South Pacific Sea is north east to these islands and Bismarck Sea is in the north-west side.

How did the Solomon Islanders get their blond hair? A number of hypotheses have been proposed over the years. Some suggested that the blond islanders had naturally dark hair that was bleached by the sun and salt water. Others proposed that the blond hair color was caused by diet. Still others suggested that it was the result of genes for blond hair left by early European explorers.

The mystery of the blond Solomon Islanders was solved in 2012 by geneticists Eimear Kenny and Sean Myles and their colleagues. Their research demonstrated that blond hair on the islands is, in fact, caused by a gene, but not one left by Europeans—blond hair in Solomon Islanders and in Europeans has completely separate evolutionary origins.

To search for the origin of blond hair among the people of the Solomon Islands, the geneticists collected saliva and hair samples from over 1200 people on the islands, from which they extracted DNA. In a type of analysis known as a genome-wide association study, they looked for statistical associations between the presence of blond hair and thousands of genetic variants scattered across the genome. Right away, they detected a strong correlation between the

presence of blond hair and a particular genetic variant located on the short arm of chromosome 9. This region of chromosome 9 contains the tyrosinase-related protein 1 (*TYRP1*) gene, which encodes an enzyme known to play a role in the production of melanin and to affect pigmentation in mice. The researchers found a single base difference between the DNA of islanders with blond hair and that of islanders with dark hair: the blonds had a thymine (T) base instead of cytosine (C) in their *TYRP1* gene.

Further research showed that blond hair in Solomon Islanders is a recessive trait, meaning that blonds carry two copies of the blond version of the gene (*TT*)—one inherited from each parent. Dark hair is dominant: dark-haired islanders carry either one (*CT*) or two (*CC*) copies of the dark-hair version of the gene. Thus, many dark-haired islanders are heterozygous, carrying a hidden copy of the blond gene that can be passed on to their offspring. A DNA analysis of 900 Solomon Islanders demonstrated that over 40% of dark-haired islanders carry a blond gene. Interestingly, the C to T mutation in the *TYRP1* gene that causes blond hair in Solomon Islanders is rare outside the South Pacific, suggesting that the mutation arose independently within the Melanesian population. There is no evidence that the gene was inherited from Europeans.

THINK-PAIR-SHARE Question 1

The genetics of blond hair in Solomon Islanders differs from that in Europeans in other ways as well. In Europeans, variations in at least eight different genes have been associated with blond hair. In 2015, researchers examined one of these genes (called *KITLG*) and found that the mutation causing blond hair occurred not in the gene itself but in a region of DNA that affects the expression of the *KITLG* gene. The *KITLG* gene produces a protein that is involved in a number of functions, including melanocyte development and melanin synthesis.

THINK-PAIR-SHARE

- Why is knowing the genetic basis of a trait such as blond hair important? Why would scientists go to the trouble to investigate the genetic basis of blond hair in Solomon Islanders?
- If a blond-haired person from northern Europe mated with a blond Solomon Islander, what proportion of their offspring would be expected to have blond hair? Explain your reasoning.

This chapter is about the principles of heredity: how genes—such as the one for blond hair in Solomon Islanders—are passed from generation to generation and how factors such as dominance influence their inheritance. The principles of heredity were first put forth by Gregor Mendel, so we begin this chapter by examining Mendel's scientific achievements. We then turn to simple genetic crosses in which a single characteristic is examined. We consider some techniques for predicting the outcome of genetic crosses, and then turn to crosses in which two or more characteristics are

examined. We see how the principles applied to simple genetic crosses and the ratios of offspring they produce can serve as the key to understanding more complicated crosses. The chapter ends with a discussion of statistical tests for analyzing crosses.

Throughout this chapter, a number of concepts are interwoven: Mendel's principles of segregation and independent assortment, probability, and the behavior of chromosomes. These concepts might at first appear to be unrelated, but they are actually different views of the same phenomenon, because the genes that undergo segregation and independent assortment are located on chromosomes. In this chapter, we examine these different views and clarify how they are related.

3.1 Gregor Mendel Discovered the Basic Principles of Heredity

It was in the early 1900s that the principles of heredity first became widely known among biologists. Surprisingly, these principles had been discovered some 44 years earlier by an Augustinian priest named Gregor Johann Mendel (1822–1884) (Figure 3.2).

James King-Holmes/Science Source.

3.2 Gregor Johann Mendel discovered the principles of heredity by experimenting with peas.

Mendel was born in what is now part of the Czech Republic. Although his parents were simple farmers with little money, he

received a sound education and was admitted to the Augustinian monastery in Brno in September 1843. After graduating from seminary, Mendel became an ordained priest and was appointed to a teaching position in a local school. He excelled at teaching, and the abbot of the monastery recommended him for further study at the University of Vienna, which he attended from 1851 to 1853. There, Mendel enrolled in the newly opened Physics Institute and took courses in mathematics, chemistry, entomology, paleontology, botany, and plant physiology. It was probably there that Mendel acquired knowledge of the scientific method, which he later applied so successfully to his genetic experiments.

After two years of study in Vienna, Mendel returned to Brno, where he taught school and began his experimental work with pea plants. He conducted breeding experiments from 1856 to 1863 and presented his results publicly at meetings of the Brno Natural Science Society in 1865. Mendel's paper based on these lectures was published in 1866. However, in spite of widespread interest in heredity, the effect of his research on the scientific community was minimal. At the time, no one seemed to have noticed that Mendel had discovered the basic principles of inheritance.

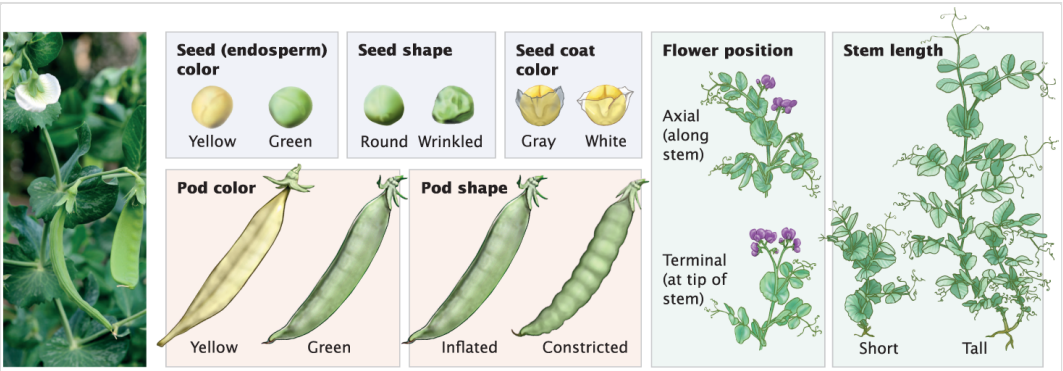
In 1868, Mendel was elected abbot of his monastery, and increasing administrative duties brought an end to his teaching and, eventually, to his genetic experiments. He died at the age of 61 on January 6, 1884, unrecognized for his contribution to genetics.

The significance of Mendel's discovery was not recognized until 1900, when three botanists—Hugo de Vries, Erich Tschermak von Seysenegg, and Carl Correns—began independently conducting similar experiments with plants and arrived at conclusions similar to those of Mendel. Coming across Mendel's paper, they interpreted their results in accord with his principles and drew attention to his pioneering work.

Mendel's Success

Mendel's approach to the study of heredity was effective for several reasons. Foremost was his choice of experimental subject, the pea plant *Pisum sativum* (**Figure 3.3**), which offered clear advantages for genetic investigation. The plant is easy to cultivate, and Mendel had the monastery garden and greenhouse at his disposal. Compared with some other plants, peas grow relatively rapidly, completing an entire generation in a single growing season. By today's standards, one generation per year seems frightfully slow—fruit flies complete a generation in 2 weeks and bacteria in 20 minutes—but Mendel was under no pressure to publish quickly and was able to follow the inheritance of individual characteristics for several generations. Had he chosen to work on an organism with a longer generation time—horses, for example—he might never have discovered the basis of inheritance. Pea plants also produce many offspring—their seeds—which allowed Mendel to detect meaningful mathematical ratios in the traits he observed in the progeny. The numerous varieties of peas

that were available to Mendel were also crucial to his success because they differed in various traits and were genetically pure. Mendel was therefore able to begin with plants of variable and known genetic makeup.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company
Photograph by Charles Stirling/Alamy.

3.3 Mendel used the pea plant *Pisum sativum* in his studies of heredity. He examined seven characteristics that appeared in the seeds and in plants grown from the seeds.

Description

The illustration shows a photo of pea plant on the extreme left with a white flower. The top 3 panels demonstrate seed colors, seed shape, and seed coat color. The seed colors are yellow and green. The seed shapes are round and wrinkled and the seed coat colors are white and gray. The bottom 2 panels show pod color and shape. The pod colors are yellow and green, and the pod shapes are inflated and constricted. In inflated pod, the pod is appearing smooth from the outside. In a constricted pod the pod hugs the beans tightly so that it looks bumpy. The last 2 panels on the right show plant characteristics: flower position and stem length. The flowers may be positioned at the terminal tips of the stems or at axial points that occur all along the stem. The flowers in this panel are purple. Stem lengths are either short or tall.

Much of Mendel's success can be attributed to the seven characteristics of pea plants that he chose for study (see Figure 3.3). He avoided characteristics that display a range of variation; instead, he focused his attention on those that exist in two easily differentiated forms, such as white versus gray seed coats, round versus wrinkled seeds, and inflated versus constricted pods.

THINK-PAIR-SHARE Question 2

Finally, Mendel was successful because he adopted an experimental approach and interpreted his results by using mathematics. Unlike many earlier investigators who simply described the *results* of crosses, Mendel formulated *hypotheses* based on his initial observations and then conducted additional crosses to test his hypotheses. He kept careful records of the numbers of progeny possessing each trait and computed ratios of the different traits. He was adept at seeing patterns in detail and was patient and thorough, conducting his experiments for 10 years before attempting to write up his results. ❯ **TRY PROBLEM 13**

CONCEPTS

Gregor Mendel put forth the basic principles of inheritance, publishing his findings in 1866. Much of Mendel's success can be attributed to the seven characteristics of pea plants that he studied and his experimental approach.

✔ CONCEPT CHECK 1

Which of the following factors did not contribute to Mendel's success in his study of heredity?

a. His use of the pea plant
b. His study of plant chromosomes
c. His adoption of an experimental approach
d. His use of mathematics

Genetic Terminology

Before we examine Mendel's crosses and the conclusions that he drew from them, a review of some terms commonly used in genetics will be helpful (Table 3.1). The term *gene* is a word that Mendel never knew. It was not coined until 1909, when Danish botanist Wilhelm Johannsen first used it. The definition of *gene* varies with the context of its use, so its definition will change as we explore different aspects of heredity. For our present use in the context of genetic crosses, we define a **gene** as an inherited factor that determines a characteristic.

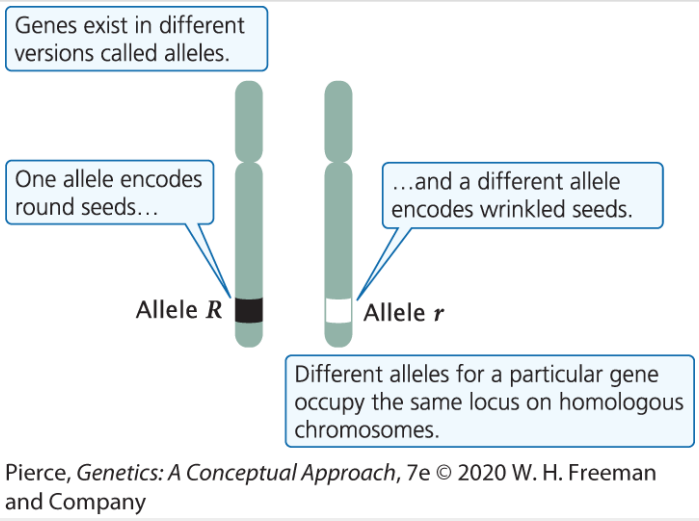
TABLE 3.1 Summary of important genetic terms

Term	Definition
Gene	An inherited factor (encoded in the DNA) that helps determine a characteristic
Allele	One of two or more alternative forms of a gene

Locus	A specific place on a chromosome occupied by an allele
Genotype	A set of alleles possessed by an individual organism
Homozygote	An individual organism possessing two of the same alleles at a locus
Heterozygote	An individual organism possessing two different alleles at a locus
Characteristic or character	An attribute or feature possessed by an organism
Phenotype or trait	The appearance or manifestation of a characteristic

Genes frequently come in different versions called **alleles** (**Figure 3.4**). In Mendel's crosses, seed shape was determined by a gene that exists as two different alleles: one allele encodes round seeds and the other encodes wrinkled seeds. All alleles for any particular gene will be found at a specific place on a chromosome, called the **locus** for that gene. (The plural of locus is *loci*; it's bad form in genetics—and incorrect—to speak of "locuses.") Thus, there is a specific place—a locus—on a chromosome in pea plants where the shape of seeds is determined. This locus may be occupied by an allele for round seeds

or an allele for wrinkled seeds. We will use the term *allele* when referring to a specific version of a gene; we will use the term *gene* to refer more generally to any allele at a locus.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

3.4 At each locus, a diploid organism possesses two alleles located on different homologous chromosomes. The alleles identified here refer to traits studied by Mendel.

Description
Allele big R is present at one locus on the chromosome on the left and encodes round seeds. Allele small R is present on the other chromosome on the right and encodes wrinkled seeds. Two caption captions read as follow: “Genes exist in different versions called alleles” and “Different alleles for a particular gene occupy the same locus on homologous chromosomes.”

The **genotype** is the set of alleles that an individual organism possesses. A diploid organism with a genotype consisting of two identical alleles is **homozygous** at that locus. One that has a genotype consisting of two different alleles is **heterozygous** at the locus.

A **phenotype** is the manifestation or appearance of a characteristic. This term can refer to any type of characteristic—physical, physiological, biochemical, or behavioral. Thus, the condition of having round seeds is a phenotype, a body weight of 50 kilograms (50 kg) is a phenotype, and having sickle-cell anemia is a phenotype. In this book, the term *characteristic* or *character* refers to a general feature, such as eye color; the term *trait* or *phenotype* refers to specific manifestations of that feature, such as blue or brown eyes.

A given phenotype arises from a genotype that develops within a particular environment. The genotype determines the potential for development; it sets certain limits, or boundaries, on that development. How the phenotype develops within those limits is determined by the effects of other genes and of environmental factors, and the balance between these effects varies from characteristic to characteristic. For some characteristics, differences between phenotypes are determined largely by differences in genotype. In Mendel's peas, for example, the genotype, not the environment, largely determined the shape of the seeds. For other characteristics, environmental differences are more important. The height reached by an oak tree at maturity is a phenotype that is strongly influenced by environmental factors, such as the availability of water, sunlight, and nutrients. Nevertheless, the tree's genotype imposes some limits on its height: an oak tree will never grow to be 300 meters (984 feet) tall, no matter how much sunlight, water, and fertilizer are provided. Thus, even the height of an oak tree is determined to some degree by genes. For many

characteristics, both genes and environment are important in determining phenotypic differences.

An obvious but important point is that only the alleles of the genotype are inherited. Although the phenotype is determined, at least to some extent, by the genotype, organisms do not transmit their phenotypes to the next generation. The distinction between genotype and phenotype is one of the most important principles of modern genetics. The next section describes Mendel's careful observation of phenotypes through several generations of breeding experiments. These experiments allowed him to deduce not only the genotypes of individual pea plants but also the rules governing their inheritance.

CONCEPTS

Each phenotype results from a genotype developing within a specific environment. The alleles of the genotype, not the phenotype, are inherited.

✔ CONCEPT CHECK 2

What is the difference between a locus and an allele? What is the difference between genotype and phenotype?

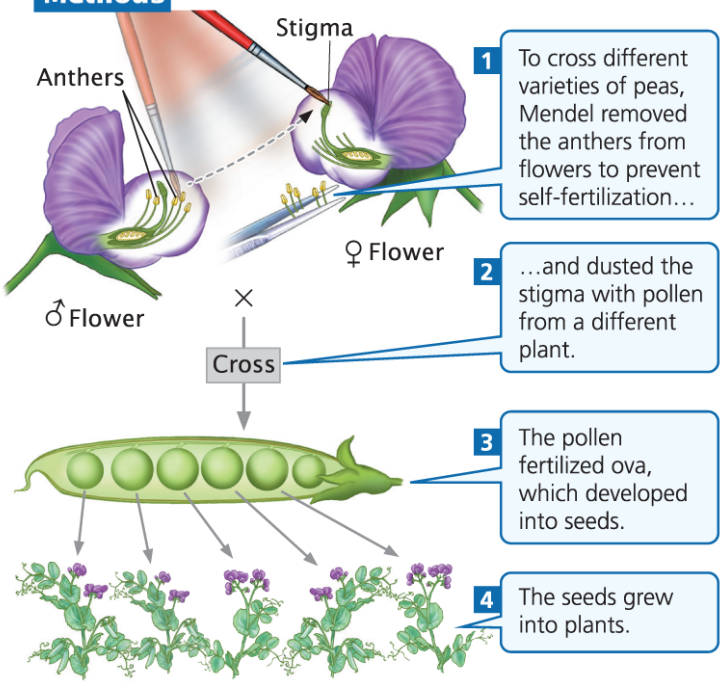
3.2 Monohybrid Crosses Reveal the Principle of Segregation and the Concept of Dominance

Mendel started with 34 varieties of peas and spent two years selecting those varieties that he would use in his experiments. He verified that each variety was pure-breeding (homozygous for each of the traits that he chose to study) by growing the plants for two generations and confirming that all offspring were the same as their parents. He then carried out a number of crosses between the different varieties. Although peas are normally self-fertilizing (each plant mates with itself), Mendel conducted crosses between different plants by opening the buds before the anthers (male sex organs) were fully developed, removing the anthers, and then dusting the stigma (female sex organ) with pollen from a different plant's anthers (**Figure 3.5**).

Experiment

Question: When peas with two different traits—round and wrinkled seeds—are crossed, will their progeny exhibit one of those traits, both of those traits, or an intermediate trait?

Methods



1. To cross different varieties of peas, Mendel removed the anthers from flowers to prevent self-fertilization…
2. …and dusted the stigma with pollen from a different plant.
3. The pollen fertilized ova, which developed into seeds.
4. The seeds grew into plants.

P generation Homozygous round seeds × Homozygous wrinkled seeds

5. Mendel crossed two homozygous varieties of peas.

Cross

F_1 generation

6. All the F_1 seeds were round. Mendel allowed plants grown from these seeds to self-fertilize.

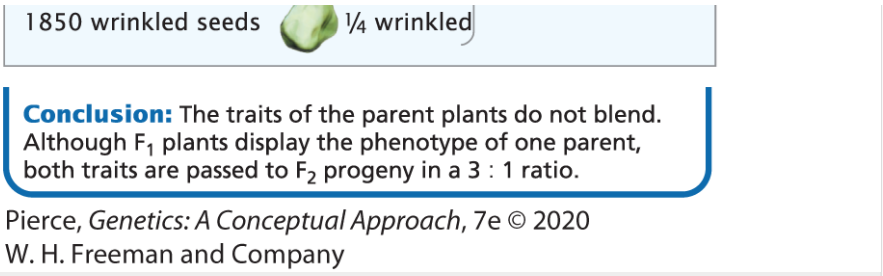
Self-fertilize

Results

F_2 generation

	Fraction of progeny seeds
5474 round seeds	¾ round

7. ¾ of F_2 seeds were round and ¼ were wrinkled, a 3 : 1 ratio.



3.5 Mendel conducted monohybrid crosses.

Description

The illustration shows the methods where a male flower with anthers and a female flower with a stigma are drawn. The first caption reads, “to cross different varieties of peas, Mendel removed the anthers from flowers to prevent self-fertilization.” Both these flowers are crossed and the second caption reads, “and dusted the stigma with pollen from a different plant.” A downward arrow shows a pea pod with peas and the third caption reads, “The pollen fertilized ova, which developed into seeds.” Each pea seed from the pod points to individual plants and the fourth caption reads, “The seeds grew into plants.” A cross is shown below this. P generation below shows homozygous round seeds crossed with homozygous wrinkled seeds. The fifth caption reads, “Mendel crossed two homozygous varieties of peas.” The F subscript 1 generation below produced from this cross shows four round peas which are self-fertilized. The sixth caption reads, “All the F subscript 1 seeds were round. Mendel allowed plants grown from these seeds to self-fertilize.” Results below show F subscript 2 generation in a fraction of progeny seeds. 5474 round seeds, three-fourth round and 1850 wrinkled seeds, one-fourth wrinkled. The seventh caption reads, “three-fourth of F subscript 2 seeds were round and one-fourth were wrinkled, a 3 to 1 ratio.” The conclusion states that the traits of the parent plants do not blend. Although F subscript 1 plants display the phenotype of one parent, both traits are passed to F subscript 2 progeny in a 3 to 1 ratio.

Mendel began by studying **monohybrid crosses**—crosses between parents that differed in a single characteristic. In one experiment, Mendel crossed a pea plant that was pure-breeding (homozygous) for round seeds with one that was pure-breeding for wrinkled seeds

(see Figure 3.5). This first generation of a cross is called the **P (parental) generation**.

After crossing the two varieties in the P generation, Mendel observed the offspring that resulted from the cross. The seed shape phenotype develops as soon as the seed matures because seed traits are determined by the newly formed embryo within the seed. For characteristics associated with the plant itself, such as stem length, the phenotype doesn't develop until the plant grows from the seed; for these characteristics, Mendel had to wait until the following spring, plant the seeds, and then observe the phenotypes of the plants that germinated.

The offspring of the parents in the P generation are the **F_1 (first filial) generation**. When Mendel examined the F_1 generation of this cross, he found that they expressed only one of the phenotypes present in the parental generation: all the F_1 seeds were round. Mendel carried out 60 such crosses and always obtained this result. Furthermore, he conducted **reciprocal crosses**: in one cross, pollen (the male gamete) was taken from a plant with round seeds, and in its reciprocal cross, pollen was taken from a plant with wrinkled seeds. Reciprocal crosses gave the same result: all the F_1 seeds were round.

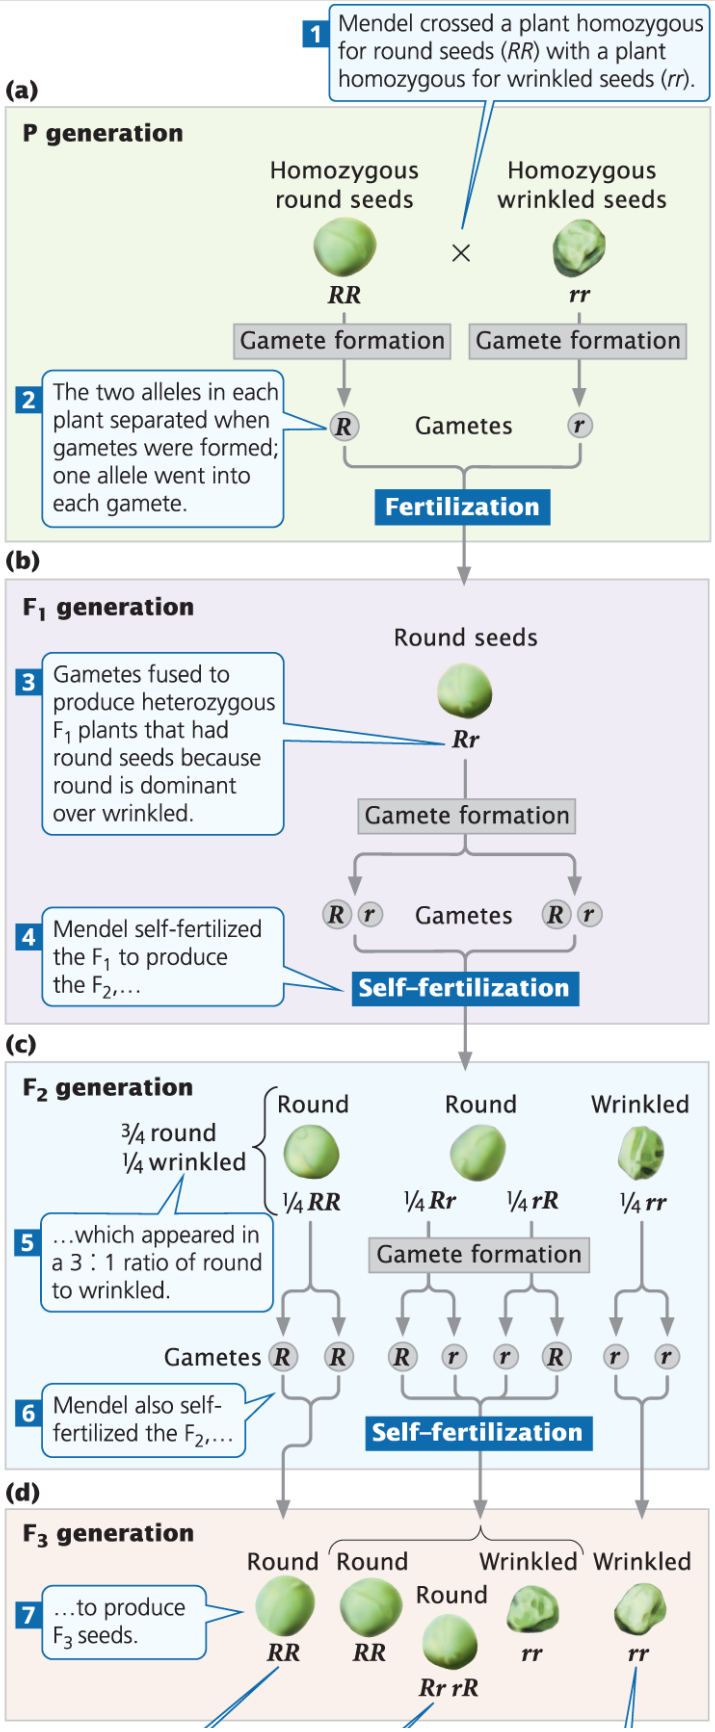
THINK-PAIR-SHARE Question 3

Mendel wasn't content with examining only the seeds arising from these monohybrid crosses, however. The following spring, he planted the F_1 seeds, cultivated the plants that germinated from them, and allowed the plants to self-fertilize, producing a second generation—the **F_2 (second filial) generation**. Both of the traits from the P generation emerged in the F_2 generation; Mendel counted 5474 round seeds and 1850 wrinkled seeds in the F_2 (see Figure 3.5). He noticed that the numbers of the round and wrinkled seeds constituted approximately a 3 to 1 ratio; that is, about $^3/_4$ of the F_2 seeds were round and $^1/_4$ were wrinkled. Mendel conducted monohybrid crosses for all seven of the characteristics that he studied in pea plants, and in all the crosses he obtained the same result: all of the F_1 resembled only one of the two parents, but both parental traits emerged in the F_2 in an approximate ratio of 3:1.

What Monohybrid Crosses Reveal

Mendel drew several conclusions from the results of his monohybrid crosses. First, he reasoned that although the F_1 plants display the phenotype of only one parent, they must inherit genetic factors from both parents because they transmit both parental phenotypes to the F_2 generation. The presence of both round and wrinkled seeds in the F_2 plants could be explained only if the F_1 plants possessed both round and wrinkled genetic factors that they had inherited from the P generation. He concluded that each plant must therefore possess two genetic factors encoding a characteristic.

The genetic factors (now called alleles) that Mendel discovered are, by convention, designated with letters: the allele for round seeds is usually represented by *R* and the allele for wrinkled seeds by *r*. The plants in the P generation of Mendel's cross possessed two identical alleles: *RR* in the round-seeded parent and *rr* in the wrinkled-seeded parent (**Figure 3.6a**).



1 Mendel crossed a plant homozygous for round seeds (RR) with a plant homozygous for wrinkled seeds (rr).

3.6 Mendel's monohybrid crosses revealed the principle of segregation and the concept of dominance.

Description

Part "a" at the top shows the P generation which consists of homozygous round seeds with genotype big R big R crossed with homozygous wrinkled seeds with genotype small R small R. The first caption reads, "Mendel crossed a plant homozygous for round seeds (big R big R) with a plant homozygous for wrinkled seeds (small R small R)." Gamete formation takes place with both the genotypes. Big R big R results in big R and small R small R results in small R. The second caption reads, "The two alleles in each plant separated when gametes were formed; one allele went into each gamete." Fertilization takes place and leads to part "b" below which represents F subscript 1 generation. F subscript 1 generation consists of big R small R progeny. The third caption reads, "Gametes fused to produce heterozygous F subscript 1 plants that had round seeds because round is dominant over wrinkled." Gamete formation takes place which includes big R small R and are self-fertilized. The fourth caption reads, "Mendel self-fertilized the F subscript 1 to produce the F subscript 2," It further leads to part "c" below which represents F subscript 2 generation. The F subscript 2 generation includes one-fourth big R big R round, one-fourth big R small R round, one-fourth small R big R round, and one-fourth small R small R wrinkled. These are three-fourth round and one-fourth wrinkled and the fifth caption reads, "which appeared in a 3 to 1 ratio of round to wrinkled." Gametes produced are big R and big R, big R and small R, small R and big R, and small R and small R. The sixth caption reads, "Mendel also self-fertilized the F subscript 2." Self-fertilization takes place which leads to part "d." Part "d" below shows the F subscript 3 generation. The seventh caption reads, "to produce F subscript 3 generation." The F subscript 3 generation include big R big R round (homozygous round peas produced plants with only round peas), big R big R, big R small R, small R big R and small R small R (Heterozygous plants produced round and wrinkled seeds in a 3 to 1 ratio), and small R small R (Homozygous wrinkled peas produced plants with only wrinkled peas.)

The second conclusion that Mendel drew from his monohybrid crosses was that the two alleles in each plant separate when gametes are formed, and one allele goes into each gamete. When two gametes (one from each parent) fuse to produce a zygote, the allele from the male parent unites with the allele from the female parent to produce the genotype of the offspring. Thus, Mendel's F_1 plants inherited an *R* allele from the round-seeded plant and an *r* allele from the wrinkled-seeded plant (**Figure 3.6b**). However, only the trait encoded by the round allele (*R*) was observed in the F_1: all the F_1 progeny had round seeds. Those traits that appeared unchanged in the F_1 heterozygous offspring Mendel called **dominant**, and those traits that disappeared in the F_1 heterozygous offspring he called **recessive**. In plants, alleles for dominant traits are often symbolized with uppercase letters (e.g., *R*), while alleles for recessive traits are often symbolized with lowercase letters (e.g., *r*). When dominant and recessive alleles are present together, the effect of the recessive allele is not observed in the phenotype. The concept of dominance was the third important conclusion that Mendel derived from his monohybrid crosses.

Mendel's fourth conclusion was that the two alleles of an individual plant separate with equal probability into the gametes. When plants of the F_1 (with genotype *Rr*) produced gametes, half of the gametes received the *R* allele for round seeds and half received the *r* allele for wrinkled seeds. The gametes then paired randomly to produce the following genotypes in equal proportions among the F_2: *RR*, *Rr*, *rR*,

rr (Figure 3.6c). Because round (*R*) is dominant to wrinkled (*r*), there were three round-seeded progeny (*RR*, *Rr*, *rR*) for every wrinkled-seeded progeny (*rr*) in the F_2. This 3:1 ratio of round-seeded to wrinkled-seeded progeny that Mendel observed in the F_2 could be obtained only if the two alleles of a genotype separated into the gametes with equal probability.

The conclusions that Mendel drew about inheritance from his monohybrid crosses have been further developed and formalized into the principle of segregation and the concept of dominance. The **principle of segregation** (**Mendel's first law**; see Table 3.2) states that each individual diploid organism possesses two alleles for any particular characteristic, one inherited from the maternal parent and one from the paternal parent. These two alleles segregate (separate) when gametes are formed, and one allele goes into each gamete. Furthermore, the two alleles segregate into gametes in equal proportions. The **concept of dominance** states that when two different alleles are present in a genotype, only the trait encoded by one of them—the dominant allele—is observed in the phenotype.

TABLE 3.2 Comparison of the principles of segregation and independent assortment

Principle	Observation	Stage of Meiosis*
Segregation (Mendel's first	1. Each individual organism possesses	Before meiosis

law)	two alleles encoding a trait.	
	2. Alleles separate when gametes are formed.	Anaphase I
	3. Alleles separate in equal proportions.	Anaphase I
Independent assortment (Mendel's second law)	Alleles at different loci separate independently.	Anaphase I

*Assumes that no crossing over occurs. If crossing over takes place, then segregation and independent assortment may also occur in anaphase II of meiosis.

Mendel confirmed these principles by allowing his F_2 plants to self-fertilize and produce an F_3 generation. He found that the plants grown from the wrinkled seeds—those displaying the recessive trait (*rr*)—produced an F_3 in which all plants produced wrinkled seeds. Because his wrinkled-seeded plants were homozygous for wrinkled alleles (*rr*), only wrinkled alleles could be passed on to their progeny (**Figure 3.6d**).

The plants grown from round seeds—the dominant trait—fell into two types (see Figure 3.6c). Following self-fertilization, about $^2/_3$ of these plants produced both round-seeded and wrinkled-seeded progeny in the F_3 generation. These plants were heterozygous (*Rr*),

so they produced $^1/_4$ *RR* (round), $^1/_2$ *Rr* (round), and $^1/_4$ *rr* (wrinkled) progeny, giving a 3:1 ratio of round to wrinkled in the F_3. About $^1/_3$ of the plants grown from round seeds were of the second type; they produced only the round-seeded trait in the F_3. These plants were homozygous for the round allele (*RR*) and could thus produce only round-seeded offspring in the F_3 generation. Mendel planted the seeds obtained in the F_3 and carried these plants through three more rounds of self-fertilization. In each generation, $^2/_3$ of the round-seeded plants produced round and wrinkled offspring, whereas $^1/_3$ produced only round offspring. These results are entirely consistent with the principle of segregation.

CONCEPTS

The principle of segregation states that each individual organism possesses two alleles that encode a characteristic. These alleles segregate when gametes are formed, and one allele goes into each gamete. The concept of dominance states that when the two alleles of a genotype are different, only the trait encoded by the dominant allele is observed.

✔ CONCEPT CHECK 3

How did Mendel know that each of his pea plants carried two alleles encoding a characteristic?

The Molecular Nature of Alleles

What exactly is an allele, and how does it determine a phenotype? Although Mendel had no information about the physical nature of the genetic factors in his crosses, modern geneticists have now determined the molecular basis of those factors and how they encode a trait such as wrinkled peas.

Alleles, such as the *R* and *r* alleles that encode round and wrinkled peas, usually represent specific DNA sequences. The locus that determines whether a pea is round or wrinkled is a sequence of DNA on pea chromosome 5 that encodes a protein called starch-branching enzyme isoform I (SBEI). The *R* allele, which produces round seeds in pea plants, encodes a normal, functional form of the SBEI enzyme. This enzyme converts a linear form of starch into a highly branched form. The *r* allele, which encodes wrinkled seeds, is a different DNA sequence that contains a mutation or error; it encodes an inactive form of the enzyme that does not produce the branched form of starch and leads to the accumulation of sucrose within the *rr* seed (the pea). Because the *rr* seed contains a large amount of sucrose, the developing seed absorbs water and swells. Later, as the seed matures, it loses water. Because *rr* seeds absorb more water and expand more during development, they lose more water during maturation and afterward appear shriveled or wrinkled. The *r* allele for wrinkled seeds is recessive because the presence of a single *R* allele in the heterozygote allows the plant to synthesize enough SBEI enzyme to produce branched starch and, therefore, round seeds.

Research has revealed that the *r* allele contains an extra 800 base pairs of DNA, which disrupt the normal coding sequence of the gene. The extra DNA appears to have come from a transposable element, a type of DNA sequence that has the ability to move from one location in the genome to another, which we will discuss further in Chapter 18.

CONNECTING CONCEPTS

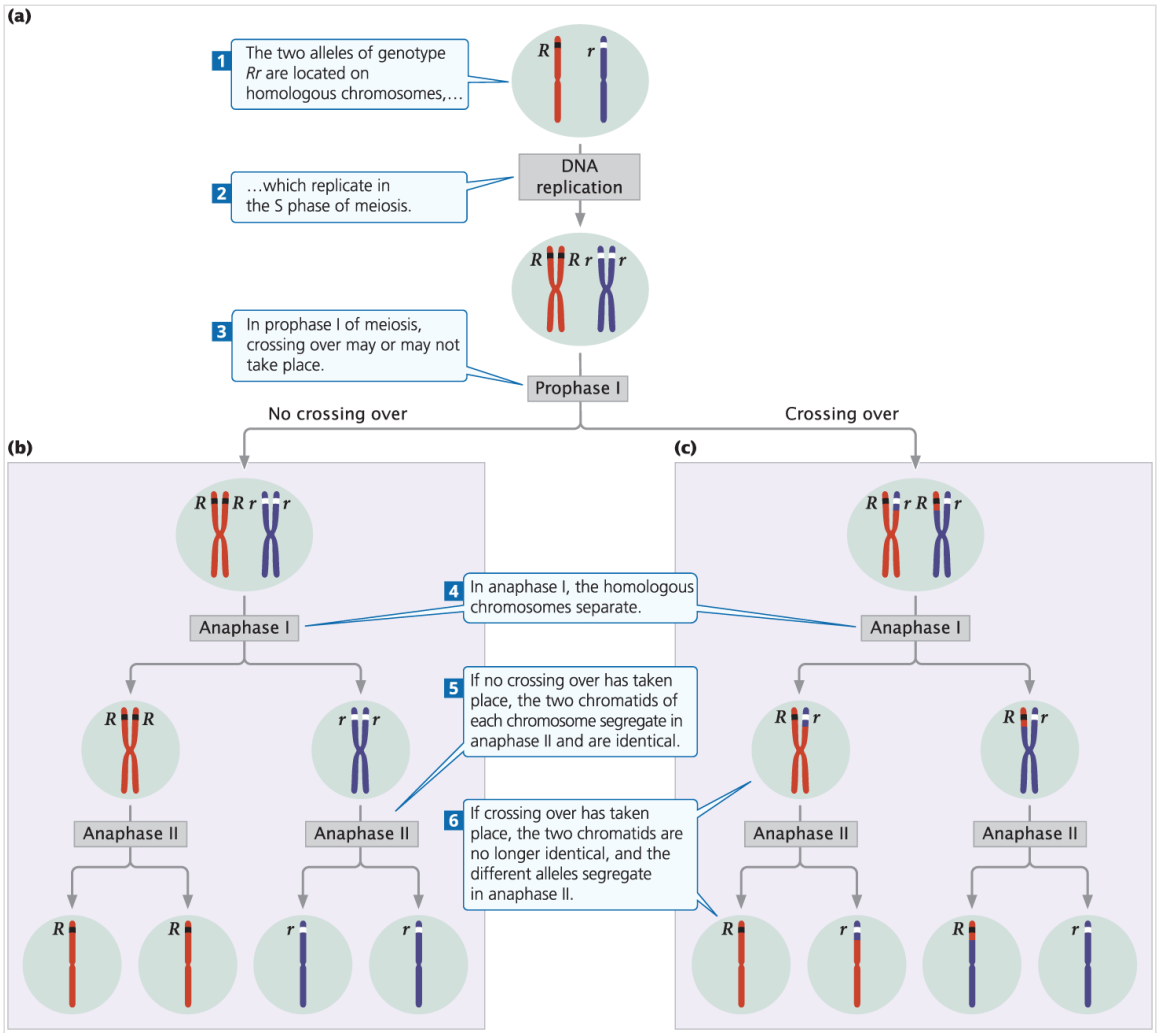
Relating Genetic Crosses to Meiosis

We have now seen how the results of monohybrid crosses are explained by Mendel's principle of segregation. Many students find that they enjoy working genetic crosses but are frustrated by the abstract nature of the symbols. Perhaps you feel the same at this point. You may be asking, "What do these symbols really represent? What does the genotype *RR* mean in regard to the biology of the organism?" The answers to these questions lie in relating the abstract symbols of crosses to the structure and behavior of chromosomes, the repositories of genetic information (see Chapter 2).

In 1900, when Mendel's work was rediscovered and biologists began to apply his principles of heredity, the relation between genes and chromosomes was still unclear. The theory that genes are located on chromosomes (the **chromosome theory of heredity**) was developed in the early 1900s by Walter Sutton, then a graduate student at Columbia University. Through the careful study of meiosis in insects, Sutton documented the fact that each homologous pair of chromosomes consists of one maternal chromosome and one paternal chromosome. Showing that these pairs segregate independently into gametes in meiosis, he concluded that this process is the biological basis for Mendel's principles of heredity. German cytologist and embryologist Theodor Boveri came to similar conclusions at about the same time.

The symbols used in genetic crosses, such as *R* and *r*, are just shorthand notations for particular sequences of DNA in the chromosomes that encode particular phenotypes. The two alleles of a genotype are found on different but homologous chromosomes. One chromosome of each homologous pair is inherited from the mother, and the other is inherited from the father. In the S phase of meiotic interphase, each chromosome replicates, producing two

copies of each allele, one on each chromatid (**Figure 3.7a**). The homologous chromosomes segregate in anaphase I, thereby separating the two different alleles (**Figure 3.7b and c**). This chromosome segregation is the basis of the principle of segregation. In anaphase II of meiosis, the two chromatids of each replicated chromosome separate, so each gamete resulting from meiosis carries only a single allele at each locus, as Mendel's principle of segregation predicts. If crossing over has taken place in prophase I of meiosis, then the two chromatids of each replicated chromosome are no longer identical, and the segregation of different alleles takes place at anaphase I and anaphase II (see Figure 3.7c).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

3.7 Segregation results from the separation of homologous chromosomes in meiosis.

Description

Part “a” on the top contains a cell with a rod-shaped maternal chromatid in red with big R gene and a rod-shaped paternal chromatid in blue with small R gene. A caption reads, “the two alleles of genotype big R small R are located on homologous chromosomes, which replicate in the S phase of meiosis.” D N A replication occurs and the next cell shows a red and a blue X-shaped chromosome. The caption reads: in prophase 1 of meiosis, crossing over may or may not take place. Below the cell with the X-shaped chromosomes, are 2 arrows showing the results of meiosis without and with cross over in part “b” and “c”, respectively. When there is no cross over, one X-shaped chromosome is 100 percent paternal and the other X-shaped chromosome is 100 percent maternal. At anaphase 1, the sister chromatids are pulled apart, leading to 2 cells. One cell has maternal chromatids with big R alleles and 1 cell has paternal chromatids with small R alleles. Part “c” on the right shows the results where crossing over did occur. There is a maternal X-shaped chromosome and a paternal X-shaped chromosome that are both heterozygous for the R allele. The caption reads as follows: in anaphase 1, the homologous chromosomes separate. If no crossing over has taken place, the 2 chromatids of each chromosome segregate in anaphase 2 and are identical. If crossing over has taken place, the 2 chromatids are no longer identical, and the different alleles segregate in anaphase 2. At the end of anaphase 2, the diagram on the left shows the 4 chromatids segregate when no crossing over takes and are identical as parents. The diagram on the right shows the segregation of 4 chromatids but 2 of them are not identical to the parents. Two of the chromatids resemble the parents, with a maternal strand with a big R allele and a paternal chromosome with a small R allele. The other two are hybrids and have the opposite allele of the parent strand.

Mendel knew nothing about chromosomes; he formulated his principles of heredity entirely on the basis of the results of the crosses that he carried out. Nevertheless, we should not forget that these principles work because they are based on the behavior of actual chromosomes in meiosis. ❯ **TRY PROBLEM 30**

Predicting the Outcomes of Genetic Crosses

One of Mendel's goals in conducting his experiments in pea plants was to develop a way to predict the outcomes of crosses between plants with different phenotypes. In this section, you will first learn a simple shorthand method for predicting outcomes of genetic crosses (the Punnett square), and then you will learn how to use probability to predict the results of crosses.

THE PUNNETT SQUARE

The Punnett square was developed by the English geneticist Reginald C. Punnett in 1917. To illustrate the Punnett square, let's examine another cross carried out by Mendel. By crossing two varieties of pea plants that differed in height, Mendel established that tall (*T*) was dominant to short (*t*). He tested his theory concerning the inheritance of dominant traits by crossing an F_1 tall plant that was heterozygous (*Tt*) with the short homozygous parental variety (*tt*). This type of cross, between an F_1 genotype and either of the parental genotypes, is called a **backcross**.

To predict the types of offspring that will result from this backcross, we must first determine which gametes will be produced by each parent (Figure 3.8a). The principle of segregation tells us that the two alleles in each parent separate and that one allele passes to each

gamete. All gametes from the homozygous *tt* short plant will receive a single short (*t*) allele. The tall plant in this cross is heterozygous (*Tt*), so 50% of its gametes will receive a tall allele (*T*) and the other 50% will receive a short allele (*t*).

3.8 The Punnett square can be used to determine the results of a genetic cross.

Description

Part “a” of the illustration on the top shows P generation. Drawings of a tall and a short pea plant are shown. A cross between a tall plant with genotype big T small T and a short plant with genotype small T small T takes place. The gametes formed are as follows: big T, small T, small T, and small T. Fertilization occurs and leads to part “b” below which demonstrates the F subscript 1 generation with a Punnett square, a table with 2 rows and 2 columns, with each row and column labeled with gametes. The data reads as follows:

Row 1 column 1: big T small T, tall

Row 1 column 2: big T small T, tall

Row 2 column 1: small T small T, short

Row 2 column 2: small T small T, short

A **Punnett square** is constructed by drawing a grid, listing the gametes produced by one parent along the upper edge, and listing the gametes produced by the other parent down the left side (**Figure 3.8b**). Each cell (that is, each block within the Punnett square) is then filled in with an allele from each of the corresponding gametes, generating the genotype of the progeny produced by the fusion of those gametes. In the upper left-hand cell of the Punnett square in Figure 3.8b, a gamete containing *T* from the tall plant unites with a gamete containing *t* from the short plant, giving the genotype of the progeny (*Tt*). It is useful to write the phenotype expressed by each genotype; here, the progeny will be tall because the tall allele is

dominant to the short allele. This process is repeated for all the cells in the Punnett square.

By simply counting, we can determine the types of progeny produced and their ratios. In Figure 3.8b, two cells contain tall (*Tt*) progeny and two cells contain short (*tt*) progeny, so the genotypic ratio expected for this cross is 2 *Tt* to 2 *tt* (a 1:1 ratio). Another way to express this result is to say that we expect $^1/_2$ of the progeny to have genotype *Tt* (and the tall phenotype) and $^1/_2$ of the progeny to have genotype *tt* (and the short phenotype).

In this cross, the genotypic ratio and the phenotypic ratio are the same, but this outcome need not be the case for all crosses. Try completing a Punnett square for the cross in which the F_1 round-seeded plants in Figure 3.6b undergo self-fertilization (you should obtain a phenotypic ratio of 3 round to 1 wrinkled and a genotypic ratio of 1 *RR* to 2 *Rr* to 1 *rr*).

CONCEPTS

The Punnett square is a shorthand method of predicting the genotypic and phenotypic ratios of progeny from a genetic cross.

✔ CONCEPT CHECK 4

If the F_1 plant depicted in Figure 3.6b is backcrossed to the parent with round seeds, what proportion of the progeny will have wrinkled seeds? (Use a Punnett square.)

a. $^3/_4$

b. $1/2$
c. $1/4$
d. 0

PROBABILITY AS A TOOL OF GENETICS

Another method for determining the outcome of a genetic cross is to use the rules of probability, as Mendel did with his crosses. **Probability** expresses the likelihood of the occurrence of a particular event. It is the number of times that a particular event takes place, divided by the number of all possible outcomes. For example, a deck of 52 cards contains only one king of hearts. The probability of drawing one card from the deck at random and obtaining the king of hearts is $1/52$ because there is only one card that is the king of hearts (one event) and there are 52 cards that can be drawn from the deck (52 possible outcomes). The probability of drawing a card and obtaining an ace is $4/52$ because there are four cards that are aces (four events) and 52 cards (possible outcomes). Probability can be expressed either as a fraction ($4/52$ in this case) or as a decimal number (0.077 in this case).

The probability of a particular event may be determined by knowing something about *how* or *how often* the event takes place. We know, for example, that the probability of rolling a six-sided die and getting a four is $1/6$ because the die has six sides and any one side is equally likely to end up on top. So, in this case, understanding the nature of

the event—the shape of the thrown die—allows us to determine its probability. In other cases, we determine the probability of an event by making a large number of observations. When a weather forecaster says that there is a 40% chance of rain on a particular day, this probability was obtained by observing a large number of days with similar atmospheric conditions and finding that it rains on 40% of those days. In this case, the probability has been determined empirically (by observation).

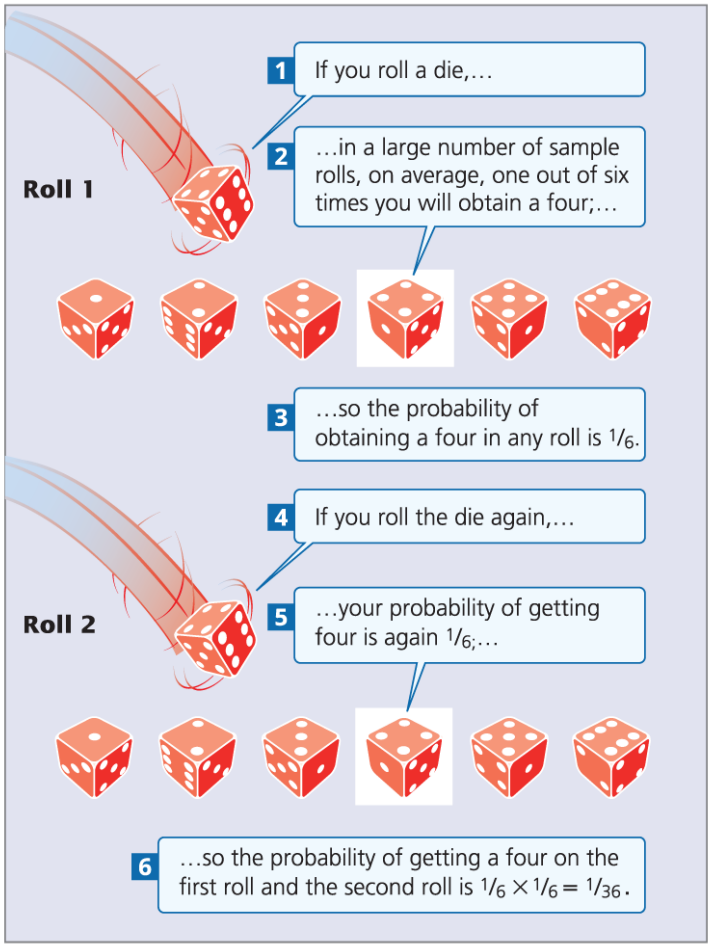
THE MULTIPLICATION RULE

Two rules of probability are useful for predicting the ratios of offspring from genetic crosses. The first is the **multiplication rule**, which states that the probability of two or more independent events taking place together is calculated by multiplying their independent probabilities.

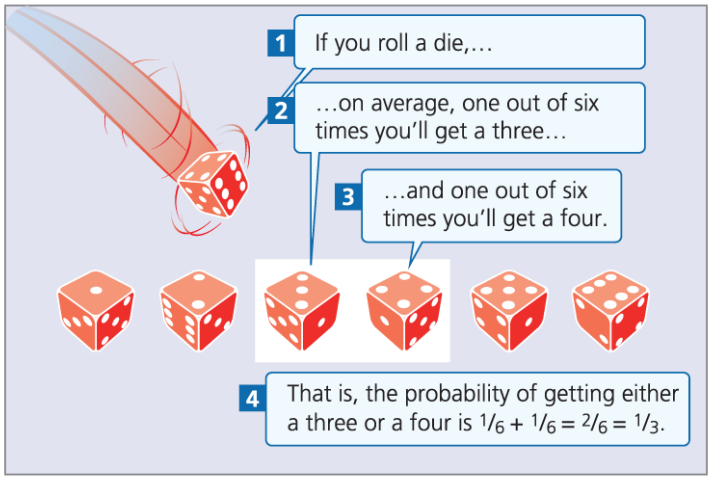
To illustrate the use of the multiplication rule, let's again consider the roll of a die. The probability of rolling one die and obtaining a four is $^1/_6$. To calculate the probability of rolling a die twice and obtaining two fours, we can apply the multiplication rule. The probability of obtaining a four on the first roll is $^1/_6$ and the probability of obtaining a four on the second roll is $^1/_6$, so the probability of rolling a four on both is $^1/_6 \times {}^1/_6 = {}^1/_{36}$ (**Figure 3.9a**). The key indicator for applying the multiplication rule is the word *and*; in the example just considered, we wanted to know the

probability of obtaining a four on the first roll *and* a four on the second roll. (It may have been some time since you worked with fractions. If you are rusty and need a review, turn to the appendix at the end of the book entitled Working with Fractions.)

(a) The multiplication rule



(b) The addition rule



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

3.9 The multiplication and addition rules can be used to determine the probability of combinations of events.

Description

Part “a” on top shows the multiplication rule. It shows pictures of a die rolled twice. With both rolls, there is also a drawing of each side of the 6-sided die. In both pictures, the die with 4 on top is highlighted. The caption in the panel read as follows, “If you roll a die, in a large number of sample rolls, on average, one out of six times you will obtain a four, so the probability of obtaining a four in any roll is one-sixth. If you roll the die again, your probability of getting four is again one-sixth, so the probability of getting a 4 on the first roll and the second roll is one-sixth multiplied by one-sixth equals one over thirty six.

Part “b” below shows the addition rule. It also shows pictures of a die being rolled, and six pictures showing all 6 sides of a die individually. The die with 3 and 4 on top are highlighted. The caption read as follows, “If you roll a die, on average, 1 out of 6 times you’ll get a 3 and one out of six times you’ll get a four. That is, the probability of getting either a 3 or a 4 is one-sixth plus one-sixth equals two-sixths or one-third.

For the multiplication rule to be valid, the events whose joint probability is being calculated must be independent—the outcome of one event must not influence the outcome of the other. For example, the number that comes up on one roll of the die has no influence on the number that comes up on the next roll, so these events are independent. However, if we wanted to know the probability of being hit on the head with a hammer and going to the hospital on the same day, we could not simply apply the multiplication rule and multiply the two probabilities together because the two events are not independent—being hit on the head with a hammer certainly influences the probability of going to the hospital.

THE ADDITION RULE

The second rule of probability frequently used in genetics is the **addition rule**, which states that the probability of any of two or more mutually exclusive events is calculated by adding the probabilities of the events. Let's look at this rule in concrete terms. To obtain the probability of throwing a die once and rolling *either* a three *or* a four, we would use the addition rule, adding the probability of obtaining a three ($^1/_6$) to the probability of obtaining a four (again, $^1/_6$), or $^1/_6 + {}^1/_6 = {}^2/_6 = {}^1/_3$ (**Figure 3.9b**). The key indicators for applying the addition rule are the words *either* and *or*.

For the addition rule to be valid, the events whose probability is being calculated must be mutually exclusive, meaning that one event excludes the possibility of the other. For example, you cannot throw a single die just once and obtain both a three and a four because only one side of the die can be on top. These events are mutually exclusive.

CONCEPTS

The multiplication rule states that the probability of two or more independent events taking place together is calculated by multiplying their independent probabilities. The addition rule states that the probability that any of two or more mutually exclusive events taking place is calculated by adding their probabilities.

✔ CONCEPT CHECK 5

If the probability of being blood type A is $^1/_8$ and the probability of being blood type O is $^1/_2$, what is the probability of being either blood type A or blood type O?

a. $^{5}/_{8}$
b. $^{1}/_{2}$
c. $^{1}/_{10}$
d. $^{1}/_{16}$

APPLYING PROBABILITY TO GENETIC CROSSES

The multiplication and addition rules of probability can be used in place of the Punnett square to predict the ratios of progeny expected from a genetic cross. Let's first consider a cross between two pea plants heterozygous for the locus that determines height, *Tt* × *Tt*. Half of the gametes produced by each plant have a *T* allele, and the other half have a *t* allele, so the probability for each type of gamete is $^{1}/_{2}$.

The gametes from the two parents can combine in four different ways to produce offspring. Using the multiplication rule, we can determine the probability of each possible combination. To calculate the probability of obtaining *TT* progeny, for example, we multiply the probability of receiving a *T* allele from the first parent ($^{1}/_{2}$) by the probability of receiving a *T* allele from the second parent ($^{1}/_{2}$). The multiplication rule should be used here because we need the probability of receiving a *T* allele from the first parent *and* a *T* allele from the second parent—two independent events. The four types of progeny from this cross and their associated probabilities are

TT	(*T* gamete and *T* gamete)	$^1/_2 \times {}^1/_2 = {}^1/_4$	tall
Tt	(*T* gamete and *t* gamete)	$^1/_2 \times {}^1/_2 = {}^1/_4$	tall
tT	(*t* gamete and *T* gamete)	$^1/_2 \times {}^1/_2 = {}^1/_4$	tall
tt	(*t* gamete and *t* gamete)	$^1/_2 \times {}^1/_2 = {}^1/_4$	short

Notice that there are two ways for heterozygous progeny to be produced: a heterozygote can either receive a *T* allele from the first parent and a *t* allele from the second or receive a *t* allele from the first parent and a *T* allele from the second.

After determining the probabilities of obtaining each progeny genotype, we can use the addition rule to determine the overall phenotypic ratios. Because of dominance, a tall plant can have genotype *TT*, *Tt*, or *tT*, so, using the addition rule, we find the probability of tall progeny to be $^1/_4 + {}^1/_4 + {}^1/_4 = {}^3/_4$. Because only one genotype (*tt*) encodes the short phenotype, the probability of short progeny is simply $^1/_4$.

Two methods have now been introduced to work genetic crosses: the Punnett square and the probability method. At this point, you may

be asking, "Why bother with probability rules and calculations? The Punnett square is easier to understand and just as quick." This is true for simple monohybrid crosses. For tackling more complex crosses that assess genes at two or more loci, however, the probability method is both clearer and quicker than the Punnett square.

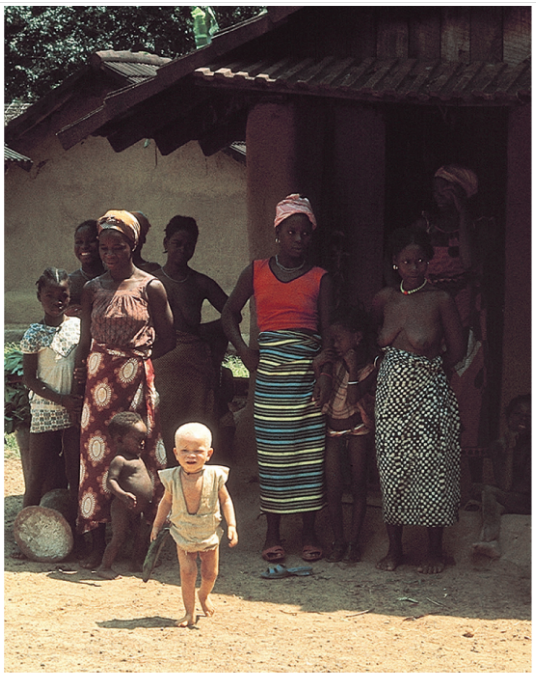
CONDITIONAL PROBABILITY

Thus far, we have used probability to predict the chances of producing certain types of progeny given only the genotypes of the parents. Sometimes, however, we have additional information that modifies, or *conditions*, the probability, a situation termed **conditional probability**. For example, assume that we cross two heterozygous pea plants (*Tt* × *Tt*) and obtain a tall progeny plant. What is the probability that this tall plant is heterozygous (*Tt*)? You might assume that the probability would be $^1/_2$, the probability of obtaining heterozygous progeny in a cross between two heterozygotes. In this case, however, we have some additional information—the phenotype of the progeny plant—which modifies that probability. When two heterozygous individuals are crossed, we expect $^1/_4$ *TT*, $^1/_2$ *Tt*, and $^1/_4$ *tt* progeny. We know that the plant in question is tall, so we can eliminate the possibility that it has genotype *tt*. Tall progeny must be either genotype *TT* or genotype *Tt*, and in a cross between two heterozygotes, these genotypes occur in

a 1:2 ratio. Therefore, the probability that a tall progeny plant is heterozygous (*Tt*) is two out of three, or $^{2}/_{3}$.

THE BINOMIAL EXPANSION AND PROBABILITY

When probability is used, it is important to recognize that there may be several different ways in which a set of events can occur. Consider two parents who are both heterozygous for albinism, a recessive condition in humans that causes reduced pigmentation in the skin, hair, and eyes (**Figure 3.10**; see also the introduction to Chapter 1). When two parents heterozygous for albinism mate ($Aa \times Aa$), the probability of their having a child with albinism (aa) is $^{1}/_{4}$, and the probability of their having a child with full pigmentation (AA or Aa) is $^{3}/_{4}$. Suppose we want to know the probability of this couple having three children with albinism. In this case, there is only one way in which this can happen: their first child has albinism *and* their second child has albinism *and* their third child has albinism. Here, we simply apply the multiplication rule: $^{1}/_{4} \times {}^{1}/_{4} \times {}^{1}/_{4} = {}^{1}/_{64}$.



Richard Hutchings/Science Source.

3.10 Albinism in humans is usually inherited as a recessive trait.

Suppose we now ask what the probability is of this couple having three children, one with albinism and two with pigmentation. This situation is more complicated. The first child might have albinism, whereas the second and third might be unaffected; the probability of this sequence of events is $^1/_4 \times {}^3/_4 \times {}^3/_4 = {}^9/_{64}$. Alternatively, the first and third children might have pigmentation, whereas the second might have albinism; the probability of this sequence is $^3/_4 \times {}^1/_4 \times {}^3/_4 = {}^9/_{64}$. Finally, the first two children might have pigmentation and the third albinism; the probability of this sequence is $^3/_4 \times {}^3/_4 \times {}^1/_4 = {}^9/_{64}$. Because *either* the first sequence *or* the second sequence *or* the third sequence produces one child with albinism and two with pigmentation, we apply the addition rule and add the probabilities: $^9/_{64} + {}^9/_{64} + {}^9/_{64} = {}^{27}/_{64}$.

If we want to know the probability of this couple having five children, two with albinism and three with pigmentation, figuring out *all* the different combinations of children and their probabilities becomes more difficult. This task is made easier if we apply the binomial expansion.

The binomial takes the form $(p + q)^n$, where p equals the probability of one event, q equals the probability of the alternative event, and n equals the number of times the event occurs. For figuring the probability of two out of five children with albinism,

$$p = \text{the probability of a child having albinism } (^1/_4)$$
$$q = \text{the probability of a child having pigmentation } (^3/_4)$$

The binomial for this situation is $(p + q)^5$ because there are five children in the family ($n = 5$). The expansion of this binomial is

$$(p+q)^5 = p^5 + 5p^4q + 10p^3q^2 + 10p^2q^3 + 5pq^4 + q^5$$

Each of the terms in the expansion provides the probability of one particular combination of traits in the children. The first term in the expansion (p^5) equals the probability of having five children with albinism because p is the probability of albinism. The second term ($5p^4q$) equals the probability of having four children with albinism and one with pigmentation, the third term ($10p^3q^2$) equals the probability of having three children with albinism and two with pigmentation, and so forth.

To obtain the probability of any combination of events, we insert the values of p and q. Thus, the probability of having two out of five children with albinism is

$$10p^2q^3 = 10\ (^1/_4)^2\ (^3/_4)^3 = {}^{270}/_{1024} = 0.26$$

We can easily figure out the probability of any desired combination of albinism and pigmentation among five children by using the other terms in the expansion.

How did we expand the binomial in this example? In general, the expansion of any binomial $(p + q)^n$ consists of a series of $n + 1$ terms. In the preceding example, $n = 5$, so there are 5 + 1 = 6 terms: p^5, $5p^4q$, $10p^3q^2$, $10p^2q^3$, $5pq^4$, and q^5. To write out the terms, first figure out their exponents. The exponent of p in the first term is always the power to which the binomial is raised, or n. In our example, $n = 5$, so our first term is p^5. The exponent of p decreases by one in each successive term, so the exponent of p is 4 in the second term (p^4), 3 in the third term (p^3), and so forth. The exponent of q is 0 (no q) in the first term and increases by one in each successive term, increasing from 0 to 5 in our example.

Next, we determine the coefficient of each term. The coefficient of the first term is always 1, so in our example, the first term is $1p^5$, or just p^5. The coefficient of the second term is always the same as the power to which the binomial is raised; in our example, this coefficient is 5, and the term is $5p^4q$. For the coefficient of the third

term, we look back at the preceding term, multiply the coefficient of the preceding term (5 in our example) by the exponent of p in that term (4), and then divide by the number of that term (second term, or 2). So the coefficient of the third term in our example is $(5 \times 4)/2 = {}^{20}/_{2} = 10$, and the term is $10p^3q^2$. We follow this procedure for each successive term. The coefficients for the terms in the binomial expansion can also be determined from Pascal's triangle (Table 3.3). The exponents and coefficients for each term in the first five binomial expansions are given in Table 3.4.

TABLE 3.3 Pascal's triangle

The numbers in each row represent the coefficients of each term in the binomial expansion $(p + q)^n$.

n	Coefficients
	1

Description

The table has the following column headers: n for first column and a collective header "coefficients" for second to thirteenth column. The row entries are as follows:

Row 1: No data; No data; No data; No data; No data; No data; No data; 1; No data; No data; No data; No data; No data; No data.

Row 2: 1; No data; No data; No data; No data; No data; 1; No data; 1; No data; No data; No data; No data; No data.

Row 3: 2; No data; No data; No data; No data; 1; No data; 2; No data; 1; No data; No data; No data; No data.

Row 4: 3; No data; No data; No data; 1 ; No data; 3 ; No data; 3; No data; 1; No data; No data; No data.

Row 5: 4; No data; No data; 1; No data; 4; No data; 6; No data; 4; No data; 1; No data; No data.

Row 6: 5; No data; 1; No data; 5; No data; 10; No data; 10; No data; 5; No data; 1; No data.

Row 7: 6; 1; No data; 6; No data; 15; No data; 20; No data; 15; No data; 6; No data; 1; No data.

Note: Each number in the triangle, except for the first, is equal to the sum of the two numbers directly above it.

TABLE 3.4 Coefficients and terms for the binomial expansion $(p + q)^n$ for $n = 1$ through 5

n	Binomial Expansion
1	$a + b$
2	$a^2 + 2ab + b^2$

3	$a^3 + 3a^2b + 3ab^2 + b^3$
4	$a^4 + 4a^3b + 6a^2b^2 + 4ab^3 + b^4$
5	$a^5 + 5a^4b + 10a^3b^2 + 10a^2b^3 + 5ab^4 + b^5$

Another way to determine the probability of any particular combination of events is to use the following formula:

$$P = \frac{n!}{s!t!}p^s q^t$$

where *P* equals the overall probability of event X with probability *p* occurring *s* times and alternative event Y with probability *q* occurring *t* times. For our albinism example, event X would be the occurrence of a child with albinism ($^1/_4$) and event Y would be the occurrence of a child with pigmentation ($^3/_4$); *s* would equal the number of children with albinism (2) and *t* would equal the number of children with pigmentation (3). The ! symbol stands for factorial, and it means the product of all the integers from *n* to 1. In this example, *n* = 5; so *n*! = 5 × 4 × 3 × 2 × 1. Applying this formula to obtain the probability of two out of five children having albinism, we obtain

$$P = \frac{5!}{2!3!}(^1/_4)^2(^3/_4)^3 = \frac{5 \times 4 \times 3 \times 2 \times 1}{2 \times 1 \times 3 \times 2 \times 1}(^1/_4)^2(^3/_4)^3 = 0.26$$

This value is the same as that obtained with the binomial expansion.

THINK-PAIR-SHARE Question 4

The Testcross

A useful tool for analyzing genetic crosses is the **testcross**, in which one individual of unknown genotype is crossed with another individual with a homozygous recessive genotype for the trait in question. Figure 3.8 illustrates a testcross (in this case, it is also a backcross). A testcross tests, or reveals, the genotype of the first individual.

Suppose you were given a tall pea plant with no information about its parents. Because tallness is a dominant trait in peas, your plant could be either homozygous (*TT*) or heterozygous (*Tt*) for the dominant allele, but you would not know which. You could determine its genotype by performing a testcross. If the plant were homozygous (*TT*), a testcross would produce all tall progeny (*TT* × *tt* → all *Tt*); if the plant were heterozygous (*Tt*), approximately half of the progeny would be tall and approximately half would be short (*TT* × *tt* → $^1/_2$ *Tt* and $^1/_2$ *tt*). When a testcross is performed, any recessive allele in the unknown genotype will be expressed in the progeny

because it will be paired with a recessive allele from the homozygous recessive parent. **› TRY PROBLEMS 18 AND 21**

THINK-PAIR-SHARE Question 5

CONCEPTS

The binomial expansion can be used to determine the probability of a particular set of events. A testcross is a cross between an individual with an unknown genotype and one with a homozygous recessive genotype. The outcome of the testcross can reveal the unknown genotype.

Genetic Symbols

As we have seen, genetic crosses are usually depicted with symbols that designate the different alleles. The symbols used for alleles are usually determined by the community of geneticists who work on a particular organism; therefore, there is no universal system for designating symbols. In plants, lowercase letters are often used to designate recessive alleles and uppercase letters to designate dominant alleles. Two or three letters may be used for a single allele: the recessive allele for heart-shaped leaves in cucumbers is designated *hl*, and the recessive allele for the abnormal sperm-head shape in mice is designated *azh*.

In animals, the most common allele for a characteristic—called the **wild type** because it is the allele usually found in the wild—is often symbolized by one or more letters and a plus sign (+). The letter or letters chosen are usually based on a mutant (less common) phenotype. For example, the recessive allele that encodes yellow eyes in the Oriental fruit fly is represented by *ye*, whereas the allele for wild-type eye color is represented by ye^+. At times, the letters for the wild-type allele are dropped and the allele is represented simply by a plus sign.

Gene names and abbreviations are usually italicized. Superscripts and subscripts are sometimes added to distinguish between genes: Lfr_1 and Lfr_2 represent dominant mutant alleles at different loci that produce lacerate leaf margins in opium poppies; El^R represents an allele in goats that restricts the length of the ears.

A slash may be used to distinguish the two alleles present in an individual genotype. For example, the genotype of a goat that is heterozygous for restricted ears might be written El^+/El^R, or simply $+/El^R$. If genotypes at more than one locus are presented together, a space separates the genotypes. For example, a goat heterozygous for a pair of alleles that produces restricted ears and heterozygous for another pair of alleles that produces goiter can be designated $El^+/El^RG/g$. Sometimes it is useful to designate the possibility of several genotypes. An underline in a genotype, such as $A_$, indicates

that any allele is possible. In this case, $A_$ might include both AA and Aa genotypes.

CONNECTING CONCEPTS

Ratios in Simple Crosses

Now that we have had some experience with genetic crosses, let's review the ratios that appear in the progeny of simple crosses, in which a single locus is under consideration and one of the alleles is dominant to the other. Understanding these ratios and the parental genotypes that produce them will enable you to work simple genetic crosses quickly, without resorting to the Punnett square. Later in this chapter, we use these ratios to work more complicated crosses that include several loci.

There are only three phenotypic ratios to understand (**Table 3.5**). The first is the 3:1 ratio, which arises in a simple genetic cross when both of the parents are heterozygous for a dominant trait (*Aa* × *Aa*). The second phenotypic ratio is the 1:1 ratio, which results from the mating of a heterozygous parent and a homozygous recessive parent. The homozygous parent in this cross must carry two recessive alleles (*Aa* × *aa*) because a cross between a homozygous dominant parent and a heterozygous parent (*AA* × *Aa*) produces offspring displaying only the dominant trait.

TABLE 3.5 Phenotypic ratios for simple genetic crosses (crosses for a single locus) with dominance

An underline in a genotype, such as *A*_, indicates that any allele is possible.

Phenotypic Ratio	Genotypes of Parents	Genotypes of Progeny
3:1	*Aa* × *Aa*	$^3/_4$ *A*_: $^1/_4$ *aa*
1:1	*Aa* × *aa*	$^1/_2$ *Aa*: $^1/_2$ *aa*
Uniform progeny	*AA* × *AA*	All *AA*
	aa × *aa*	All *aa*

	AA × *aa*	All *Aa*
	AA × *Aa*	All *A_*

The third phenotypic ratio is not really a ratio: all the offspring have the same phenotype (uniform progeny). Several combinations of parental genotypes can produce this outcome (see Table 3.5). A cross between any two homozygous parents—either between two parents of the same homozygous genotype (*AA* × *AA* or *aa* × *aa*) or between two parents with different homozygous genotypes (*AA* × *aa*)—produces progeny all having the same phenotype. Progeny of a single phenotype can also result from a cross between a homozygous dominant parent and a heterozygote (*AA* × *Aa*).

If we are interested in the ratios of genotypes instead of phenotypes, there are still only three outcomes to remember (**Table 3.6**): the 1:2:1 ratio, produced by a cross between two heterozygotes; the 1:1 ratio, produced by a cross between a heterozygote and a homozygote; and uniform progeny, produced by a cross between two homozygotes. These simple phenotypic and genotypic ratios, and the parental genotypes that produce them, provide the key to understanding crosses not only for a single locus but also, as you will see in the next section, for multiple loci.

TABLE 3.6 Genotypic ratios for simple genetic crosses (crosses for a single locus)

Genotypic Ratio	Genotypes of Parents	Genotypes of Progeny
1:2:1	*Aa* × *Aa*	$^1/_4$ *AA*: $^1/_2$ *Aa*: $^1/_4$ *aa*
1:1	*Aa* × *aa*	$^1/_2$ *Aa*:$^1/_2$ *aa*
	Aa × *AA*	$^1/_2$ *Aa*:$^1/_2$ *AA*
Uniform progeny	*AA* × *AA*	All *AA*
	aa × *aa*	All *aa*
	AA × *aa*	All *Aa*

3.3 Dihybrid Crosses Reveal the Principle of Independent Assortment

We now extend Mendel's principle of segregation to some more complex crosses that include alleles at multiple loci. Understanding the nature of these crosses will require an additional principle: the principle of independent assortment.

Dihybrid Crosses

In addition to his work on monohybrid crosses, Mendel crossed varieties of peas that differed in *two* characteristics—that is, he performed **dihybrid crosses**. For example, he crossed one homozygous variety that had seeds that were round and yellow with another homozygous variety that had seeds that were wrinkled and green. The seeds of all the F_1 progeny were round and yellow. He then allowed the F_1 to self-fertilize and obtained the following progeny in the F_2: 315 round, yellow seeds; 101 wrinkled, yellow seeds; 108 round, green seeds; and 32 wrinkled, green seeds. Mendel recognized that these traits appeared in a ratio of approximately 9 : 3 : 3 : 1; that is, $^{9}/_{16}$ of the progeny were round and yellow, $^{3}/_{16}$ were wrinkled and yellow, $^{3}/_{16}$ were round and green, and $^{1}/_{16}$ were wrinkled and green.

The Principle of Independent Assortment

Mendel carried out a number of dihybrid crosses for pairs of characteristics and always obtained a 9:3:3:1 ratio in the F_2. This ratio makes perfect sense in regard to the principle of segregation and the concept of dominance if we add a third principle, which Mendel recognized in his dihybrid crosses: the **principle of independent assortment** (Mendel's second law). This principle states that alleles at different loci separate independently of one another (see Table 3.2).

A common mistake is to think that the principle of segregation and the principle of independent assortment refer to two different processes. The principle of independent assortment is really an extension of the principle of segregation. The principle of segregation states that the two alleles at a locus separate when gametes are formed; the principle of independent assortment states that when these two alleles separate, their separation is independent of the separation of alleles at *other* loci.

Let's see how the principle of independent assortment explains the results that Mendel obtained in the dihybrid cross previously described. Each pea plant possesses two alleles encoding each characteristic, so the parent plants must have had genotypes *RR YY* and *rr yy* (**Figure 3.11a**). The principle of segregation tells us that the

alleles at each locus separate, and that one allele for each locus passes into each gamete. The gametes produced by the round, yellow parent therefore contained alleles *RY*, whereas the gametes produced by the wrinkled, green parent contained alleles *ry*. These two types of gametes united to produce the F_1, all with genotype *Rr Yy*. Because round is dominant to wrinkled and yellow is dominant to green, the phenotype of the F_1 was round and yellow.

Experiment

Question: Do alleles encoding different traits separate independently?

Methods

(a)

P generation

Round, yellow seeds × Wrinkled, green seeds

RR YY × *rr yy*

Gametes: *RY* × *ry*

Fertilization

(b)

F_1 generation

Round, yellow seeds

Rr Yy

Gametes: *RY*, *ry*, *Ry*, *rY*

Self-fertilization

Results

(c)

F_2 generation

	RY	*ry*	*Ry*	*rY*
RY	*RR YY*	*Rr Yy*	*RR Yy*	*Rr YY*
ry	*Rr Yy*	*rr yy*	*Rr yy*	*rr Yy*
Ry	*RR Yy*	*Rr yy*	*RR yy*	*Rr Yy*
rY	*Rr YY*	*rr Yy*	*Rr Yy*	*rr YY*

Phenotypic ratio
9 round, yellow : 3 round, green :
3 wrinkled, yellow : 1 wrinkled, green

Conclusion: The allele encoding color separated independently of the allele encoding seed shape, producing a 9 : 3 : 3 : 1 ratio in the F_2 progeny.

3.11 Mendel's dihybrid crosses revealed the principle of independent assortment.

Description

The methods involve Part "a" on top with P generation. It shows round yellow seeds with genotype big R big R big Y big Y crossed with green wrinkled seeds with genotype small R small R small Y small Y. Gametes produced are big R big Y and small R small Y respectively. Fertilization takes place and leads to part "b" below which represents F subscript 1 generation, which consists of round yellow seeds with genotype big R small R big Y small Y. Four types of gametes are produced as follows: big R big Y, small R small Y, big R small Y, and small R big Y. Self-fertilization takes place and leads to part "c" below. Part c shows results through F subscript 2 generation. The results of the cross are represented with a Punnett square of 4 rows and 4 columns, each headed with gametes.

Row 1 column 1: an image shows a round yellow seed with genotype big R big R big Y big Y.

Row 1 column 2: an image shows a round yellow seed with genotype big R small R big Y small Y.

Row 1 column 3: an image shows a round yellow seed with genotype big R big R big Y small Y.

Row 1 column 4: an image shows a round yellow seed with genotype big R small R big Y big Y.

Row 2 column 1: an image shows a round yellow seed with genotype big R small R big Y small Y.

Row 2 column 2: an image shows a wrinkled green seed with genotype small R small R small Y small Y.

Row 2 column 3: an image shows a round green seed with genotype big R small R small Y small Y.

Row 2 column 4: an image shows a wrinkled yellow seed with genotype small R small R big Y small Y.

Row 3 column 1: an image shows a round yellow seed with genotype big R big R big Y small Y.

Row 3 column 2: an image shows a round green seed with genotype big R small R small Y small Y.

Row 3 column 3: an image shows a round green seed with genotype big R big R small Y small Y.

Row 3 column 4: an image shows a round yellow seed with genotype big R small R big Y small Y.

Row 4 column 1: an image shows a round yellow seed with genotype big R small R big Y big Y.

Row 4 column 2: an image shows a wrinkled yellow seed with genotype small R small R big Y small Y.

Row 4 column 3: an image shows a round yellow seed with genotype big R small R big Y small Y.

Row 4 column 4: an image shows a wrinkled yellow seed with genotype small R small R big Y big Y.

A caption below reads, “phenotypic ratio: 9 round, yellow to 3 round, green to 3 wrinkled, yellow to 1 wrinkled green.”

The conclusion states that the allele encoding color separated independently of the allele encoding seed shape, producing a 9 to 3 to 3 to 1 ratio in the F subscript 2 progeny.

When Mendel allowed the F_1 plants to self-fertilize to produce the F_2, the alleles at each locus separated, and one of those alleles

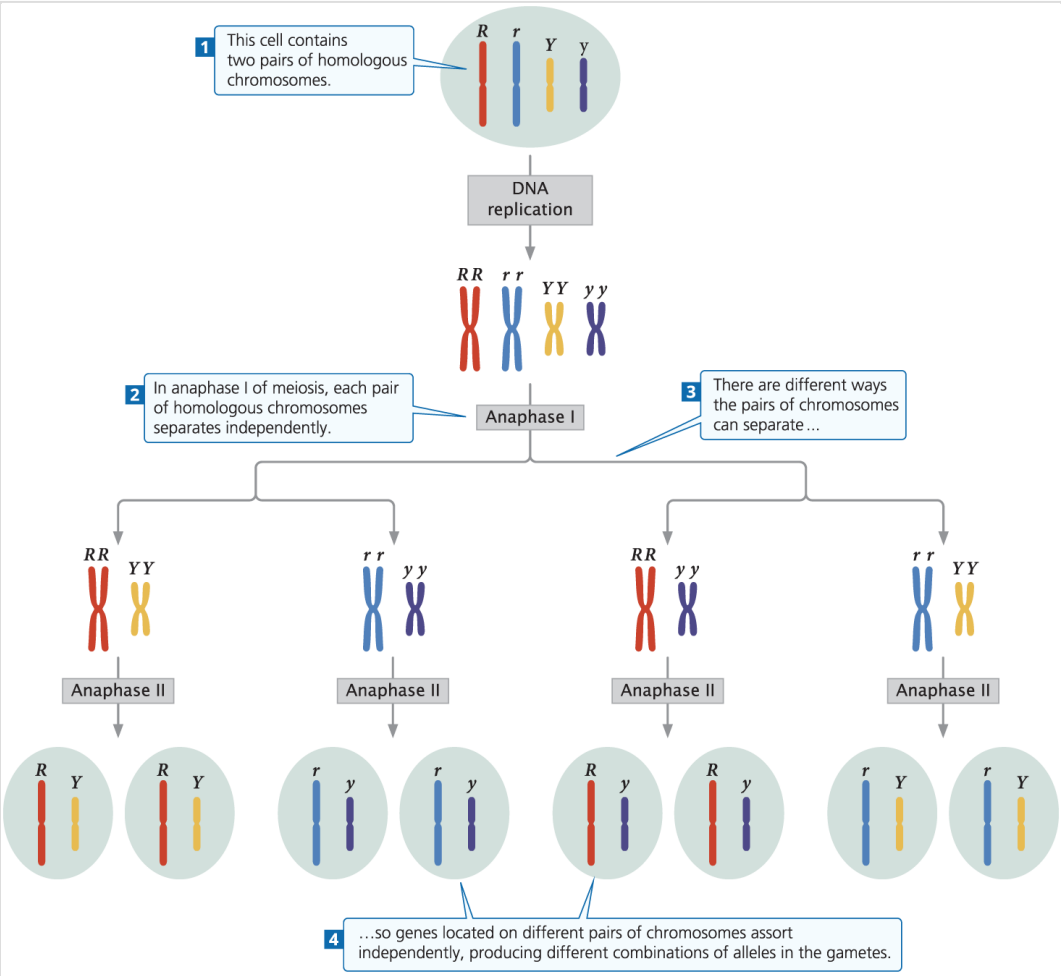
passed into each gamete. This event is where the principle of independent assortment becomes important. The two pairs of alleles can separate in two ways: (1) *R* separates with *Y*, and *r* separates with *y*, to produce gametes *RY* and *ry*, or (2) *R* separates with *y*, and *r* separates with *Y*, to produce gametes *Ry* and *rY*. The principle of independent assortment tells us that the alleles at each locus separate independently; thus, both kinds of separation take place with equal frequency, and all four types of gametes (*RY*, *ry*, *Ry*, and *rY*) are produced in equal proportions (Figure 3.11b). When these four types of gametes are combined to produce the F_2 generation, the progeny consist of $^{9}/_{16}$ round and yellow, $^{3}/_{16}$ round and green, $^{3}/_{16}$ wrinkled and yellow, and $^{1}/_{16}$ wrinkled and green, resulting in a 9:3:3:1 phenotypic ratio (Figure 3.11c).

THINK-PAIR-SHARE Question 6

Relating the Principle of Independent Assortment to Meiosis

An important qualification of the principle of independent assortment is that it applies to characteristics encoded by loci located on different chromosomes. Like the principle of segregation, it is based wholly on the behavior of chromosomes in meiosis. Each pair of homologous chromosomes separates independently of all

other pairs in anaphase I of meiosis (Figure 3.12), so genes located on different pairs of homologs will assort independently. Genes that happen to be located on the same chromosome will travel together during anaphase I of meiosis and will arrive at the same destination—within the same gamete (unless crossing over takes place). So genes located on the same chromosome do not assort independently (unless they are located sufficiently far apart that crossing over takes place in every meiotic division, a situation that will be discussed fully in Chapter 7).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

3.12 The principle of independent assortment results from the independent separation of chromosomes in anaphase I of meiosis.

Description

The illustration begins with a cell that contains two pairs of homologous chromosomes as follows: red large rod shaped chromosome big R, blue large rod shaped chromosome small R, yellow short rod shape d chromosome big Y, and purple short rod shaped chromosome small Y. A caption reads, this cell contains two pairs of homologous chromosomes. The cell undergoes chromosome replication and yields 4 different X shaped chromosomes with the following genotypes: red large X shaped chromosome with genotype big R big R, blue large X shaped chromosome with genotype small R small R, yellow short X shaped chromosome with genotype big Y big Y, and purple short X shaped chromosome with genotype small Y small Y. These chromosomes separate independently during anaphase 1. A caption reads, in anaphase 1 of meiosis, each pair of homologous chromosomes separates independently. There are different ways the pairs of chromosomes can separate.

The different ways these chromosomes can separate are: red large X shaped chromosome with genotype big R big R and yellow short X shaped chromosome with genotype big Y big Y; blue large X shaped chromosome with genotype small R small R and purple short X shaped chromosome with genotype small Y small Y on a branch. Red large X shaped chromosome with genotype big R big R and purple short X shaped chromosome with genotype small Y small Y; blue large X shaped chromosome with genotype small R small R and yellow short X shaped chromosome with genotype big Y big Y on the other branch. All these chromosome pairs undergo anaphase 2 and genes located on different pairs of chromosomes assort independently, producing different combinations of alleles in the gametes. The following gametes are produced:

Red large X shaped chromosome with genotype big R big R and yellow short X shaped chromosome with genotype big Y big Y produce two gametes with red rod shaped chromosome with genotype big R and yellow short rod shaped chromosome with genotype big Y each.

Blue large X shaped chromosome with genotype small R small R and purple short X shaped chromosome with genotype small Y small Y produce two gametes with blue large

rod shaped chromosome with genotype small R and purple short rod shaped chromosome with genotype small Y each.

Red large X shaped chromosome with genotype big R big R and purple short X shaped chromosome with genotype small Y small Y produce two gametes with red large rod shaped chromosome with genotype big R and purple short rod shaped chromosome with genotype small Y each.

Blue large X shaped chromosome with genotype small R small R and yellow short X shaped chromosome with genotype big Y big Y produce two gametes with blue large rod shaped chromosome with genotype small R and yellow short rod shaped chromosome with genotype big Y each.

A caption reads, so genes located on different pairs of chromosomes assort independently, producing different combinations of alleles in the gametes.

CONCEPTS

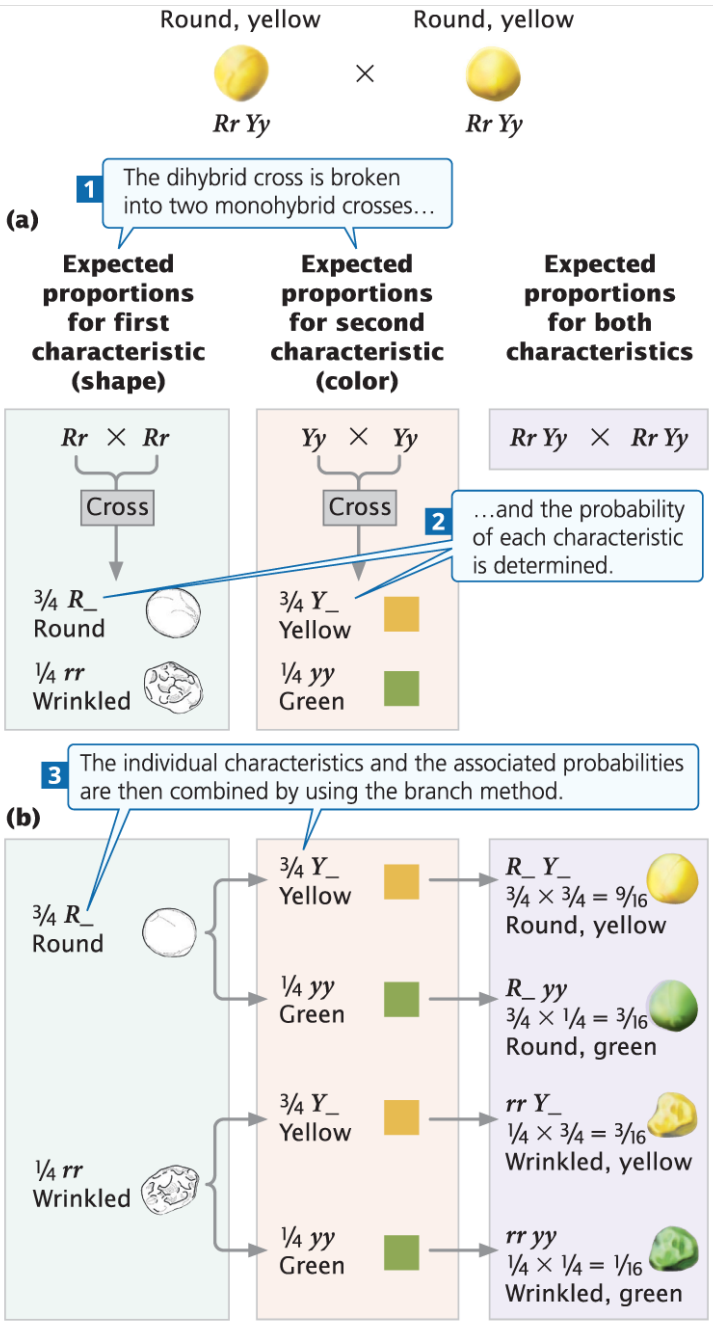
The principle of independent assortment states that genes encoding different characteristics separate independently of one another when gametes are formed, owing to the independent separation of homologous pairs of chromosomes in meiosis. Genes located close together on the same chromosome do not, however, assort independently.

✔ CONCEPT CHECK 6

How are the principles of segregation and independent assortment related, and how are they different?

Applying Probability and the Branch Diagram to Dihybrid Crosses

When the genes at two loci separate independently, a dihybrid cross can be understood as two monohybrid crosses. Let's examine Mendel's dihybrid cross (*Rr Yy* × *Rr Yy*) by considering each characteristic separately (**Figure 3.13a**). If we consider only the shape of the seeds, the cross was *Rr* × *Rr*, which yields a 3:1 phenotypic ratio ($^3/_4$ round and $^1/_4$ wrinkled progeny; see Table 3.5). Next, we consider the other characteristic, the color of the seeds. The cross was *Yy* × *Yy*, which produces a 3:1 phenotypic ratio ($^3/_4$ yellow and $^1/_4$ green progeny).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

3.13 A branch diagram can be used to determine the phenotypes and expected proportions of offspring from a dihybrid cross (*Rr Yy* × *Rr Yy*).

Description

The dibyhrid cross is a self-cross between round yellow seeds with genotype big R small R big Y small Y. Part “a” on top shows three distinct panels. First is for the expected proportions of the first characteristic (shape), second is for the expected proportions of the second characteristic (color), and third is for the expected proportions of both characteristics. A caption reads, “The dihybrid cross is broken into two monohybrid crosses.” The first panel on the left shows a self-cross between big R small R, which produces three-fourth round with genotype big R blank and one-fourth wrinkled with genotype small R small R. The second panel in the center shows a self-cross between big Y small Y, which produces three-fourth yellow with genotype big Y blank and one-fourth green with genotype small Y small Y. The third panel on the right shows a self-cross between big R small R big Y small Y. A caption extending out from three-fourth round and three-fourth yellow reads, “and the probability of each characteristic is determined.” Part “b” below shows a horizontal branch diagram and a caption reads, “The individual characters and the associated probabilities are then combined by using the branch method.” The branch diagram has two different branches for round seeds and wrinkled seeds.

First branch: Three-fourth big R blank, round branches into two sub-branches. The first sub-branch: three-fourth big Y blank, yellow which gives big R blank big Y blank (round yellow), three-fourth multiplied by three-fourth equals 9 over 16. The second sub-branch: one-fourth small Y small Y, green which gives big R blank small Y small Y (round green), three-fourth multiplied by one-fourth equals 3 over 16.

Second branch: One-fourth small R small R, wrinkled also branches into two sub-branches. The first sub-branch: three-fourth big Y blank, yellow which gives small R small R big Y blank (wrinkled yellow), one-fourth multiplied by three-fourth equals 3 over 16. The second sub-branch: one-fourth small Y small Y, green which gives small R small R small Y small Y, (wrinkled green), one-fourth multiplied by one-fourth equals 1 over 16.

We can now combine these monohybrid ratios by using the multiplication rule to obtain the proportion of progeny with different combinations of seed shape and color. The proportion of progeny with round and yellow seeds is $^{3}/_{4}$ (the probability of round) $\times$ $^{3}/_{4}$ (the probability of yellow) = $^{9}/_{16}$. The proportion of progeny with

round and green seeds is $^3/_4 \times {}^1/_4 = {}^3/_{16}$; the proportion of progeny with wrinkled and yellow seeds is $^1/_4 \times {}^3/_4 = {}^3/_{16}$; and the proportion of progeny with wrinkled and green seeds is $^1/_4 \times {}^1/_4 = {}^1/_{16}$.

Branch diagrams are a convenient way of organizing all the combinations of characteristics in the progeny of a cross (**Figure 3.13b**). In the first column, list the proportions of the phenotypes for one characteristic (here, seed shape: $^3/_4$ round and $^1/_4$ wrinkled). In the second column, list the proportions of the phenotypes for the next characteristic (seed color: $^3/_4$ yellow and $^1/_4$ green) twice, next to each of the phenotypes in the first column: write "$^3/_4$ yellow" and "$^1/_4$ green" next to the round phenotype and again next to the wrinkled phenotype. Check to make sure that the proportions for each characteristic sum to one (i.e., $^3/_4$ yellow and $^1/_4$ green = 1.0). Now, draw lines between the phenotypes in the first column and each of the phenotypes in the second column. Follow each branch of the diagram, multiplying the probabilities for each trait along that branch. One branch leads from round to yellow, yielding round and yellow progeny. Another branch leads from round to green, yielding round and green progeny, and so forth. We calculate the probability of progeny with a particular combination of traits by using the multiplication rule: the probability of round ($^3/_4$) and yellow ($^3/_4$) seeds is $^3/_4 \times {}^3/_4 = {}^9/_{16}$. The advantage of the branch diagram is that it helps us keep track of all the potential combinations of traits that may appear in the progeny. It can be used to determine phenotypic or genotypic ratios for any number of characteristics.

Using probability is much faster than using the Punnett square for crosses that include multiple loci. Genotypic and phenotypic ratios can be quickly worked out by combining, using the multiplication rule, the simple ratios in Tables 3.5 and 3.6. The probability method is particularly efficient if we need the probability of only a *particular* phenotype or genotype among the progeny of a cross. Suppose that we need to know the probability of obtaining the genotype *Rr yy* in the F_2 of the dihybrid cross in Figure 3.11. The probability of obtaining the *Rr* genotype in a cross of *Rr* × *Rr* is $^1/_2$, and that of obtaining the *yy* genotype in a cross of *Yy* × *Yy* is $^1/_4$ (see Table 3.6). Using the multiplication rule, we find the probability of *Rr yy* to be $^1/_2 \times {}^1/_4 = {}^1/_8$.

To illustrate the advantage of the probability method, consider the cross *Aa Bb cc Dd Ee* × *Aa Bb Cc dd Ee*. Suppose that we want to know the probability of obtaining offspring with the genotype *aa bb cc dd ee*. If we use a Punnett square to determine this probability, we might be working on the solution for months. However, we can quickly figure the probability of obtaining this one genotype by breaking this cross into a series of single-locus crosses:

Progeny cross	Genotype	Probability
Aa × *Aa*	*aa*	$^1/_4$
Bb × *Bb*	*bb*	$^1/_4$

cc × *Cc*	*cc*	$^1/_2$
Dd × *dd*	*dd*	$^1/_2$
Ee × *Ee*	*ee*	$^1/_4$

The probability of an offspring from this cross having genotype *aa bb cc dd ee* is now easily obtained by using the multiplication rule: $^1/_4 \times {}^1/_4 \times {}^1/_2 \times {}^1/_2 \times {}^1/_4 = {}^1/_{256}$. This calculation assumes that the genes at these five loci all assort independently.

Now that you've had some experience working genetic crosses, explore Mendel's principles of heredity by setting up some of your own crosses in (A) **Animation 3.1**.

CONCEPTS

A cross including several characteristics can be worked by breaking it down into single-locus crosses and using the multiplication rule to determine the proportions of combinations of characteristics (provided that the genes assort independently).

The Dihybrid Testcross

Let's practice using the branch diagram by determining the types and proportions of phenotypes in a dihybrid testcross between the

round and yellow F_1 pea plants (*Rr Yy*) obtained by Mendel in his dihybrid cross and the wrinkled and green pea plants (*rr yy*), as depicted in **Figure 3.14**. First, break the cross down into a series of single-locus crosses. The cross *Rr* × *rr* yields $^1/_2$ round (*Rr*) progeny and $^1/_2$ wrinkled (*rr*) progeny. The cross *Yy* × *yy* yields $^1/_2$ yellow (*Yy*) progeny and $^1/_2$ green (*yy*) progeny. Using the multiplication rule, we find the proportion of round and yellow progeny to be $^1/_2$ (the probability of round) × $^1/_2$ (the probability of yellow) = $^1/_4$. Four combinations of traits appear in the offspring in the following proportions: $^1/_4$ *Rr Yy*, round and yellow; $^1/_4$ *Rr yy*, round and green; $^1/_4$ *rr Yy*, wrinkled and yellow; and $^1/_4$ *rr yy*, wrinkled and green.

W. H. Freeman and Company

3.14 A branch diagram can be used to determine the phenotypes and expected proportions of offspring from a dihybrid testcross (*Rr Yy* × *rr yy*).

Description

The dibyhrid cross is between round yellow seeds with genotype big R small R big Y small Y and wrinkled green seeds with genotype small R small R small Y small Y. The illustration shows three distinct panels. First is for the expected proportions of the first characteristic, second is for the expected proportions of the second characteristic, and third is for the expected proportions of both characteristics. The first panel on the left shows a cross

between big R small R and small R small R, which produces one-half round with genotype big R small R and one-half wrinkled with genotype small R small R. The second panel in the center shows a cross between big Y small Y and small Y small Y, which produces one-half yellow with genotype big Y small Y and one-fourth green with genotype small Y small Y. The third panel on the right shows a cross between big R small R big Y small Y and small R small R small Y small Y. Below is a horizontal branch diagram. The branch diagram has two different branches for round seeds and wrinkled seeds.

First branch: one-half big R small R, round branches into two sub-branches. The first sub-branch: one-half big Y small Y, yellow which gives big R small R big Y small Y (round yellow), one-half multiplied by one-half equals one-fourth. The second sub-branch: one-half small Y small Y, green which gives big R small R small Y small Y (round green), one-half multiplied by one-half equals one-fourth.

Second branch: One-half small R small R, wrinkled also branches into two sub-branches. The first sub-branch: one-half big Y small Y, yellow which gives small R small R big Y small Y (wrinkled yellow), one-half multiplied by one-half equals one-fourth. The second sub-branch: one-half small Y small Y, green which gives small R small R small Y small Y, (wrinkled green), one-half multiplied by one-half equals one-fourth.

THINK-PAIR-SHARE Question 7

WORKED PROBLEM

The principles of segregation and independent assortment are important not only because they explain how heredity works but also because they provide the means for predicting the outcome of genetic crosses. This predictive power has made genetics a powerful tool in agriculture and other fields, and the ability to apply the principles of heredity is an important skill for all students of

genetics. Practice with genetic problems is essential for mastering the basic principles of heredity; no amount of reading and memorization can substitute for the experience gained by deriving solutions to specific problems in genetics.

You may find genetics problems difficult if you are unsure of where to begin or how to organize a solution to the problem. In genetics, every problem is different, so no common series of steps can be applied to all genetics problems. Logic and common sense must be used to analyze a problem and arrive at a solution. Nevertheless, certain steps can facilitate the process, and solving the following problem will serve to illustrate those steps.

In mice, black coat color (*B*) is dominant to brown (*b*), and a solid pattern (*S*) is dominant to a white-spotted pattern (*s*). Color and spotting are controlled by genes that assort independently. A homozygous black, spotted mouse is crossed with a homozygous brown, solid mouse. All the F_1 mice are black and solid. A testcross is then carried out by mating the F_1 mice with brown, spotted mice.

a. Give the genotypes of the parents and the F_1 mice.
b. Give the genotypes and phenotypes, along with their expected ratios, for the progeny expected from the testcross.

Solution Strategy

What information is required in your answer to the problem?

First, determine what question or questions the problem is asking. Is it asking for genotypes or genotypic ratios or phenotypic ratios? This problem asks you to provide the *genotypes* of the parents and the F_1, the *expected genotypes* and *phenotypes* of the progeny of the testcross, and their *expected proportions*.

What information is provided to solve the problem?

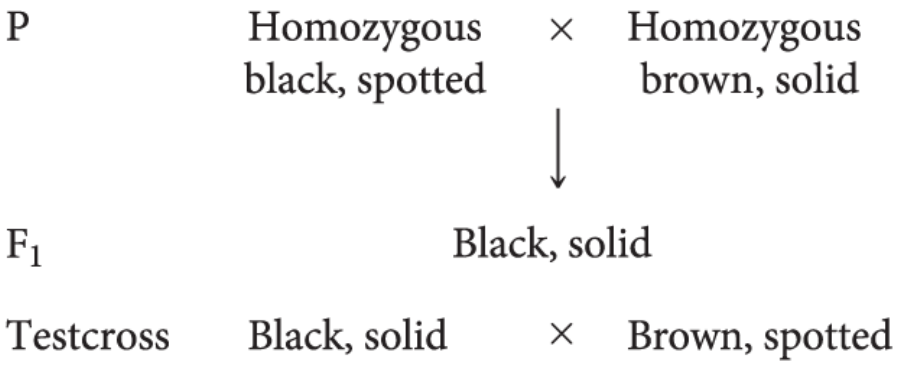
Next, determine what information is provided that will be necessary to solve the problem. This problem gives important information about the dominance relations of the traits involved and the genes that encode them:

- Black is dominant to brown.
- Solid is dominant to spotted.
- The genes for the two characteristics assort independently.
- Symbols for the different alleles: *B* for black, *b* for brown, *S* for solid, and *s* for spotted.

It is often helpful to write down the symbols at the beginning of the solution:

B—black	*S*—solid
b—brown	*s*—spotted

Next, write out the crosses given in the problem:



Description
In the parent generation labeled as P, homozygous black, spotted with genotype big B big B small S small S is crossed with homozygous brown, solid with genotype small B small B big S big S. A downward arrow points to black, solid in the F subscript 1 generation with genotype big B blank big S blank. Below F subscript 1 generation, a test cross is shown between black, solid with genotype big B blank big S blank and black spotted with genotype small B small B small S small S.

For help with this problem, review:

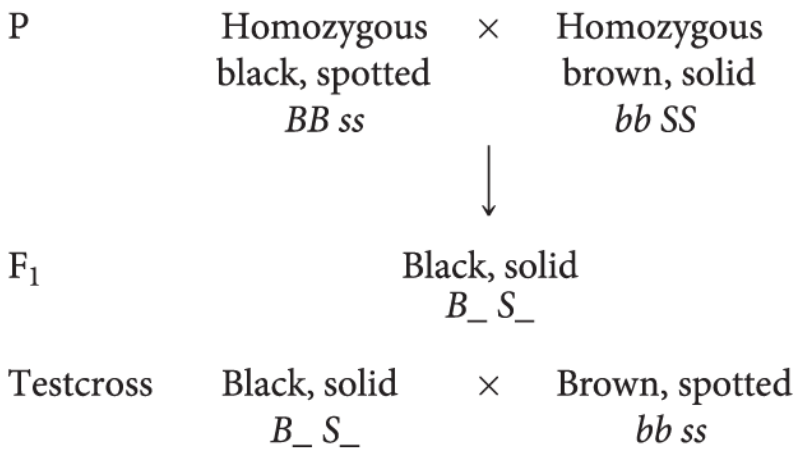
If you need help solving the problem, review those sections of the chapter that cover the relevant information. For this problem, review Sections 3.2 and 3.3.

Solution Steps

STEP 1 Write down any genetic information that can be determined from the phenotypes alone.

From their phenotypes and the statement that they are homozygous, you know that the P-generation mice must be *BB ss* and *bb SS*. The F_1 mice are black and solid, both of which are dominant traits, so the

F_1 mice must possess at least one black allele (*B*) and one solid allele (*S*). At this point, you may not be certain about the other alleles, so you can represent the genotype of the F_1 as *B_ S_*, where _ means that any allele is possible. The brown, spotted mice used in the testcross must be *bb ss* because both brown and spotted are recessive traits that will be expressed only if two recessive alleles are present. Record these genotypes on the crosses that you wrote out:



Description
In parent generation, homozygous black spotted is crossed with homozygous brown solid. A downward arrow points to black, solid in the F subscript 1 generation. A test cross is shown below between black solid and black spotted.

STEP 2 Break the problem down into smaller parts.

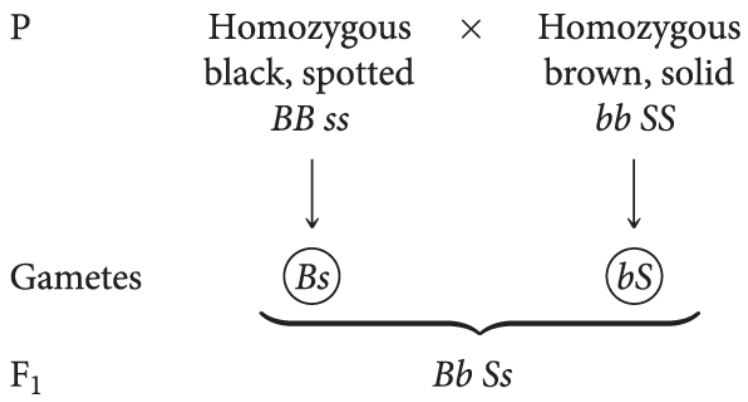
First, determine the genotype of the F_1. After this genotype has been determined, you can predict the results of the testcross and determine the genotypes and phenotypes of the progeny of the testcross.

Second, because this cross includes two independently assorting loci, it can be conveniently broken down into two single-locus crosses: one for coat color and the other for spotting.

Third, you can use a branch diagram to determine the proportion of progeny of the testcross with different combinations of the two traits.

STEP 3 Work the different parts of the problem.

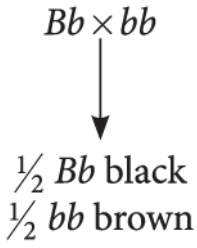
Start by determining the genotype of the F_1 progeny. Mendel's first law indicates that the two alleles at a locus separate, one going into each gamete. Thus, the gametes produced by the black, spotted parent contain *B s* and the gametes produced by the brown, solid parent contain *b S*, which combine to produce F_1 progeny with the genotype *Bb Ss*:



Description
In the parent generation, homozygous black, spotted with genotype big B big B small S small S is crossed with homozygous brown, solid with genotype small B small B big S big

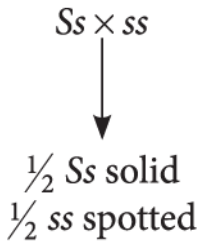
S. Gametes produced are big B small S and small B big S respectively. These gametes produce the F subscript 1 generation with genotype big B small B big S small S.

Use the F_1 genotype to work the testcross (*Bb Ss* × *bb ss*), breaking it into two single-locus crosses. First, consider the cross for coat color: *Bb* × *bb*. Any cross between a heterozygote and a homozygous recessive genotype produces a 1:1 phenotypic ratio of progeny (see Table 3.5):



Description
Big B small B is crossed with small B small B. It yields one-half big B small B, black and one-half small B small B, brown.

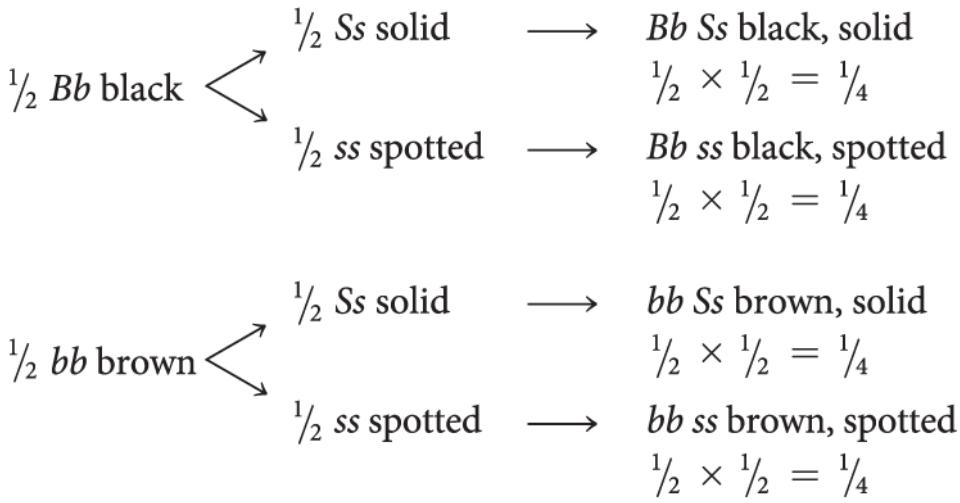
Next, consider the cross for spotting: *Ss* × *ss*. This cross is also between a heterozygote and a homozygous recessive genotype and produces $^1/_2$ solid (*Ss*) and $^1/_2$ spotted (*ss*) progeny (see Table 3.5).



Description

Big S small S is crossed with small S small S. It yields one-half big S small S, solid and one-half small S small S, spotted.

Finally, determine the proportions of progeny with combinations of these characters by using a branch diagram.



Description
The branch diagram has two different branches for black mice and brown mice.

First branch: one-half big B small B, black branches into two sub-branches. The first sub-branch: one-half big S small S, solid which gives big B small B big S small S (black solid), one-half multiplied by one-half equals one-fourth. The second sub-branch: one-half small S small S, spotted which gives big B small B small S small S (black spotted), one-half multiplied by one-half equals one-fourth.

Second branch: One-half small B small B, brown also branches into two sub-branches. The first sub-branch: one-half big S small S, solid which gives small B small B big S small S (brown solid), one-half multiplied by one-half equals one-fourth. The second sub-branch: one-half small S small S, spotted which gives small B small B small S small S, (brown spotted), one-half multiplied by one-half equals one-fourth.

STEP 4 Check all work.

As a last step, reread the problem, checking to see if your answers are consistent with the information provided. You have used the genotypes *BB ss* and *bb SS* in the P generation. Do these genotypes encode the phenotypes given in the problem? Are the F_1 progeny phenotypes consistent with the genotypes that you assigned? The answers are consistent with the information.

» Now that we have stepped through a genetics problem together, try your hand at **Problem 33** at the end of this chapter.

3.4 Observed Ratios of Progeny May Deviate from Expected Ratios by Chance

When two individual organisms of known genotype are crossed, we expect certain ratios of genotypes and phenotypes among the progeny; these expected ratios are based on the Mendelian principles of segregation, independent assortment, and dominance. The ratios of genotypes and phenotypes *actually* observed among the progeny, however, may deviate from these expectations.

For example, in German cockroaches, brown body color (*Y*) is dominant to yellow body color (*y*). If we cross a brown, heterozygous cockroach (*Yy*) with a yellow cockroach (*yy*), we expect a 1:1 ratio of brown (*Yy*) and yellow (*yy*) progeny. Among 40 progeny, we therefore expect to see 20 brown and 20 yellow offspring. However, the observed numbers might deviate from these expected values; we might in fact see 22 brown and 18 yellow progeny.

Chance plays a critical role in genetic crosses, just as it does in flipping a coin. When you flip a coin, you expect a 1:1 ratio—$^1/_2$ heads and $^1/_2$ tails. If you flipped a coin 1000 times, the proportion of heads and tails obtained would probably be very close to that expected 1:1 ratio. However, if you flipped the coin 10 times, the ratio of heads to tails might be quite different from 1:1. You could

easily get 6 heads and 4 tails, or 3 heads and 7 tails, just by chance. You might even get 10 heads and 0 tails. The same thing happens in genetic crosses. We may expect 20 brown and 20 yellow cockroaches, but 22 brown and 18 yellow progeny *could* arise as a result of chance.

The Chi-Square (χ^2) Goodness-of-Fit Test

If you expected a 1:1 ratio of brown and yellow cockroaches but the cross produced 22 brown and 18 yellow cockroaches, you probably wouldn't be too surprised, even though it wasn't a perfect 1:1 ratio. In this case, it seems reasonable to assume that chance produced the deviation between the expected and the observed results. But if you observed 25 brown and 15 yellow cockroaches, would you still assume that this result represents a 1:1 ratio? Something other than chance might have caused this deviation. Perhaps the inheritance of this characteristic is more complicated than was assumed, or perhaps some of the yellow progeny died before they were counted. Clearly, we need some means of evaluating how likely it is that chance is responsible for a deviation between the observed and the expected numbers.

To evaluate the role of chance in producing deviations between observed and expected values, a statistical test called the **chi-square**

goodness-of-fit test is used. This test provides information about how well observed values fit expected values. Before we learn how to use this test, however, it is important to understand what it does and does not indicate about a genetic cross. The chi-square test cannot tell us whether a genetic cross has been correctly carried out, whether the results are correct, or whether we have chosen the correct genetic explanation for the results. What it does indicate is the *probability* that the difference between the observed and the expected values is due to chance. In other words, it indicates the likelihood that chance alone could produce the deviation between the expected and the observed values.

If we expected 20 brown and 20 yellow progeny from a genetic cross, the chi-square test gives us the probability that we might observe 25 brown and 15 yellow progeny simply owing to chance deviations from the expected 20:20 ratio. This hypothesis—that chance alone is responsible for a deviation between observed and expected values—is sometimes called the *null hypothesis*. Statistical tests such as the chi-square test cannot prove that the null hypothesis is correct, but they can help us decide whether we should reject it. When the probability calculated with the chi-square test is high, we assume that chance alone produced the deviation, and we do not reject the null hypothesis. When the probability is low, we assume that some factor other than chance—some significant factor—produced the deviation; for example, the mortality rate of the yellow cockroaches might be higher than that of the brown cockroaches. When the

probability that chance produced the deviation is low, we reject the null hypothesis.

To use the chi-square goodness-of-fit test, we first determine the expected results. The chi-square test must always be applied to *numbers* of progeny, not to proportions or percentages. Let's consider a locus for coat color in domestic cats, for which black color (*B*) is dominant to gray (*b*). If we crossed two heterozygous black cats (*Bb* × *Bb*), we would expect a 3:1 ratio of black and gray kittens. Imagine that a series of such crosses yields a total of 50 kittens—30 black and 20 gray. These numbers are our *observed* values. We can obtain the *expected* numbers by multiplying the expected proportions by the total number of observed progeny. In this case, the expected number of black kittens is $^3/_4 \times 50 = 37.5$, and the expected number of gray kittens is $^1/_4 \times 50 = 12.5$. Note that it is biologically impossible to have 37.5 or 12.5 kittens, because kittens only come in whole numbers, but the expected number is 37.5, so that is what we should use in the chi-square calculations.

The chi-square (χ^2) value is calculated by using the following formula:

$$\chi^2 = \sum \frac{(\text{observed} - \text{expected})^2}{\text{expected}}$$

where Σ means the sum. We calculate the sum of all the squared differences between observed and expected values divided by the

expected values. To calculate the chi-square value for our black and gray kittens, we first subtract the number of *expected* black kittens from the number of *observed* black kittens (30 − 37.5 = − 7.5) and square this value: $-7.5^2 = 56.25$. We then divide this result by the expected number of black kittens, 56.25/37.5 = 1.5. We repeat the calculations on the number of expected gray kittens: $(20 - 12.5)^2/12.5 = 4.5$. To obtain the overall chi-square value, we sum the (observed − expected)^2/expected values: 1.5 + 4.5 = 6.0.

The next step is to determine the probability associated with this calculated chi-square value, which is the probability that the deviation between the observed and the expected results is due to chance. This step requires us to compare our calculated chi-square value (6.0) with theoretical values in a chi-square table that have the same degrees of freedom. The degrees of freedom represent the number of ways in which the expected classes are free to vary. For a chi-square goodness-of-fit test, the degrees of freedom are equal to $n - 1$, in which n is the number of different expected phenotypes. Here, we lose one degree of freedom because the total number of expected progeny must equal the total number of observed progeny. In our example, there are two expected phenotypes (black and gray), so $n = 2$, and the degree of freedom equals 2 − 1 = 1.

Now that we have our calculated chi-square value and have figured out the associated degrees of freedom, we are ready to obtain the probability from a chi-square table (**Table 3.7**). The degrees of freedom are given in the left-hand column of the table and the

probabilities are given at the top; within the body of the table are chi-square values associated with these probabilities. First, we find the row for the appropriate degrees of freedom; for our example with 1 degree of freedom, it is the first row of the table. Then, we find our calculated chi-square value (6.0) among the theoretical values in this row. The theoretical chi-square values increase, and the probabilities decrease, from left to right. Our chi-square value of 6.0 falls between the value of 5.024, associated with a probability of 0.025, and the value of 6.635, associated with a probability of 0.01. Thus, the probability associated with our chi-square value is less than 0.025 and greater than 0.01. So there is less than a 2.5% probability that the deviation that we observed between the expected and the observed numbers of black and gray kittens could be due to chance.

P, probability; *df*, degrees of freedom.

*Most scientists assume that when $P < 0.05$, a significant difference exists between the observed and the expected values in a chi-square test.

Most scientists use the 0.05 probability level as their cutoff value: if the probability of chance being responsible for the deviation between observed and expected values is greater than or equal to 0.05, they accept that chance may be responsible for the deviation. When the probability is less than 0.05, scientists assume that chance is not responsible and that a significant difference from the expected values exists. The expression *significant difference* means that a factor other than chance is responsible for the deviation between the observed and the expected values. In regard to the kittens, perhaps one of the genotypes had a greater mortality rate before the progeny were counted, or perhaps other genetic factors skewed the observed ratios.

In choosing 0.05 as the cutoff value, scientists have agreed to assume that chance is responsible for deviations between observed and expected values unless there is strong evidence to the contrary. Bear in mind that even if we obtain a probability of, say, 0.01, there is still a 1% probability that the deviation between the observed and the

expected values is due to nothing more than chance. Calculation of the chi-square value is illustrated in Figure 3.15. ❯ **TRY** PROBLEM 38

W. H. Freeman and Company

3.15 A chi-square goodness-of-fit test is used to determine the probability that the difference between observed and expected values is due to chance.

Description

A cross between purple flowers and white flowers shows P through F subscript 2 generation. In P generation at the top, purple flowers are crossed with white flowers and the F subscript 1 generation has purple flowers only while the F subscript 2 generation has 105 purple and 45 white flowers. Drawings of purple and white flowers are shown. A caption extending out from the P generation Cross and the Self-fertilization F subscript 1 generation reads, “A plant with purple flowers is crossed with a plant with white flowers, and the F subscript 1 are self-fertilized to produce 105 F subscript 2 progeny with purple flowers and 45 with white flowers (an apparent 3 to 1 ratio).”

The observed and expected values for different phenotypes below are as follows:

Purple: observed, 105; expected, three-fourth multiplied by 150 equals 112 point 5.

White: observed, 45; expected, one-fourth multiplied by 150 equals 37 point 5.

Total: 150

A corresponding caption reads, “The expected values are obtained by multiplying the expected proportion by the total and then the chi-square value is calculated.” The calculation is as follows:

Chi-square equals summation start fraction left parenthesis O minus E right parenthesis squared over E end fraction. Chi-square equals start fraction left parenthesis 105 minus 112 point 5 right parenthesis squared over 112 point 5 end fraction plus start fraction left parenthesis 45 minus 37 point 5 right parenthesis squared over 37 point 5 end fraction. Chi-square equals start fraction 56 point 2 5 over 112 point 5 end fraction plus start fraction 56 point 2 5 over 37 point 5 end fraction. Chi square equals 0 point 5 plus 1 point 5 equals 2 point 0. Degrees of freedom equals n minus 1. Degrees of freedom equals 2 minus 1 equals 1. Probability (from table 3 point 7) 0 point 1 is less than P is less than 0 point 5. A corresponding caption reads, “The probability associated with the calculated chi-square value is between 0 point 10 and 0 point 50, indicating a high probability that the difference between observed and expected values is due to chance.”

The conclusion states that no significant difference between observed and expected values.

THINK-PAIR-SHARE Question 8

CONCEPTS

Differences between observed and expected ratios among the progeny of a cross can arise by chance. The chi-square goodness-of-fit test can be used to evaluate whether deviations between observed and expected numbers are likely to be due to chance or to some other, significant factor.

✔ CONCEPT CHECK 7

A chi-square test comparing observed and expected numbers of progeny is carried out, and the probability associated with the calculated chi-square value is 0.72. What does this probability represent?

a. Probability that the correct results were obtained
b. Probability of obtaining the observed numbers
c. Probability that the difference between observed and expected numbers is significant
d. Probability that the difference between observed and expected numbers could be due to chance

Chapter 3 Review

CHAPTER SUMMARY

Section 3.1 Learning Objective: Be able to explain how Gregor Mendel discovered the principles of heredity.

- Gregor Mendel discovered the principles of heredity. His success can be attributed to his choice of the pea plant as an experimental organism, the use of characteristics with a few easily distinguishable phenotypes, his experimental approach, the use of mathematics to interpret his results, and careful attention to detail.
- Genes are inherited factors that determine a characteristic. Alternative forms of a gene are called alleles. The alleles are located at a specific place, called a locus, on a chromosome, and the set of alleles that an individual organism possesses is its genotype. A phenotype is the manifestation or appearance of a characteristic and may refer to a physical, physiological, biochemical, or behavioral characteristic. Only the genotype—not the phenotype—is inherited.

Section 3.2 Learning Objective: Be able to use principles of heredity to predict progeny produced in a simple genetic cross.

- The principle of segregation states that a diploid individual organism possesses two alleles encoding a trait and that these two alleles separate in equal proportions when gametes are formed.
- The concept of dominance indicates that when two different alleles are present in a heterozygote, only the trait encoded by one of them, the dominant allele, is observed in the phenotype. The other allele is said to be recessive.
- The two alleles of a genotype are located on homologous chromosomes. The separation of homologous chromosomes in anaphase I of meiosis brings about the segregation of alleles.
- Probability is the likelihood that a particular event will occur. The multiplication rule states that the probability of two or more independent events occurring together is calculated by multiplying the probabilities of the independent events. The addition rule states that the probability of any of two or more mutually exclusive events occurring is calculated by adding the probabilities of the events.
- The binomial expansion can be used to determine the probability of a particular combination of events.
- A testcross, which reveals the genotype (homozygote or heterozygote) of an individual organism that has a dominant trait, consists of crossing that individual with one that has the homozygous recessive genotype.

Section 3.3 Learning Objective: Be able to predict the progeny of crosses involving two or more loci.

- The principle of independent assortment states that genes encoding different characteristics separate independently when gametes are formed. Independent assortment is based on the random separation of homologous pairs of chromosomes in anaphase I of meiosis; it takes place when genes encoding different characteristics are located on different pairs of chromosomes.

Section 3.4 Learning Objective: Be able to use the chi-square goodness-of-fit test to determine the probability that observed numbers of progeny differ from expected numbers.

- Observed ratios of progeny from a genetic cross may deviate from the expected ratios owing to chance. The chi-square goodness-of-fit test can be used to determine the probability that a difference between observed and expected numbers could be due to chance.

WORKED PROBLEMS

Problem 1

Short hair (*S*) in rabbits is dominant to long hair (*s*). The following crosses are carried out, producing the progeny shown. Give all possible genotypes of the parents in each cross.

	Parents	Progeny

a.	short × short	4 short and 2 long
b.	short × short	8 short
c.	short × long	12 short
d.	short × long	3 short and 1 long
e.	long × long	2 long

» Solution Strategy

What information is required in your answer to the problem?

All possible genotypes of the parents in each cross.

> **Note:** The problem asks for all possible genotypes of the parents.

What information is provided to solve the problem?

- Short hair is dominant to long hair.
- Phenotypes of the parents in each cross.
- Phenotypes and number of progeny of each cross.

For help with this problem, review:

Connecting Concepts: Ratios in Simple Crosses in Section 3.2.

» Solution Steps

For this problem, it is useful to first gather as much information about the genotypes of the parents as possible on the basis of their phenotypes. We can then look at the types of progeny produced to provide the missing information.

a. short $\times$ short $\rightarrow$ 4 short and 2 long

> **Note:** When both parents are heterozygotes (*Ss* × *Ss*), we expect to see a 3:1 ratio in progeny, but just by chance the progeny exhibited a 4:2 ratio.

Because short hair is dominant to long hair, a rabbit with short hair could be either *SS* or *Ss*. The two long-haired offspring must be homozygous (*ss*) because long hair is recessive and will appear in the phenotype only when two alleles for long hair are present. Because each parent contributes one of the two alleles found in the progeny, each parent must be carrying the *s* allele and must therefore be *Ss*.

b. short $\times$ short $\rightarrow$ 8 short

The short-haired parents could be *SS* or *Ss*. All eight of the offspring are short haired (S_), so at least one of the parents is likely to be homozygous (*SS*); if both parents were heterozygous, we would expect $^1/_4$ of the progeny to be long haired (*ss*), but we do not observe any long-haired progeny. The other parent could be homozygous (*SS*) or heterozygous (*Ss*); as long as one parent

is homozygous, all the offspring will be short haired. It is theoretically possible, although unlikely, that both parents are heterozygous (*Ss* × *Ss*). If both were heterozygous, we would expect two of the eight progeny to be long haired. Although no long-haired progeny are observed, it is possible that just by chance no long-haired rabbits were produced among the eight progeny of the cross.

c. short × long 12 short

The short-haired parent could be *SS* or *Ss*. The long-haired parent must be *ss*. If the short-haired parent were heterozygous (*Ss*), half of the offspring would be expected to be long haired, but we don't see any long-haired progeny. Therefore, this parent is most likely homozygous (*SS*). It is theoretically possible, although unlikely, that the parent is heterozygous and just by chance no long-haired progeny were produced.

d. short × long 3 short and 1 long

On the basis of its phenotype, the short-haired parent could be homozygous (*SS*) or heterozygous (*Ss*), but the presence of one long-haired offspring tells us that the short-haired parent must be heterozygous (*Ss*). The long-haired parent must be homozygous (*ss*).

e. long × long 2 long

Because long hair is recessive, both parents must be homozygous for a long-hair allele (*ss*).

Problem 2

In cats, black coat color is dominant to gray. A female black cat whose mother is gray mates with a gray male. If this female has a litter of six kittens, what is the probability that three will be black and three will be gray?

» Solution Strategy

What information is required in your answer to the problem?

The probability that in a litter of six kittens, three will be black and three will be gray.

What information is provided to solve the problem?

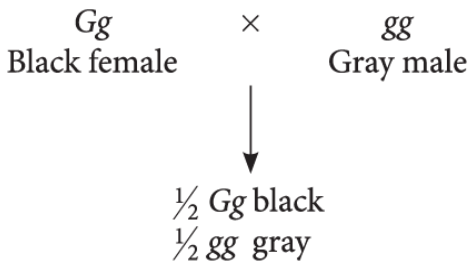
- Black is dominant to gray.
- The mother of the litter is black and her mother is gray.
- The father of the litter is gray.

For help with this problem, review:

The Binomial Expansion and Probability in **Section 3.2**.

» Solution Steps

Because black (*G*) is dominant to gray (*g*), a black cat may be homozygous (*GG*) or heterozygous (*Gg*). The black female in this problem must be heterozygous (*Gg*) because her mother is gray (*gg*) and she must have inherited one of her mother's alleles. The gray male must be homozygous (*gg*) because gray is recessive. Thus, the cross is



Description
The P generation shows a black female with genotype big G small G is crossed with a gray male with genotype small G small G. The genotypes of the progenies are as follows: one half big G small G black and one half small G small G gray.

Hint: We can determine the female parent's genotype from her phenotype and her mother's phenotype.

We can use the binomial expansion to determine the probability of obtaining three black and three gray kittens in a litter of six. Let *p* equal the probability of a kitten being black and *q* equal the probability of a kitten being gray. The binomial is $(p + q)^6$, the expansion of which is

Recall: The binomial expansion can be used to determine the probability of different combinations of traits in the progeny of a cross.

$$(p+q)^6 = p^6 + 6p^5q^1 + 15p^4q^2 + 20p^3q^3 + 15p^2q^4 + 6p^1q^5 + q^6$$

Hint: See the discussion of Binomial Expansion and Probability for an explanation of how to expand the binomial.

The probability of obtaining three black and three gray kittens in a litter of six is provided by the term $20p^3q^3$. The probabilities of p and q are both $^1/_2$, so the overall probability is $20(^1/_2)^3(^1/_2)^3 = {}^{20}/_{64} = {}^5/_{16}$.

Problem 3

In corn, purple kernels are dominant to yellow kernels, and full kernels are dominant to shrunken kernels. A corn plant that has purple and full kernels is crossed with a plant that has yellow and shrunken kernels, and the following progeny are obtained:

purple, full	112
purple, shrunken	103
yellow, full	91
yellow, shrunken	94

What are the most likely genotypes of the parents and progeny? Test your genetic hypothesis with a chi-square test.

» Solution Strategy

What information is required in your answer to the problem?

a. The genotypes of parents and progeny.
b. A chi-square test comparing the observed and expected results and the interpretation of the chi-square test.

What information is provided to solve the problem?

- Purple kernels are dominant to yellow kernels, and full kernels are dominant to shrunken kernels.
- The phenotypes of the parents.
- The phenotypes and numbers of progeny of the cross.

For help with this problem, review:

Sections 3.3 and 3.4.

» Solution Steps

The best way to begin this problem is by breaking the cross down into simple crosses for a single characteristic (kernel color or kernel shape):

P	purple × yellow	full × shrunken
F_1	112 + 103 = 215 purple	112 + 91 = 203 full
	91 + 94 = 185 yellow	103 + 94 = 197 shrunken

Hint: A good strategy in a cross involving multiple characteristics is to analyze the results for each characteristic separately.

In this cross, purple × yellow produces approximately $^1/_2$ purple and $^1/_2$ yellow (a 1:1 ratio). A 1:1 ratio is usually the result of a cross between a heterozygote and a homozygote. Because purple is dominant, the purple parent must be heterozygous (*Pp*) and the yellow parent must be homozygous (*pp*). The purple progeny produced by this cross will be heterozygous (*Pp*), and the yellow progeny must be homozygous (*pp*).

Now let's examine the other character. Full × shrunken produces $^1/_2$ full and $^1/_2$ shrunken, or a 1:1 ratio, so these progeny phenotypes are also produced by a cross between a heterozygote (*Ff*) and a homozygote (*ff*); the full-kernel progeny will be heterozygous (*Ff*), and the shrunken-kernel progeny will be homozygous (*f f*).

Now combine the two crosses and use the multiplication rule to obtain the overall genotypes and the proportions of each genotype:

Recall: The multiplication rule states that the probability of two or more independent events occurring together is calculated by multiplying their independent probabilities.

P	Purple, full *Pp Ff*	×	Yellow, shrunken *pp ff*
F_1	*Pp Ff* = ½ purple	×	½ full = ¼ purple, full
	Pp ff = ½ purple	×	½ shrunken = ¼ purple, shrunken
	Pp Ff = ½ yellow	×	½ full = ¼ yellow, full
	Pp ff = ½ yellow	×	½ shrunken = ¼ yellow, shrunken

Description
The P generation at the top shows a purple full parent with genotype big P small P big F small F is crossed with a yellow shrunken parent with genotype small P small P small F small F. The F subscript 1 generation obtained below is as follows:

Big P small P big F small F equals one half purple crossed with one half full equals one fourth purple, full.

Big P small P small F small F equals one half purple crossed with one half shrunken equals one fourth purple, shrunken.

Big P small P big F small F equals one half yellow crossed with one half full equals one fourth yellow, full.

Big P small P small F small F equals one half yellow crossed with one half shrunken equals one fourth yellow, shrunken.

Our genetic calculations predict that from this cross, we should see $^1/_4$ purple, full-kernel progeny; $^1/_4$ purple, shrunken-kernel progeny; $^1/_4$ yellow, full-kernel progeny; and $^1/_4$ yellow, shrunken-kernel progeny. A total of 400 progeny were produced, so $^1/_4 \times 400 = 100$ of

each phenotype are expected. Therefore, the observed numbers do not fit the expected numbers exactly.

Could the difference between what we observe and what we expected be due to chance? If the probability is high that chance alone is responsible for the difference between observed and expected values, we will assume that the progeny have been produced in the 1:1:1:1 ratio predicted for the cross. If the probability is low that the difference between observed and expected values is due to chance, we will assume that the progeny really are not in the predicted ratio and that some other, *significant* factor must be responsible for the deviation from our expectations.

The observed and expected numbers are

Phenotype	Observed	Expected
purple, full	112	$^1/_4 \times 400 = 100$
purple, shrunken	103	$^1/_4 \times 400 = 100$
yellow, full	91	$^1/_4 \times 400 = 100$
yellow, shrunken	94	$^1/_4 \times 400 = 100$

To determine the probability that the difference between observed and expected numbers is due to chance, we calculate a chi-square

value using the formula

$$\begin{aligned}
\chi^2 &= \Sigma[(\text{observed} - \text{expected})^2/\text{expected}]: \\
\chi^2 &= \frac{(112-100)^2}{100} + \frac{(103-100)^2}{100} \\
&\quad + \frac{(91-100)^2}{100} + \frac{(94-100)^2}{100} \\
&= \frac{12^2}{100} + \frac{3^2}{100} + \frac{9^2}{100} + \frac{6^2}{100} \\
&= \frac{144}{100} + \frac{9}{100} + \frac{81}{100} + \frac{36}{100} \\
&= 1.44 + 0.09 + 0.81 + 0.36 = 2.70
\end{aligned}$$

Hint: See Figure 3.15 for help on how to carry out a chi-square test.

The next step is to determine the probability associated with this calculated chi-square value, which is the probability that the deviation between the observed and the expected results is due to chance. This step requires us to compare our calculated chi-square value (2.70) with theoretical values in a chi-square table that have the same degrees of freedom. The degrees of freedom for a chi-square goodness-of-fit test are $n - 1$, where n equals the number of expected phenotypic classes. In this case, there are four expected phenotypic classes, so the degrees of freedom equal 4 − 1 = 3. We must now look up the chi-square value in a chi-square table (see Table 3.7). We select the row corresponding to 3 degrees of freedom and look along this row to find our calculated chi-square value. The

calculated chi-square value of 2.7 lies between 2.366 (a probability of 0.5) and 6.251 (a probability of 0.1). The probability (*P*) associated with the calculated chi-square value is therefore $0.5 > P > 0.1$. This *P* is the probability that the difference between what we observed and what we expected is due to chance, which in this case is relatively high, so chance is probably responsible for the deviation. We can conclude that the progeny *do* appear in the 1:1:1:1 ratio predicted by our genetic explanation.

ANSWERS TO CONCEPT CHECKS

1. b
2. A locus is a place on a chromosome where genetic information encoding a characteristic is located. An allele is a version of a gene that encodes a specific trait. A genotype is the set of alleles possessed by an individual organism, and a phenotype is the manifestation or appearance of a characteristic.
3. The traits encoded by both alleles appeared in the F_2 progeny.
4. d
5. a
6. Both the principle of segregation and the principle of independent assortment refer to the separation of alleles in anaphase I of meiosis. The principle of segregation says that

these alleles separate, and the principle of independent assortment says that they separate independently of alleles at other loci.

7. d

Chapter 3 Assessment

COMPREHENSION QUESTIONS

Section 3.1

1. Why was Mendel's approach to the study of heredity so successful?

2. What is the difference between genotype and phenotype?

Section 3.2

3. What is the principle of segregation? Why is it important?

4. CONNECT How are Mendel's principles different from the concept of blending inheritance discussed in Chapter 1?

5. What is the concept of dominance?

6. What are the addition and multiplication rules of probability, and when should they be used?

7. Give the genotypic ratios that may appear among the progeny of simple crosses and the genotypes of the parents that may give rise to each ratio.

8. What is the chromosome theory of heredity? Why was it important?

Section 3.3

9. What is the principle of independent assortment? How is it related to the principle of segregation?

10.

In which stages of mitosis and meiosis are the principles of segregation and independent assortment at work?

Section 3.4

11. How is the chi-square goodness-of-fit test used to analyze genetic crosses? What does the probability associated with a chi-square value indicate about the results of a cross?

APPLICATION QUESTIONS AND PROBLEMS

Introduction

12. If blond hair in the Solomon Islanders had originated from early European explorers, what would you predict the researchers

would have found when they conducted their genetic study of the islanders?

Section 3.1

13. *What characteristics of an organism would make it suitable for studies of the principles of inheritance? Name several organisms that have these characteristics.

Section 3.2

14. *In cucumbers, orange fruit color (*R*) is dominant to cream fruit color (*r*). A cucumber plant homozygous for orange fruit is crossed with a plant homozygous for cream fruit. The F_1 are intercrossed to produce the F_2.

    a. Give the genotypes and phenotypes of the parents, the F_1, and the F_2.

    b. Give the genotypes and phenotypes of the offspring of a backcross between the F_1 and the orange-fruited parent.

    c. Give the genotypes and phenotypes of a backcross between the F_1 and the cream-fruited parent.

15. CONNECT **Figure 1.1** shows three girls, one of whom has albinism. Could the three girls shown in the photograph be sisters? Why or why not?

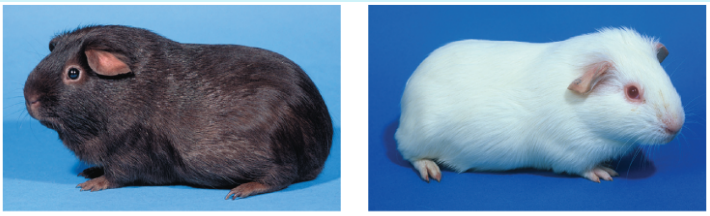
16. DATA ANALYSIS J. W. McKay crossed a stock melon plant that produced tan seeds with a plant that produced red seeds and obtained the following results (J. W. McKay. 1936. *Journal of Heredity* 27:110–112).

Cross	F_1	F_2
tan ♀ × red ♂	13 tan seeds	93 tan, 24 red, seeds

a. Explain the inheritance of tan and red seeds in this plant.

b. Assign symbols for the alleles in this cross, and give genotypes for all the individual plants.

17. DATA ANALYSIS CONNECT *White (*w*) coat color in guinea pigs is recessive to black (*W*). In 1909, W. E. Castle and J. C. Phillips transplanted an ovary from a black guinea pig into a white female whose ovaries had been removed. They then mated this white female with a white male. All the offspring from the mating were black (W. E. Castle and J. C. Phillips. 1909. *Science* 30:312–313).



Wegner/ARCO/Nature Picture Library; Nigel Cattlin/Alamy.

a. Explain the results of this cross.

b. Give the genotype of the offspring of this cross.

c. What, if anything, does this experiment indicate about the validity of the pangenesis and the germ-plasm theories discussed in Chapter 1?

18. *In cats, blood type A results from an allele (I^A) that is dominant to an allele (i^B) that produces blood type B. There is no O blood type. The blood types of male and female cats that were mated and the blood types of their kittens follow. Give the most likely genotypes for the parents of each litter.

	Male parent	Female parent	Kittens
a.	A	B	4 with type A, 3 with type B
b.	B	B	6 with type B
c.	B	A	8 with type A
d.	A	A	7 with type A, 2

			with type B
e.	A	A	10 with type A
f.	A	B	4 with type A, 1 with type B

19. Figure 3.8 shows the results of a cross between a tall pea plant and a short pea plant.

    a. What phenotypes and proportions will be produced if a tall F_1 plant is backcrossed to the short parent?

    b. What phenotypes and proportions will be produced if a tall F_1 plant is backcrossed to the tall parent?

20. Joe has a white cat named Sam. When Joe crosses Sam with a black cat, he obtains $^1/_2$ white kittens and $^1/_2$ black kittens. When the black kittens are interbred, all the kittens that they produce are black. On the basis of these results, would you conclude that white or black coat color in cats is a recessive trait? Explain your reasoning.

21. *In sheep, lustrous fleece results from an allele (L) that is dominant to an allele (l) for normal fleece. A ewe (adult female) with lustrous fleece is mated with a ram (adult male) with

normal fleece. The ewe then gives birth to a single lamb with normal fleece. From this single offspring, is it possible to determine the genotypes of the two parents? If so, what are their genotypes? If not, why not?

Jeffrey van Daele/FeaturePics.

22. *Alkaptonuria is a metabolic disorder in which affected people produce black urine. Alkaptonuria results from an allele (*a*) that is recessive to the allele for normal metabolism (*A*). Sally has normal metabolism, but her brother has alkaptonuria. Sally's

father has alkaptonuria, and her mother has normal metabolism.

a. Give the genotypes of Sally, her mother, her father, and her brother.

b. If Sally's parents have another child, what is the probability that this child will have alkaptonuria?

c. If Sally marries a man with alkaptonuria, what is the probability that their first child will have alkaptonuria?

23. In rabbits, coat color is a genetically determined trait. Some black females always produce black progeny, whereas other black females produce black progeny and white progeny. Explain how this occurs.

24. Hairlessness in American rat terriers is recessive to the presence of hair. Suppose that you have a rat terrier with hair. How can you determine whether this dog is homozygous or heterozygous for the hairy trait?

25. *What is the probability of rolling one six-sided die and obtaining the following numbers?

a. 2

b. 1 or 2

c. An even number

d. Any number but a 6

26. *What is the probability of rolling two six-sided dice and obtaining the following numbers?

    a. 2 and 3

    b. 6 and 6

    c. At least one 6

    d. Two of the same number (two 1s, two 2s, two 3s, etc.)

    e. An even number on both dice

    f. An even number on at least one die

27. *In a family of seven children, what is the probability of obtaining the following distribution of boys and girls?

    a. All boys

    b. All children of the same sex

    c. Six girls and one boy

    d. Four boys and three girls

    e. Four girls and three boys

28. Phenylketonuria (PKU) is a disease that results from a recessive gene. Suppose that two unaffected parents produce a child with PKU.

a. What is the probability that a sperm from the father will contain the PKU allele?

b. What is the probability that an egg from the mother will contain the PKU allele?

c. What is the probability that their next child will have PKU?

d. What is the probability that their next child will be heterozygous for the PKU gene?

29. CONNECT *In German cockroaches, curved wings (*cv*) are recessive to normal wings (cv^+). A homozygous cockroach having normal wings is crossed with a homozygous cockroach having curved wings. The F_1 are intercrossed to produce the F_2. Assume that the pair of chromosomes containing the locus for wing shape is metacentric. Draw this pair of chromosomes as it would appear in the parents, the F_1, and each class of F_2 progeny at metaphase I of meiosis. Assume that no crossing over takes place. At each stage, label a location for the alleles for wing shape (*cv* and cv^+) on the chromosomes.

30. CONNECT *In guinea pigs, the allele for black fur (*B*) is dominant to the allele for brown (*b*) fur. A black guinea pig is crossed with a brown guinea pig, producing five F_1 black guinea pigs and six F_1 brown guinea pigs.

a. How many copies of the black allele (*B*) will be present in each cell of an F_1 black guinea pig at the following stages: G_1, G_2, metaphase of mitosis, metaphase I of meiosis, metaphase II of meiosis, and after the second cytokinesis following meiosis? Assume that no crossing over takes place.

b. How many copies of the brown allele (*b*) will be present in each cell of an F_1 brown guinea pig at the same stages as those listed in part *a*? Assume that no crossing over takes place.

Section 3.3

31. In watermelons, bitter fruit (*B*) is dominant to sweet fruit (*b*), and yellow spots (*S*) are dominant to no spots (*s*). The genes for these two characteristics assort independently. A homozygous plant that has bitter fruit and yellow spots is crossed with a homozygous plant that has sweet fruit and no spots. The F_1 are intercrossed to produce the F_2.

    a. What are the phenotypic ratios in the F_2?

    b. If an F_1 plant is backcrossed with the bitter, yellow-spotted parent, what phenotypes and proportions are expected in the offspring?

    c. If an F_1 plant is backcrossed with the sweet, unspotted parent, what phenotypes and proportions are expected in the

offspring?

32. **Figure 3.11** shows the results of a dihybrid cross involving seed shape and seed color.

    a. What proportion of the round and yellow F_2 progeny from this cross is homozygous at both loci?

    b. What proportion of the round and yellow F_2 progeny from this cross is homozygous at least at one locus?

33. *In cats, curled ears result from an allele (*Cu*) that is dominant to an allele (*cu*) for normal ears. Black color results from an independently assorting allele (*G*) that is dominant to an allele for gray (*g*). A gray cat homozygous for curled ears is mated with a homozygous black cat with normal ears. All the F_1 cats are black and have curled ears.

    a. If two of the F_1 cats mate, what phenotypes and proportions are expected in the F_2?

    b. An F_1 cat mates with a stray cat that is gray and possesses normal ears. What phenotypes and proportions of progeny are expected from this cross?

Jean-Michel Labat/Science Source.

34. *The following two genotypes are crossed: *Aa Bb Cc dd Ee* × *Aa bb Cc Dd Ee*. What will the proportion of the following genotypes be among the progeny of this cross?

    a. *Aa Bb Cc Dd Ee*

    b. *Aa bb Cc dd ee*

    c. *aa bb cc dd ee*

    d. *AA BB CC DD EE*

35. In mice, an allele for apricot eyes (*a*) is recessive to an allele for brown eyes (a^+). At an independently assorting locus, an allele

for tan coat color (t) is recessive to an allele for black coat color (t^+). A mouse that is homozygous for brown eyes and black coat color is crossed with a mouse having apricot eyes and a tan coat. The resulting F_1 are intercrossed to produce the F_2. In a litter of eight F_2 mice, what is the probability that two will have apricot eyes and tan coats?

36. In cucumbers, dull fruit (D) is dominant to glossy fruit (d), orange fruit (R) is dominant to cream fruit (r), and bitter cotyledons (B) are dominant to non-bitter cotyledons (b). The three characters are encoded by genes located on different pairs of chromosomes. A plant homozygous for dull, orange fruit and bitter cotyledons is crossed with a plant that has glossy, cream fruit and non-bitter cotyledons. The F_1 are intercrossed to produce the F_2.

    a. Give the phenotypes and their expected proportions in the F_2.

    b. An F_1 plant is crossed with a plant that has glossy, cream fruit and non-bitter cotyledons. Give the phenotypes and expected proportions among the progeny of this cross.

37.

*Alleles *A* and *a* are located on a pair of metacentric chromosomes. Alleles *B* and *b* are located on a pair of acrocentric chromosomes (see Chapter 2). A cross is made between individuals having the following genotypes: *Aa Bb* × *aa bb*.

a. Draw the chromosomes as they would appear in each type of gamete produced by these individuals.

b. For each type of progeny resulting from this cross, draw the chromosomes as they would appear in a cell at G_1, G_2, and metaphase of mitosis.

Section 3.4

38. *J. A. Moore investigated the inheritance of spotting patterns in leopard frogs (J. A. Moore. 1943. *Journal of Heredity* 34:3–7). The pipiens phenotype had the normal spots that give leopard frogs their name. In contrast, the burnsi phenotype lacked spots on its back. Moore carried out the following crosses, producing the progeny indicated.

Parent phenotypes	Progeny phenotypes
burnsi × burnsi	39 burnsi, 6 pipiens
burnsi × pipiens	23 burnsi, 33 pipiens
burnsi × pipiens	196 burnsi, 210 pipiens

a. On the basis of these results, is the burnsi phenotype most likely inherited as a dominant trait or as a recessive trait?

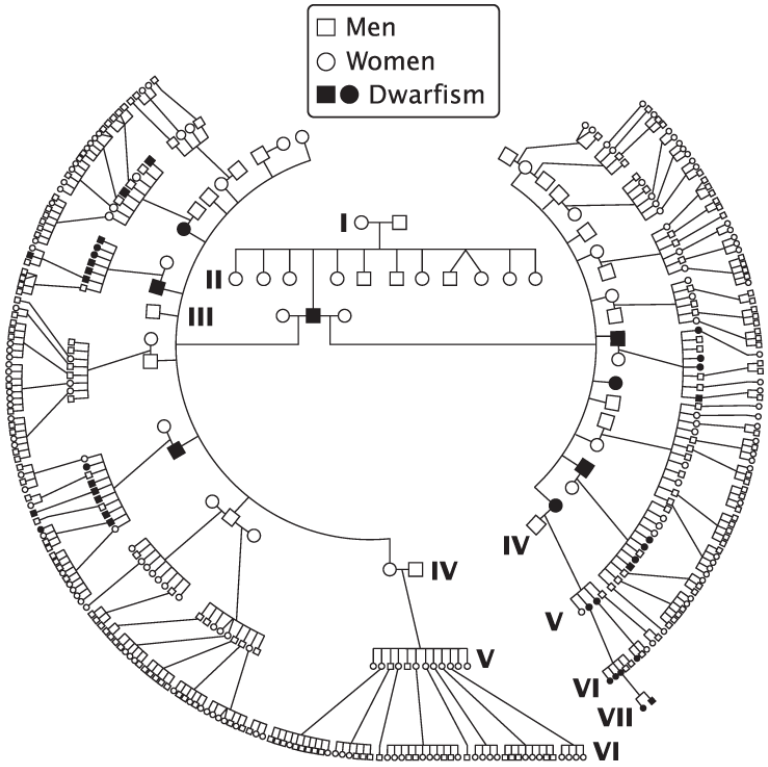
b. Give the most likely genotypes of the parent in each cross (use *B* for the burnsi allele and B^+ for the pipiens allele).

c. Use a chi-square test to evaluate the fit of the observed numbers of progeny to the number expected on the basis of your proposed genotypes.

39. In the 1800s, a man with dwarfism who lived in Utah produced a large number of descendants: 22 children, 49 grandchildren, and 250 great-grandchildren (see the illustration of a family pedigree below), many of whom also exhibited dwarfism (F. F. Stephens. 1943. *Journal of Heredity* 34:229–235). The type of dwarfism found in this family is called Schmid-type metaphyseal chondrodysplasia, although it was originally thought to be achondroplastic dwarfism. Among the families of this kindred, dwarfism appeared only in members who had one parent with dwarfism. When one parent exhibited dwarfism, the following numbers of children were produced.

Family in which one parent had dwarfism	Children with normal stature	Children with dwarfism
A	15	7
B	4	6
C	1	6

D	6	2
E	2	2
F	8	4
G	4	4
H	2	1
I	0	1
J	3	1
K	2	3
L	2	1
M	2	0
N	1	0
O	0	2
Total	52	40



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

[Data from *the Journal of Heredity* 34:232.]

Description
Generations 1 through 3 are in the center and generations 4 through 6 have large number of people. They are drawn as circles around the first 3 generations. Men are represented as squares and women as circles. The trait for dwarfism is shown with a filled circle or square. Generation 3 has one male dwarf. The male in generation 3 has 4 dwarf children out of 11 with one female and 3 dwarf children out of 10 with another female. None of the non-dwarfs had dwarf children. The people who were dwarfs had some children who were dwarfs.

a. With the assumption that Schmid-type metaphyseal chondrodysplasia is rare, is this type of dwarfism inherited as a dominant or a recessive trait? Explain your reasoning.

b. On the basis of your answer for part *a*, what is the expected ratio of children with dwarfism to children with normal stature in the families given in the table? Use a chi-square test to determine if the total number of children with each phenotype in these families (52 with normal stature, 40 with dwarfism) is significantly different from the number expected.

c. Use chi-square tests to determine if the numbers of children with each phenotype in family C (1 with normal stature, 6 with dwarfism) and in family D (6 with normal stature, 2 with dwarfism) are significantly different from the numbers expected on the basis of your proposed mode of inheritance. How would you explain these deviations from the overall ratio expected?

40.

Pink-eye and albino are two recessive traits found in the deer mouse *Peromyscus maniculatus*. In pink-eyed mice, the eye is devoid of color and appears pink because of the blood vessels within it. Albino mice are completely lacking color, both in their fur and in their eyes. F. H. Clark crossed pink-eyed mice with albino mice; the resulting F_1 had normal coloration in their fur and eyes. He then crossed these F_1 mice with mice that were pink eyed and albino and obtained the following progeny. It is hard to distinguish between mice that are albino and mice that are both pink eyed and albino, so he combined these two phenotypes (F. H. Clark. 1936. *Journal of Heredity* 27:259–260).

Phenotype	**Number of progeny**

wild-type fur, wild-type eye color	12
wild-type fur, pink-eye	62
albino albino, pink-eye }	78
Total	152

a. Give the expected numbers of progeny with each phenotype if the genes for pink-eye and albino assort independently.

b. Use a chi-square test to determine if the observed numbers of progeny fit the number expected with independent assortment.

41. *In the California poppy, an allele for yellow flowers (*C*) is dominant to an allele for white flowers (*c*). At an independently assorting locus, an allele for entire petals (*F*) is dominant to an allele for fringed petals (*f*). A plant that is homozygous for yellow and entire petals is crossed with a plant that has white and fringed petals. A resulting F_1 plant is then crossed with a plant that has white and fringed petals, and the following progeny are produced: 54 yellow and entire; 58 yellow and fringed; 53 white and entire; 10 white and fringed.

a. Use a chi-square test to compare the observed numbers of progeny having each phenotype with those expected for the cross.

b. What conclusion can you draw from the results of the chi-square test?

c. Suggest an explanation for the results.

CHALLENGE QUESTIONS

Section 3.2

42. Dwarfism is a recessive trait in Hereford cattle; the gene causing this trait has not been identified. A rancher in western Texas discovers that several of the calves in his herd are dwarfs, and he wants to eliminate this undesirable trait from the herd as rapidly as possible. Suppose that the rancher hires you as a genetic consultant to advise him on how to breed the dwarfism trait out of the herd. What crosses would you advise the rancher to conduct to ensure that the allele causing dwarfism is eliminated from the herd?

43. *A geneticist discovers an obese mouse in his laboratory colony. He breeds this obese mouse with a normal mouse. All the F_1 mice from this cross are normal in size. When he interbreeds two F_1 mice, eight of the F_2 mice are normal in size and two are obese. The geneticist then intercrosses two of his obese mice, and he finds that all the progeny from this cross are obese. These results lead the geneticist to conclude that obesity in mice results from a recessive allele.

A second geneticist at a different university also discovers an obese mouse in her laboratory colony. She carries out the same crosses as the first geneticist and obtains the same results. She also concludes that obesity in mice results from a recessive allele.

One day the two geneticists meet at a genetics conference, learn of each other's experiments, and decide to exchange mice. They both find that when they cross two obese mice from the different laboratories, all the offspring are normal; however, when they cross two obese mice from the same laboratory, all the offspring are obese. Explain their results.

44.

Albinism is a recessive trait in humans (see the introduction to Chapter 1). A geneticist studies a series of families in which both parents have pigmentation and at least one child has albinism. The geneticist reasons that both parents in these families must be heterozygotes and that albinism should appear in $^1/_4$ of their children. To his surprise, the geneticist finds that the frequency of albinism among the children of these families is significantly greater than $^1/_4$. Can you think of an explanation for the higher-than-expected frequency of albinism among these families?

45. Two distinct phenotypes are found in the salamander *Plethodon cinereus*: a red form and a black form. Some biologists have speculated that the red phenotype is due to an allele that is dominant to an allele for black. Unfortunately, these

salamanders will not mate in captivity, so the hypothesis that red is dominant to black has never been tested.

One day, a genetics student is hiking through the forest and finds 30 female salamanders, some red and some black, laying eggs. The student places each female with her eggs (about 20 to 30 eggs per female) in a separate plastic bag and takes them back to the lab. There, the student successfully raises the eggs until they hatch. After the eggs have hatched, the student records the phenotypes of the juvenile salamanders, along with the phenotypes of their mothers. Thus, the student has the phenotypes for 30 females and their progeny, but no information is available about the phenotypes of the fathers.

Explain how the student can determine whether red is dominant to black with this information on the phenotypes of the females and their offspring.

ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Introduction

1. About 40% of Solomon Islanders carry a gene for blond hair, and yet only 5%–10% of these people actually have blond hair. Why is the proportion of people with blond hair only 5%–10% when so many people carry genes for blond hair?

Section 3.1

2. Why was Mendel's success dependent on his studying characteristics that exhibit only two easily distinguished phenotypes, such as white versus gray seed coats and round versus wrinkled seeds? Would he have been less successful if he had instead studied traits such as seed weight or leaf length, which vary much more in their phenotypes? Explain your answer.

Section 3.2

3. Geneticists often carry out reciprocal crosses when they are studying the inheritance of traits. Why do geneticists use reciprocal crosses?

4. Red hair in humans is inherited as a recessive trait. Bill and Sarah both have black hair. They marry and have four children, three of whom have red hair. Bill says it isn't genetically possible for two black-haired people to have $^3/_4$ red-haired children, and he accuses Sarah of infidelity. Sarah asserts that Bill doesn't understand genetics and probability, and that it is possible for two black-haired people to have $^3/_4$ red-haired children. Who is correct and why?

5. Suppose that you are raising Mongolian gerbils. You notice that some of your gerbils have white spots, whereas others have solid coats. What type of crosses could you carry out to determine whether white spots are due to a recessive or a dominant allele?

Section 3.3

6. Are Mendel's principles of segregation and independent assortment even relevant today in the age of genomics, when it is possible to sequence an organism's entire genome and determine all of its genetic information? Why is it important to study these principles, and how can they be used?

7. In cats, short hair (*L*) is dominant to long hair (*l*), and stripes (*A*) are dominant to solid color (*a*). A cat with genotype *Ll Aa* mates with a cat that is *Ll aa*, and they produce a litter of six kittens. What is the probability that four of the six kittens will have both long hair and stripes?

Section 3.4

8. In corn, purple kernels (*P*) are dominant to yellow kernels (*p*), and starchy kernels (*Su*) are dominant to sugary kernels (*su*). A corn plant grown from a purple and starchy kernel is crossed with a plant grown from a yellow and sugary kernel, and the following progeny (kernels) are produced:

Phenotype	Number
purple, starchy	150
purple, sugary	142
yellow, starchy	161

yellow, sugary	115

Formulate a hypothesis about the genotypes of the parents and offspring in this cross. Perform a chi-square goodness-of-fit test comparing the observed numbers of progeny with the numbers expected based on your genetic hypothesis. What conclusion can you draw based on the results of your chi-square test? Can you suggest an explanation for the observed results?

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Introduction

1. Draw a concept map that explains the genetic basis of blond hair in Solomon Islanders using the following terms: Solomon Islanders, Europeans, blond hair, recessive trait, dark hair, melanin, chromosome 9, dominant trait, *TYRP1*, *KITLG*, *TT*, *CT*, *CC*.

Section 3.1

2. Outline the relationships among important genetic terminology by creating a concept map that relates the following terms: phenotype, gene, homozygous, heterozygous, locus, allele, genotype.

Section 3.2

3. Using a concept map, compare and contrast the principle of segregation (Mendel's first law) and the principle of independent assortment (Mendel's second law).

SaplingPlus Self-study tools that will help you practice what you've learned and reinforce this chapter's concepts are available online. Go to www.saplinglearning.com.

CHAPTER 4

Sex Determination and Sex-Linked Characteristics

© Matej Kastelic/Alamy.

In European traditions, dragons are often portrayed as large lizards. This statue adorns the Dragon Bridge in Ljubljana, Slovenia.

The Sex of a Dragon

Dragons are the stuff of kids' tales and nightmares—giant fire-breathing reptiles that destroy everything in their path. These mythical creatures have a long history, appearing in folk traditions of

both Europe and Asia. Almost always reptilian, dragons were originally depicted as snakelike, but since the Middle Ages they have been increasingly drawn with legs, often imagined as large lizards. In European traditions, dragons are usually evil, but in Asian myths, dragons are a symbol of benevolent power and sometimes of fertility.

Real dragons are found in the deserts of central Australia. Known as central bearded dragons (*Pogona vitticeps*), these lizards grow up to two feet in length (**Figure 4.1**). Like some of their mythical relatives, they possess numerous spines that run from head to tail. Their color varies widely, from brown to gray, red, yellow, orange, or even white. Bearded dragons derive their name from a pouch that projects from the underside of the chin, often appearing dark in color,like a man's beard. When threatened, they open their mouths and hiss, imitating their mythological namesake (but, disappointingly, without the fire). But it is through their sex that bearded dragons have become best known to geneticists.

© Juniors Bildarchiv GmbH/Alamy.

4.1 A central bearded dragon (*Pogona vitticeps*).

As we learn in this chapter, organisms employ an amazing variety of mechanisms to determine sex—whether an organism is male or female. In some, such as humans, sex is determined by chromosomes: females possess two identical sex chromosomes (X chromosomes), and males possess a single X and a different chromosome, called Y. In others, such as birds, butterflies, and some reptiles, sex is still chromosomal, but it is the male that possesses two identical sex chromosomes (called Z chromosomes) and the female that has two different sex chromosomes (called Z and W). There are even some animals for which sex is not determined by sex chromosomes at all but is primarily a function of the environment: in turtles and alligators, sex is influenced by the temperature at which the eggs are incubated, with males produced at one temperature and females at another.

For many years, scientists thought that sex determination could be genetic or environmental, but not both. In 2015, however, scientists reported the results of field and laboratory studies demonstrating unequivocally that sex in bearded dragons is determined by sex chromosomes *and* the temperature at which their eggs are incubated.

A female bearded dragon lays a clutch of 11 to 30 eggs in a nest in the sand. The female then leaves the nest, and the eggs develop unattended, warmed by the desert sun. Eventually, baby dragons emerge from the eggs.

Bearded dragons have sex chromosomes: males are normally ZZ and females are ZW. Scientists discovered, however, that over 20% of wild-caught females examined in one year had ZZ sex chromosomes, which are expected only in males. The scientists found that when they incubated eggs with ZZ embryos at temperatures below 32°C, the offspring were all males (as expected), but as they increased the incubation temperature, more and more ZZ embryos developed as females. At 36°C, almost all the ZZ individuals were females. They concluded that ZZ females found in the wild probably hatched from warm nests. Matings between ZZ males and ZZ females produced viable and fertile offspring, all ZZ; for unknown reasons, ZZ females themselves lay twice as many eggs as normal ZW females. In contrast to ZZ lizards, which can be male or female depending on incubation temperature, ZW lizards are always female. One concern of the researchers was how these lizards might respond to future

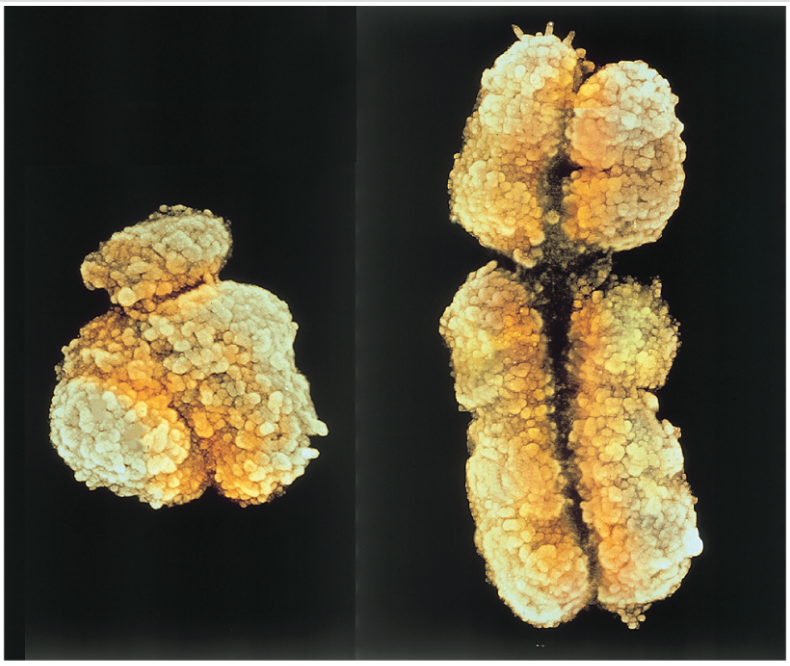
climate change. If the environment warms significantly, only females may be produced, leading to the extinction of the species.

THINK-PAIR-SHARE

- Climate warming could lead to all-female populations of bearded dragons, resulting in extinction of the species. What are some other potential effects of climate warming on natural populations of organisms?
- High incubation temperatures reverse the sex of ZZ bearded dragons, causing them to develop as females instead of males. Imagine that temperature also caused sex reversal in ZW individuals, so that high temperatures caused ZW individuals to develop as males instead of females (this doesn't actually happen in bearded dragons). What would be the result of a mating between a normal ZW female and a sex-reversed ZW male?

In Chapter 3, we studied Mendel's principles of segregation and independent assortment and saw how these concepts explain much about the nature of inheritance. After Mendel's principles were rediscovered in 1900, biologists began to conduct genetic studies on a wide array of different organisms. As they applied Mendel's principles more widely, they observed exceptions that made it necessary to devise extensions of those basic principles. In this chapter, we explore one of those extensions: the inheritance of characteristics encoded by genes located on the sex chromosomes, which often differ between males and females (**Figure 4.2**). These characteristics, and the genes that produce them, are referred to as sex linked. To understand the inheritance of sex-linked characteristics, we must first know how sex is determined—why some members of a species are male and others are female. Thus, the first part of this chapter focuses on sex determination. The

second part examines how characteristics encoded by genes on the sex chromosomes are inherited and some of the consequences of this inheritance. In Chapter 5, we will explore some additional ways in which sex and inheritance interact.



Biophoto Associates/Science Source.

4.2 The human male sex chromosome (Y, at the left) differs from the human female sex chromosome (X, at the right) in size and shape.

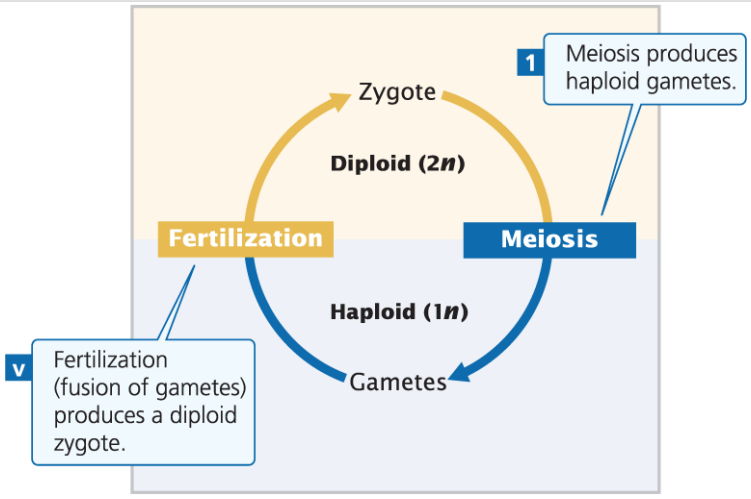
Description
The Y-chromosome has 3 distinct thick sections clumped together and is relatively half the size of the elongated X-chromosome with 4 sections.

As we consider sex determination and sex-linked characteristics, it will be helpful to keep two important principles in mind. First, there are several different mechanisms of sex determination, and ultimately, a species' mechanism of sex determination controls its

inheritance of sex-linked characteristics. Second, like other pairs of chromosomes, the X and Y sex chromosomes pair in the course of meiosis and segregate, but throughout most of their length, they are not homologous (their gene sequences do not encode the same characteristics): most genes on the X chromosome are different from genes on the Y chromosome. Consequently, males and females do not possess the same numbers of alleles at sex-linked loci. This difference in the number of sex-linked alleles produces distinct patterns of inheritance in males and females.

4.1 Sex Is Determined by a Number of Different Mechanisms

Sexual reproduction is the formation of offspring that are genetically distinct from their parents; most often, two parents contribute genes to their offspring, and those genes are assorted into new combinations through meiosis. Among most eukaryotes, sexual reproduction consists of two processes that lead to an alternation of haploid and diploid cells: meiosis produces haploid gametes (spores in plants), and fertilization produces diploid zygotes (Figure 4.3).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

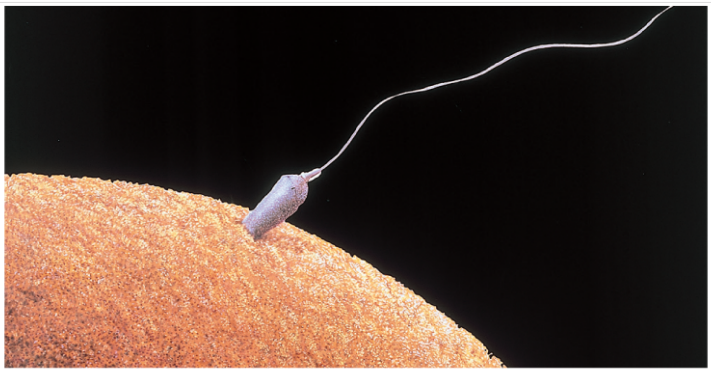
4.3 In most eukaryotic organisms, sexual reproduction consists of an alternation of haploid (1*n*) and diploid (2*n*) cells.

Description

The illustration is divided into two parts diploid (2 n) and haploid (1 n). It starts with zygote in diploid stage, which undergoes meiosis to produce gametes that are haploid. A caption

reads, Meiosis produces haploid gametes. Gametes then undergo fertilization to produce zygote. A caption reads, Fertilization (fusion of gametes) produces a diploid zygote. The cycle repeats.

The term **sex** refers to sexual phenotype. Most organisms have two sexual phenotypes: male and female. The fundamental difference between males and females is gamete size: males produce small gametes, and females produce relatively large gametes (**Figure 4.4**).



Francis Leroy, Biocosmos/Science Source.

4.4 Male and female gametes differ in size. In this photograph, a human sperm (with flagellum) penetrates a human egg.

The mechanism by which biological sex is established is termed **sex determination**. We define the sex of an individual organism in reference to its phenotype. Sometimes an individual organism has chromosomes or genes that are normally associated with one sex but an anatomy corresponding to the opposite sex. For instance, the cells of human females normally have two X chromosomes, and the cells of males have one X chromosome and one Y chromosome. A few rare individuals have male anatomy although their cells each

contain two X chromosomes. Even though these people are genetically female, we refer to them as male because their sexual phenotype is male. (As we see later in the chapter, these XX males usually have a small piece of the Y chromosome that is attached to another chromosome.)

Gender is not the same as sex. Biological sex refers to the anatomical and physiological phenotype of an individual. Gender is a category assigned by the individual or others based on behavior and cultural practices. One's gender need not coincide with one's biological sex.

CONCEPTS

In sexual reproduction, two parents contribute genes to produce an offspring that is genetically distinct from both parents. In most eukaryotes, sexual reproduction consists of meiosis, which produces haploid gametes (or spores), and fertilization, which produces a diploid zygote.

✔ CONCEPT CHECK 1

What process causes the genetic variation seen in offspring produced by sexual reproduction?

As discussed in the introduction to this chapter, there are many ways in which sex differences arise. What are some of the different ways in which sex is determined in different organisms?

In some species, both sexes are present in the same organism, a condition termed **hermaphroditism**; organisms that bear both male and female reproductive structures are said to be **monoecious** (meaning "one house"). Species in which an individual organism has either male or female reproductive structures are said to be **dioecious** ("two houses"). Humans are dioecious. Among dioecious species, sex may be determined chromosomally, genetically, or environmentally.

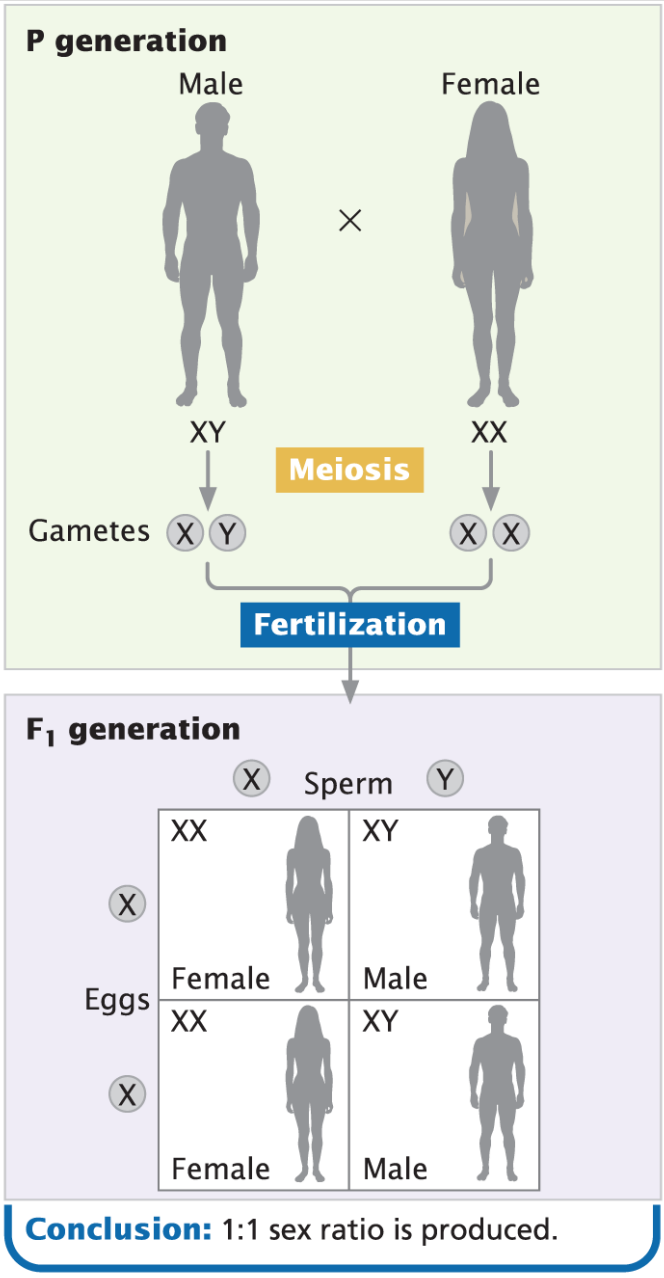
Chromosomal Sex-Determining Systems

The chromosome theory of heredity (see Chapter 3) states that genes are located on chromosomes, which serve as vehicles for the segregation of genes in meiosis. Definitive proof of this theory was provided by the discovery that the sex of certain insects is determined by the presence or absence of particular chromosomes.

In 1891, Hermann Henking noticed a peculiar structure in the nuclei of cells from male insects. Understanding neither its function nor its relation to sex, he called this structure the X body. Later, Clarence E. McClung studied the X body in grasshoppers and recognized that it was a chromosome. McClung called it the accessory chromosome, but it eventually became known as the X chromosome, from Henking's original designation. McClung observed that the cells of

female grasshoppers had one more chromosome than the cells of male grasshoppers, and he concluded that accessory chromosomes played a role in sex determination. In 1905, Nettie Stevens and Edmund Wilson demonstrated that in grasshoppers and other insects, the cells of females have two X chromosomes, whereas the cells of males have a single X. In some insects, they counted the same number of chromosomes in the cells of males and females but saw that one chromosome pair was different: two X chromosomes were found in female cells, whereas a single X chromosome plus a smaller chromosome, which they called Y, was found in male cells.

Stevens and Wilson also showed that the X and Y chromosomes separate into different cells in sperm formation: half of the sperm receive an X chromosome and the other half receive a Y. All eggs produced by the female in meiosis receive one X chromosome. A sperm containing a Y chromosome unites with an X-bearing egg to produce an XY male, whereas a sperm containing an X chromosome unites with an X-bearing egg to produce an XX female. This distribution of X and Y chromosomes in sperm accounts for the 1:1 sex ratio observed in most dioecious organisms (**Figure 4.5**). Because sex is inherited like other genetically determined characteristics, Stevens and Wilson's discovery that sex is associated with the inheritance of a particular chromosome also demonstrated that genes are located on chromosomes.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

4.5 Inheritance of sex in organisms with X and Y chromosomes results in equal numbers of male and female offspring.

Description

The illustration shows P generation where a male human with genotype big X big Y is crossed with a female human with genotype big X big X. Meiosis occurs and the gametes

produced are as follows: big X and big Y from male, big X and big X from female. Fertilization occurs and F subscript 1 generation is obtained. A Punnett square with two rows and two columns has the following entries:

The row headers represent eggs and are as follows: big X and big X.

The column headers represent sperm and are as follows: big X and big Y.

Row 1 column 1: big X big X (female)

Row 1 column 2: big X big Y (male)

Row 2 column 1: big X big X (female)

Row 2 column 2: big X big Y (male)

The conclusion states that 1 is to 1 sex ratio is produced.

As Stevens and Wilson found for insects, sex in many organisms is determined by a pair of chromosomes, the **sex chromosomes**, which differ between males and females. The nonsex chromosomes, which are the same for males and females, are called **autosomes**. We think of sex in organisms with sex chromosomes as being determined by the presence of the sex chromosomes, but in fact, the individual genes located on the sex chromosomes, in conjunction with the genes on the autosomes, are usually responsible for the sexual phenotypes.

XX-XO SEX DETERMINATION

The mechanism of sex determination in the grasshoppers studied by McClung, called the XX-XO system, is one of the simplest

mechanisms of chromosomal sex determination. In this system, females have two X chromosomes (XX) and males possess a single X chromosome (XO). There is no O chromosome—the letter O signifies the absence of a sex chromosome.

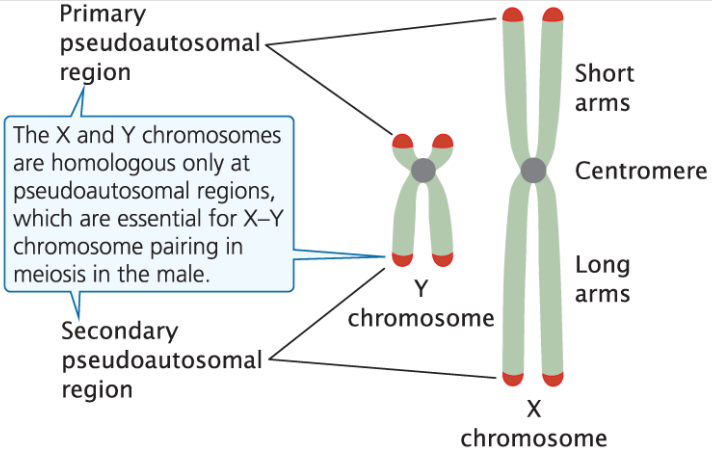
In meiosis in females, the two X chromosomes pair and then separate, and one X chromosome enters each haploid egg. In males, the single X chromosome segregates in meiosis to half the sperm cells; the other half receive no sex chromosome. Because males produce two different types of gametes with respect to the sex chromosomes, they are said to be the **heterogametic sex**. Females, which produce gametes that are all the same with respect to the sex chromosomes, are the **homogametic sex**. In the XX-XO system, the sex of an individual is therefore determined by which type of male gamete fertilizes the egg. X-bearing sperm unite with X-bearing eggs to produce XX zygotes, which develop into females. Sperm lacking an X chromosome unite with X-bearing eggs to produce XO zygotes, which develop into males.

XX-XY SEX DETERMINATION

In many species, the cells of males and females have the same number of chromosomes, but the cells of females have two X chromosomes (XX) and the cells of males have a single X chromosome and a smaller sex chromosome, the Y chromosome (XY). In humans and many other organisms, the Y chromosome is acrocentric (**Figure 4.6**), not Y shaped, as is often assumed. In this

sex-determining system, the male is the heterogametic sex—half of his gametes have an X chromosome and half have a Y chromosome. The female is the homogametic sex—all her eggs contain an X chromosome. Many organisms, including some plants, insects, and reptiles, and all mammals (including humans), have the XX-XY sex-determining system. Other organisms have variations of the XX-XY system; for example, the duck-billed platypus has an interesting system in which females have five pairs of X chromosomes and males have five pairs of X and Y chromosomes.

THINK-PAIR-SHARE Question 1



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

4.6 The X and Y chromosomes in humans differ in size and genetic content. They are homologous only in the pseudoautosomal regions.

Description

The caption in the figure reads as follows: the X and Y chromosomes are homologous only at the pseudoautosomal regions, which are essential for X-Y chromosome pairing in meiosis in the male. In the drawing, the telomeric regions at the tips of the short arms of

the X and Y chromosomes are labeled the primary pseudoautosomal regions and are colored red. The telomeric regions at the tips of the long arms of the chromosomes are labeled the secondary pseudoautosomal regions and are also colored red. The short arm of Y chromosome is small as compared to its long arm and Y chromosome is shorter as compared to the X chromosome.

Although the X and Y chromosomes are not generally homologous, they do pair and segregate into different cells in meiosis. They can pair because these chromosomes are homologous in small regions called the **pseudoautosomal regions** (see Figure 4.6), in which they carry the same genes. In humans, there are pseudoautosomal regions at both tips of the X and Y chromosomes.

ZZ-ZW SEX DETERMINATION

In the ZZ-ZW sex-determining system, found in the bearded dragons discussed in the chapter introduction, the female is heterogametic and the male is homogametic. To prevent confusion with the XX-XY system, the sex chromosomes in this system are called Z and W, but the chromosomes do not resemble Zs and Ws. Females in this system are ZW; after meiosis, half of the eggs have a Z chromosome and the other half have a W chromosome. Males are ZZ; all sperm contain a single Z chromosome. The ZZ-ZW system is found in birds, some reptiles, butterflies, some amphibians, and some fishes.

THINK-PAIR-SHARE Question 2

CONCEPTS

The discovery that the presence or absence of particular chromosomes determines sex in insects provided evidence that genes are located on chromosomes. In XX-XO sex determination, the male is XO and heterogametic, and the female is XX and homogametic. In XX-XY sex determination, the male is XY and the female is XX; in this system, the male is heterogametic. In ZZ-ZW sex determination, the female is ZW and the male is ZZ; in this system, the female is the heterogametic sex.

✔ CONCEPT CHECK 2

How does the heterogametic sex differ from the homogametic sex?

a. The heterogametic sex is male; the homogametic sex is female.
b. Gametes of the heterogametic sex have different sex chromosomes; gametes of the homogametic sex all have the same sex chromosome.
c. Gametes of the heterogametic sex all contain a Y chromosome; gametes of the homogametic sex all contain an X chromosome.

Genic Sex Determination

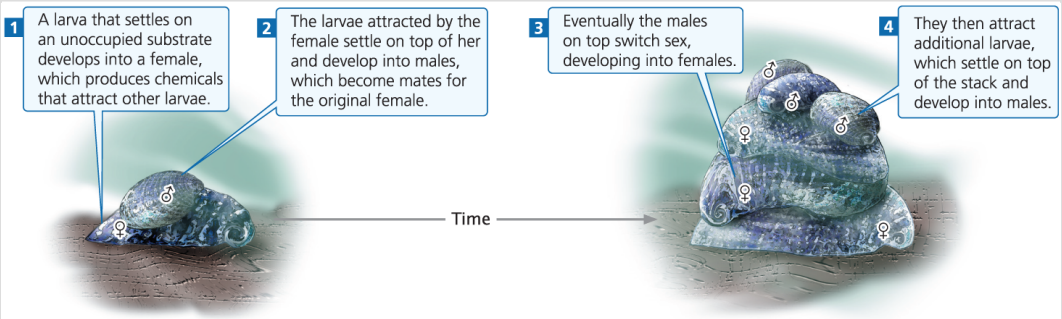
In some organisms, sex is genetically determined, but there are no obvious differences in the chromosomes of males and females: there are no sex chromosomes. These organisms have **genic sex determination**: genotypes at one or more loci determine the sex of an individual. Scientists have observed genic sex determination in some plants, fungi, protozoans, and fishes.

It is important to understand that even in chromosomal sex-determining systems, sex is actually determined by individual genes. In mammals, for example, a gene (*SRY*, discussed later in this chapter) located on the Y chromosome determines the male phenotype. In both genic sex determination and chromosomal sex determination, sex is controlled by individual genes; the difference is that with chromosomal sex determination, the sex chromosomes also look different in males and females.

Environmental Sex Determination

In a number of organisms, sex is determined fully or in part by environmental factors. A fascinating example of environmental sex determination is seen in the marine mollusk *Crepidula fornicata*, also known as the common slipper limpet (**Figure 4.7**). Slipper limpets live in stacks, one on top of another. Each limpet begins life as a swimming larva. The first larva to settle on a solid, unoccupied substrate develops into a female limpet. It then produces chemicals that attract other larvae, which settle on top of it. These larvae develop into males, which then serve as mates for the limpet below. After a period of time, the males on top develop into females and, in turn, attract additional larvae, which settle on top of the stack, develop into males, and serve as mates for the limpets under them. Limpets can form stacks of a dozen or more animals; the uppermost animals are always male. This type of sexual development is called **sequential hermaphroditism**; each individual animal can be both

male and female, although not at the same time. In *C. fornicata*, sex is determined environmentally by the limpet's position in the stack.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

4.7 In *Crepidula fornicata*, the common slipper limpet, sex is determined by an environmental factor—the limpet's position in the stack.

Description

The illustration shows the conversion of two slipper limpets into a larger stack of limpets with time. On the left side, two common slipper limpets are present. The first caption of four, corresponding to the rear bottom of the first pile, reads, "A larva that settles on an unoccupied substrate develops into a female, which produces chemicals that attract other larvae." The second caption, referring to the top of the pile, reads, "The larvae attracted by the female settle on top of her and develop into males, which become mates for the original female." A rightward arrow from the two slipper limpets to the pile of many indicates time and the slipper limpet converts to the stack of limpets on the right side. The third caption refers to the position of the original male on the stack of limpets, which is now occupied by a female, and reads, "Eventually the males on top switch sex developing into females." The fourth caption refers to the top of the stack and reads, "They then attract additional larvae, which settle on top of the stack and develop into males."

Environmental factors are also important in determining sex in some reptiles; the sexual phenotype of many turtles, crocodiles, alligators, and a few birds is affected by temperature during embryonic development. In some turtles, for example, warm incubation

temperatures produce more females, whereas cool temperatures produce males. In alligators, the reverse is true. In a few species, sex chromosomes determine whether individuals are male or female, but environmental factors can override this chromosomal sex determination. As discussed in the introduction to this chapter, bearded dragons are normally male when ZZ and female when ZW, but when the eggs are incubated at high temperatures, ZZ individuals develop into phenotypic females. Some of the different types of sex determination are summarized in Table 4.1.

TABLE 4.1 Some common sex-determining systems

System	Mechanism		Heterogametic Sex	Organisms
XX-XO	Females XX	Males X	Male	Some grasshoppers and other insects
XX-XY	Females XX	Males XY	Male	Many insects, fishes, amphibians, reptiles; mammals, including humans
ZZ-ZW	Females ZW	Males ZZ	Female	Butterflies, birds; some reptiles and amphibians
Genic sex determination	No distinct sex chromosomes Sex determined by genes on undifferentiated chromosomes		Varies	Some plants, fungi, protozoans, and fishes
Environmental sex determination	Sex determined by environmental factors		None	Some invertebrates, turtles, and alligators

Now that we have surveyed some of the different ways in which sex can be determined, we will examine one mechanism (the XX-XY system) in detail. Sex determination is XX-XY in both fruit flies and humans, but as we will see, the ways in which the X and Y chromosomes determine sex in these two organisms are quite different. ❯ **TRY PROBLEMS 4 AND 21**

CONCEPTS

In genic sex determination, sex is determined by genes at one or more loci, but there are no obvious differences in the chromosomes of males and females. In environmental sex determination, sex is determined fully or in part by environmental factors.

✔ CONCEPT CHECK 3

How do chromosomal, genic, and environmental sex-determining systems differ?

Sex Determination in *Drosophila melanogaster*

The fruit fly *Drosophila melanogaster* has eight chromosomes: three pairs of autosomes and one pair of sex chromosomes. Usually, females have two X chromosomes, and males have an X chromosome and a Y chromosome. In the 1920s, Calvin Bridges proposed that sex in *Drosophila* was determined not by the number of X and Y chromosomes but rather by the balance of female-

determining genes on the X chromosome and male-determining genes on the autosomes. He suggested that a fly's sex is determined by the so-called X : A ratio that is the number of X chromosomes divided by the number of haploid sets of autosomes. Normal flies possess two haploid sets of autosomes and either two X chromosomes (females) or one X chromosome and a Y chromosome (males). Bridges proposed that an X : A ratio of 1.0 produces a female fly and that an X : A ratio of 0.5 produces a male fly. He also suggested that an X : A ratio between 1.0 and 0.5 produces an intersex fly, with a mixture of male and female characteristics. An X : A ratio of less than 0.5 or greater than 1.0 produces developmentally abnormal flies called metamales and metafemales, respectively. When Bridges and others examined flies with different numbers of sex chromosomes and autosomes, the X : A ratio appeared to correctly predict the phenotypic sex of the flies (Table 4.2).

TABLE 4.2 Chromosome complements and sexual phenotypes in *Drosophila*

Sex-Chromosome Complement	Haploid Sets of Autosomes	X : A Ratio	Sexual Phenotype
XX	AA	1.0	Female
XY	AA	0.5	Male
XO	AA	0.5	Male

XXY	AA	1.0	Female
XXX	AA	1.5	Metafemale
XXXY	AA	1.5	Metafemale
XX	AAA	0.67	Intersex
XO	AAA	0.33	Metamale
XXXX	AAA	1.3	Metafemale

Although the X : A ratio correctly *predicts* the sexual phenotype, research now suggests that the *mechanism* of sex determination is not a balance between X-linked genes and autosomal genes, as Bridges proposed. Researchers have located a number of genes on the X chromosome that affect sexual phenotype, but few autosomal sex-determining genes (required for the X : A ratio hypothesis) have been identified. New evidence indicates that genes on the X chromosome are the primary sex determinant. The influence of the number of sets of autosomes on sex is indirect, affecting the timing of developmental events and therefore how long sex-determining genes on the X chromosome are active. For example, XX flies with three autosomal sets (XX, AAA) have an X : A ratio of 0.67 and develop an intersex phenotype. In these flies, the presence of three autosomal sets causes a critical developmental stage to shorten, not allowing female factors encoded on the X chromosomes enough

time to accumulate, with the result that the flies end up with an intersex phenotype. Thus, the number of autosomal sets of chromosomes influences sex determination in *Drosophila*, but not through the action of autosomal genes, as envisioned by Bridges.

CONCEPTS

Although the sexual phenotype of a fruit fly is predicted by the X : A ratio, sex is actually determined by genes on the X chromosome.

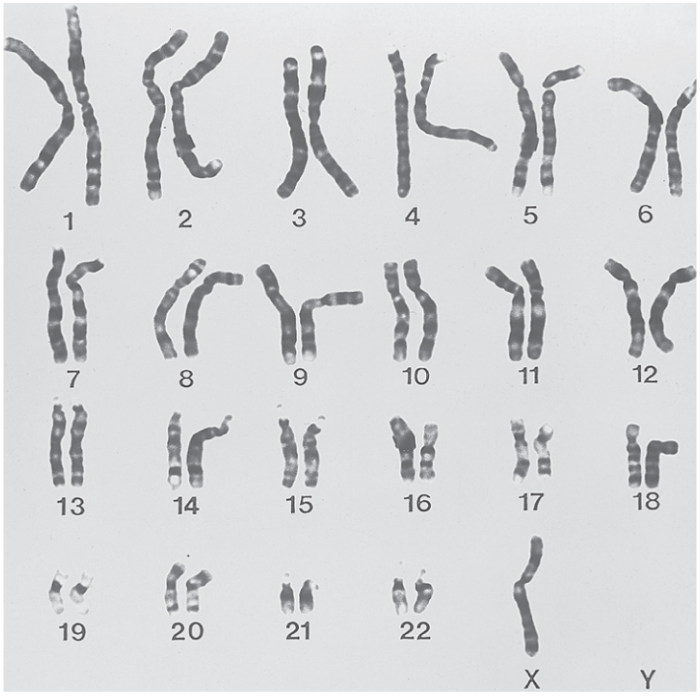
Sex Determination in Humans

Humans, like *Drosophila*, have XX-XY sex determination, but in humans, maleness is primarily determined by the presence of a particular gene (*SRY*) on the Y chromosome. The phenotypes that result from abnormal numbers of sex chromosomes, which arise when the sex chromosomes do not segregate properly in meiosis or mitosis, illustrate the importance of the Y chromosome in human sex determination.

TURNER SYNDROME

People who have **Turner syndrome** are female and often have underdeveloped secondary sex characteristics. This syndrome is

seen in 1 of 3000 female births. Affected women are frequently short and have a low hairline, a relatively broad chest, and folds of skin on the neck. Their intelligence is usually within the normal range. Many women who have Turner syndrome are sterile. In 1959, Charles Ford used new techniques to study human chromosomes and discovered that cells from a 14-year-old girl with Turner syndrome had only a single X chromosome (**Figure 4.8**); this chromosome complement is usually referred to as XO. Many people with Turner syndrome have some cells that are XX and other cells that are XO, a situation referred to as mosaicism (see p. 158).



Dept. of Clinical Cytogenetics, Addenbrookes Hospital/Science Photo Library/Science Source.

4.8 People with Turner syndrome have a single X chromosome in their cells.

Description

The illustration shows the pairs 1 through 18 are gradually decreasing in length. Pairs 19 through 22 are smaller in size. In the sex chromosome pair 23, only one X chromosome is present and the Y chromosome is missing indicating Turner syndrome.

There are no known cases in which a person is missing both X chromosomes, an indication that at least one X chromosome is necessary for human development. Presumably, embryos missing both Xs spontaneously abort in the early stages of development.

KLINEFELTER SYNDROME

People who have **Klinefelter syndrome**, which has a frequency of about 1 in 1000 male births, have cells with one or more Y chromosomes and multiple X chromosomes. The cells of most males with this condition are XXY (**Figure 4.9**), but the cells of a few males with Klinefelter syndrome are XXXY, XXXXY, or XXYY. Men with this condition frequently have small testes and reduced facial and pubic hair. They are often taller than normal and sterile; most have intelligence within the normal range.

Biophoto Associates/Science Source.

4.9 People with Klinefelter syndrome have a Y chromosome and two or more X chromosomes in their cells.

Description
The illustration shows both the chromosomes in a pair are roughly of same size. In the sex chromosome pair 23, two long X chromosomes are present along with a smaller Y chromosome indicating Klinefelter syndrome.

POLY-X FEMALES

In about 1 in 1000 female births, the infant's cells possess three X chromosomes, a condition often referred to as **triple-X syndrome**. These individuals have no distinctive features other than a tendency to be tall and thin. Although a few are sterile, many menstruate regularly and are fertile. The incidence of intellectual disability among triple-X females is slightly greater than that in the general population, but most XXX females have intelligence within the normal range. Much rarer are females whose cells contain four or

five X chromosomes. These females usually have normal female anatomy but are intellectually disabled and have a number of physical problems. The severity of intellectual disability increases as the number of X chromosomes increases beyond three.

XYY MALES

Males with an extra Y chromosome (XYY) occur with a frequency of about 1 in 1000 male births. These individuals have no distinctive physical characteristics other than a tendency to be several inches taller than the average for XY males. Their IQ is usually within the normal range; however, some studies suggest that learning difficulties may be more common in this group than in XY males.

THE ROLE OF SEX CHROMOSOMES

The phenotypes associated with sex-chromosome anomalies allow us to make several inferences about the role of sex chromosomes in human sex determination:

1. The X chromosome contains genetic information essential for both sexes; at least one copy of an X chromosome is required for human development.
2. The male-determining gene is located on the Y chromosome. A single copy of this chromosome, even in the presence of several X chromosomes, usually produces a male phenotype.

3. The absence of the Y chromosome usually results in a female phenotype.
4. Genes affecting fertility are located on the X and Y chromosomes. A female usually needs at least two copies of the X chromosome to be fertile.
5. Additional copies of the X chromosome may upset normal development in both males and females, producing physical problems and intellectual disabilities that increase as the number of extra X chromosomes increases.

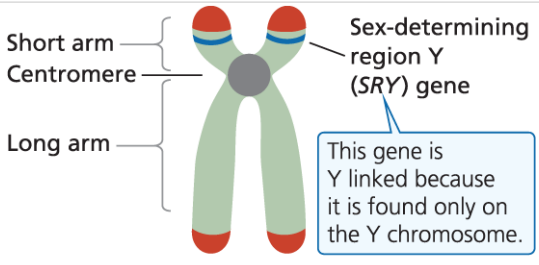
THE MALE-DETERMINING GENE IN HUMANS

The Y chromosome in humans, and in all other mammals, is of paramount importance in producing a male phenotype. However, scientists have discovered a few rare XX males whose cells apparently lack a Y chromosome. For many years, these males presented an enigma: How could a male phenotype exist without a Y chromosome? Close examination eventually revealed a small part of the Y chromosome attached to another chromosome, usually the X. This finding indicates that it is not the entire Y chromosome that determines maleness in humans; rather, it is a gene on the Y chromosome.

Early in development, all humans possess undifferentiated gonads and both male and female reproductive ducts. Then, about six weeks after fertilization, a gene on the Y chromosome becomes active. This gene causes the neutral gonads to develop into testes, which begin

to secrete two hormones: testosterone and anti-Müllerian hormone. Testosterone and other androgens induce the development of male characteristics, and anti-Müllerian hormone causes the degeneration of the female reproductive ducts. In the absence of this male-determining gene, the neutral gonads become ovaries, and female features develop. In mice, the regression of male reproductive ducts in females is promoted by another protein called chicken ovalbumin upstream promoter transcription factor 2 (COUP-TFII).

The male-determining gene in humans, called the **sex-determining region Y (*SRY*) gene**, was discovered in 1990 (**Figure 4.10**). This gene is found in XX males and is missing from rare XY females; it is also found on the Y chromosome of other mammals. Definitive proof that *SRY* is the male-determining gene came when scientists placed a copy of this gene in XX mice by means of genetic engineering. The XX mice that received this gene, although sterile, developed into anatomical males.



Pierce, *Genetics: A Conceptual Approach*, 7e
© 2020 W. H. Freeman and Company

4.10 The *SRY* gene, located on the Y chromosome, causes the development of male characteristics.

Description
The illustration shows an X-shaped Y chromosome. Centromere is labeled as the point where the chromatids are joined. The short arm is the region above the centromere and long arm is the region below the centromere. The short arm is relatively shorter than the long arm. Two bands representing sex-determining region, or S R Y gene are labeled on the short arms of both the chromatids as thin blue bands on each side. The tips of both the chromatids are colored red. A caption reads, the S R Y gene is Y-linked because it is found only on the Y chromosome.

The *SRY* gene encodes a protein called a transcription factor (see Chapter 13), which binds to DNA and stimulates the transcription of genes that promote the differentiation of the testes. Although *SRY* is the primary determinant of maleness in humans, a number of other genes (some X linked, others Y linked, and still others autosomal) also have roles in fertility and the development of sexual phenotypes.

THINK-PAIR-SHARE Question 3

CONCEPTS

The presence of the *SRY* gene on the Y chromosome causes a human embryo to develop as a male. In the absence of this gene, a human embryo develops as a female.

✔ CONCEPT CHECK 4

What is the phenotype of a person who has XXXY sex chromosomes?

a. Klinefelter syndrome

b. Turner syndrome
c. Poly-X female

ANDROGEN-INSENSITIVITY SYNDROME

Although the *SRY* gene is the primary determinant of sex in human embryos, several other genes influence sexual development, as illustrated by women with androgen-insensitivity syndrome. These individuals have female external sexual characteristics. Indeed, most are unaware of their condition until they reach puberty and fail to menstruate. Examination by a gynecologist reveals that the vagina ends blindly and that the uterus, oviducts, and ovaries are absent. Inside the abdominal cavity, a pair of testes produce levels of testosterone normally seen in males. The cells of a woman with androgen-insensitivity syndrome contain an X and a Y chromosome.

How can a person be female in appearance when her cells contain a Y chromosome and she has testes that produce testosterone? The answer lies in the complex relation between genes and sex in humans. In a human embryo with a Y chromosome, the *SRY* gene causes the gonads to develop into testes, which produce testosterone. Normally, testosterone stimulates embryonic tissues to develop male characteristics. But for testosterone to have its effect, it must bind to an androgen receptor. This receptor is defective in females with androgen-insensitivity syndrome; consequently, their cells do not respond to testosterone, and female characteristics

develop. The gene for the androgen receptor is located on the X chromosome, so people with this condition always inherit it from their mothers.

Androgen-insensitivity syndrome illustrates several points about the influence of genes on a person's sex. First, this condition demonstrates that human sexual development is a complex process, influenced not only by the *SRY* gene on the Y chromosome but also by other genes found elsewhere. Second, it shows that most people carry genes for both male and female characteristics, as illustrated by the fact that those with androgen-insensitivity syndrome have the capacity to develop female characteristics even though they have a Y chromosome. Indeed, the genes for most male and female secondary sex characteristics are present not on the sex chromosomes but on the autosomes. The key to maleness and femaleness lies not in the genes but in the control of their expression. › **TRY PROBLEM 17**

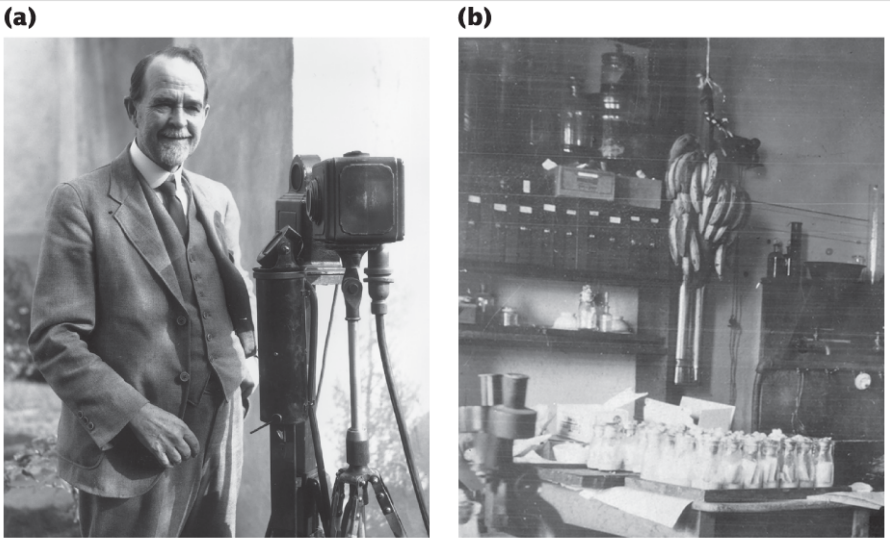
4.2 Sex-Linked Characteristics Are Determined by Genes on the Sex Chromosomes

In Chapter 3, we learned several basic principles of heredity that Mendel discovered in his experiments with pea plants. A major extension of these Mendelian principles is the pattern of inheritance exhibited by **sex-linked characteristics**: characteristics determined by genes located on the sex chromosomes. Genes on the X chromosome determine **X-linked characteristics**; those on the Y chromosome determine **Y-linked characteristics**. Because the Y chromosome of many organisms contains little genetic information, most sex-linked characteristics are X linked. Males and females differ in their sex chromosomes, so the pattern of inheritance for sex-linked characteristics differs from that exhibited by genes located on autosomes.

X-Linked White Eyes in *Drosophila*

The first person to provide an explanation for sex-linked inheritance was the American biologist Thomas Hunt Morgan (**Figure 4.11**). Morgan began his career as an embryologist, but the discovery of Mendel's principles inspired him to begin conducting genetic experiments, initially on mice and rats. In 1909, Morgan switched his

research to *Drosophila melanogaster*; a year later, he discovered among the flies of his laboratory colony a single male that possessed white eyes, in stark contrast to the red eyes of normal fruit flies. This fly had a tremendous effect on Morgan's career as a biologist and on the future of genetics.



Part a: Associated Press. Part b: American Philosophical Society.

4.11 Thomas Hunt Morgan's work with *Drosophila* helped unravel many basic principles of genetics, including X-linked inheritance. (a) Morgan. (b) The Fly Room, where Morgan and his students conducted genetic research.

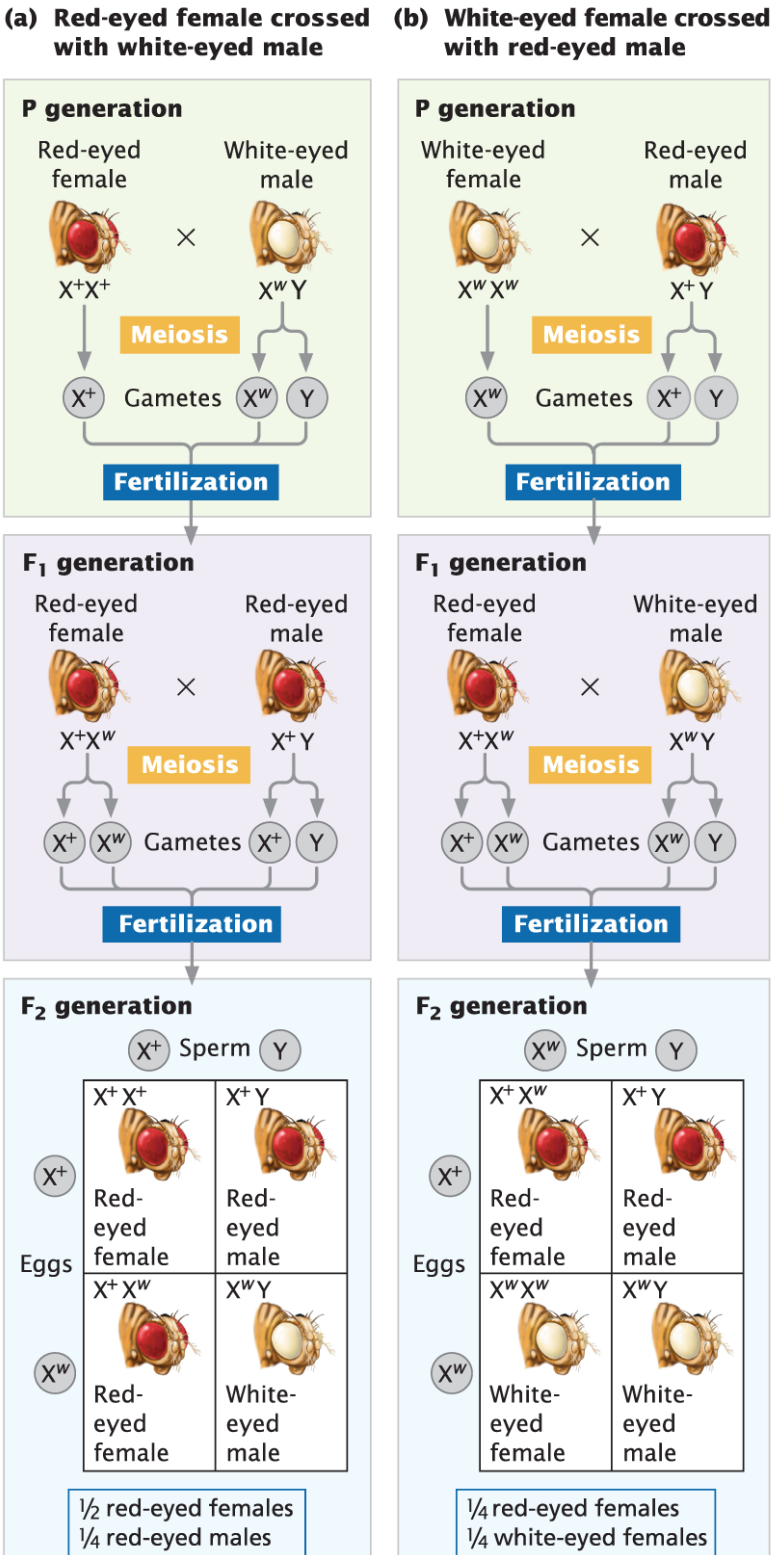
To investigate the inheritance of the white-eye trait in fruit flies, Morgan systematically carried out a series of genetic crosses. First, he crossed pure-breeding red-eyed females with his white-eyed male, producing F_1 progeny that had red eyes (Figure 4.12a). Morgan's results from this initial cross were consistent with Mendel's principles: a cross between a homozygous dominant individual and a homozygous recessive individual produced heterozygous offspring exhibiting the dominant trait. These results suggested that white

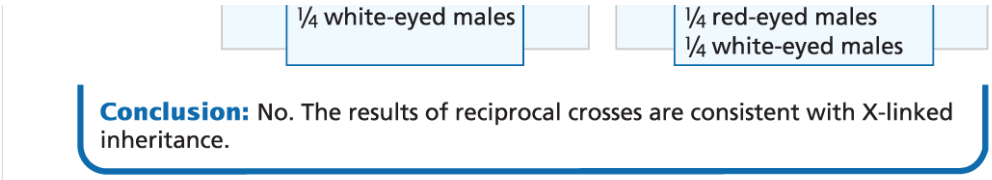
eyes are a simple recessive trait. When Morgan crossed the F_1 flies with each other, however, he found that all the female F_2 flies possessed red eyes, but half the male F_2 flies had red eyes and the other half had white eyes. This finding was clearly not the expected result for a simple recessive trait, which should appear in one-fourth of both male and female F_2 offspring.

Experiment

Question: Are white eyes in fruit flies inherited as an autosomal recessive trait?

Methods Perform reciprocal crosses.





Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

4.12 Morgan's crosses demonstrated the X-linked inheritance of white eyes in fruit flies. (a) Original and F_1 crosses. (b) Reciprocal crosses.

Description

The experiment question is: Are white eyes in fruit flies inherited as an autosomal recessive trait? The Methods involve Perform reciprocal crosses. Illustration "a" shows a cross between a red-eyed female and a white-eyed male. The P generation has a red-eyed female with genotype big X superscript positive big X superscript positive crossed with a white-eyed male with genotype big X superscript W big Y. Meiosis occurs and the gametes produced are as follows: big X superscript positive from the female and big X superscript W and big Y from the male. Fertilization occurs and the results show F subscript 1 generation. The F subscript 1 generation has a red-eyed female with genotype big X superscript positive big X superscript W crossed with a red-eyed male with genotype big X superscript positive big Y. Meiosis occurs and gametes produced are as follows: big X superscript positive and big X superscript W from the female and big X superscript positive and big Y from the male. Fertilization occurs and the results show the F subscript 2 generation. A Punnett square with 2 rows and 2 columns shows the following entries:

The column headers represent sperms and are as follows: big X superscript positive and big Y.

The row headers represent eggs and are as follows: big X superscript positive and big X superscript W.

Row 1 column 1: big X superscript positive big X superscript positive (red-eyed female)

Row 1 column 2: big X superscript positive big Y (red-eyed male)

Row 2 column 1: big X superscript positive big X superscript W (red-eyed female)

Row 2 column 2: big X superscript W big Y (white-eyed male)

Text below reads, “One-half red-eyed females, one-fourth red-eyed males, and one-fourth white eyed males.”

The illustration “b” shows a cross between a white-eyed female and a red-eyed male. The P generation has a white-eyed female with genotype big X superscript W big X superscript W crossed with a red-eyed male with genotype big X superscript positive big Y. Meiosis occurs and the gametes produced are as follows: big X superscript W from the female and big X superscript positive and big Y from the male. Fertilization occurs and the results show F subscript 1 generation. The F subscript 1 generation has a red-eyed female with genotype big X superscript positive big X superscript W crossed with a white-eyed male with genotype big X superscript W big Y. Meiosis occurs and the gametes produced are as follows: big X superscript positive and big X superscript W from the female and big X superscript positive and big Y from the male. Fertilization occurs and the results show the F subscript 2 generation. A Punnett square with 2 rows and 2 columns has the following entries.

The column headers represent sperms and are as follows: big X superscript W and big Y.

The row headers represent eggs and are as follows: big X superscript positive and big X superscript W.

Row 1 column 1: big X superscript positive big X superscript W (red-eyed female)

Row 1 column 2: big X superscript positive big Y (red-eyed male)

Row 2 column 1: big X superscript W big X superscript W (white-eyed female)

Row 2 column 2: big X superscript W big Y (white-eyed male)

Text below reads, “One-fourth red-eyed females, one-fourth white eyed females, one-fourth red-eyed males, and one-fourth white-eyed males.”

The conclusion states that no, the results of reciprocal crosses are consistent with X-linked inheritance.

To explain this unexpected result, Morgan proposed that the locus affecting eye color is on the X chromosome (i.e., that eye color is X

linked). He also recognized that eye-color alleles are present on the X chromosome only; no homologous allele is present on the Y chromosome. Because the cells of females possess two X chromosomes, females can be homozygous or heterozygous for the eye-color alleles. The cells of males, on the other hand, possess only a single X chromosome and can carry only a single eye-color allele. Males, therefore, cannot be homozygous or heterozygous but are said to be **hemizygous** for X-linked loci.

To verify his hypothesis that the white-eye trait is X linked, Morgan conducted additional crosses. He predicted that a cross between a white-eyed female and a red-eyed male would produce all red-eyed females and all white-eyed males (**Figure 4.12b**). When Morgan performed this cross, the results were exactly as predicted. Note that this cross is the reciprocal of the original cross and that the two reciprocal crosses produced different results in the F_1 and F_2 generations. Morgan also crossed the F_1 heterozygous females with their white-eyed father, the red-eyed F_2 females with white-eyed males, and white-eyed females with white-eyed males. In all these crosses, the results were consistent with Morgan's conclusion that the white-eye trait is an X-linked characteristic. You can view the results of Morgan's crosses in (A) **Animation 4.1**.

Nondisjunction and the Chromosome Theory of Inheritance

When Morgan crossed his original white-eyed male with homozygous red-eyed females, all 1237 of the progeny had red eyes except for 3 white-eyed males. Morgan attributed these white-eyed F_1 males to the occurrence of further random mutations. However, flies with these unexpected phenotypes continued to appear in his crosses. Although uncommon, they appeared far too often to be due to spontaneous mutation. Calvin Bridges, who was one of Morgan's students, set out to investigate the genetic basis of these exceptions.

Bridges found that the exceptions arose only in certain strains of white-eyed flies. When he crossed a white-eyed female from one of those strains with a red-eyed male, about 5% of the male offspring had red eyes and about 5% of the female offspring had white eyes. In this cross, the expected result is that every male fly should inherit its mother's X chromosome and should have the genotype X^wY and white eyes. Furthermore, every female fly should inherit a dominant red-eye allele on its father's X chromosome, along with a white-eye allele on its mother's X chromosome; thus, all the female progeny should be X^+X^w and have red eyes (see the F_1 progeny in Figure 4.12b). The continual appearance of red-eyed males and white-eyed females in this cross was therefore unexpected.

BRIDGES'S EXPLANATION

To explain the appearance of red-eyed males and white-eyed females in his cross, Bridges hypothesized that the exceptional white-eyed females of this strain actually possessed two X chromosomes and a

Y chromosome (X^wX^wY). In *Drosophila*, flies with XXY sex chromosomes normally develop as females, in spite of possessing a Y chromosome (see Table 4.2). About 90% of the time, the two X chromosomes of the X^wX^wY females separate from each other in anaphase I of meiosis, with an X and a Y chromosome entering one gamete and a single X entering another gamete (**Figure 4.13**). When these gametes are fertilized by sperm from a normal red-eyed male, white-eyed males and red-eyed females are produced. About 10% of the time, the two X chromosomes in the females fail to separate in anaphase I of meiosis, a phenomenon known as **nondisjunction**. When nondisjunction of the Xs occurs, half of the eggs receive two copies of the X chromosome and the other half receive only a Y chromosome (see Figure 4.13). When these eggs are fertilized by sperm from a normal red-eyed male, four combinations of sex chromosomes are produced. An egg with two X chromosomes that is fertilized by an X-bearing sperm produces an $X^+X^wX^w$ zygote, which usually dies. When an egg carrying two X chromosomes is fertilized by a Y-bearing sperm, the resulting zygote is X^wX^wY, which develops into a white-eyed female. An egg with only a Y chromosome that is fertilized by an X-bearing sperm produces an X^+Y zygote, which develops into a normal red-eyed male. If the egg with only a Y chromosome is fertilized by a Y-bearing sperm, the resulting zygote has two Y chromosomes and no X chromosome, and dies. Nondisjunction of the X chromosomes among X^wX^wY white-eyed females therefore produces a few white-eyed females and red-eyed males, which is exactly what Bridges found in his crosses. The

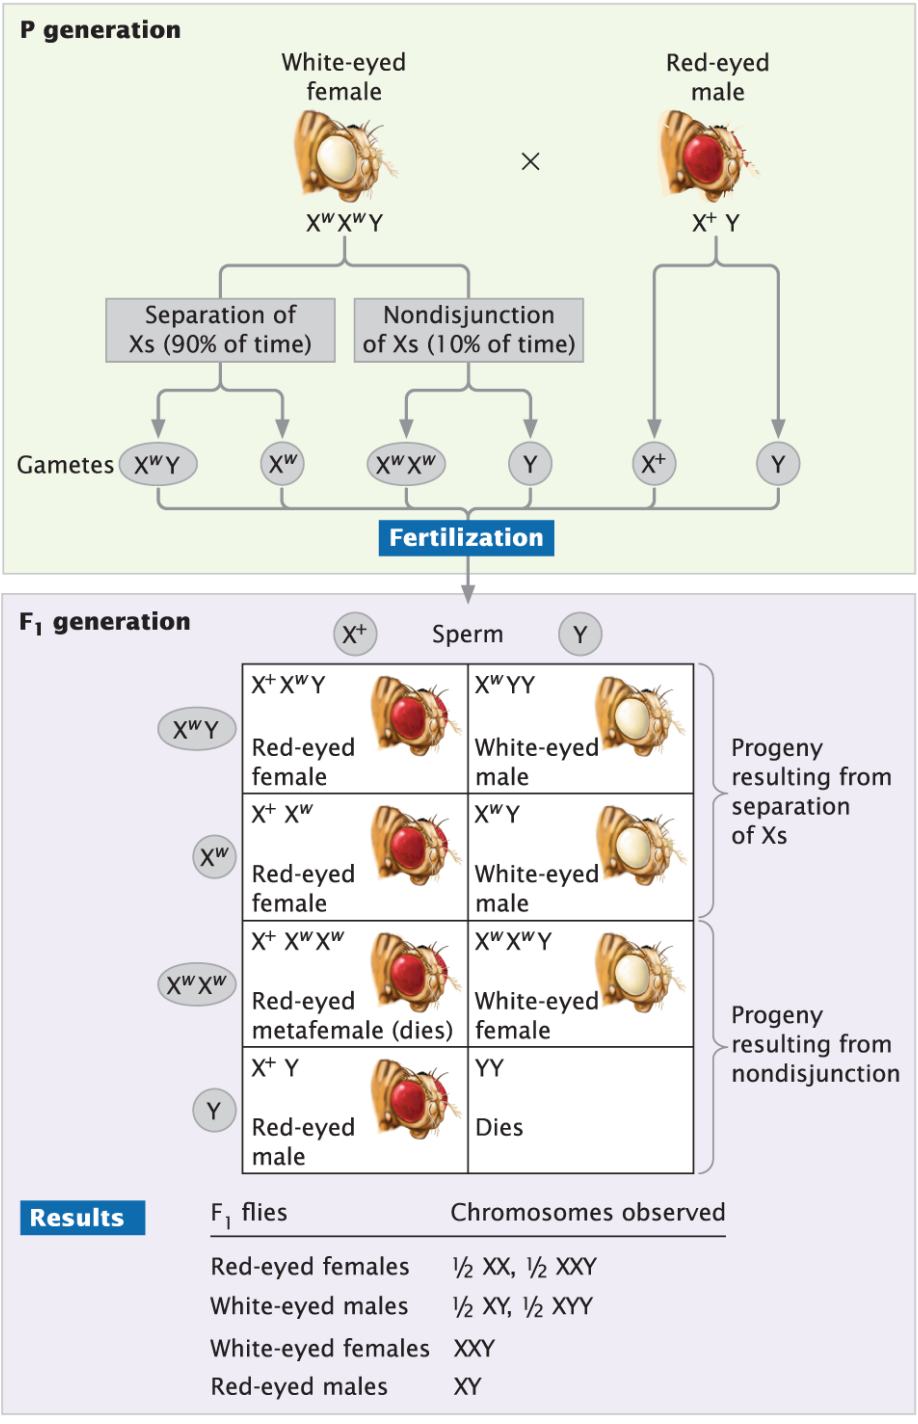
results of Bridges's crosses are further explained in **Animation 4.1**.

Experiment

Question: In a cross between a white-eyed female and a red-eyed male, why are a few white-eyed females and red-eyed males produced?

Methods

Hypothesis: White-eyed females and red-eyed males in F_1 result from nondisjunction in an XXY female.



Results

F_1 flies	Chromosomes observed
Red-eyed females	½ XX, ½ XXY
White-eyed males	½ XY, ½ XYY
White-eyed females	XXY
Red-eyed males	XY

Conclusion: The white-eyed females and red-eyed males in the F_1 result from nondisjunction of the X chromosomes in an XXY female.

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

4.13 Bridges's crosses proved that the gene for white eyes is located on the X chromosome.

Description

The experiment question is: In a cross between a white-eyed female and a red-eyed male, why are a few white-eyed females and red-eyed males produced? The methods below read, Hypothesis: White-eyed females and red-eyed males in F subscript 1 result from nondisjunction in an big X big X big Y female.

The illustration shows P generation where a white-eyed female with genotype big X superscript W big X superscript W big Y is crossed with a red-eyed male with genotype big X superscript positive big Y. Gametes are produced from the female in two ways. Separation of X's (90 percent of time) produces the following gametes: big X superscript W big Y and big X superscript W. Non-disjunction of X's (10 percent of time) produces the following gametes: big X superscript W big X superscript W and big Y. Gametes produced from the male fly are as follows: big X superscript positive and big Y. Fertilization occurs and F subscript 1 generation is obtained. A Punnett square with 4 rows and 2 columns has the following entries:

The row headers are as follows: 1, big X superscript W big Y; 2, big X superscript W; 3, big X superscript W big X superscript W; and 4, big Y.

The column headers represent sperms and are as follows: big X superscript positive and big Y.

The following progenies result from separation of X's:

Row 1 column 1: big X superscript positive big X superscript W big Y (Red-eyed Female)

Row 1 column 2: big X superscript W big Y big Y (White-eyed Male)

Row 2 column 1: big X superscript positive big X superscript W (Red-eyed Female)

Row 2 column 2: big X superscript W big Y (White-eyed Male)

The following progenies result from non-disjunction:

Row 3 column 1: big X superscript positive big X superscript W big X superscript W (Red-eyed metafemale (dies))

Row 3 column 2: big X superscript W big X superscript W big Y (White-eyed Female)

Row 4 column 1: big X superscript positive big Y (Red-eyed Male)

Row 4 column 2: big Y big Y (dies)

The results below show the chromosomes observed in F subscript 1 flies as follows:

Red-eyed females; chromosomes observed, one-half big X big X and one-half big X big X big Y.

White-eyed males; chromosomes observed, one-half big X big Y and one-half big X big Y big Y.

White-eyed females; chromosomes observed, big X big X big Y.

Red-eyed males; chromosomes observed, big X big Y.

The conclusion states that the white-eyed females and red-eyed males in the F subscript 1 result from nondisjunction of the X chromosomes in a big X big X big Y female.

CONFIRMATION OF BRIDGES'S HYPOTHESIS

Bridges's hypothesis predicted that the white-eyed females from his crosses would possess two X chromosomes and one Y chromosome and that the red-eyed males would possess a single X chromosome. To verify his hypothesis, Bridges examined the chromosomes of his flies and found precisely what he had predicted. The significance of Bridges's study is not that it explained the appearance of an occasional odd fly in his colony but that he was able to link the inheritance of a specific gene (*w*) to the presence of a specific

chromosome (X). This association between genotype and chromosomes provided unequivocal evidence that sex-linked genes are located on the X chromosome and confirmed the chromosome theory of inheritance. ❯ **TRY** PROBLEM 22

CONCEPTS

By showing that the appearance of rare phenotypes is associated with the inheritance of particular chromosomes, Bridges proved that sex-linked genes are located on the X chromosome and that the chromosome theory of inheritance is correct.

✔ CONCEPT CHECK 5

What was the genotype of the few F_1 red-eyed males obtained by Bridges when he crossed a white-eyed female with a red-eyed male?

a. X^+
b. X^wX^+Y
c. X^+Y
d. X^+X^+Y

X-Linked Color Blindness in Humans

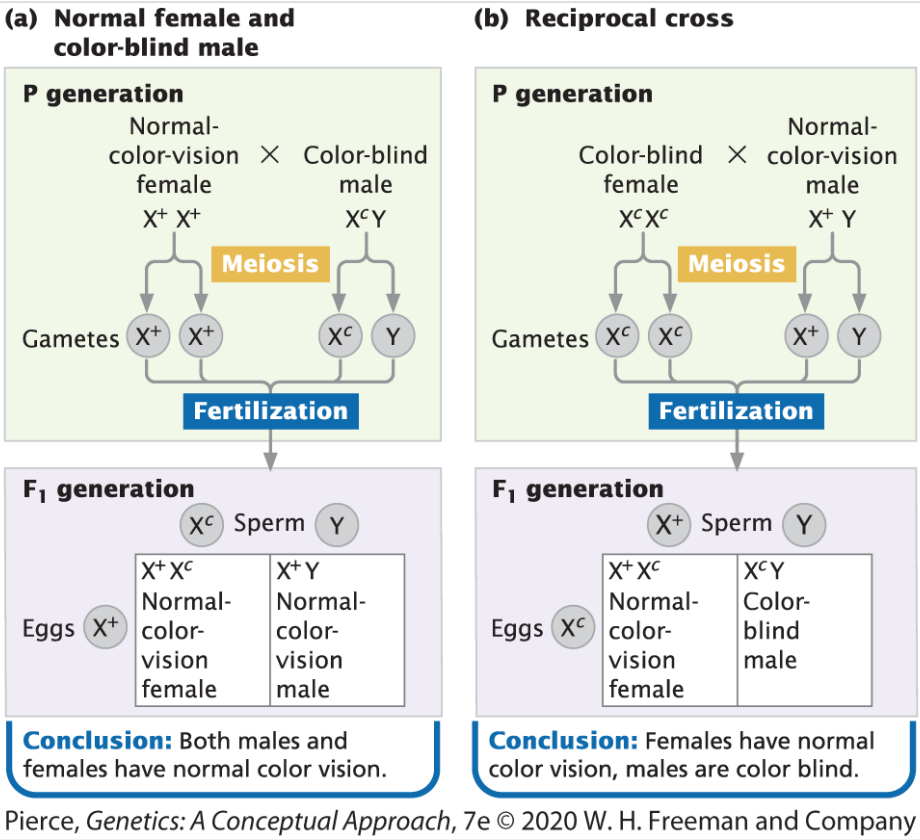
To further examine X-linked inheritance, let's consider another X-linked characteristic: red–green color blindness in humans. The human eye perceives color through light-sensing cone cells that line the retina. Each cone cell contains one of three pigments capable of

absorbing light of a particular wavelength: one absorbs blue light, a second absorbs red light, and a third absorbs green light. The human eye actually detects only three colors—blue, red, and green—but the brain mixes the signals from different cone cells to create the wide spectrum of colors that we perceive. Each of the three pigments is encoded by a separate locus; the locus for the blue pigment is found on chromosome 7, and those for the green and the red pigments lie close together on the X chromosome.

The most common types of human color blindness are caused by defects of the red and green pigments; we will refer to these conditions as red–green color blindness. Mutations that produce defective color vision are generally recessive, and because the genes encoding the red and the green pigments are located on the X chromosome, red–green color blindness is inherited as an X-linked recessive trait. (See Chapter 8 for additional information about the genes that cause red–green color blindness.)

We will use the symbol X^c to represent an allele for red–green color blindness and the symbol X^+ to represent an allele for normal color vision. Females possess two X chromosomes, so there are three possible genotypes among females: X^+X^+ and X^+X^c, which produce normal color vision, and X^cX^c, which produces color blindness. Males have only a single X chromosome and two possible genotypes: X^+Y, which produces normal color vision, and X^cY, which produces color blindness.

Let's consider what happens when a woman homozygous for normal color vision mates with a color-blind man (Figure 4.14a). All the gametes produced by the woman contain an allele for normal color vision. Half of the man's gametes receive the X chromosome, with the color-blindness allele, and the other half receive the Y chromosome, which carries no alleles affecting color vision. When an X^c-bearing sperm unites with the X^+-bearing egg, a heterozygous female with normal color vision (X^+X^c) is produced. When a Y-bearing sperm unites with the X^+-bearing egg, a hemizygous male with normal color vision (X^+Y) is produced.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

4.14 Red–green color blindness is inherited as an X-linked recessive trait in humans.

Description

The illustration “a” shows a normal female crossed with a color-blind male. The P generation has a normal color-vision female with genotype big X superscript positive big X superscript positive crossed with a color-blind male with genotype big X superscript C big Y. Meiosis occurs and the following gametes are produced: big X superscript positive and big X superscript positive from the female, big X superscript C and big Y from the male. Fertilization occurs and F subscript 1 generation is obtained. A Punnett square with 1 row and 2 columns shows the following data:

The column headers represent sperm and are as follows: big X superscript C and big Y.

The row header represents eggs and is as follows: big X superscript positive.

Row 1 column 1: big X superscript positive big X superscript C (Normal color vision

Female)

Row 1 column 2: big X superscript positive big Y (Normal color vision

Male).

A caption below reads, Conclusion: Both males and females have normal color vision.

Illustration “b” shows the reciprocal cross. The P generation has a color-blind female with genotype big X superscript C big X superscript C crossed with a normal color- vision male with genotype big X superscript positive big Y. Meiosis occurs and the gametes produced are as follows: big X superscript C, big X superscript C, big X superscript positive, and big Y. Fertilization occurs and F subscript 1 generation is obtained.

A Punnett square with 1 row and 2 columns shows the following:

The column headers represent sperm and are as follows: big X superscript positive and big Y.

The row header represents eggs and is as follows: big X superscript C.

Row 1 column 1: big X superscript positive big X superscript C (Normal color vision

Female)

Row 1 column 2: big X superscript C big Y (Color blind Male).

The conclusion states that females have normal color vision, males are color blind.

Now consider the reciprocal cross between a color-blind woman and a man with normal color vision (**Figure 4.14b**). The woman produces only X^c-bearing gametes. The man produces some gametes that contain the X chromosome and others that contain the Y chromosome. Males inherit the X chromosome from their mothers, so because both of the mother's X chromosomes bear the X^c allele, all the male offspring of this cross will be color blind. In contrast, females inherit an X chromosome from each parent; thus, all the female offspring of this cross will be heterozygous with normal color vision. A female is color blind only when she inherits color-blindness alleles from both parents, whereas a male need only inherit a color-blindness allele from his mother to be color blind; for this reason, color blindness and most other rare X-linked recessive traits are more common in males than in females.

In these crosses for color blindness, notice that an affected woman passes the X-linked recessive trait to her sons but not to her daughters, whereas an affected man passes the trait to his grandsons through his daughters but never to his sons. X-linked recessive characteristics may therefore appear to alternate between the sexes, appearing in females in one generation and in males in the next generation.

Recall that the X and Y chromosomes pair in meiosis because they are homologous at the small pseudoautosomal regions. Genes in

these regions of the X and Y chromosomes are homologous, just like those on autosomes, and they exhibit autosomal patterns of inheritance rather than the sex-linked inheritance seen for most genes on the X and Y chromosomes.

THINK-PAIR-SHARE Questions 4 and 5

WORKED PROBLEM

Now that we understand the pattern of X-linked inheritance, let's apply our knowledge to answer a specific question.

Red–green color blindness is an X-linked recessive trait. Betty has normal color vision, but her mother is color blind. Bill is color blind. If Bill and Betty have a child together, what is the probability that the child will be color blind?

Solution Strategy

What information is required in your answer to the problem?

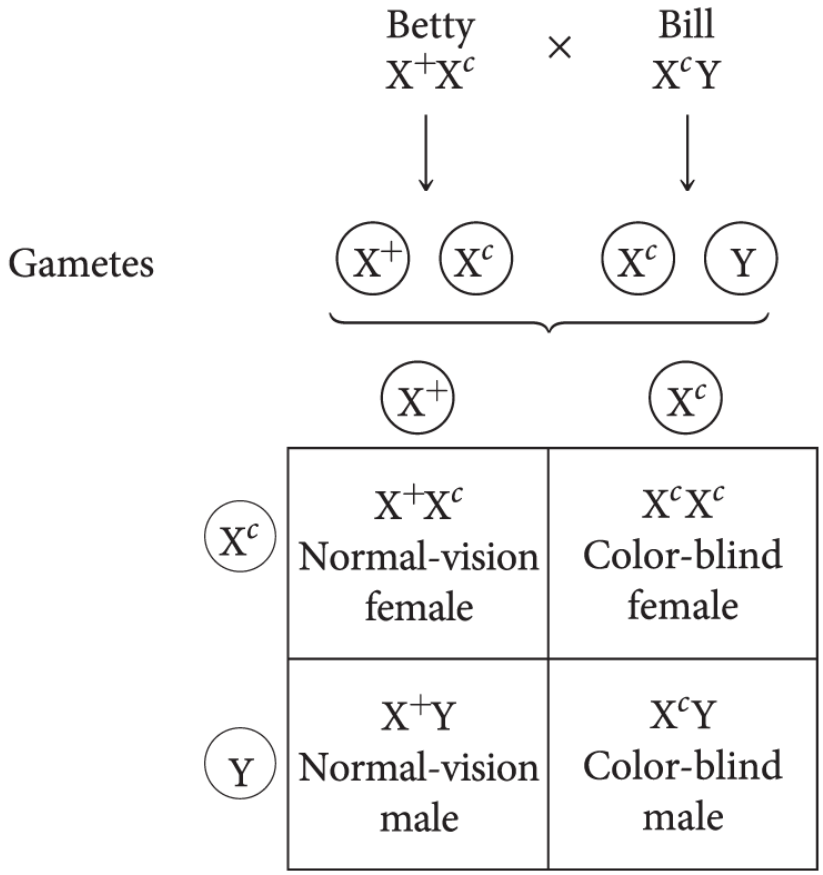
The probability that Bill and Betty's child will be color blind.

What information is provided to solve the problem?

Red–green color blindness is an X-linked recessive trait. The phenotypes of Betty, Betty's mother, and Bill.

Solution Steps

Because color blindness is an X-linked recessive trait, Betty's color-blind mother must be homozygous for the color-blindness allele (X^cX^c). Females inherit one X chromosome from each of their parents, so Betty must have inherited a color-blindness allele from her mother. Because Betty has normal color vision, she must have inherited an allele for normal color vision (X^+) from her father; thus, Betty is heterozygous (X^+X^c). Bill is color blind. Because males are hemizygous for X-linked alleles, he must be (X^cY). A mating between Betty and Bill is represented as



Description

Betty has genotype big X superscript positive big X superscript C and the gametes produced are as follows: big X superscript positive and big X superscript C. Bill has genotype big X superscript C big Y and the gametes produced are as follows: big X superscript C and big Y. A Punnett square with 2 rows and 2 columns has the following entries:

The column headers are as follows: big X superscript positive and big X superscript C

The row headers are as follows: big X superscript C and big Y

Row 1 column 1: big X superscript positive big X superscript C (Normal-vision

Female)

Row 1 column 2: big X superscript C big X superscript C (Color-blind Female)

Row 2 column 1: big X superscript positive big Y (Normal-vision Male)

Row 2 column 2: big X superscript C big Y (Color-blind Male)

Thus, the overall probability that their child will be color blind is $1/2$.

THINK-PAIR-SHARE Question 6

❯❯ Get some additional practice with X-linked inheritance by working **Problem 24** at the end of this chapter.

CONCEPTS

Characteristics determined by genes on the sex chromosomes are called sex-linked characteristics. In organisms with XX-XY sex determination, diploid females have two alleles at each X-linked locus, whereas diploid males possess a single allele at each X-linked locus. Females inherit X-linked alleles from both parents, but males inherit a single X-linked allele from their mothers.

✔ CONCEPT CHECK 6

Hemophilia (reduced blood clotting) is an X-linked recessive disease in humans. A woman with hemophilia mates with a man who exhibits normal blood clotting. What is the probability that their child will have hemophilia?

Symbols for X-Linked Genes

There are several different ways to record genotypes for X-linked characteristics. Sometimes these genotypes are written in the same way as those for autosomal characteristics. In this case, hemizygous males are simply given a single allele: for example, the genotype of a female *Drosophila* with white eyes is *ww*, and the genotype of a white-eyed hemizygous male is *w*. Another method is to include the Y chromosome, designating it with a diagonal slash (/). With this method, the white-eyed female's genotype is still *ww*, and the white-eyed male's genotype is *w*/. Perhaps the most useful method is to record the X and Y chromosomes in the genotype, designating the X-linked alleles with superscripts, as is done in this chapter. With this method, a white-eyed female is X^wX^w and a white-eyed male is X^wY. The use of Xs and Ys in the genotype has the advantage of reminding us that the genes are X linked and that the male must always have a single allele, inherited from the mother.

Z-Linked Characteristics

In organisms with ZZ-ZW sex determination, males are the homogametic sex (ZZ) and carry two sex-linked (usually referred to as Z-linked) alleles; thus, males may be homozygous or heterozygous. Females are the heterogametic sex (ZW) and possess only a single Z-linked allele. The inheritance of Z-linked characteristics is the same as that of X-linked characteristics, except that the pattern of inheritance in males and females is reversed.

One example of a Z-linked characteristic is the cameo phenotype in Indian blue peafowl (*Pavo cristatus*). In these birds, the wild-type plumage is a glossy metallic blue. The female peafowl is ZW and the male is ZZ. Cameo plumage, which produces brown feathers, results from a Z-linked allele (Z^{ca}) that is recessive to the wild-type blue allele (Z^{Ca+}). If a blue female ($Z^{Ca+}W$) is crossed with a cameo male ($Z^{ca}Z^{ca}$), all the F_1 females are cameo ($Z^{ca}W$) and all the F_1 males are blue ($Z^{Ca+}Z^{ca}$), as shown in **Figure 4.15**. When the F_1 are interbred, $^1/_4$ of the F_1 are blue males ($Z^{Ca+}Z^{ca}$), $^1/_4$ are blue females ($Z^{Ca+}W$), $^1/_4$ are cameo males ($Z^{ca}Z^{ca}$), and $^1/_4$ are cameo females ($Z^{ca}W$). The reciprocal cross of a cameo female with a homozygous blue male produces an F_1 generation in which all offspring are blue and an F_2 generation consisting of $^1/_2$ blue males ($Z^{Ca+}Z^{Ca+}$ and $Z^{Ca+}Z^{ca}$), $^1/_4$ blue females ($Z^{Ca+}W$), and $^1/_4$ cameo females ($Z^{ca}W$).

The column headers represent eggs and are as follows: big Z superscript big C small A positive and big W.

Row 1 column 1: big Z superscript big C small A positive big Z superscript big C small A positive (blue male).

Row 1 column 2: big Z superscript big C small A positive big W (blue female).

Row 2 column 1: big Z superscript big C small A positive big Z superscript small C small A (blue male).

Row 2 column 2: big Z superscript small C small A big W (cameo female).

A caption below reads, “Conclusion: one-half blue males, one-fourth blue females, and one-fourth cameo females.”

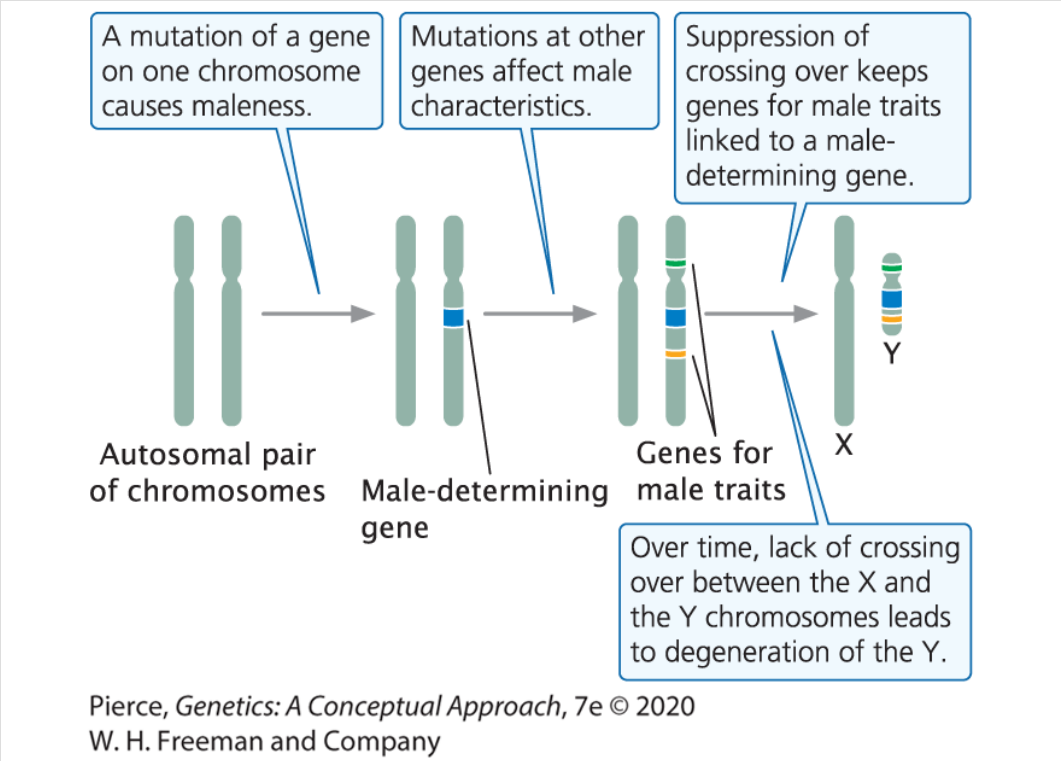
In organisms with ZZ-ZW sex determination, the female always inherits her W chromosome from her mother, and she inherits her Z chromosome, along with any Z-linked alleles, from her father. In this system, the male inherits Z chromosomes, along with any Z-linked alleles, from both his mother and his father. This pattern of inheritance is the reverse of that of X-linked alleles in organisms with XX-XY sex determination. › **TRY** PROBLEM 35

Y-Linked Characteristics

Y-linked traits—also called holandric traits—exhibit a distinct pattern of inheritance. These traits are present only in males, because only males possess a Y chromosome, and are always inherited from the father. Furthermore, all male offspring of a male with a Y-linked trait will display this trait, because every male inherits his Y chromosome from his father. › **TRY** PROBLEM 48

EVOLUTION OF THE Y CHROMOSOME

Research on sex chromosomes has led to the conclusion that the X and Y chromosomes in many organisms evolved from a pair of autosomes. The first step in this evolutionary process took place when one member of a pair of autosomes acquired a gene that determines maleness, such as the *SRY* gene found in humans today (**Figure 4.16**). This step took place in mammals about 250 million years ago. Any individual organism with a copy of the chromosome containing this gene then became male. Additional mutations occurred on the proto-Y chromosome, affecting traits that are beneficial only in males, such as sperm development. The genes that encode these types of traits are advantageous only if they are present in males. Natural selection favors the suppression of crossing over for most of the length of the X and Y chromosomes because this suppression prevents genes that encode male traits from appearing in females. Crossing over can still take place between the two X chromosomes in females, but there is little crossing over between the X and the Y chromosomes, except for the small pseudoautosomal regions in which the X and the Y chromosomes continue to pair in meiosis, as stated earlier.



4.16 Evolution of the Y chromosome.

Description

The illustration shows an autosomal pair of chromosomes where both are of same length and their short arm are shorter than long arm. A mutation of a gene occurs in the second chromosome. A caption reads, “A mutation of a gene on one chromosome causes maleness.” A blue band below centromere of the second chromosome represents male determining gene. Mutations occur at other genes. A caption reads, “Mutations at other genes affect male characteristics.” The second chromosome now has two genes for male traits: a green colored band representing one gene is above the centromere and another yellow colored band representing other gene is below the centromere (also below the male determining gene). A caption reads, “Over time, lack of crossing over between the X and the Y chromosomes leads to degeneration of the Y.” Another caption reads, “Suppression of crossing over keeps genes for male traits linked to male determining gene.” Finally, one X chromosome remains intact but the other chromosome of the autosomal pair with male-determining gene becomes extremely shorter and relatively thicker. This Y chromosome has a male determining gene and two genes for male traits.

For reasons that are beyond the scope of this discussion, the lack of crossing over led to (and continues to lead to) an accumulation of mutations on and a loss of genetic material from the Y chromosome (see Figure 4.16). Over millions of years, the Y chromosome slowly degenerated, losing DNA and genes until it became greatly reduced in size and contained little genetic information. This degeneration produced the Y chromosome found in males today. Indeed, the Y chromosomes of humans and many other organisms are small and contain little genetic information; therefore, few characteristics exhibit Y-linked inheritance. Some researchers have predicted that the human Y chromosome will continue to lose genetic information in the future and will completely disappear from the species in about 10 million years, a disheartening prospect for those of us with a Y chromosome (and perhaps some of those with two Xs). However, new research suggests that decay of the human Y chromosome has come to a halt and that no genes have been lost in the last 6 million years. The genes that remain on the Y chromosome appear to be remarkably stable. Internal recombination within the Y chromosome (described in the next section) may have aided in slowing down or preventing the complete decay of the human Y chromosome.

Among animals, sex chromosomes have independently evolved from autosomes many times. This phenomenon has even been observed in mammals: the sex chromosomes of monotremes (egg-laying mammals such as the duck-billed platypus) evolved from different

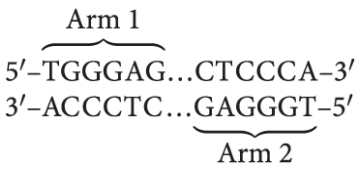
autosomes than did the sex chromosomes of placental and marsupial mammals.

THINK-PAIR-SHARE Question 7

CHARACTERISTICS OF THE HUMAN Y CHROMOSOME

The genetic sequence of most of the human Y chromosome was determined as part of the Human Genome Project (see Chapter 20). This work revealed that about two-thirds of the Y chromosome consists of short DNA sequences that are repeated many times and contain no active genes. The other third consists of just a few genes. Only about 350 genes have been identified on the human Y chromosome, compared with thousands on most chromosomes, and only about half of those identified encode proteins. Some of the protein-encoding genes found on the Y chromosome have homologous genes on the X chromosome. The function of most Y-linked genes is poorly understood; many appear to influence male sexual development and fertility. Others play a role in gene regulation and protein stability. Some are expressed throughout the body, but many are expressed predominantly or exclusively in the testes. Although the Y chromosome has relatively few genes, research with *Drosophila* suggests that it carries genetic elements that affect the expression of numerous genes on autosomes and X chromosomes.

A surprising feature revealed by sequencing is the presence of eight massive palindromic sequences on the Y chromosome. A palindrome is a sentence or word, such as *rotator*, that reads the same backward and forward. A palindromic sequence in DNA is a sequence that reads the same on both strands of the double helix, creating two nearly identical copies stretching out from a central point, such as



Description
The illustration shows both the template and complementary strands. From 5 prime to 3 prime the sequence is as follows: (arm 1 begins) big T big G big G big G big A big G (arm 1 ends) ellipsis big C big T big C big C big C big A. The complementary strand has the following sequence from 3 prime to 5 prime: big A big C big C big C big T big C ellipsis (arm 2 begins) big G big A big G big G big G big T (arm 2 ends).

Thus, a palindromic sequence in DNA appears twice, very much like the two copies of a DNA sequence that are found on two homologous chromosomes. And just as it does with homologous chromosomes, recombination can take place between the two palindromic sequences on the Y chromosome. As already mentioned, the X and the Y chromosomes are not homologous at most of their sequences, and most of the Y chromosome does not undergo crossing over with the X chromosome. This lack of interchromosomal recombination leads to an accumulation of deleterious mutations on the Y

chromosome and the loss of genetic material. Evidence suggests that the two arms of the Y chromosome recombine with each other, which partly compensates for the absence of recombination between the X and the Y chromosomes. This internal recombination may help to maintain some sequences and functions of genes on the Y chromosome and prevent its total degeneration.

Although the palindromic sequences afford opportunities for recombination, which helps prevent the decay of the Y chromosome over evolutionary time, they occasionally have harmful effects. Recent research has revealed that recombination between the palindromes can lead to rearrangements of the Y chromosome that cause anomalies of sexual development. In some cases, recombination between the palindromes leads to deletion of the *SRY* gene, producing an XY female. In other cases, recombination deletes other Y-chromosome genes that take part in sperm production. Sometimes recombination produces a Y chromosome with two centromeres; such a chromosome may break as the centromeres are pulled in opposite directions in mitosis. The broken Y chromosomes may be lost in mitosis, resulting in XO cells and Turner syndrome.

CONCEPTS

Y-linked traits exhibit a distinct pattern of inheritance: they are present only in males, and all male offspring of a male with a Y-linked trait inherit the trait. Palindromic sequences within the Y chromosome can undergo internal recombination, but such recombination may lead to chromosome anomalies.

✔ CONCEPT CHECK 7

What unusual feature of the Y chromosome allows some recombination among the genes found on it?

THE USE OF Y-LINKED GENETIC MARKERS

DNA sequences in the Y chromosome undergo mutation with the passage of time and thus vary among individual males. These mutations create variations in DNA sequence that, like Y-linked traits, are passed from father to son and can therefore be used as genetic markers to study male ancestry. Although the markers themselves do not encode any physical traits, they can be detected with the use of molecular methods. Mutations can readily accumulate in the Y chromosome because so much of it is nonfunctional. Many of these mutations are unique; they arise only once and are passed down through the generations. Individual males possessing the same set of mutations are therefore assumed to be related, and the distribution of these genetic markers on Y chromosomes provides clues about the genetic relationships of present-day people.

Y-linked genetic markers have been used to study the offspring of Thomas Jefferson, principal author of the Declaration of Independence and third president of the United States. In 1802, a political enemy accused Jefferson of fathering a child by his slave

Sally Hemings, but the evidence was circumstantial. Hemings, who worked in the Jefferson household and accompanied Jefferson on a trip to Paris, had five children. Jefferson was accused of fathering the first child, but rumors about the paternity of the other children circulated as well. Descendants of Hemings's children maintained that they were part of the Jefferson line, but some Jefferson descendants refused to recognize their claim.

To resolve this long-standing controversy, geneticists examined markers from the Y chromosomes of male-line descendants of Hemings's first son (Thomas Woodson), her last son (Eston Hemings), and a paternal uncle of Thomas Jefferson with whom Jefferson had Y chromosomes in common (descendants of Jefferson's uncle were used because Jefferson himself had no verified male descendants). Geneticists determined that Jefferson possessed a rare and distinctive set of genetic markers on his Y chromosome. The same markers were also found on the Y chromosomes of the male-line descendants of Eston Hemings. The probability of such a match arising by chance is less than 1%. The markers were not found on the Y chromosomes of the descendants of Thomas Woodson. Together with the circumstantial historical evidence, these matching markers suggest that Jefferson (or a male-line relative of Jefferson) was the father of Eston Hemings but not Thomas Woodson.

Y-chromosome sequences have also been used extensively to examine past patterns of male migration and the genetic relationships among different human populations. Female lineages

can be traced through sequences on mitochondrial DNA, which are inherited from the mother (see Chapter 11).

CONNECTING CONCEPTS

Recognizing Sex-Linked Inheritance

What features should we look for to identify a trait as sex linked? A common misconception is that any genetic characteristic in which the phenotypes of males and females differ must be sex linked. In fact, the expression of many *autosomal* characteristics differs between males and females. The genes that encode these characteristics are the same in both sexes, but their expression is influenced by sex hormones. The different sex hormones of males and females cause the same genes to generate different phenotypes in males and females.

Another misconception is that any characteristic that is found more frequently in one sex than in the other is sex linked. A number of autosomal traits are expressed more commonly in one sex than in the other. These traits are said to be sex-influenced. Some autosomal traits are expressed in only one sex; these traits are said to be sex-limited. Both sex-influenced and sex-limited characteristics will be considered in more detail in Chapter 5.

Several features of sex-linked characteristics make them easy to recognize. Y-linked traits are found only in males, but observing a trait only in males does not guarantee that it is Y linked because some autosomal characteristics are expressed only in males. Y-linked traits are unique, however, in that *all* the male offspring of an affected male express the father's phenotype. Furthermore, a Y-linked trait can be inherited only from the father's side of the family. Thus, a Y-linked trait can be inherited only from the paternal grandfather (the father's father), never from the maternal grandfather (the mother's father).

X-linked characteristics also exhibit a distinctive pattern of inheritance. X linkage is a possible explanation when reciprocal crosses give different results. If a characteristic is X linked, a cross between an affected male and an unaffected female will not give the same results as a cross between an affected female and an unaffected male. For almost all autosomal characteristics, reciprocal crosses give the same result. We should not conclude, however, that when the reciprocal crosses give different results, the characteristic is necessarily X linked. Other sex-associated forms of inheritance, considered in Chapter 5, also produce different results in reciprocal crosses. The key to recognizing X-linked inheritance is to remember that a

male always inherits his X chromosome from his mother, not from his father. Thus, an X-linked characteristic is not passed directly from father to son; if a male clearly inherits a trait from his father—and his mother is not heterozygous—it cannot be X linked.

4.3 Dosage Compensation Equalizes the Amount of Protein Produced by X-Linked and Autosomal Genes in Some Animals

In species with XX-XY sex determination, differences between males and females in their number of X chromosomes present a special problem in development. In females, there are two copies of the X chromosome and two copies of each autosome, so genes on the X chromosomes and on autosomes are "in balance." In males, however, there is only a single X chromosome, while there are two copies of every autosome. Because the amount of a protein produced is often a function of the number of gene copies encoding that protein, males are likely to produce smaller amounts of a protein encoded by X-linked genes than of a protein encoded by autosomal genes. This difference can be detrimental because protein concentration often plays a critical role in development.

Some animals have overcome this problem by evolving mechanisms to equalize the amounts of protein produced by the single X and by two autosomes in the heterogametic sex. These mechanisms are referred to as **dosage compensation**. In fruit flies, dosage compensation is achieved by a doubling of the activity of the genes on the X chromosome of males, but not that of females. In placental mammals, the expression of dosage-sensitive genes on

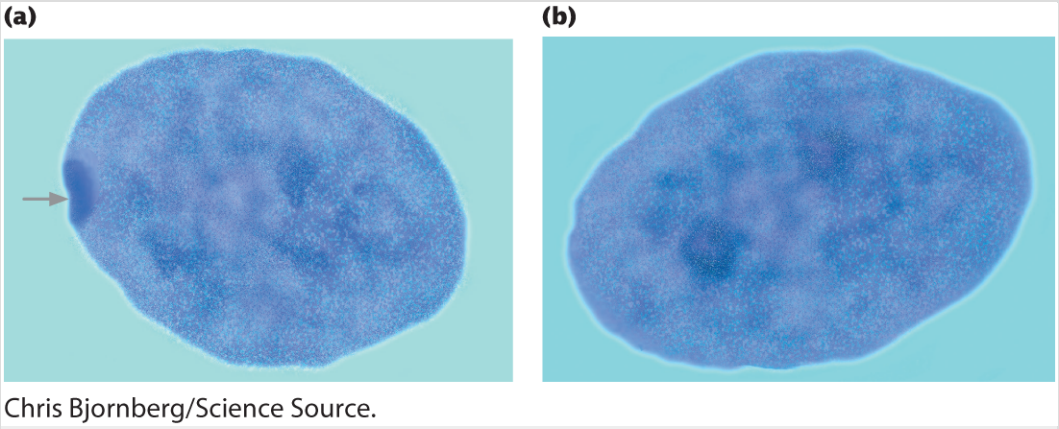
the X chromosomes of both males and females has increased, coupled with inactivation of one of the X chromosomes in females, so that expression of X-linked and autosomal genes is balanced in both males and females.

For unknown reasons, the presence of sex chromosomes does not always produce problems of gene dosage, and dosage compensation of X-linked genes is not universal. A number of animals do not exhibit obvious mechanisms of dosage compensation; these animals include butterflies and moths, birds, some fishes, and even the duck-billed platypus. As we see in the next section, even in placental mammals, a number of genes escape dosage compensation.

The Lyon Hypothesis

In 1949, Murray Barr observed condensed, darkly staining bodies in the nuclei of cells from female cats (**Figure 4.17**); these structures became known as **Barr bodies**. Mary Lyon proposed, in 1961, that the Barr body was an inactive X chromosome; her hypothesis (now generally accepted for placental mammals) has become known as the **Lyon hypothesis**. She suggested that within each female cell, one of the two X chromosomes is inactivated. Which X chromosome is inactivated is random; if a cell contains more than two X chromosomes, all but one of them are inactivated. The

number of Barr bodies present in human cells with different complements of sex chromosomes is shown in Table 4.3. Lyon's hypothesis led to important insights into the process of development, the expression of X-linked traits, and X-linked genetic diseases.



Chris Bjornberg/Science Source.

4.17 A Barr body is an inactivated X chromosome. (a) Female cell with a Barr body (indicated by arrow). (b) Male cell without a Barr body.

TABLE 4.3 Number of Barr bodies in human cells with different complements of sex chromosomes

Sex Chromosomes	Syndrome	Number of Barr Bodies
XX	None	1
XY	None	0
XO	Turner	0

XXY	Klinefelter	1
XXYY	Klinefelter	1
XXXY	Klinefelter	2
XXXXY	Klinefelter	3
XXX	Triple-X	2
XXXX	Poly-X female	3
XXXXX	Poly-X female	4

One of the outstanding geneticists of the twentieth century, Mary Lyon (**Figure 4.18**) conducted significant research in mouse genetics, including important work on mutagenesis, chromosome inversions, and the *t* complex, a genetic element on mouse chromosome 17 that causes some chromosomes to be preferentially transmitted during meiosis. Lyon also developed many techniques that are used today in mouse genetics, helping to make the mouse an important model genetic organism.

© Miron Latyszewski, Courtesy MRC Harwell/Mary Lyon.

4.18 Mary Lyon.

As a result of X inactivation, female placental mammals are functionally hemizygous at the cellular level for X-linked genes. In females that are heterozygous at an X-linked locus, approximately 50% of the cells express one allele and 50% express the other allele; thus, in heterozygous females, proteins encoded by both alleles are produced, but not within the same cell. This functional hemizygosity means that the cells in an individual female are not identical with respect to the expression of the genes on the X

chromosome; females are mosaics for the expression of X-linked genes.

Random X inactivation takes place early in development—in humans, it occurs within the first few weeks of development. After an X chromosome has become inactivated in a cell, it remains inactive in that cell and in all somatic cells that descend from that cell. Thus, neighboring cells tend to have the same X chromosome inactivated, producing a patchy pattern (mosaic) for the expression of an X-linked characteristic in heterozygous females.

This patchy distribution of gene expression can be seen in tortoiseshell and calico cats (**Figure 4.19**). Although many genes contribute to coat color and pattern in domestic cats, a single X-linked locus determines the presence of orange color. There are two possible alleles at this locus: X^+, which produces non-orange (usually black) fur, and X^o, which produces orange fur. Males are hemizygous and thus may be black (X^+Y) or orange (X^oY) but not black and orange. (Rare tortoiseshell males can arise from the presence of two X chromosomes, X^+X^oY.) Females may be black (X^+X^+), orange (X^oX^o), or tortoiseshell (X^+X^o), with the tortoiseshell pattern arising from a patchy mixture of black and orange fur. Each orange patch is a clone of cells derived from an original cell in which the black allele was inactivated, and each black patch is a clone of cells derived from an original cell in which the orange allele was inactivated.

Robert Adrian Hillman/Shutterstock.

4.19 The patchy distribution of color on tortoiseshell cats results from the random inactivation of one X chromosome in females.

The Lyon hypothesis suggests that the presence of variable numbers of X chromosomes should not affect the phenotype in mammals because any X chromosomes in excess of one should be inactivated. However, people with Turner syndrome (XO) differ from XX females, and those with Klinefelter syndrome (XXY) differ from XY males. How do the phenotypes of these conditions arise in the face of dosage compensation?

The phenotypes associated with these conditions probably arise because some X-linked genes escape inactivation. Indeed, the nature of X inactivation is more complex than originally envisioned. Studies of individual genes now reveal that only about 75% of X-linked human genes are permanently inactivated. About 15% completely escape X inactivation, meaning that these genes produce twice as much protein in females as they do in males. The

remaining 10% are inactivated in some females but not in others. The reason for this variation among females is not known. Furthermore, recent research indicates that X inactivation does not actually equalize dosage of many X-linked and autosomal genes in humans and mice. › **TRY** PROBLEM 47

Mechanism of Random X Inactivation

Random inactivation of X chromosomes requires two steps. In the first step, the cell somehow assesses, or counts, how many X chromosomes are present. In the second step, one X chromosome is selected to become the active X chromosome, and all others are inactivated.

Although some details of X-chromosome inactivation remain unknown, several genes and sequences that participate in the process have been identified. Foremost among them is a gene called *Xist* (for *X-i*nactive *s*pecific *t*ranscript). On the X chromosomes destined to be inactivated, the *Xist* gene is active, producing a 17,000-nucleotide-long RNA molecule that coats the X chromosome and inactivates the genes on it by recruiting protein complexes that alter chromatin structure. On the X chromosome destined to be active, other genes repress the activity of *Xist* so that the *Xist* RNA never coats the X chromosome, and genes on this chromosome

remain active. The mechanism of X inactivation is discussed in more detail in Chapter 21.

CONCEPTS

In placental mammals, all but one X chromosome are inactivated in each cell; which of the X chromosomes is inactivated is random and varies from cell to cell.

✔ CONCEPT CHECK 8

How many Barr bodies does a male with XXXYY chromosomes have in each of his cells?

Chapter 4 Review

CHAPTER SUMMARY

Section 4.1 Learning Objective: Be able to outline the different mechanisms by which sex may be determined.

- Sexual reproduction is the production of offspring that are genetically distinct from their parents. Most organisms have two sexual phenotypes—males and females. Males produce small gametes; females produce large gametes.
- The mechanism by which sex is specified is termed sex determination. Sex may be determined by differences in specific chromosomes, genotypes, or environment.
- The sex chromosomes of males and females differ in number and appearance. The homogametic sex produces gametes that are all identical with regard to sex chromosomes; the heterogametic sex produces gametes that differ in their sex-chromosome composition.
- In the XX-XO system of sex determination, females possess two X chromosomes, whereas males possess a single X chromosome. In the XX-XY system, females possess two X chromosomes, whereas males possess a single X chromosome and a single Y chromosome. In the ZZ-ZW system, males possess two Z chromosomes, whereas females possess a Z chromosome and a W chromosome.

- Some organisms have genic sex determination, in which genotypes at one or more loci determine the sex of an individual organism. Still others have environmental sex determination.
- In *Drosophila melanogaster*, sex can be predicted by the X : A ratio but is primarily determined by genes on the X chromosome.
- In humans, sex is ultimately determined by the presence or absence of the *SRY* gene located on the Y chromosome.

Section 4.2 Learning Objective: Be able to predict the types and proportions of progeny produced in crosses involving traits determined by genes on sex chromosomes.

- Sex-linked characteristics are determined by genes on the sex chromosomes. X-linked characteristics are encoded by genes on the X chromosome, and Y-linked characteristics are encoded by genes on the Y chromosome.
- A female inherits X-linked alleles from both parents; a male inherits X-linked alleles from his female parent only.
- Y-linked characteristics are found only in males and are passed from a father to all his sons.
- The sex chromosomes evolved from autosomes. Crossing over between the X and the Y chromosomes has been suppressed, but palindromic sequences within the Y chromosome allow for internal recombination on the Y chromosome. This internal recombination sometimes leads to chromosome rearrangements that can adversely affect sexual development.

Section 4.3 Learning Objective: Be able to explain how dosage compensation equalizes the amount of protein produced by X-linked and autosomal genes.

- In placental mammals, one of the two X chromosomes in females is normally inactivated. Which X chromosome is inactivated is random and varies from cell to cell. Some X-linked genes escape X inactivation, and other X-linked genes may be inactivated in some females but not in others. X inactivation is controlled by the *Xist* gene.

WORKED PROBLEMS

Problem 1

A fruit fly has XXXYY sex chromosomes; all the autosomal chromosomes are normal. What sexual phenotype does this fly have?

» Solution Strategy

What information is required in your answer to the problem?

The sexual phenotype of a fly with sex chromosomes XXXYY.

What information is provided to solve the problem?

- The fly has sex chromosomes XXXYY.

- All autosomal chromosomes are normal.

For help with this problem, review:

Sex Determination in *Drosophila melanogaster* in Section 4.1.

» Solution Steps

Sex in fruit flies is predicted by the X : A ratio—the ratio of the number of X chromosomes to the number of haploid autosomal sets. An X : A ratio of 1.0 produces a female fly; an X : A ratio of 0.5 produces a male. If the X : A ratio is greater than 1.0, the fly is a metafemale; if it is less than 0.5, the fly is a metamale; if the X : A ratio is between 1.0 and 0.5, the fly is intersex.

This fly has three X chromosomes and normal autosomes, so the X : A ratio in this case is $^{3}/_{2}$, or 1.5. Thus, this fly is a metafemale.

> **Recall:** *Drosophila melanogaster* normally has two sets of autosomes.

Problem 2

In *Drosophila melanogaster*, forked bristles are caused by an allele (X^{f}) that is X linked and recessive to an allele for normal bristles (X^{+}). Brown eyes are caused by an allele (b) that is autosomal and recessive to an allele for red eyes (b^{+}). A female fly that is

homozygous for normal bristles and red eyes mates with a male fly that has forked bristles and brown eyes. The F_1 are intercrossed to produce the F_2. What will be the phenotypes and proportions of the F_2 flies from this cross?

» Solution Strategy

What information is required in your answer to the problem?

Phenotypes and proportions of the F_2 flies.

What information is provided to solve the problem?

- Forked bristles are X-linked recessive.
- Brown eyes are autosomal recessive.
- Phenotypes of the parents of the cross.
- The F_1 are intercrossed to produce the F_2.

For help with this problem, review:

X-linked Color Blindness in Humans in Section 4.2.

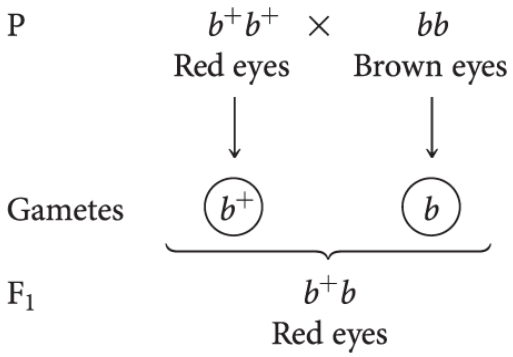
Section 3.3 in Chapter 3.

» Solution Steps

This problem is best worked by breaking the cross down into two separate crosses, one for the X-linked genes that determine the type

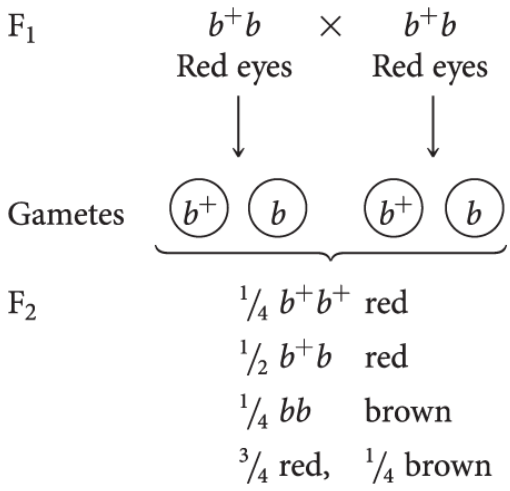
of bristles and one for the autosomal genes that determine eye color.

Let's begin with the autosomal characteristics. A female fly that is homozygous for red eyes (b^+b^+) is crossed with a male with brown eyes. Because brown eyes are recessive, the male fly must be homozygous for the brown-eye allele (bb). All the offspring of this cross will be heterozygous (b^+b) and will have red eyes:



Description
Genotype of the parent fly (P generation) for red eyes is as follows: small B superscript positive small B superscript positive. Genotype of the parent fly for brown eyes is as follows: small B small B. Genotypes of the gametes produced are as follows: small B superscript positive and small B, respectively. The F subscript 1 progeny produced from the cross has red eyes with small B superscript positive small B.

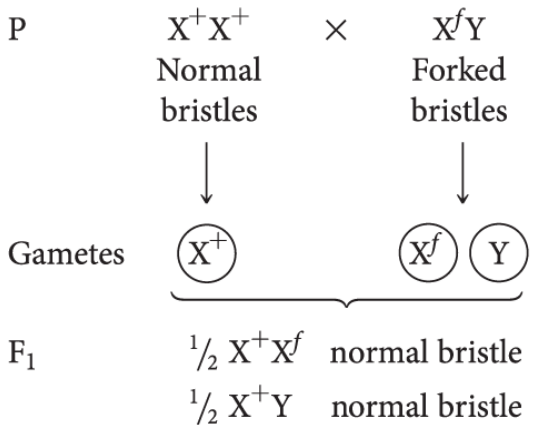
The F_1 are then intercrossed to produce the F_2. Whenever two individual organisms heterozygous for an autosomal recessive characteristic are crossed, $^3/_4$ of the offspring will have the dominant trait, and $^1/_4$ will have the recessive trait; thus, $^3/_4$ of the F_2 flies will have red eyes, and $^1/_4$ will have brown eyes:



Description

The illustration shows F subscript 1 generation in which two red-eyed flies with genotype small B superscript positive small B are intercrossed. The gametes obtained from each of them are as follows: small B superscript positive and small B. F subscript 2 generation is shown below the gametes and their genotypes are as follows: one-fourth small B superscript positive small B superscript positive (red); one-half small B superscript positive small B (red); one-fourth small B small B (brown). A text below reads three-fourth red and one-fourth brown.

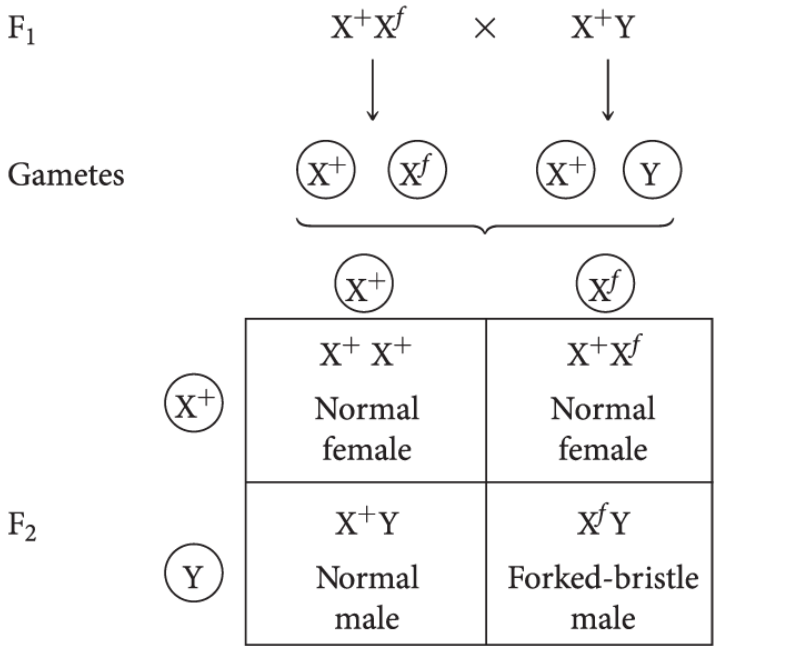
Next, we work out the results for the X-linked characteristic. A female that is homozygous for normal bristles (X^+X^+) is crossed with a male that has forked bristles (X^fY). Thefemale F_1 from this cross are heterozygous (X^+X^f), receiving an X chromosome with a normal-bristle allele (X^+) from their mother and an X chromosome with a forked-bristle allele (X^f) from their father. The male F_1 are hemizygous (X^+Y), receiving an X chromosome with a normal-bristle allele (X^+) from their mother and a Y chromosome from their father:



Description
Genotype of the parent (P generation) with normal bristles is as follows: big X superscript positive big X superscript positive. Genotype of the parent with forked bristles is as follows: big X superscript small F big Y. Genotypes of the gametes produced are as follows: big X superscript positive and big X superscript positive and big Y, respectively. Half of the progenies produced in the F subscript 1 generation have big X superscript positive big X superscript small F (normal bristles) and the other half have genotype big X superscript positive big Y (normal bristles).

Recall: Females have two X-linked alleles, but males have only a single X-linked allele.

When these F_1 are intercrossed, $^1/_2$ of the F_1 will be normal-bristle females, $^1/_4$ will be normal-bristle males, and $^1/_4$ will be forked-bristle males:



½ normal female, ¼ normal male, ¼ forked-bristle male

Description

The illustration shows female with genotype, big X superscript positive big X superscript small F, is crossed with male with big X superscript positive big Y. Genotypes of the gametes produced are as follows: big X superscript positive, big X superscript small F from big X superscript positive big X superscript small F and big X superscript positive and big Y from big X superscript positive big Y. F subscript 2 generation is obtained. A punnett square having 2 rows and 2 columns shows the following entries:

Row headers are as follows: big X superscript positive and big Y.

Column headers are as follows: big X superscript positive and big X superscript small F.

Row 1 column 1: big X superscript positive big X superscript positive.

Row 1 column 2: big X superscript positive big X superscript small F.

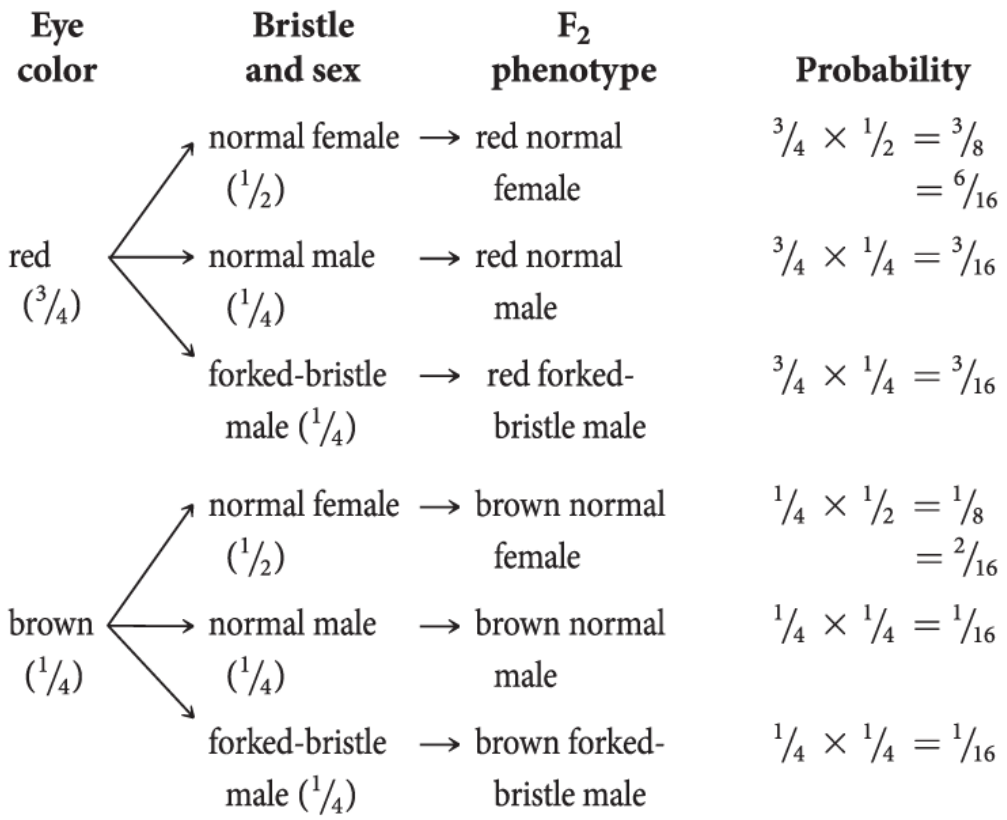
Row 2 column 1: big X superscript positive big Y.

Row 2 column 2: big X superscript small F big Y.

Text at the bottom reads one-half normal female, one-half normal male, and one-fourth forked-bristle male.

To obtain the phenotypic ratio in the F_2, we now combine these two crosses by using the multiplication rule and a branch diagram:

Recall: The multiplication rule states that the probability of two independent events occurring together is the multiplication of their independent probabilities.



Description
First tier of the branch diagram on the left shows eye color as follows: three-fourth red and one-fourth brown. Second tier of the branch diagram to its right shows bristle and sex as follows: red normal female one-half, red normal male one-fourth, and red forked-bristle male one-fourth, brown normal female one-half, brown normal male one-fourth, and brown forked-bristle male one-fourth. Third tier of the branch diagram on the right shows F subscript 2 phenotype and the fourth tier on the extreme right shows probability for each of the phenotype of third tier respectively as follows: red normal female; three-fourth multiplied by one-half equals three-eighth equals six over sixteen, red normal male; three-

fourth multiplied by one-fourth equals three over sixteen, red forked-bristle male; three-fourth multiplied by one-fourth equals three over sixteen, brown normal female; one-fourth multiplied by one-half equals one-eighth equals two over sixteen, brown normal male; one-fourth multiplied by one-fourth equals one over sixteen, and brown forked-bristle male; one-fourth multiplied by one-fourth equals one over sixteen. The first three entries from second, third, and fourth tier correspond to red eye color and the last three entries from second, third, and fourth tier correspond to brown eye color.

Hint: The branch diagram is a convenient way of keeping up with all the different combinations of traits.

ANSWERS TO CONCEPT CHECKS

1. Meiosis
2. b
3. In chromosomal sex determination, males and females have chromosomes that are distinguishable. In genic sex determination, sex is determined by genes, but the chromosomes of males and females are indistinguishable. In environmental sex determination, sex is determined fully or in part by environmental effects.
4. a
5. c
6. All of their male offspring will have hemophilia, and none of their female offspring will have hemophilia, so the overall probability of hemophilia in their offspring is $^1/_2$.

7. Eight large palindromes allow crossing over within the Y chromosome.
8. Two Barr bodies.

Chapter 4 Assessment

COMPREHENSION QUESTIONS

Section 4.1

1. What is considered to be the fundamental difference between males and females of most organisms?

2. How do monoecious organisms differ from dioecious organisms?

3. Describe the XX-XO system of sex determination. In this system, which is the heterogametic sex, and which is the homogametic sex?

4. *How does sex determination in the XX-XY system differ from sex determination in the ZZ-ZW system?

5. What is the pseudoautosomal region? How does the inheritance of traits encoded by genes in this region differ from the inheritance of other Y-linked characteristics?

6. What is meant by genic sex determination?

7. How does sex determination in *Drosophila* differ from sex determination in humans?

8. Give the typical sex-chromosome complement found in the cells of people with Turner syndrome, with Klinefelter syndrome, and with androgen-insensitivity syndrome. What is the sex-chromosome complement of triple-X females?

Section 4.2

9. What characteristics are exhibited by an X-linked trait?

10. Explain how Bridges's study of nondisjunction in *Drosophila* helped prove the chromosome theory of inheritance.

11. What characteristics are exhibited by a Y-linked trait?

Section 4.3

12. Explain why tortoiseshell cats are almost always female and why they have a patchy distribution of orange and black fur.

13. What is a Barr body? How is it related to the Lyon hypothesis?

APPLICATION QUESTIONS AND PROBLEMS

Introduction

14. As discussed in the introduction to this chapter, sex in bearded dragons is determined by both sex chromosomes and temperature. What, if any, would be the effect of unusually cool

temperatures during the breeding season on the sex ratio of bearded dragons? What would be the effect of unusually warm temperatures on the sex ratio?

Section 4.1

15. *What is the sexual phenotype of fruit flies having the following chromosomes?

Sex chromosomes	Autosomal chromosomes
a. XX	all normal
b. XY	all normal
c. XO	all normal
d. XXY	all normal
e. XYY	all normal
f. XXYY	all normal
g. XXX	all normal
h. XX	four haploid sets
i. XXX	four haploid sets
j. XXX	three haploid sets

k. X	three haploid sets
l. XY	three haploid sets
m. XX	three haploid sets

16. CONNECT If nondisjunction of the sex chromosomes takes place in meiosis I (see Chapter 2) in the male in **Figure 4.5**, what sexual phenotypes and proportions of offspring will be produced?

17. *For each of the following chromosome complements, what is the phenotypic sex of a person who has

    a. XY with the *SRY* gene deleted?

    b. XX with a copy of the *SRY* gene on an autosomal chromosome?

    c. XO with a copy of the *SRY* gene on an autosomal chromosome?

    d. XXY with the *SRY* gene deleted?

    e. XXYY with one copy of the *SRY* gene deleted?

18. A normal female *Drosophila* produces abnormal eggs that contain all of her chromosomes (a complete diploid set). She mates with a normal male *Drosophila* that produces normal sperm. What will the sex of the progeny from this cross be?

19. In certain salamanders, the sex of a genetic female can be altered, changing her into a functional male; these salamanders are called sex-reversed males. When a sex-reversed male is mated with a normal female, approximately $^2/_3$ of the offspring are female and $^1/_3$ are male. How is sex determined in these salamanders? Explain the results of this cross.

20. In some mites, males pass genes to their grandsons, but they never pass genes to their sons. Explain.

21. *In organisms with the ZZ-ZW sex-determining system, from which of the following possibilities can a female inherit her Z chromosome?

	Yes	No
Her mother's mother	_____	_____
Her mother's father	_____	_____
Her father's mother	_____	_____
Her father's father	_____	_____

Section 4.2

22. *When Bridges crossed white-eyed females with red-eyed males, he obtained a few red-eyed males and white-eyed females (see **Figure 4.13**). What types of offspring would be produced if these red-eyed males and white-eyed females were crossed with each other?

23. *Joe has classic hemophilia, an X-linked recessive disease. Could Joe have inherited the gene for this disease from the following people?

	Yes	No
a. His mother's mother	_____	_____
b. His mother's father	_____	_____
c. His father's mother	_____	_____
d. His father's father	_____	_____

24. *In *Drosophila*, yellow body color is due to an X-linked gene that is recessive to the gene for gray body color.

Courtesy Dr. Masa-Toshi Yamamoto, Drosophila Genetic Resource Center, Kyoto Institute of Technology.

a. A homozygous gray female is crossed with a yellow male. The F_1 are intercrossed to produce the F_2. Give the genotypes and phenotypes, along with the expected proportions, of the F_1 and F_2 progeny.

b. A yellow female is crossed with a gray male. The F_1 are intercrossed to produce the F_2. Give the genotypes and phenotypes, along with the expected proportions, of the F_1 and F_2 progeny.

c. A yellow female is crossed with a gray male. The F_1 females are backcrossed with gray males. Give the genotypes and phenotypes, along with the expected proportions, of the F_2 progeny.

d. If the F_2 flies in part *b* mate randomly, what are the expected phenotypes and proportions of flies in the F_3?

25. Coat color in cats is determined by genes at several different loci. At one locus on the X chromosome, one allele (X^+) encodes black fur; another allele (X^o) encodes orange fur. Females can be black

(X^+X^+), orange (X^oX^o), or a mixture of orange and black called tortoiseshell (X^+X^o). Males are either black (X^+Y) or orange (X^oY). Bill has a female tortoiseshell cat named Patches. One night Patches escapes from Bill's house, spends the night out, and mates with a stray male. Patches later gives birth to the following kittens: one orange male, one black male, two tortoiseshell females, and one orange female. Give the genotypes of Patches, her kittens, and the stray male with which Patches mated.

26. *Red–green color blindness in humans is due to an X-linked recessive gene. Both John and Cathy have normal color vision. After 10 years of marriage to John, Cathy gave birth to a color-blind daughter. John filed for divorce, claiming that he is not the father of the child. Is John justified in his claim of nonpaternity? Explain why. If Cathy had given birth to a color-blind son, would John be justified in claiming nonpaternity?

27. CONNECT Maria has red–green color blindness; Juan has normal color vision. Together, Maria and Juan have two children, Maggi and Daniel. Draw the sex chromosomes of Maggi and Daniel at the following stages, and label on these chromosomes the alleles for color blindness and normal color vision (see Chapter 2 for stages of meiosis). Assume that no crossing over has occurred.

    a. Metaphase of mitosis

    b. Metaphase I of meiosis

    c. Metaphase II of meiosis

28. Red–green color blindness in humans is due to an X-linked recessive gene. A woman whose father is color blind possesses one eye with normal color vision and one eye with color blindness.

    a. Propose an explanation for this woman's vision pattern. Assume that no new mutations have spontaneously arisen.

    b. Would it be possible for a man to have one eye with normal color vision and one eye with color blindness?

29. In 1875, Charles Darwin, author of *On the Origin of Species*, wrote of a peculiar family from Sind, a province in northwest India (C. Darwin. *The Variation of Animals and Plants under Domestication*, 2nd ed. 1875. London: John Murray, London. p. 319):

    > … in which ten men, in the course of four generations, were furnished in both jaws taken together, with only four small and weak incisor teeth and with eight posterior molars. The men thus affected have little hair on the body, and become bald early in life. They also suffer much during hot weather from excessive dryness of the skin. It is remarkable that no instance has occurred of a daughter being thus affected …. Though daughters in the above family are never affected, they transmit the tendency to their sons; and no case has occurred of a son transmitting it to his sons.

    The men in this family had a condition that is now known as hypohidrotic ectodermal dysplasia. Darwin's account is an accurate description of the symptoms and inheritance of this disorder. (a) Based on Darwin's description, what is the most likely mode of inheritance for hypohidrotic ectodermal dysplasia? What evidence in Darwin's description supports your conclusion? (See also Problem 47 and Think-Pair-Share Question 8.)

30. *Bob has XXY chromosomes (Klinefelter syndrome) and is color blind. His mother and father have normal color vision, but his maternal grandfather is color blind. Assume that Bob's chromosome abnormality arose from nondisjunction in meiosis. In which parent and in which meiotic division did nondisjunction take place? Assume no crossing over has taken place. Explain your answer.

31. Xg is an antigen found on red blood cells. This antigen is caused by an X-linked allele (X^a) that is dominant over an allele for the absence of the antigen (X^-). The inheritance of these X-linked alleles was studied in children with chromosome abnormalities to determine where nondisjunction of the sex chromosomes took place. For each type of mating in parts *a* through *d*, indicate whether nondisjunction took place in the mother or in the father and, if possible, whether it took place in meiosis I or meiosis II (assume no crossing over).

    a. $X^aY \times X^-X^- \rightarrow X^a$ (Turner syndrome)

    b. $X^aY \times X^aX^- \rightarrow X^-$ (Turner syndrome)

    c. $X^aY \times X^-X^- \rightarrow X^aX^-Y$ (Klinefelter syndrome)

    d. $X^aY \times X^aX^- \rightarrow X^-X^-Y$ (Klinefelter syndrome)

32. The Talmud, an ancient book of Jewish civil and religious laws, states that if a woman bears two sons who die of bleeding after circumcision (removal of the foreskin from the penis), any additional sons that she has should not be circumcised. (The bleeding is most likely due to the X-linked disorder hemophilia.)

Furthermore, the Talmud states that the sons of her sisters must not be circumcised, whereas the sons of her brothers should be. Is this religious law consistent with sound genetic principles? Explain your answer.

33.

Craniofrontonasal syndrome (CFNS) is a birth defect in which premature fusion of the cranial sutures leads to abnormal head shape, widely spaced eyes, nasal clefts, and various other skeletal abnormalities. George Feldman and his colleagues looked at several families in which offspring had CFNS and recorded the results shown in the following table (G. J. Feldman. 1997. *Human Molecular Genetics* 6:1937–1941).

			Offspring			
Family number	**Parents**		**Normal**		**CFNS**	
	Father	**Mother**	**Male**	**Female**	**Male**	**Female**
1	normal	CFNS	1	0	2	1
5	normal	CFNS	0	2	1	2
6	normal	CFNS	0	0	1	2
8	normal	CFNS	1	1	1	0
10a	CFNS	normal	3	0	0	2
10b	normal	CFNS	1	1	2	0
12	CFNS	normal	0	0	0	1
13a	normal	CFNS	0	1	2	1
13b	CFNS	normal	0	0	0	2
7b	CFNS	normal	0	0	0	2

a. On the basis of these results, what is the most likely mode of inheritance for CFNS?

b. Give the most likely genotypes of the parents in family 1 and in family 10a.

34. Miniature wings (X^m) *in Drosophila* result from an X-linked allele that is recessive to the allele for long wings (X^+). Give the genotypes of the parents in each of the following crosses.

Male parent	Female parent	Male offspring	Female offspring
a. long	Long	231 long, 250 miniature	560 long
b. miniature	Long	610 long	632 long
c. miniature	Long	410 long, 417 miniature	412 long, 415 miniature
d. long	Miniature	753 miniature	761 long
e. long	Long	625 long	630 long

35. *In chickens, congenital baldness is due to a Z-linked recessive gene. A bald rooster is mated with a normal hen. The F_1 from this cross are interbred to produce the F_2. Give the genotypes and

phenotypes, along with their expected proportions, among the F_1 and F_2 progeny.

36. If the blue F_1 females in **Figure 4.15b** are backcrossed to the blue males in the P generation, what phenotypes and proportions of offspring will be produced?

37. Red–green color blindness is an X-linked recessive trait in humans. Polydactyly (extra fingers and toes) is an autosomal dominant trait. Martha has normal fingers and toes and normal color vision. Her mother is normal in all respects, but her father is color blind and polydactylous. Bill is color blind and polydactylous. His mother has normal color vision and normal fingers and toes. If Bill and Martha mate, what phenotypes and proportions of children can they produce?

38. A *Drosophila* mutation called *singed* (*s*) causes the bristles to be bent and misshapen. A mutation called *purple* (*p*) causes the fly's eyes to be purple in color instead of the normal red. Flies homozygous for *singed* and *purple* were crossed with flies that were homozygous for normal bristles and red eyes. The F_1 were intercrossed to produce the F_2, and the following results were obtained.

Cross 1	
P	male, singed bristles, purple eyes × female, normal bristles, red eyes
F_1	420 female, normal bristles, red eyes

	426 male, normal bristles, red eyes
F_2	337 female, normal bristles, red eyes
	113 female, normal bristles, purple eyes
	168 male, normal bristles, red eyes
	170 male, singed bristles, red eyes
	56 male, normal bristles, purple eyes
	58 male, singed bristles, purple eyes

Cross 2	
P	female, singed bristles, purple eyes × male, normal bristles, red eyes
F_1	504 female, normal bristles, red eyes
	498 male, singed bristles, red eyes
F_2	227 female, normal bristles, red eyes
	223 female, singed bristles, red eyes
	225 male, normal bristles, red eyes
	225 male, singed bristles, red eyes

78 female, normal bristles, purple eyes	
76 female, singed bristles, purple eyes	
74 male, normal bristles, purple eyes	
72 male, singed bristles, purple eyes	

a. What are the modes of inheritance of *singed* and *purple?* Explain your reasoning.

b. Give genotypes for the parents and offspring in the P, F_1, and F_2 generations of cross 1 and cross 2.

39. The following two genotypes are crossed: *Aa Bb Cc* $X^+X^r \times$ *Aa BB cc* X^+Y, where *a, b,* and *c* represent alleles of autosomal genes, and X^+ and X^r represent X-linked alleles in an organism with XX-XY sex determination. What is the probability of obtaining genotype *aa Bb Cc* X^+X^+ in the progeny? See Chapter 3 for a review of autosomal inheritance.

40. *Miniature wings in *Drosophila* result from an X-linked allele (X^m) that is recessive to the allele for long wings (X^+). Sepia eyes are produced by an autosomal allele (*s*) that is recessive to an allele for red eyes (s^+).

a. A female fly that has miniature wings and sepia eyes is crossed with a male that has normal wings and is homozygous for red

eyes. The F_1 flies are intercrossed to produce the F_2. Give the phenotypes, as well as their expected proportions, of the F_1 and F_2 flies.

b. A female fly that is homozygous for normal wings and has sepia eyes is crossed with a male that has miniature wings and is homozygous for red eyes. The F_1 flies are intercrossed to produce the F_2. Give the phenotypes, as well as their expected proportions, of the F_1 and F_2 flies.

41. Suppose that a recessive gene that produces a short tail in mice is located in the pseudoautosomal region. A short-tailed male mouse is mated with a female mouse that is homozygous for a normal tail. The F_1 mice from this cross are intercrossed to produce the F_2. Give the phenotypes, as well as their proportions, of the F_1 and F_2 mice.

42. *A color-blind woman and a man with normal color vision have three sons and six daughters. All the sons are color blind. Five of the daughters have normal color vision, but one of them is color blind. The color-blind daughter is 16 years old, is short for her age, and has not undergone puberty. Explain how this girl inherited her color blindness.

43. CONNECT Orange coat color in cats is an X-linked trait that is recessive to black. A black female cat had a father who was orange. How many copies of the orange allele will be present in the following cells in oogenesis of this black female? See Figure 2.20 for a review of oogenesis in animals.

a. primary oocyte

b. first polar body

c. ovum

Section 4.3

44. *How many Barr bodies would you expect to see in a human cell containing the following chromosomes?

    a. XX

    b. XY

    c. XO

    d. XXY

    e. XXYY

    f. XXXY

    g. XYY

    h. XXX

    i. XXXX

45. A woman with normal chromosomes mates with a man who also has normal chromosomes.

    a. Suppose that, in the course of oogenesis, the woman's sex chromosomes undergo nondisjunction in meiosis I; the man's chromosomes separate normally. Give all possible

combinations of sex chromosomes that this couple's children might inherit and the number of Barr bodies that you would expect to see in each of the cells of each child.

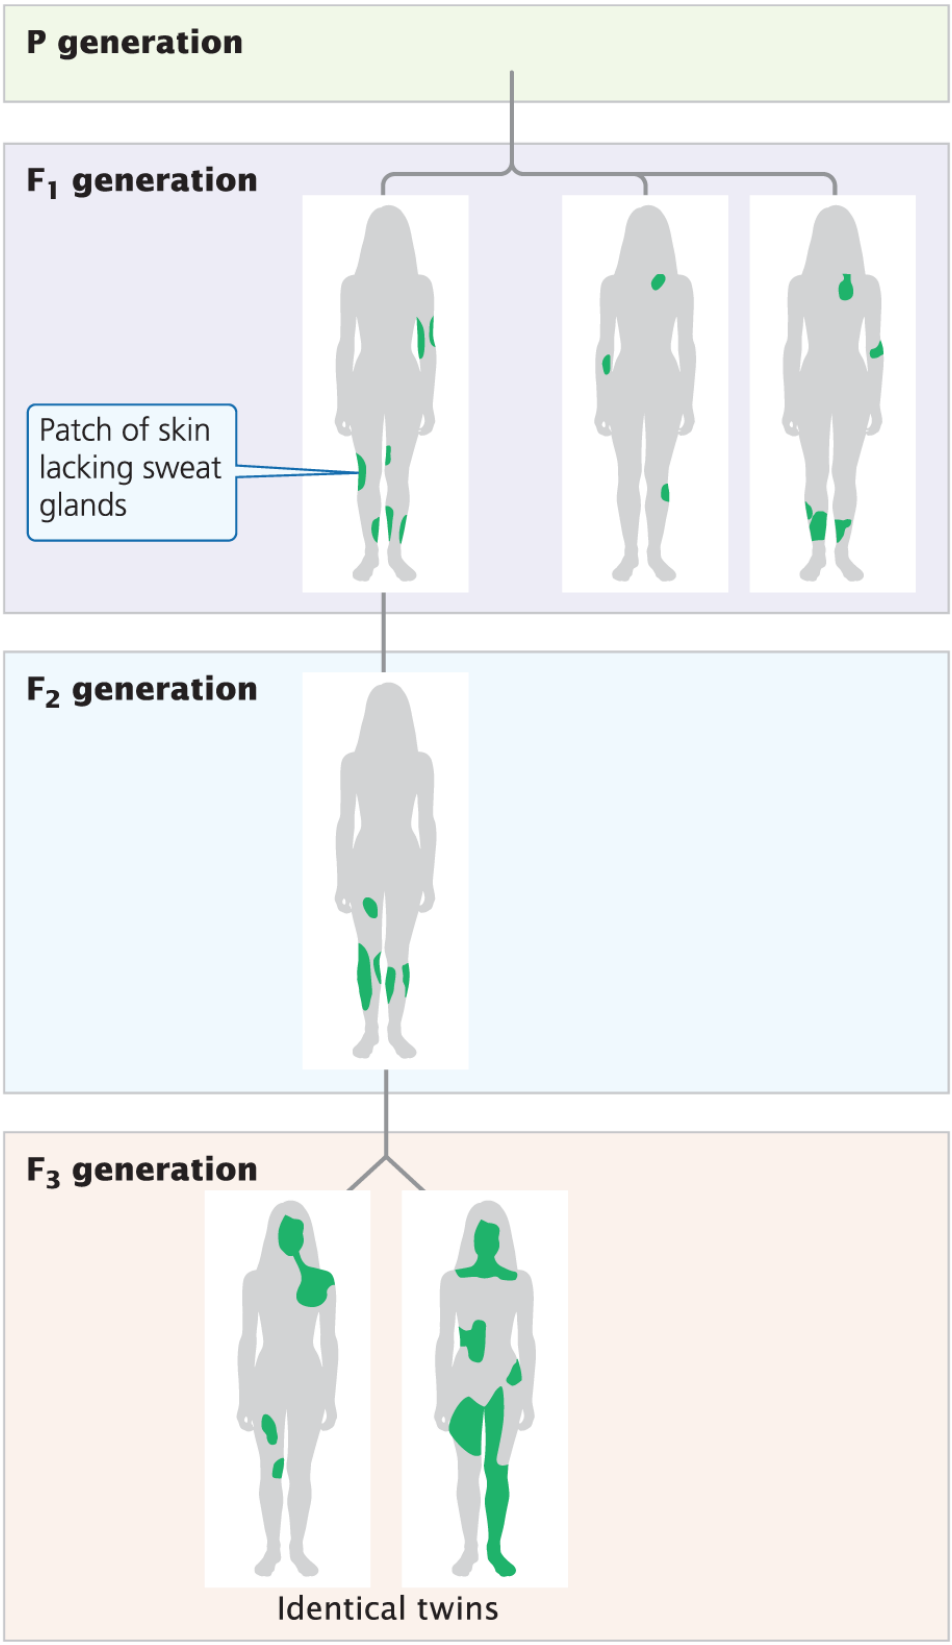
b. What chromosome combinations and numbers of Barr bodies would you expect to see if the chromosomes separate normally in oogenesis but nondisjunction of the sex chromosomes takes place in meiosis I of spermatogenesis?

46. What is the most likely sex and genotype of the cat shown in **Figure 4.19**?

47. *Hypohidrotic ectodermal dysplasia (also known as anhidrotic ectodermal dysplasia) is an X-linked recessive disorder in humans characterized by small teeth, no sweat glands, and sparse body hair. This trait is usually seen in men, but women who are heterozygous carriers of the trait often have irregular patches of skin with few or no sweat glands (see the illustration).

    a. Explain why women who are heterozygous carriers of a recessive gene for hypohidrotic ectodermal dysplasia have irregular patches of skin lacking sweat glands.

    b. Why does the distribution of the patches of skin lacking sweat glands differ among the females depicted in the illustration, even between the identical twins?



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description
The illustration represents all the generations in different boxes. The boxes contain gray outlines of female figures with green patches on the figure representing areas of skin lacking sweat glands. The P generation on the top box is empty. The F subscript 1 generation below has 3 females. Female 1 has 5 small green patches on her legs and 2 on one arm. Female 2 has 1 on leg, one on arm and one on shoulder. Female 3 has 3 green patches on legs, 1 on arm and one on chest. Female 1 from the F subscript 1 generation has one female progeny in the F subscript 2 generation below. This female progeny has 5 green patches on her legs, which appear to be larger in size than the previous generation. The female from F subscript 2 generation has two female identical twins in F subscript 3 generation below. In twin 1, a relatively larger green patch is present on the face that extends to the shoulder and 2 small patches are on the leg. In twin 2, green patches appear on entire face, neck, collar bone area, almost an entire leg, top of the other leg, a spot on the hip and stomach.

CHALLENGE QUESTIONS

Section 4.2

48. CONNECT *A geneticist discovers a male mouse with greatly enlarged testes in his laboratory colony. He suspects that this trait results from a new mutation that is either Y linked or autosomal dominant. How could he determine whether the trait is autosomal dominant or Y linked? See Chapter 3 for a review of autosomal inheritance.

Section 4.3

49. Human females who are heterozygous for an X-linked recessive allele sometimes exhibit mild expression of the trait. However, such mild expression of X-linked traits in females who are heterozygous for X-linked alleles is not seen in *Drosophila.* What might cause this difference in the expression of X-linked genes between human females and female *Drosophila?* (Hint: In *Drosophila*, dosage compensation is accomplished by doubling the activity of genes on the X chromosome of males.)

50.

Identical twins (also called monozygotic twins) are derived from a single egg fertilized by a single sperm, creating a zygote that later divides into two (see Chapter 6). Because identical twins originate from a single zygote, they are genetically identical. Caroline Loat and her colleagues examined nine measures of social, behavioral, and cognitive ability in 1000 pairs of identical male twins and 1000 pairs of identical female twins (C. S. Loat et al. 2004. *Twin Research* 7:54–61). They found that for three of the measures (prosocial behavior, peer problems, and verbal ability), the two male twins of a pair tended to be more alike in their scores than were the two female twins of a pair. Propose a possible explanation for this observation. What might this observation indicate about the location of genes that influence prosocial behavior, peer problems, and verbal ability?

51. Occasionally, a mouse X chromosome is broken into two pieces and each piece becomes attached to a different autosome. In this event, the genes on only one of the two pieces undergo X

inactivation. What does this observation indicate about the mechanism of X-chromosome inactivation?

💬 ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Section 4.1

1. The duck-billed platypus has a unique mechanism of sex determination: females have five pairs of X chromosomes ($X_1X_1X_2X_2X_3X_3X_4X_4X_5X_5$) and males have five pairs of X and Y chromosomes ($X_1Y_1X_2Y_2X_3Y_3X_4Y_4X_5Y_5$). Do you think each of the X and Y chromosome pairs in males assorts independently of other X and Y pairs during meiosis? Why or why not?

2. Most organisms with XX-XY sex determination have pseudoautosomal regions, portions of the X and Y chromosomes that are homologous. Would you predict that organisms with ZZ-ZW sex determination have pseudoautosomal regions of homology between Z and W chromosomes? Explain your answer.

3. Both men and women produce testosterone, but concentrations of testosterone in the blood are generally higher in men than in women. However, the testosterone levels of some XX females fall within the range of testosterone levels of XY men. This overlap has created controversy within women's sports. Testosterone is known to increase muscle mass and enhance some types of athletic performance, so some people have suggested that women

with naturally high testosterone levels have an unfair competitive advantage. In 2011, the International Association of Athletics Federations (IAAF) adopted a policy that limited levels of testosterone in female athletes, saying that female athletes must not have a blood testosterone concentration greater than 10 nanomoles per liter (nmol/L), a level typically seen in men. Some elite female athletes have natural testosterone levels above this limit and have challenged the policy. Do you think that it is fair for XX females with naturally high testosterone (levels typically found in XY males) to compete in women's sports? Do they have an unfair advantage in competition with other women? What about male athletes with naturally high levels of testosterone? Do they have an unfair advantage over other males? In general, what role does genetics play in athletic competition—do some individuals have genes that give them an unfair advantage in competition?

Section 4.2

4. How is the inheritance of X-linked traits different from the inheritance of autosomal traits? How is the inheritance of X-linked and autosomal traits similar? List as many differences and similarities as you can.

5. On average, what proportion of X-linked genes in the first individual are the same (inherited from a common ancestor) as those in the second individual?

   a. A male and his mother

   b. A female and her mother

c. A male and his father

d. A female and her father

e. A male and his brother

f. A female and her sister

g. A male and his sister

h. A female and her brother

6. Red–green color blindness is an X-linked recessive trait. Susan has normal color vision, but her father is color blind. Susan mates with Bob, who has normal color vision.

   a. What is the probability that Susan and Bob will have a color-blind son?

   b. Susan and Bob have a daughter named Betty, who has normal color vision. If Betty mates with a man with normal color vision, and they have a son, what is the probability that the son will be color blind?

7. As pointed out in the section Evolution of the Y Chromosome, some researchers have predicted that the human Y chromosome will continue to lose genetic information in the future and will completely disappear from the species in about 10 million years. What would happen if the Y chromosome disappeared from the human species?

8. Hypohidrotic ectodermal dysplasia is an X-linked recessive disorder in humans characterized by small and reduced numbers

of teeth, no sweat glands, and sparse body hair (see Application Problems 29 and 47). The disorder is caused by mutations in the *EDA* gene, which produces a protein called ectodysplasin A1 (EDA1). In 2018, physicians reported the successful treatment of three boys with this disorder by administering synthetically produced EDA1 during in utero development at 26 to 31 weeks of gestation (H. Schneider, F. Faschingbauer, S. Schuepbach-Mallepell, et al. 2018. Prenatal correction of X-Linked hypohidrotic ectodermal dysplasia, *New England Journal of Medicine* 37:1604-1610). This treatment had a dramatic effect: after birth, the boys had normal sweating and increased numbers of teeth, although they still lacked hair. However, additional research found that administration of EDA1 after birth had no effect on boys with hypohidrotic ectodermal dysplasia. (a) Explain why treatment of EDA1 during intra uterine development produced a positive effect but treatment after birth had no effect. (b) Give a possible reason for development of hair was unaffected by the EDA1 treatment.

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Introduction

1. Outline the mechanism of sex determination in central bearded dragons by creating a concept map using the following terms: central bearded dragon, ZZ males, ZW females, genetic sex determination, environmental sex determination, ZZ females.

Section 4.1

2. Create a concept map that displays the different ways that sex can be determined using the following terms: sex determination, environmental sex determination, XX-XO, ZZ-ZW, XX-XY, genic sex determination, chromosomal sex determination, male is heterogametic sex, female is heterogametic sex.

Section 4.2

3. Create a concept map that explains the mechanism of dosage compensation in mammals. Your concept map should include at least 10 concepts and connecting lines.

SaplingPlus Self-study tools that will help you practice what you've learned and reinforce this chapter's concepts are available online. Go to www.saplinglearning.com.

CHAPTER 5

Extensions and Modifications of Basic Principles

Courtesy of Dr. Reiko Kuroda.

The direction of shell coiling in *Lymnaea* snails is determined by genetic maternal effect. Shown here are two *Lymnaea stagnalis*: a snail with a left-handed (sinistral) shell on the left and a snail with a right-handed (dextral) shell on the right.

The Odd Genetics of Left-Handed Snails

At the start of the twentieth century, Mendel's work on inheritance in pea plants became widely known (see Chapter 3), and a number of biologists set out to verify his conclusions by conducting crosses with other organisms. Biologists quickly confirmed that Mendel's principles applied not just to peas but also to corn, beans, chickens, mice, guinea pigs, humans, and many other organisms. At the same time, biologists began to discover exceptions—traits whose inheritance was more complex than that of the simple dominant and recessive traits that Mendel had observed. One of these exceptions was the spiral of a snail's shell.

The direction of coiling in snail shells is called chirality. Most snail shells spiral downward in a clockwise or right-handed direction. These shells are said to be dextral. A few snails have shells that coil in the opposite direction, spiraling downward in a counterclockwise or left-handed direction. These shells are said to be sinistral. Most snail species have shells that are all dextral or all sinistral; only in a few rare instances do both dextral and sinistral shells coexist in the same species.

In the 1920s and 1930s, Arthur Boycott, of the University of London, investigated the genetics of shell coiling in *Lymnaea peregra*, a common pond snail in Britain. In this species, most snails are

dextral, but a few sinistral snails occur in some populations. Boycott learned from amateur naturalists of a pond near Leeds, England, where an abnormally high number of sinistral snails could be found. He obtained four sinistral snails from this location and began to investigate the genetics of shell chirality.

Boycott's research was complicated by the fact that these snails are hermaphroditic, meaning that a snail can self-fertilize, or *self* (mate with itself). If a suitable partner is available, the snails are also capable of *outcrossing*—mating with another individual. Boycott found that if he isolated a newly hatched snail and reared it alone, it would eventually produce offspring, so he knew that it had selfed. But when he placed two snails together and one produced offspring, he had no way of knowing whether it had mated with itself or with the other snail. Boycott's research required rearing large numbers of snails in isolation and in pairs, raising their offspring, and determining the direction of shell coiling for each offspring. To facilitate the work, he enlisted the aid of several amateur scientists. One of his helpers was Captain C. Diver, a friend who worked as an assistant for the British Parliament. Since Parliament met for only part of the year, Diver had time on his hands and eagerly enlisted to assist with the research. Together, Boycott, Diver, and other assistants carried out numerous breeding experiments, selfing and crossing snails and raising the progeny in jam jars. They eventually raised more than 6000 broods and determined the direction of coiling in a million snails.

Initially, their results were puzzling—shell coiling did not appear to conform to Mendel's principles of heredity. Eventually, they realized that dextral was dominant to sinistral but with a peculiar twist: the phenotype of a snail was determined *not* by its own genotype but by the genotype of its mother. This phenomenon—determination of the phenotype by the genotype of the mother—is called genetic maternal effect. Genetic maternal effect often arises because the maternal parent produces a substance, encoded by her own genotype, that is deposited in the cytoplasm of the egg and that influences early development of the offspring.

In 2016, several researchers found that direction of coiling in *Lymnaea* snails is determined by the *Lsdia1* gene, which plays a role in cytoskeleton formation. Sinistral snails possess a mutation in their *Lsdia1* alleles that prevents a functional protein from being produced. How the absence of this protein switches the direction of shell coiling is not yet clear.

THINK-PAIR-SHARE

- The introduction to this chapter discusses the genetic basis of chirality in snails and the research of Arthur Boycott, whose work established the mode of inheritance for this trait. In the course of his research, Boycott enlisted the aid of several amateur scientists—individuals who were not trained as scientists and had other jobs. The research would have been impossible without the aid of these people. In the past, amateur scientists such as these often made important contributions to science, but the practice is less frequent today. Discuss some possible reasons for the decline in contributions to research by amateur scientists. Are there any areas where amateur scientists still actively contribute?

- Genetic maternal effect is often seen in mammals. For example, research shows that the maternal genotype influences adult body size in mice. Why might these types of genetic effects be more common in mammals than in other organisms, such as fishes, amphibians, or reptiles?

Boycott's research on the direction of coiling in snails demonstrated that not all characteristics are inherited as simple dominant and recessive traits, like the shapes and colors of peas that Mendel described. This demonstration doesn't mean that Mendel was wrong; rather, it indicates that Mendel's principles are not, by themselves, sufficient to explain the inheritance of all genetic characteristics. Our modern understanding of genetics has been greatly enriched by the discovery of a number of modifications and extensions of Mendel's basic principles, which are the focus of this chapter.

5.1 Additional Factors at a Single Locus Can Affect the Results of Genetic Crosses

In Chapter 3, we learned that the principle of segregation and the principle of independent assortment enable us to predict the outcomes of genetic crosses. Here, we examine several additional factors acting at individual loci that can alter the phenotypic ratios predicted by Mendel's principles.

Types of Dominance

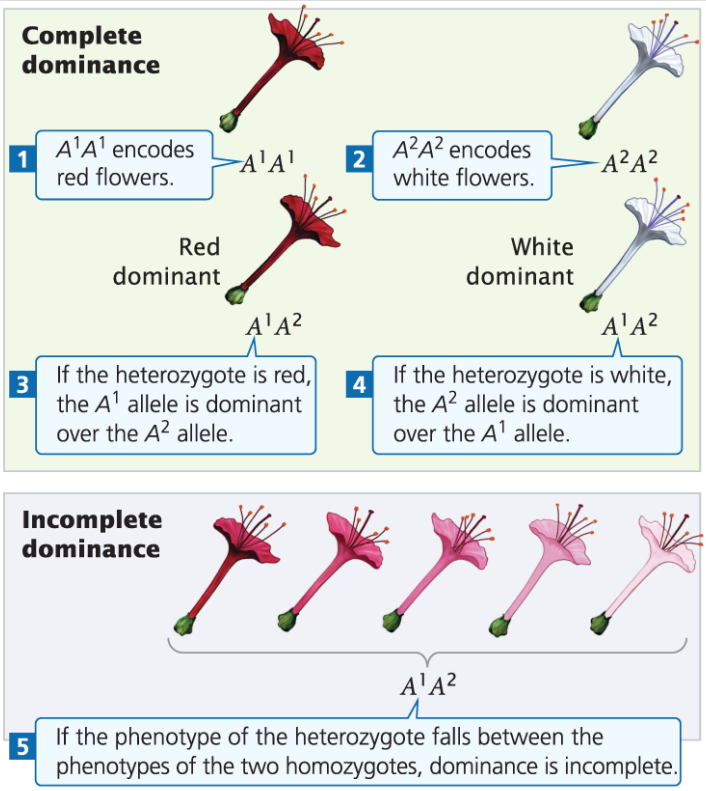
One of Mendel's important contributions to the study of heredity is the concept of dominance—the idea that although an individual organism possesses two different alleles for a characteristic, the trait encoded by only one of the alleles is observed in the phenotype. With dominance, the heterozygote possesses the same phenotype as one of the homozygotes.

Mendel observed dominance in all the traits he chose to study extensively, but he was aware that not all characteristics exhibit dominance. For example, he conducted some crosses to look at the length of time that pea plants take to flower. When he crossed two homozygous varieties that differed in their flowering time by an

average of 20 days, the length of time taken by the F_1 plants to flower was intermediate between those of the two parents. When the heterozygote has a phenotype intermediate between the phenotypes of the two homozygotes, the trait is said to display *incomplete dominance*.

COMPLETE AND INCOMPLETE DOMINANCE

Dominance can be understood in regard to how the phenotype of the heterozygote relates to the phenotypes of the two homozygotes. In the example presented in the upper panel of **Figure 5.1**, one homozygous genotype, A^1A^1, produces red pigment, resulting in red flowers; another, A^2A^2, produces no pigment, resulting in white flowers. The phenotype of the heterozygote determines the type of dominance. If the heterozygote (A^1A^2) produces the same amount of pigment as the A^1A^1 homozygote, resulting in red flowers, then the A^1 allele displays **complete dominance** over the A^2 allele; that is, red is dominant to white. If, on the other hand, the heterozygote produces no pigment, resulting in flowers with the same color as the A^2A^2 homozygote (white), then the A^2 allele is completely dominant, and white is dominant to red.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

5.1 The type of dominance exhibited by a trait depends on how the phenotype of the heterozygote relates to the phenotypes of the homozygotes.

Description

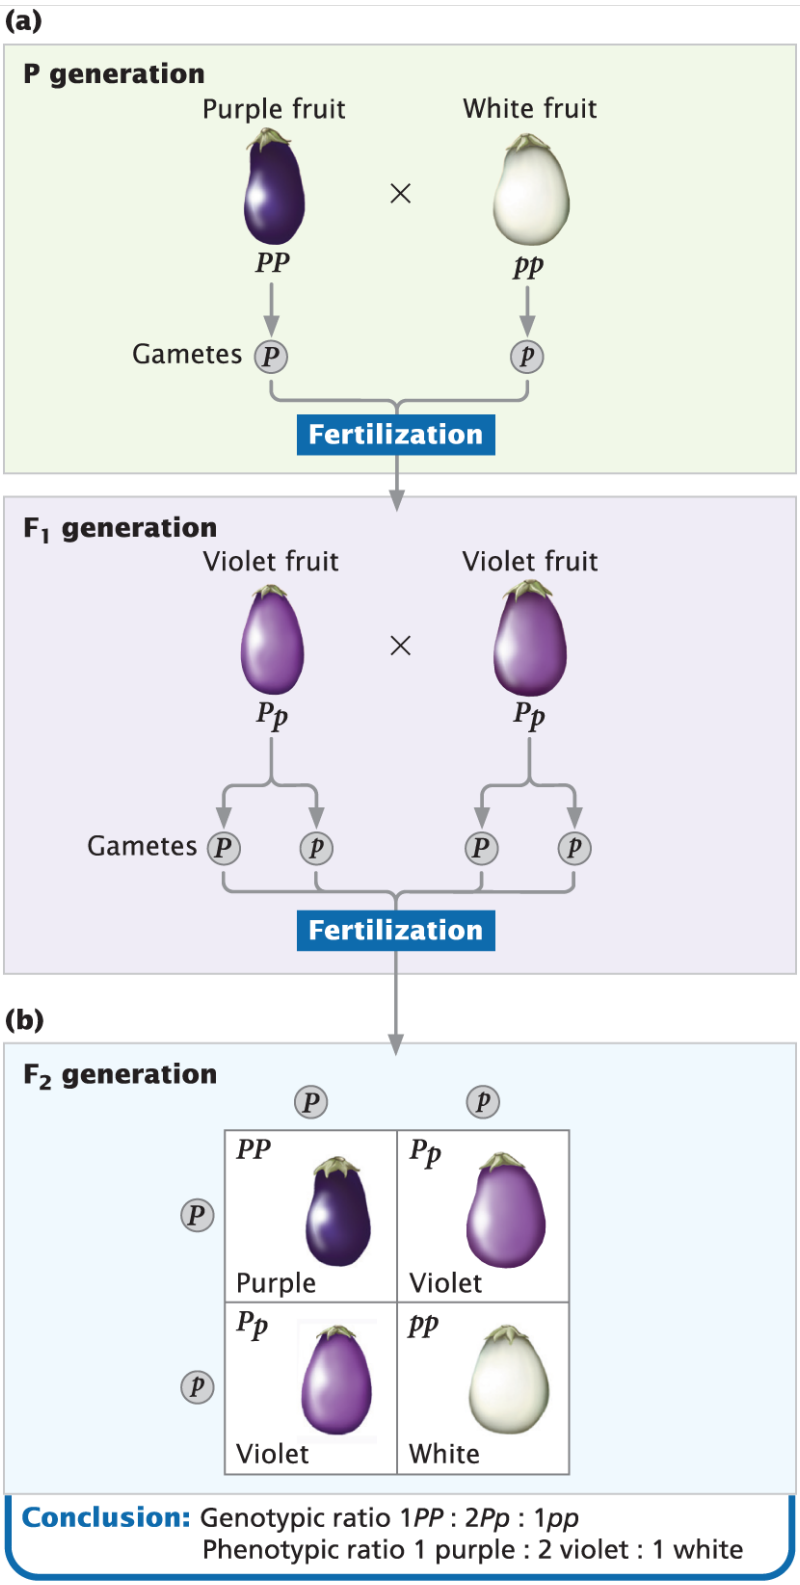
Complete dominance shows a red flower with genotype big A superscript 1 big A superscript 1 and a white flower with genotype big A superscript 2 big A superscript 2. The first caption corresponds to the red flower and reads, “big A superscript 1 big A superscript 1 encodes red flowers.” The second caption refers to the white flower and reads, “big A superscript 2 big A superscript 2 encodes white flowers.” Below the red flower, is a red flower labeled red dominant and below the white flower, is a white flower labeled white dominant. Both the flowers have the genotype big A superscript 1 big A superscript 2. The third caption below the red dominant flower and reads, “If the heterozygote is red, the big A superscript 1 allele is dominant over the big A superscript 2 allele.” The fourth caption below the white dominant flower and reads, “If the heterozygote is white, the big A superscript 2 allele is dominant over the big A superscript 1 allele.”

Five flowers are present in a series below that represents incomplete dominance. The color of flowers change from red to light pink gradually from left to right. All the flowers have the genotype big A superscript 1 big A superscript 2. The fifth caption reads, “If the phenotype of the heterozygote falls between the phenotypes of the two homozygotes, dominance is incomplete.”

When the phenotype of the heterozygote falls in between the phenotypes of the two homozygotes, dominance is incomplete. With **incomplete dominance**, the heterozygote need not be exactly intermediate between the two homozygotes (see the lower panel of Figure 5.1); it might be a slightly lighter shade of red or a slightly pink shade of white. As long as the heterozygote’s phenotype can be differentiated from those of the two homozygotes and falls between them, dominance is incomplete.

Incomplete dominance is also exhibited in the fruit color of eggplant. When a homozygous plant that produces purple fruit (*PP*) is crossed with a homozygous plant that produces white fruit (*pp*), all the heterozygous F_1 (*Pp*) plants produce violet fruit (**Figure 5.2a**). When the F_1 are crossed with each other, $^1/_4$ of the F_2 are purple (*PP*), $^1/_2$ are violet (*Pp*), and $^1/_4$ are white (*pp*), as shown in **Figure 5.2b**. Note that this 1:2:1 ratio is different from the 3:1 ratio that we would observe if eggplant fruit color exhibited complete dominance. Another example of incomplete dominance is feather color in chickens. A cross between a homozygous black chicken and a homozygous white chicken produces F_1 chickens that are gray. If

these gray F_1 chickens are intercrossed, they produce F_2 birds in a ratio of 1 black : 2 gray : 1 white.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

5.2 Fruit color in eggplant is inherited as an incompletely dominant trait.

Description
The part (a) shows P and F subscript 1 generation. In P generation, a purple eggplant with genotype big P big P is a crossed with a white eggplant with genotype small P small P. Gametes produced are big P and small P, respectively. Fertilization occurs and produces violet eggplants in the F subscript 1 generation shown below. Violet fruits with genotype big P small P are inter-crossed. Gametes produced are big P and small P for each plant. Fertilization takes place again and F subscript 2 generation is produced below in part (b).

The part (b) shows a Punnett square with 2 rows and 2 columns with gametes on its sides.

Row headers are as follows: big P and small P.

Column headers are as follows: big P and small P.

Row entries are depicted are as follows:

Row 1 column 1: big P big P (purple)

Row 1 column 2: big P small P (violet)

Row 2 column 1: big P small P (violet)

Row 2 column 2: small P small P (white)

A caption at the bottom reads, Conclusion: Genotypic ratio 1 big P big P to 2 big P small P to 1 small P small P. Phenotypic ratio 1 purple to 2 violet to 1 white.

We should now add the 1:2:1 ratio to the phenotypic ratios for simple crosses presented in Chapter 3 (see Table 3.5). A 1:2:1 phenotypic ratio arises in the progeny of a cross between two parents that are heterozygous for a characteristic that exhibits incomplete dominance ($Aa \times Aa$). The genotypic ratio among these progeny is also 1:2:1. When a trait displays incomplete dominance,

the genotypic ratios and phenotypic ratios of the offspring are the *same* because each genotype has its own phenotype. The important thing to remember about dominance is that it affects the way that genes are *expressed* (the phenotype) but not the way that genes are *inherited*.

CONCEPTS

Incomplete dominance is exhibited when the heterozygote has a phenotype intermediate between the phenotypes of the two homozygotes. When a trait exhibits incomplete dominance, a cross between two heterozygotes produces a 1:2:1 phenotypic ratio in the progeny.

✔ CONCEPT CHECK 1

If an F_1 eggplant in Figure 5.2 is used in a testcross, what proportion of the progeny from this cross will be white?

a. All the progeny
b. $^1/_2$
c. $^1/_4$
d. 0

CODOMINANCE

Another type of interaction between alleles is **codominance**. How is codominance different from incomplete dominance? In codominance, the phenotype of the heterozygote is not intermediate between the phenotypes of the homozygotes; rather, the

heterozygote simultaneously expresses the phenotypes of both homozygotes. An example of codominance is seen in the MN blood types of humans.

The MN blood-group locus encodes one of the types of antigens on the surface of red blood cells. Unlike foreign antigens of the ABO and Rh blood groups (the alleles of which encode red-blood-cell antigens), foreign MN antigens do not elicit a strong immunological reaction; therefore, the MN blood types are not routinely considered in blood transfusions. At the MN locus, there are two alleles: the L^{M} allele, which encodes the M antigen; and the L^{N} allele, which encodes the N antigen. Homozygotes with genotype $L^{M}L^{M}$ express the M antigen on the surface of their red blood cells and have the M blood type. Homozygotes with genotype $L^{N}L^{N}$ express the N antigen and have the N blood type. Heterozygotes with genotype $L^{M}L^{N}$ exhibit codominance and express both the M and the N antigens; they have blood type MN.

Some students might ask why the pink flowers illustrated in the lower panel of Figure 5.1 exhibit incomplete dominance—that is, why is this outcome not an example of codominance? The flowers would exhibit codominance only if the heterozygote produced both red and white pigments, which then combined to produce a pink phenotype. However, in our example, the heterozygote produces only red pigment. The pink phenotype comes about because the amount of pigment produced by the heterozygote is less than the amount produced by the $A^{1}A^{1}$ homozygote. So in that case, the

alleles clearly exhibit incomplete dominance, not codominance. The differences between complete dominance, incomplete dominance, and codominance are summarized in Table 5.1. ❯ TRY PROBLEM 13

TABLE 5.1 Differences between complete dominance, incomplete dominance, and codominance

Type of Dominance	Definition
Complete dominance	Phenotype of the heterozygote is the same as the phenotype of one of the homozygotes.
Incomplete dominance	Phenotype of the heterozygote is intermediate (falls within the range) between the phenotypes of the two homozygotes.
Codominance	Phenotype of the heterozygote includes the phenotypes of both homozygotes.

LEVEL OF PHENOTYPE OBSERVED MAY AFFECT DOMINANCE

Many phenotypes can be observed at several different levels, including the anatomical level, the physiological level, and the molecular level. The type of dominance exhibited by a characteristic

depends on the level at which the phenotype is examined. This dependency is seen in cystic fibrosis, a common genetic disorder in Caucasians that is usually considered to be a recessive disease. People who have cystic fibrosis produce large quantities of thick, sticky mucus, which plugs up the airways of the lungs and clogs the ducts leading from the pancreas to the intestine, causing frequent respiratory infections and digestive problems. Even with medical treatment, people with cystic fibrosis suffer chronic, life-threatening medical problems.

The gene responsible for cystic fibrosis resides on the long arm of chromosome 7. It encodes a protein termed *cystic fibrosis transmembrane conductance regulator* (CFTR), which acts as a gated channel in the cell membrane and regulates the movement of chloride ions into and out of the cell. People with cystic fibrosis have a mutated, dysfunctional form of CFTR that causes the channel to stay closed, so chloride ions build up in the cell. This buildup causes the formation of thick mucus and produces the symptoms of the disease.

Most people have two copies of the normal *CFTR* allele and produce only functional CFTR protein. Those with cystic fibrosis possess two mutated *CFTR* alleles and produce only the defective CFTR protein. Heterozygotes, who have one normal and one defective *CFTR* allele, produce both functional and defective CFTR protein. Thus, at the molecular level, the normal and defective *CFTR* alleles are codominant because both alleles are expressed in the heterozygote.

However, because one functional allele produces enough functional CFTR protein to allow normal chloride ion transport, heterozygotes exhibit no adverse effects, and the mutated *CFTR* allele appears to be recessive at the physiological level. The type of dominance expressed by an allele, as illustrated in this example, is thus a function of the phenotypic effect of the allele that we observe.

THINK-PAIR-SHARE Question 1

CHARACTERISTICS OF DOMINANCE

Several important characteristics of dominance should be emphasized. First, dominance is a result of interactions between genes at the same locus (allelic genes); in other words, dominance is *allelic* interaction. Second, dominance does not alter the way in which the genes are inherited; it influences only the way in which they are expressed as a phenotype. The allelic interaction that characterizes dominance is therefore interaction between the *products* of the genes. Finally, the type of dominance exhibited frequently depends on the level at which the phenotype is examined. As seen for cystic fibrosis, an allele may exhibit codominance at one level and be recessive at another level.

CONCEPTS

Dominance entails interactions between genes at the same locus (allelic genes) and is an aspect of the phenotype; dominance does not affect the way in which genes are inherited. The type of dominance exhibited by a characteristic frequently depends on the level at which the phenotype is examined.

✔ CONCEPT CHECK 2

How do complete dominance, incomplete dominance, and codominance differ?

Penetrance and Expressivity

In the genetic crosses presented thus far, we have considered only the interactions of alleles and have assumed that every individual organism having a particular genotype expresses the expected phenotype. We have assumed, for example, that in peas, the genotype *Rr* always produces round seeds and that the genotype *rr* always produces wrinkled seeds. For some characteristics, however, such an assumption is incorrect: the genotype does not always produce the expected phenotype, a phenomenon termed **incomplete penetrance**.

Incomplete penetrance is seen in human polydactyly, the condition of having extra fingers or toes (**Figure 5.3**). There are several different forms of human polydactyly, but the trait is usually caused by a dominant allele. Occasionally, people possess the allele for polydactyly (as evidenced by the fact that their children inherit the

polydactyly) but nevertheless have a normal number of fingers and toes. In these cases, the gene for polydactyly is not fully penetrant. **Penetrance** is defined as the percentage of individual organisms having a particular genotype that express the expected phenotype. For example, if we examined 42 people having an allele for polydactyly and found that only 38 of them were polydactylous, the penetrance would be ${}^{38}/_{42} = 0.90\ (90\%)$.

SPL/Science Source.

5.3 Human polydactyly (extra digits) exhibits incomplete penetrance and variable expressivity.

A related concept is that of **expressivity**, the degree to which a trait is expressed. In addition to incomplete penetrance, polydactyly exhibits variable expressivity. Some polydactylous people possess

extra fingers or toes that are fully functional, whereas others possess only a small tag of extra skin.

Incomplete penetrance and variable expressivity are due to the effects of other genes and environmental factors that can alter or completely suppress the effect of a particular gene. For example, a gene may encode an enzyme that produces a particular phenotype only within a limited temperature range. At higher or lower temperatures, the enzyme does not function, so the phenotype is not expressed; the allele encoding such an enzyme is therefore penetrant only within a particular temperature range (see also Environmental Effects on the Phenotype in Section 5.5). Many characteristics exhibit incomplete penetrance and variable expressivity; thus, the mere presence of a gene does not guarantee its expression. **› TRY PROBLEM 15**

CONCEPTS

Penetrance is the percentage of individuals having a particular genotype that express the associated phenotype. Expressivity is the degree to which a trait is expressed. Incomplete penetrance and variable expressivity result from the influence of other genes and environmental factors on the phenotype.

✔ CONCEPT CHECK 3

How does incomplete dominance differ from incomplete penetrance?

a. Incomplete dominance refers to alleles at the same locus; incomplete penetrance refers to alleles at different loci.

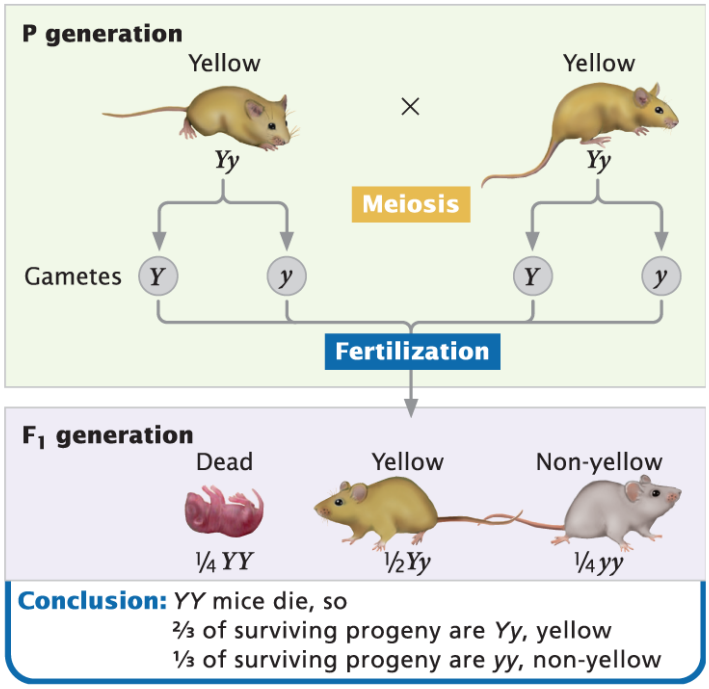
b. Incomplete dominance ranges from 0% to 50%; incomplete penetrance ranges from 51% to 99%.
c. In incomplete dominance, the heterozygote is intermediate between the homozygotes; in incomplete penetrance, heterozygotes express phenotypes of both homozygotes.
d. In incomplete dominance, the heterozygote is intermediate between the homozygotes; in incomplete penetrance, some individuals do not express the expected phenotype.

Lethal Alleles

A **lethal allele** causes death at an early stage of development—often before birth—so that some genotypes do not appear among the progeny. An example of a lethal allele, originally described by Erwin Baur in 1907, is found in snapdragons. The *aurea* strain in these plants has yellow leaves. When two plants with yellow leaves are crossed, $^2/_3$ of the progeny have yellow leaves and $^1/_3$ have green leaves. When green is crossed with green, all the progeny have green leaves; when yellow is crossed with green, however, $^1/_2$ of the progeny have green leaves and $^1/_2$ have yellow leaves, confirming that all yellow-leaved snapdragons are heterozygous.

Another example of a lethal allele is one that determines yellow coat color in mice. A cross between two yellow heterozygous mice produces an initial genotypic ratio of $^1/_4$ *YY*, $^1/_2$ *Yy*, and $^1/_4$ *yy*, but the homozygous *YY* mice die early in development and do not appear among the progeny, resulting in a 2:1 ratio of *Yy* (yellow) to *yy* (non-yellow) in the offspring (**Figure 5.4**). A 2:1 ratio is almost always

produced by a recessive lethal allele, so observing this ratio among the progeny of a cross between individuals with the same phenotype is a strong clue that one of the alleles is lethal. In this example, as in that of yellow leaves in snapdragons, the lethal allele (*Y*) is recessive because it causes death only in homozygotes. Unlike its effect on *survival*, the effect of the yellow allele on *color* is dominant; in both mice and snapdragons, a single copy of the allele in heterozygotes produces a yellow color. These examples illustrate the point made earlier (pp. 114–115) that the type of dominance depends on the aspect of the phenotype examined.



5.4 The 2:1 ratio produced by a cross between two yellow mice results from a lethal allele.

Description

Two yellow mice each with genotype big Y small Y are crossed in generation P and each produce 2 gametes; an big Y and an small Y. Fertilization occurs and results in one-fourth dead mice of genotype big Y big Y, one-half yellow mice of genotype big Y small Y, and one-fourth non-yellow mice of genotype small Y small Y in the F subscript 1 generation shown below.

A caption at the bottom reads, “Conclusion: big Y big Y mice die, so two-third of surviving progeny are big Y small Y, yellow; one-third of surviving progeny are small Y small Y, non-yellow.”

Many lethal alleles in nature are recessive, but lethal alleles can also be dominant; in this case, homozygotes and heterozygotes for the allele die. Truly dominant lethal alleles cannot be transmitted unless they are expressed after the onset of reproduction. › **TRY** PROBLEM 17

CONCEPTS

A lethal allele causes death at an early developmental stage, so that one or more genotypes are missing from the progeny of a cross. Lethal alleles therefore modify the ratio of progeny resulting from a cross.

✔ CONCEPT CHECK 4

A cross between two green corn plants yields $^{2}/_{3}$ progeny that are green and $^{1}/_{3}$ progeny that are yellow. What is the genotype of the green progeny?

a. *WW*
b. *Ww*
c. *ww*
d. *W*_(*WW* and *Ww*)

Multiple Alleles

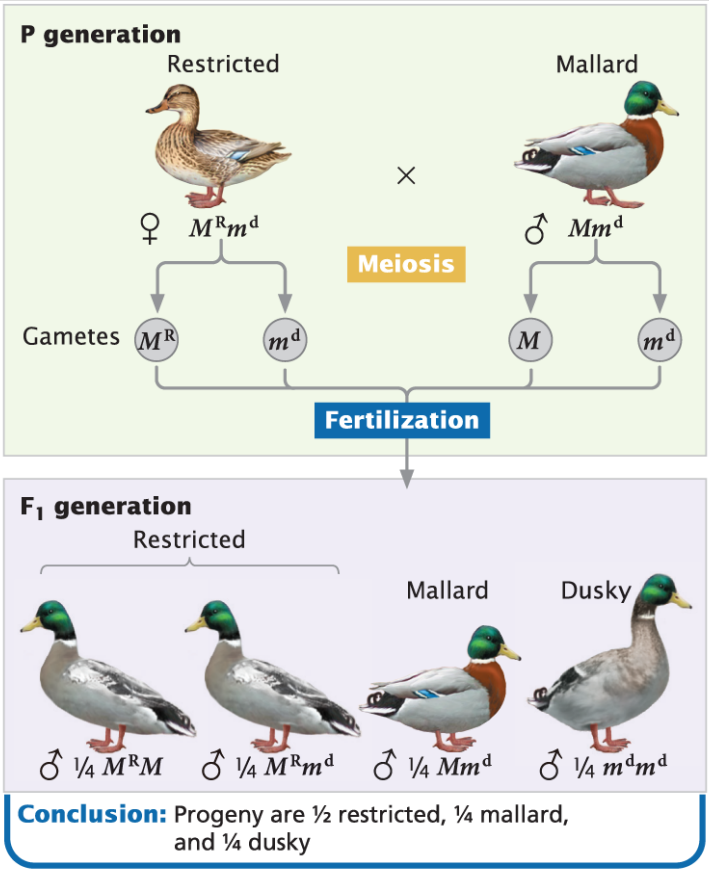
Most of the genetic systems that we have examined so far consist of two alleles. In Mendel's peas, for instance, one allele encoded round seeds and another encoded wrinkled seeds; in cats, one allele produced a black coat and another produced a gray coat. For some loci, however, more than two alleles are present within a group of organisms—the locus has **multiple alleles** (which may also be referred to as an *allelic series*). Although there may be more than two alleles present within a *group* of organisms, the genotype of each individual diploid organism still consists of only two alleles. The inheritance of characteristics encoded by multiple alleles is no different from the inheritance of characteristics encoded by two alleles except that a greater variety of genotypes and phenotypes are possible.

PLUMAGE PATTERNS IN DUCKS

An example of multiple alleles is found at a locus that determines the plumage pattern of mallard ducks. One allele, M, produces the wild-type *mallard* pattern. A second allele, M^{R} produces a different pattern called *restricted*, and a third allele, m^{d}, produces a pattern termed *dusky*. In this allelic series, restricted is dominant to mallard and dusky, and mallard is dominant to dusky: $M^{R} > M > m^{d}$. The six genotypes possible with these three alleles, and their resulting phenotypes, are

Genotype	Phenotype
$M^R M^R$	restricted
$M^R M$	restricted
$M^R m^d$	restricted
MM	mallard
Mm^d	mallard
$m^d m^d$	dusky

In general, the number of genotypes possible will be $[n(n + 1)/2]$, where n equals the number of different alleles at a locus. Working crosses with multiple alleles is no different from working crosses with two alleles; Mendel's principle of segregation still holds, as shown in the cross between a restricted duck and a mallard duck (Figure 5.5). › **TRY** PROBLEM 19



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

5.5 Mendel's principle of segregation applies to crosses with multiple alleles. In this example, three alleles determine the type of plumage in mallard ducks: M^R (restricted) > M (mallard) > m^d (dusky). Note that the phenotypes of male and female mallard ducks differ. The restricted pattern of a female duck is shown for the female parent. All the progeny in the F_1 have male plumage patterns.

Description

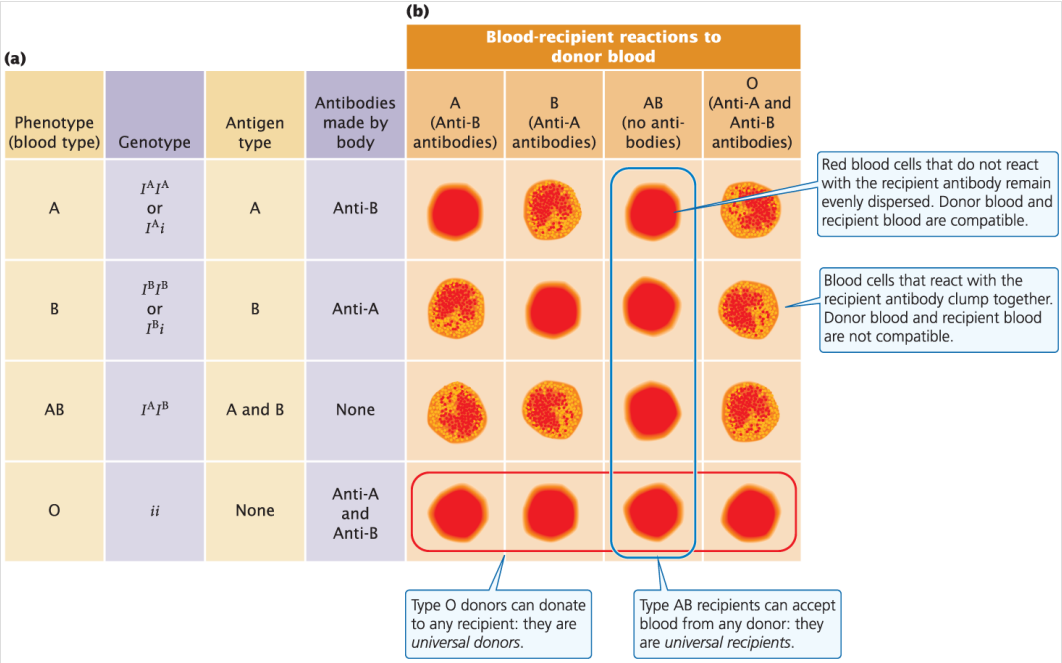
In generation P, a restricted female duck with genotype big M superscript big R small M superscript small D is crossed with a male mallard with genotype big M small M superscript small D. Gametes produced are as follows: big M superscript big R and small M superscript small D from female duck and big M and small M superscript small D from male duck. Fertilization occurs and the F subscript 1 generation is obtained below. The F subscript 1 generation shows one-fourth male with genotype big M superscript big R big M (restricted), one-fourth male with genotype big M superscript big R small M superscript

small D (restricted), one-fourth male with genotype big M small M superscript small D (mallard), and one-fourth male with genotype small M superscript small D small M superscript small D (dusky). A caption at the bottom reads: Progeny are one half restricted, one-fourth mallard, and one-fourth dusky.

THE ABO BLOOD GROUP IN HUMANS

Another multiple-allele system is found at the locus for the ABO blood group, which determines your ABO blood type. What do you know about ABO blood types?

The ABO locus, like the MN locus, encodes antigens on the surface of red blood cells. The three common alleles for the ABO blood group locus are I^A, which encodes the A antigen; I^B, which encodes the B antigen; and i, which encodes no antigen (O). We can represent the dominance relations among the ABO alleles as follows: $I^A > i$, $I^B > i$, $I^A = I^B$. The I^A and the I^B alleles are dominant to i and are codominant with each other; the AB phenotype is due to the presence of an I^A allele and an I^B allele, which results in the production of A and B antigens on red blood cells. A person with genotype ii produces neither antigen and has blood type O. The six common genotypes at this locus and their phenotypes are shown in Figure 5.6a.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

5.6 ABO blood types and the outcomes of possible blood transfusions.

Description

Table (a) has four columns and four rows. The column headers are as follows: Phenotype (blood type), Genotype, Antigen type, and Antibodies made by body.

The row entries for table (a) are as follows:

Row 1: Blood type, A; genotype, big I superscript A big I superscript A or big I superscript big A small I; antigen type, A; antibodies made by body, Anti-B.

Row 2: Blood type, B; genotype, big I superscript B big I superscript B or big I superscript big B small I; antigen type, B; antibodies made by body, Anti-A.

Row 3: Blood type, A B; genotype, big I superscript A big I superscript B; antigen type, A and B; antibodies made by body, none.

Row 4: Blood type, O; genotype, small I small I; antigen type, none; antibodies made by body, Anti-A and Anti-B.

Table (b) titled “blood recipient reactions to donor blood” has four columns and four rows.

The column headers for table (b) are as follows: A (Anti-B antibodies), B (Anti-A antibodies), A B (no antibodies), and O (Anti-A and Anti-B antibodies).

The row entries for table (b) are as follows:

Row 1: For blood type A; 1, evenly dispersed red blood cells; 2, clumps of red blood cells; 3, evenly dispersed red blood cells; 4, clumps of red blood cells.

Row 2: For blood type B; 1, clumps of red blood cells; 2, evenly dispersed red blood cells; 3, evenly dispersed red blood cells; 4, clumps of red blood cells.

Row 3: For blood type A B; 1, clumps of red blood cells; 2, clumps of red blood cells; 3, evenly dispersed red blood cells; 4, clumps of red blood cells.

Row 4: For blood type O; 1, evenly dispersed red blood cells; 2, evenly dispersed red blood cells; 3, evenly dispersed red blood cells; 4, evenly dispersed red blood cells.

A rectangular boundary is formed around the third column and the caption besides reads: Red blood cells that do not react with the recipient antibody remain evenly dispersed. Donor blood and recipient blood are compatible. A rectangular boundary is formed around the fourth row and the caption besides reads: Type O donors can donate to any recipient: they are universal donors. The region where both the boundaries intersect that is the fourth entry in third column and third entry of fourth column has a caption that reads: Type A B recipients can accept blood from any donor: they are universal recipients.

A caption referring to the fourth entry of the second row reads: Blood cells that react with the recipient antibody clump together. Donor blood and recipient blood are not compatible.

The body produces antibodies against any foreign antigens (see Figure 5.6a). For instance, a person with blood type A produces anti-B antibodies because the B antigen is foreign to that person. A person with blood type B produces anti-A antibodies, and a person with blood type AB produces neither anti-A nor anti-B antibodies because neither the A nor the B antigen is foreign to that person. A person with blood type O possesses no A or B antigens;

consequently, that person produces both anti-A antibodies and anti-B antibodies. The presence of antibodies against foreign ABO antigens means that successful blood transfusions are possible only between people with certain compatible blood types (**Figure 5.6b**).

The inheritance of alleles at the ABO locus is illustrated by a paternity suit against the movie actor Charlie Chaplin. In 1941, Chaplin met a young actress named Joan Barry, with whom he had an affair. The affair ended in February 1942, but 20 months later, Barry gave birth to a baby girl and claimed that Chaplin was the father. Barry then sued for child support. At this time, blood typing had just come into widespread use, and Chaplin's attorneys had Chaplin, Barry, and the child blood typed. Barry had blood type A, her child had blood type B, and Chaplin had blood type O. Could Chaplin have been the father of Barry's child?

Your answer should be no. Joan Barry had blood type A, which can be produced by either genotype I^AI^A or genotype I^Ai. Her baby possessed blood type B, which can be produced by either genotype I^BI^B or genotype I^Bi. The baby could not have inherited the I^B allele from Barry (Barry could not carry an I^B allele if she were blood type A); therefore, the baby must have inherited the i allele from her. Barry must have had genotype I^Ai, and the baby must have had genotype I^Bi. Because the baby girl inherited her i allele from Barry, she must have inherited the I^B allele from her father. Having blood type O, produced only by genotype ii, Chaplin could not have been

the father of Barry's child. While blood types can be used to exclude the possibility of paternity (as in this case), they cannot prove that a particular person is the parent of a child because many different people have the same blood type.

In the course of the trial to settle the paternity suit against Chaplin, three pathologists testified that it was genetically impossible for Chaplin to have fathered the child. Nevertheless, the jury ruled that Chaplin was the father and ordered him to pay child support and Barry's legal expenses. **› TRY PROBLEM 24**

COMPOUND HETEROZYGOTES

Different alleles often give rise to the same phenotype. For example, cystic fibrosis, as we saw earlier in this section, arises from defects in alleles at the *CFTR* locus, which encodes a protein that controls the movement of chloride ions into and out of the cell. Over a thousand different alleles at the *CFTR* locus that can cause cystic fibrosis have been discovered worldwide. Because cystic fibrosis is an autosomal recessive condition, one must normally inherit two defective *CFTR* alleles to have cystic fibrosis. In some people with cystic fibrosis, these two defective alleles are identical, meaning that the person is homozygous. Other people with cystic fibrosis are heterozygous, possessing two different defective alleles. An individual who carries two different alleles at a locus that result in a recessive phenotype is referred to as a **compound heterozygote**.

CONCEPTS

More than two alleles (multiple alleles) may be present at a locus within a group of organisms, although each individual diploid organism still has only two alleles at that locus. A compound heterozygote possesses two different alleles that result in a recessive phenotype.

✔ CONCEPT CHECK 5

How many genotypes are possible at a locus with five alleles?

a. 30
b. 27
c. 15
d. 5

5.2 Gene Interaction Takes Place When Genes at Multiple Loci Determine a Single Phenotype

In the dihybrid crosses that we examined in Chapter 3, each locus had an independent effect on the phenotype. When Mendel crossed a homozygous pea plant that produced round and yellow seeds (*RR YY*) with a homozygous plant that produced wrinkled and green seeds (*rr yy*), and then allowed the F_1 to self-fertilize, he obtained F_2 progeny in the following proportions:

$^9/_{16}\ R_Y_$	round, yellow
$^3/_{16}\ R_yy$	round, green
$^3/_{16}\ rr\ Y_$	wrinkled, yellow
$^1/_{16}\ rr\ yy$	wrinkled, green

In this example, the two loci showed two kinds of independence. First, the genes at each locus were independent in their *assortment* in meiosis, which produced the 9:3:3:1 ratio of phenotypes in the progeny, in accord with Mendel's principle of independent assortment. Second, the genes were independent in their *phenotypic expression*: the *R* and *r* alleles affected only the shape of the seed and had no influence on the color of the seed; the *Y* and *y* alleles affected only color and had no influence on the shape of the seed.

Frequently, genes exhibit independent assortment but do not act independently in their phenotypic expression; instead, the effects of genes at

one locus depend on the presence of genes at other loci. This type of interaction between the effects of genes at different loci (genes that are not allelic) is termed **gene interaction**. With gene interaction, it is the products of genes at different loci that interact to produce new phenotypes that are not predictable from the single-locus effects alone. In our consideration of gene interaction, we will focus primarily on interactions between the effects of genes at two loci, although interactions among genes at three, four, or more loci are common.

CONCEPTS

In gene interaction, genes at different loci contribute to the determination of a single phenotypic characteristic.

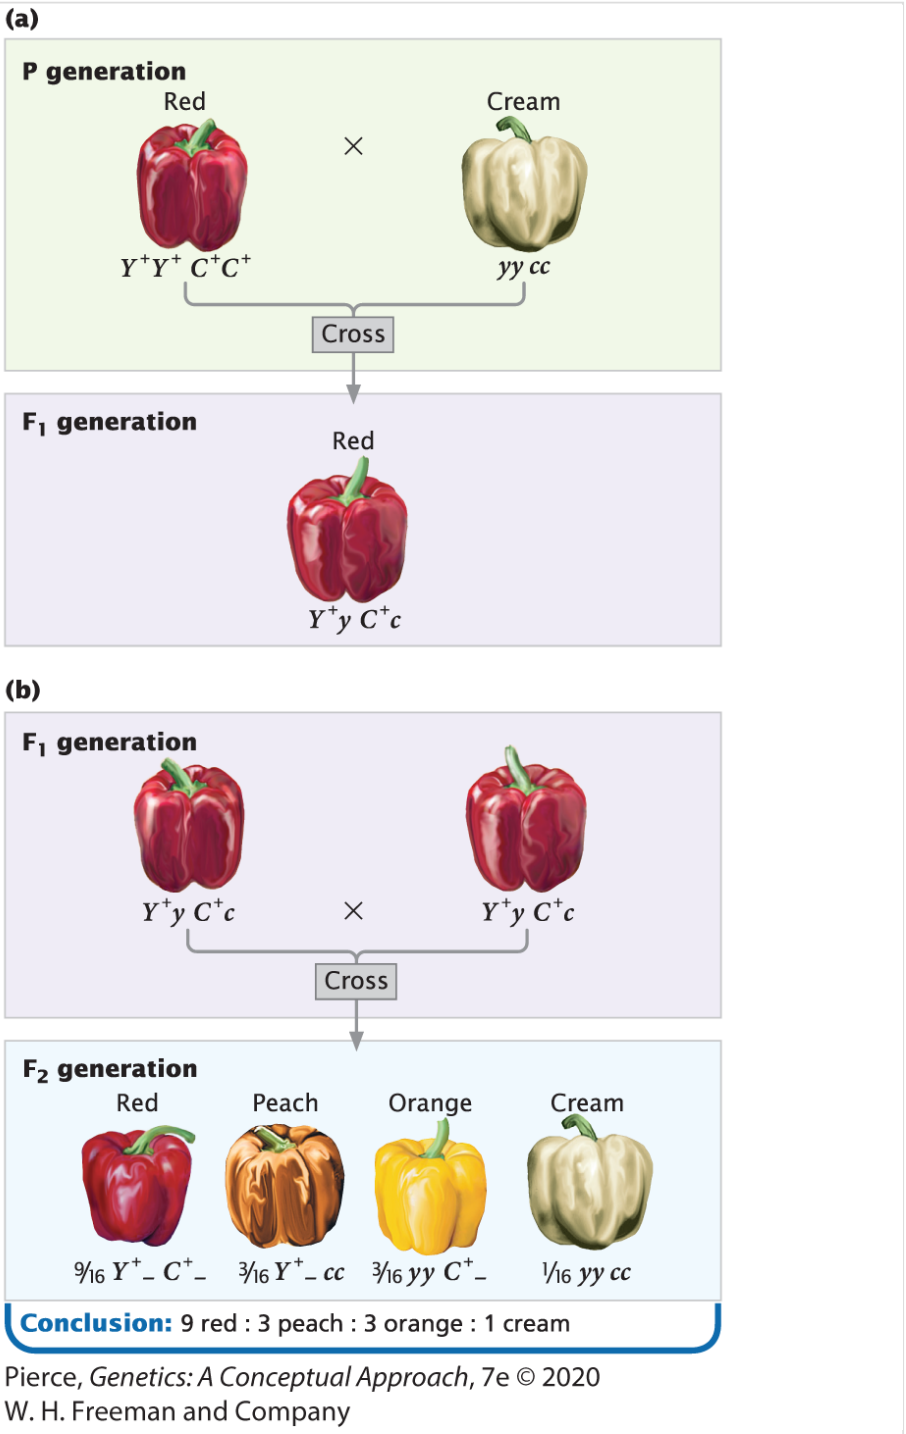
✔ CONCEPT CHECK 6

How does gene interaction differ from dominance?

Gene Interaction That Produces Novel Phenotypes

Let's begin by examining gene interaction in which genes at two loci interact to produce a single characteristic. Fruit color in the pepper *Capsicum annuum* is determined in this way. Certain types of peppers produce fruits in one of four colors: red, peach, orange (sometimes called yellow), or cream (white). If a homozygous plant with red peppers is crossed with a homozygous plant with cream peppers, all the F_1 plants have red peppers (**Figure 5.7a**). When the F_1 are crossed with each other, the F_2 show a ratio of 9 red : 3 peach : 3 orange : 1 cream (**Figure 5.7b**). This dihybrid ratio (see Chapter 3) is

produced by a cross between two plants that are both heterozygous for two loci ($Y^+y\ C^+c \times Y^+y\ C^+c$). In this example, the *Y* locus and the *C* locus interact to produce a single phenotype—the color of the pepper:



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

5.7 Interaction between genes at two loci determines a single characteristic, fruit color, in the pepper *Capsicum annuum*.

Description
The part a shows P generation with the following genotype: big Y superscript positive big Y superscript positive (red) and small Y small Y small C small C (cream). F subscript 1 generation below produced after cross shows the following genotype: big Y superscript positive small Y big C superscript positive small C (red). The part b shows F subscript 1 generation where two red peppers with same genotype big Y superscript positive small Y big C superscript positive small C are crossed to produce F subscript 2 generation. The F subscript 2 generation shown below has the following genotype: nine over sixteen Y superscript positive underscore C superscript positive underscore (red), three over sixteen big Y superscript positive underscore small C small C (peach), three over sixteen small Y small Y big C superscript positive underscore (orange), and one over sixteen small Y small Y small C small C (cream). A caption below reads, Conclusion: 9 red to 3 peach to 3 orange to 1 cream.

Genotype	Phenotype
$Y^+_\ C^+_$	Red
$Y^+_\ cc$	Peach
$yy\ C^+_$	Orange
$yy\ cc$	Cream

To illustrate how Mendel's rules of heredity can be used to understand the inheritance of characteristics determined by gene interaction, let's consider a testcross between an F_1 plant from the cross in Figure 5.7 ($Y^+y\ C^+c$) and a plant with cream peppers ($yy\ cc$). As outlined in Chapter 3 for independent loci, we can work this cross by breaking it down into two simple crosses. At the first locus, the heterozygote Y^+y is crossed with the homozygote yy; this cross produces $^1/_2\ Y^+y$ and $^1/_2\ yy$ progeny. Similarly, at the second locus, the

heterozygous genotype C^+c is crossed with the homozygous genotype *cc*, producing $^1/_2$ C^+c and $^1/_2$ *cc* progeny. In accord with Mendel's principle of independent assortment, these single-locus ratios can be combined by using the multiplication rule: the probability of obtaining the genotype Y^+y C^+c is the probability of Y^+y $(^1/_2)$ multiplied by the probability of C^+c $(^1/_2)$, or $^1/_2 \times {}^1/_2 = {}^1/_4$. The probabilities of the progeny genotypes resulting from the testcross are

Progeny genotype	Probability at each locus		Overall probability	Phenotype
Y^+y C^+c	$^1/_2 \times {}^1/_2$	=	$^1/_4$	red peppers
Y^+y *cc*	$^1/_2 \times {}^1/_2$	=	$^1/_4$	peach peppers
yy C^+c	$^1/_2 \times {}^1/_2$	=	$^1/_4$	orange peppers
yy cc	$^1/_2 \times {}^1/_2$	=	$^1/_4$	cream peppers

When you work problems involving gene interaction, it is especially important to determine the probabilities of single-locus genotypes and to multiply the probabilities of *genotypes,* not phenotypes, because the phenotypes cannot be determined without considering the effects of the genotypes at all the contributing loci. **› TRY PROBLEM 25**

Gene Interaction with Epistasis

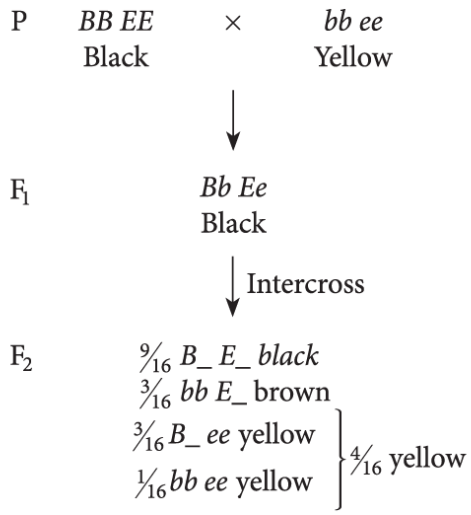
Sometimes the effect of gene interaction is that one gene masks (hides) the effect of another gene at a different locus, a phenomenon known as **epistasis**. In the examples of gene interaction that we have already examined, genes at different loci interacted to determine a single phenotype, but one gene did not *mask* the effect of a gene at another locus, meaning that there was no epistasis. Epistasis is similar to dominance, except that dominance entails the masking of genes at the *same* locus (allelic genes). In epistasis, the gene that does the masking is called an **epistatic gene**; the gene whose effect is masked is a **hypostatic gene**. Epistatic genes may be recessive or dominant in their effects.

RECESSIVE EPISTASIS

Recessive epistasis is seen in the genes that determine coat color in Labrador retrievers. These dogs may be black, brown (frequently called chocolate), or yellow; their different coat colors are determined by interactions between genes at two loci (although a number of other loci also help to determine coat color; see pp. 126–128). One locus determines the type of pigment produced by the skin cells: a dominant allele *B* encodes black pigment, whereas a recessive allele *b* encodes brown pigment. Alleles at a second locus affect the *deposition* of the pigment in the shaft of the hair; dominant allele *E* allows dark pigment (black or brown) to be deposited, whereas recessive allele *e* prevents the deposition of dark pigment, causing the hair to be yellow. The presence of genotype *ee* at the second locus therefore masks the expression of the black and brown alleles at the first locus. The genotypes that determine coat color and their phenotypes are

Genotype	Phenotype
*B_ E_*	Black
*bb E_*	Brown
B_ ee	Yellow
bb ee	Yellow

If we cross a black Labrador that is homozygous for the dominant alleles (*BB EE*) with a yellow Labrador that is homozygous for the recessive alleles (*bb ee*) and then intercross the F_1, we obtain progeny in the F_2 in a 9:3:4 ratio:

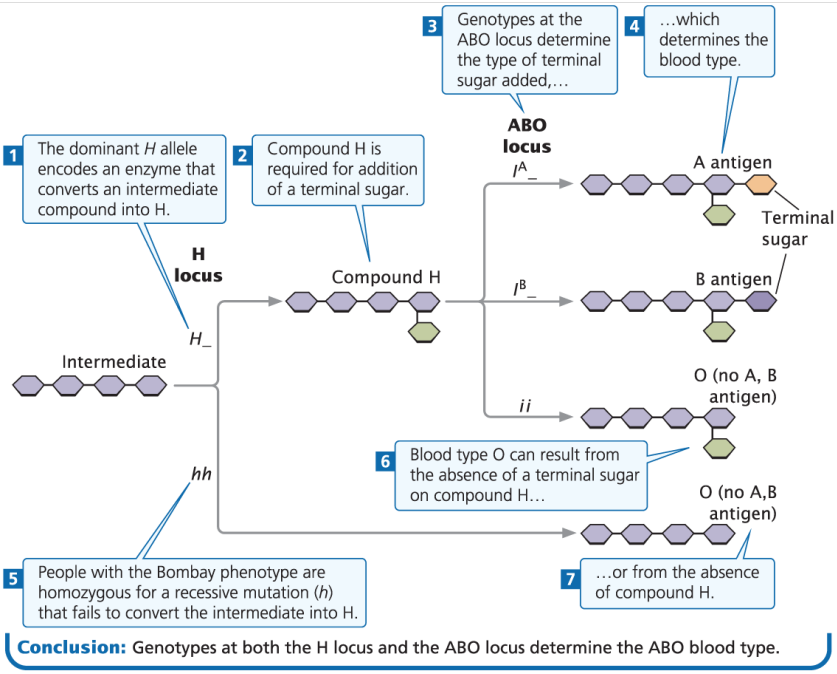


Description
The P generation shows black Labrador with genotype big B big B big E big E crossed with yellow Labrador with genotype small B small B small E small E. The F subscript 1 generation below shows black progeny with genotype big B small B big E small E. Intercross results in F subscript 2 generation below which consists of nine over sixteen big B blank big E blank, black; three over sixteen small B small B big E blank, brown; three over sixteen big B blank small E small E, yellow; one over sixteen small B small B, small E small E, yellow. Four over sixteen progeny in F subscript 2 generation are yellow.

Notice that yellow dogs can carry alleles for either black or brown pigment, but these alleles are not expressed in their coat color.

In this example of gene interaction, allele *e* is epistatic to *B* and *b* because *e* masks the expression of the alleles for black and brown pigments, and alleles *B* and *b* are hypostatic to *e*. In this case, *e* is a recessive epistatic allele because two copies of *e* must be present to mask the expression of the black and brown pigments. **› TRY PROBLEM 29**

Another recessive epistatic gene determines a rare blood type called the Bombay phenotype; this gene masks the expression of alleles at the ABO locus. As mentioned earlier in the chapter, the alleles at the ABO locus encode antigens on the red blood cells; the antigens consist of short chains of carbohydrates embedded in the outer membranes of red blood cells. The difference between the A and the B antigens is a function of chemical differences in the terminal sugar of the chain. The I^A and I^B alleles actually encode different enzymes, which add sugars designated A or B to the ends of the carbohydrate chains (**Figure 5.8**). The common substrate on which these enzymes act is a molecule called compound H. In individuals with blood type O, either the enzyme encoded by the *i* allele adds no sugar to compound H or no functional enzyme is specified.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

5.8 Expression of the ABO antigens depends on alleles at the H locus. The H locus encodes a precursor to the antigens, called compound H. Alleles at the ABO locus determine which types of terminal sugars are added to compound H.

Description

The branch diagram involves 3 steps and the process starts with an intermediate and divides into two branches based on big H locus through big H blank and small H small H. A caption reads, “The dominant big H allele encodes an enzyme that converts an intermediate compound into H.” Through big H blank, compound big H is formed on the right side and shows one added molecule at terminal position in the intermediate. A caption reads, “Compound H is required for addition of a terminal sugar.” Compound H branches into three divisions based on big A big B big O locus. A caption reads, “Genotypes at the big A big B big O locus determine the type of terminal sugar added which determines the blood type.” The first branch produces big A-antigen with a terminal sugar in compound big H through big I superscript A blank. The second branch produces big B-antigen with a terminal sugar in compound big H through big I superscript B blank. The third branch produces big O (no big A, big B antigen) with no added terminal sugar in compound big H through small I small I. The second branch from the intermediate directly leads to big O blood type through small H small H without the inclusion of compound big H. A caption from small H small H reads, “People with the Bombay phenotype are homozygous for a recessive mutation (small h) that fails to convert the intermediate into big H.” A caption from blood type big O reads, “Blood-type big O can result from the absence of a terminal sugar on compound big H or from the absence of compound big H.” A caption at

the bottom reads, “Conclusion: Genotypes at both the big H locus and the big A big B big O locus determine the big A big B big O blood type.”

In most people, a dominant allele (*H*) at the H locus encodes an enzyme that makes compound H, but people with the Bombay phenotype are homozygous for a recessive mutation (*h*) that encodes a defective enzyme. The defective enzyme is incapable of making compound H, and because compound H is not produced, no ABO antigens are synthesized. Thus, the expression of the alleles at the ABO locus depends on the genotype at the H locus.

Genotype	Compound H present	ABO phenotype
*H_* I^AI^A, *H_* I^Ai	Yes	A
*H_* I^BI^B, *H_* I^Bi	Yes	B
*H_* I^AI^B	Yes	AB
H_ii	Yes	O
hh I^AI^A, *hh* I^Ai, *hh* I^BI^B, *hh* I^Bi, *hh* I^AI^B, and *hh ii*	No	O

In this example, the alleles at the ABO locus are hypostatic to the recessive *h* allele.

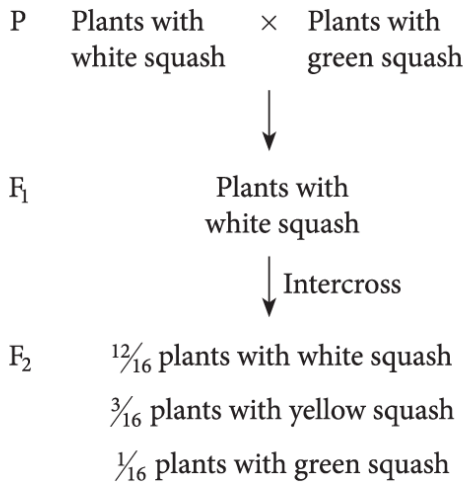
The Bombay phenotype provides us with a good opportunity for considering how epistasis can arise when genes affect a series of steps in a biochemical pathway. The ABO antigens are produced in a multistep biochemical pathway

(see Figure 5.8) that depends on enzymes that make compound H and on other enzymes that convert compound H into the A or B antigen. Note that blood type O may arise in one of two ways: (1) from failure to add a terminal sugar to compound H (genotype *H_ii*) or (2) from failure to produce compound H (genotype *hh_*). Many cases of epistasis arise in similar ways. A gene (such as *h*) that has an effect on an early step in a biochemical pathway will be epistatic to genes (such as I^A and I^B) that affect subsequent steps because the effects of the genes in a later step depend on the product of the earlier reaction.

DOMINANT EPISTASIS

In *recessive* epistasis, the presence of two recessive alleles (the homozygous genotype) inhibits the expression of an allele at a different locus. In *dominant* epistasis, however, only a single copy of an allele is required to inhibit the expression of an allele at a different locus.

Dominant epistasis is seen in the interaction of two loci that determine fruit color in summer squash, which is commonly found in one of three colors: yellow, white, or green. When a homozygous plant that produces white squash is crossed with a homozygous plant that produces green squash and the F_1 plants are crossed with each other, the following results are obtained:



Description
The P generation shows plants with white squash crossed with plants with green squash. Fertilization occurs and F subscript 1 generation is obtained below. F subscript 1 generation has plants with white squash. Intercross produces F subscript 2 generation below which has twelve-sixteenth plants with white squash, three-sixteenth plants with yellow squash, and one-sixteenth plants with green squash.

How can gene interaction explain these results?

In the F_2, $^{12}/_{16}$, or $^{3}/_{4}$, of the plants produce white squash, and $^{3}/_{16} + {}^{1}/_{16} = {}^{4}/_{16} = {}^{1}/_{4}$ of the plants produce colored squash. This outcome is the familiar 3:1 ratio produced by a cross between two heterozygotes, which suggests that a dominant allele at one locus inhibits the production of pigment, resulting in white progeny. If we use the symbol *W* to represent the dominant allele that inhibits pigment production, then genotype *W*_ inhibits pigment production and produces white squash, whereas *ww* allows pigment production and results in colored squash.

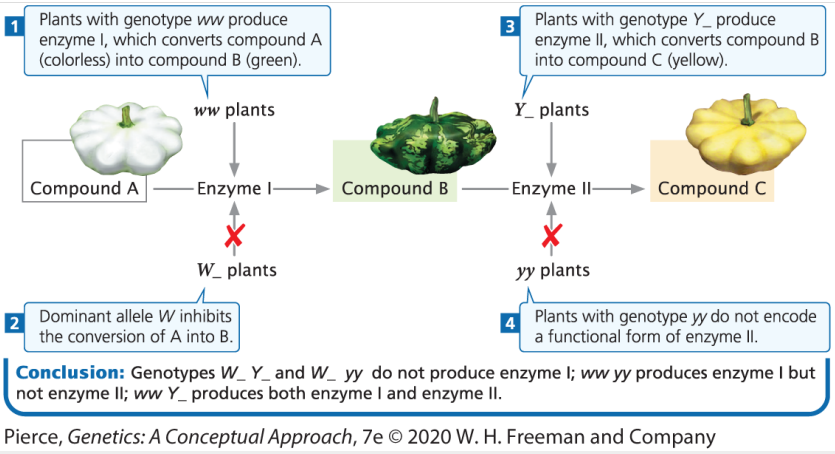
Among those *ww* F_2 plants with pigmented fruit, we observe $^{3}/_{16}$ yellow and $^{1}/_{16}$ green (a 3:1 ratio). This observation suggests that a second locus determines the type of pigment produced in the squash, with yellow (*Y*_) dominant to green (*yy*). This locus is expressed only in *ww* plants, which lack

the dominant inhibitory allele *W*. We can assign the genotype *ww Y_* to plants that produce yellow squash and the genotype *ww yy* to plants that produce green squash. The genotypes and their associated phenotypes are

*W_ Y_*	white squash
W_ yy	white squash
*ww Y_*	yellow squash
ww yy	green squash

Allele *W* is epistatic to *Y* and *y*: it masks the expression of these pigment-producing genes. Allele *W* is a dominant epistatic allele because, in contrast with *e* in Labrador retriever coat color and with *h* in the Bombay phenotype, a single copy of the allele is sufficient to inhibit pigment production.

Yellow pigment in the squash is most likely produced in a two-step biochemical pathway (**Figure 5.9**). A colorless (white) compound (designated A in Figure 5.9) is converted by enzyme I into green compound B, which is then converted into compound C by enzyme II. Compound C is the yellow pigment in the fruit. Plants with the genotype *ww* produce enzyme I and may be green or yellow, depending on whether enzyme II is present. When allele *Y* is present at a second locus, enzyme II is produced and compound B is converted into compound C, producing a yellow fruit. When two copies of allele *y*, which does not encode a functional form of enzyme II, are present, the fruit remains green. The presence of *W* at the first locus inhibits the conversion of compound A into compound B; plants with genotype *W_* do not make compound B, and their fruit remains white, regardless of which alleles are present at the second locus.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

5.9 Yellow pigment in summer squash is produced in a two-step biochemical pathway.

Description

Compound A is a colorless summer squash shown on the left side. An enzyme 1 with genotype small W small W converts compound A into compound B on the right side. A caption reads, 1: “Plants with genotype small W small W produce enzyme 1, which converts compound A (colorless) into compound B (green).” Another caption reads, 2: “Dominant allele big W inhibits the conversion of A into B.” Compound B is green in color. Another enzyme, called Enzyme 2 with genotype big Y blank coverts compound B into compound C on the extreme right side. Compound C is yellow in color. A caption reads, 3: “Plants with genotype big Y blank produce enzyme 2, which converts compound B into compound C (yellow).” Another caption reads, 4: “Plants with genotype small Y small Y do not encode a functional form of enzyme 2.”

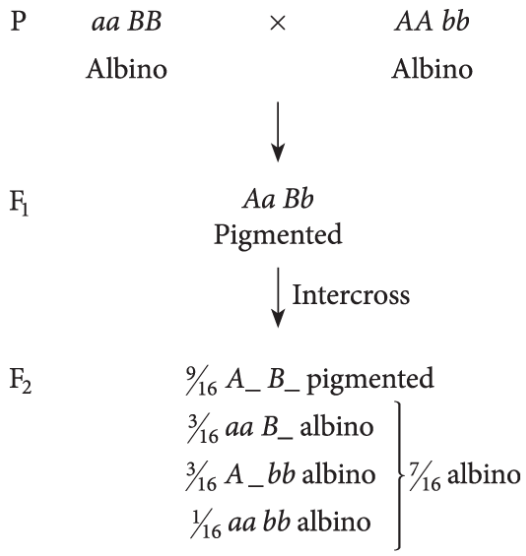
DUPLICATE RECESSIVE EPISTASIS

Finally, let’s consider duplicate recessive epistasis, in which two recessive alleles at either of two different loci are capable of suppressing a phenotype. This type of epistasis is illustrated by albinism in snails.

Albinism, the absence of pigment, is a common genetic trait in many plants and animals. Pigment is almost always produced through a multistep biochemical pathway; thus, albinism may entail gene interaction. Robert T. Dillon and Amy R. Wethington found that albinism in the common

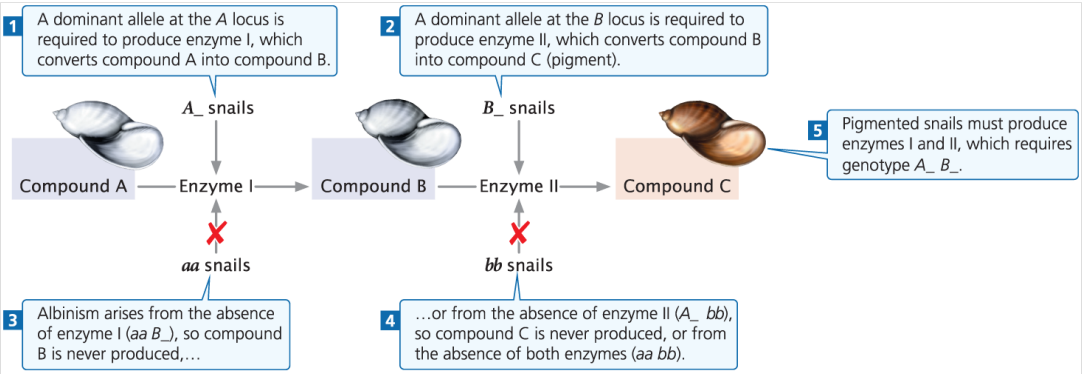
freshwater snail *Physa heterostropha* can result from the presence of two recessive alleles at either of two different loci. They collected inseminated snails from a natural population and placed them in cups of water, where the snails laid eggs. Some of the eggs hatched into albino snails. When two of these albino snails were crossed, all of the F_1 were pigmented. When the F_1 were intercrossed, the F_2 consisted of $^9/_{16}$ pigmented snails and $^7/_{16}$ albino snails. How did this 9:7 ratio arise?

The 9:7 ratio seen in the F_2 snails can be understood as a modification of the 9:3:3:1 ratio obtained when two individuals heterozygous for two loci are crossed. The 9:7 ratio arises when dominant alleles at both loci (*A*_ *B*_) produce pigmented snails and any other genotype produces albino snails:



Description
The P generation on the top shows two albinos: One albino has genotype small A small A big B big B and the other has genotype big A big A small B small B. They are crossed and a F subscript 1 generation is obtained below. The results of this cross include heterozygous progeny with genotype big A small A big B small B and are pigmented. Intercross produces the F subscript 2 generation below. The progeny are listed as follows: nine over sixteen big A blank big B blank, pigmented; three over sixteen small A small A big B blank, albino; three over sixteen big A blank small B small B, albino; and one over sixteen small A small A small B small B, albino. Thus, 7 over 16 in F subscript 2 generation are albino.

The 9:7 ratio in these snails can be explained by a two-step pathway of pigment production (Figure 5.10). Pigment (compound C) is produced only when compound A is converted into compound B by enzyme I and compound B is converted into compound C by enzyme II. At least one dominant allele *A* at the first locus is required to produce enzyme I; similarly, at least one dominant allele *B* at the second locus is required to produce enzyme II. Albinism arises from the absence of compound C, which may happen in one of three ways. First, two recessive alleles at the first locus (genotype *aa B_*) may prevent the production of enzyme I, so compound B is never produced. Second, two recessive alleles at the second locus (genotype *A_ bb*) may prevent the production of enzyme II; in this case, compound B is never converted into compound C. Third, two recessive alleles may be present at both loci (*aa bb*), causing the absence of both enzyme I and enzyme II. In this example of gene interaction, *a* is epistatic to *B*, and *b* is epistatic to *A*; *both* are recessive epistatic alleles because the presence of two copies of either allele *a* or allele *b* is necessary to suppress pigment production. This example differs from the suppression of coat color in Labrador retrievers in that recessive alleles at either of two loci are capable of suppressing pigment production in the snails, whereas recessive alleles at a single locus suppress pigment expression in the dogs.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

5.10 Pigment is produced in a two-step biochemical pathway in snails.

Description
Compound A on the left side is a colorless snail and an enzyme 1 with genotype big A blank converts it into compound B on the right side, which is also colorless. A caption reads, 1: “A dominant allele at the big A locus is required to produce enzyme 1, which converts compound A into compound B.” Another caption reads, 3: “Albinism arises from the absence of enzyme 1 (small A small A big B blank), so compound B is never produced ellipsis”. Another enzyme, called Enzyme 2 with genotype big B blank coverts compound B into compound C on the extreme right side, which is pigmented. A caption reads, 2: “A dominant allele at the big B locus is required to produce enzyme 2, which converts compound B into compound C (pigment).” Another caption reads, 4: “ellipsis or from the absence of enzyme 2 (big A blank small B small B), so compound C is never produced, or from the absence of both enzymes (small A small A small B small B).” The last caption reads, “Pigmented snails must produce enzymes 1 and 2, which requires genotype big A blank big B blank.”

CONCEPTS

Epistasis is the masking of the expression of one gene by another gene at a different locus. The epistatic gene does the masking; the hypostatic gene is masked. Epistatic alleles can be dominant or recessive.

✔ CONCEPT CHECK 7

A number of all-white cats are crossed, and they produce the following types of progeny: $^{12}/_{16}$ all-white, $^{3}/_{16}$ black, and $^{1}/_{16}$ gray. What is the genotype of the black progeny?

a. *Aa*
b. *Aa Bb*
c. *A_ B_*
d. *A_ bb*

CONNECTING CONCEPTS CONNECT

Interpreting Phenotypic Ratios Produced by Gene Interaction

A number of modified phenotypic ratios that result from gene interaction are shown in **Table 5.2**. Each of these examples represents a modification of the basic 9:3:3:1 dihybrid ratio. In interpreting the genetic basis of these modified ratios, we should keep several points in mind. First, the inheritance of the genes

producing these characteristics is no different from the inheritance of genes encoding simple genetic characteristics. Mendel's principles of segregation and independent assortment still apply; each individual organism possesses two alleles at each locus, which separate in meiosis, and genes at the different loci assort independently. The only difference is in how the *products* of the genotypes interact to produce the phenotype. Thus, we cannot consider the expression of genes at each locus separately; instead, we must take into consideration how the genes at different loci interact.

TABLE 5.2 Modified dihybrid phenotypic ratios due to gene interaction

	Genotype					
Ratio*	***A_ B_***	***A_ bb***	***aa B_***	***aa bb***	**Type of Interaction**	**Example Discussed in Chapter**
9 : 3 : 3 : 1	9	3	3	1	None	Seed shape and seed color in peas
9 : 3 : 4	9	3	4		Recessive epistasis	Coat color in Labrador retrievers
12 : 3 : 1	12		3	1	Dominant epistasis	Color in squash
9 : 7	9	7			Duplicate recessive epistasis	Albinism in snails
9 : 6 : 1	9	6		1	Duplicate interaction	—
15 : 1	15			1	Duplicate dominant epistasis	—
13 : 3	13		3		Dominant and recessive epistasis	—

*Each ratio is produced by a dihybrid cross (*Aa Bb* × *Aa Bb*). Shaded bars represent combinations of genotypes that give the same phenotype.

Description

The table shows four genotypes. 1, upper case A underscore big B underscore. 2, big A underscore small B small B. 3, small A small A big B underscore. 4, small A small A small B small B. Ratio of the four genotypes is 9 to 3 to 3 to 1, respectively. Type of interaction is none and the example discussed in chapter is seed shape and seed color in peas. Ratio is 9 to 3 to 4 (4 collectively for the last two genotypes that give the same phenotype). Type of interaction is recessive epistasis and the example discussed in chapter is coat color in Labrador retrievers. Ratio is 12 to 3 to 1 (12 collectively for the first two genotypes that give the same phenotype). Type of interaction is dominant epistasis and the example discussed in chapter is coat color in squash. Ratio is 9 to 7 (7 collectively for the last three genotypes that give the same phenotype). Type of interaction is duplicate recessive epistasis and example discussed in chapter is albinism in snails. Ratio is 9 to 6 to 1 (6 collectively for the second and third genotypes that give the same phenotype). Type of interaction is duplicate interaction and there is no example discussed in the chapter. Ratio is 15 to 1 (15 collectively for the first three genotypes that give the same phenotype). Type of interaction is duplicate dominant epistasis and there is no example discussed in the chapter. Ratio is 13 to 3 (13 collectively for the first, second, and fourth genotypes that give the same phenotype). Type of interaction is dominant and recessive epistasis and there is no example discussed in the chapter. A caption at the bottom of the table

reads each ratio is produced by a dihybrid cross (big A small A cross big A small A big B small B). Shaded bars represent combinations of genotypes that give the same phenotype.

A second point is that in the examples that we have considered, the phenotypic proportions were always in sixteenths because, in all the crosses, pairs of alleles segregated at two independently assorting loci. The probability of inheriting one of the two alleles at a locus is $^1/_2$. Because there are two loci, each with two alleles, the probability of inheriting any particular combination of genes is $(^1/_2)^4 = {}^1/_{16}$. For a trihybrid cross, the progeny proportions should be in sixty-fourths, because $(^1/_2)^6 = {}^1/_{64}$. In general, the progeny proportions should be in fractions of $(^1/_2)^{2n}$, where *n* equals the number of loci with two alleles segregating in the cross.

Crosses rarely produce exactly 16 progeny; therefore, modifications of the dihybrid ratio are not always obvious. Modified dihybrid ratios are more easily seen if the number of individuals of each phenotype is expressed in sixteenths:

$$\frac{x}{16} = \frac{\text{number of progeny with a phenotype}}{\text{total number of progeny}}$$

where *x*/16 equals the proportion of progeny with a particular phenotype. If we solve for *x* (the proportion of the particular phenotype in sixteenths), we have

$$x = \frac{\text{number of progeny with a phenotype} \times 16}{\text{total number of progeny}}$$

For example, suppose that we cross two homozygotes, interbreed the F_1, and obtain 63 red, 21 brown, and 28 white F_2 individuals. Using the preceding formula, we find the phenotypic ratio in the F_2 to be red = (63 × 16) / 112 = 9; brown = (21 × 16) / 112 = 3; and white = (28 × 16) / 112 = 4. The phenotypic ratio is 9:3:4.

A final point to consider is how to assign genotypes to the phenotypes in modified ratios that result from gene interaction. Don't try to *memorize* the genotypes associated with all the modified ratios in Table 5.2. Instead, practice relating modified ratios to known ratios, such as the 9:3:3:1 dihybrid ratio. Suppose that we obtain $^{15}/_{16}$ green progeny and $^1/_{16}$ white progeny in a cross between two plants. If we compare this 15:1 ratio with the standard 9:3:3:1 dihybrid ratio, we see that $^9/_{16} + {}^3/_{16} + {}^3/_{16}$ equals $^{15}/_{16}$. All the genotypes associated with these proportions in the dihybrid cross (*A_ B_*, *A_ bb*, and *aa B_*) must give the same phenotype, the green progeny. Genotype *aa bb* makes up $^1/_{16}$ of the progeny in a dihybrid cross—the white progeny in this cross.

In assigning genotypes to phenotypes in modified ratios, students sometimes become confused about which letters to assign to which phenotype. Suppose that we obtain the following phenotypic ratio: $^9/_{16}$ black: $^9/_{16}$ brown: $^4/_{16}$ white. Which genotype do we assign to the brown progeny, *A_ bb* or *aa B_*? Either answer is correct because the letters are just arbitrary symbols for the genetic information. The important

thing to realize about this ratio is that the brown phenotype arises when two recessive alleles are present at one locus.

WORKED PROBLEM

A homozygous strain of yellow corn is crossed with a homozygous strain of purple corn. The F_1 are intercrossed, producing an ear of corn with 119 purple kernels and 89 yellow kernels (the progeny). What is the genotype of the yellow kernels?

Solution Strategy

What information is required in your answer to the problem?

The genotype of the yellow kernels.

What information is provided to solve the problem?

- A homozygous yellow corn plant is crossed with a homozygous purple corn plant.
- The numbers of purple and yellow progeny produced by the cross.

Solution Steps

We should first consider whether the cross between yellow and purple strains might be a monohybrid cross for a simple dominant trait, which would produce a 3:1 ratio in the F_2 ($Aa \times Aa \rightarrow {}^3/_4 A_$ and ${}^1/_4\, aa$). Under this hypothesis, we would expect 156 purple progeny and 52 yellow progeny:

Phenotype	Genotype	Observed number	Expected number
purple	*A_*	119	$^3/_4 \times 208 = 156$
yellow	*aa*	89	$^1/_4 \times 208 = 52$
Total		208	

We see that the expected numbers do not closely fit the observed numbers. If we performed a chi-square test (see Chapter 3), we would obtain a calculated chi-square value of 35.08, which has a probability much less than 0.05, indicating that it is extremely unlikely that when we expect a 3:1 ratio, we would obtain 119 purple progeny and 89 yellow progeny just by chance. Therefore, we can reject the hypothesis that these results were produced by a monohybrid cross.

Another possible hypothesis is that the observed F_2 progeny are in a 1:1 ratio. However, we learned in Chapter 3 that a 1:1 ratio is produced by a cross between a heterozygote and a homozygote (*Aa* × *aa)*, and in this cross, both original parental strains were homozygous. Furthermore, a chi-square test comparing the observed numbers with an expected 1:1 ratio yields a calculated chi-square value of 4.32, which has a probability of less than 0.05.

Next, we should look to see if the results can be explained by a dihybrid cross (*Aa Bb* × *Aa Bb*). A dihybrid cross results in phenotypic proportions that are in sixteenths. We can apply the formula given earlier in the chapter to determine the number of sixteenths for each phenotype:

$$
\begin{aligned}
x &= \frac{\text{number of progeny with a phenotype} \times 16}{\text{total number of progeny}} \\
x_{(\text{purple})} &= \frac{119 \times 16}{208} = 9.15 \\
x_{(\text{yellow})} &= \frac{89 \times 16}{208} = 6.85
\end{aligned}
$$

Thus, purple and yellow appear in an approximate ratio of 9:7.

We can test this hypothesis with a chi-square test:

Phenotype	Genotype	Observed number	Expected number
purple	?	119	$^{9}/_{16} \times 208 = 117$
yellow	?	89	$^{7}/_{16} \times 208 = 91$
Total		208	

$$
\begin{aligned}
\chi^2 &= \sum \frac{(\text{observed} - \text{expected})^2}{\text{expected}} \\
&= \frac{(119 - 117)^2}{117} + \frac{(89 - 91)^2}{91} \\
&= 0.034 + 0.044 = 0.078 \\
\text{Degree of freedom} &= n - 1 = 2 - 1 = 1 \\
P &> 0.05
\end{aligned}
$$

The probability associated with the chi-square value is greater than 0.05, indicating that there is a good fit between the observed results and a 9:7 ratio.

We now need to determine how a dihybrid cross can produce a 9:7 ratio and what genotypes correspond to the two phenotypes. A dihybrid cross without epistasis produces a 9:3:3:1 ratio:

$$Aa\ Bb \times Aa\ Bb$$

$$\downarrow$$

$$A_\ B_\ {}^{9}/_{16}$$
$$A_\ bb\ {}^{3}/_{16}$$
$$aa\ B_\ {}^{3}/_{16}$$
$$aa\ bb\ {}^{1}/_{16}$$

Description
The illustration shows big A small A big B small B crossed with big A small A big B small B. An arrow pointing downward points to the 4 different types of progeny as follows: big A blank big B blank describes nine over sixteen of the offspring. Big A blank small B small B are three over sixteen of the progeny. Small A small A big B blank are three over sixteen of the offspring. Small A small A small B small B are one over sixteen of the offspring.

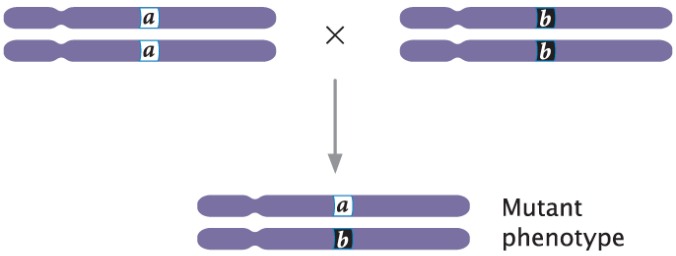
Because ${}^{9}/_{16}$ of the progeny from the corn cross are purple, purple must be produced by genotypes *A*_ *B*_; in other words, individual kernels that have at least one dominant allele at the first locus and at least one dominant allele at the second locus are purple. The proportions of all the other genotypes (*A*_ *bb*, *aa B*_, and *aa bb*) sum to ${}^{7}/_{16}$, which is the proportion of the progeny in the corn cross that are yellow, so any individual kernel that does not have a dominant allele at both the first and the second locus is yellow.

» Now test your understanding of epistasis by working **Problem 26** at the end of the chapter.

Complementation: Determining Whether Mutations Are at the Same Locus or at Different Loci

How do we know whether different mutations that affect a characteristic occur at the same locus (are allelic) or at different loci? In fruit flies, for example, *white* is an X-linked recessive mutation that produces white eyes instead of the red eyes found in wild-type flies; *apricot* is an X-linked recessive mutation that produces light orange eyes. Do the *white and apricot* mutations occur at the same locus or at different loci? We can use the complementation test to answer this question.

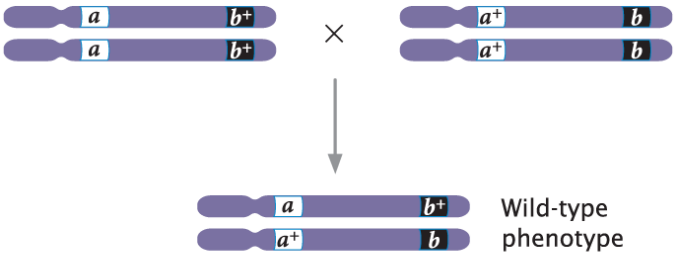
To carry out a **complementation test** on recessive mutations (*a* and *b*), parents that are homozygous for different mutations are crossed, producing offspring that are heterozygous. If the mutations are allelic (occur at the same locus), then the heterozygous offspring have only mutant alleles (*a b*) and exhibit a mutant phenotype:



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The first homologous pair has small A written at one locus on the long arm of both of its chromosomes. The second homologous pair has small B written at one locus on the long arm of both of its chromosomes. An arrow pointing downwards shows the resultant homologous chromosome with a mutant phenotype with small A written on one chromosome at a locus and small B on another.

If, on the other hand, the mutations occur at different loci, each of the homozygous parents possesses wild-type genes at the other locus (*aa* b^+b^+ and a^+a^+ *bb*); so the heterozygous offspring inherit a mutant allele and a wild-type allele at each locus. In this case, the presence of a wild-type allele complements the mutation at each locus, and the heterozygous offspring have the wild-type phenotype:



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The first homologous pair has small A written at one locus and small B superscript positive written at another locus on the long arm of both of its chromosomes. The second homologous pair has small A superscript positive written at one locus and small B written at another locus on the long arm of both of its chromosomes. An arrow pointing downward shows the resultant homologous chromosome with a wild-type phenotype with small A at a locus and small B superscript positive at another locus on one chromosome and small A superscript positive at a locus and small B at another locus on the other chromosome.

Complementation has taken place if an individual organism possessing two recessive mutations has a wild-type phenotype, indicating that the mutations are at nonallelic genes. There is a lack of complementation when two recessive mutations occur at the same locus, producing a mutant phenotype.

When the complementation test is applied to *white* and *apricot* mutations, all the heterozygous offspring have light-colored eyes, demonstrating that white eyes and apricot eyes are produced by mutations that occur at the same locus and are allelic.

THINK-PAIR-SHARE Question 2

CONCEPTS

A complementation test is used to determine whether two mutations occur at the same locus (are allelic) or at different loci.

✔ CONCEPT CHECK 8

Brindle (tiger-striped appearance) is a recessive trait in bulldogs and in Chihuahuas. What types of crosses would you carry out to determine whether the *brindle* genes in bulldogs and in Chihuahuas are at the same locus?

The Complex Genetics of Coat Color in Dogs

The genetics of coat color in dogs is an excellent example of the complex interactions between genes that may take part in the determination of a phenotype. Domestic dogs come in an amazing variety of shapes, sizes, and colors. For thousands of years, people have been breeding dogs for particular traits, producing the large number of types that we see today. Each breed of dog carries a selection of alleles from the ancestral dog gene pool; these alleles define the features of a particular breed. The genome of the domestic dog was completely sequenced in 2004, greatly facilitating the study of canine genetics.

Here we consider four loci (in the list that follows) that are important in producing many of the noticeable differences in color and pattern among breeds of dogs. In interpreting the genetic basis of differences in the coat colors of dogs, consider how the expression of a particular gene is modified

by the effects of other genes. Keep in mind that additional loci not listed here can modify the colors produced by these four loci and that not all geneticists agree on the genetics of color variation in some breeds.

1. **Agouti (*A*) locus.** This locus has five common alleles that determine the depth and distribution of color in a dog's coat:

A^s	Solid black pigment.
a^w	Agouti, or wolflike gray. Hairs encoded by this allele have a salt-and-pepper appearance, produced by a band of yellow pigment on a black hair.
a^y	Yellow. The black pigment is markedly reduced, so the entire hair is yellow.
a^s	Saddle markings (dark color on the back, with extensive tan markings on the head and legs).
a^t	Bicolor (dark color over most of the body, with tan markings on the feet and eyebrows).

   Alleles A^s and a^y are generally dominant to the other alleles, but the dominance relations are complex and not yet completely understood.
2. **Black (*B*) locus.** This locus determines whether black pigment can be formed. The actual color of a dog's coat depends on the effects of genes at other loci (such as the *A* and *E* loci). Two alleles are common:

B	Allows black pigment to be produced.
b	Black pigment cannot be produced; pigmented dogs can be

	chocolate, liver, tan, or red.

Allele *B* is dominant to allele *b*.

3. **Extension (*E*) locus.** Four alleles at this locus determine where the genotype at the *A* locus is expressed. For example, if a dog has the A^s allele (solid black) at the *A* locus, then black pigment will either be extended throughout the coat or be restricted to some areas, depending on the alleles present at the *E* locus. Areas where the *A* locus is not expressed may appear yellow, red, or tan, depending on the presence of particular alleles at other loci. When A^s is present at the *A* locus, the four alleles at the *E* locus have the following effects:

E^m	Black mask with a tan coat.
E	The *A* locus is expressed throughout (solid black).
e^{br}	Brindle, in which black and yellow are in layers to give a tiger-striped appearance.
e	No black in the coat, but the nose and eyes may be black.

The dominance relations among these alleles are poorly known.

4. **Spotting (*S*) locus**. Alleles at this locus determine whether white spots will be present. There are four common alleles:

S	No spots.
s^i	Irish spotting: numerous white spots.
s^p	Piebald spotting: various amounts of white.

s^w	Extreme white piebald: almost all white.

Allele *S* is completely dominant to alleles s^i, s^p, and s^w; alleles s^i and s^p are dominant to allele s^w ($S > s^i$, $s^p > s^w$). The relation between s^i and s^p is poorly defined; indeed, they may not be separate alleles. Genes at other poorly known loci also modify spotting patterns.

To illustrate how genes at these loci interact in determining a dog's coat color, let's consider a few examples.

LABRADOR RETRIEVER

Labrador retrievers (Figure 5.11a) may be black, brown, or yellow. Most are homozygous A^sA^s *SS*; thus, they vary only at the *B* and *E* loci. The A^s allele allows dark pigment to be expressed; whether a dog is black depends on which genes are present at the *B* and *E* loci. As discussed earlier in the chapter, all black Labradors must carry at least one *B* allele and one *E* allele (*B*_ *E*_). Brown dogs are homozygous *bb* and have at least one *E* allele (*bb E*_). Yellow dogs are a result of the presence of *ee* (*B*_ *ee* or *bb ee*). Labrador retrievers are homozygous for the *S* allele, which produces a solid color; the few white spots that appear in some dogs of this breed are due to other modifying genes.

Part a: imagebroker/Alamy. Part b: RFcompany/age fotostock. Part c: Stockbyte/Getty Images.

5.11 Coat color in dogs is determined by interactions between genes at a number of loci. (a) Most Labrador retrievers are genotype A^SA^S *SS*, varying only at the *B* and *E* loci. (b) Most

beagles are genotype $a^S a^S$ *BB* $s^P s^P$. (c) Dalmatians are genotype $A^S A^S$ *EE* $s^w s^w$, varying at the *B* locus, which makes the dogs black (*B_*) or brown (*bb*).

BEAGLE

Most beagles (Figure 5.11b) are homozygous $a^s a^s$ *BB* $s^p s^p$, although other alleles at these loci are occasionally present. The a^s allele produces the saddle markings—dark back and sides, with tan head and legs—that are characteristic of the breed. Allele *B* allows black to be produced, but its distribution is limited by the a^s allele. Most beagles are *E_*, but the genotype *ee* does occasionally arise, leading to a few all-tan beagles. White spotting in beagles is due to the s^P allele.

DALMATIAN

Dalmatians (Figure 5.11c) have an interesting genetic makeup. Most are homozygous $A^s A^s$ *EE* $s^w s^w$, so they vary only at the *B* locus. Notice that these dogs possess genotype $A^s A^s$ *EE*, which allows for a solid coat that would be black if genotype *B_* were present, or brown (called liver) if genotype *bb* were present. However, the presence of the s^w allele produces a white coat, masking the expression of the solid color. The dog's color appears only in the pigmented spots, which are due to the presence of an allele at yet another locus that allows the color to penetrate in a limited number of spots.

Table 5.3 gives the common genotypes of other breeds of dogs. **› TRY PROBLEM 33**

TABLE 5.3 Common genotypes in different breeds of dogs

Breed	Usual Homozygous Genotypes*	Other Alleles Present Within the Breed

St. Bernard	$a^{y}a^{y}$ *BB*	E^{m}, *E* s^{i}, s^{P}, s^{w}

* Most dogs in the breed are homozygous for these genes; a few individual dogs may possess other alleles at these loci. Data from: M. B. Willis, *Genetics of the Dog* (London: Witherby, 1989).

5.3 Sex Influences the Inheritance and Expression of Genes in a Variety of Ways

In Chapter 4, we considered characteristics encoded by genes located on the sex chromosomes (sex-linked traits) and how their inheritance differs from the inheritance of characteristics encoded by autosomal genes. X-linked traits, for example, are passed from father to daughter but never from father to son, and Y-linked traits are passed from father to all sons. Here we examine additional influences of sex, including the effect of the sex of an individual organism on the expression of autosomal genes, on characteristics determined by genes located in the cytoplasm, and on characteristics for which the genotype of only the maternal parent determines the phenotype of the offspring. Finally, we look at situations in which the expression of autosomal genes is affected by the sex of the parent from whom the genes are inherited.

Sex-Influenced and Sex-Limited Characteristics

Sex-influenced characteristics are determined by autosomal genes and are inherited according to Mendel's principles, but they are expressed differently in males and females. In this case, a particular

trait is more readily expressed in one sex; in other words, the trait has higher penetrance in one of the sexes.

For example, the presence of a beard on some goats is determined by an allele at an autosomal locus (B^b) that is dominant in males and recessive in females. In males, a single beard allele is required for the expression of this trait: both the homozygote ($B^b\ B^b$) and the heterozygote ($B^b\ B^+$) have beards, whereas the $B^+\ B^+$ male is beardless. In contrast, females require two beard alleles in order for this trait to be expressed: the homozygote $B^b\ B^b$ has a beard, whereas the heterozygote ($B^b\ B^+$) and the other homozygote ($B^+\ B^+$) are beardless.

Genotype	Males	Females
$B^+\ B^+$	beardless	beardless
$B^+\ B^b$	bearded	beardless
$B^b\ B^b$	bearded	bearded

The key to understanding the expression of the beard allele is to look at the heterozygote. In males (for which the presence of a beard is dominant), the heterozygous genotype produces a beard, but in females (for which the absence of a beard is dominant), the heterozygous genotype produces a goat without a beard.

Figure 5.12a illustrates a cross between a beardless male ($B^+ B^+$) and a bearded female ($B^b B^b$). The alleles separate into gametes according to Mendel's principle of segregation, and all the F_1 are heterozygous ($B^+ B^b$). Because the trait is dominant in males and recessive in females, all the F_1 males will be bearded and all the F_1 females will be beardless. When the F_1 are crossed with each other, $^1/_4$ of the F_2 progeny are $B^b B^b$, $^1/_2$ are $B^b B^+$, and $^1/_4$ are $B^+ B^+$ (**Figure 5.12b**). Because male heterozygotes are bearded, $^3/_4$ of the males in the F_2 possess beards; because female heterozygotes are beardless, only $^1/_4$ of the females in the F_2 are bearded.

5.12 Genes that encode sex-influenced characteristics are inherited according to Mendel's principles but are expressed differently in males and females.

Description

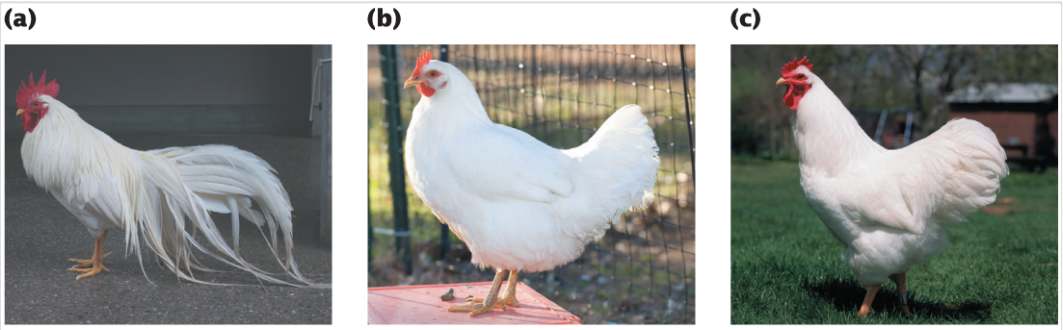
The part (a) on the top shows a cross between a beardless male goat with genotype big B superscript positive big B superscript positive and a bearded female goat with genotype big B superscript small B big B superscript small B in the P generation. After meiosis, the male goat produces big B superscript positive gametes and the female goat produces big B superscript small B gametes. Fertilization occurs and leads to F subscript 1 generation below which consists of a bearded male with genotype big B superscript positive big B superscript small B and a beardless female with genotype big B superscript positive big B superscript small B.

The part (b) below shows a cross in the F subscript 1 generation to produce F subscript 2 generation. The progeny produced in F subscript 1 generation are crossed. Meiosis results in the production of big B superscript positive and big B superscript small B gametes from each of the parents. These gametes undergo fertilization and produces F subscript 2 generation below as follows: one-fourth beardless male with genotype big B superscript positive big B superscript positive; one-half bearded males with genotype big B superscript positive big B superscript small B; one-fourth bearded males with genotype big B superscript small B big B superscript small B; one-fourth beardless females with genotype big B superscript positive big B superscript positive; one-half beardless females with genotype big B superscript positive big B superscript small B; one-fourth bearded females with genotype big B superscript small B big B superscript small B.

A caption at the bottom reads, "Conclusion: three-fourth of the males are bearded, one fourth of the females are bearded."

A **sex-limited characteristic** is encoded by autosomal genes that are expressed in only one sex; the trait has zero penetrance in the other sex. In domestic chickens, for example, some males display a

plumage pattern called cock feathering (Figure 5.13a). Other males and all females display a pattern called hen feathering (Figure 5.13b and c). Cock feathering is an autosomal recessive trait that is limited to males. Because the trait is autosomal, the same genotypes are found in males and females, but the phenotypes produced by these genotypes differ between males and females:



Part a: Moment Open/Getty Images. Part b: Guy J. Sagi/Shutterstock. Part c: James Marshall/Getty Images.

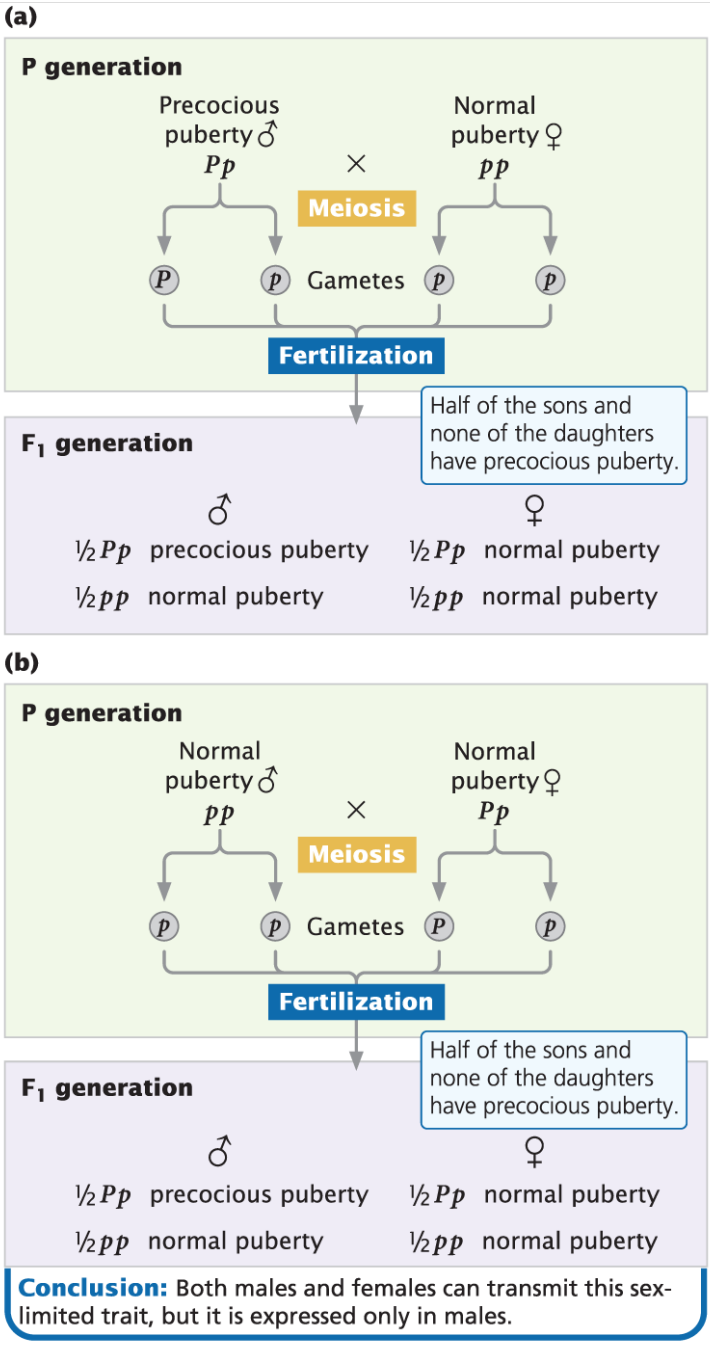
5.13 A sex-limited characteristic is encoded by autosomal genes that are expressed in only one sex. An example is cock feathering in chickens, an autosomal recessive trait that is limited to males. (a) Cock-feathered male. (b) Hen-feathered female. (c) Hen-feathered male.

Genotype	Male phenotype	Female phenotype
HH	hen feathering	hen feathering
Hh	hen feathering	hen feathering
hh	cock feathering	hen feathering

An example of a sex-limited characteristic in humans is male-limited precocious puberty. There are several types of precocious puberty in humans, most of which are not genetic. Male-limited precocious puberty, however, results from an autosomal dominant allele (*P*) that is expressed only in males; females with this allele are normal in phenotype. Males with precocious puberty undergo puberty at an early age, usually before the age of four. At this time, the penis enlarges, the voice deepens, and pubic hair develops. There is no impairment of sexual function; affected males are fully fertile. Most are short as adults because the long bones stop growing after puberty.

Because the trait is rare, affected males are usually heterozygous (*Pp*). A male with precocious puberty who mates with a woman who has no family history of this condition will transmit the allele for precocious puberty to half of their children (**Figure 5.14a**), but it will be expressed only in the sons. If one of the heterozygous daughters (*Pp*) mates with a male who exhibits normal puberty (*pp*), half of their sons will exhibit precocious puberty (**Figure 5.14b**). Thus, a sex-limited characteristic can be inherited from either parent, although the trait appears in only one sex. **› TRY PROBLEM 35**

THINK-PAIR-SHARE Questions 3, 4, and 5



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

5.14 Sex-limited characteristics are inherited according to Mendel's principles.

Precocious puberty is an autosomal dominant trait that is limited to males.

Description

Part (a) shows a cross between a male with precocious puberty with genotype big P small P and a normal puberty female with genotype small P small P. Meiosis occurs and results in the formation of gametes below. Big P and small P are the gametes formed from male while small P and small P are formed from female. Fertilization occurs and results in the formation of F subscript 1 generation below. A caption reads, “Half of the sons and none of the daughters have precocious puberty.” F subscript 1 generation are as follows: one-half precocious puberty males of genotype big P small P; one-half normal puberty males of genotype small P small P; one-half normal puberty females of genotype big P small P; and one-half of normal puberty females of genotype small P small P.

Part (b) shows a cross between a male with normal puberty with genotype small P small P and a normal puberty female with genotype big P small P. Meiosis occurs and results in the formation of gametes below. Small P and small P are the gametes formed from male while big P and small P are formed from female. Fertilization occurs and results in the formation of F subscript 1 generation below. A caption reads, “Half of the sons and none of the daughters have precocious puberty.” F subscript 1 generation are as follows: one-half precocious puberty males of genotype big P small P; one-half normal puberty males of genotype small P small P; one-half normal puberty females of genotype big P small P; and one-half of normal puberty females of genotype small P small P. A caption below reads, “Conclusion: Both males and females can transmit this sex limited trait, but it is expressed only in males.”

CONCEPTS

Sex-influenced characteristics are encoded by autosomal genes that are more readily expressed in one sex. Sex-limited characteristics are encoded by autosomal genes whose expression is limited to one sex.

✔ CONCEPT CHECK 9

How do sex-influenced and sex-limited characteristics differ from sex-linked characteristics?

Cytoplasmic Inheritance

Mendel's principles of segregation and independent assortment are based on the assumption that genes are located on chromosomes in the nucleus of the cell. For most genetic characteristics, this assumption is valid, and Mendel's principles allow us to predict the types of offspring that will be produced in a genetic cross. Not all the genetic material of a cell is found in the nucleus, however. Some characteristics are encoded by genes located in the cytoplasm, and these characteristics exhibit **cytoplasmic inheritance**.

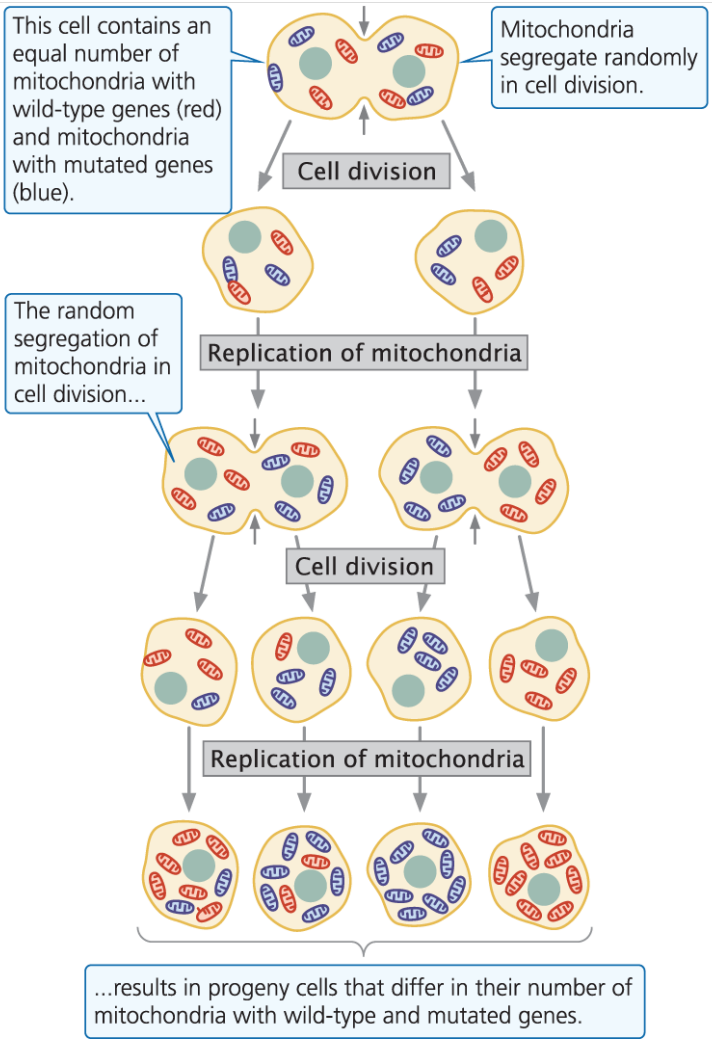
A few organelles, notably chloroplasts and mitochondria, contain DNA. The human mitochondrial genome contains about 16,569 nucleotides of DNA, encoding 37 genes. Compared with the nuclear genome, which contains some 3 billion nucleotides encoding some 20,000 genes, the mitochondrial genome is very small; nevertheless, mitochondrial and chloroplast genes encode some important characteristics. The molecular characteristics of this extranuclear DNA are discussed in Chapter 11; here, we focus on *patterns* of cytoplasmic inheritance.

Cytoplasmic inheritance differs from the inheritance of characteristics encoded by nuclear genes in several important respects. A zygote inherits nuclear genes from both parents, but typically all its cytoplasmic organelles, and thus all its cytoplasmic genes, come from only one of the gametes, usually the egg. A sperm from the male parent generally contributes only a set of nuclear

genes. Thus, most cytoplasmically inherited traits are present in both males and females and are passed from mother to offspring, never from father to offspring. Reciprocal crosses, therefore, give different results when cytoplasmic genes encode a trait. In a few organisms, however, cytoplasmic genes are inherited from the male parent only or from both parents.

Cytoplasmically inherited characteristics frequently exhibit extensive phenotypic variation because no mechanism analogous to mitosis or meiosis ensures that cytoplasmic genes are evenly distributed during cell division. Thus, different cells and different individual offspring will contain various proportions of cytoplasmic genes.

Consider mitochondrial genes. Most cells contain thousands of mitochondria, and each mitochondrion contains from 2 to 10 copies of the mitochondrial DNA (mtDNA). Suppose that half of the mitochondria in a cell contain a normal wild-type copy of mtDNA and the other half contain a mutated copy (**Figure 5.15**). During cell division, the mitochondria segregate into the progeny cells at random. Just by chance, one cell may receive mostly mutated mtDNA and another cell may receive mostly wild-type mtDNA. Therefore, different progeny from the same mother, and even different cells within an individual offspring, may vary in their phenotypes. Traits encoded by chloroplast DNA (cpDNA) are similarly variable. The characteristics exhibited by cytoplasmically inherited traits are summarized in **Table 5.4**.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

5.15 Cytoplasmically inherited characteristics frequently exhibit extensive phenotypic variation because different cells and different individual offspring may contain different proportions of cytoplasmic genes.

Description

The flowchart starts with a dividing parent cell with a constriction with one nucleus and four mitochondria (two blue and two red) on each side of the constriction. The first caption reads, “This cell contains an equal number of mitochondria with wild-type genes (in red) and mitochondria with mutated genes (in blue).” The second caption reads, “Mitochondria segregate randomly in cell division". First cell division takes place and daughter cells with equal number of red and blue mitochondria are produced below. Replication of

mitochondria occurs and two dividing cells similar to the initial parent cell are present. In the first cell, 3 red and 1 blue mitochondria are present on one side of constriction and 3 red and 1 blue are present on the other. In the second cell, 4 blue mitochondria are present on one side of the constriction and 4 red are present on the other. A caption reads, "The random segregation of

mitochondria in cell division ellipsis". Second cell division takes place and 4 daughter cells are produced below with different number of mitochondria. Cell 1 has 3 red and 1 blue, cell 2 has 1 red and 3 blue, cell 3 has 4 blue, and cell 4 has 4 red mitochondria. Replication of mitochondria takes place again and the 4 cells have doubled their number of mitochondria in the same color. A caption below reads, "ellipsis results in progeny cells that differ in their number of mitochondria with wild-type and mutated genes."

TABLE 5.4 Characteristics of cytoplasmically inherited traits

1. Present in males and females.
2. Usually inherited from one parent, typically the maternal parent.
3. Reciprocal crosses give different results.
4. Exhibit extensive phenotypic variation, even within a single family.

VARIEGATION IN FOUR-O'CLOCKS

In 1909, cytoplasmic inheritance was recognized by Carl Correns as an exception to Mendel's principles. Correns, one of the biologists

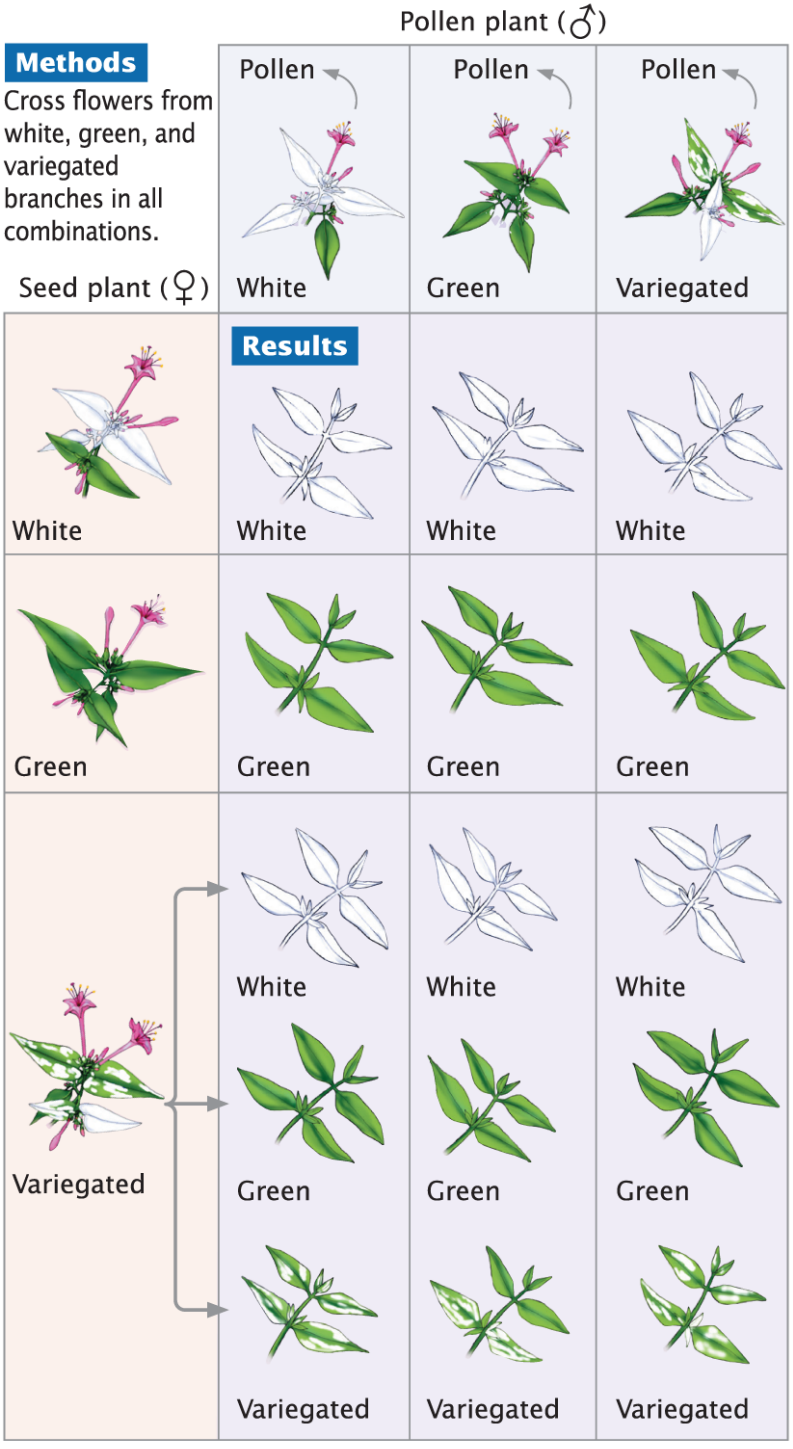
who rediscovered Mendel's work, studied the inheritance of leaf variegation in the four-o'clock plant, *Mirabilis jalapa*. Correns found that some of the leaves and stems of one variety of four-o'clock were variegated, displaying a mixture of green and white splotches. He also noted that some branches of the variegated strain had all-green leaves; other branches had all-white leaves. Each branch produced flowers, so Correns was able to cross flowers from variegated, green, and white branches in all combinations (**Figure 5.16**). The seeds from flowers on green branches always gave rise to green progeny, no matter whether the pollen was from a green, white, or variegated branch. Similarly, flowers on white branches always produced white progeny. Flowers on the variegated branches gave rise to green, white, and variegated progeny in no particular ratio.

Experiment

Question: How is stem and leaf color inherited in the four-o'clock plant?

Methods

Cross flowers from white, green, and variegated branches in all combinations.



Conclusion: The phenotype of the progeny is determined by the phenotype of the branch from which the seed originated, not from the branch on which the pollen originated. Stem

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

5.16 Crosses for stem and leaf color in four-o'clocks illustrate cytoplasmic inheritance.

Description

The illustration begins with a question that reads, How is stem and leaf color inherited in the

four-o'clock plant? The methods show a text that reads, Cross fowers from white, green, and variegated branches in all

combinations. The table consists of 4 columns and 4 rows. In each cell of the table, is a picture of the plant and a word describing the phenotype. The first row and the first column include row and column headers respectively. The inner columns and rows (3 multiplied by 3) show the results of the crosses between the entries of each row header and column header. A text in the first column of the first row reads: Cross ¬flowers from white, green, and variegated branches in all combinations (methods). The column headers show leaf and stem colors of male pollen plant as follows: white, green, and variegated. The row headers show leaf and stem colors of female seed plant as follows: white, green, and variegated. The row entries of results for each column are as follows:

Row 1: White, white, white

Row 2: Green, green, green

For variegated, the result is branched into three parts for each column as follows:

Row 3: White, green, variegated; white, green, variegated; and white, green, variegated;

A caption at the bottom reads, "Conclusion: The phenotype of the progeny is determined by the phenotype of the branch from which the seed originated, not from the branch on which the pollen originated. Stem and leaf color exhibit cytoplasmic inheritance."

Correns's crosses demonstrated the cytoplasmic inheritance of variegation in four-o'clocks. The phenotypes of the offspring were determined entirely by the maternal parent, never by the paternal parent (the source of the pollen). Furthermore, the production of all three phenotypes by flowers on variegated branches is consistent with cytoplasmic inheritance. The white color in these plants is caused by a defective gene in cpDNA, which results in a failure to produce the green pigment chlorophyll. Cells from green branches contain normal chloroplasts only, cells from white branches contain abnormal chloroplasts only, and cells from variegated branches contain a mixture of normal and abnormal chloroplasts. In the flowers from variegated branches, the random segregation of chloroplasts in the course of oogenesis produces some egg cells with only normal cpDNA, which develop into green progeny; other egg cells with only abnormal cpDNA, which develop into white progeny; and still other egg cells with a mixture of normal and abnormal cpDNA, which develop into variegated progeny.

MITOCHONDRIAL DISEASES

A number of human diseases (mostly rare ones) that exhibit cytoplasmic inheritance have been identified. These disorders arise from mutations in mtDNA, most of which occur in genes encoding components of the electron-transport chain, which generates most of the ATP (adenosine triphosphate) in aerobic cellular respiration. One such disease is Leber hereditary optic neuropathy (LHON). People who have this disorder experience rapid loss of vision in both

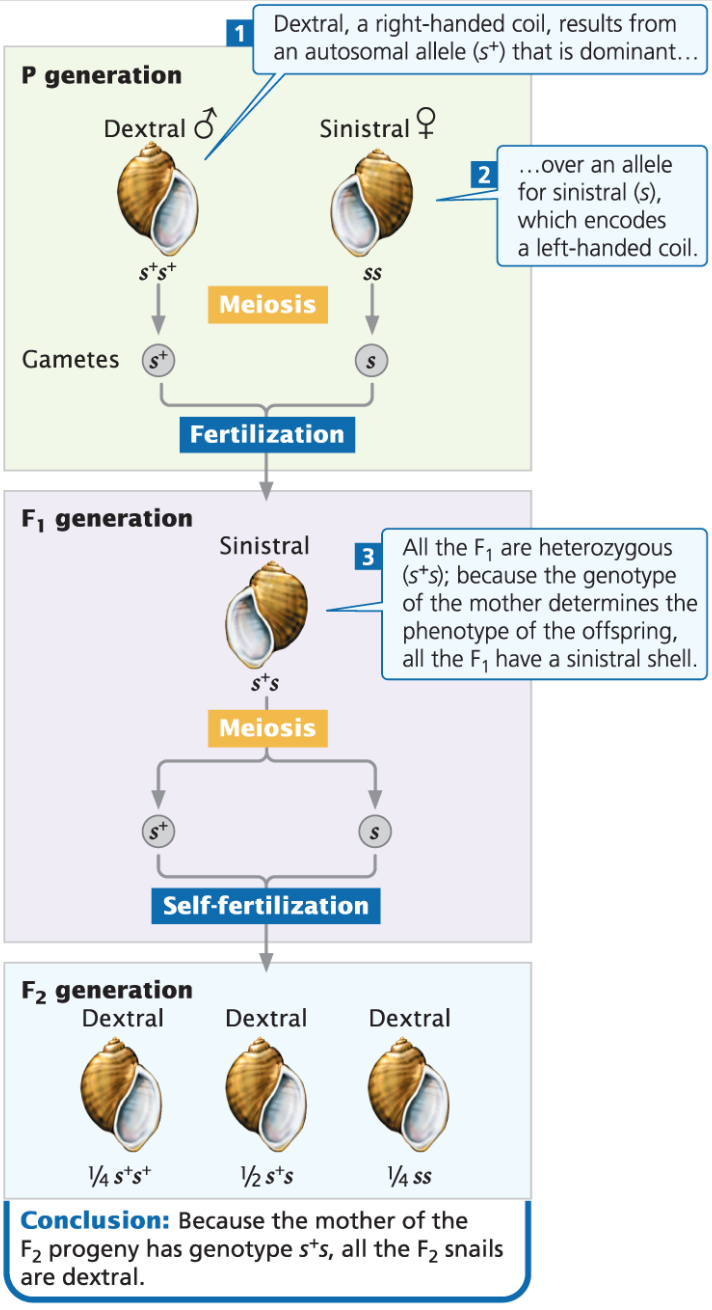
eyes, which results from the death of cells in the optic nerve. This loss of vision typically occurs in early adulthood (usually between the ages of 20 and 24), but it can occur any time after adolescence. There is much clinical variation in the severity of the disease, even within the same family. Leber hereditary optic neuropathy exhibits cytoplasmic inheritance: the trait is passed from a mother to all her children, sons and daughters alike.

Genetic Maternal Effect

A genetic phenomenon that is sometimes confused with cytoplasmic inheritance is **genetic maternal effect**, in which the phenotype of the offspring is determined by the genotype of the mother. In cytoplasmic inheritance, the genes for a characteristic are inherited from only one parent, usually the mother. In genetic maternal effect, the genes are inherited from both parents, but the offspring's phenotype is determined not by its own genotype but by the genotype of its mother.

Genetic maternal effect frequently arises when substances present in the cytoplasm of an egg (encoded by the mother's nuclear genes) are pivotal in early development. An excellent example is the direction of shell coiling in the snail *Lymnaea peregra* (**Figure 5.17**), described in the introduction to this chapter. The direction of coiling is determined by a pair of alleles; the allele for dextral (right-handed) coiling (s^+) is dominant to the allele for sinistral (left-handed) coiling

(*s*). However, the direction of coiling is determined not by a snail's own genotype but by the genotype of its mother. The direction of coiling is affected by the way in which the egg cytoplasm divides soon after fertilization, which in turn is determined by a substance produced by the mother and passed to the offspring in the cytoplasm of the egg.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

5.17 In genetic maternal effect, the genotype of the maternal parent determines the phenotype of the offspring. Chirality (the direction of shell coiling) in the snail *Lymnaea peregra* is a characteristic that exhibits genetic maternal effect.

Description
In generation P on the top, a dextral male snail with genotype small S superscript positive small S superscript positive is crossed with a sinistral female with genotype small S small S. A caption reads, “Dextral, a right-handed coil, results from an autosomal allele (small S superscript positive) that is dominant over an allele for sinistral (small S), which encodes a left-handed coil.” Meiosis results in the formation of gametes as follows: small S superscript positive from the male and small S from the female. Fertilization occurs and leads to the big F subscript 1 generation below which has sinistral offspring with genotype small S superscript positive small S. A caption referring to the progeny reads, “All the big F subscript 1 are heterozygous (small S superscript positive small S); because the genotype of the mother determines the phenotype of the offspring, all the big F subscript 1 have a sinistral shell.” This progeny produced in F subscript 1 generation undergoes meiosis and forms two gametes with genotype small S superscript positive and small S respectively which are self-fertilized. This self-fertilization results in the production of progeny subscript 2 generation below. The progeny are as follows: one-fourth dextral with genotype small S superscript positive small S superscript positive; one-half dextral with genotype S superscript positive small S; and one-fourth dextral with genotype small S small S. A caption reads, Conclusion: Because the mother of the big F subscript 2 progeny has genotype small s superscript positive small s, all the F subscript 2 snails are dextral.

If a male homozygous for dextral alleles ($s^+ s^+$) is crossed with a female homozygous for sinistral alleles (ss), all the F_1 are heterozygous ($s^+ s$), but they all have sinistral shells because the genotype of the mother (ss) encodes sinistral coiling (see Figure 5.17). If these F_1 snails self-fertilize, the genotypic ratio of the F_2 is 1 $s^+ s^+$: 2 $s^+ s$: 1 ss. Notice, however, that the phenotype of all the F_2 snails is dextral, regardless of their genotypes. The F_2 offspring are dextral because the genotype of their mother ($s^+ s$), which encodes a dextral shell, determines their phenotype. With genetic maternal effect, the phenotype of the progeny is not necessarily the same as

the phenotype of the mother because the progeny's phenotype is determined by the mother's *genotype*, not her phenotype. Neither the male parent's nor the offspring's own genotype has any role in the offspring's phenotype. However, a male does influence the phenotype of the F_2 generation: by contributing to the genotypes of his daughters, he affects the phenotypes of their offspring. Genes that exhibit genetic maternal effect are therefore transmitted through males to future generations. In contrast, genes that exhibit cytoplasmic inheritance are transmitted through only one of the sexes (usually the female). › **TRY** PROBLEM 39

CONCEPTS

Characteristics exhibiting cytoplasmic inheritance are encoded by genes in the cytoplasm and are usually inherited from one parent, most commonly the mother. In genetic maternal effect, the genotype of the mother determines the phenotype of the offspring.

✔ CONCEPT CHECK 10

How might you determine whether a particular trait is due to cytoplasmic inheritance or to genetic maternal effect?

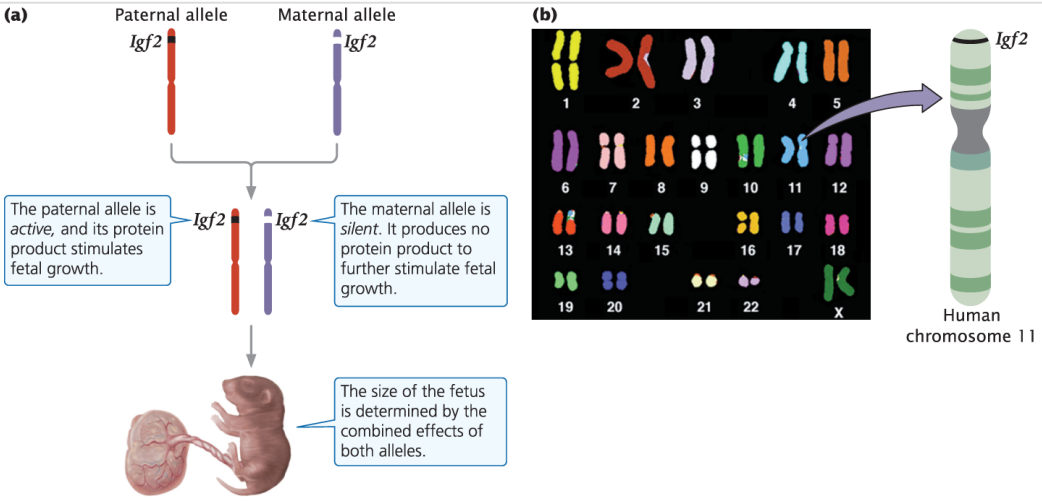
Genomic Imprinting

A basic tenet of Mendelian genetics is that the parental origin of a gene does not affect its expression and, therefore, reciprocal crosses

give identical results. We have seen, however, that there are some genetic characteristics—those encoded by X-linked genes and cytoplasmic genes—for which reciprocal crosses do not give the same results. In these cases, males and females do not contribute the same genetic material to the offspring. Males and females do contribute the same number of autosomal genes to their offspring, and paternal and maternal autosomal genes have long been assumed to have equal effects. However, the expression of some autosomal genes is significantly affected by their parental origin. This differential expression of genetic material depending on whether it is inherited from the male or the female parent is called **genomic imprinting**. Although the number of imprinted genes is unknown, recent research suggests that more genes may be imprinted than previously suspected (see Chapter 21).

A gene that exhibits genomic imprinting in both mice and humans is *Igf2*, which encodes a protein called insulin-like growth factor 2 (Igf2). Offspring inherit one *Igf2* allele from their mother and one from their father. The paternal copy of *Igf2* is actively expressed in the fetus and placenta, but the maternal copy is completely silent (**Figure 5.18**). Both male and female offspring possess *Igf2* genes; the key to whether the gene is expressed is the sex of the parent transmitting the gene. In the present example, the gene is expressed only when it is transmitted by a male parent. In some way that is not completely understood, the paternal *Igf2* allele (but not the maternal allele) promotes placental and fetal growth; when the paternal copy

of *Igf2* is deleted in mice, a small placenta and low-birth-weight offspring result. In other genomically imprinted traits, only the copy of the gene transmitted by the female parent is expressed.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company
Courtesy of Dr. Thomas Ried and Dr. Evelin Schrock.

5.18 Genomic imprinting of the *Igf2* gene in mice and humans affects fetal growth. (a) The paternal *Igf2* allele is active in the fetus and placenta, whereas the maternal allele is silent. (b) The human *Igf2* locus is on the short arm of chromosome 11; the locus in mice is on chromosome 7.

Description

Part “a” on the left shows the paternal allele with big I small G small F 2 locus on a red chromosome with a black bar, indicating it is active. The maternal chromosome is blue and the big I small G small F 2 locus is colored white. A caption referring to the paternal allele reads, “The paternal allele is active and its protein product stimulates fetal growth.” Another caption referring to the maternal allele reads, “The maternal allele is silent. It produces no protein product to further stimulate fetal growth.” At the bottom of the figure is a picture of a mouse fetus along with a caption that reads, “The size of the fetus is determined by the combined effects of both alleles.”

Part “b” shows a picture of the human genome hybridized with fluorescent probes and an arrow from chromosome 11 to a drawing of chromosome 11 with the I small G small F 2 gene labeled. This gene is represented as a black band near the tip of its short arm.

Genomic imprinting has been implicated in several human disorders, including Prader–Willi and Angelman syndromes. Children with Prader–Willi syndrome have small hands and feet, short stature, poor sexual development, and intellectual disability. These children are small at birth and nurse poorly, but as toddlers they develop voracious appetites and frequently become obese. Many people with Prader–Willi syndrome are missing a small region on the long arm of chromosome 15. The deletion of this region is always inherited from the *father*. Thus, children with Prader–Willi syndrome lack a paternal copy of genes on the long arm of chromosome 15.

The deletion of this same region of chromosome 15 can also be inherited from the *mother*, but this inheritance results in a completely different set of symptoms, producing Angelman syndrome. Children with Angelman syndrome exhibit frequent laughter, uncontrolled muscle movement, a large mouth, and unusual seizures. They are missing a maternal copy of genes on the long arm of chromosome 15. For normal development to take place, copies of this region of chromosome 15 from both male and female parents are apparently required.

Many imprinted genes in mammals are associated with fetal growth. Imprinting has also been reported in plants, with differential expression of paternal and maternal genes in the endosperm, which, like the placenta in mammals, provides nutrients for the growth of

the embryo. The mechanism of imprinting is still under investigation, but the methylation of DNA—the addition of methyl (CH_2) groups to DNA nucleotides (see Chapters 10 and 17)—is essential to the process. In mammals, methylation is erased in the germ cells each generation and then reestablished in the course of gamete formation, with sperm and eggs undergoing different levels of methylation, which then cause the differential expression of male and female alleles in the offspring. Some of the different ways in which sex interacts with heredity are summarized in **Table 5.5**.

TABLE 5.5 Influences of sex on heredity

Genetic Phenomenon	Phenotype Determined by
Sex-linked characteristic	Genes located on the sex chromosomes
Sex-influenced characteristic	Autosomal genes that are more readily expressed in one sex
Sex-limited characteristic	Autosomal genes whose expression is limited to one sex
Genetic maternal effect	Nuclear genotype of the maternal parent
Cytoplasmic inheritance	Cytoplasmic genes, which are usually inherited from only one parent

Genomic imprinting	Genes whose expression is affected by the sex of the transmitting parent

EPIGENETICS

Genomic imprinting is just one form of a phenomenon known as **epigenetics**. Most traits are encoded by genetic information that resides in the sequence of the nucleotide bases of DNA—the genetic code, which will be discussed in Chapter 15. However, some traits are determined by modifications to DNA or chromatin—such as DNA methylation—that affect the way in which DNA sequences are expressed. These changes are often stable and heritable in the sense that they are passed from one cell to another. For example, in genomic imprinting, whether a gene passes through the egg or the sperm determines how much methylation of the DNA takes place. The pattern of methylation on a gene is copied when the DNA is replicated and therefore remains on the gene as it is passed from cell to cell through mitosis. However, the methylation may be modified or removed when the DNA passes through a gamete, so a gene that is methylated in sperm may be unmethylated when it is eventually passed down to a daughter's egg. Ultimately, the amount of methylation determines whether the gene is expressed in the offspring.

These types of reversible changes to DNA that influence the expression of traits are termed epigenetic marks. The inactivation of

one of the X chromosomes in female mammals (discussed in Chapter 4) is another type of epigenetic change. We will consider epigenetic changes in more detail in Chapter 21.

CONCEPTS

In genomic imprinting, the expression of a gene is influenced by the sex of the parent transmitting the gene to the offspring. Epigenetic marks are reversible changes in DNA that do not alter the base sequence but may affect how a gene is expressed.

✔ CONCEPT CHECK 11

What type of epigenetic mark is responsible for genomic imprinting?

5.4 Anticipation Is the Stronger or Earlier Expression of Traits in Succeeding Generations

Another genetic phenomenon that is not explained by Mendel's principles is **anticipation**, in which a genetic trait becomes more strongly expressed, or is expressed at an earlier age, as it is passed from generation to generation. In the early 1900s, several physicians observed that many patients with moderate to severe myotonic dystrophy—an autosomal dominant muscle disorder—had ancestors who were only mildly affected by the disease. These observations led to the concept of anticipation. The concept quickly fell out of favor with geneticists, however, because there was no obvious mechanism to explain it; traditional genetics held that genes are passed unaltered from parents to offspring. Geneticists tended to attribute anticipation to observational bias.

Research has now reestablished anticipation as a legitimate genetic phenomenon. The mutation that causes myotonic dystrophy consists of an unstable region of DNA that can increase in size as the gene is passed from generation to generation. The age of onset and the severity of the disease are correlated with the size of the unstable region; an increase in the size of the region over generations produces anticipation. The phenomenon has now been

implicated in a number of genetic diseases. We will examine these interesting types of mutations in more detail in Chapter 18.

CONCEPTS

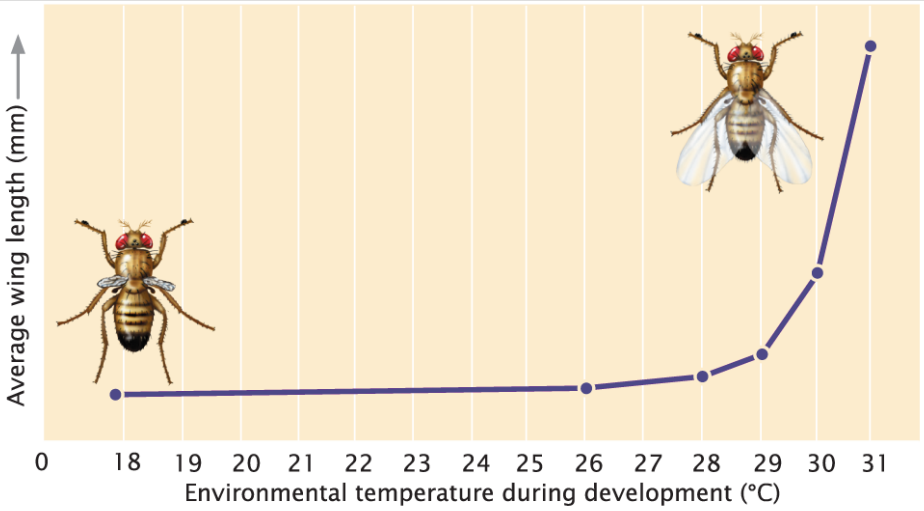
Anticipation is the stronger or earlier expression of a genetic trait in succeeding generations. It is caused by an unstable region of DNA that increases in size from generation to generation.

5.5 Phenotypes May Be Influenced by Environmental Factors and Multiple Genes

Often, phenotypes are not the result of a variation at a single gene but instead are influenced by environmental factors and multiple loci.

Environmental Effects on the Phenotype

In Chapter 3, we learned that each phenotype is the result of a genotype that develops within a particular environment; each genotype may produce several different phenotypes, depending on the environmental conditions in which development takes place. For example, a fruit fly that is homozygous for the *vestigial* mutation (*vg vg*) develops reduced wings when raised at a temperature below 29°C, but the same genotype develops much longer wings when raised at 31°C (**Figure 5.19**).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

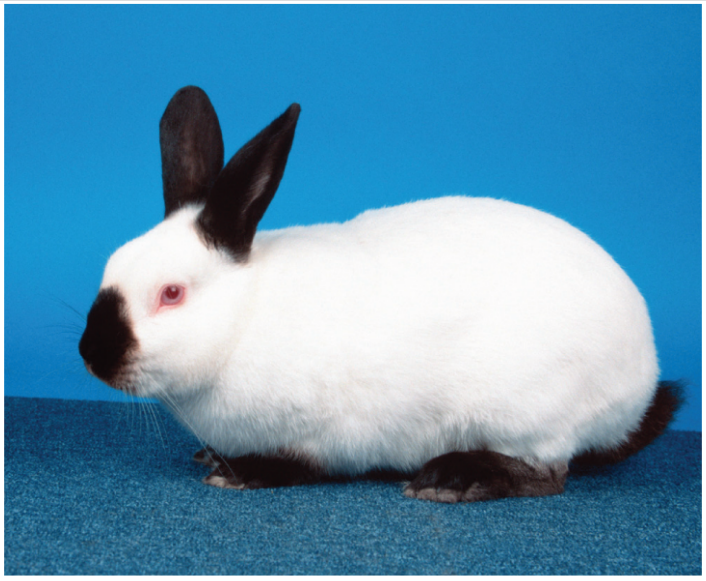
5.19 The expression of the *vestigial* mutation in *Drosophila* is temperature dependent. When reared at temperatures below 29°C, flies homozygous for *vestigial* have greatly reduced wings; at temperatures above 31°C, the flies develop normal wings. [Data from M. H. Harnly, *Journal of Experimental Zoology* 56:363–379, 1936.]

Description

The horizontal axis represents environmental temperature during development in degree Celsius ranging from 18 to 31 with an interval of 1. The vertical axis represents average wing length in m m and begins from 0. The curve starts above 18 degree Celsius, remains constant till it approaches 26 degree Celsius, rises gradually as it reaches 29 degree Celsius, and eventually rises exponentially as it approaches 31 degree Celsius. The fly has no wings when the curve begins and has wings as the curve rises towards the end of the graph. All values are approximate.

For most of the characteristics we have discussed so far, the effect of the environment on the phenotype has been slight. Mendel's peas with genotype *yy*, for example, developed green seeds regardless of the environment in which they were raised. Similarly, people with genotype $I^A I^A$ have the A antigen on their red blood cells regardless

of their diet, socioeconomic status, or family environment. For other phenotypes, however, environmental effects play a more important role. The phenotypic expression of some genotypes depends critically on the presence of a specific environment. For example, the *himalayan* allele in rabbits produces dark fur at the extremities of the body—on the nose, ears, and feet (**Figure 5.20**). The dark pigment develops, however, only when a rabbit is reared at a temperature of 25°C or lower; if a Himalayan rabbit is reared at 30°C, no dark patches develop. The expression of the *himalayan* allele is thus temperature dependent; an enzyme necessary for the production of dark pigment is inactivated at higher temperatures. The pigment is restricted to the nose, ears, and feet of a Himalayan rabbit because the animal's core body temperature is normally above 25°C and the enzyme is functional only in the cells of the relatively cool extremities. The *himalayan* allele is an example of a **temperature-sensitive allele**, an allele whose product is functional only at certain temperatures. Similarly, vestigial wings in *Drosophila melanogaster* are caused by a temperature-dependent mutation (see Figure 5.19).



Petra Wegner/Alamy.

5.20 The expression of the *himalayan* allele is temperature dependent. This rabbit was reared below 25°C. Its pigment is restricted to the extremities where the body temperature falls below 25°C and the enzyme that produces pigment is functional.

Environmental factors also play an important role in the expression of a number of human genetic diseases. Phenylketonuria (PKU) is due to an autosomal recessive allele that causes intellectual disability. The disorder arises from a defect in an enzyme that normally metabolizes the amino acid phenylalanine. When this enzyme is defective, phenylalanine is not metabolized, and its buildup causes neurological damage in children. A simple environmental change, putting an affected child on a low-phenylalanine diet, prevents the development of intellectual disability.

THINK-PAIR-SHARE Question 6

These examples illustrate the point that genes and their products do not act in isolation; rather, they frequently interact with environmental factors. Occasionally, environmental factors alone can produce a phenotype that is the same as the phenotype produced by a genotype; such a phenotype is called a **phenocopy**. In fruit flies, for example, the autosomal recessive mutation *eyeless* produces greatly reduced eyes. The eyeless phenotype can also be produced by exposing the larvae of normal flies to sodium metaborate.

CONCEPTS

The expression of many genes is modified by the environment. A phenocopy is a phenotype produced by environmental effects that mimics the phenotype produced by a genotype.

✔ CONCEPT CHECK 12

How can you determine whether a phenotype such as reduced eyes in fruit flies is due to a recessive mutation or is a phenocopy?

The Inheritance of Continuous Characteristics

So far, we've dealt primarily with characteristics that have only a few distinct phenotypes. In Mendel's peas, for example, the seeds were either smooth or wrinkled, yellow or green; the coats of dogs were

black, brown, or yellow; blood types were A, B, AB, or O. Such characteristics, which have a few easily distinguished phenotypes, are called **discontinuous characteristics**.

Not all characteristics exhibit discontinuous phenotypes, however. Human height is an example; people do not come in just a few distinct heights but rather display a wide range of heights. Indeed, there are so many possible phenotypes of human height that we must use a measurement to describe a person's height. Such characteristics are said to exhibit a continuous distribution of phenotypes, and they are termed **continuous characteristics**. Because they have many possible phenotypes and must be described in quantitative terms, continuous characteristics are also called **quantitative characteristics**.

Continuous characteristics frequently arise because genes at many loci interact to produce the phenotypes. When a single locus with two alleles encodes a characteristic, there are three genotypes possible: *AA*, *Aa*, and *aa.* With two loci, each with two alleles, there are $3^2 = 9$ genotypes possible. The number of genotypes encoding a characteristic is 3^n, where n equals the number of loci, each with two alleles, that influence the characteristic. For example, when a characteristic is determined by eight loci, each with two alleles, there are $3^8 = 6561$ different genotypes possible for this characteristic. If each genotype produces a different phenotype, many phenotypes will be possible. The slight differences between the phenotypes will be indistinguishable, and the characteristic will

appear to be continuous. Characteristics encoded by genes at many loci are called **polygenic characteristics**.

The converse of polygeny is **pleiotropy**, in which one gene affects multiple characteristics. Many genes exhibit pleiotropy. Phenylketonuria, mentioned earlier, results from a recessive allele; people homozygous for this allele, if untreated, exhibit intellectual disability, blue eyes, and light skin color. The lethal allele that causes yellow coat color in mice is also pleiotropic. In addition to its lethality and its effect on coat color, the gene causes a diabetes-like condition, obesity, and an increased propensity to develop tumors.

The phenotypes of many continuous characteristics are also influenced by environmental factors. In these cases, each genotype is capable of producing a range of phenotypes, and the particular phenotype that results depends on both the genotype and the environmental conditions in which the genotype develops. For example, there may be only three genotypes at a single locus, but because each genotype produces a range of phenotypes associated with different environments, the phenotype of the characteristic will exhibit a continuous distribution. Many continuous characteristics are both polygenic and influenced by environmental factors; such characteristics are called **multifactorial characteristics** because many factors help determine the phenotype. Human height is an example of a multifactorial characteristic; variation in height is determined by a number of genes as well as environmental factors such as nutrition.

The inheritance of continuous characteristics may appear to be complex, but the alleles at each locus follow Mendel's principles and are inherited in the same way as alleles encoding simple, discontinuous characteristics. However, because many genes are involved, because environmental factors influence the phenotype, and because the phenotypes do not sort out into a few distinct types, we cannot observe the distinct ratios that have allowed us to interpret the genetic basis of discontinuous characteristics. To analyze continuous characteristics, we must employ special statistical tools, which will be discussed in Chapter 24. › **TRY PROBLEM 45**

CONCEPTS

Discontinuous characteristics exhibit a few distinct phenotypes; continuous characteristics exhibit a range of phenotypes. A continuous characteristic is frequently produced when genes at many loci and environmental factors combine to determine a phenotype.

✔ CONCEPT CHECK 13

What is the difference between polygeny and pleiotropy?

Chapter 5 Review

CHAPTER SUMMARY

Section 5.1 Learning Objective: Be able to work and interpret genetic crosses involving factors that affect inheritance at a single locus, including different types of dominance, incomplete penetrance, lethal alleles, and multiple alleles.

- Dominance is an interaction between genes at the same locus (allelic genes) and can be understood in regard to how the phenotype of the heterozygote relates to the phenotypes of the homozygotes.
- Dominance is complete when a heterozygote has the same phenotype as one homozygote. It is incomplete when the heterozygote has a phenotype intermediate between those of two parental homozygotes. In codominance, the heterozygote exhibits traits of both parental homozygotes.
- The type of dominance does not affect the inheritance of an allele; it does affect the phenotypic expression of the allele. The classification of dominance depends on the level at which the phenotype is examined.
- Penetrance is the percentage of individuals having a particular genotype that exhibit the expected phenotype. Expressivity is the degree to which a character is expressed.
- Lethal alleles cause the death of an individual possessing them at an early stage of development and may alter the phenotypic

ratios resulting from a cross.
- The existence of multiple alleles refers to the presence of more than two alleles at a locus within a group of individuals. The presence of multiple alleles increases the number of genotypes and phenotypes that are possible.

Section 5.2 Learning Objective: Be able to work and interpret genetic crosses involving gene interaction.

- Gene interaction refers to interaction between genes at different loci to produce a single phenotype. An epistatic gene at one locus suppresses, or masks, the expression of hypostatic genes at other loci. Gene interaction frequently produces phenotypic ratios that are modifications of dihybrid ratios.

Section 5.3 Learning Objective: Be able to work and interpret genetic crosses in which sex influences the inheritance and expression of genes.

- Sex-influenced characteristics are encoded by autosomal genes that are expressed more readily in one sex. Sex-limited characteristics are encoded by autosomal genes that are expressed in only one sex.
- In cytoplasmic inheritance, the genes that encode a characteristic are found in the organelles and are usually inherited from a single (typically maternal) parent. In genetic maternal effect, an offspring inherits genes from both parents, but the nuclear genes of the mother determine the offspring's phenotype.

- Genomic imprinting refers to differential expression of autosomal genes depending on the sex of the parent transmitting the genes. Epigenetic effects such as genomic imprinting are caused by alterations to DNA—such as DNA methylation—that do not affect the DNA base sequence.

Section 5.4 Learning Objective: Be able to explain anticipation.

- Anticipation refers to the stronger expression of a genetic trait, or its expression at an earlier age, in succeeding generations.

Section 5.5 Learning Objective: Be able to describe how environmental effects and multiple genes influence the expression of some traits.

- Phenotypes are often modified by environmental effects. A phenocopy is a phenotype produced by an environmental effect that mimics a phenotype produced by a genotype.
- Continuous characteristics are those that exhibit a wide range of phenotypes; they are frequently produced by the combined effects of many genes and environmental effects.

WORKED PROBLEMS

Problem 1

A geneticist crosses two yellow mice with straight hair and obtains the following progeny:

$^1/_2$	yellow, straight
$^1/_6$	yellow, fuzzy
$^1/_4$	gray, straight
$^1/_{12}$	gray, fuzzy

a. Provide a genetic explanation for the results, and assign genotypes to the parents and progeny of this cross.
b. What additional crosses might be carried out to determine if your explanation is correct?

» Solution Strategy

What information is required in your answer to the problem?

a. A genetic explanation for the inheritance of color and hair type in the mice. Genotypes of the parents.
b. Examples of other crosses that might be carried out to determine if the explanation given in your answer to part *a* is correct.

What information is provided to solve the problem?

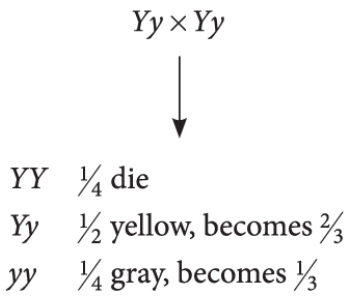
- Phenotypes of the parents.
- Phenotypes and proportions of different types of progeny.

For help with this problem, review:

Lethal Alleles in Section 5.1 and ratios for simple genetic crosses (Table 3.5).

» Solution Steps

a. This cross concerns two separate characteristics—color and hair type. First, let's look at the inheritance of color. Two yellow mice are crossed, producing $^1/_2 + {}^1/_6 = {}^3/_6 + {}^1/_6 = {}^4/_6 = {}^2/_3$ yellow mice and $^1/_4 + {}^1/_{12} = {}^3/_{12} + {}^1/_{12} = {}^4/_{12} = {}^1/_3$ gray mice. We learned in this chapter that a 2:1 ratio is often produced when a recessive lethal allele is present:

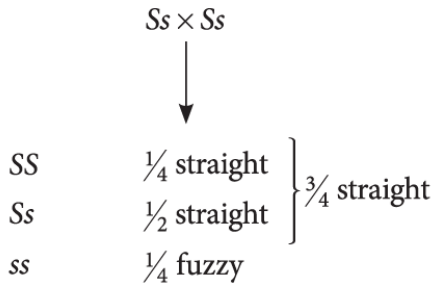


Description
The illustration shows a mice with genotype big Y small Y is intercrossed with another mice of same genotype. A downward arrow points to the progenies produced as follows: big Y big Y, one-fourth die; big Y small Y: one-half yellow, becomes two-third; small Y small Y: one-fourth gray, becomes one-third.

Hint: Examine the progeny ratios for each trait separately.

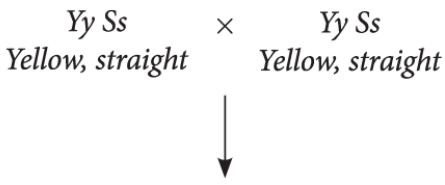
Recall: A 2 : 1 ratio is usually produced by a lethal allele.

Now, let's examine the inheritance of the hair type. Two mice with straight hair are crossed, producing $^1/_2 + {}^1/_4 = {}^2/_4 + {}^1/_4 = {}^3/_4$ mice with straight hair and $^1/_6 + {}^1/_{12} = {}^2/_{12} + {}^1/_{12} = {}^3/_{12} = {}^1/_4$ mice with fuzzy hair. We learned in Chapter 3 that a 3:1 ratio is usually produced by a cross between two individuals heterozygous for a simple dominant allele:



Description
The illustration shows a parent with genotype big S small S is intercrossed with another parent of same genotype. A downward arrow points to the progenies produced: big S big S one-fourth straight; big S small S one-half straight; small S small S: one-fourth fuzzy. Three-fourth have straight hair.

We can now combine both loci and assign genotypes to all the individual mice in the cross:



Phenotype	Genotype	Probability at each locus	Combined probability
yellow, straight	*Yy S_*	$\frac{2}{3} \times \frac{3}{4}$	$= \frac{6}{12} = \frac{1}{2}$
yellow, fuzzy	*Yy ss*	$\frac{2}{3} \times \frac{1}{4}$	$= \frac{2}{12} = \frac{1}{6}$
gray, straight	*yy S_*	$\frac{1}{3} \times \frac{3}{4}$	$= \frac{3}{12} = \frac{1}{4}$
gray, fuzzy	*yy ss*	$\frac{1}{3} \times \frac{1}{4}$	$= \frac{1}{12}$

Description
The illustration shows two mice with yellow, straight hair crossing. The progenies produced are present below. The phenotype, genotype, probability at each locus, and combined probability. This data are written in a table format as follows:

Phenotype: yellow straight; genotype: big Y small Y big S underscore; probability at each locus: two-third multiplied by three-fourth; combined probability equals six over twelve equals one-half.

Phenotype: yellow fuzzy; genotype: big Y small Y small S small S; probability at each locus: two-third multiplied by one-fourth; combined probability equals two over twelve equals one-sixth.

Phenotype: gray straight; genotype: small Y small Y big S underscore; probability at each locus: one-third multiplied by three-fourth; combined probability equals three over twelve equals one-fourth.

Phenotype: gray fuzzy; genotype: small Y small Y small S small S; probability at each locus: one-third multiplied by one-fourth; combined probability equals one over twelve.

b. We could carry out a number of different crosses to test our hypothesis that yellow is a recessive lethal and straight is dominant to fuzzy. For example, a cross between any two yellow mice should always produce $^2/_3$ yellow and $^1/_3$ gray offspring,

and a cross between two gray mice should produce only gray offspring. A cross between two fuzzy mice should produce only fuzzy offspring.

Problem 2

In some sheep, horns are produced by an autosomal allele that is dominant in males and recessive in females. A horned female is crossed with a hornless male. One of the resulting F_1 females is crossed with a hornless male. What proportion of the male and female progeny from this cross will have horns?

» Solution Strategy

What information is required in your answer to the problem?

Proportions of male and female progeny that have horns.

What information is provided to solve the problem?

- The presence of horns is due to an autosomal gene that is dominant in males and recessive in females.
- A horned female is crossed with a hornless male. A resulting F_1 female is crossed with a hornless male to produce progeny.

For help with this problem, review:

Sex-Influenced and Sex-Limited Characteristics in Section 5.3.

» Solution Steps

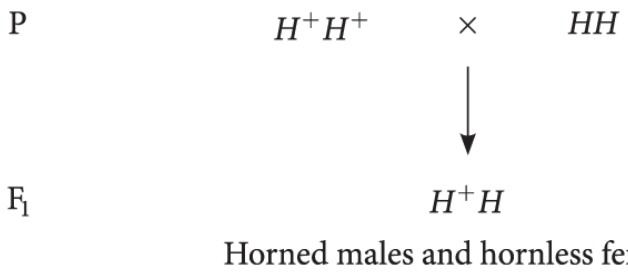
The presence of horns in these sheep is an example of a sex-influenced characteristic. Because the phenotypes associated with the genotypes differ between the two sexes, let's begin this problem by writing out the genotypes and phenotypes for each sex. We will let H represent the allele that encodes horns and H^+ represent the allele that encodes hornless. In males, the allele for horns is dominant to the hornless allele, which means that males homozygous (HH) and heterozygous ($H^+ H$) for this gene are horned. Only males homozygous for the recessive hornless allele ($H^+ H^+$) are hornless. In females, the allele for horns is recessive, which means that only females homozygous for this allele (HH) are horned; females heterozygous ($H^+ H$) and homozygous ($H^+ H^+$) for the hornless allele are hornless. The following table summarizes the genotypes and their associated phenotypes:

Genotype	Male phenotype	Female phenotype
HH	horned	horned
HH^+	horned	hornless
$H^+ H^+$	hornless	hornless

Hint: Write out the genotypes and the associated phenotype for each sex.

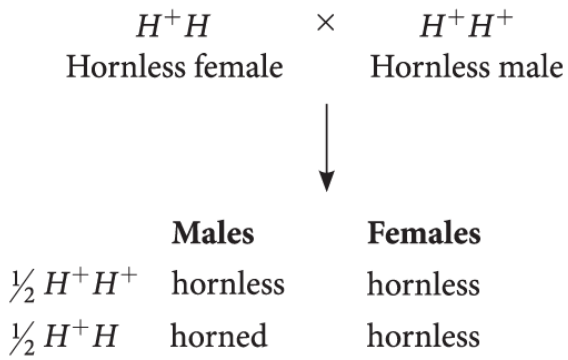
Recall: When a trait is dominant, both the homozygote and the heterozygote express the trait in their phenotypes.

In the problem, a horned female is crossed with a hornless male. From the preceding table, we see that a horned female must be homozygous for the allele for horns (*HH*), and that a hornless male must be homozygous for the hornless allele ($H^+ H^+$), so all the F_1 will be heterozygous; the F_1 males will be horned and the F_1 females will be hornless, as shown in the following diagram:



Description
The illustration shows cross between parents (P) with genotypes, big H superscript positive big H superscript positive and big H big H. The cross produces the following progeny in in F subscript 1 generation below: horned males and hornless females with genotype, big H superscript positive big H.

A heterozygous hornless F_1 female ($H^+ H$) is then crossed with a hornless male ($H^+ H^+$):



Description
The illustration shows a hornless female with genotype big H superscript positive big H is crossed with a hornless female with genotype big H superscript positive big H superscript positive. The cross produces the following progenies below: one-half hornless males with genotype big H superscript positive big H superscript positive; one-half hornless females with genotype big H superscript positive big H superscript positive; one-half hornless females with genotype big H superscript positive big H; and one-half horned males with genotype big H superscript positive big H.

Therefore, $^1/_2$ of the male progeny will be horned, but none of the female progeny will be horned.

IMPORTANT TERMS

complete dominance
incomplete dominance
codominance
incomplete penetrance
penetrance
expressivity
lethal allele

multiple alleles
compound heterozygote
gene interaction
epistasis
epistatic gene
hypostatic gene
complementation test
complementation
sex-influenced characteristic
sex-limited characteristic
cytoplasmic inheritance
genetic maternal effect
genomic imprinting
epigenetics
anticipation
temperature-sensitive allele
phenocopy
discontinuous characteristic
continuous characteristic
quantitative characteristic
polygenic characteristic
pleiotropy
multifactorial characteristic

ANSWERS TO CONCEPT CHECKS

1. b

2. With complete dominance, the heterozygote expresses the same phenotype as one of the homozygotes. With incomplete dominance, the heterozygote has a phenotype that is intermediate between those of the two homozygotes. With codominance, the heterozygote has a phenotype that simultaneously expresses the phenotypes of both homozygotes.
3. d
4. b
5. c
6. Gene interaction is interaction between genes at different loci. Dominance is interaction between alleles at a single locus.
7. d
8. Cross a bulldog homozygous for *brindle* with a Chihuahua homozygous for *brindle*. If the two *brindle* genes are allelic, all the offspring will be brindle: $bb \times bb \rightarrow$ all bb (brindle). If, on the other hand, brindle in the two breeds is due to recessive genes at different loci, then none of the offspring will be brindle: $a^+a^+ bb \times aa\ \mathrm{b}^+\mathrm{b}^+ \rightarrow a^+a\ b^+b$.
9. Both sex-influenced and sex-limited characteristics are encoded by autosomal genes whose expression is affected by the sex of the individual organism possessing the genes. Sex-linked characteristics are encoded by genes on the sex chromosomes.
10. Cytoplasmically inherited traits are encoded by genes in the cytoplasm, which is usually inherited only from the female parent. Therefore, a trait due to cytoplasmic inheritance will always be passed through females. Traits due to genetic maternal effect are encoded by autosomal genes and can therefore be passed through males, although any individual

organism's trait is determined by the genotype of the maternal parent.

11. Methylation of DNA.
12. Cross two eyeless flies and cross an eyeless fly with a wild-type fly. Raise the offspring of both crosses in the same environment. If the trait is due to a recessive mutation, all the offspring of the two eyeless flies should be eyeless, whereas at least some of the offspring of the eyeless and wild-type flies should be wild type. If the trait is a phenocopy, there should be no differences in the progeny of the two crosses.
13. Polygeny refers to the influence of multiple genes on the expression of a single characteristic. Pleiotropy refers to the effect of a single gene on the expression of multiple characteristics.

Chapter 5 Assessment

COMPREHENSION QUESTIONS

Section 5.1

1. What are some important characteristics of dominance?
2. What is incomplete penetrance, and what causes it?

Section 5.2

3. What is gene interaction? What is the difference between an epistatic gene and a hypostatic gene?
4. What is a recessive epistatic gene?
5. What is a complementation, test and what is it used for?

Section 5.3

6. What characteristics are exhibited by a cytoplasmically inherited trait?
7. What is genomic imprinting?
8. What is the difference between genetic maternal effect and genomic imprinting?

9. What is the difference between a sex-influenced gene and a gene that exhibits genomic imprinting?

Section 5.4

10. What characteristics do you expect to see in a trait that exhibits anticipation?

Section 5.5

11. What are continuous characteristics, and how do they arise?

APPLICATION QUESTIONS AND PROBLEMS

Sections 5.1 through 5.4

12. Match each of the following terms with its correct definition (parts *a* through *i*).

    _____ Phenocopy
    _____ Pleiotropy
    _____ Polygenic trait
    _____ Penetrance
    _____ Sex-limited trait
    _____ Genetic maternal effect
    _____ Genomic imprinting
    _____ Sex-influenced trait
    _____ Anticipation

a. The percentage of individuals with a particular genotype that express the expected phenotype.
b. A trait determined by an autosomal gene that is more easily expressed in one sex.
c. A trait determined by an autosomal gene that is expressed in only one sex.
d. A trait that is determined by an environmental effect and that has the same phenotype as a genetically determined trait.
e. A trait determined by genes at many loci.
f. The expression of a trait is affected by the sex of the parent that transmits the gene to the offspring.
g. The trait appears earlier or is more severe in succeeding generations.
h. A gene affects more than one phenotype.
i. The genotype of the maternal parent influences the phenotype of the offspring.

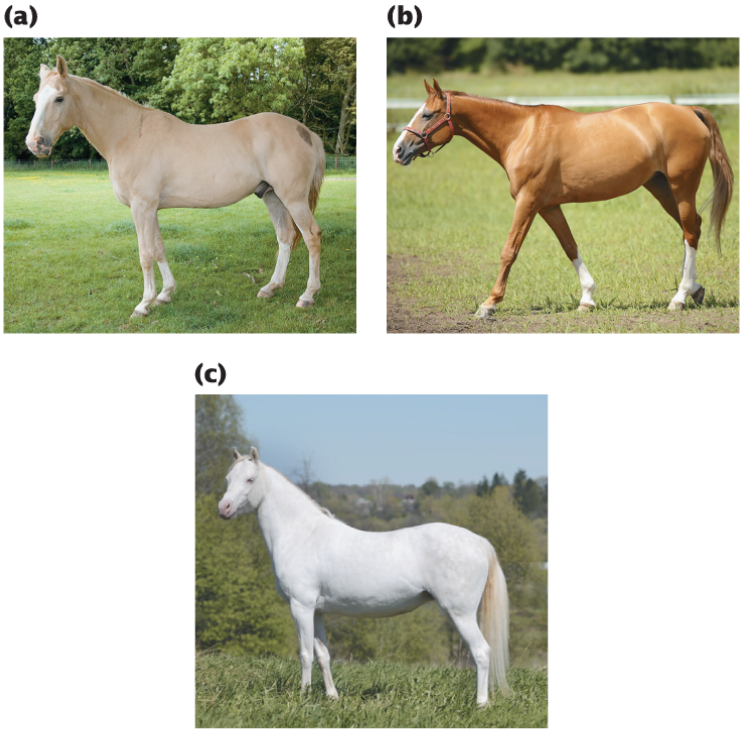
Section 5.1

13. *Palomino horses have a golden yellow coat, chestnut horses have a brown coat, and cremello horses have a coat that is almost white. A series of crosses between the three different types of horses produced the following offspring:

Cross	Offspring
palomino × palomino	13 palomino, 6 chestnut, 5 cremello
chestnut × chestnut	16 chestnut

cremello × cremello	13 cremello
palomino × chestnut	8 palomino, 9 chestnut
palomino × cremello	11 palomino, 11 cremello
chestnut × cremello	23 palomino

a. Explain the inheritance of the palomino, chestnut, and cremello phenotypes in horses.
b. Assign symbols for the alleles that determine these phenotypes, and list the genotypes of all parents and offspring given in the preceding table.



Part a: Keith J. Smith/Alamy. Part b: jirijura/Getty Images.
Part c: Olga_i/Shutterstock.

Coat color: (a) palomino; (b) chestnut; (c) cremello.

14. The L^M and L^N alleles at the MN blood-group locus exhibit codominance. Give the expected genotypes and phenotypes and their ratios in progeny resulting from the following crosses.

    a. $L^ML^M \times L^ML^N$

    b. $L^NL^N \times L^NL^N$

    c. $L^ML^N \times L^ML^N$

    d. $L^ML^N \times L^NL^N$

    e. $L^ML^M \times L^NL^N$

15. *Assume that long ear lobes in humans are an autosomal dominant trait that exhibits 30% penetrance. A person who is heterozygous for long ear lobes mates with a person who is homozygous for normal ear lobes. What is the probability that their first child will have long ear lobes?

16. DATA ANALYSIS Club foot is one of the most common congenital skeletal abnormalities, with a worldwide incidence of about 1 in 1000 births. Both genetic and nongenetic factors are thought to be responsible for club foot. C. A. Gurnett et al. (2008. *American Journal of Human Genetics* 83:616–622) identified a family in which club foot was inherited as an autosomal dominant trait with incomplete penetrance. They discovered a mutation in the *PITXI* gene that caused club foot in this family. Through DNA testing, they determined that 11 people in the family carried the *PITXI*

mutation, but only 8 of these people had club foot. What is the penetrance of the *PITX1* mutation in this family?

17. *When a Chinese hamster with white spots is crossed with another hamster that has no spots, approximately $^1/_2$ of the offspring have white spots and $^1/_2$ have no spots. When two hamsters with white spots are crossed, $^2/_3$ of the offspring possess white spots and $^1/_3$ have no spots.

    a. What is the genetic basis of white spotting in Chinese hamsters?

    b. How might you go about producing Chinese hamsters that breed true for white spotting?

18.

In the early 1900s, Lucien Cuénot studied the genetic basis of yellow coat color in mice (discussed on p. 116). He carried out a number of crosses between two yellow mice and obtained what he thought was a 3:1 ratio of yellow to gray mice in the progeny. The following table gives Cuénot's actual results, along with the results of a much larger series of crosses carried out by Castle and Little (W. E. Castle and C. C. Little. 1910. *Science* 32:868–870).

Progeny resulting from crosses of yellow × yellow mice

Investigators	Yellow progeny	Non-yellow progeny	Total progeny
Cuénot	263	100	363

Castle and Little	800	435	1235
Both combined	1063	535	1598

a. Using a chi-square test, determine whether Cuénot's results are significantly different from the 3:1 ratio that he thought he observed. Are they different from a 2:1 ratio?

b. Determine whether Castle and Little's results are significantly different from a 3:1 ratio. Are they different from a 2:1 ratio?

c. Combine the results of Castle and Little and Cuénot and determine whether they are significantly different from a 3:1 ratio and a 2:1 ratio.

d. Offer an explanation for the different ratios that Cuénot and Castle and Little obtained.

19. *In the pearl-millet plant, color is determined by three alleles at a single locus: Rp^1 (red), Rp^2 (purple), and *rp* (green). Red is dominant to purple and green, and purple is dominant to green ($Rp^1 > Rp^2 > rp$). Give the expected phenotypes and ratios of offspring produced by the following crosses.

a. $Rp^1/Rp^2 \times Rp^1/rp$

b. $Rp^1/rp \times Rp^2/rp$

c. $Rp^1/Rp^2 \times Rp^1/Rp^2$

d. $Rp^2/Rp \times Rp/Rp$

e. $Rp/Rp \times Rp^1/Rp^2$

20. If there are five alleles at a locus, how many genotypes can there be at this locus? How many different kinds of homozygotes can there be? How many genotypes and homozygotes can there be with eight alleles at a locus?

21. Turkeys have black, bronze, or black-bronze plumage. Examine the results of the following crosses:

Parents	Offspring
Cross 1: black and bronze	all black
Cross 2: black and black	$^3/_4$ black, $^1/_4$ bronze
Cross 3: black-bronze and black-bronze	all black-bronze
Cross 4: black and bronze	$^1/_2$ black, $^1/_4$ bronze, $^1/_4$ black-bronze
Cross 5: bronze and black-bronze	$^1/_2$ bronze, $^1/_2$ black-bronze
Cross 6: bronze and bronze	

	$^3/_4$ bronze, $^1/_4$ black-bronze

Do you think these differences in plumage arise from incomplete dominance between two alleles at a single locus? If yes, support your conclusion by assigning symbols to each allele and providing genotypes for all turkeys in the crosses. If your answer is no, provide an alternative explanation and assign genotypes to all turkeys in the crosses.

22. In rabbits, an allelic series helps to determine coat color: *C* (full color), c^{ch} (chinchilla, gray color), c^{h} (Himalayan, white with black extremities), and *c* (albino, all-white). The *C* allele is dominant to all others, c^{ch} is dominant to c^{h} and *c*, c^{h} is dominant to *c*, and *c* is recessive to all the other alleles. This dominance hierarchy can be summarized as $C > c^{ch} > c^{h} > c$. The rabbits in the following list are crossed and produce the progeny shown. Give the genotypes of the parents for each cross:

Phenotypes of parents	Phenotypes of offspring
a. full color × albino	$^1/_2$ full color, $^1/_2$ albino
b. Himalayan × albino	$^1/_2$ Himalayan, $^1/_2$ albino
c. full color × albino	$^1/_2$ full color, $^1/_2$ chinchilla
d. full color × Himalayan	$^1/_2$ full color, $^1/_4$ Himalayan, $^1/_4$ albino

e. full color × full color	$^3/_4$ full color, $^1/_4$ albino

23. In this chapter, we considered Joan Barry's paternity suit against Charlie Chaplin and how, on the basis of blood types, Chaplin could not have been the father of her child.

    a. What blood types are possible for the father of Barry's child?

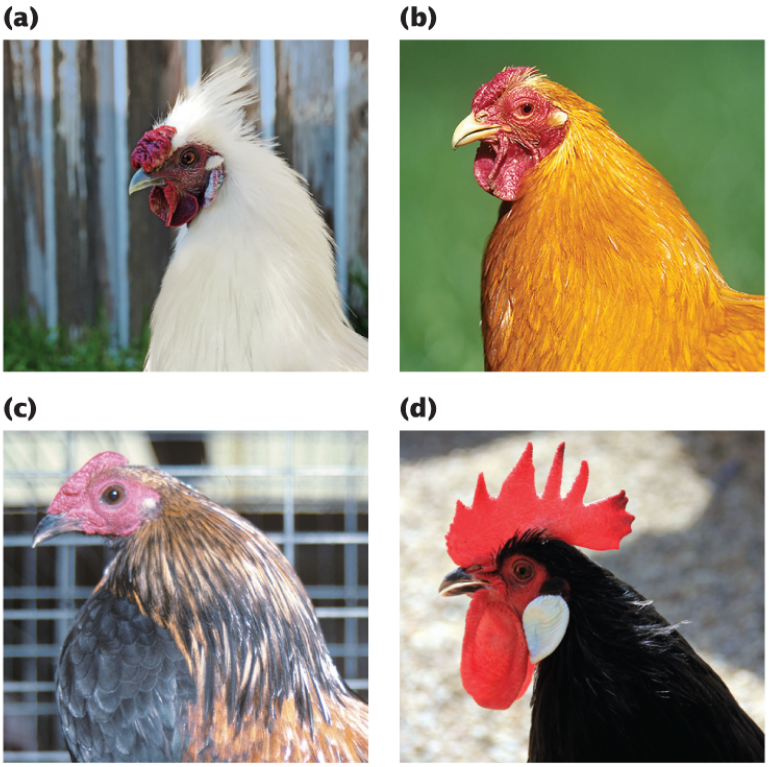
    b. If Chaplin had possessed one of these blood types, would that prove that he fathered Barry's child?

24. *A woman has blood type A M. She has a child with blood type AB MN. Which of the following blood types could *not* be that of the child's father? Explain your reasoning.

George	O	N
Tom	AB	MN
Bill	B	MN
Claude	A	N
Henry	AB	M

Section 5.2

25. *In chickens, comb shape is determined by alleles at two loci (*R*, *r* and *P*, *p*). A walnut comb is produced when at least one dominant allele *R* is present at one locus and at least one dominant allele *P* is present at a second locus (genotype *R*_ *P*_). A rose comb is produced when at least one dominant allele is present at the first locus and two recessive alleles are present at the second locus (genotype *R*_ *pp*). A pea comb is produced when two recessive alleles are present at the first locus and at least one dominant allele is present at the second (genotype *rr P*_). If two recessive alleles are present at the first and at the second loci (*rr pp*), a single comb is produced. Progeny with what types of combs and in what proportions will result from the following crosses?



Part a: ANGHI/Getty Images. Part b: Juniors Bildarchiv GmbH/ Alamy Stock Photo. Part c: Dapne Godfrey Trust/Animals Animals. Part d: FL collection/Alamy Stock Photo.

Comb shape: (a) walnut; (b) rose; (c) pea; (d) single.

a. *RR PP* × *rr pp*

b. *Rr Pp* × *rr pp*

c. *Rr Pp* × *Rr Pp*

d. *Rr pp* × *Rr pp*

e. *Rr pp* × *rr Pp*

f. *Rr pp* × *rr pp*

26.

*Tatuo Aida investigated the genetic basis of color variation in the medaka (*Aplocheilus latipes*), a small fish found in Japan (T. Aida. 1921. *Genetics* 6:554–573). Aida found that genes at two loci (*B*, *b* and *R*, *r*) determine the color of the fish: fish with a dominant allele at both loci (*B*_ *R*_) are brown, fish with a dominant allele at the *B* locus only (*B*_ *rr*) are blue, fish with a dominant allele at the *R* locus only (*bb R*_) are red, and fish with recessive alleles at both loci (*bb rr*) are white. Aida crossed a homozygous brown fish with a homozygous white fish. He then backcrossed the F_1 with the homozygous white parent and obtained 228 brown fish, 230 blue fish, 237 red fish, and 222 white fish.

a. Give the genotypes of the backcross progeny.

b. Use a chi-square test to compare the observed numbers of backcross progeny with the number expected. What conclusion can you make from your chi-square results?

c. What results would you expect for a cross between a homozygous red fish and a white fish?

d. What results would you expect if you crossed a homozygous red fish with a homozygous blue fish and then backcrossed the F_1 with a homozygous red parental fish?

27. A variety of opium poppy (*Papaver somniferum*) with lacerate leaves was crossed with a variety that has normal leaves. All the F_1 had lacerate leaves. Two F_1 plants were interbred to produce the F_2. Of the F_2, 249 had lacerate leaves and 16 had normal leaves. Give genotypes for all the plants in the P, F_1, and F_2 generations. Explain how lacerate leaves are determined in the opium poppy.

28.

E. W. Lindstrom crossed two corn plants with green seedlings and obtained the following progeny: 3583 green seedlings, 853 virescent-white seedlings, and 260 yellow seedlings (E. W. Lindstrom. 1921. *Genetics* 6:91–110).

a. Give the genotypes for the green, virescent-white, and yellow progeny.

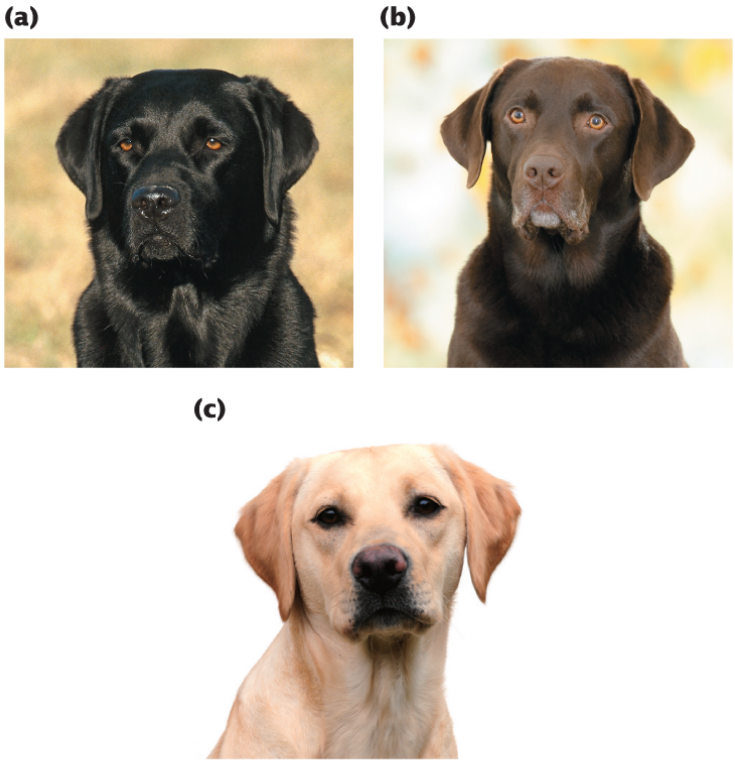
b. Explain how color is determined in these seedlings.

c. Is there epistasis among the genes that determine color in the corn seedlings? If so, which gene is epistatic and which is hypostatic?

29. *A dog breeder liked yellow and brown Labrador retrievers. In an attempt to produce yellow and brown puppies, he mated a yellow Labrador male and a brown Labrador female. Unfortunately, all the puppies produced in this cross were black. (See pp. 126–128 for a discussion of the genetic basis of coat color in Labrador retrievers.)

a. Explain this result.

b. How might the breeder go about producing yellow and brown Labradors?



Parts a and b: Juniors Bildarchiv/Alamy.
Part c: c.byatt-norman/Shutterstock.

Coat color in Labrador retrievers: (a) black; (b) brown; (c) yellow.

30. When a yellow female Labrador retriever was mated with a brown male, half of the puppies were brown and half were yellow. The same female, when mated with a different brown male, produced only brown offspring. Explain these results.

31. *A summer-squash plant that produces disc-shaped fruit is crossed with a summer-squash plant that produces long fruit. All the F_1 have disc-shaped fruit. When the F_1 are intercrossed, F_2 progeny are produced in the following ratio: $^9/_{16}$ disc-shaped fruit : $^6/_{16}$ spherical fruit : $^1/_{16}$ long fruit. Give the genotypes of the F_2 progeny.

32. Some sweet-pea plants have purple flowers and others have white flowers. A homozygous variety of sweet pea that has purple flowers is crossed with a homozygous variety that has white flowers. All the F_1 have purple flowers. When these F_1 self-fertilize, the F_2 appear in a ratio of $^9/_{16}$ purple to $^7/_{16}$ white.

    a. Give genotypes for the purple and white flowers in these crosses.

    b. Draw a hypothetical biochemical pathway to explain the production of purple and white flowers in sweet peas.

33. *Refer to the discussion of how coat color and pattern are determined in dogs.

    a. Why are Irish setters not black in color?

    b. Can a poodle crossed with any other breed produce spotted puppies? Why or why not?

c. If a St. Bernard is crossed with a Doberman, what will be the coat color of the offspring: solid, yellow, saddle, or bicolor?

d. If a Rottweiler is crossed with a Labrador retriever, what will be the coat color of the offspring: solid, yellow, saddle, or bicolor?

Section 5.3

34. Male-limited precocious puberty results from a rare, sex-limited autosomal allele (*P*) that is dominant to the allele for normal puberty (*p*) and is expressed only in males. Bill underwent precocious puberty, but his brother Jack and his sister Beth underwent puberty at the usual time, between the ages of 10 and 14. Although Bill's mother and father underwent normal puberty, two of his maternal uncles (his mother's brothers) underwent precocious puberty. All of Bill's grandparents underwent normal puberty. Give the most likely genotypes for all the relatives mentioned in this family.

35. *In some goats, the presence of horns is produced by an autosomal gene that is dominant in males and recessive in females. A horned female is crossed with a hornless male. The F_1 offspring are intercrossed to produce the F_2. What proportion of the F_2 females will have horns?

36. In goats, a beard is produced by an autosomal allele that is dominant in males and recessive in females. We'll use the symbol B^b for the beard allele and B^+ for the beardless allele. Another independently assorting autosomal allele that produces a black coat (*W*) is dominant to the allele for white coat (*w*). Give the

phenotypes and their expected proportions for the following crosses.

a. B^+B^b *Ww male* × B^+B^b *Ww female*

b. B^+B^b *Ww male* × B^+B^b *Ww female*

c. B^+B^+ *Ww male* × B^bB^b *Ww female*

d. B^+B^b *Ww male* × B^bB^b *Ww female*

37. Cock feathering in chickens is an autosomal recessive trait that is limited to males. List all possible genotypes for the chicken shown in

a. **Figure 5.13a**

b. **Figure 5.13b**

c. **Figure 5.13c**

38. J. K. Breitenbecher (1921. *Genetics* 6:65–86) investigated the genetic basis of color variation in the four-spotted cowpea weevil (*Bruchus quadrimaculatus*). The weevils were red, black, white, or tan. Breitenbecher found that four alleles (R, R^b, R^w, and r) at a single locus determine color. The alleles exhibit a dominance hierarchy, with red (R) dominant to all other alleles, black (R^b) dominant to white (R^w) and tan (r), white dominant to tan, and tan recessive to all others ($R \rightarrow R^b \rightarrow R^w \rightarrow r$). The following genotypes encode each of the colors:

RR, RR^b, RR^w, Rr	red

R^bR^b, R^bR^w, R^br	black
R^wR^w, R^wr	white
Rr	tan

Color variation in this species is limited to females: males carry color genes but are always tan regardless of their genotype. For each of the following crosses carried out by Breitenbecher, give all possible genotypes of the parents.

Parents	Progeny
a. tan ♀ × tan ♂	78 red ♀, 70 white ♀, 184 tan ♂
b. black ♀ × tan ♂	151 red ♀, 49 black ♀, 61 tan ♀, 249 tan ♂
c. white ♀× tan ♂	32 red ♀, 31 tan ♂
d. black ♀ × tan ♂	3586 black ♀, 1282 tan ♀, 4791 tan ♂
e. white ♀ × tan ♂	594 white ♀, 189 tan ♀, 862 tan ♂
f. black ♀ ×	88 black ♀, 88 tan ♀, 186 tan ♂

tan ♂	
g. tan ♀ × tan ♂	47 white ♀, 51 tan ♀, 100 tan ♂
h. red ♀ × tan ♂	1932 red ♀, 592 tan ♀, 2587 tan ♂
i. white ♀ × tan ♂	13 red ♀, 6 white ♀, 5 tan ♀, 19 tan ♂
j. red ♀ × tan ♂	190 red ♀, 196 black ♀, 311 tan ♂
k. black ♀ × tan ♂	1412 black ♀, 502 white ♀, 1766 tan ♂

39. *The direction of shell coiling in the snail *Lymnaea peregra* (discussed in the introduction to this chapter) results from genetic maternal effect. An autosomal allele for a right-handed, or dextral, shell (s^+) is dominant to the allele for a left-handed, or sinistral, shell (s). A pet snail called Martha is sinistral and reproduces only as a female (the snails are hermaphroditic). Indicate which of the following statements are true and which are false. Explain your reasoning in each case.

a. Martha's genotype *must* be *ss*.

b. Martha's genotype *cannot* be s^+s^+.

c. All the offspring produced by Martha *must* be sinistral.

d. At least some of the offspring produced by Martha *must* be sinistral.

e. Martha's mother *must* have been sinistral.

f. All of Martha's brothers *must* be sinistral.

40. If the F_2 dextral snails with genotype s^+s in **Figure 5.17** undergo self-fertilization, what phenotypes and proportions are expected to occur in the progeny?

41. Hypospadias, a birth defect in human males in which the urethra opens on the shaft instead of at the tip of the penis, results from an autosomal dominant gene in some families. Females who carry the gene show no effects. Is this birth defect an example of an X-linked trait, a Y-linked trait, a sex-limited trait, a sex-influenced trait, or genetic maternal effect? Explain your answer.

42. In unicorns, two autosomal loci interact to determine the type of tail. One locus controls whether a tail is present at all; the allele for a tail (*T*) is dominant to the allele for tailless (*t*). If a unicorn has a tail, then alleles at a second locus determine whether the tail is curly or straight. Farmer Baldridge has two unicorns with curly tails: when he crosses them, $^1/_2$ of the progeny have curly tails, $^1/_4$ have straight tails, and $^1/_4$ do not have a tail. Give the genotypes of the parents and progeny in Farmer Baldridge's cross. Explain how he obtained the 2:1:1 phenotypic ratio in his cross.

43. In 1983, a sheep farmer in Oklahoma noticed in his flock a ram that possessed increased muscle mass in his hindquarters. Many of the offspring of this ram possessed the same trait, which

became known as the callipyge phenotype (*callipyge* is Greek for "beautiful buttocks"). The mutation that caused the callipyge phenotype was eventually mapped to a position on the sheep chromosome 18.

When the male callipyge offspring of the original mutant ram were crossed with normal females, they produced the following progeny: $^1/_4$ male callipyge, $^1/_4$ female callipyge, $^1/_4$ male normal, and $^1/_4$ female normal. When the female callipyge offspring of the original mutant ram were crossed with normal males, all the offspring were normal. Analysis of the chromosomes of these offspring of callipyge females showed that half of them received a chromosome 18 with the allele encoding callipyge from their mother. Propose an explanation for the inheritance of the allele for callipyge. How might you test your explanation?

Section 5.5

44. Which of the following statements describes an example of a phenocopy? Explain your reasoning.

    a. Phenylketonuria results from a recessive mutation that causes light skin as well as intellectual disability.

    b. Human height is influenced by genes at many different loci.

    c. Dwarf plants and mottled leaves in tomatoes are caused by separate genes that are linked.

    d. Vestigial wings in *Drosophila* are produced by a recessive mutation. This trait is also produced by high temperature

during development.

e. Intelligence in humans is influenced by both genetic and environmental factors.

45. *Long ears in some dogs are an autosomal dominant trait. Two dogs mate and produce a litter in which 75% of the puppies have long ears. Of the dogs with long ears in this litter, $^1/_3$ are known to be phenocopies. What are the most likely genotypes of the two parents of this litter?

46.

White eyes is an X-linked recessive mutation in *Drosophila* that results in eyes that are devoid of the normal red pigment seen in wild-type flies (see Chapter 4). The white locus encodes an ABC transporter protein that, when functional, moves a variety of substances across the cell membrane including pigment precursors. When the transporter protein is defective due to a mutation at the white locus, the precursors are not present inside the cell and no eye pigments are produced. Mutations at the white locus also affect mating behavior and the fly's ability to recover from oxygen deprivation.

a. What phenomenon is illustrated by the different phenotypic effects of mutations at the white locus?

b. Propose an explanation for why mutations at the white eye locus have such differing effects as eye color, mating behavior, and physiology.

47. The fly with vestigial wings shown in the lower-left corner of Figure 5.19 is crossed with the fly with normal wings shown in the upper-right corner of the figure. If the progeny are reared at 31°C, what percentage will have vestigial wings?

CHALLENGE QUESTIONS

Section 5.1

48. DATA ANALYSIS Pigeons have long been the subject of genetic studies. Indeed, Charles Darwin bred pigeons in the hope of unraveling the principles of heredity but was unsuccessful. A series of genetic investigations in the early 1900s worked out the hereditary basis of color variation in these birds. W. R. Horlancher was interested in the genetic basis of kiteness, a color pattern that consists of a mixture of red and black stippling of the feathers. He carried out the following crosses to investigate the genetic relation of kiteness to black and red feather color (W. R. Horlancher. 1930. *Genetics* 15:312–346).

Cross	Offspring
kitey × kitey	16 kitey, 5 black, 3 red
kitey × black	6 kitey, 7 black
red × kitey	18 red, 9 kitey, 6 black

a. On the basis of these results, propose a hypothesis to explain the inheritance of kitey, black, and red feather color in pigeons. (Hint: Assume that two loci are involved and some type of epistasis occurs.)

b. For each of the preceding crosses, test your hypothesis by using a chi-square test.

Section 5.3

49. Suppose that you are tending a mouse colony at a genetic research institute, and one day you discover a mouse with twisted ears. You breed this mouse with twisted ears and find that the trait is inherited. Both male and female mice may have twisted ears, but when you cross a twisted-eared male with a normal-eared female, you obtain results that differ from those obtained when you cross a twisted-eared female with a normal-eared male: the reciprocal crosses give different results. Describe how you would determine whether this trait results from a sex-linked gene, a sex-influenced gene, genetic maternal effect, a cytoplasmically inherited gene, or genomic imprinting. What crosses would you conduct, and what results would be expected with these different types of inheritance?

ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Section 5.1

1. Over a thousand different alleles at the *CFTR* locus have been discovered that can cause cystic fibrosis. What difficulties might the presence of so many different alleles at this locus create for the diagnosis and treatment of cystic fibrosis?

Section 5.2

2. Could you carry out a complementation test on two dominant mutations? Why or why not?

Section 5.3

3. In goats, a beard is produced by an autosomal allele that is dominant in males and recessive in females. Is it possible to cross two bearded goats and obtain a beardless male offspring? Why or why not? What about a bearded female offspring?

4. In chickens, cock feathering is an autosomal recessive trait that is limited to males. Is it possible to cross a cock-feathered male with a hen-feathered female and get male progeny that are cock-feathered? Explain your reasoning.

5. Suppose you observed a new mutant phenotype, notched ears, that appears only in male mice. How might you go about determining whether notched ears is a Y-linked trait or a sex-limited trait? What crosses would you carry out to distinguish between these two modes of inheritance?

6. Phenylketonuria (PKU) is an autosomal recessive disease that results from a defect in an enzyme that normally metabolizes the amino acid phenylalanine; when this enzyme is defective, high

levels of phenylalanine cause brain damage. In the past, most children with PKU became intellectually disabled. Fortunately, intellectual disability can be prevented in these children by carefully controlling the amount of phenylalanine in the diet. The diet is usually applied during childhood, when brain development is taking place. As a result of this treatment, many people with PKU now reach reproductive age. Children born to women with PKU (who are no longer on a phenylalanine-restricted diet) frequently have low birth weight, developmental abnormalities, and intellectual disabilities. However, children of men with PKU do not have these problems.

a. Provide an explanation for these observations.

b. What type of genetic effect is this? Explain your reasoning.

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Introduction

1. Explain how the direction of coiling in *Lymnaea peregra* is determined by creating a concept map that includes the following terms: *Lymnaea peregra*, outcrossing, shell coiling, genetic maternal effect, dextral, sinistral, dominant allele, self-fertilization, genotype of maternal parent, recessive allele.

Section 5.1

2. Create a concept map that outlines the different types of dominance and their relationships.

Section 5.3

3. Create a concept map illustrating the ways that sex may influence heredity. Include the following terms in your map (you may add additional terms): influences of sex on heredity, sex-influenced characteristic, cytoplasmic inheritance, genomic imprinting, sex-linked characteristic, sex-limited characteristic, genetic maternal effect, sex chromosomes, autosomes, organelle DNA.

Section 5.5

4. With a concept map, depict the relationships among the following terms: characteristics, discontinuous characteristics, phenocopy, continuous characteristics, quantitative characteristics, polygenic characteristics, many genes, environmental factors.

SaplingPlus Self-study tools that will help you practice what you've learned and reinforce this chapter's concepts are available online. Go to www.saplinglearning.com.

CHAPTER 6

Pedigree Analysis, Applications, and Genetic Testing

Phanie/Science Source.

Fingerprints are unique to each person. A few people have a condition known as adermatoglyphia (ADG), in which fingerprints are completely absent; this condition is inherited as an autosomal dominant trait. Shown here is a human fingerprint superimposed on DNA sequence information.

The Mystery of the Missing Fingerprints

In 2007, a 29-year-old Swiss woman attempted to enter the United States. Although her appearance matched the photograph on her passport, she failed a fingerprint check, not because her fingerprints matched those of a terrorist, but rather because she had no fingerprints at all—her fingers were completely devoid of any prints. She was delayed for several hours as puzzled immigration officials tried to decide what to do about a person with no fingerprints.

Fingerprints are among our most unique and permanent traits. No two individuals, not even identical twins, share the same fingerprints. Fingerprints are technically termed *epidermal ridges* or *dermatoglyphic patterns*; these patterns are found on our fingers, toes, palms, and the soles of our feet. Epidermal ridges appear long before birth—they are fully formed by the 17th week of pregnancy—and are permanent for life. Research shows that fingerprint patterns are clearly influenced by heredity, but random factors also play a role. One of the first scientists to study fingerprints was Francis Galton, a cousin of Charles Darwin. In the late 1800s, Galton established that no two individuals have the same fingerprints and showed that fingerprints of relatives are more similar than those of unrelated people.

The complete absence of fingerprints, as exhibited by the Swiss woman at the airport, is an extremely rare condition known as adermatoglyphia (ADG). Dubbed "immigration delay disease" because of the hassle it creates when people with the condition attempt to cross borders, ADG has been documented in only a few people from four families around the world. In ADG, fingerprints are absent at birth and never develop. Otherwise, the disorder produces no harmful effects.

In 2011, geneticists in Israel and Switzerland solved the mystery of missing fingerprints in people with ADG. Janna Nousbeck and her colleagues examined the condition in a large Swiss family in which some members had normal fingerprints and other members were missing them entirely (**Figure 6.1**). In this family, ADG exhibits the hallmark characteristics of an autosomal dominant trait. The researchers took blood samples from family members who lacked fingerprints and from those with normal fingerprints. They extracted DNA from the blood and genotyped the family members for 6000 single-nucleotide polymorphisms (SNPs), which are DNA sequences that vary in a single nucleotide. By comparing the SNPs of family members with and without fingerprints, they were able to determine that the gene for ADG was located in a specific interval on the long arm of chromosome 4. One of the genes in this region is *SMARCAD1*, which encodes a short form of a protein found exclusively in the skin. Sequencing of the gene revealed that family members with ADG possessed a mutation not found in those with fingerprints. The mutation causes abnormal splicing in RNA transcribed from the

gene, with the result that the RNA is less stable. How the decreased stability of this RNA leads to ADG is not known, but scientists hope that the identification of this gene will lead to a better understanding of how fingerprints develop.

W. H. Freeman and Company

6.1 Pedigree of Swiss family with adermatoglyphia (absence of fingerprints). Squares represent males; circles represent females. Colored squares and circles are people with adermatoglyphia.

Description

Generation 1 has a couple with the male positive for adermatoglyphia. Both the male and female in generation 1 are crossed out. Generation 2 has 1 female with the condition, one female without the condition, and one male with the condition. Both of the siblings with adermatoglyphia mate with unaffected people and have offspring. In generation 3, the positive female from generation 2 has 2 male offspring with the condition, a set of twin females without the condition, and 1 female without the condition. From these siblings, one of the positive males mates with a female and both of their female offspring in generation 4 are positive for adermatoglyphia. The positive male from generation 2 has 2 male offspring and 1 female offspring in generation 3 and all of them have adermatoglyphia.

THINK-PAIR-SHARE

- If identical twins share 100% of the same genes, why do they have different fingerprints?
- What characteristics of the pedigree in Figure 6.1 suggest that adermatoglyphia in this family is inherited as an autosomal dominant trait?

The absence of fingerprints is just one of a large number of human traits and diseases that are currently the focus of intensive genetic research. In this chapter, we consider human genetic characteristics and examine three important techniques used by geneticists to investigate these characteristics: pedigrees, twin studies, and adoption studies. At the end of the chapter, we see how the information garnered with these techniques can be used in genetic counseling and prenatal diagnosis.

Keep in mind as you read this chapter that many important characteristics are influenced by both genes and environment, and that separating these factors in humans is always difficult. Studies of twins and adopted people are designed to distinguish the effects of genes and environment, but such studies are based on assumptions that may be difficult to meet for some human characteristics, particularly behavioral ones. Therefore, it's always prudent to interpret the results of such studies with caution.

6.1 The Study of Genetics in Humans Is Constrained by Special Features of Human Biology and Culture

Humans are both the best and the worst of all organisms for genetic study. On the one hand, we know more about human anatomy, physiology, and biochemistry than about that of most other organisms, so many well-characterized traits are available for study. Families often keep detailed records about their members extending back many generations. Furthermore, a number of important human diseases have a genetic component, so the incentive for understanding human inheritance is tremendous. On the other hand, the study of human genetic characteristics presents some major challenges.

First, controlled matings are not possible. With other organisms, geneticists carry out specific crosses to test their hypotheses about inheritance. We have seen, for example, that the testcross provides a convenient way to determine whether an individual with a dominant trait is homozygous or heterozygous. Unfortunately (for the geneticist at least), matings between humans are usually determined by romance, family expectations, or—occasionally—accident rather than by the requirements of science.

Another challenge is that humans have a long generation time. Human reproductive age is not normally reached until 10 to 14 years after birth, and most people do not reproduce until they are 18 years of age or older; thus, generation time in humans is usually about 20 years. This long generation time means that even if geneticists could control human crosses, they would have to wait an average of 40 years just to observe the F_2 progeny. In contrast, generation time in *Drosophila* is 2 weeks; in bacteria, it's a mere 20 minutes.

Finally, human family size is generally small. Observation of even the simple genetic ratios that we learned in Chapter 3 would require a substantial number of progeny in each family. When parents produce only 2 children, the detection of a 3:1 ratio is impossible. Even an extremely large family of 10 to 15 children would not permit the recognition of a dihybrid 9 : 3 : 3 : 1 ratio.

Although these special constraints make genetic studies of humans more complex, understanding human heredity is tremendously important. Therefore, geneticists have been forced to develop techniques that are uniquely suited to human biology and culture. ❯

TRY PROBLEM 18

THINK-PAIR-SHARE Question 1

CONCEPTS

The study of human inheritance is constrained by the inability to control genetic crosses, a long generation time, and a small number of offspring.

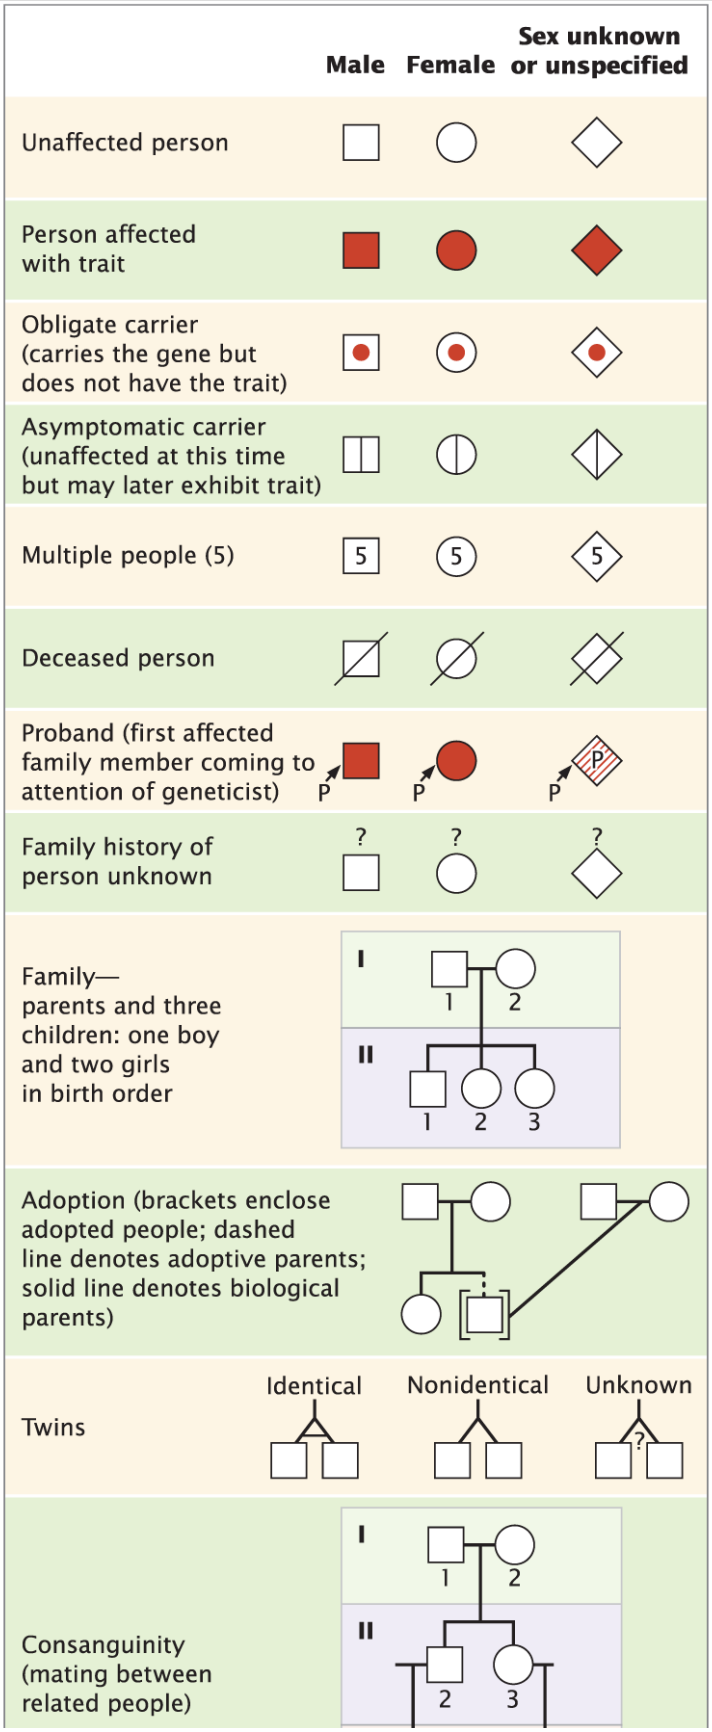
6.2 Geneticists Often Use Pedigrees to Study the Inheritance of Characteristics in Humans

An important technique used by geneticists to study human inheritance is the analysis of pedigrees. A **pedigree** is a pictorial representation of a family history, essentially a family tree that outlines the inheritance of one or more characteristics. When a particular characteristic or disease is observed in a person, a geneticist often studies the family of that affected person by drawing a pedigree. Today, computer programs are often used to create and analyze pedigrees. These programs may calculate a variety of genetic parameters from pedigree, including measures of relatedness, inbreeding coefficients (see Chapter 25), genotype predictions, genetic risk values, and estimates of linkage among genes (see Chapter 7).

Symbols Used in Pedigrees

The symbols commonly used in pedigrees are summarized in **Figure 6.2**. Males in a pedigree are represented by squares, females by circles. A horizontal line drawn between two symbols representing a man and a woman indicates a mating; children are connected to their parents by vertical lines extending downward from the parents.

The pedigree shown in **Figure 6.3a** illustrates a family with Waardenburg syndrome, an autosomal dominant type of deafness that may be accompanied by fair skin, a white forelock, and visual problems (**Figure 6.3b**). People who exhibit the trait of interest are represented by filled circles and squares; in the pedigree of Figure 6.3a, the filled symbols represent members of the family who have Waardenburg syndrome. Unaffected members are represented by open circles and squares. The person from whom the pedigree is initiated is called the **proband** and is usually designated by the letter *P* and an arrow (IV-2 in Figure 6.3a).



Male

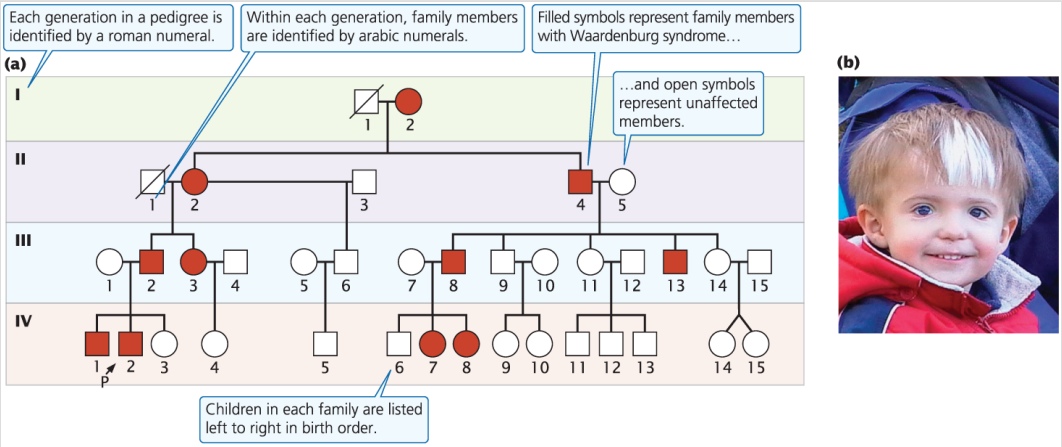
6.2 Standard symbols are used in pedigrees.

Description

In a pedigree, a male is represented by a square, a female by a circle, and a person of unknown sex by a diamond. Unaffected individuals have uncolored shapes. For affected persons, the shape is filled in with red. Obligate carriers that carry the gene but do not display the trait are represented by the shape with a smaller colored circle inside. Asymptomatic carriers are those who are unaffected at this time but may later exhibit trait have a vertical line drawn in the center of the symbols. Multiple persons may be indicated by a number inside the shape rather than multiple shapes. A deceased person will have the shape crossed out with a slash. The proband, or the first affected family member coming to the attention of the geneticist, is indicated with the solid color and a capital P with an arrow pointing to the shape from a left side. A person of unknown sex who is proband may have multiple lines inside the shape rather than it being completely filled in. When a person has an unknown family history, there is a question mark over their corresponding symbol. Each generation is indicated by a roman numeral and each person in a generation is numbered. In a family with parents and three children out of which one is boy and two girls in birth order, a pedigree chart is drawn is as follows: Two blocks are present. One has Roman numeral 1 written on left and has a square and a circle connected by a horizontal line in between. From the line, a perpendicular line is drawn downwards to another block with roman numeral 2 written on left. The line divides into 3 branches that have labeled shapes at the end as follows: 1 square, 2 circle, and 3 circle. Adoption is denoted by square brackets enclosing the symbol. Dashed line represents adoptive parents and solid line represents biological parents. The lines between twins are angled downward and triangular in shape. For identical twins, an extra line is drawn between the lines, resulting in a shape that looks like an big A. Unknown twin status is designated with a question mark below the upside down V. Consanguinity or mating between related people is indicated by two parallel vertical lines drawn between the symbols.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company
Part b: Courtesy of Guy Rowland.

6.3 Pedigree of a person with Waardenburg syndrome. The proband (P) is the person from whom this pedigree is initiated. (a) Waardenburg syndrome is inherited as an autosomal dominant trait. (b) The syndrome is characterized by deafness, fair skin, visual problems, and a white forelock.

Description

Part “a” shows a pedigree chart. The pedigree chart a shows a couple in generation 1 where male is crossed out and the female is affected. A caption reads, “Each generation in a pedigree is identified by a Roman numeral.” The couple from generation 1 has one affected son and one affected daughter in the generation 2. A caption reads, “Within each generation, family members are identified by Arabic numerals.” The affected female in generation 2 mates with an unaffected male who is crossed out and has one affected son and affected female in the generation 3. The affected female from generation 2 also mates with another unaffected male and has an unaffected son in generation 3. The affected male from generation 2 mates with an unaffected female and has 2 affected sons, 1 unaffected son, and 2 unaffected daughters in generation 3. The affected male and female who were children of affected female and unaffected crossed out male from generation 2 mate with an unaffected female and an unaffected male respectively. The male has 2 affected sons and an unaffected daughter in generation 4. One of these sons is a proband. The female has 1 unaffected daughter in generation 4. The unaffected son in generation 3 who is child of affected female from generation 2 and an unaffected man, mates with an unaffected female and has one unaffected son in generation 4. Affected son of affected male from generation 2, mates with unaffected female and has 2 affected daughters and 1

unaffected son in generation 4. A caption reads, “Children in each family are listed left to right in birth order.” Unaffected son of affected male from generation 2, mates with an unaffected female and has two unaffected daughters in generation 4. An unaffected daughter of affected male from generation 2, mates with an unaffected male and has 3 unaffected sons. Another unaffected daughter of affected male from generation 2, mates with an unaffected male and has non-identical unaffected daughters in generation 4. Part “b” shows a photo of a child with a white forelock due to Waardenburg syndrome.

Let’s look closely at Figure 6.3 and consider some additional features of a pedigree. Each generation in a pedigree is identified by a roman numeral; within each generation, family members are assigned arabic numerals, and children in each family are listed in birth order from left to right. Person II-4, a man with Waardenburg syndrome, mated with II-5, an unaffected woman, and they produced five children. The oldest of their children is III-8, a male with Waardenburg syndrome, and the youngest is III-14, an unaffected female. ❯ **TRY** **PROBLEM 19a**

Analysis of Pedigrees

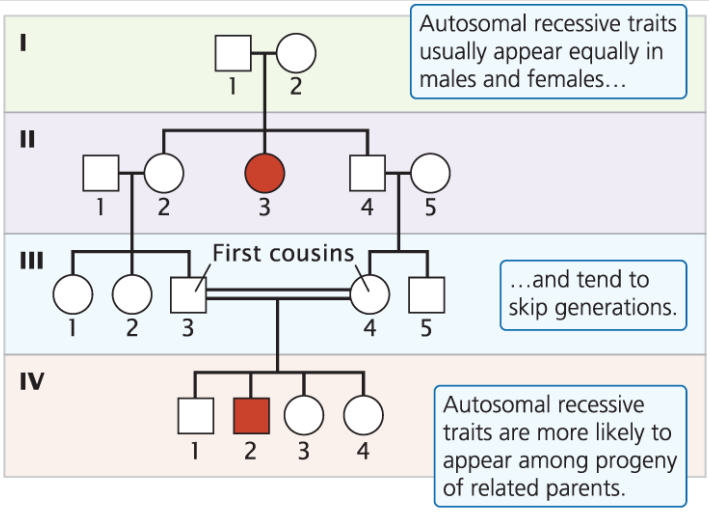
The limited number of offspring in most human families means that clear Mendelian ratios are usually impossible to discern in a single pedigree. Pedigree analysis requires a certain amount of genetic sleuthing, based on recognizing patterns associated with different modes of inheritance. For example, autosomal dominant traits should appear with equal frequency in both sexes and should not skip generations, provided that the trait is fully penetrant (see

Penetrance and Expressivity in Chapter 5) and not sex-influenced (see Sex-Influenced and Sex-Limited Characteristics in Chapter 5).

Certain patterns may exclude the possibility of a particular mode of inheritance. For instance, a son inherits his X chromosome from his mother. If we observe that a trait is passed from father to son, we can exclude the possibility of X-linked inheritance. In the following sections, the traits discussed are assumed to be fully penetrant and rare.

Autosomal Recessive Traits

Autosomal recessive traits normally appear with equal frequency in both sexes (unless penetrance differs in males and females) and appear only when a person inherits two alleles for the trait, one from each parent. If the trait is uncommon, most parents of affected offspring are heterozygous and unaffected; consequently, the trait seems to skip generations (**Figure 6.4**). Frequently, a recessive allele may be passed on for a number of generations without the trait appearing in a pedigree. When both parents are heterozygous, approximately one-fourth of the offspring are expected to express the trait, but this ratio will not be obvious unless the family is large. In the rare event that both parents are affected by an autosomal recessive trait, all the offspring will be affected.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

6.4 Autosomal recessive traits normally appear with equal frequency in both sexes and often skip generations.

Description

Generation 1 shows an unaffected couple. A caption reads, “Autosomal recessive traits usually appear equally in males and females and tend to skip generations.” The couple has 1 unaffected daughter, 1 affected daughter, and 1 unaffected son in generation 2. The unaffected female from generation 2 mates with an unaffected male and has 2 unaffected daughters and 1 unaffected son in generation 3. The unaffected male from generation 2 mates with an unaffected female and has 1 unaffected daughter and 1 unaffected son in generation 3. The unaffected son of unaffected female from generation 2 mates with the unaffected daughter of unaffected male from generation 2. As they are first cousins, it is a case of consanguinity. They have 2 unaffected daughters, 1 affected son, and 1 unaffected son in generation 4. A caption reads, “Autosomal recessive traits are more likely to appear among progeny of related parents.”

When a recessive trait is rare, most people outside affected families are homozygous for the normal allele. Thus, when an affected person mates with someone outside the family ($aa \times AA$), usually none of the children display the trait, although all will be carriers

(i.e., heterozygous). A recessive trait is more likely to appear in a pedigree when two people within the same family mate, because there is a greater chance of both parents carrying the same recessive allele. Mating between closely related people is called **consanguinity**. In the pedigree shown in Figure 6.4, individuals III-3 and III-4 are first cousins, and both are heterozygous for the recessive allele; when two heterozygotes mate, one-fourth of their children are expected to have the recessive trait.

CONCEPTS

Autosomal recessive traits appear with equal frequency in males and females. Affected children are commonly born to unaffected parents who are carriers of the gene for the trait, and the trait tends to skip generations. Recessive traits appear more frequently among the offspring of consanguineous matings.

✔ CONCEPT CHECK 1

Autosomal recessive traits often appear in pedigrees in which there have been consanguineous matings because these traits

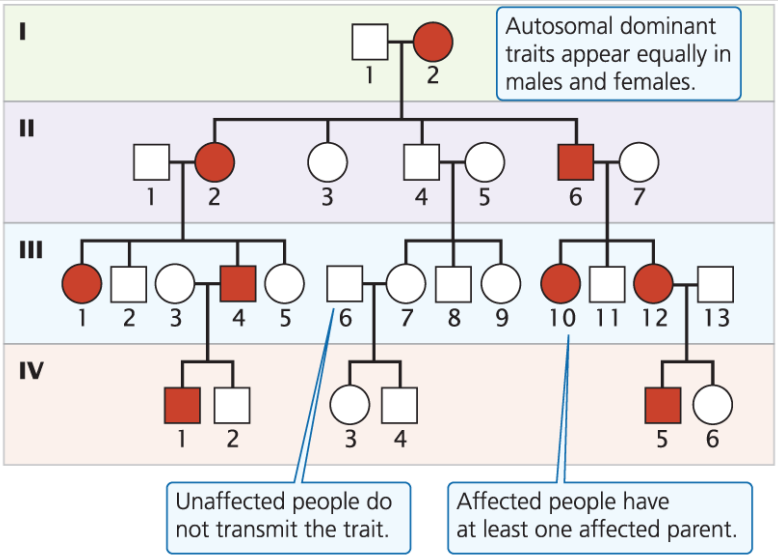
a. tend to skip generations.
b. appear only when both parents carry a copy of the gene for the trait, which is more likely when the parents are related.
c. usually arise in children born to parents who are unaffected.
d. appear equally in males and females.

A number of human metabolic diseases are inherited as autosomal recessive traits. One of them is Tay–Sachs disease. Children with Tay–Sachs disease appear healthy at birth but become listless and

weak at about 6 months of age. Gradually, their physical and neurological conditions worsen, leading to blindness, deafness, and eventually death at two to three years of age. The disease results from the accumulation of a lipid called G_{M2} ganglioside in the brain. A normal component of brain cells, G_{M2} ganglioside is usually broken down by an enzyme called hexosaminidase A, but children with Tay–Sachs disease lack this enzyme. Excessive G_{M2} ganglioside accumulates in the brain, causing swelling and, ultimately neurological symptoms. Heterozygotes have only one normal copy of the allele encoding hexosaminidase A and produce only about half the normal amount of the enzyme. However, this amount is enough to ensure that G_{M2} ganglioside is broken down normally, and heterozygotes are usually healthy.

Autosomal Dominant Traits

Autosomal dominant traits appear in both sexes with equal frequency, and both sexes are capable of transmitting these traits to their offspring. Every person with a dominant trait must have inherited the allele from at least one parent; autosomal dominant traits therefore do not skip generations (**Figure 6.5**). Exceptions to this rule arise when people acquire the trait as a result of a new mutation or when the trait has incomplete penetrance.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

6.5 Autosomal dominant traits normally appear with equal frequency in both sexes and do not skip generations.

Description

Generation 1 has a couple where the male is unaffected and the female is affected. Text reads, “Autosomal dominant traits appear equally in males and females.” They have 1 affected daughter, 1 unaffected daughter, 1 affected son, and 1 unaffected son in generation 2. The affected female from generation 2 mates with an unaffected male and has 1 affected son, 1 unaffected son, 1 affected daughter, and 1 unaffected daughter in generation 3. An unaffected male from generation 2 mates with an unaffected female and has 2 unaffected daughters and 1 unaffected son in generation 3. The affected male from generation 2 mates with an unaffected female and has 2 affected daughters and an unaffected son in generation 3. A caption reads, “Affected people have at least one affected parent.” The affected son of affected female from generation 2 mates with an unaffected female and has 1 affected son and 1 unaffected son in generation 4. An unaffected daughter of the unaffected male from generation 2 mates with an unaffected male and has 1 unaffected daughter and 1 unaffected son in generation 4. A caption reads, “Unaffected people do not transmit the trait.” An affected daughter of the affected male from generation 2 mates with an unaffected male and has 1 affected son and 1 unaffected daughter in generation 4.

If an autosomal dominant allele is rare, most people displaying the trait are heterozygous. When one parent is affected and heterozygous and the other parent is unaffected, approximately half of the offspring will be affected. If both parents have the trait and are heterozygous, approximately three-fourths of the children will be affected. Unaffected people do not transmit the trait to their descendants, provided that the trait is fully penetrant. In Figure 6.5, we see that none of the descendants of II-4 (who is unaffected) have the trait.

THINK-PAIR-SHARE Question 2

CONCEPTS

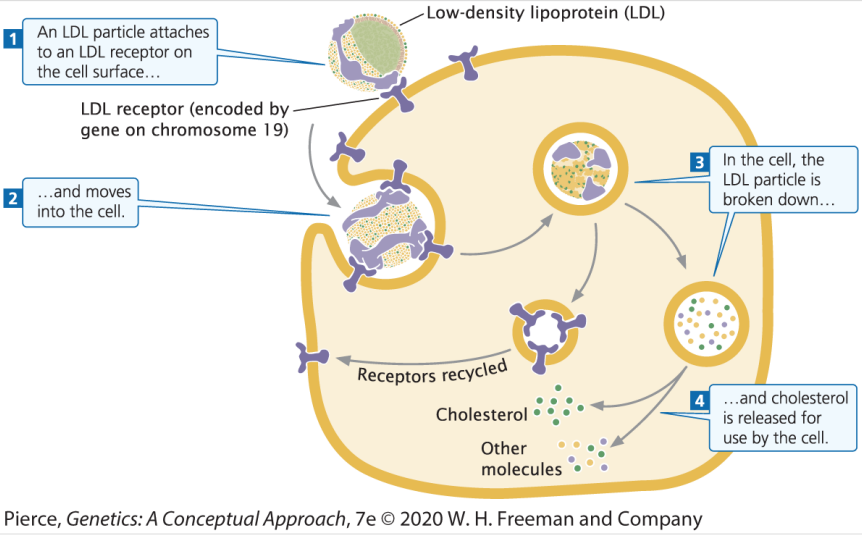
Autosomal dominant traits appear in both sexes with equal frequency. An affected person has an affected parent (unless the person carries new mutations), and the trait does not skip generations. Unaffected people do not transmit the trait.

✔ CONCEPT CHECK 2

When might you see an autosomal dominant trait skip generations?

One condition that is usually considered to be an autosomal dominant trait is familial hypercholesterolemia, an inherited disease in which blood cholesterol is greatly elevated owing to a defect in cholesterol transport. Cholesterol is normally transported throughout the body in small soluble particles called lipoproteins

(Figure 6.6). A principal lipoprotein in the transport of cholesterol is low-density lipoprotein (LDL). When an LDL molecule reaches a cell, it attaches to an LDL receptor, which then moves the LDL through the cell membrane into the cytoplasm, where it is broken down and its cholesterol is released for use by the cell.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

6.6 Low-density lipoprotein (LDL) particles transport cholesterol. The LDL receptor moves LDL from the bloodstream through the cell membrane into the cytoplasm.

Description

The illustration shows a cell with multiple L D L receptors, encoded by gene on chromosome 19, over its surface. A caption reads, “An L D L particle attaches to an L D L receptor on the cell surface and moves into the cell.” The L D L particle then enters into the cell by forming a vesicle. Another caption reads, “In the cell, the L D L particle is broken down and cholesterol is released for use by the cell.” From this vesicle, two vesicles are formed. One vesicle has cholesterol and other molecules and the other has receptors for recycling. The receptors are again recycled and are attached back to the surface. The vesicle with L D L fragments then disintegrates into cholesterol and other molecules.

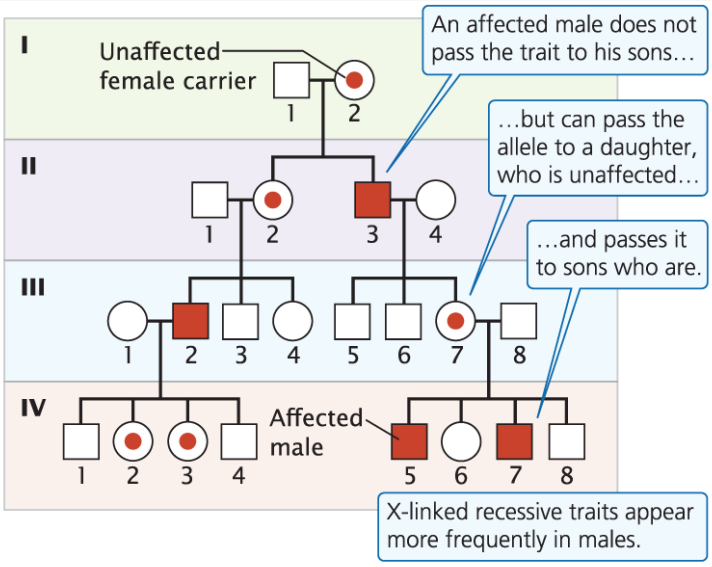
Familial hypercholesterolemia occurs when there is a defect in the gene that normally encodes the LDL receptor. The disease is usually considered an autosomal dominant disorder because heterozygotes are deficient in LDL receptors and have elevated blood levels of cholesterol, which lead to increased risk of coronary artery disease. People who are heterozygous for familial hypercholesterolemia have blood LDL levels that are twice the normal levels and usually have heart attacks by the age of 35.

Very rarely, a person inherits two defective alleles for the LDL receptor. Such individuals don't make any functional LDL receptors; their blood cholesterol levels are more than six times the normal levels, and they may suffer a heart attack as early as age 2 and almost inevitably by age 20. Because homozygotes are more severely affected than heterozygotes, familial hypercholesterolemia is said to be incompletely dominant. However, homozygotes are rarely seen, and the common heterozygous form of the disease appears as a simple dominant trait in most pedigrees.

X-Linked Recessive Traits

X-linked recessive traits have a distinctive pattern of inheritance (Figure 6.7). First, these traits appear more frequently in males than in females because males need inherit only a single copy of the allele to display the trait, whereas females must inherit two copies of the allele, one from each parent, to be affected. Second, because a male

inherits his X chromosome from his mother, affected males are usually born to unaffected mothers who carry an allele for the trait. Because the trait is passed from unaffected female to affected male to unaffected female, it tends to skip generations (see Figure 6.7). When a woman is heterozygous, approximately half of her sons will be affected and half of her daughters will be unaffected carriers. For example, we know that females I-2, II-2, and III-7 in Figure 6.7 are carriers because they transmit the trait to approximately half of their sons. Individuals like these females, whose heterozygous genotype can be definitively determined from the pedigree, are called *obligate carriers*.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

6.7 X-linked recessive traits appear more often in males than in females and are not passed from father to son. Obligate carriers are indicated in this pedigree to help illustrate the X-linked recessive mode of inheritance.

Description

The first generation shows a couple with an unaffected male and a female with a red dot inside the circle labeled as an unaffected female carrier. This couple mates and has 2 offspring: an affected male and a carrier female offspring. A caption reads, “An affected male does not pass the trait to his sons but can pass the allele to a daughter, who is unaffected and passes it to sons who are.” The female carrier in generation 2 mates with an unaffected male and has 1 unaffected daughter and 2 sons, one of which is affected. The affected male from generation 2 mates with an unaffected female and has two unaffected sons and a carrier unaffected daughter. An affected son of the carrier female from generation 2 mates with an unaffected female and has 2 carrier unaffected daughters and 2 unaffected sons in generation 4. A carrier daughter of the affected male from generation 2 mates with an unaffected male and has 2 affected sons, 1 unaffected daughter, and an unaffected son in generation 4. A text below reads, “X-linked recessive traits appear more frequently in males.”

A third important characteristic of X-linked recessive traits is that they are not passed from father to son, because a son inherits his father’s Y chromosome, not his X. In Figure 6.7, there is no case in which both a father and his son are affected. All daughters of an affected man, however, will be carriers (if their mother is homozygous for the normal allele). When a woman displays an X-linked recessive trait, she must be homozygous for the trait, and all her sons will also display the trait.

CONCEPTS

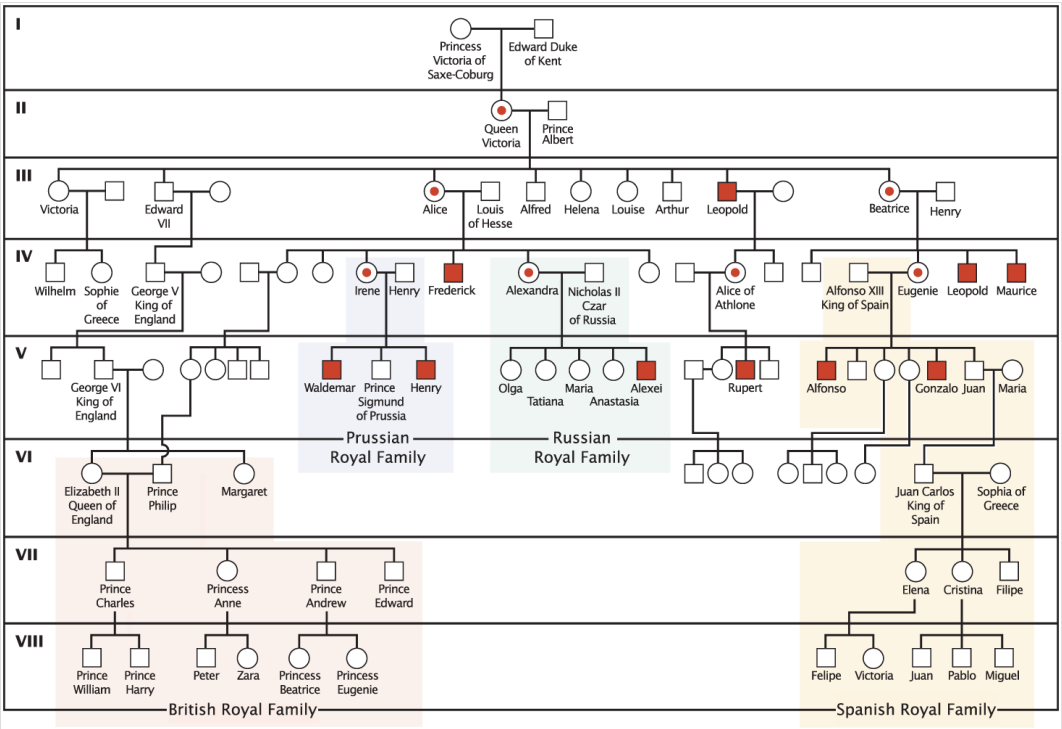
X-linked recessive traits appear more often in males than in females and are not passed from father to son. Affected sons are usually born to unaffected mothers who are carriers of the gene for the trait; thus, X-linked recessive traits tend to skip generations.

✔ CONCEPT CHECK 3

How can you distinguish between an autosomal recessive trait with higher penetrance in males and an X-linked recessive trait?

An example of an X-linked recessive trait in humans is hemophilia A, also called classic hemophilia. Hemophilia results from the absence of a protein necessary for blood to clot. The complex process of blood clotting consists of a cascade of reactions that includes more than 13 different clotting factors. For this reason, there are several types of clotting disorders, each due to a glitch in a different step of the clotting pathway.

Hemophilia A results from abnormal or missing factor VIII, one of the proteins in the clotting cascade. The gene for factor VIII is located on the tip of the long arm of the X chromosome, so hemophilia A is an X-linked recessive disorder. People with hemophilia A bleed excessively; even small cuts and bruises can be life threatening. Spontaneous bleeding occurs in joints such as elbows, knees, and ankles, producing pain, swelling, and erosion of the bone. Fortunately, bleeding in people with hemophilia A can be controlled by administering concentrated doses of factor VIII. The inheritance of hemophilia A is illustrated by the family of Queen Victoria of England (**Figure 6.8**).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

6.8 Classic hemophilia in the royal families of Europe. This blood-clotting disorder is inherited as an X-linked recessive trait.

Description

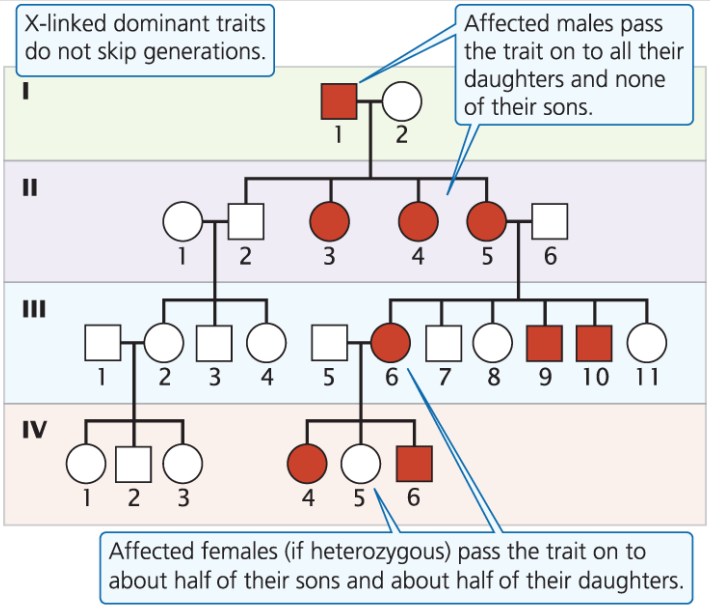
The pedigree includes the names of the royal family members. It starts with Princess Victoria of Saxe-Coburg and Edward Duke of Kent, who are both unaffected. Their daughter, Queen Victoria, becomes a carrier and mates with Prince Albert who is unaffected. They have 9 children in generation 3: Victoria (unaffected), Edward the Seventh (unaffected), Alice (unaffected carrier), Alfred (unaffected), Helena (unaffected), Louise (unaffected), Arthur (unaffected), Leopold (affected), and Beatrice (unaffected carrier). Victoria mates with an unaffected male and has 1 son named Wilhelm and 1 daughter named Sophie of Greece. Edward the Seventh mates with an unaffected female and has 1 son named George the Fifth King of England. Alice mates with Louis of Hessen and has 3 unaffected daughters, 2 carrier but unaffected daughters named Irene and Alexandra, and 1 affected son named Frederick. Leopold mates with an unaffected female and has 1 unaffected but carrier daughter named Alice of Athlone. Beatrice mates with unaffected Henry and has 1 unaffected but carrier daughter named Eugenie, 1 unaffected son, 2 affected sons named Leopold and Maurice. George the Fifth King of England mates with an unaffected female and has two unaffected sons, one of whom is named George the

Sixth King of England. One unaffected daughter of Alice from generation 3 mates with an unaffected male and has 2 unaffected sons and 2 unaffected daughters where one of these daughter has a son named Prince Philip. Irene from generation 4 mates with unaffected Henry and has 2 affected sons named Waldemar and Henry and 1 unaffected son named Prince Sigmund of Prussia. This family is labeled as Prussian Royal Family. Alexandra from generation 4 mates with Nicholas the Second Czar of Russia. They have 4 unaffected daughters named Olga, Tatiana, Marie, Anastasia, and an affected son named Alexis. This is the Russian Royal Family. Alice of Athlone from generation 4 mates with an unaffected male and has 1 unaffected daughter, 1 affected son named Rupert, and 1 unaffected son. Eugenie from generation 4 mates with Alfonso the Thirteenth King of Spain and has 2 affected sons named Alfonso and Gonzalo, 2 unaffected daughters and 2 unaffected sons one of whom is named Juan. George the Sixth King of England mates with an unaffected female and has two unaffected daughters named Elizabeth the Second Queen of England and Margaret. One unaffected son of Alice of Athlone has 2 unaffected daughters and 1 unaffected son in generation 6. One unaffected daughter of Eugenie from generation 4 has 2 unaffected daughters and 1 unaffected son in generation 6. Another unaffected daughter of Eugenie has 1 unaffected daughter in generation 6. Juan mates with unaffected Maria and has an unaffected son named Juan Carlos King of Spain. Elizabeth the Second Queen of England mates with Prince Philip and has 3 unaffected sons named Prince Charles, Prince Andrew, Prince Edward, and 1 unaffected daughter named Princess Anne. Juan Carlos King of Spain from generation 6 mates with unaffected Sophia of Greece and has 2 unaffected daughters named Elena, Cristina, and 1 unaffected son named Filipe. Prince Charles has two unaffected sons named Prince William and Prince Harry in generation 8. Princess Anne has 1 unaffected son named Peter and 1 unaffected daughter named Zara in generation 8. Prince Andrew has two unaffected daughters named Princess Beatrice and Princess Eugenie. This family from Elizabeth the Second Queen of England is British Royal Family. Elena has 1 unaffected daughter named Victoria and 1 unaffected son named Felipe in generation 8. Cristina has 3 unaffected sons named Juan, Pablo, and Miguel in generation 8. This family starting from Alfonso the Eighth King of Spain is Spanish Royal Family. This pedigree chart shows 10 affected males and 7 unaffected but carrier females. Through the few generations shown in the pedigree, only 1 male out of 10 positive for hemophilia mated and had offspring.

X-Linked Dominant Traits

X-linked dominant traits appear in both males and females, although they often appear more frequently in females than in males. Each person with an X-linked dominant trait must have an affected parent (unless the person possesses a new mutation or the trait has incomplete penetrance). X-linked dominant traits do not skip generations (**Figure 6.9**); affected men pass the trait to all their daughters and none of their sons, as is seen in the children of I-1 in Figure 6.9. In contrast, affected women (if heterozygous) pass the trait to about half of their sons and about half of their daughters, as seen in the children of III-6 in the pedigree. As with X-linked recessive traits, a male inherits an X-linked dominant trait only from his mother; the trait is not passed from father to son. This fact is what distinguishes X-linked dominant inheritance from autosomal dominant inheritance, in which a male can inherit the trait from his father. A female, on the other hand, inherits an X chromosome from both her mother and her father, so females can receive an X-linked dominant trait from either parent.

THINK-PAIR-SHARE Question 3



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

6.9 X-linked dominant traits affect both males and females. An affected male must have an affected mother.

Description

The pedigree chart shows generation 1 has a couple with affected male and unaffected female. A text reads, “X-linked dominant traits do not skip generations.” A caption reads, “Affected males pass the trait on to all their daughters and none of their sons.” The couple has 3 affected daughters and 2 unaffected sons in generation 2. One unaffected male from generation 2 mates with an unaffected female and has 2 unaffected daughters and 1 unaffected son in generation 3. One of the affected females from generation 2 mates with an unaffected male and has 1 affected daughter, 2 unaffected daughters, 1 unaffected son, and 2 affected sons. A caption reads, “Affected females (if heterozygous) pass the trait on to about half of their sons and about half of their daughters.” One unaffected daughter of the unaffected male from generation 2 mates with an unaffected male and has 1 unaffected son and 2 unaffected daughters in generation 4. The affected daughter of the affected female from generation 2 mates with an unaffected man and has 1 affected daughter, 1 unaffected daughter, and 1 affected son in generation 4.

CONCEPTS

X-linked dominant traits affect both males and females. Affected males must have affected mothers (unless the males possess a new mutation), and they pass the trait to all their daughters.

✔ CONCEPT CHECK 4

A male affected with an X-linked dominant trait will have what proportion of offspring affected with the trait?

a. $^1/_2$ sons and $^1/_2$ daughters
b. All sons and no daughters
c. All daughters and no sons
d. $^3/_4$ daughters and $^1/_4$ sons

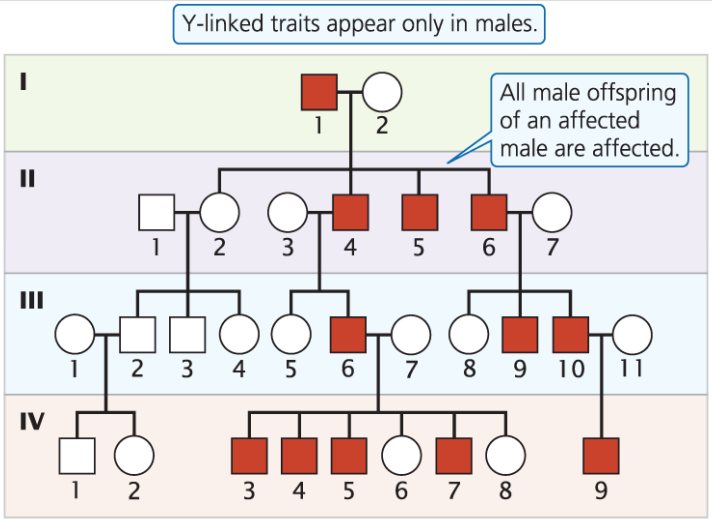
An example of an X-linked dominant trait in humans is hypophosphatemia, or familial vitamin-D-resistant rickets. People with this trait have features that superficially resemble those produced by rickets: bone deformities, stiff spines and joints, bowed legs, and mild growth deficiencies. This disorder, however, is resistant to treatment with vitamin D, which normally cures rickets. X-linked hypophosphatemia results from the defective transport of phosphate, especially in cells of the kidneys. People with this disorder excrete large amounts of phosphate in their urine, resulting in low levels of phosphate in the blood and reduced deposition of minerals in the bone. The disorder is treated with high doses of calcitriol (a hormonally active form of vitamin D) and phosphate. As

is common with X-linked dominant traits, males with hypophosphatemia are often more severely affected than females.

Y-Linked Traits

Y-linked traits exhibit a specific, easily recognized pattern of inheritance. Only males are affected, and the trait is passed from father to son. If a man is affected, all his male offspring should also be affected, as is the case for I-1, II-4, II-6, III-6, and III-10 of the pedigree in **Figure 6.10**. Y-linked traits do not skip generations. As mentioned in Chapter 4, little genetic information is found on the human Y chromosome. Maleness (encoded by the *SRY* gene) is one of the few traits in humans that has been shown to be Y linked. Because each male has a single Y chromosome, there is only one copy of each Y-linked allele; therefore, Y-linked traits are neither dominant nor recessive.

THINK-PAIR-SHARE Question 4



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

6.10 Y-linked traits appear only in males and are passed from a father to all his sons.

Description

The pedigree shows generation 1 has a couple where the male is affected and female is unaffected.

A text reads, “Y-linked traits appear only in males.” The couple has 1 unaffected daughter and 3 affected sons in generation 2. A caption reads, “All male offspring of an affected male are affected.” The unaffected female from generation 2 mates with an unaffected male and has 1 unaffected daughter and 2 unaffected sons in generation 3. One of the affected males from generation 2 mates with an unaffected female and has 1 affected son and 1 unaffected daughter in generation 3. Another affected male from generation 2 mates with an unaffected female and has 2 affected sons and 1 unaffected daughter in generation 3. An unaffected male, son of unaffected female from generation 2, mates with an unaffected female and has 1 unaffected son and 1 unaffected daughter in generation 4. One affected son of affected male from generation 2 mates with an unaffected female and has 4 affected sons and 2 unaffected daughters in generation 4. Another affected son of the affected male from generation 2 mates with an unaffected female and has 1 affected son in generation 2.

CONCEPTS

Y-linked traits appear only in males and are passed from a father to all his sons.

✔ CONCEPT CHECK 5

What features of a pedigree would distinguish between a Y-linked trait and a trait that is rare, autosomal dominant, and sex-limited to males?

The major characteristics of autosomal recessive, autosomal dominant, X-linked recessive, X-linked dominant, and Y-linked traits are summarized in Table 6.1. ❯ **TRY** PROBLEM 22

TABLE 6.1 Pedigree characteristics of autosomal recessive, autosomal dominant, X-linked recessive, X-linked dominant, and Y-linked traits

Autosomal Recessive Trait

1. Usually appears in both sexes with equal frequency.
2. Tends to skip generations.
3. Affected offspring are usually born to unaffected parents.
4. When both parents are heterozygous, approximately one-fourth of the offspring will be affected.
5. Appears more frequently among the children of consanguineous marriages.

Autosomal Dominant Trait

1. Usually appears in both sexes with equal frequency.
2. Both sexes transmit the trait to their offspring.
3. Does not skip generations.
4. Affected offspring must have an affected parent unless they possess a new mutation.
5. When one parent is affected (heterozygous) and the other parent is unaffected, approximately half of the offspring will be affected.
6. Unaffected parents do not transmit the trait.

X-Linked Recessive Trait

1. Usually more males than females are affected.
2. Affected sons are usually born to unaffected mothers; thus, the trait skips generations.
3. Approximately half of a carrier (heterozygous) mother's sons are affected.
4. Never passed from father to son.
5. All daughters of affected fathers are carriers.

X-Linked Dominant Trait

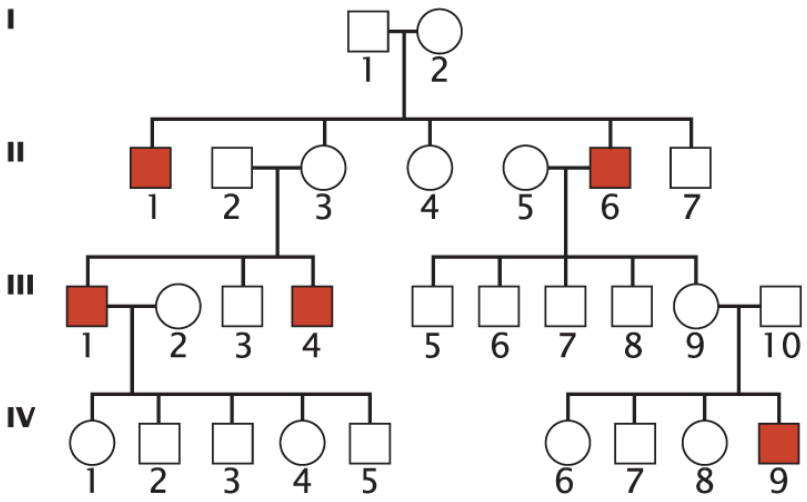
1. Both males and females are usually affected; often, more females than males are affected.
2. Does not skip generations. Affected sons must have an affected mother; affected daughters must have either an affected mother or an affected father.
3. Affected fathers pass the trait to all their daughters.
4. Affected mothers (if heterozygous) pass the trait to half of their sons and half of their daughters.

Y-Linked Trait

1. Only males are affected.
2. Passed from father to all sons.
3. Does not skip generations.

WORKED PROBLEM

The following pedigree represents the inheritance of a rare disorder in an extended family. What is the most likely mode of inheritance for this disease? (Assume that the trait is fully penetrant.)



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description

All of the affected members are males. 2 in generation 2, 2 in generation 3, and 1 in generation 4. The first generation, both parents are unaffected. They have 5 offspring: 2 positive males, 2 negative females, and 1 negative male. One negative female and 1 positive male mate and have offspring. The female mates a negative male, and they have 2 positive male and 1 negative male offspring. The positive male from generation 2 mates a negative female, and they have 5 negative offspring: 4 male and 1 female. The female mates a negative male, and they have 1 positive male, 2 negative female, and 1 negative male offspring.

Solution Strategy

What information is required in your answer to the problem?

The most likely mode of inheritance for the trait shown in the pedigree.

What information is provided to solve the problem?

- The pedigree, which includes information about the sex and family relationships of affected individuals.
- The trait is rare.

Solution Steps

To answer this question, we should consider each mode of inheritance and determine which, if any, we can eliminate. The trait appears only in males, so autosomal dominant and autosomal recessive modes of inheritance are unlikely because traits with these modes appear equally in males and females. Additionally, autosomal dominance can be eliminated because some affected individuals do not have an affected parent.

The trait is observed only among males in this pedigree, which might suggest Y-linked inheritance. However, affected men should pass a Y-linked trait to all their sons, which is not the case here; II-6 is an affected man who has four unaffected male offspring. Therefore, we can eliminate Y-linked inheritance.

X-linked dominance can be eliminated because affected men should pass an X-linked dominant trait on to all their female offspring, and II-6 has an unaffected daughter (III-9).

X-linked recessive traits often appear more commonly in males, and affected males are usually born to unaffected female carriers; the pedigree shows this pattern of inheritance. If the disorder is an X-

linked trait, about half the sons of a heterozygous carrier mother should be affected. II-3 and III-9 are suspected carriers, and about half of their male children (three of five) are affected. Another important characteristic of an X-linked recessive trait is that it is not passed from father to son. We observe no father-to-son transmission in this pedigree. X-linked recessive is therefore the most likely mode of inheritance.

» For additional practice, try to determine the mode of inheritance for the pedigrees in **Problem 25** at the end of the chapter.

Genetic Mosaicism

A factor that can complicate the interpretation of pedigrees is the presence of mosaicism. A long-held assumption in genetics was that every cell in the body contains the same genetic information. Yet from time to time, geneticists discovered exceptions to this rule. In 1976, researchers published the curious case of a woman who had two different blood types. Most of her red blood cells were type O, but a few cells were type A. In 1998, a 52-year-old woman needed a kidney transplant. When her three children were genetically tested to see if any of them might be a potential donor, two of the children had genotypes that could not have come from their mother, even though she had given birth to them. Further testing revealed that the mother actually had two different types of cells in her body: the

genotype of her blood cells was different from that of her skin and some organs. These individuals, in which different cells of the body have different genetic constitutions, are referred to as **genetic mosaics** or chimeras.

Genetic mosaicism can arise from a number of different processes. Often, somatic mutations or errors in the separation of chromosomes during early development lead to genetically distinct groups of cells within the body. There can also be exchanges of cells and DNA between twins or between mother and child during pregnancy. Mosaicism was once thought to be rare, but the increasing use of DNA sequencing has revealed that it may be common. For example, in 2012, researchers sequenced skin cells and discovered that 30% of the cells contained genetic variants called copy-number variations (CNVs, see Chapter 8). Another study examined CNVs in diverse tissues from six people and also found major differences in CNVs, even within a single person.

6.3 Studying Twins and Adoptions Can Help Assess the Importance of Genes and Environment

Twins and adoptions provide natural experiments for separating the effects of genes and environmental factors on differences in traits. These two techniques have been widely used in genetic studies.

Types of Twins

Twins are of two types. **Dizygotic (nonidentical) twins** arise when two separate eggs are fertilized by two different sperm, producing genetically distinct zygotes. **Monozygotic (identical) twins** result when a single egg, fertilized by a single sperm, splits early in development into two separate embryos.

Because monozygotic twins result from a single egg and sperm (a single, "mono," zygote), they're genetically identical (except for epigenetic differences—see Chapter 21—or rare somatic mutations); thus, identical twins share 100% of their genes (**Figure 6.11a**). Dizygotic twins (**Figure 6.11b**), on the other hand, share, on average, only 50% of their genes, which is the same percentage that any pair of siblings shares. Like other siblings, dizygotic twins may be of the same sex or of different sexes. The only difference between dizygotic

twins and other siblings is that dizygotic twins are the same age and shared the same uterine environment. Dizygotic twinning often runs in families, and the tendency to produce dizygotic twins is influenced by both heredity and environmental factors. There appears to be little genetic tendency for producing monozygotic twins. The frequency of dizygotic twinning in the United States has doubled since 1980, largely because of fertility treatments, which often stimulate women to ovulate multiple eggs.

THINK-PAIR-SHARE Question 5

(a)

(b)

Part a: f4foto/Alamy. Part b: Courtesy of Randi Rossignol.

6.11 Two types of twins. Monozygotic twins (a) are identical; dizygotic twins (b) are nonidentical.

CONCEPTS

Dizygotic twins develop from two eggs fertilized by two separate sperm; on average, they share 50% of their genes. Monozygotic twins develop from a single egg, fertilized by a single sperm, that splits into two embryos; they share 100% of their genes.

✔ CONCEPT CHECK 6

Why are monozygotic twins genetically identical, whereas dizygotic twins share only 50% of their genes on average?

a. Monozygotic twins tend to look more similar.
b. Monozygotic twins develop from two different eggs fertilized by the same sperm, whereas dizygotic twins develop from two eggs fertilized by two different sperm.
c. Monozygotic twins develop from a single egg fertilized by one sperm, whereas dizygotic twins develop from a single egg fertilized by two different sperm.
d. Monozygotic twins develop from a single egg fertilized by a single sperm, whereas dizygotic twins develop from two eggs fertilized by two different sperm.

Concordance in Twins

Comparisons of dizygotic and monozygotic twin pairs can be used to assess the importance of genetic and environmental factors in producing differences in a characteristic. Such assessments are often made by calculating the concordance for a trait. If both members of a twin pair have a trait, the twins are said to be *concordant*; if only one member of the pair has the trait, the twins are said to be *discordant*. **Concordance** is the percentage of twin pairs that are concordant for a trait. Because identical twins share 100% of their genes and dizygotic twins share, on average, only 50%, genetically influenced traits should exhibit higher concordance in monozygotic twins. For instance, when one member of a monozygotic twin pair has epilepsy (**Table 6.2**), the other twin of the pair has epilepsy about 59% of the time; thus, the monozygotic concordance for epilepsy is 59%. When a dizygotic twin has epilepsy, however, the other twin has epilepsy only 19% of the time (19%

dizygotic concordance). The higher concordance in monozygotic twins suggests that genes influence epilepsy, a finding supported by the results of other family studies of this disease. In contrast, the concordance of death from acute infection is similar in monozygotic and dizygotic twin pairs, suggesting that variation in death from infection has little inherited tendency. Concordances for several additional human traits and diseases are listed in Table 6.2.

TABLE 6.2 Concordance of monozygotic and dizygotic twins for several traits

	Concordance (%)	
Trait	**Monozygotic**	**Dizygotic**
Heart attack (males)	39	26
Heart attack (females)	44	14
Bronchial asthma	47	24
Cancer (all sites)	12	15
Epilepsy	59	19
Death from acute infection	7.9	8.8
Rheumatoid arthritis	32	6
Multiple sclerosis	28	5

[Data from: (1 and 2) B. Havald and M. Hauge, U.S. Public Health Service Publication 1103 (1963), pp. 61–67; (3, 4, 5, and 6) B. Havald and M. Hauge, *Genetics and the Epidemiology of Chronic Diseases* (U.S. Department of Health, Education, and Welfare, 1965); (7) J. S. Lawrence, *Annals of Rheumatic Diseases* 26:357–379, 1970; (8) G. C. Ebers et al., *American Journal of Human Genetics* 36:495, 1984.]

The use of twins in genetic research rests on the important assumption that when concordance for monozygotic twins is greater

than that for dizygotic twins, it is because monozygotic twins are more similar in their genes and not because they have experienced a more similar environment. The degree of environmental similarity between monozygotic twins and dizygotic twins is assumed to be the same. This assumption may not always be correct, particularly for human behaviors. Because they look alike, identical twins may be treated more similarly by parents, teachers, and peers than are nonidentical twins. Evidence of this similar treatment is seen in the past tendency of parents to dress identical twins alike. In spite of this potential complication, twin studies have played a pivotal role in the study of human genetics. › **TRY** PROBLEM 32

THINK-PAIR-SHARE Question 6

A Twin Study of Asthma

To illustrate the use of twins in genetic research, let's consider a study of asthma. Asthma is characterized by constriction of the airways and the secretion of mucus into the air passages, causing coughing, labored breathing, and wheezing (Figure 6.12). Severe cases can be life threatening. Asthma is a major health problem in industrialized countries and appears to be on the rise. The incidence of childhood asthma varies widely around the globe; some of the highest rates (from 21% to 27%) are found in Australia, the United Kingdom, Sweden, and Brazil.

Stockbyte/Getty Images.

6.12 Twin studies show that asthma, characterized by constriction of the airways, is caused by a combination of genetic and environmental factors. Inhalers are often used to deliver asthma medication to the lungs.

A number of environmental stimuli are known to precipitate asthma attacks, including dust, pollen, air pollution, respiratory infections, exercise, cold air, and emotional stress. Allergies frequently accompany asthma, suggesting that asthma is a disorder of the immune system, but the precise relation between immune function and asthma is poorly understood. Numerous studies have shown that genetic factors are important in asthma.

A genetic study of childhood asthma was conducted as part of the Twins Early Development Study in England, an ongoing research project that studies more than 15,000 twin pairs born in the United Kingdom between 1994 and 1996. These twins were assessed for

language, cognitive development, behavioral problems, academic achievement, and other traits at various ages, and the genetic and environmental contributions to a number of their traits were examined. In the asthma study, researchers looked at a sample of 4910 twin pairs at age 4. Parents of the twins were asked whether either of their twins had been prescribed medication to control asthma; those children receiving asthma medication were considered to have asthma. The concordance for the monozygotic twins (65% among 1658 twin pairs) was significantly higher than that for the dizygotic twins (37% among 3252 twin pairs), and the researchers concluded that among the 4-year-olds included in the study, asthma was strongly influenced by genetic factors. The fact that even monozygotic twins were discordant 35% of the time indicates that environmental factors also play a role in asthma.

CONCEPTS

Higher concordance for monozygotic twins than for dizygotic twins indicates that genetic factors play a role in determining differences in a trait. Less than 100% concordance for monozygotic twins indicates that environmental factors play a significant role.

✔ CONCEPT CHECK 7

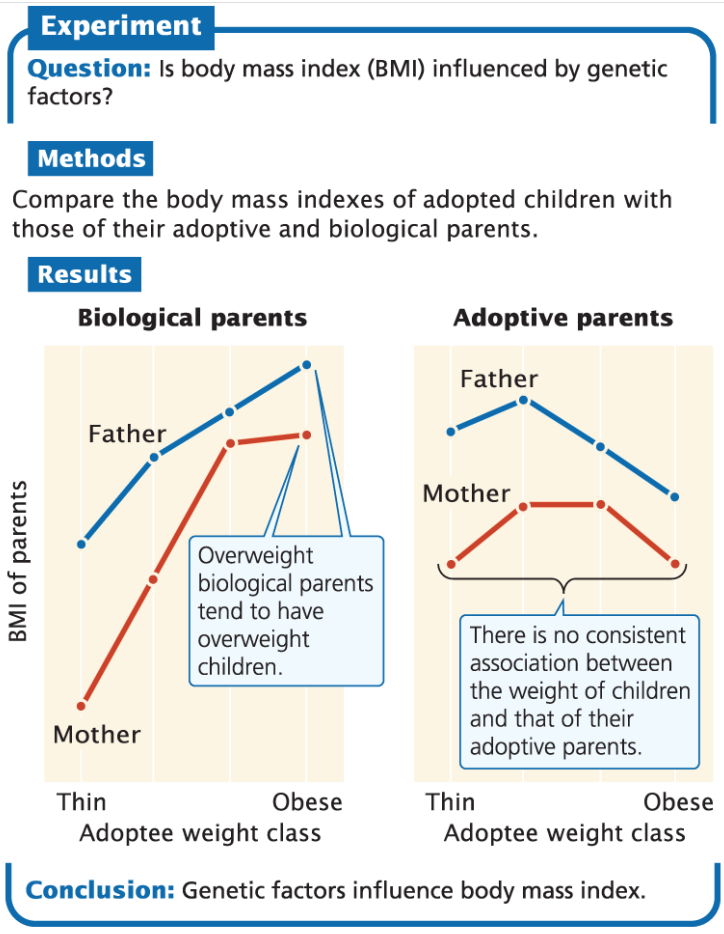
A trait exhibits 100% concordance for both monozygotic and dizygotic twins. What conclusion can you draw about the role of genetic factors in determining differences in the trait?

a. Genetic factors are extremely important.
b. Genetic factors are somewhat important.
c. Genetic factors are unimportant.
d. Both genetic and environmental factors are important.

Adoption Studies

Another technique used by geneticists to analyze human inheritance is the study of families involved in adoptions. This approach is one of the most powerful for distinguishing the effects of genes and environment on characteristics.

For a variety of reasons, many children are separated from their biological parents soon after birth and adopted by adults with whom they have no genetic relationship. These adoptees share no more genes with their adoptive parents, on average, than any two randomly chosen individuals share; however, they do share an environment with their adoptive parents. In contrast, the adoptees share 50% of their genes with each of their biological parents, but do not share the same environment with them. If adoptees and their adoptive parents show similarities in a characteristic, these similarities can be attributed to environmental factors. If, on the other hand, adoptees and their biological parents show similarities, these similarities are probably due to genetic factors. Comparisons of adoptees with their adoptive parents and with their biological parents can therefore help define the roles of genetic and environmental factors in the determination of human variation. For example, adoption studies were instrumental in showing that schizophrenia has a genetic basis. Adoption studies have also shown that variation in obesity is at least partly influenced by genetics (**Figure 6.13**).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

6.13 Adoption studies demonstrate that variation in obesity is influenced by genetics. In these studies, obesity was measured by body mass index (BMI). [Data from the *New England Journal of Medicine* 314:195, 1986.]

Description

The illustration shows the following question for the experiment: Is body mass index (B M I) in uenced by genetic

factors? The methods below include the text, Compare the body mass indexes of adopted children with

those of their adoptive and biological parents. The results include two line graphs: The first graph shows results for biological parents. The horizontal axis represents Adoptee weight class and has two markings from left to right: thin and obese. The vertical axis represents

B M I of parents. The graph shows the following information: The line representing mother rises upwards steeply from a little above the thin marking and then its slope becomes almost plateauing as it approaches obese. The line representing father is above the line for mothers. It rises steeply upwards, then becomes a more shallow but consistent incline. A caption referring to both lines reads, “Overweight biological parents tend to have overweight children.”

The second graph shows results for adoptive parents. The horizontal and vertical axis represents the same parameters. The graph shows the following information: The line representing mother rises upwards from high above the thin marking, plateaus between the markings, then declines to reach the same level as the start point above the obese marking. The line representing father is higher than the start point for mothers, rises a little upwards, then enters a steady decline as it approaches obese, but remains above the line representing mother. A caption referring to both lines reads, “There is no consistent association between the weight of children and that of their adoptive parents.” The conclusion states that genetic factors in uence body mass index.

Adoption studies assume that the environments of biological and adoptive families are independent (i.e., not more alike than would be expected by chance). This assumption may not always be correct because adoption agencies carefully choose adoptive parents and may select a family that resembles the adoptee’s biological family. Thus, some of the similarity between adoptees and their biological parents may be due to these similar environments and not to shared genetic factors. In addition, adoptees and their biological mothers share the same environment during prenatal development. **› TRY PROBLEM 35**

CONCEPTS

Similarities between adoptees and their genetically unrelated adoptive parents indicate that environmental factors affect variation in a particular characteristic; similarities between adoptees and their biological parents indicate that genetic factors influence variation in the characteristic.

✔ CONCEPT CHECK 8

What assumptions underlie the use of adoption studies in genetics?

a. Adoptees have no contact with their biological parents after birth.
b. The adoptive parents and biological parents are not related.
c. The environments of biological and adoptive parents are independent.
d. All of the above

6.4 Genetic Counseling and Genetic Testing Provide Information to Those Concerned about Genetic Diseases and Traits

Our knowledge of human genetic diseases and disorders has expanded rapidly in recent years. The Online Mendelian Inheritance in Man Web site now lists more than 24,000 human genetic diseases, disorders, genes, and traits that have a simple genetic basis. Research has provided a great deal of information about the inheritance, chromosomal location, biochemical basis, and symptoms of many of these genetic traits, diseases, and disorders. This information is often useful to people who have a genetic condition.

Genetic Counseling

Genetic counseling is a field that provides information to patients with genetic disorders and others who are concerned about hereditary conditions. It is an educational process that helps patients and family members deal with many aspects of having a genetic condition: its diagnosis, symptoms and treatment, and mode of inheritance. Genetic counseling also helps patients and their families cope with the psychological and physical stress that may be

associated with the disorder. Clearly, all of these considerations cannot be handled by a single health professional; most genetic counseling is done by a team that may include genetic counselors, physicians, medical geneticists, and laboratory personnel. Table 6.3 lists some common reasons for seeking genetic counseling.

TABLE 6.3 Common reasons for seeking genetic counseling

1. A person knows of a genetic disease in the family.
2. A couple has given birth to a child with a genetic disease, birth defect, or chromosome abnormality.
3. A couple has a child who is intellectually disabled or has a close relative who is intellectually disabled.
4. An older woman becomes pregnant or wants to become pregnant. There is disagreement about the age at which a prospective mother who has no other risk factors should seek genetic counseling; many experts suggest that it should be age 35 or older.
5. Husband and wife are closely related (e.g., first cousins).
6. A couple experiences difficulties achieving a successful pregnancy.
7. A pregnant woman is concerned about exposure to an environmental substance (drug, chemical, or virus) that causes birth defects.
8. A couple needs assistance in interpreting the results of a prenatal or other test.
9. Both prospective parents are known carriers for a recessive genetic disease or both belong to an ethnic group with a high frequency of a genetic disease.

Genetic counseling usually begins with a diagnosis of a condition that may have a genetic basis. On the bases of a physical examination, biochemical tests, DNA testing, chromosome analysis, family history, and other information, a physician determines the cause of the condition. An accurate diagnosis is critical because appropriate treatment and the probability of passing the condition

on depend on the diagnosis. For example, there are a number of different types of dwarfism, caused by chromosome abnormalities, single-gene mutations, hormonal imbalances, and environmental factors. People who have dwarfism resulting from an autosomal dominant gene have a 50% chance of passing the condition on to their children, whereas people who have dwarfism caused by a rare recessive gene have a low likelihood of doing so.

When the nature of the condition is known, a genetic counselor meets with the patient and members of the patient's family and explains the diagnosis. A family pedigree may be constructed, and the probability of transmitting the condition to future generations can be calculated for different family members. The counselor helps the family interpret the genetic risks and explains various available reproductive options, including prenatal diagnosis, artificial insemination, and in vitro fertilization. Family members often have questions about genetic testing that may be available to help determine whether they carry a particular genetic mutation. The counselor helps them decide whether genetic testing is appropriate for them and which tests to apply. After the test results are in, the genetic counselor usually helps family members interpret the results.

A family's decision about future pregnancies frequently depends on the magnitude of the genetic risk, the severity and effects of the condition, the importance they place on having children, and their religious and cultural views. Traditionally, genetic counselors have

been trained to apply *nondirected* counseling, which means that they provide information and facilitate discussion but do not bring their own opinions and values into the discussion. The goal of nondirected counseling is for the family to reach its own decision on the basis of the best available information.

Because of the growing number of genetic tests available and the complexity of assessing genetic risk, there is now some movement away from completely nondirected counseling. The goal is still to provide the family with information about all options and to reach the decision that is best for them, but that goal may sometimes require the counselor to recommend certain options, much as a physician recommends the most appropriate medical treatments for his or her patient.

Who does genetic counseling? In the United States, over 7000 health professionals are certified in genetics by the American Board of Medical Genetics and Genomics or the American Board of Genetic Counseling. About half of them are specifically trained in genetic counseling, usually through a special two-year master's degree program that provides education in both genetics and counseling. Most of the remainder are physicians and scientists certified in medical or clinical genetics. Because of the shortage of genetic counselors and medical geneticists, information about genetic testing and genetic risk is often conveyed by primary care physicians, nurses, and social workers. **› TRY PROBLEM 10**

CONCEPTS

Genetic counseling is an educational process that provides patients and their families with information about a genetic condition, its medical implications, the mode of inheritance, and reproductive options.

Genetic Testing

The ultimate goal of genetic testing is to recognize the potential for a genetic condition at an early stage. In some cases, genetic testing allows people to make informed choices about reproduction. In other cases, genetic testing allows early intervention that may lessen or even prevent the development of a condition. For those who know that they are at risk for a genetic condition, genetic testing may help alleviate anxiety associated with the uncertainty of their situation. Genetic testing includes prenatal testing and postnatal testing.

Prenatal genetic tests are those that are conducted before birth and now include procedures for diagnosing several hundred genetic diseases and disorders (**Table 6.4**). The major purpose of prenatal tests is to provide families with the information that they need to make choices during pregnancies and, in some cases, to prepare for the birth of a child with a genetic condition. Several approaches to prenatal diagnosis are described in the following sections.

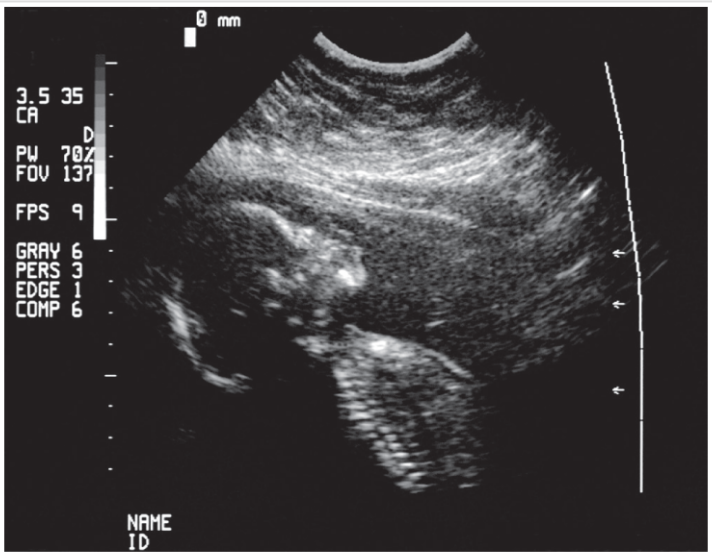
TABLE 6.4 Examples of genetic diseases and disorders that can be detected prenatally and the techniques used in their detection

Disorder	Method of Detection
Chromosome abnormalities	Examination of a karyotype from cells obtained by amniocentesis or chorionic villus sampling. Some forms can be detected by DNA analysis of maternal blood.
Cleft lip and palate	Ultrasound
Cystic fibrosis	DNA analysis of cells obtained by amniocentesis or chorionic villus sampling
Dwarfism	Ultrasound or X-ray; some forms can be detected by DNA analysis of cells obtained by amniocentesis or chorionic villus sampling
Hemophilia	Fetal blood sampling* or DNA analysis of cells obtained by amniocentesis or chorionic villus sampling
Lesch–Nyhan syndrome	Biochemical tests on cells obtained by amniocentesis or chorionic villus sampling
Neural-tube defects	Initial screening with maternal blood test, followed by biochemical tests on amniotic fluid obtained by amniocentesis or by the detection of birth defects with the use of ultrasound
Osteogenesis imperfecta	Ultrasound or X-ray
Phenylketonuria	DNA analysis of cells obtained by amniocentesis or chorionic villus sampling
Sickle-cell anemia	Fetal blood sampling* or DNA analysis of cells obtained by amniocentesis or chorionic villus sampling
Tay–Sachs disease	Biochemical tests on cells obtained by amniocentesis or chorionic villus sampling

*A sample of fetal blood is obtained by inserting a needle into the umbilical cord.

ULTRASONOGRAPHY

Some genetic conditions can be detected through direct visualization of the fetus. This is most commonly done by **ultrasonography**—usually referred to as *ultrasound*. In this technique, high-frequency sound is beamed into the uterus; when the sound waves encounter dense tissue, they bounce back and are transformed into a picture (**Figure 6.14**). In this way, the size and position of the fetus can be determined, and conditions such as neural-tube defects (defects in the development of the spinal column and the skull) and skeletal abnormalities can be detected. Ultrasound is a standard procedure performed during pregnancy to estimate the age of the fetus, determine its sex, and check for the presence of developmental disorders or other problems.

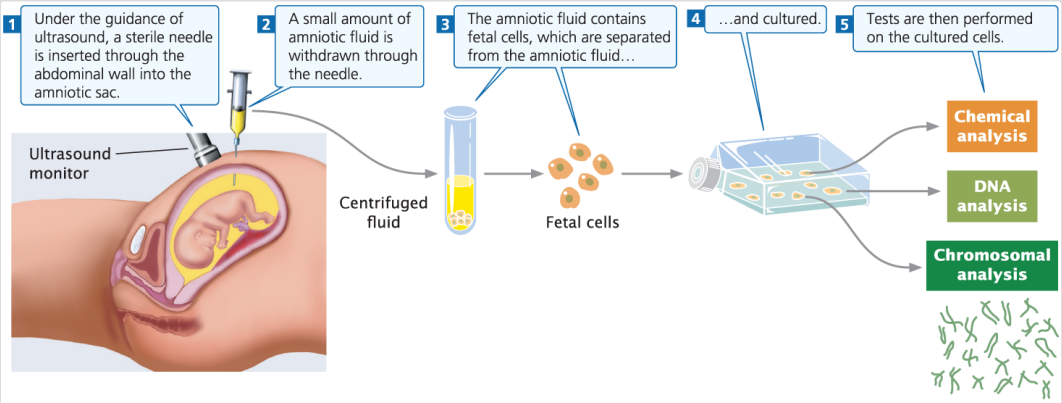


PhotoDisc/Media Bakery.

6.14 Ultrasonography can be used to detect some genetic disorders in a fetus and to locate the fetus during amniocentesis and chorionic villus sampling.

AMNIOCENTESIS

Traditional prenatal testing requires fetal tissue, which can be obtained in several ways. The most widely used method is **amniocentesis**, a procedure for obtaining a sample of amniotic fluid from the uterus of a pregnant woman (Figure 6.15). Amniotic fluid—the substance that fills the amniotic sac and surrounds the developing fetus—contains fetal cells that can be cultured and used for genetic testing.



6.15 Amniocentesis is a procedure for obtaining fetal cells for genetic testing.

Description

The illustration shows a woman's stomach with a fetus inside on the left. An ultrasound monitor is placed on top of the stomach and a needle is inserted into the amniotic sac. The first caption pointing towards the ultrasound monitor reads, "Under the guidance of ultrasound, a sterile needle is inserted through the abdominal wall into the amniotic sac." The second caption pointing towards the needle reads, "A small amount of amniotic fluid is withdrawn through the needle." Centrifuged fluid obtained from the needle is then transferred to a test tube on the right. The third caption reads, "The amniotic fluid contains fetal cells, which are separated from the amniotic fluid and cultured." Round-shaped fetal cells are obtained from amniotic fluid and cultured. The culture is eventually sent for chemical analysis, D N A analysis, and chromosomal analysis. The final caption reads, "Tests are then performed on the cultured cells."

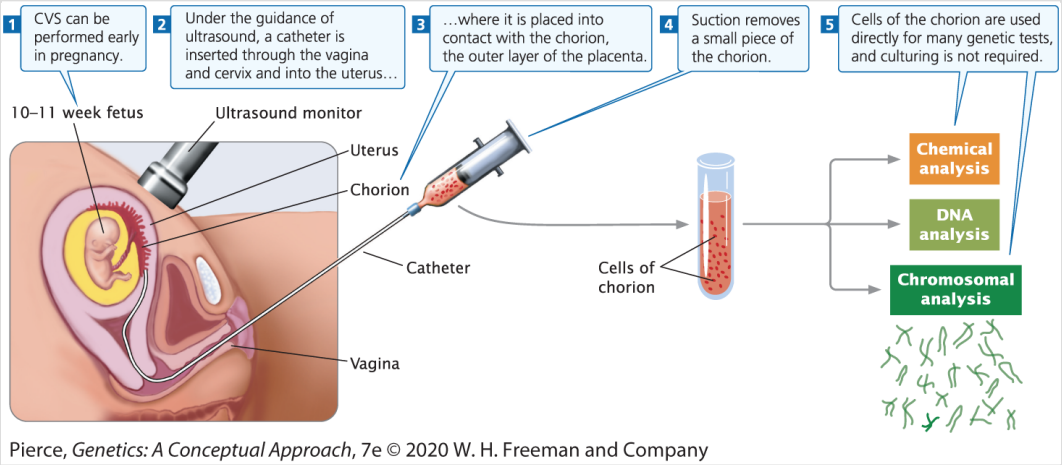
Amniocentesis is routinely performed as an outpatient procedure either with or without the use of a local anesthetic (see Figure 6.15). Genetic tests are then performed on the cultured cells. Complications with amniocentesis (mostly miscarriage) are uncommon, arising in only about 1 in 1600 procedures.

CHORIONIC VILLUS SAMPLING

A major disadvantage of amniocentesis is that it generally cannot be performed until about the 15th to 18th week of a pregnancy (although some obstetricians successfully perform amniocentesis earlier). The cells obtained by amniocentesis must then be cultured before genetic tests can be performed, which requires yet more time. For these reasons, genetic information about the fetus may not be available until the 17th or 18th week of pregnancy. By this stage, if abortion is chosen, it carries a greater risk of complications and is often stressful for the parents. **Chorionic villus sampling (CVS)** can be performed earlier (between the 10th and 12th weeks of pregnancy) and collects a larger amount of fetal tissue, which eliminates the necessity of culturing the cells.

In CVS, a catheter—a soft plastic tube—is placed in contact with the chorion, the outer layer of the placenta (**Figure 6.16**). Suction is then applied, and a small piece of the chorion is removed. Although the chorion is composed of fetal cells, it is a part of the placenta, which is expelled from the uterus after birth; the tissue that is removed is not actually from the fetus. This tissue contains millions of actively

dividing cells that can be used directly in many genetic tests. Chorionic villus sampling has a somewhat higher risk of complications than amniocentesis; the results of several studies suggest that this procedure may increase the incidence of limb defects in the fetus when performed earlier than the 10th week of pregnancy.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

6.16 Chorionic villus sampling (CVS) is another procedure for obtaining fetal cells for genetic testing.

Description

The illustration shows a woman's uterus with a fetus inside on the left. The fetus is labeled as 10 to 11 weeks old. The illustration also shows vagina and chorion marked. The ultra sound monitor is placed on top of the stomach. A thin tube known as catheter is attached to a syringe and is inserted into the vagina and threads through the inner cavity to the right side of the fetus. The first caption pointing towards 10 to 11 week fetus reads, "C V S can be performed early in pregnancy." The second caption reads, "Under the guidance of ultrasound, a catheter is inserted through the vagina and cervix and into the uterus where it is placed into contact with the chorion, the outer layer of the placenta." The next caption pointing towards the syringe reads, "Suction removes a small piece of the chorion." Cells of chorion are obtained from the syringe and are placed in a test tube on the right. These cells are eventually sent for chemical analysis, D N A analysis, and chromosomal analysis.

> The final caption reads, “Cells of the chorion are used directly for many genetic tests, and culturing is not required.”

Fetal cells obtained by amniocentesis or by CVS can be used to prepare a **karyotype**, which is a picture of a complete set of metaphase chromosomes. Karyotypes can be studied for chromosome abnormalities (see Chapter 8). Biochemical analyses can be conducted on fetal cells to determine the presence of particular metabolic products of genes. To detect genetic diseases for which the DNA sequence of the causative gene has been determined, the DNA sequence (DNA testing; see Chapter 19) can be examined for defective alleles.

MATERNAL BLOOD SCREENING TESTS

Increased risk of some genetic conditions can be detected by examining levels of certain substances in the blood of the mother (referred to as a **maternal blood screening tests**). However, these tests do not determine the presence of a genetic problem; rather, they simply indicate that the fetus is at increased risk of a problem and hence are referred to as *screening* tests. When increased risk is detected, follow-up tests (additional blood screening tests, ultrasound, amniocentesis, or all three) are usually conducted.

One substance examined in maternal blood screening tests is α-fetoprotein, a protein that is normally produced by the fetus during

development and is present in fetal blood, amniotic fluid, and the mother's blood during pregnancy. The level of α-fetoprotein is significantly higher than normal when the fetus has a neural-tube defect or one of several other disorders. Some chromosome abnormalities produce lower-than-normal levels of α-fetoprotein. Measuring the amount of α-fetoprotein in the mother's blood gives an indication of these conditions.

One typical test, carried out between the 9th and 13th weeks of pregnancy, measures human chorionic gonadotropin (hCG, a pregnancy hormone) and a substance called pregnancy-associated plasma protein A (PAPP-A). When the fetus has certain chromosome abnormalities, the level of PAPP-A tends to be low and the level of hCG tends to be high. The risk of a chromosome abnormality is calculated on the basis of the levels of hCG and PAPP-A in the mother's blood along with the results of ultrasound. Another test, referred to as the quad screen, is usually conducted in the second trimester of pregnancy and measures the levels of four substances: α-fetoprotein, hCG, estriol, and inhibin. The risk of chromosome abnormalities and certain other birth defects is calculated on the basis of the combined levels of the four substances plus the mother's age, weight, ethnic background, and number of fetuses. The quad screen successfully detects Down syndrome (due to three copies of chromosome 21) approximately 80% of the time and has a false positive rate of about 5%.

NONINVASIVE PRENATAL SCREENING

Prenatal tests that use only maternal blood are highly desirable because they are noninvasive and pose no risk to the fetus. In addition to maternal blood screening tests, which measure chemical substances produced by the fetus or placenta, these noninvasive tests include procedures collectively called **noninvasive prenatal screening (NIPS)**, which directly examines fetal DNA found in maternal blood. These tests can be performed as early as the 9th to 10th week of pregnancy.

During pregnancy, a few fetal cells are released into the mother's circulatory system, where they mix with and circulate with her blood. When these fetal cells break down, they release free-floating fragments of fetal DNA, which can be sequenced and analyzed. By comparing the number of copies of genetic variants found on different chromosomes, it is possible to determine if there are extra copies of some fetal chromosomes present and therefore to screen for Down syndrome, trisomy 18, trisomy 13, and other chromosome abnormalities (see Chapter 8) in the fetus. When a chromosome abnormality is detected, diagnosis is confirmed with amniocentesis or chorionic villus sampling. Research suggests that noninvasive prenatal screening for Down syndrome is more accurate and has a much lower false positive rate than traditional maternal blood screening procedures that rely on levels of substances such as α-fetoprotein, hCG, estriol, and inhibin. Recently, researchers used measurement of cell-free fetal RNA (see RNA sequencing in Chapter

20) to accurately estimate gestational age and estimate the risk of preterm birth.

Prenatal genetic screening tests based on DNA in the mother's blood occasionally reveal information about the mother's genetic makeup or health. For example, sometimes DNA analysis detects the presence of a Y chromosome, but ultrasound reveals a female fetus. In a few rare instances, this finding is due to a previously undiagnosed sex chromosome anomaly of the mother (although there are other potential explanations as well). Occasionally, testing can reveal the presence of undiagnosed cancer in the mother. Whether and how this type of incidental genetic information should be conveyed to the mother, who did not request genetic testing on herself, remains the subject of discussion among genetic counselors.

Noninvasive prenatal screening technology creates the potential in the future to use a single blood sample from the mother to test for hundreds of genetic diseases and even for ordinary traits in the fetus. At the present time, this is technically difficult and beyond routine clinical practice due to the confounding effects of maternal DNA, but researchers have demonstrated that they can sequence the entire fetal genome from a maternal blood sample. This possibility raises a number of social and ethical questions about the use of such information in reproductive decisions.

PREIMPLANTATION GENETIC DIAGNOSIS

Prenatal genetic tests provide today's prospective parents with increasing amounts of information about the health of their future children. New reproductive technologies provide couples with options for using this information. One of these technologies is in vitro fertilization. In this procedure, hormones are used to induce ovulation. The ovulated eggs are surgically removed from the surface of the ovary, placed in a laboratory dish, and fertilized with sperm. The resulting embryo is then implanted in the uterus. Thousands of babies resulting from in vitro fertilization have now been born.

Genetic testing can be combined with in vitro fertilization to allow the implantation of embryos that are free of a specific genetic defect. Called **preimplantation genetic diagnosis (PGD)**, this technique enables people who carry a genetic defect to avoid producing a child with the disorder. For example, if a woman is a carrier of an X-linked recessive disease, approximately half of her sons are expected to have the disease. Through in vitro fertilization and PGD, an embryo without the disorder can be selected for implantation in her uterus.

The procedure begins with the production of several single-celled embryos through in vitro fertilization. The embryos are allowed to divide several times until they reach the 8- or 16-cell stage. At this point, one cell is removed from each embryo and tested for the genetic abnormality. Removing a single cell at this early stage does not harm the embryo. Once the embryos that are free of the disorder

have been identified, a healthy embryo is selected and implanted in the woman's uterus.

Preimplantation genetic diagnosis requires the ability to conduct genetic testing on a single cell. Such testing is possible with the use of the polymerase chain reaction, through which minute quantities of DNA can be amplified (replicated) quickly (see Chapter 19). Once the cell's DNA has been amplified, the DNA sequence is examined. Preimplantation genetic diagnosis has resulted in the birth of thousands of healthy children. Its use raises a number of ethical concerns because it can be used as a means of selecting for or against genetic traits that have nothing to do with medical concerns. For example, it can potentially be used to select for a child with genes for a certain eye color or genes for increased height.

NEWBORN SCREENING

Testing for genetic disorders in newborn infants is called **newborn screening**. All states in the United States and many other countries require by law that newborn infants be tested for some genetic diseases and conditions. The Secretary of the U.S. Department of Health and Human Services recommends mandatory screening for 35 genetic conditions (**Table 6.5**), and many states use this list for newborn testing. These genetic conditions were chosen because early identification can lead to effective treatment. For example, as mentioned in Chapter 5, phenylketonuria is an autosomal recessive disease that, if not treated at an early age, can result in intellectual

disability. But early intervention, through the administration of a modified diet, prevents this outcome.

TABLE 6.5 Genetic conditions recommended for screening in newborns by the Secretary of the U.S. Department of Health and Human Services (The Recommended Uniform Screening Panel Core Conditions, as of July 2018)

Genetic Condition
Propionic acidemia
Methylmalonic acidemia (methylmalonyl-CoA mutase)
Methylmalonic acidemia (cobalamin disorders)
Isovaleric acidemia
3-Methylcrotonyl-CoA carboxylase deficiency
3-Hydroxy-3-methyglutaric aciduria
Holocarboxylase synthase deficiency
β-Ketothiolase deficiency
Glutaric acidemia type I
Carnitine uptake defect/carnitine transport defect
Medium-chain acyl-CoA dehydrogenase deficiency
Very long-chain acyl-CoA dehydrogenase deficiency
Long-chain L-3 hydroxyacyl-CoA dehydrogenase deficiency
Trifunctional protein deficiency
Argininosuccinic aciduria
Citrullinemia, type I
Maple syrup urine disease
Homocystinuria
Classic phenylketonuria
Tyrosinemia, type I

Primary congenital hypothyroidism
Congenital adrenal hyperplasia
S,S disease (sickle cell anemia)
S, β-thalassemia
S,C disease
Biotinidase deficiency
Critical congenital heart disease
Cystic fibrosis
Classic galactosemia
Glycogen storage disease type II (Pompe)
Hearing loss
Severe combined immunodeficiencies
Mucopolysaccharidosis type 1
X-linked adrenoleukodystrophy
Spinal muscular atrophy due to homozygous deletion of exon 7 in SMN1

From: https://www.hrsa.gov/advisory-committees/heritable-disorders/rusp/index.html

PRESYMPTOMATIC GENETIC TESTING

In addition to testing for genetic diseases in fetuses and newborns, testing of healthy adults for genes that might predispose them to a genetic condition in the future is possible. This type of testing is known as **presymptomatic genetic testing**. For example, presymptomatic testing is available for members of families in which an autosomal dominant form of breast cancer occurs. In this case, early identification of the disease-causing allele allows for closer surveillance and the early detection of tumors.

Presymptomatic testing is also available for some genetic diseases for which no treatment is available, such as Huntington disease, an autosomal dominant disease that leads to slow physical and mental deterioration in middle age.

HETEROZYGOTE SCREENING

Another form of genetic testing in adults is **heterozygote screening**. In this type of screening, members of a population are tested to identify heterozygous carriers of recessive disease-causing alleles—people who are healthy but have the potential to produce children with a particular disease.

Testing for Tay–Sachs disease is a successful example of heterozygote screening. In the general population of North America, the frequency of Tay–Sachs disease is only about 1 person in 360,000. Among Ashkenazi Jews (descendants of Jewish people who settled in eastern and central Europe), the frequency is 100 times greater. A simple blood test is used to identify Ashkenazi Jews who carry the allele for Tay–Sachs disease. If a man and woman are both heterozygotes, approximately one-fourth of their children are expected to have Tay–Sachs disease. Couples identified as heterozygous carriers may use that information in deciding whether to have children. A prenatal test is also available for determining if the fetus of an at-risk couple will have Tay–Sachs disease. Screening programs have led to a significant decline in the number of children

of Ashkenazi ancestry born with Tay–Sachs disease (now fewer than 10 children per year in the United States).

PHARMACOGENETIC TESTING

Genetic testing is becoming increasingly important in guiding drug treatment. In some cases, a drug's effectiveness is influenced by a patient's genotype; in other cases, individuals with certain genotypes may be more likely to suffer from adverse drug reactions.

Warfarin provides a good example of how genetic testing can be used in conjunction with drug treatment. Warfarin is the most common anticoagulant (blood thinner) used worldwide. It is often administered to people with certain heart problems and after surgery to prevent the formation of clots in the blood vessels, which can obstruct blood flow and lead to tissue death. An effective dose of warfarin is critical: too little, and blood clots are not prevented; too much, and internal bleeding results. Unfortunately, people vary greatly in their responses to warfarin, and some of this variation is due to genes. For example, *CYP2C9* is a gene that encodes an enzyme that metabolizes warfarin. Over 30 different alleles occur at this locus. People who are homozygous for the *CYP2C9*1* allele metabolize warfarin normally, but individuals who are homozygous or heterozygous for the *CYP2CP9*2* or *CYP2CP9*3* alleles metabolize warfarin at a much lower rate and therefore require a lower dose. If given the usual dose of warfarin, these people are at greater risk of

bleeding. Genetic variation at *CYP2CP* and another locus called *VKORC1* accounts for up to 30% of the variation in response to warfarin dose and risk of bleeding. Some hospitals are screening patients for variation at these genes to help determine the proper warfarin dose to administer. A study conducted by Vanderbilt University in Nashville, Tennessee, found that over 90% of all patients carried one or more genetic variants that affected their response to five common drugs, including warfarin. **› TRY PROBLEM 12**

THINK-PAIR-SHARE Questions 7 and 8

CONCEPTS

Genetic testing is used to screen newborns for genetic diseases, detect individuals who are heterozygous for recessive diseases, detect disease-causing alleles in those who have not yet developed symptoms of a disease, and detect defective alleles in unborn babies. Preimplantation genetic diagnosis combined with in vitro fertilization allows for the selection of embryos that are free from specific genetic diseases. Genetic testing is also being used to guide individual drug treatment.

✔ CONCEPT CHECK 9

How does preimplantation genetic diagnosis differ from prenatal genetic testing?

Interpreting Genetic Tests

Today, more than a thousand genetic tests are clinically available, and several hundred more are available through research studies. Future research will greatly increase the number and complexity of genetic tests. Many of these tests will be for complex multifactorial diseases that are influenced by both genetics and environment, such as coronary artery disease, diabetes, asthma, some types of cancer, and depression.

Interpreting the results of genetic tests is often complicated by several factors. First, some genetic diseases can be caused by many different mutations. For example, more than a thousand different mutations at a single locus can cause cystic fibrosis, an autosomal recessive disease in which chloride ion transport is defective (see Chapter 5). Genetic tests typically screen for only the most common mutations; uncommon and rare mutations are not detected. Therefore, a negative result does not mean that a genetic defect is absent; it indicates only that the person being tested does not have one of the common mutations. The DNA of an affected person can be examined to determine the nature of the mutation, and other family members can then be screened for the same mutation, but this option is not possible if affected family members are unavailable or unwilling to be tested.

A second problem lies in interpreting the results of genetic tests. For a classic genetic disease such as Tay–Sachs disease, the inheritance of two copies of the gene virtually ensures that a person will have the disease. However, this is not the case for many genetic diseases

for which penetrance is incomplete and environmental factors play a role. For these conditions, carrying a disease-predisposing mutation only elevates a person's risk of acquiring the disease. The risk associated with a particular mutation is a statistical estimate, based on the average effect of the mutation on many people. In this case, the calculated risk may provide little useful information to a specific person. It is also important to keep in mind that for many genetic traits and disorders, no genetic test exists.

CONCEPTS

Interpreting genetic tests is complicated by the presence of multiple causative mutations, incomplete penetrance, and the influence of environmental factors.

Direct-to-Consumer Genetic Testing

Genome sequencing and new molecular technologies now make it possible to determine a person's risk of a large number of diseases and disorders. **Direct-to-consumer genetic tests** attempt to make this information available to any consumer, without involving a health-care provider. Several companies sold such tests in the United States prior to 2013, when their sale was restricted by the U.S. Food and Drug Administration (FDA). In 2017, the FDA began allowing direct-to-consumer genetic tests that provide information on predisposition to certain diseases. These tests are potentially

capable of screening for a large array of genetic conditions in adults and children—everything from single-gene disorders such as cystic fibrosis to multifactorial conditions such as obesity, cardiovascular disease, potential for athletic performance, and predisposition to nicotine addiction.

Most direct-to-consumer genetic tests are advertised and ordered through the Internet. Geneticists, public-health officials, and consumer advocates have raised a number of concerns about direct-to-consumer genetic testing, including concerns that some tests are offered without appropriate information and genetic counseling and that consumers are often not equipped to interpret the results. Direct-to-consumer tests are also available for paternity testing and for determining ancestry (see next section). › **TRY** PROBLEM 15

THINK-PAIR-SHARE Question 9

Genealogies and Genetic Testing for Ancestry

Many people are curious about their ancestry. A number of Web sites facilitate the collection of genealogical records, with over 100 million users in 2018. Some of these genealogical databases automatically detect similarities between family trees and offer the option to merge family records from different sources, creating very

large groups with thousands or even millions of individuals connected by shared ancestry. In addition, DNA tests are available to help people study their ancestry. For example, the Genographic Project, sponsored by National Geographic, determines ancient ancestry based on DNA testing; it provides information on regional ancestry—the proportion of one's genome that comes from nine ancestral source populations—as well as the presence of any Neanderthal DNA in one's genome. Other databases compile data from genetic testing to help people find their biological relatives.

Researchers have begun to use genealogical and ancestry databases for examining questions about human genetics and evolution, including the inheritance of traits, the genetic structure of populations, migration, and changing patterns of relatedness and fertility. For example, researchers examined over 60,000 participants of direct-to-consumer genetic testing to study the genetics of earlobe attachment and demonstrated that—contrary to common wisdom—free versus attached earlobes are not inherited as a simple genetic trait; rather, this trait is polygenic and determined by variation at a number of different genes. The use of these databases for research and other purposes has, however, raised ethical concerns about using the information in ways that were not anticipated by the participants.

Genetic Discrimination and Privacy

With the development of so many new genetic tests, concerns have been raised about the privacy of genetic information and the potential for genetic discrimination. Research shows that many people at risk for genetic diseases avoid genetic testing because they fear that the results would make it difficult for them to obtain insurance or that the information might adversely affect their employability. Some of those who do seek genetic testing pay for it themselves and use aliases to prevent the results from becoming part of their health records. Fears about genetic discrimination have been reinforced by past practices. In the 1970s, some people who were identified as carriers of sickle-cell anemia (an autosomal recessive disorder that is common among African Americans) faced employment discrimination and had difficulty obtaining health insurance, in spite of the fact that carriers are healthy.

In response to these concerns, the U.S. Congress passed the **Genetic Information Nondiscrimination Act (GINA)** in 2008. This law prohibits health insurers from using genetic information to make decisions about health-insurance coverage and rates. It also prevents employers from using genetic information in employment decisions and prohibits health insurers and employers from asking or requiring a person to take a genetic test. Results of genetic testing receive some degree of protection by other federal regulations that cover the uses and disclosure of individual health information. However, GINA covers health insurance and employment only; it does not apply to life, disability, and long-term care insurance. › **TRY PROBLEM 16**

CONCEPTS

The growing number of genetic tests and their increasing complexity have raised several concerns, including concerns about genetic discrimination and the privacy of test results.

Chapter 6 Review

CHAPTER SUMMARY

Section 6.1 Learning Objective: Be able to explain why pedigrees are often used in the study of human genetics.

- Constraints on the genetic study of human traits include the inability to conduct controlled crosses, long generation time, small family size, and the difficulty of separating genetic and environmental influences. Pedigrees are often used to study the inheritance of traits in humans.

Section 6.2 Learning Objective: Be able to use pedigrees to analyze the genetic basis of traits in humans.

- Special symbols and formats are used to construct pedigrees.
- Autosomal recessive traits typically appear with equal frequency in both sexes and tend to skip generations. When both parents are heterozygous for a particular autosomal recessive trait, approximately one-fourth of their offspring will have the trait. Recessive traits are more likely to appear in families with consanguinity (mating between closely related people).

- Autosomal dominant traits usually appear equally in both sexes and do not skip generations. When one parent is affected and heterozygous for an autosomal dominant trait, approximately half of the offspring will have the trait. Unaffected people do not normally transmit an autosomal dominant trait to their offspring.
- X-linked recessive traits appear more frequently in males than in females. When a woman is a heterozygous carrier for an X-linked recessive trait and a man is unaffected, approximately half of their sons will have the trait and half of their daughters will be unaffected carriers. X-linked traits are not passed from father to son.
- X-linked dominant traits appear in both males and females but more frequently in females. They do not skip generations. Affected men pass an X-linked dominant trait to all their daughters but none of their sons. Heterozygous women pass the trait to half of their sons and half of their daughters.
- Y-linked traits appear only in males and are passed from a father to all his sons.

Section 6.3 Learning Objective: Be able to explain how twins and adoption studies are used to assess the role of genetic and environmental factors in human traits.

- A trait's higher concordance in monozygotic than in dizygotic twins indicates a genetic influence on the trait; less than 100% concordance in monozygotic twins indicates environmental influences on the trait.

- Similarities between adopted children and their biological parents indicate the importance of genetic factors in the expression of a trait; similarities between adopted children and their genetically unrelated adoptive parents indicate the influence of environmental factors.

Section 6.4 Learning Objective: Be able to describe genetic counseling and explain how genetic testing is used to help people concerned about genetic traits.

- Genetic counseling provides information and support to people concerned about hereditary conditions in their families.
- Genetic testing includes prenatal diagnosis, screening for disease-causing alleles in newborns, the detection of people heterozygous for recessive alleles, presymptomatic testing for the presence of a disease-causing allele in at-risk people, and testing to evaluate the effectiveness and safety of drug treatment.
- The interpretation of genetic tests may be complicated by the presence of numerous causative mutations, incomplete penetrance, and the influence of environmental factors.
- The availability of direct-to-consumer genetic tests has raised concerns about the adequacy of the information provided and the absence of genetic counseling. Genealogical Web sites and genetic tests provide information about ancestry and are sometimes used to find biological relatives.
- Genetic testing has raised concerns about genetic discrimination and the privacy of test results. The Genetic Information Nondiscrimination Act prohibits the use of genetic

information in decisions on health insurability and employment.

WORKED PROBLEMS

Problem 1

Joanna has "short fingers" (brachydactyly). She has two older brothers who are identical twins; both have short fingers. Joanna's two younger sisters have normal fingers. Joanna's mother has normal fingers, and her father has short fingers. Joanna's paternal grandmother (her father's mother) has short fingers; her paternal grandfather (her father's father), who is now deceased, had normal fingers. Both of Joanna's maternal grandparents (her mother's parents) have normal fingers. Joanna marries Tom, who has normal fingers; they adopt a son named Bill, who has normal fingers. Bill's biological parents both have normal fingers. After adopting Bill, Joanna and Tom produce two children: an older daughter with short fingers and a younger son with normal fingers.

a. Using standard symbols and labels, draw a pedigree illustrating the inheritance of short fingers in Joanna's family.
b. What is the most likely mode of inheritance for short fingers in this family?
c. If Joanna and Tom have another biological child, what is the probability (based on your answer to part *b*) that this child will have short fingers?

» Solution Strategy

What information is required in your answer to the problem?

a. A pedigree to represent the family, drawn with correct symbols and labeling.
b. The most likely mode of inheritance for short fingers.
c. The probability that Joanna and Tom's next child will have short fingers.

What information is provided to solve the problem?

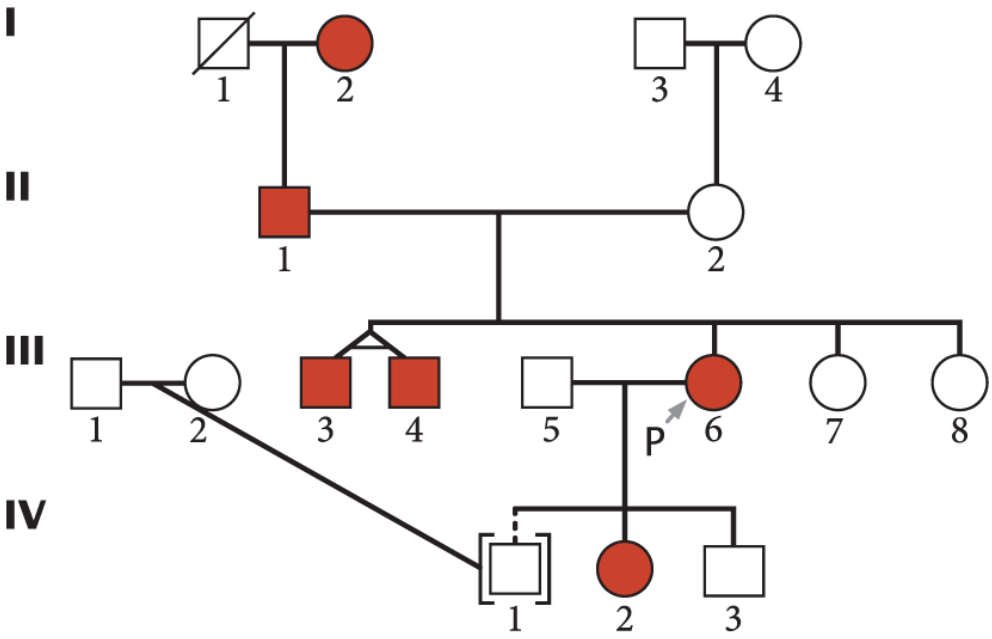
The phenotypes of Joanna and Tom and their family members.

For help with this problem, review:

The information on pedigrees in Section 6.2.

» Solution Steps

a. In the pedigree for the family, use filled circles (females) and filled squares (males) to represent family members with the trait of interest (short fingers). Connect Joanna's identical twin brothers to the line above by drawing diagonal lines that have a horizontal line between them. Enclose Bill, the adopted child of Joanna and Tom, in brackets; connect him to his biological parents by drawing a diagonal line and to his adoptive parents by a dashed line.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

Generation 1 shows two couples, couple 1 has an unaffected male crossed out and an affected female. Couple 2 has both unaffected male and female. Couple 1 mates and has an affected son in generation 2. Couple 2 mates and has an unaffected daughter. Both these offspring in generation 2 mate and have 1 affected daughter who is a proband, 2 unaffected daughter, and a pair of affected identical twin sons in generation 3. Another couple in generation 3 has unaffected male and unaffected female. They mate and have an unaffected son in generation 4. The proband female from generation 3 mates with an unaffected male and has 1 affected daughter, 1 unaffected son and adopts the unaffected son of the unaffected couple from generation 3.

Hint: See Figure 6.2 for a review of symbols used in a pedigree.

b. The most likely mode of inheritance for short fingers in this family is autosomal dominant. The trait appears equally in

males and females and does not skip generations. When one parent has the trait, it appears in approximately half of that parent's sons and daughters, although the number of children in the families is small. We can eliminate Y-linked inheritance because the trait is found in females as well as males. If short fingers were X-linked recessive, females with the trait would be expected to pass the trait to all their sons, but Joanna (III-6), who has short fingers, produced a son with normal fingers. For X-linked dominant traits, affected men should pass the trait to all their daughters; because male II-1 has short fingers and produced two daughters without short fingers (III-7 and III-8), we know that the trait cannot be X-linked dominant. The trait is unlikely to be autosomal recessive because it does not skip generations and because approximately half the children of affected parents have the trait.

See Table 6.1 for a review of the characteristics of different modes of inheritance.

c. If having short fingers is an autosomal dominant trait, Tom must be homozygous (*bb*) because he has normal fingers. Joanna must be heterozygous (*Bb*) because she and Tom have produced both short-fingered and normal-fingered offspring. In a cross between a heterozygote and a homozygote, half the progeny are expected to be heterozygous and the other half homozygous ($Bb \times bb \rightarrow {}^1/_2Bb, {}^1/_2bb$), so the probability that Joanna and Tom's next biological child will have short fingers is ${}^1/_2$.

Problem 2

Concordance for a series of traits was measured in monozygotic twins and dizygotic twins; the results are shown in the following table. For each trait, indicate whether the concordances suggest genetic influences, environmental influences, or both. Explain your reasoning.

		Concordance (%)	
	Characteristic	**Monozygotic**	**Dizygotic**
a.	ABO blood type	100	65
b.	Diabetes	85	36
c.	Coffee drinking	80	80
d.	Smoking	75	42
e.	Schizophrenia	53	16

» Solution Strategy

What information is required in your answer to the problem?

For each trait, whether it is influenced by genetic factors, environmental factors, or both.

What information is provided to solve the problem?

Concordance for each trait in monozygotic and dizygotic twins.

For help with this problem, review:

Concordance in Twins in Section 6.3.

» Solution Steps

a. The concordance for ABO blood type in monozygotic twins is 100%. This high concordance in monozygotic twins does not, by itself, indicate a genetic basis for the trait. Because concordance for ABO blood type is substantially lower in dizygotic twins, we would be safe in concluding that genes play a role in determining differences in ABO blood types.

> **Recall:** The influence of genetic factors on the trait is indicated by higher concordance in monozygotic twins than dizygotic twins.

b. The concordance for diabetes is substantially higher in monozygotic twins than in dizygotic twins; therefore, we can conclude that genetic factors play some role in susceptibility to diabetes. The fact that monozygotic twins show a concordance less than 100% suggests that environmental factors also play a role.

> **Recall:** Less than 100% concordance in monozygotic twins indicates that environmental factors play a role in the trait.

c. Both monozygotic and dizygotic twins exhibit the same high concordance for coffee drinking, so we can conclude that there

is little genetic influence on coffee drinking. The fact that monozygotic twins show a concordance less than 100% suggests that environmental factors play a role.

d. The concordance for smoking is lower in dizygotic twins than in monozygotic twins, so genetic factors appear to influence the tendency to smoke. The fact that monozygotic twins show a concordance less than 100% suggests that environmental factors also play a role.
e. Monozygotic twins exhibit substantially higher concordance for schizophrenia than do dizygotic twins, so we can conclude that genetic factors influence this psychiatric disorder. Because the concordance of monozygotic twins is substantially less than 100%, we can conclude that environmental factors play a role in the disorder as well.

IMPORTANT TERMS

pedigree

monozygotic twins
concordance
genetic counseling
ultrasonography
amniocentesis

chorionic villus sampling (CVS)
karyotype
maternal blood screening test
noninvasive prenatal genetic screening (NIPS)
preimplantation genetic diagnosis (PGD)
newborn screening
presymptomatic genetic testing
heterozygote screening
direct-to-consumer genetic test
Genetic Information Nondiscrimination Act (GINA)

ANSWERS TO CONCEPT CHECKS

1. b
2. It might skip generations when a new mutation arises or the trait has incomplete penetrance.
3. If it is X-linked recessive, the trait will not be passed from father to son.
4. c
5. If the trait were Y linked, an affected male would pass it on to all his sons, whereas if the trait were autosomal and sex-limited, affected heterozygous males would pass it on to only half of their sons on average.
6. d
7. c
8. d

9. Preimplantation genetic diagnosis determines the presence of disease-causing genes in an embryo at an early stage, before the embryo is implanted in the uterus and initiates pregnancy. Prenatal genetic testing determines the presence of disease-causing genes or chromosomes in a developing fetus.

Chapter 6 Assessment

COMPREHENSION QUESTIONS

Section 6.1

1. What three factors complicate the task of studying the inheritance of human characteristics?

Section 6.2

2. Who is the proband in a pedigree? Is the proband always found in the last generation of the pedigree? Why or why not?

3. For each of the following modes of inheritance, describe the features that will be exhibited in a pedigree in which the trait is present: autosomal recessive, autosomal dominant, X-linked recessive, X-linked dominant, and Y-linked inheritance.

4. How does the pedigree of an autosomal recessive trait differ from the pedigree of an X-linked recessive trait?

5. Other than the fact that a Y-linked trait appears only in males, how does the pedigree of a Y-linked trait differ from the pedigree of an autosomal dominant trait?

Section 6.3

6. What are the two types of twins, and how do they arise?

7. Explain how a comparison of concordance in monozygotic and dizygotic twins can be used to determine the extent to which the expression of a trait is influenced by genes or by environmental factors.

8. How are adoption studies used to separate the effects of genes and environment in the study of human characteristics?

Section 6.4

9. What is genetic counseling?

10. *Give at least four different reasons for seeking genetic counseling.

11. Briefly define newborn screening, heterozygote screening, presymptomatic genetic testing, and prenatal diagnosis.

12. *Compare the advantages and disadvantages of amniocentesis versus chorionic villus sampling for prenatal diagnosis.

13. What is preimplantation genetic diagnosis?

14. How does heterozygote screening differ from presymptomatic genetic testing?

15. *What are direct-to-consumer genetic tests? What are some of the concerns about these tests?

16. *What activities does the Genetic Information Nondiscrimination Act prohibit?

17. How might genetic testing lead to genetic discrimination?

APPLICATION QUESTIONS AND PROBLEMS

Section 6.1

18. *If humans have characteristics that make them unsuitable for genetic analysis, such as long generation time, small family size, and uncontrolled crosses, why do geneticists study humans? Give several reasons why humans have been the focus of so much genetic study.

Section 6.2

19. *Joe is color blind. Both his mother and his father have normal color vision, but his mother's father (Joe's maternal grandfather) is color blind. All Joe's other grandparents have normal color vision. Joe has three sisters—Patty, Betsy, and Lora—all with normal color vision. Joe's oldest sister, Patty, is married to a man with normal color vision; they have two children: a 9-year-old color-blind boy and a 4-year-old girl with normal color vision.

a. Using standard symbols and labels, draw a pedigree of Joe's family.

b. What is the most likely mode of inheritance for color blindness in Joe's family?

c. If Joe marries a woman who has no family history of color blindness, what is the probability that their first child will be a color-blind boy?

d. If Joe marries a woman who is a carrier of the color-blind allele, what is the probability that their first child will be a color-blind boy?

e. If Patty and her husband have another child, what is the probability that the child will be a color-blind boy?

20. Consider the pedigree shown in **Figure 6.3a**.

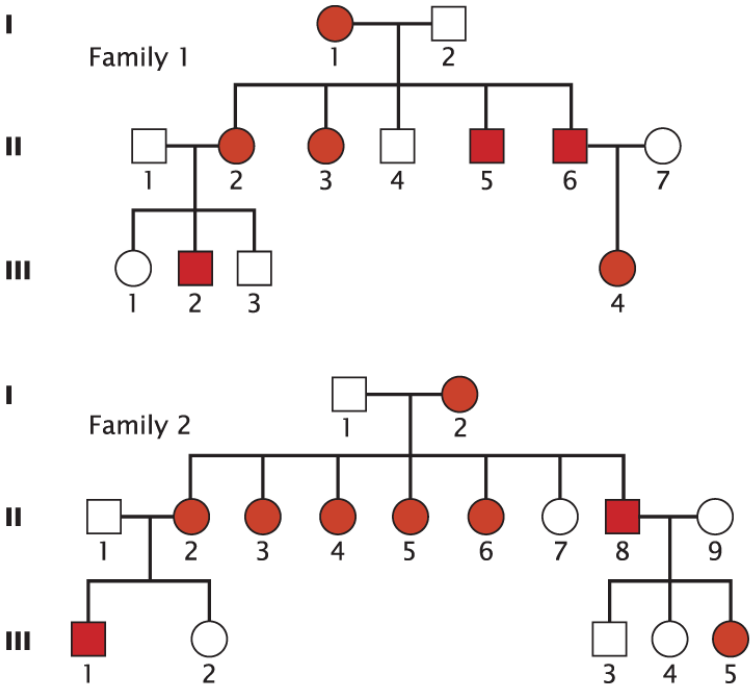
a. If individual IV-7 married a person who was unaffected with Waardenburg syndrome, what is the probability that their first child would have Waardenburg syndrome? Explain your reasoning.

b. If individuals IV-4 and IV-5 mated and produced a child, what is the probability that the child would have Waardenburg syndrome? Explain your reasoning.

21.

Many studies have suggested a strong genetic predisposition to migraine headaches, but the mode of inheritance is not clear. L. Russo and colleagues examined

migraine headaches in several families, two of which are shown below. What is the most likely mode of inheritance for migraine headaches in these families? Explain your reasoning.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

(Data from L. Russo et al. 2005. *American Journal of Human Genetics* 76:327–333)

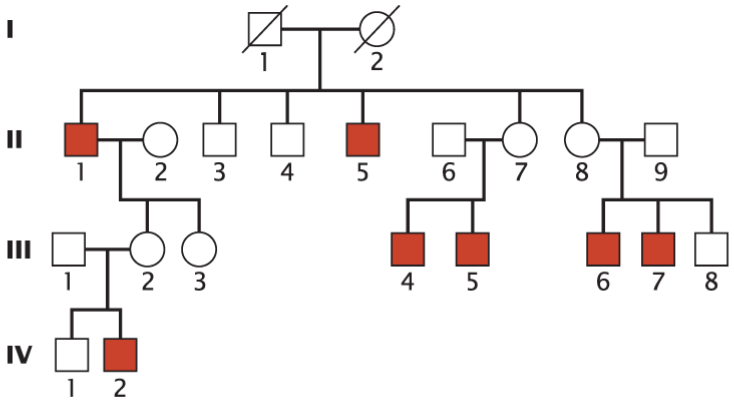
Description

In the case of first family shown at the top: in generation 1, the female is affected and passes the trait on to 4 of 5 children. Half of the affected children are boys and half are girls. Only one affected male and female have children. The female has three children, one of which, a male, is affected with the trait. For the other child in generation 2, he has one female child who is also affected with the trait. In the case of second family shown below: in generation 1, the female is affected and passes the trait on to 6 of 7 children. Six of 7 children are girls. Five of the girls and the one boy are affected with the trait. Only one affected male and female have children. The female has two children, one of which, a male, is affected. For the other male child in generation 2, he has three children, and one, a female displays the trait.

22. DATA ANALYSIS *Dent disease is a rare disorder of the kidney in which reabsorption of filtered solutes is impaired and there is progressive renal failure. R. R. Hoopes and colleagues studied mutations associated with Dent disease in the following family:

a. On the basis of this pedigree, what is the most likely mode of inheritance for the disease? Explain your reasoning.

b. Based on your answer to part *a*, give the most likely genotypes for all family members in the pedigree.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

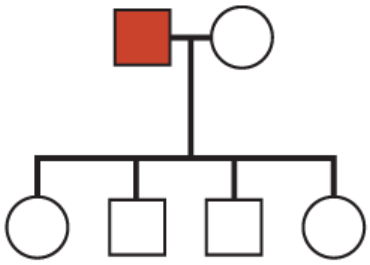
(Data from R. R. Hoopes et al. 2005. *American Journal of Human Genetics* 76:260–267)

Description
Generation 1 has 2 unaffected parents crossed out. They had 6 offspring: 2 positive males, 2 negative males, and 2 negative females. Of these offspring, 1 positive male and 2 negative females mated and had offspring. The male had 2 female offspring negative for the trait and 1 out of 2 grandsons positive for the disorder. The 2 negative females had 5 sons, 4 of which were positive for the disorder. They had no female offspring.

23. CONNECT Read again the introductory story for Chapter 3, The Genetics of Blond Hair in the South Pacific. Based on the information provided in this story, draw a pedigree of a typical Solomon Islander family in which blond hair occurs. Be sure to incorporate the mode of inheritance for blond hair in Pacific Islanders and correct symbols for a pedigree.

24. A man with a specific unusual genetic trait marries an unaffected woman and they have four children. Pedigrees of this family are shown in parts *a* through *e*, but the presence or absence of the trait in the children is not indicated. For each type of inheritance, indicate how many children of each sex are expected to express the trait by filling in the appropriate circles and squares. Assume that the trait is rare and fully penetrant.

a. Autosomal recessive trait

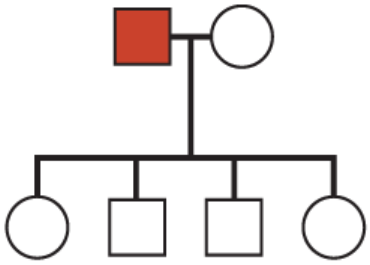


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description

The pedigree chart shows a couple in generation 1 where male is affected and female is unaffected. The couple has 2 unaffected daughters and 2 unaffected sons in generation 2.

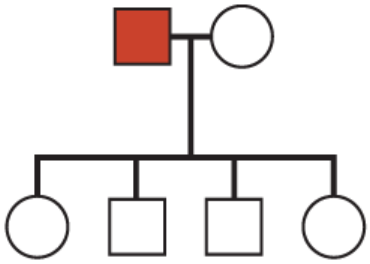
b. Autosomal dominant trait



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The pedigree chart shows a couple in generation 1 where male is affected and female is unaffected. The couple has 2 unaffected daughters and 2 unaffected sons in generation 2.

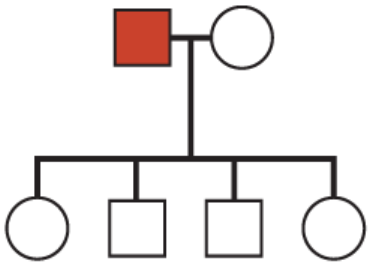
c. X-linked recessive trait



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The pedigree chart shows a couple in generation 1 where male is affected and female is unaffected. The couple has 2 unaffected daughters and 2 unaffected sons in generation 2.

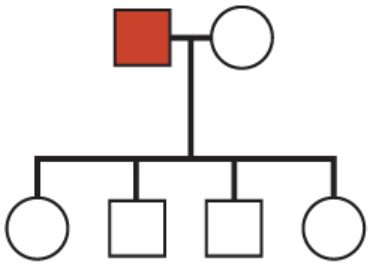
d. X-linked dominant trait



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The pedigree chart shows a couple in generation 1 where male is affected and female is unaffected. The couple has 2 unaffected daughters and 2 unaffected sons in generation 2.

e. Y-linked trait

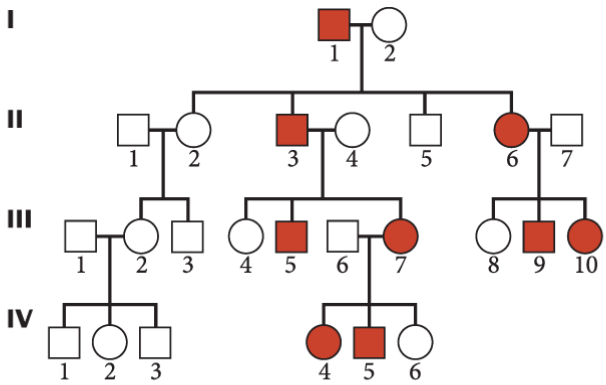


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The pedigree chart shows a couple in generation 1 where male is affected and female is unaffected. The couple has 2 unaffected daughters and 2 unaffected sons in generation 2.

25. *For each of the following pedigrees, give the most likely mode of inheritance, assuming that the trait is rare. Carefully explain your reasoning.

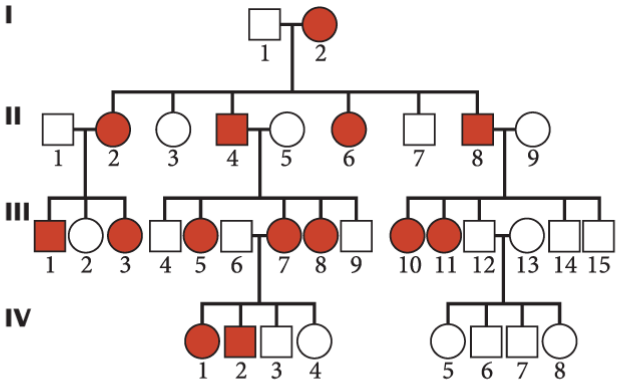
a.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description
In generation 1, the male is affected. They have 2 sons and 2 daughters. Of these, one son and one daughter are affected. The unaffected daughter has 2 kids and one of her kids has 3 kids. None of the people display the trait. The affected male and female from generation 2 both have offspring and pass down the trait. The male has 2 girls and one son. Of these, one male and female display the trait. The daughter from generation 3 has 3 offspring, of which one son and one daughter display the trait. The male offspring from generation 2 has 3 children (2 daughters and 1 son), of which one male and one female display the trait.

b.

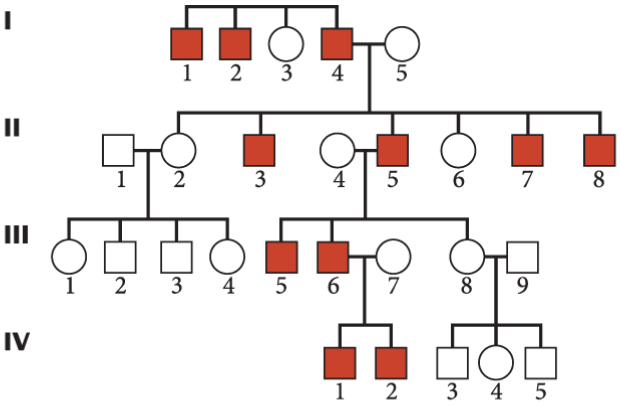


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description

In generation 1, the female is affected. The couple has 6 offspring: 2 positive females, 1 negative female, 2 positive males, and 1 negative male. Of these offspring, 1 positive female and 2 positive males mate and have offspring. The positive female mates a negative male, and they have 1 positive male, 1 negative female, and one positive female. Both positive males from generation 2 mate a negative partner, and have 10 offspring: 5 negative males and 5 positive females. Of these offspring, one negative male and one positive female mate and have offspring. The male has 2 negative male and 2 negative female offspring. The positive female mates a negative male, and they have one positive male, one positive female, one negative male, and one negative female offspring.

c.

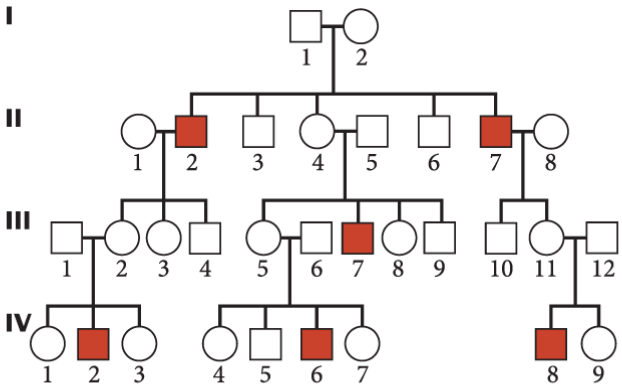


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description

In generation 1, there are 4 siblings, 3 positive brothers and one negative sister. Of these siblings, only one positive male mates and has offspring. The female parent is negative for the trait. They have 4 positive male and 2 negative female offspring. Of the 6, one negative female and one positive male mate negative partners and have offspring. The female has no positive offspring. The male has 2 positive male and one negative female offspring. One male and one female mate and have offspring. The one male has 2 male offspring, both of which are positive for the trait. The female has 2 male and 1 female offspring, all of which are negative for the trait.

d.

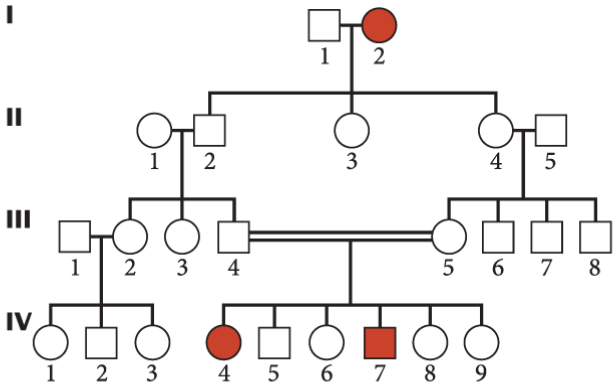


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description

In generation 1, the male and female parents are both negative. They have 5 offspring: 2 positive males, 2 negative males, and one negative female. 3 of these offspring mate negative partners and have offspring. Of the positive males, they have 3 negative female and 2 negative male offspring. Two of these females mate negative partners, and they have 3 negative females and 2 positive male offspring. In generation 2, the negative female gives birth to 2 negative females, 1 positive male, and one negative male offspring. Only one negative female mates a negative partner and has children. She has 2 negative females, 1 negative male, and 1 positive male offspring.

e.

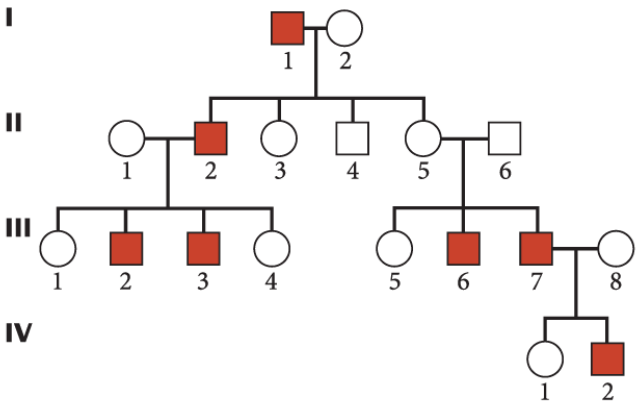


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

Generation 1 has a couple where male is unaffected and female is affected. The couple has 1 unaffected son and 2 unaffected daughters in generation 2. The unaffected male from generation 2 mates with an unaffected female and has 2 unaffected daughters and 1 unaffected son. One unaffected female from generation 2 mates with an unaffected male and has 3 unaffected sons and 1 unaffected daughter. One unaffected daughter of the unaffected male from generation 2 mates with an unaffected male and has 2 unaffected daughters and 1 unaffected son in generation 4. The unaffected son of the unaffected male from generation 2 mates with the unaffected daughter of the unaffected female from generation 2. This is a consanguineous mating between cousins. They have 1 affected daughter, 1 affected son, 1 unaffected son, and 3 unaffected daughters in generation 4.

26. The trait represented in the following pedigree is expressed only in the males of the family. Is the trait Y linked? Why or why not? If you believe that the trait is not Y linked, propose an alternative explanation for its inheritance.

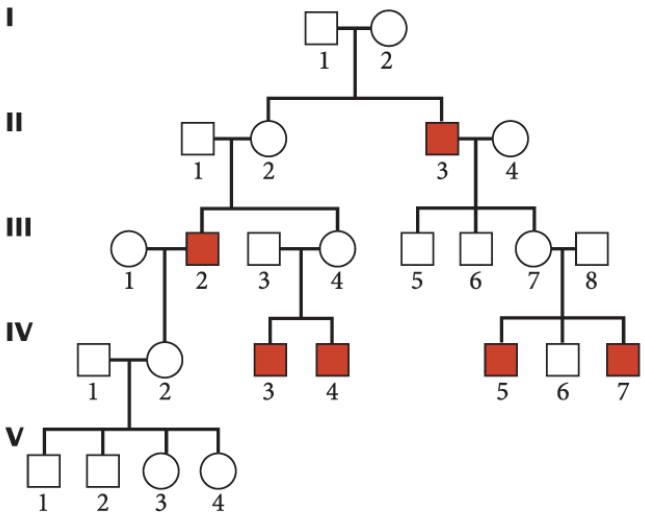


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

The pedigree chart shows generation 1 where male is positive and female is negative. They have 4 offsprings: 1 positive male, 1 negative male, and 2 negative females in generation 2. Of these offspring, one positive male and one negative female mate negative partners and have offspring. The positive male has 2 positive male and 2 negative female offspring. The negative female from generation 2 has 1 negative female and 2 positive male offspring. One of these positive males mates and has one negative female and one positive male offspring.

27. DATA ANALYSIS The following pedigree illustrates the inheritance of Nance–Horan syndrome, a rare genetic condition in which affected people have cataracts and abnormally shaped teeth.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

[Data from D. Stambolian et al., 1990. *American Journal of Human Genetics* 47:15.]

Description

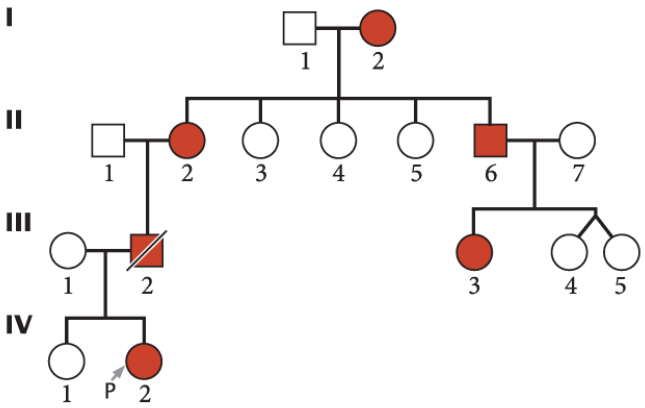
Generation 1 has a couple where the male and female are both unaffected. The couple has 1 unaffected daughter and 1 affected son in generation 2. The unaffected female from generation 2 mates with an unaffected male and has 1 unaffected daughter and 1 affected son in generation 3. The affected male from generation 2 mates with an unaffected female and has 1 unaffected daughter and 2 unaffected sons in generation 3. The affected male from generation 3 mates with an unaffected female and has 1 unaffected daughter in generation 4. Unaffected daughter of unaffected female from generation 2 mates with an unaffected male and has 1 affected daughter and 1 affected son in generation 4. Unaffected daughter of affected male from generation 2 mated with an unaffected male and has 2 affected sons and 1 unaffected son in generation 4. Unaffected daughter of affected male from generation 3 mates with an unaffected male and has 2 unaffected daughters and 2 unaffected sons in generation 5.

a. On the basis of this pedigree, what do you think is the most likely mode of inheritance for Nance–Horan syndrome?

b. If couple III-7 and III-8 have another child, what is the probability that the child will have Nance–Horan syndrome?

c. If III-2 and III-7 were to mate, what is the probability that one of their children would have Nance–Horan syndrome?

28. DATA ANALYSIS The following pedigree illustrates the inheritance of ringed hair, a condition in which each hair is differentiated into light and dark zones. What mode or modes of inheritance are possible for the ringed-hair trait in this family?



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

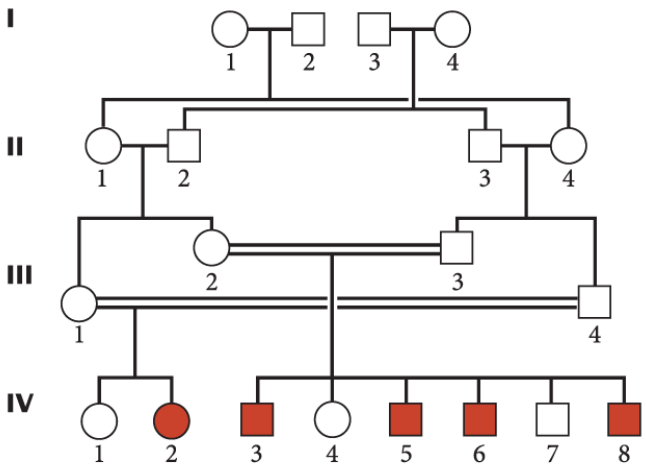
[Data from L. M. Ashley and R. S. Jacques. 1950. *Journal of Heredity* 41:83.]

Description

Generation 1 has a couple where there is an affected female and an unaffected male. They have 5 offspring: 1 affected son, 1 affected daughter, and 3 unaffected daughters in generation 2. The affected female from generation 2 mates with an unaffected male and has an affected son is crossed out in generation 3. The affected male from generation 2 mates with an unaffected female and has 1 affected daughter and a pair of non-identical unaffected twin daughters in generation 3. The

affected male crossed out from generation 3 mates with an unaffected female and has 1 affected daughter who is a proband and 1 unaffected daughter in generation 4.

29. DATA ANALYSIS Ectrodactyly is a rare condition in which the fingers are absent and the hand is split. This condition is usually inherited as an autosomal dominant trait. Ademar Freire-Maia reported the appearance of ectrodactyly in a family in São Paulo, Brazil, whose pedigree is shown here. Is this pedigree consistent with autosomal dominant inheritance? If not, what mode of inheritance is most likely? Explain your reasoning.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

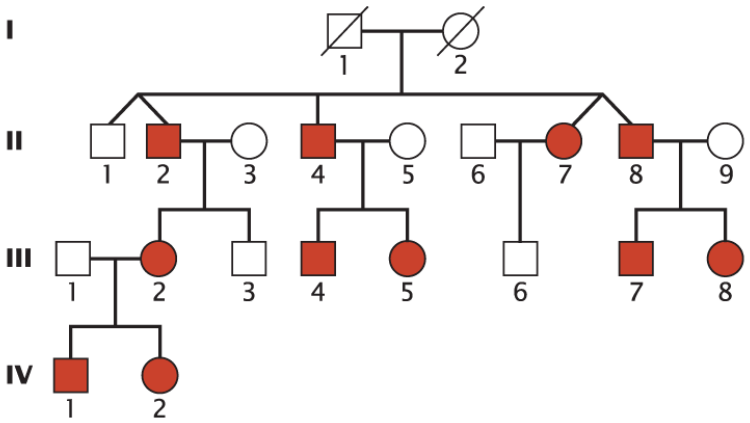
[Data from A. Freire-Maia. 1971. *Journal of Heredity* 62:53.]

Description

Generation 1 shows two couples where males and females are unaffected in both the couples. Couple 1 has 2 unaffected daughters in generation 2 and couple 2 has 2 unaffected sons in generation 2. One daughter of couple 1 mates with a son of couple 2. They have 2 unaffected daughters in generation 3. The other daughter of couple 1 mates with the other son of couple 2 and has 2 unaffected sons in

generation 3. One unaffected female from generation 3 mates with 1 unaffected male from generation 3. This is consanguineous mating and has 1 unaffected daughter, 4 affected sons, and 1 unaffected son in generation 4. Another unaffected female from generation 3 mates with another unaffected male from generation 3 which is also a consanguineous mating. They have 1 affected daughter and 1 unaffected daughter in generation 4.

30. DATA ANALYSIS The complete absence of one or more teeth (tooth agenesis) is a common trait in humans—indeed, more than 20% of humans lack one or more of their third molars. However, more severe tooth agenesis, defined as the absence of six or more teeth, is less common and is frequently an inherited condition. L. Lammi and colleagues examined tooth agenesis in the Finnish family shown in the pedigree below.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

[Data from L. Lammi et al., 2004. *American Journal of Human Genetics* 74:1043–1050.]

Description
Generation 1 has a couple with an unaffected male crossed out and an unaffected female crossed out. They have 2 pairs of non-identical twins and 1 affected son in

generation 2. First pair of twins has 1 unaffected son and 1 affected son. Second pair of twins has 1 affected daughter and 1 affected son. The affected son from first twin pair mates with an unaffected female and has 1 affected daughter and 1 unaffected son in generation 3. The affected son who is a singleton mates with an unaffected female and has 1 affected son and 1 affected daughter in generation 3. The affected female from second pair of twins mates with an unaffected male and has 1 unaffected son in generation 3. The affected male from second pair of twins mates with an unaffected female and has 1 affected son and 1 affected daughter in generation 3. The affected daughter of the affected male from first pair of twins mates with an unaffected male and has 1 affected daughter and 1 affected son in generation 4.

a. What is the most likely mode of inheritance for tooth agenesis in this family? Explain your reasoning.

b. Are the two sets of twins in this family monozygotic or dizygotic twins? What is the basis of your answer?

c. If IV-2 married a man who had a full set of teeth, what is the probability that their child would have tooth agenesis?

d. If III-2 and III-7 married and had a child, what is the probability that their child would have tooth agenesis?

31. CONNECT How did our approach in Chapter 3 to determine whether a trait is recessive or dominant differ from our use of pedigrees in this chapter to determine whether a trait is recessive or dominant?

Section 6.3

32. *A geneticist studies a series of characteristics in pairs of monozygotic and dizygotic twins, obtaining the following concordances. For each characteristic, indicate whether these concordances suggest genetic influences, environmental influences, or both. Explain your reasoning.

	Concordance (%)	
Characteristic	**Monozygotic**	**Dizygotic**
Migraine headaches	60	30
Eye color	100	40
Measles	90	90
Club foot	30	10
High blood pressure	70	40
Handedness	70	70
Tuberculosis	5	5

33. On the basis of the concordances shown in Table 6.2, is variation in rheumatoid arthritis influenced by genetic factors, environmental factors, or both? Explain your reasoning.

34. DATA ANALYSIS M. T. Tsuang and colleagues studied drug dependence in male twin pairs (M. T. Tsuang et al. 1996. *American Journal of*

Medical Genetics 67:473–477). They found that 82 out of 313 monozygotic twin pairs were concordant for abuse of one or more illicit drugs, whereas 40 out of 243 dizygotic twin pairs were concordant for the same trait. Calculate the concordances for drug abuse in these monozygotic and dizygotic twins. On the basis of these data, what conclusion can you draw concerning the roles of genetic and environmental factors in drug abuse?

35.

*In a study of schizophrenia (a mental disorder including disorganization of thought and withdrawal from reality), researchers looked at the prevalence of the disorder in the biological and adoptive parents of people who were adopted as children; they found the following results:

	Prevalence of schizophrenia	
Adoptees	**Biological parents**	**Adoptive parents**
With schizophrenia	12	2
Without schizophrenia	6	4

[Data from S. S. Kety et al., 1978, in *The Nature of Schizophrenia: New Approaches to Research and Treatment*, L. C. Wynne, R. L. Cromwell, and S. Matthysse, Eds. New York: Wiley, pp. 25–37.]

What can you conclude from these results concerning the role of genetics in schizophrenia? Explain your reasoning.

36. Which conclusions are supported by **Figure 6.13**?

    a. Adoptive fathers of obese children have a higher BMI than adoptive fathers of thin children.

    b. Adoptive mothers of thin children have a lower BMI than adoptive mothers of obese children.

    c. Biological fathers of obese children have a higher BMI than adoptive fathers of thin children.

    d. Both a and b.

    e. Both a and c.

37. What, if any, ethical issues might arise from the widespread use of noninvasive prenatal screening?

CHALLENGE QUESTIONS

Section 6.1

38. Many genetic studies, particularly those of recessive traits, have focused on small, isolated human populations, such as those on

islands. Suggest one or more advantages that isolated populations might have for the study of recessive traits.

Section 6.2

39. Draw a pedigree that represents an autosomal dominant trait, sex-limited to males, and that excludes the possibility that the trait is Y linked.

40.

A. C. Stevenson and E. A. Cheeseman studied deafness in a family in Northern Ireland and recorded the following pedigree (A. C. Stevenson and E. A. Cheeseman. 1956. *Annals of Human Genetics* 20:177–231).

    a. If you consider only generations I through III, what is the most likely mode of inheritance for this type of deafness?

    b. Provide a possible explanation for the cross between III-7 and III-9 and the results for generations IV through V.

Section 6.3

41. Dizygotic twinning often runs in families, and its frequency varies among ethnic groups, whereas monozygotic twinning rarely runs in families, and its frequency is quite constant among ethnic groups. These observations have been interpreted as evidence of a genetic basis for variation in dizygotic twinning but little genetic basis for variation in monozygotic twinning. Can you suggest a possible reason for these differences in the genetic tendencies toward dizygotic and monozygotic twinning?

W. H. Freeman and Company

[Data from A. C. Stevenson and E. A. Cheeseman. 1956. *Annals of Human Genetics* 20:177–231.]

Description

Generation 1 consists of 2 couples: one set of parents are both negative and the other set are both positive for the trait of deafness. The set of parents that are both positive for deafness have 3 positive females and 1 positive male offspring. The negative set of parents have 8 offsprings: 3 negative females, 1 negative male, 2 positive females, and 2 positive males. One of the positive males from this family mates with one of the positive females from the other family. They have 3 positive males and one positive female offspring. Another couple is shown in generation 2, They are both negative for the trait, but 3 of their 8 children are positive. One of the positive females from this family mates with one of the positive males from the other family in generation 3. They have 6 male offsprings, none of which express the trait for deafness. 2 of these males mate with negative partners, and they have 4 male offspring, none possessing the trait for deafness.

🗣️ ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Section 6.1

1. Pedigrees are used in the study of some nonhuman organisms. (a) List some nonhuman organisms for which pedigrees are often used. (b) What characteristics of these organisms make pedigree analysis practical and useful?

Section 6.2

2. How would the presence of incomplete penetrance (see Chapter 5) affect the interpretation of pedigrees? Do you think it would more strongly affect the interpretation of autosomal recessive or autosomal dominant traits? Explain your reasoning.

3. Explain why X-linked recessive traits are often more common in males, but X-linked dominant traits are often more common in females.

4. Why are there so few Y-linked traits in humans? (Hint: See Chapter 4.)

Section 6.3

5. The frequency of dizygotic twinning is higher in older women. Can you think of some possible evolutionary reasons for the

occurrence of more dizygotic twins in older women?

6. Trait X displays 98% concordance in both monozygotic and dizygotic twins. Do these concordances suggest that trait X is influenced by (a) genetic factors; (b) environmental factors; or (c) both genetic and environmental factors? Explain your reasoning.

7. Huntington disease (HD) is a genetic disorder that usually first appears in middle age and, over time, leads to involuntary movements, impaired speech, difficulty swallowing and speaking, and cognitive decline. There is no cure for HD, and affected individuals eventually die, usually after 10 to 15 years of progressively worsening symptoms. Huntington disease is inherited as an autosomal dominant disorder. Presymptomatic genetic testing for HD is available for people with a family history of the disease.

   Individuals who have a parent with HD have a 50% chance of inheriting the HD gene and eventually having HD. Some of these individuals want to know if they will eventually get the disease, and they undergo presymptomatic genetic testing. Others do not want to know, given that there is no cure or effective treatment for the disease. If you were at risk for HD, would you want to undergo genetic testing? What are some reasons for and against having a genetic test for HD?

8. Many genetic counselors will not provide presymptomatic genetic testing for Huntington disease to people younger than

age 18. Why are there concerns about offering this and many other genetic tests to minors? What types of presymptomatic genetic testing might be appropriate for minors?

9. Do you think direct-to-consumer tests that provide information about the risk of developing medical conditions (such as breast cancer or Alzheimer disease) should be made available to the public? List some arguments for and against providing this service.

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Introduction

1. Draw a concept map relating the following terms in the introductory story about missing fingerprints: fingerprints, dermatoglyphic patterns, Francis Galton, adermatoglyphia, immigration delay disease, autosomal dominant inheritance, SNPs, *SMARCAD1*, abnormal splicing

CHAPTER 7

Linkage, Recombination, and Eukaryotic Gene Mapping

Benjamin Pierce.

Genes associated with variation in fear and aggression in dogs have been mapped to several specific chromosomal locations using genome-wide association studies. Pictured here is Molly, a dog who exhibits little fear and aggression.

Mapping Fear and Aggression in Dogs

Our Labrador retriever, Molly, is the most laid-back dog I've ever known. Molly doesn't understand the definition of a stranger and greets all visitors to our house with a vigorous wag of her tail. She is equally amiable toward other dogs. Confronted with an aggressive dog, she simply rolls over on her back. Nothing seems to make her anxious or fearful. She even loves going to the veterinarian, where she greets other dogs and the staff with great enthusiasm.

Not all dogs are so inclined, and indeed some breeds are consistently more aggressive and fearful than others. Fear and aggression have played important roles in dog evolution: compared to wild wolves, all domestic dogs have reduced aggression and fear toward humans, and early humans undoubtedly selected for tameness when they first domesticated dogs from their wolf ancestors some 30,000 years ago.

For many years, geneticists have been interested in the genetic underpinnings of behavioral traits like fear and aggression, not just in dogs but also in humans. This information could potentially be used to treat behavioral illnesses in humans that include fear, anxiety, and aggression. Unfortunately, studying the genetic basis of behavioral variation in humans is challenging because of the complexity of behavioral traits, long generation time, the inability to conduct controlled crosses, and small family size (see Chapter 6). Thus, geneticists have recently turned to dogs as a model for understanding how genes affect behavior.

In 2016, Isain Zapata and his colleagues published the results of a study that mapped genes affecting fear and aggression in dogs. To locate genes involved in these behaviors, they conducted a genome-wide association study, in which they looked for statistical associations between behavioral traits among dogs from 11 breeds and 175,000 genetic markers called single nucleotide polymorphisms (SNPs, pronounced “snips”). Scattered across the genome, SNPs are positions at which individuals differ in a single nucleotide. (The details of locating genes with genome-wide association studies are discussed later in this chapter). Genome-wide association studies in dogs are facilitated by the fact that dogs in different breeds are genetically distinct, while dogs within breeds are genetically similar.

What the researchers found was that fear in the dogs toward human strangers, as well as aggression toward both strange humans and unfamiliar dogs, was associated with genetic markers at two specific places in the genome: one spot on chromosome 18 and another on the X chromosome. Interestingly, aggression toward the dogs’ owners appeared to have a different genetic cause and was associated with different genes on chromosomes 15 and 34. The researchers were able to correlate these chromosomal locations to several known genes, some of which are expressed in those portions of the brain that are known to be associated with fear and aggression. These genes also showed signatures of strong past selection, suggesting that through artificial selection during dog

domestication, humans helped shape the variation found today at these genes.

To validate their findings, the researchers conducted another study on a different cohort of dogs, and results confirmed their earlier finding of associations of loci on chromosomes 18 and X with fear and aggression directed toward strangers and other dogs. Finally, the researchers used their genetic results to create a model that, based on genetic makeup, could predict fear and aggression in dogs, and tested this model in a third group of dog breeds. The model had a 58% success rate of predicting the level of fear and aggression observed in the dog breeds based on the particular genetic variants they possessed, versus a 7% random chance of success.

THINK-PAIR-SHARE

- Dogs are increasingly being used as a genetic model for the study of human traits and behaviors. Why are dogs a good genetic model organism for understanding human traits? Can you also think of some reasons why dogs are *not* a good genetic model organism? (Hint: See Chapter 1 for a discussion of model genetic organisms.)

This chapter explores the inheritance of genes and genetic markers located on the same chromosome. These linked genes do not strictly obey Mendel's principle of independent assortment; rather, they tend to be inherited together. This tendency requires a new approach to understanding their inheritance and predicting the

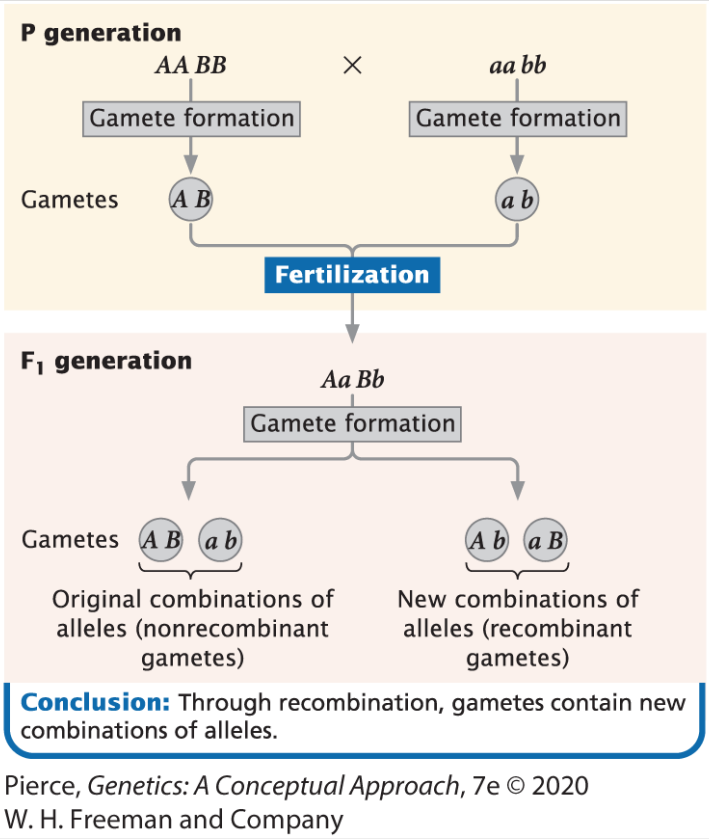
types of offspring that will be produced by a cross. A critical piece of information necessary for making these predictions is the arrangement of the genes on the chromosomes; thus, it will be necessary to think about the relation between genes and chromosomes. A key to understanding the inheritance of linked genes is to make the conceptual connection between the genotypes in a cross and the behavior of chromosomes in meiosis.

We begin our exploration of linkage by comparing the inheritance of two linked genes with the inheritance of two genes that assort independently. We then examine how recombination breaks up linked genes. Next, we use our knowledge of linkage and recombination for predicting the results of genetic crosses in which genes are linked as well as for mapping genes. Later in the chapter, we focus on physical methods of determining the chromosomal locations of genes. The final section examines variation in rates of recombination.

7.1 Linked Genes Do Not Assort Independently

Chapter 3 introduced Mendel's principles of segregation and independent assortment. Let's take a moment to review these two important concepts. The principle of segregation states that each diploid organism possesses two alleles at a locus that separate in meiosis, and that one allele passes into each gamete. The principle of independent assortment provides additional information about the process of segregation: it tells us that the two alleles at a locus separate independently of alleles at other loci.

The independent separation of alleles results in *recombination,* the sorting of alleles into new combinations. Consider a cross between individuals that are homozygous for two different pairs of alleles: *AA BB* × *aa bb*. The first parent, *AA BB*, produces gametes with the alleles *A B*, and the second parent, *aa bb*, produces gametes with the alleles *a b*, resulting in F_1 progeny with genotype *Aa Bb* (**Figure 7.1**). *Recombination* means that when one of the F_1 progeny reproduces, the combination of alleles in its gametes may differ from the combinations in the gametes of its parents. In other words, the F_1 may produce gametes with new allele combinations *A b* or *a B* in addition to parental gametes *A B* or *a b*.



7.1 Recombination is the sorting of alleles into new combinations.

Description

P generation at the top shows a cross between two parents with following genotypes: big A big A big B big B and small A small A small B small B. Their respective gametes formed are as follows: big A big B and small A small B. Fertilization occurs and F subscript 1 generation is obtained below. The F subscript 1 generation has offspring with the following genotype: big A small A big B small B. Gamete formation occurs and 2 pairs of gametes are formed: First pair: big A big B and small A small B. A text below reads, Original combinations of alleles (nonrecombinant gametes). The second pair: big A small B and small A big B. A caption below reads, New combinations of alleles (recombinant gametes).

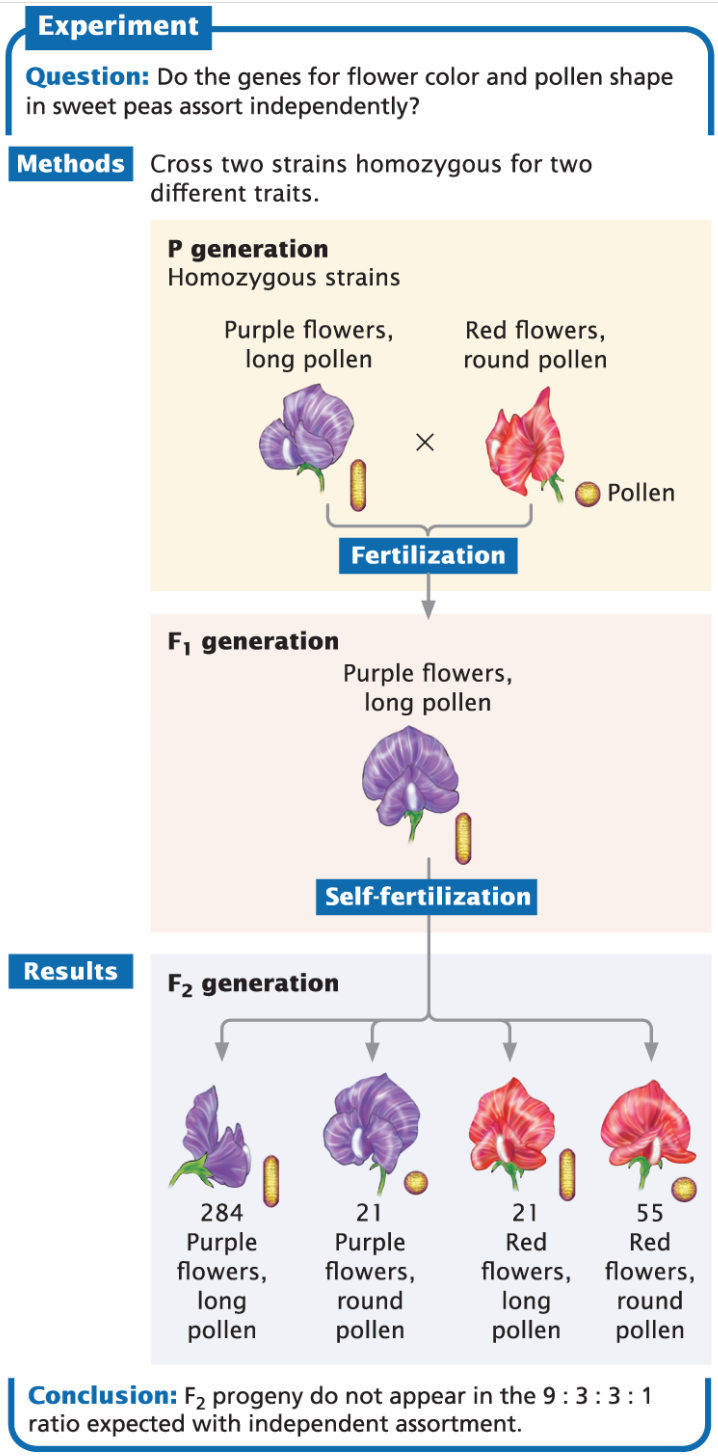
Mendel derived his principles of segregation and independent assortment by observing the progeny of genetic crosses, but he had no idea what biological processes produced these phenomena. In

1903, Walter Sutton proposed a biological basis for Mendel's principles, called the chromosome theory of heredity, which holds that genes are found on chromosomes (see Chapter 3). Let's restate Mendel's two principles in relation to the chromosome theory of heredity. The principle of segregation states that a diploid organism possesses two alleles for a characteristic, each of which is located at the same position, or locus, on one of the two homologous chromosomes. These chromosomes segregate in meiosis, and each gamete receives one homolog. The principle of independent assortment states that in meiosis, each pair of homologous chromosomes assorts independently of other homologous pairs. With this new perspective, it is easy to see that because the number of chromosomes in most organisms is limited, there are certain to be more genes than chromosomes, so some genes must be present on the same chromosome and should not assort independently. Genes located close together on the same chromosome are called **linked genes** and belong to the same **linkage group**. Linked genes travel together in meiosis, eventually arriving at the same destination (the same gamete), and are not expected to assort independently. All of the characteristics examined by Mendel in peas did display independent assortment, and the first genetic characteristics studied in other organisms also seemed to assort independently. How could genes be carried on a limited number of chromosomes and yet assort independently?

This apparent inconsistency between the principle of independent assortment and the chromosome theory of heredity soon

disappeared as biologists began finding genetic characteristics that did not assort independently. One of the first cases was reported in sweet peas by William Bateson, Edith Rebecca Saunders, and Reginald C. Punnett in 1905. They crossed a homozygous strain of peas that had purple flowers and long pollen grains with a homozygous strain that had red flowers and round pollen grains. All the F_1 had purple flowers and long pollen grains, indicating that purple was dominant over red and long was dominant over round. When they intercrossed the F_1, however, the resulting F_2 progeny did not appear in the 9 : 3 : 3 : 1 ratio expected with independent assortment (Figure 7.2). An excess of F_2 plants had purple flowers and long pollen or red flowers and round pollen (the parental phenotypes). Although Bateson, Saunders, and Punnett were unable to explain these results, we now know that the two loci that they examined lie close together on the same chromosome and therefore do not assort independently.

THINK-PAIR-SHARE Question 1



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

7.2 Nonindependent assortment of flower color and pollen shape in sweet peas.

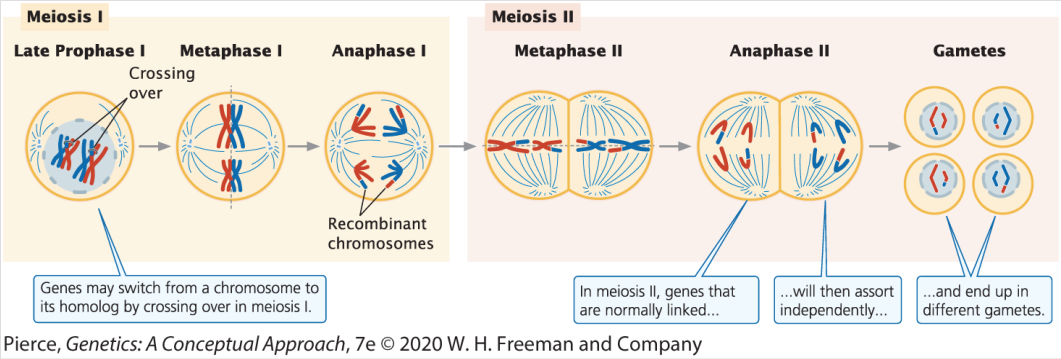
Description

The figure begins with the question as follows: Do the genes for flower color and pollen shape in sweet peas assort independently? The methods below involve the following text: Cross two strains homozygous for two different traits. P generation below shows a purple flower with long pollen crossed with a red flower with round pollen. Fertilization occurs and F subscript 1 generation is obtained below where all are purple flowers with long pollen. Self-fertilization occurs and results show F subscript 2 generation below. The results include F subscript 2 generation that has 284 purple flowers with long pollen, 21 purple flowers with round pollen, 21 red flowers with long pollen, and 55 red flowers with round pollen. A caption below reads, Conclusion: F subscript 2 progeny do not appear in the 9 is to 3 is to 3 is to 1

ratio expected with independent assortment

7.2 Linked Genes Segregate Together While Crossing Over Produces Recombination Between Them

Genes that are close together on the same chromosome usually segregate as a unit and are therefore inherited together. However, genes occasionally switch from one homologous chromosome to the other through the process of crossing over (see Chapter 2), as illustrated in **Figure 7.3**. Crossing over results in recombination: it breaks up the associations of genes that are close together on the same chromosome. Linkage and crossing over can be seen as processes that have opposite effects: linkage keeps particular genes together, and crossing over mixes them up, producing new combinations of genes. In Chapter 5, we considered a number of exceptions and extensions to Mendel's principles of heredity. The concept of linked genes adds a further complication to interpretations of the results of genetic crosses. However, with an understanding of how linkage affects heredity, we can analyze crosses for linked genes and successfully predict the types of progeny that will be produced.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.3 Crossing over takes place in meiosis and is responsible for recombination.

Description

Meiosis 1 on the left has late prophase 1, metaphase 1, and anaphase 1 stages. In the cells, there are 2 sets of homologous chromosomes where each one has a red and a blue counterpart within the nuclear envelope. A caption reads, Genes may switch from a chromosome to its homolog by crossing over in meiosis 1. During metaphase 1, spindle fibers are formed from one cell pole to another and new combination of a chromosome is represented by the hybrid color pattern in the recombinant chromosome. These chromosomes now align at the center of the cell. During anaphase 1, the recombined chromosomes are being pulled apart. Meiosis 2 on the right shows metaphase 2, anaphase 2, and the resulting gametes. During metaphase 2, the cell has two compartments and the spindle fibers are now drawn vertically in each of the compartments. The chromosomes are now aligned horizontally at the center of the cell. During anaphase 2, each sister chromatid is pulled towards the cell poles. A caption reads, In meiosis 2, genes that are normally linked will then assort independently and end up in different gametes. Four gametes are formed, and a portion of one of the 2 chromosomes is recombined. The chromosomes are in nuclear envelope in each of the gametes formed.

Notation for Crosses with Linkage

In analyzing crosses with linked genes, we must know not only the genotypes of the individuals crossed but also the arrangement of the genes on the chromosomes. To keep track of this arrangement, we introduce a new system of notation for presenting crosses with linked genes. Consider a cross between an individual homozygous for dominant alleles at two linked loci and another individual homozygous for recessive alleles at those loci (*AA BB* × *aa bb*). For linked genes, it's necessary to write out the specific alleles as they are arranged on each of the homologous chromosomes:

$$\frac{A \quad B}{A \quad B} \times \frac{a \quad b}{a \quad b}$$

Description
The homologous chromosomes are indicated by a double line. The first pair has big A gene on the far left and the big B gene on the far right for both the chromosomes. The second pair has small A gene on the left end and small B on the right end for both the chromosomes.

In this notation, each horizontal line represents one of the two homologous chromosomes. Because they inherit one chromosome from each parent, the F_1 progeny will have the following genotype:

$$\frac{A \quad B}{a \quad b}$$

Description
The drawing shows genes big A on the left and big B on the right, above the horizontal straight line representing the top chromosome. A parallel line below represents bottom homologous chromosome. Below this line, small A is on the left and small B is on the right.

Here, the importance of designating the alleles on each chromosome is clear. One chromosome has the two dominant alleles A and B, whereas the homologous chromosome has the two recessive alleles a and b. The notation can be simplified by drawing only a single line, with the understanding that genes located on the same side of the line lie on the same chromosome:

$$\frac{A \quad B}{a \quad b}$$

Description
A single line represents a pair of homologous chromosomes. Above the line, big A is on the left and big B is on the right. Below the line, small A is on the left and small B is on the right.

This notation can be simplified further by separating the alleles on each chromosome with a slash: AB/ab.

Remember that the two alleles at a locus are always located on different homologous chromosomes and therefore must lie on opposite sides of the line. Consequently, we would *never* write the genotypes as

$$\frac{A \quad a}{B \quad b}$$

Description
A single line represents a pair of homologous chromosomes. Above the line, big A is on the left and small A is on the right. Below the line, big B is on the left and small B is on the right.

because the alleles A and a can *never* be on the same chromosome. It is also important to keep the genes in the same order on both sides of the line; thus, we would *never* write

$$\frac{A \quad B}{b \quad a}$$

Description
A single line represents a pair of homologous chromosomes. Above the line, big A is on the left and big B is on the right. Below the line, small B is on the left and small A is on the right.

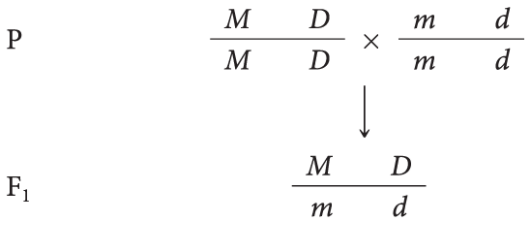
because it would imply that alleles A and b are allelic (at the same locus).

Complete Linkage Compared with Independent Assortment

In this section, we first consider what happens to genes that exhibit complete linkage, meaning that they are located very close together on the same chromosome and do not exhibit crossing over. Genes are rarely completely linked, but by assuming that no crossing over takes place, we can see the effect of linkage more clearly. We then consider what happens when genes assort independently. Finally, we consider the results obtained if the genes are linked but exhibit some crossing over.

A testcross reveals the effects of linkage. For example, if a heterozygous individual is test-crossed with a homozygous recessive individual (*Aa Bb* × *aa bb*), the alleles that are present in the gametes contributed by the heterozygous parent will be expressed in the phenotype of the offspring because the homozygous parent cannot contribute dominant alleles that might mask them. Consequently, traits that appear in the progeny reveal which alleles were transmitted by the heterozygous parent.

Consider a pair of linked genes in tomato plants. One of the genes affects the type of leaf: an allele for mottled leaves (*m*) is recessive to an allele that produces normal leaves (*M*). Nearby on the same chromosome, another gene determines the height of the plant: an allele for dwarf (*d*) is recessive to an allele for tall (*D*). Testing for linkage can be done with a testcross, which requires a plant that is heterozygous for both characteristics. A geneticist might produce this heterozygous plant by crossing a variety of tomato that is homozygous for normal leaves and tall height with a variety that is homozygous for mottled leaves and dwarf height:



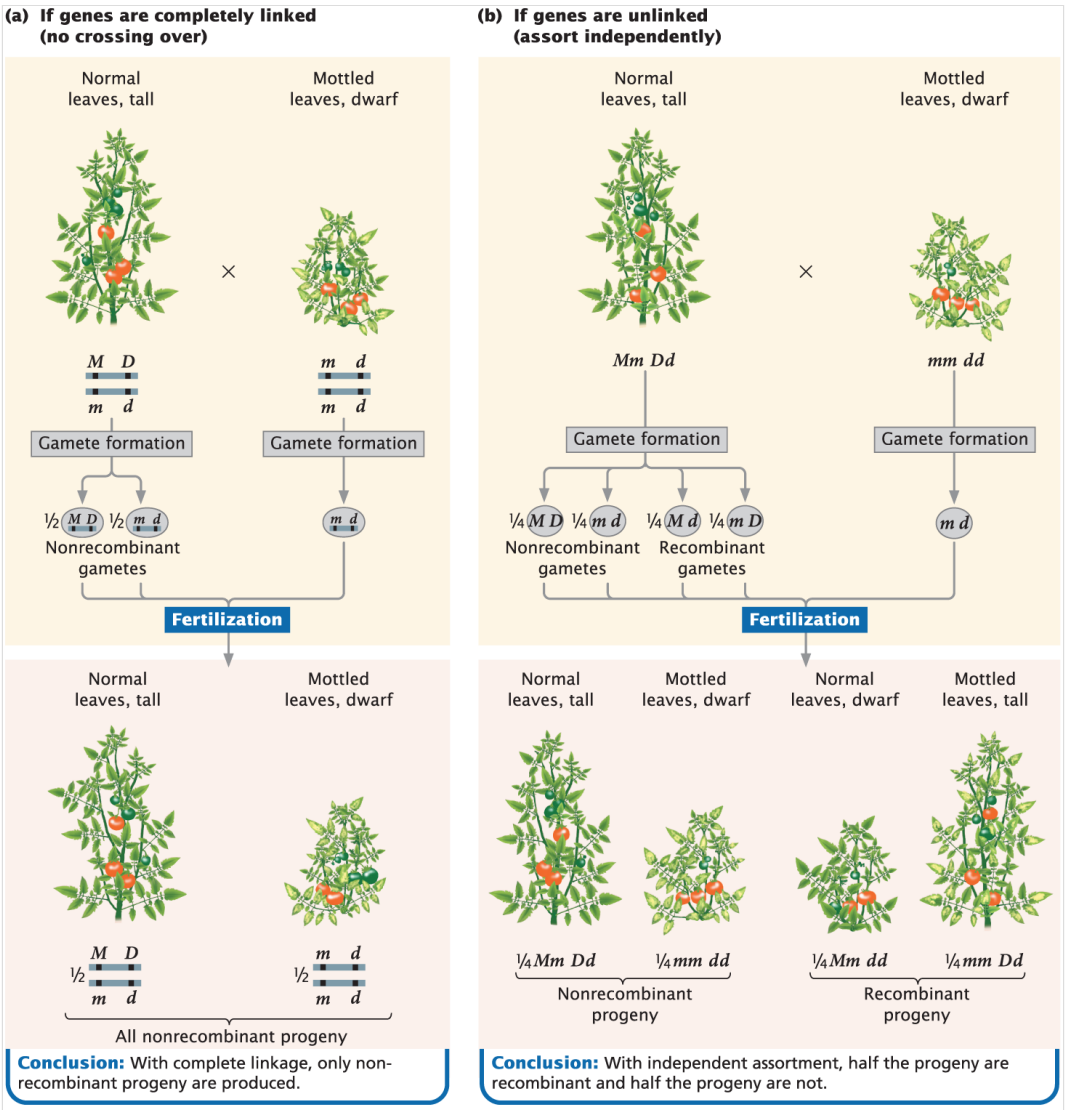
Description
In the P generation at the top, one parent has big M on the left and big D on the right, both above and below the line. The other parent has small M on the left and small D on the right,

both above and below the line. Crossing takes place and F subscript 1 generation is obtained below. This generation shows progeny with big M on the left and big D on the right, on the top of the line and small M on the left and small D on the right, below the line.

The geneticist would then use this F_1 heterozygote in a testcross, crossing it with a plant that is homozygous for mottled leaves and dwarf height:

$$\frac{M \quad D}{M \quad D} \times \frac{m \quad d}{m \quad d}$$

The results of this testcross are diagrammed in **Figure 7.4a**. The heterozygote produces two types of gametes: some with the $\underline{M \quad D}$ chromosome and others with the $\underline{m \quad d}$ chromosome. Because no crossing over takes place, these gametes are the only types produced by the heterozygote. Notice that the gametes produced by the heterozygote contain only combinations of alleles that were present in its parents (the P generation): either the allele for normal leaves together with the allele for tall height (*M* and *D*) or the allele for mottled leaves together with the allele for dwarf height (*m* and *d*). Gametes that contain only original combinations of alleles that were present in the parents are **nonrecombinant gametes**, or *parental gametes*.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.4 A testcross reveals the effects of linkage. Results of a testcross for two loci in tomatoes that determine leaf type and plant height.

Description

Part a on the left shows the results when genes are completely linked (no crossing over). The P generation has a tall tomato plant with normal leaves crossed with a dwarf tomato plant with mottled leaves. The tall plant has genes big M on the left and big D on the right, above the line and small M on the left and small D on the right, below the line. The dwarf plant has small M on the left and small D on the right, both above and below the line. Gamete formation occurs. For tall plant, nonrecombinant gametes are formed where one-half gametes have big M big D and one-half gametes have small M small D. For dwarf

plant, gametes have small M small D. Fertilization occurs and in F subscript 1 generation below, one-half progeny are tall with normal leaves with genotype big M big D small M small D while one-half progeny are dwarf with mottled leaves with genotype small M small D small M small D. All the progenies are nonrecombinant. A caption reads, Conclusion: With complete linkage, only nonrecombinant progeny are produced.

Part b on the right shows the results if genes are unlinked (assort independently). It shows a cross between a tall plant with normal leaves and a dwarf plant with mottled leaves. The tall plant has the genotype big M small M big D small D. The dwarf plant has the genotype small M small M small D small D. Gamete formation occurs. The tall plant has the following gametes: one-fourth big M big D and one-fourth small M small D that are nonrecombinant; one-fourth big M small D and one-fourth small M big D that are recombinant gametes. Dwarf plant has following gametes: small M small D. Fertilization occurs and the following progenies are produced in F subscript 1 generation:

Nonrecombinant progeny: one-fourth big M small M big D small D (tall plants with normal leaves) and one-fourth small M small M small D small D (dwarf plants with mottled leaves).

Recombinant progeny: one-fourth big M small M small D small D (dwarf plants with normal leaves) and one-fourth small M small M big D small D (tall plants with mottled leaves). A caption below reads, Conclusion: With independent assortment, half the progeny are recombinant and half the progeny are not.

The homozygous parent in the testcross produces only one type of gamete, which contains chromosome $\underline{m \quad d}$. When its gametes pair with the two types of gametes generated by the heterozygous parent (see Figure 7.4a), two types of progeny result: half have normal leaves and are tall:

$$\frac{M \quad D}{m \quad d}$$

and half have mottled leaves and are dwarf:

$$\frac{m \quad d}{m \quad d}$$

These progeny display the original combinations of traits present in the P generation and are **nonrecombinant progeny**, or *parental progeny*. No new combinations of the two traits, such as normal leaves with dwarf height or mottled leaves with tall height, appear in the offspring because the genes affecting the two traits are completely linked and are inherited together. New combinations of traits could arise only if the physical connection between *M* and *D* or between *m* and *d* were broken.

These results are distinctly different from the results that are expected when genes assort independently (**Figure 7.4b**). If the *M* and *D* loci assorted independently, the heterozygous plant (*Mm Dd*) would produce four types of gametes: two nonrecombinant gametes containing the original combinations of alleles (*M D* and *m d*) and two gametes containing new combinations of alleles (*M d* and *m D*). Gametes with new combinations of alleles are called **recombinant gametes**. With independent assortment, nonrecombinant and recombinant gametes are produced in equal proportions. These four types of gametes join with the single type of gamete produced by the homozygous parent of the testcross to produce four kinds of progeny in equal proportions (see Figure 7.4b). The progeny with new combinations of traits formed from recombinant gametes are termed **recombinant progeny**.

CONCEPTS

A testcross in which one of the individuals is heterozygous for two completely linked genes yields two types of progeny, each type displaying one of the original combinations of traits present in the P generation. In contrast, independent assortment produces four types of progeny in a 1: 1: 1: 1 ratio—two types of recombinant progeny and two types of nonrecombinant progeny in equal proportions.

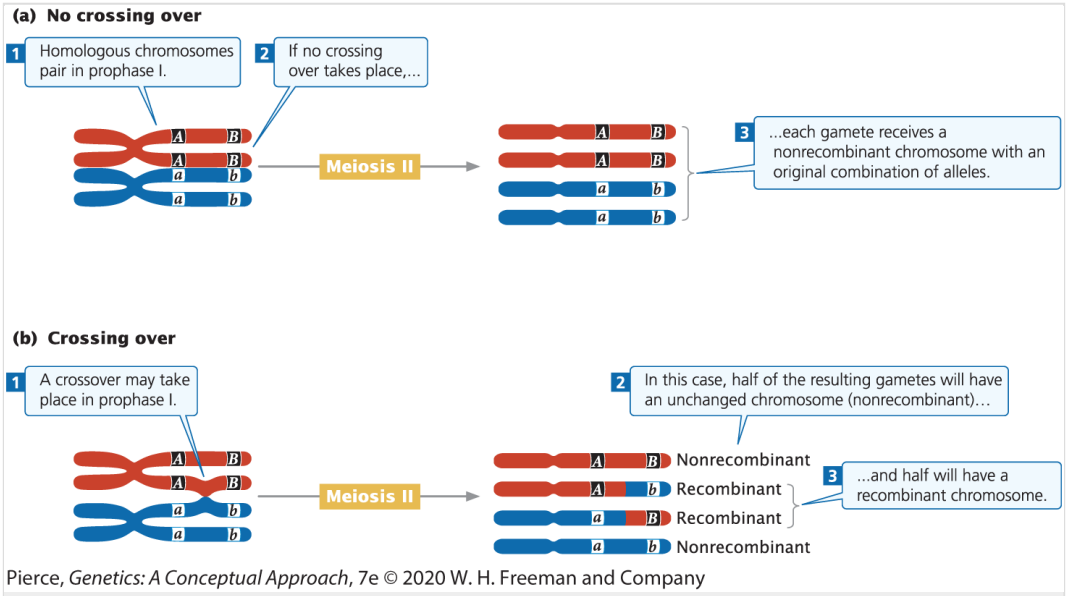
Crossing Over Between Linked Genes

Usually, there is some crossing over between genes that lie on the same chromosome, which produces new combinations of traits. Genes that exhibit crossing over are said to be incompletely linked. Let's see how incomplete linkage affects the results of a cross.

THEORY

The effect of crossing over on the inheritance of two linked genes is shown in **Figure 7.5**. Crossing over, which takes place in prophase I of meiosis, is the exchange of genetic material between nonsister chromatids (see Figures 2.16 and 2.18). After a single crossover has taken place, the two chromatids that did not participate in crossing over are unchanged; gametes that receive these chromatids are nonrecombinants. The other two chromatids, which did participate in crossing over, now contain new combinations of alleles; gametes

that receive these chromatids are recombinants. For each meiosis in which a single crossover takes place, two nonrecombinant gametes and two recombinant gametes are produced. This result is the same as that produced by independent assortment (see Figure 7.4b), so if crossing over between two loci takes place in every meiosis, it is impossible to determine whether the genes are on the same chromosome and crossing over took place or whether the genes are on different chromosomes.



7.5 A single crossover produces half nonrecombinant gametes and half recombinant gametes.

Description

Part a at the top shows the arrangement of gametes when no crossing over occurs. Two X-shaped chromosomes are drawn one below the other where one is red and the other is blue. The chromosome above has big A on the left and big B on the right of its long arm of top chromatid and big A on the left and big B on the right of the long arm of below sister chromatid. The chromosome below has small A on the left and small B on the right of the long arm of the top chromatid and small A on the left and small B on the right of the long

arm of the below chromatid. A caption reads, Homologous chromosomes pair in prophase 1. Another caption reads, If no crossing over takes place each gamete receives a nonrecombinant chromosome with an original combination of alleles. Meiosis 2 occurs and 4 gametes are formed where 2 gametes are red and have big A on the left and big B on the right of their respective long arm, while 2 gametes are blue and have small A on the left and small B on the right of their respective long arm.

Part b below shows the arrangement of gametes when crossing over occurs. Two X-shaped chromosomes are drawn one above the other where one is red and the other is blue. At one point on the long arms of one sister chromatid of one chromosome and one sister chromatid of the other chromosome, they are joined. The red chromosome has big A on the left and big B on the right of the long arm of the top chromatid and big A on the left and big B on the right of the below sister chromatid. The blue chromosome below has small A on left and small B on the right of the long arm of top chromatid and small A on the left and small B on the right of the below chromatid. A caption reads, A crossover may take place in prophase 1. Meiosis 2 occurs and 4 gametes are formed. The first gamete is red and has big A on the left and big B on the right of its long arm (non-recombinant). The second gamete is red with big A on the left and small B (blue part) on the right of the long arm (recombinant). The third gamete is blue and has small A on the left and big B (red part) on the right of the long arm (recombinant). The fourth gamete is blue and has small A on left and small B on the right of its long arm (non-recombinant). A caption reads, In this case, half of the resulting gametes will have an unchanged chromosome (nonrecombinant) and half will have a recombinant chromosome.

For closely linked genes, however, crossing over does not take place in every meiosis. In meioses in which there is no crossing over, only nonrecombinant gametes are produced. In meioses in which there is a single crossover, half the gametes are recombinants and half are nonrecombinants (because a single crossover affects only two of the four chromatids). Because each crossover leads to half recombinant gametes and half nonrecombinant gametes, the total percentage of recombinant gametes is always half the percentage of meioses in

which crossing over takes place. Even if crossing over between two genes takes place in every meiosis, only 50% of the resulting gametes are recombinants. Thus, the frequency of recombinant gametes is always half the frequency of crossing over, and the maximum proportion of recombinant gametes is 50%.

CONCEPTS

Linkage between genes causes them to be inherited together and reduces recombination; crossing over breaks up the associations of such genes. In a testcross for two linked genes, each crossover produces two recombinant gametes and two nonrecombinants. The frequency of recombinant gametes is half the frequency of crossing over, and the maximum frequency of recombinant gametes is 50%.

✔ CONCEPT CHECK 1

For single crossovers, the frequency of recombinant gametes is half the frequency of crossing over because

a. a testcross between a homozygote and a heterozygote produces $^1/_2$ heterozygous and $^1/_2$ homozygous progeny.
b. the frequency of recombination is always 50%.
c. each crossover takes place between only two of the four chromatids of a homologous pair.
d. crossovers take place in about 50% of meioses.

APPLICATION

Let's apply what we have learned about linkage and recombination to a cross between tomato plants that differ in the genes that encode

leaf type and plant height. Assume now that these genes are linked and that some crossing over takes place between them. Suppose a geneticist carried out the testcross described earlier:

$$\frac{M \quad D}{m \quad d} \times \frac{m \quad d}{m \quad d}$$

When crossing over takes place between the genes for leaf type and height, two of the four gametes produced are recombinants. When there is no crossing over, all four resulting gametes are nonrecombinants. Because each crossover produces half recombinant gametes and half nonrecombinant gametes, the majority of gametes produced by the heterozygous parent will be nonrecombinants (**Figure 7.6a**). These gametes then unite with gametes produced by the homozygous recessive parent, which contain only the recessive alleles, resulting in mostly nonrecombinant progeny and a few recombinant progeny (**Figure 7.6b**). In this testcross, we see that 55 of the progeny have normal leaves and are tall and that 53 have mottled leaves and are dwarf. These plants are the nonrecombinant progeny, containing the original combinations of traits that were present in the parents. Of the 123 progeny, 15 have new combinations of traits that were not seen in the parents: 8 have normal leaves and are dwarf, and 7 have mottled leaves and are tall. These plants are the recombinant progeny.

7.6 Crossing over between linked genes produces nonrecombinant and recombinant offspring. In this testcross, genes are linked, and there is some crossing over.

Description

Part a at the top shows the P generation. A tall tomato plant with normal leaves with genotype big M big D small M small D is crossed with a dwarf tomato plant with mottled leaves with genotype small M small D small M small D. Gamete formation occurs. The tall plant has the following gametes: When no crossing over occurs: 1 gamete has big M big D and 1 gamete has small M small D (these are nonrecombinant gametes 100 percent). When crossing over occurs: of the two left gametes, 1 gamete has big M big D and 1 gamete has small M small D (these are nonrecombinant gametes 50 percent). A callout refers to the non-crossing over gametes and the left two crossing over gametes and reads as follows, Meioses with and without crossing over together result in more than 50 percent nonrecombinant gametes on average. Of the two right gametes, 1 gamete has big M small D and 1 gamete has small M big D (these are recombinant gametes 50 percent). The dwarf plant has the following gametes: small M small D. Fertilization occurs and leads to part b below where F subscript 1 generation is obtained. It shows the following progeny:

Nonrecombinant progeny: 55 tall plants with normal leaves with genotype big M big D small M small D and 53 dwarf plants with mottled leaves with genotype small M small D small M small D.

Recombinant progeny: 8 dwarf plants with normal leaves with genotype big M small D small M small D and 7 tall plants with mottled leaves with genotype small M big D small M small D.

A caption below reads, Conclusion: With linked genes and some crossing over, nonrecombinant progeny predominate.

The results of a cross such as the one illustrated in Figure 7.6 reveal several things. A testcross for two independently assorting genes is expected to produce a 1 : 1 : 1 : 1 phenotypic ratio in the progeny. The progeny of this cross clearly do not exhibit such a ratio, so we might suspect that the genes are not assorting independently. When linked genes undergo some crossing over, the result is mostly nonrecombinant progeny and a few recombinant progeny. This result is what we observe among the progeny of the testcross illustrated in Figure 7.6, so we conclude that the two genes show evidence of linkage with some crossing over.

Calculating Recombination Frequency

The percentage of recombinant progeny produced in a cross is called the **recombination frequency** (or *rate of recombination*), which is calculated as follows:

$$\text{recombination frequency} = \frac{\text{number of recombinant progeny}}{\text{total number of progeny}} \times 100\%$$

In the testcross shown in Figure 7.6, 15 progeny exhibit new combinations of traits, so the recombination frequency is

$$\frac{8 + 7}{55 + 53 + 8 + 7} \times 100\% = \frac{15}{123} \times 100\% = 12.2\%$$

Thus, 12.2% of the progeny exhibit new combinations of traits resulting from crossing over. The recombination frequency can also

be expressed as a decimal fraction (0.122). **› TRY PROBLEM 15**

THINK-PAIR-SHARE Question 2

Coupling and Repulsion

In crosses for linked genes, the arrangement of alleles on the homologous chromosomes is critical in determining the outcome of the cross. For example, consider the inheritance of two genes in the Australian blowfly, *Lucilia cuprina*. In this species, one locus determines the color of the thorax: a purple thorax (p) is recessive to the normal green thorax (p^+). A second locus determines the color of the puparium: a black puparium (b) is recessive to the normal brown puparium (b^+). The loci for thorax color and puparium color are located close together on the same chromosome. Suppose that we test-cross a fly that is heterozygous at both loci with a fly that is homozygous recessive at both. Because these genes are linked, there are two possible arrangements on the chromosomes of the heterozygous fly. The dominant alleles for green thorax (p^+) and brown puparium (b^+) might reside on one chromosome of the homologous pair, and the recessive alleles for purple thorax (p) and black puparium (b) might reside on the other homologous chromosome:

$$\frac{p^+ \quad b^+}{p \quad b}$$

Description
The chromosomes are represented by a straight, horizontal line. The alleles above the line are small P superscript positive small B superscript positive and alleles below the line are small P small B.

This arrangement, in which wild-type alleles are found on one chromosome and mutant alleles are found on the other chromosome, is referred to as the **coupling**, or **cis, configuration**.

Alternatively, one chromosome might carry the alleles for green thorax (p^+) and black puparium (b), and the other chromosome might carry the alleles for purple thorax (p) and brown puparium (b^+):

$$\frac{p^+ \quad b}{p \quad b^+}$$

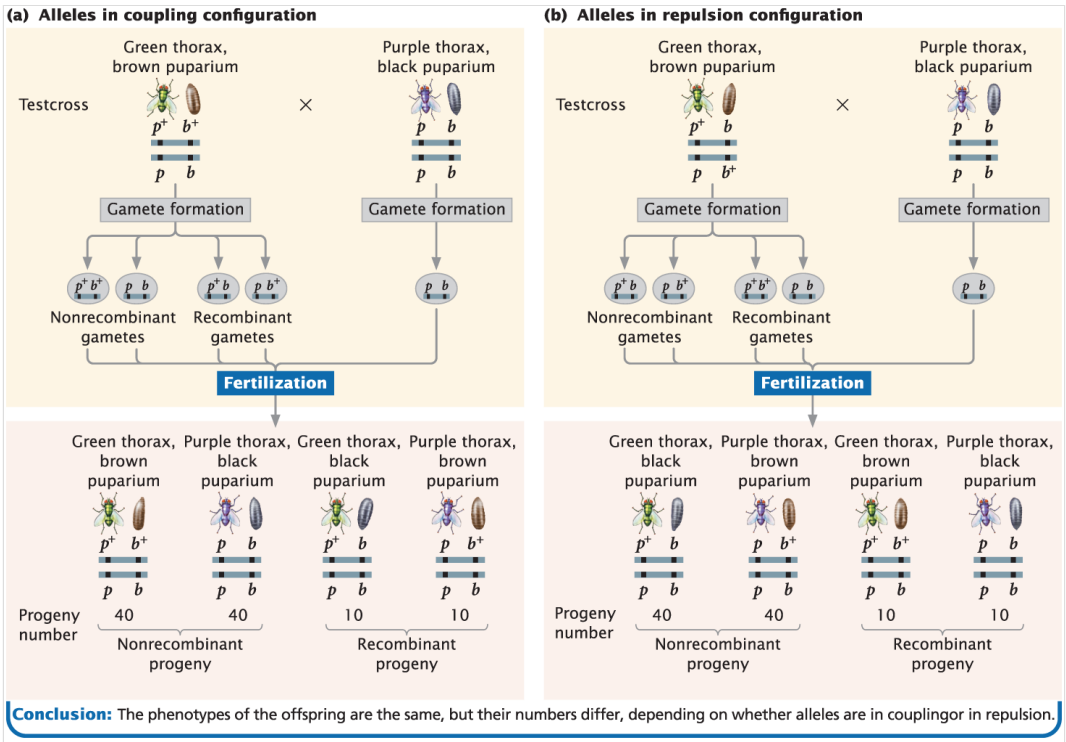
Description
The chromosomes are represented by a straight, horizontal line. The alleles above the line are small P superscript positive small B and alleles below the line are small P small B superscript positive.

This arrangement, in which each chromosome contains one wild-type and one mutant allele, is called the **repulsion**, or **trans, configuration**. Whether the alleles in the heterozygous parent are in

coupling or repulsion determines which phenotypes will be most common among the progeny of a testcross.

When the alleles of the heterozygous parent are in the coupling configuration, the most numerous progeny types are those with a green thorax and brown puparium and those with a purple thorax and black puparium (**Figure 7.7a**). However, when the alleles are in repulsion, the most numerous progeny types are those with a green thorax and black puparium and those with a purple thorax and brown puparium (**Figure 7.7b**). Notice that because the alleles are in repulsion, the phenotypes of the nonrecombinant progeny (green thorax with black puparium and purple thorax with brown puparium) are not the same as the phenotypes of the parents (green thorax with brown puparium and purple thorax with black puparium). Nonrecombinant progeny are those that resulted from a chromosome that did not undergo recombination and that need not have the same phenotype as the parents. Notice also that the genotypes of the parents in Figure 7.7a and b are the same ($p^+p\ b^+b \times pp\ bb$) and that the dramatic difference in the phenotypic ratios of the progeny in the two crosses results entirely from the configuration—coupling or repulsion—of the chromosomes. Knowledge of the arrangement of the alleles on the chromosomes is essential to accurately predicting the outcome of crosses in which genes are linked.

THINK-PAIR-SHARE Question 3



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.7 The arrangement (coupling or repulsion) of linked genes on a chromosome affects the results of a testcross. Linked loci in the Australian blowfly (*Lucilia cuprina*) determine the color of the thorax and that of the puparium.

Description

Figure a on the left shows results when alleles are in coupling configuration. P generation shows a testcross between a fly with a green thorax and a brown puparium and a fly and a purple thorax and a black puparium. The genotype of the green fly is small P superscript positive small B superscript positive small P small B, while that of the purple fly is small P small B small P small B. Gamete formation occurs and the following gametes are formed: For the green fly, nonrecombinant gametes are small P superscript positive small B superscript positive and small P small B. Recombinant gametes are small P superscript positive small B and small P small B superscript positive. For the purple fly, gametes are small P small B. Fertilization occurs and the F subscript 1 generation is obtained below: Nonrecombinant progeny or flies: 40 green thorax brown puparium (small P superscript positive small B superscript positive small P small B) and 40 purple thorax black puparium (small P small B small P small B). Recombinant progeny or flies: 10 green thorax black puparium (small P superscript positive small B small P small B) and 10 purple thorax brown puparium (small P small B superscript positive small P small B).

Figure b on the right shows results when alleles are in repulsion configuration. In this test cross, P generation shows a green fly with brown puparium. Its genotype is small P superscript positive small B small P small B superscript positive. The green fly is crossed with a purple fly with black puparium, which has the genotype small P small B small P small B. Gamete formation occurs and following gametes are formed: For the green fly, nonrecombinant gametes are small P superscript positive small B and small P small B superscript positive. Recombinant gametes are small P superscript positive small B superscript positive and small P small B. For the purple fly, gametes formed are small P small B. Fertilization occurs and F subscript 1 generation is obtained below. Nonrecombinant progeny: 40 green thorax black puparium (small P superscript positive small B small P small B) and 40 purple thorax brown puparium (small P small B superscript positive small P small B). Recombinant progeny: 10 green thorax brown puparium (small P superscript positive small B superscript positive small P small B) and 10 purple thorax black puparium (small P small B small P small B). A caption below reads, Conclusion: The phenotypes of the offspring are the same, but their numbers differ, depending on whether alleles are in coupling or in repulsion.

CONCEPTS

The arrangement of linked alleles on the chromosomes is critical for determining the outcome of a cross. When two wild-type alleles are on one homologous chromosome and two mutant alleles are on the other, the alleles are in the coupling configuration; when each chromosome contains one wild-type allele and one mutant allele, the alleles are in repulsion.

✔ CONCEPT CHECK 2

The following testcross produces the progeny shown: *Aa Bb* × *aa bb* → 10 *Aa Bb*, 40 *Aa bb*, 40 *aa Bb*, 10 *aa bb.* Were the *A* and *B* alleles in the *Aa Bb* parent in coupling or in repulsion?

CONNECTING CONCEPTS CONNECT

Relating Independent Assortment, Linkage, and Crossing Over

We have now considered three situations for genes at different loci. First, the genes may be located on different chromosomes; in this case, they exhibit independent assortment and combine randomly when gametes are formed. An individual heterozygous at two loci (*Aa Bb*) produces four types of gametes (*A B*, *a b*, *A b*, and *a B*) in equal proportions: two types of nonrecombinants and two types of recombinants. In a testcross, these gametes will result in four types of progeny in equal proportions (**Table 7.1**).

TABLE 7.1 Results of a testcross (*Aa Bb* × *aa bb*) with complete linkage, independent assortment, and linkage with some crossing over

Situation	Progeny of Testcross	
Independent assortment	*Aa Bb* (nonrecombinant)	25%
	aa bb (nonrecombinant)	25%
	Aa bb (recombinant)	25%
	aa Bb (recombinant)	25%
Complete linkage (genes in coupling)	*Aa Bb* (nonrecombinant)	50%
	aa bb (nonrecombinant)	50%
Linkage with some crossing over	$Aa\ Bb$ (nonrecombinant) $aa\ bb$ (nonrecombinant)	More than 50%
(genes in coupling)	$Aa\ bb$ (recombinant) $aa\ Bb$ (recombinant)	Less than 50%

Second, the genes may be completely linked—meaning that they are on the same chromosome and lie so close together that crossing over between them is rare. In this case, the genes do not recombine. An individual heterozygous for two completely linked genes in the coupling configuration

$$\frac{A \quad B}{a \quad b}$$

Description

A single line represents a pair of homologous chromosomes. Above the line, big A is on the left and big B is on the right. Below the line, small A is on the left and small B is on the right.

produces only nonrecombinant gametes containing alleles *A B* or *a b*; the alleles do not assort into new combinations such as *A b* or *a B*. In a testcross, completely linked genes produce only two types of progeny, both nonrecombinants, in equal proportions (see Table 7.1).

The third situation, incomplete linkage, is intermediate between the two extremes of independent assortment and complete linkage. Here, the genes are physically linked on the same chromosome, which prevents independent assortment. However, occasional crossovers break up the linkage and allow the genes to recombine. With incomplete linkage, an individual heterozygous at two loci produces four types of gametes—two types of recombinants and two types of nonrecombinants—but the nonrecombinants are produced more frequently than are the recombinants because crossing over between these loci does not take place in every meiosis. In the testcross, these gametes result in four types of progeny, with the nonrecombinants more frequent than the recombinants (see Table 7.1).

Earlier in the chapter, the term *recombination* was defined as the sorting of alleles into new combinations. We've now considered two types of recombination that differ in their mechanisms. Interchromosomal recombination takes place between genes located on *different* chromosomes. It arises from independent assortment—the random segregation of chromosomes in anaphase I of meiosis—and is the kind of recombination that Mendel discovered while studying dihybrid crosses. A second type of recombination, intrachromosomal recombination, takes place between genes located on the *same* chromosome. This recombination arises from crossing over—the exchange of genetic material in prophase I of meiosis. Both recombination mechanisms produce new allele combinations in the gametes, so they cannot be distinguished by examining the types of gametes produced. Nevertheless, they can often be distinguished by the *frequencies* of types of gametes: interchromosomal recombination produces 50% nonrecombinant gametes and 50% recombinant gametes, whereas intrachromosomal recombination frequently produces more than 50% nonrecombinant gametes and less than 50% recombinant gametes. However, when the genes are very far apart on the same chromosome, crossing over takes place in every meiotic division, leading to 50% recombinant gametes and 50% nonrecombinant gametes. This result is the same as in independent assortment of genes located on different chromosomes (interchromosomal recombination). Thus, intrachromosomal recombination of

genes that lie far apart on the same chromosome and interchromosomal recombination are phenotypically indistinguishable.

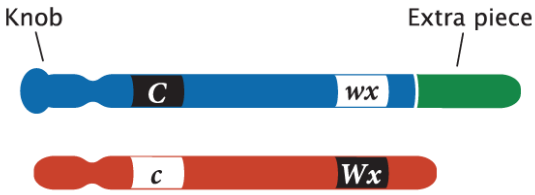
Evidence for the Physical Basis of Recombination

Walter Sutton's chromosome theory of inheritance, which stated that genes are physically located on chromosomes (see Chapter 3), was supported by Nettie Stevens and Edmund Wilson's discovery that sex was associated with a specific chromosome in insects and by Calvin Bridges's demonstration that nondisjunction of X chromosomes was related to the inheritance of eye color in *Drosophila* (see Chapter 4). Further evidence for the chromosome theory of heredity came in 1931, when Harriet Creighton and Barbara McClintock (**Figure 7.8**) obtained evidence that intrachromosomal recombination was the result of physical exchange between chromosomes. Creighton and McClintock discovered a strain of corn that had an abnormal chromosome 9, containing a densely staining knob at one end and a small piece of another chromosome attached to the other end. This aberrant chromosome allowed them to visually distinguish the two members of a homologous pair.

Karl Maramorosch/Courtesy of Cold Spring Harbor Laboratory Archives.

7.8 Barbara McClintock (left) and Harriet Creighton (right) provided evidence that genes are located on chromosomes.

Creighton and McClintock focused on the inheritance of two traits in corn determined by genes on chromosome 9. At one locus, a dominant allele (*C*) produced colored kernels, whereas a recessive allele (*c*) produced colorless kernels. At a second, linked locus, a dominant allele (*Wx*) produced starchy kernels, whereas a recessive allele (*wx*) produced waxy kernels. They obtained a plant that was heterozygous at both loci in repulsion, with the alleles for colored and waxy on the aberrant chromosome and the alleles for colorless and starchy on the normal chromosome:



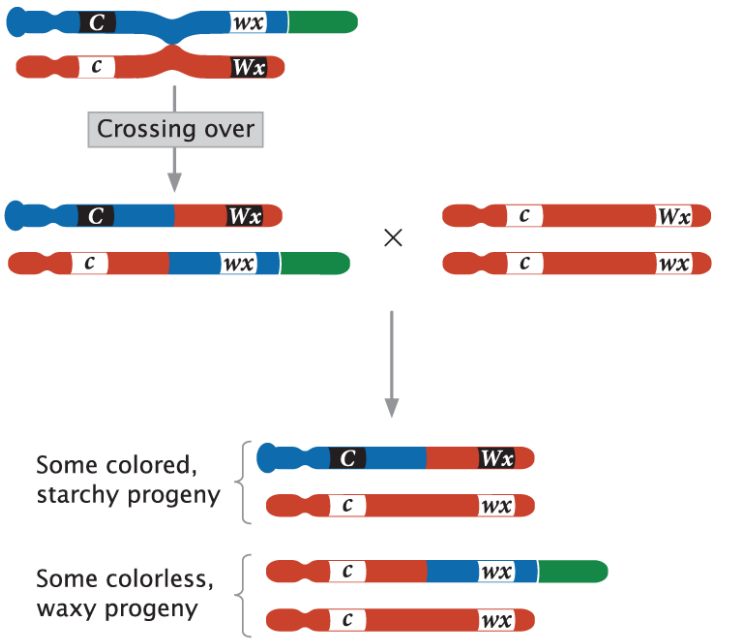
Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The diagram starts with a drawing of two chromosomes containing the alleles. The top chromosome has a region labeled as knob at the end of the short arm and a region labeled as extra piece (green) at the end of the long arm. The second chromosome does not contain these 2 features. The top chromosome has big C and small W small X alleles on its long arm. The bottom chromosome has small C and big W small X alleles on its long arm.

They then crossed this heterozygous plant with one that was homozygous for colorless and heterozygous for waxy (with both chromosomes normal):

$$\frac{C \quad wx}{c \quad Wx} \times \frac{c \quad Wx}{c \quad wx}$$

This cross produces different combinations of traits in the progeny, but the only way that colorless and waxy progeny can arise is through crossing over in the doubly heterozygous parent:



Note: Not all progeny genotypes are shown.

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

A line drawing shows a cross between the two chromosomes. One chromosome has big C and small W small X on top and small C and big W small X on bottom. The chromosome it is crossed with has small C and big W small X on top and small C and small W small X on bottom.

Crossing over occurs between the two chromosomes. The result shows two chromosomes below. The top chromosome has big C with a knob and big W small X and the bottom chromosome has small C and small W small X with the extra piece (green). This is crossed with two normal chromosomes containing alleles, small C and big W small X. The crossover event occurs. The resultant chromosomes are drawn below. One resultant chromosome has the knob on the short arm, big C and big W small X, and normal long arm. The other chromosome has the normal short arm, small C and small W small X. Both these chromosomes are some colored and starchy. The third chromosome has an extra piece (green) on the long arm and alleles small C small W small X and the fourth chromosome has a normal chromosome with alleles, small C and small W small X. Both these chromosomes are labeled colorless, waxy progeny.

A caption below reads, Note: Not all progeny genotypes are shown.

Notice that if crossing over entails physical exchange between the chromosomes, then the colorless, waxy progeny resulting from recombination should have a chromosome with an extra piece, but not a knob. Furthermore, some of the colored, starchy progeny should have a chromosome with a knob, but not the extra piece. This outcome is precisely what Creighton and McClintock observed, confirming the chromosomal theory of inheritance. Curt Stern provided a similar demonstration by using chromosomal markers in *Drosophila* at about the same time. We will examine the molecular basis of recombination in more detail in Chapter 12.

Predicting the Outcomes of Crosses with Linked Genes

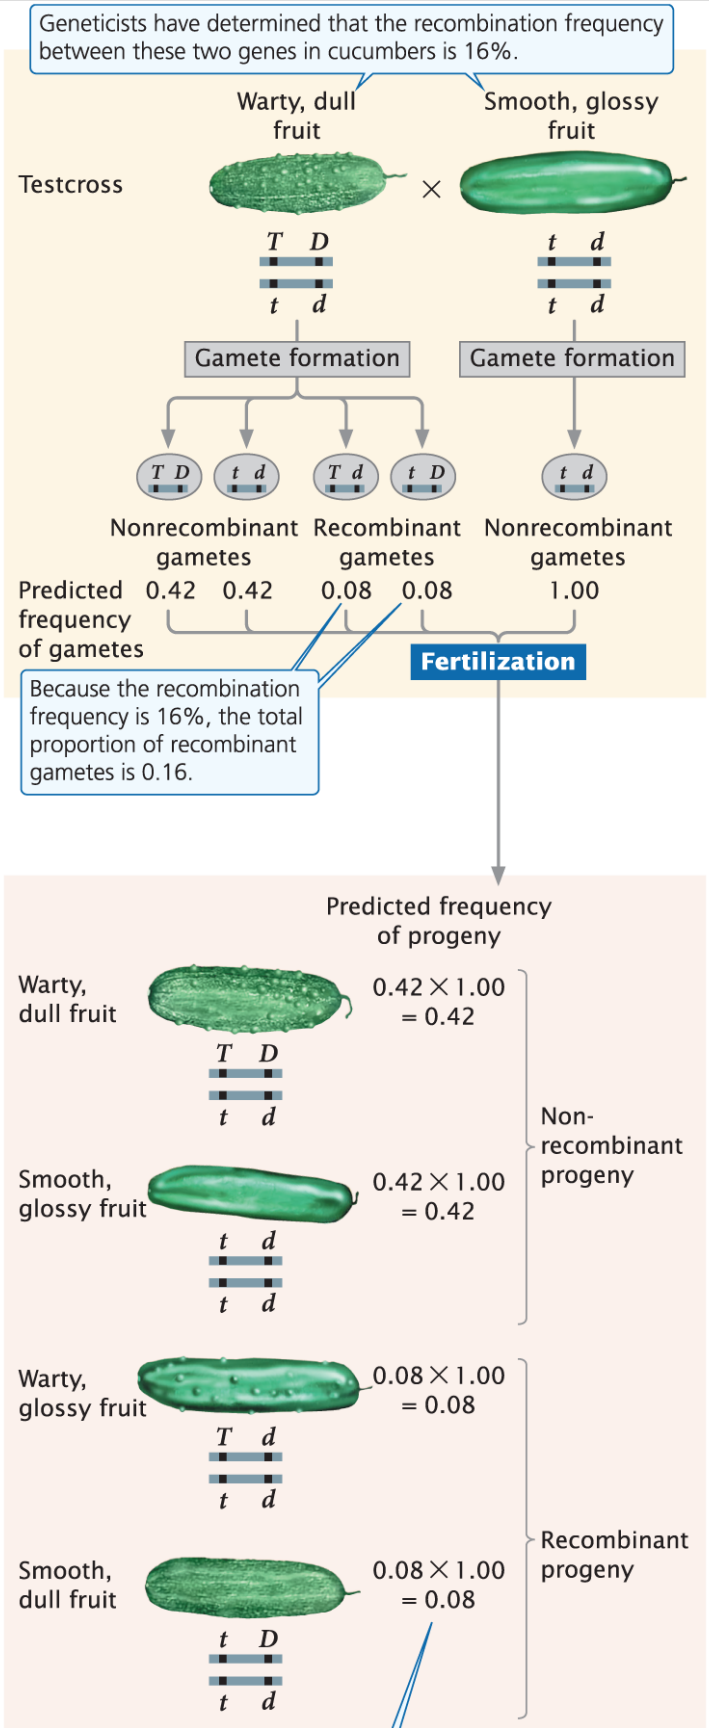
Knowing the arrangement of alleles on a chromosome allows us to predict the types of progeny that will result from a cross entailing linked genes and to determine which of these types will be the most numerous. Determining the *proportions* of the types of offspring requires an additional piece of information: the recombination frequency. The recombination frequency provides us with information about how often the alleles in the gametes appear in new combinations, allowing us to predict the proportions of offspring phenotypes that will result from a specific cross that entails linked genes.

In cucumbers, smooth fruit (*t*) is recessive to warty fruit (*T*), and glossy fruit (*d*) is recessive to dull fruit (*D*). Geneticists have determined that these two genes exhibit a recombination frequency of 16%. Suppose that we cross a plant that is homozygous for warty and dull fruit with a plant that is homozygous for smooth and glossy fruit, and then carry out a testcross using the F_1:

$$\frac{T \quad D}{t \quad d} \times \frac{t \quad d}{t \quad d}$$

What types and proportions of progeny will result from this testcross?

Four types of gametes will be produced by the heterozygous parent, as shown in **Figure 7.9**: two types of nonrecombinant gametes (*T D* and *t d*) and two types of recombinant gametes (*T d* and *t D*). The recombination frequency tells us that 16% of the gametes produced by the heterozygous parent will be recombinants. Because there are two types of recombinant gametes, each should arise with a frequency of $^{16\%}/_{2} = 8\%$. This frequency can also be represented as a probability of 0.08. All the other gametes will be nonrecombinants, so they should arise with a frequency of 100% − 16% = 84%. Because there are two types of nonrecombinant gametes, each should arise with a frequency of $^{84\%}/_{2} = 42\%$ (or 0.42). The other parent in the testcross is homozygous and therefore produces only a single type of gamete (*t d*) with a frequency of 100% (or 1.00).



Geneticists have determined that the recombination frequency between these two genes in cucumbers is 16%.

7.9 The recombination frequency allows us to predict the proportions of offspring expected for a cross entailing linked genes.

Description

The figure shows a test cross between a warty dull fruit with genotype big T big D small T small D and a smooth glossy fruit with genotype small T small D small T small D. A caption reads, Geneticists have determined that the recombination frequency between 2 genes in cucumbers is 16 percent. All possible gametes are shown, recombinant and nonrecombinant. Below the drawing of the gametes are the predicted frequencies of the gametes.

For warty, dull fruit, gametes formed are as follows:

Nonrecombinant gametes: big T big D and small T small D (predicted frequency 0 point 4 2 and 0 point 4 2 respectively).

Recombinant gametes: big T small D and small T big D (0 point 0 8 and 0 point 0 8 respectively).

A caption reads, Because the recombination frequency is 16 percent, the total proportion of recombinant gametes is 0 point 1 6.

For smooth, glossy fruit:

Nonrecombinant gamete formed: small T small D (1 point 0 0)

Fertilization occurs and F subscript 1 generation is obtainedbelow. The progenies formed are as follows:

Nonrecombinant progeny:

Warty dull fruit, with genotype big T big D small T small D with predicted frequency 0 point 4 2 multiplied by 1 equals 0 point 4 2.

Smooth glossy fruit with genotype small T small D small T small D with predicted frequency 0 point 4 2 multiplied by 1 equals 0 point 4 2.

Recombinant progeny:

Warty, glossy fruit with genotype big T small D small T small D with predicted frequency 0 point 0 8 multiplied by 1 equals 0 point 0 8.

Smooth, dull fruit small T big D small T small D with predicted frequency 0 point 0 8 multiplied by 1 equals 0 point 0 8.

A caption reads, The predicted frequencies of the progeny are obtained by multiplying the frequencies of the gametes.

Four types of progeny result from the testcross (see Figure 7.9). The expected proportion of each progeny type can be determined by using the multiplication rule (see Chapter 3), multiplying together the probability of each gamete. For example, testcross progeny with warty and dull fruit

$$\frac{T \quad D}{t \quad d}$$

appear with a frequency of 0.42 (the probability of inheriting a gamete with chromosome $\underline{T \quad D}$ from the heterozygous parent) × 1.00 (the probability of inheriting a gamete with chromosome $\underline{t \quad d}$ from the recessive parent) = 0.42. The proportions of the other types of F_2 progeny can be calculated in a similar manner (see Figure 7.9). This method can be used for predicting the outcome of any cross with linked genes for which the recombination frequency is known.

THINK-PAIR-SHARE Question 4

Testing for Independent Assortment

In some crosses, it is obvious that the genes are linked because there are clearly more nonrecombinant progeny than recombinant progeny. In other crosses, the difference between independent assortment and linkage isn't as obvious. For example, suppose we did a testcross for two pairs of alleles, such as *Aa Bb* × *aa bb*, and observed the following numbers of progeny: 54 *Aa Bb*, 56 *aa bb*, 42 *Aa bb*, and 48 *aa Bb*. Is this outcome the 1 : 1 : 1 : 1 ratio we would expect if *A* and *B* assorted independently? Not exactly, but it's pretty close. Perhaps these genes assorted independently and chance produced the slight deviations between the observed numbers and the expected 1 : 1 : 1 : 1 ratio. Alternatively, the genes might be linked, but considerable crossing over might be taking place between them, and so the number of nonrecombinants is only slightly greater than the number of recombinants. How do we distinguish between the role of chance and the role of linkage in producing deviations from the results expected with independent assortment?

We encountered a similar problem in crosses in which genes were unlinked: the problem of distinguishing between deviations due to chance and those due to other factors. We addressed this problem (in Chapter 3) with the chi-square goodness-of-fit test, which helps

us evaluate the likelihood that chance alone is responsible for deviations between the numbers of progeny that we observe and the numbers that we expect according to the principles of inheritance. Here, we are interested in a different question: Is the inheritance of alleles at one locus independent of the inheritance of alleles at a second locus? If the answer to this question is yes, then the genes are assorting independently; if the answer is no, then the genes are probably linked.

A possible way to test for independent assortment is to calculate the expected probability of each progeny type, assuming independent assortment, and then use the chi-square goodness-of-fit test to evaluate whether the observed numbers deviate significantly from the expected numbers. With independent assortment, we expect $1/4$ of each phenotype: $1/4$ *Aa Bb*, $1/4$ *aa bb*, $1/4$ *Aa bb*, and $1/4$ *aa Bb*. This expected probability of each genotype is based on the multiplication rule (see Chapter 3). For example, if the probability of *Aa* is $1/2$ and the probability of *Bb* is $1/2$, then the probability of *Aa Bb* is $1/2 \times 1/2 = 1/4$. In this calculation, we are making two assumptions: (1) that the probability of each single-locus genotype is $1/2$, and (2) that genotypes at the two loci are inherited independently $(1/2 \times 1/2 = 1/4)$.

One problem with this approach is that a significant chi-square value can result from a violation of either assumption. If the genes are linked, then the inheritance of genotypes at the two loci is not independent (assumption 2), and we will get a significant deviation

between observed and expected numbers. But we can also get a significant deviation if the probability of each single-locus genotype is not $^1/_2$ (assumption 1), even when the genotypes are assorting independently. We may obtain a significant deviation, for example, if individuals with one genotype have a lower probability of surviving or if the penetrance of a genotype is not 100%. We could test both assumptions by conducting a series of chi-square tests, first testing the inheritance of genotypes at each locus separately (assumption 1) and then testing for independent assortment (assumption 2). However, a faster method is to test for independence in genotypes with a *chi-square test of independence*.

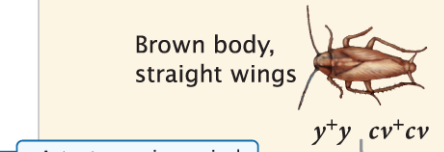
THE CHI-SQUARE TEST OF INDEPENDENCE

The chi-square test of independence allows us to evaluate whether the segregation of alleles at one locus is independent of the segregation of alleles at another locus without making any assumption about the probability of single-locus genotypes. In the chi-square goodness-of-fit test, the expected value is based on a theoretical relation: for example, the expected ratio in a genetic cross. For the chi-square test of independence, the expected value is based strictly on the observed values, along with the assumption that they are independent.

To illustrate this analysis, let's examine the results of a cross between German cockroaches, in which yellow body (*y*) is recessive

to brown body (y^+), and curved wings (cv) are recessive to straight wings (cv^+). A testcross ($y^+y\ cv^+cv \times yy\ cvcv$) produces the progeny shown in **Figure 7.10a**. If the segregation of alleles at each locus is independent, then the proportions of progeny with y^+y and yy genotypes should be the same for cockroaches with genotype cv^+cv and for cockroaches with genotype $cvcv$. The converse is also true: the proportions of progeny with cv^+cv and $cvcv$ genotypes should be the same for cockroaches with genotype y^+y and for cockroaches with genotype yy.

(a)



Brown body, straight wings × Yellow body, curved wings

y^+y cv^+cv × yy $cvcv$

1 A testcross is carried out between cockroaches differing in two characteristics.

Cross

63	y^+y cv^+cv	brown body, straight wings
28	y^+y $cvcv$	brown body, curved wings
33	yy cv^+cv	yellow body, straight wings
77	yy $cvcv$	yellow body, curved wings

(b) Contingency table

2 To test for independent assortment of alleles encoding the two traits, a table is constructed...

Segregation of y^+ and y 3 ...with genotypes for one locus along the top...

Segregation of cv^+ and cv 4 ...and genotypes for the other locus along the left side.

	y^+y	yy	Row totals
cv^+cv	63	33	96
cv cv	28	77	105
Column totals	91	110	201 Grand total

5 Numbers of each genotype are placed in the table cells, and the row totals, column totals, and grand total are computed.

(c)

Genotype	Number observed	Number expected $\left(\frac{\text{row total} \times \text{column total}}{\text{grand total}}\right)$
y^+y cv^+cv	63	$\frac{96 \times 91}{201} = 43.46$
y^+y $cvcv$	28	$\frac{105 \times 91}{201} = 47.54$
yy cv^+cv	33	$\frac{96 \times 110}{201} = 52.54$
yy $cvcv$	77	$\frac{105 \times 110}{201} = 57.46$

6 The expected numbers of progeny, assuming independent assortment, are calculated.

(d)

7 A chi-square value is calculated.

$$\chi^2 = \Sigma \frac{(\text{observed} - \text{expected})^2}{\text{expected}}$$

$$= \frac{(63 - 43.46)^2}{43.46} + \frac{(28 - 47.54)^2}{47.54} + \frac{(33 - 52.54)^2}{52.54} + \frac{(77 - 57.46)^2}{57.46}$$

$$= 8.79 + 8.03 + 7.27 + 6.64$$

$$= 30.73$$

(e)

$\text{df} = (\text{number of rows} - 1) \times (\text{number of columns} - 1)$

8 The probability is less than 0.005, indicating that

7.10 A chi-square test of independence can be used to determine if genes at two loci are assorting independently.

Description

Part a at the top shows a cockroach with brown body, straight wings with genotype small Y superscript positive small Y small C small V superscript positive small C small V crossed with a cockroach with yellow body, curved wings with genotype small Y small Y small C small V small C small V. Cross is conducted and a caption reads, A testcross is carried out between cockroaches differing in two characteristics. In the F subscript 1 generation, there are four types of progeny obtained. 63 have genotype small Y superscript positive small Y small C small V superscript positive small C small V and are brown cockroaches with straight wings. 28 have the genotype small Y small Y superscript positive small C small V small C small V and are brown, curved-wing cockroaches. 33 have genotype small Y small Y small C small V superscript positive small C small V and are yellow, straight-winged cockroaches. 77 have the genotype small Y small Y small C small V small C small V and are yellow curved-winged cockroaches.

Part b below shows a contingency table with 4 columns and 3 rows. A caption reads, To test for independent assortment of alleles encoding the two traits, a table is constructed with genotypes for one locus along the top and genotypes for the other locus along the left side. The headers of the columns represents segregation of small Y superscript positive and small Y and are labeled with each of the genotypes small Y superscript positive small Y and small Y small Y, with the last column header labeled row totals. The row entries are as follows:

Row 1: small C small V superscript positive small C small V; 63; 33; 96.

Row 2: small C small V small C small V; 28; 77; 105.

Row 3: column totals; 91; 110; 201 (grand total).

Another caption reads, Numbers of each genotype are placed in the table cells, and the row totals, column totals, and grand total are computed.

Part c below shows a table with 4 rows and 3 columns. The column headers are as follows: Genotype, number observed, and a formula for number expected as follows: left parenthesis row total multiplied by column total over grand total right parenthesis. The row entries are as follows:

Row 1: small Y superscript positive small Y small C small V superscript positive small C small V; 63; 96 multiplied by 91 over 201 equals 43 point 4 6

Row 2: small Y superscript positive small Y small C small V small C small V; 28; 105 multiplied by 91 over 201 equals 47 point 5 4

Row 3: small Y small Y small C small V superscript positive small C small V; 33; 96 multiplied by 110 over 201 equals 52 point 4 6

Row 4: small Y small Y small C small V small C small V; 77; 105 multiplied by 110 over 201 equals 57 point 4 6

A caption reads, The expected numbers of progeny, assuming independent assortment, are calculated.

Part d below shows calculated chi-square value. Chi square equals sigma start fraction left parenthesis observed minus expected right parenthesis squared over expected end fraction equals start fraction left parenthesis 63 minus 43 point 4 6 right parenthesis squared over 43 point 4 6 end fraction plus start fraction left parenthesis 28 minus 47 point 5 4 right parenthesis squared over 47 point 5 4 end fraction plus left parenthesis 33 minus 52 point 5 4 right parenthesis squared over 52 point 5 4 plus start fraction left parenthesis 77 minus 57 point 4 6 right parenthesis squared over 57 point 4 6 end fraction equals 8 point 7 9 plus 8 point 0 3 plus 7 point 2 7 plus 6 point 6 4 equals 30 point 7 3. A caption reads, A chi-square value is calculated.

Part e below shows calculation for probability. small D small F equals left parenthesis number of rows minus 1 right parenthesis multiplied by left parenthesis number of columns minus 1 right parenthesis. small D small F equals left parenthesis 2 minus 1 right parenthesis multiplied by left parenthesis 2 minus 1 right parenthesis equals 1 multiplied by 1 equals 1. big P is less than 0 point 0 0 5. A caption reads, The probability is less than 0

point 0 0 5, indicating that the difference between numbers of observed and expected progeny is probably not due to chance.

A caption below reads, Conclusion: The genes for body color and type of wing are not assorting independently and must be linked.

To determine whether the proportions of progeny with genotypes at the two loci are independent, we first construct a table of the observed numbers of progeny, somewhat like a Punnett square, except that we put the genotypes that result from the segregation of alleles at one locus along the top and the genotypes that result from the segregation of alleles at the other locus along the side (**Figure 7.10b**). Next, we compute the total for each row, the total for each column, and the grand total (the sum of all row totals or the sum of all column totals, which should be the same). These totals will be used to compute the expected values for the chi-square test of independence.

Our next step is to compute the expected numbers for each combination of genotypes (each cell in the table) under the assumption that the segregation of alleles at the *y* locus is independent of the segregation of alleles at the *cv* locus. If the segregation of alleles at each locus is independent, the expected number for each cell can be computed with the following formula:

$$\text{expected number} = \frac{\text{row total} \times \text{column total}}{\text{grand total}}$$

For the cell of the table corresponding to genotype y^+y cv^+cv (the upper-left cell of the table in Figure 7.10b), the expected number is

$$\frac{96 \text{ (row toal)} \times 91 \text{ (column total)}}{201 \text{ (grand total)}} = \frac{8736}{201} = 43.46$$

The expected numbers for each cell calculated by this method are given in **Figure 7.10c**.

We now calculate a chi-square value by using the same formula that we used for the chi-square goodness-of-fit test in Chapter 3:

$$x^2 = \sum \frac{(\text{observed} - \text{expected})^2}{(\text{expected})}$$

Recall that Σ means "sum" and that we are adding together the (observed−expected)^2/expected values for the four types of progeny. The observed and expected numbers of cockroaches from the testcross give us a calculated chi-square value of 30.73 (**Figure 7.10d**).

To determine the probability associated with this chi-square value, we need the degrees of freedom. Recall from Chapter 3 that the degrees of freedom are the number of ways in which the observed classes are free to vary from the expected values. In general, for the chi-square test of independence, the degrees of freedom equal the number of rows in the table minus 1, multiplied by the number of columns in the table minus 1 (**Figure 7.10e**), or

$$\text{df} = (\text{number of rows} - 1) \times (\text{number of columns} - 1)$$

In our example, there are two rows and two columns, and so the degrees of freedom are

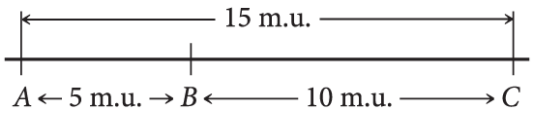
$$\text{df} = (2 - 1) \times (2 - 1) = 1 \times 1 = 1$$

Therefore, our calculated chi-square value is 30.73, with 1 degree of freedom. We can use Table 3.7 to find the associated probability. Looking at Table 3.7, we find that our calculated chi-square value is larger than the largest chi-square value given for 1 degree of freedom, which has a probability of 0.005. Thus, our calculated chi-square value has a probability of less than 0.005. This very small probability indicates that the genotypes are not in the proportions that we would expect if independent assortment were taking place. Our conclusion, then, is that these genes are not assorting independently and must be linked. As in the case of the chi-square goodness-of-fit test, geneticists generally consider that any chi-square value for the test of independence with a probability of less than 0.05 means that the observed values are significantly different from the expected values and is therefore evidence that the genes are not assorting independently. **› TRY PROBLEM 17**

Gene Mapping with Recombination Frequencies

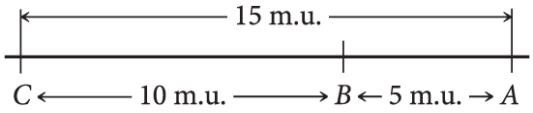
Thomas Hunt Morgan and his students developed the idea that physical distances between genes on a chromosome are related to their rates of recombination. They hypothesized that crossover events take place more or less at random up and down the chromosome and that two genes that lie far apart are more likely to undergo a crossover than are two genes that lie close together. They proposed that recombination frequencies could provide a convenient way to determine the order of genes along a chromosome and would give estimates of the relative distances between the genes. Chromosome maps calculated by using the genetic phenomenon of recombination are called **genetic maps**. In contrast, chromosome maps calculated by using physical distances along the chromosome (often expressed as numbers of base pairs) are called **physical maps**.

Distances on genetic maps are measured in **map units** (abbreviated m.u.); one map unit equals a 1% recombination rate. Map units are also called **centiMorgans (cM)**, in honor of Thomas Hunt Morgan. Genetic distances measured with recombination rates are approximately additive: if the distance from gene *A* to gene *B* is 5 m.u., the distance from gene *B* to gene *C* is 10 m.u., and the distance from gene *A* to gene *C* is 15 m.u., then gene *B* must be located between genes *A* and *C*. On the basis of the map distances just given, we can draw a simple genetic map for genes *A*, *B*, and *C*, as shown here:



Description
A line is drawn and the gene locations are indicated with notches in the line. On the left is big A and in the middle is big B. The distance 5 m u and arrows projecting from right and left is written between big A and big B. Between big B and big C is the distance 10 m u written with arrows projecting right and left. Above the line is written the total distance, 15 m u with arrows extending all the way to big A and big C.

We could just as plausibly draw this map with *C* on the left and *A* on the right:

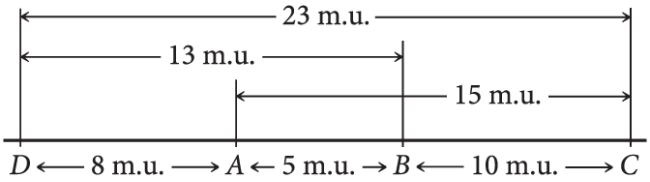


Description
From the left, their sequence is big A, big B, and big C. Distance between big A and big B is 5 m u. Distance between big B and big C is 10 m u. Total distance from big A to big C is 15 m u.

Both maps are correct and equivalent because, with information about the relative positions of only three genes, the most that we can determine is which gene lies in the middle. If we obtained distances to an additional gene, then we could position *A* and *C* relative to that gene. An additional gene *D*, examined through genetic crosses, might yield the following recombination frequencies:

Gene pair	Recombination frequency (%)
A and *D*	8
B and *D*	13
C and *D*	23

Notice that *C* and *D* exhibit the highest rate of recombination; therefore, *C* and *D* must be farthest apart, with genes *A* and *B* between them. Using the recombination frequencies and remembering that 1 m.u. = 1% recombination, we can now add *D* to our map:



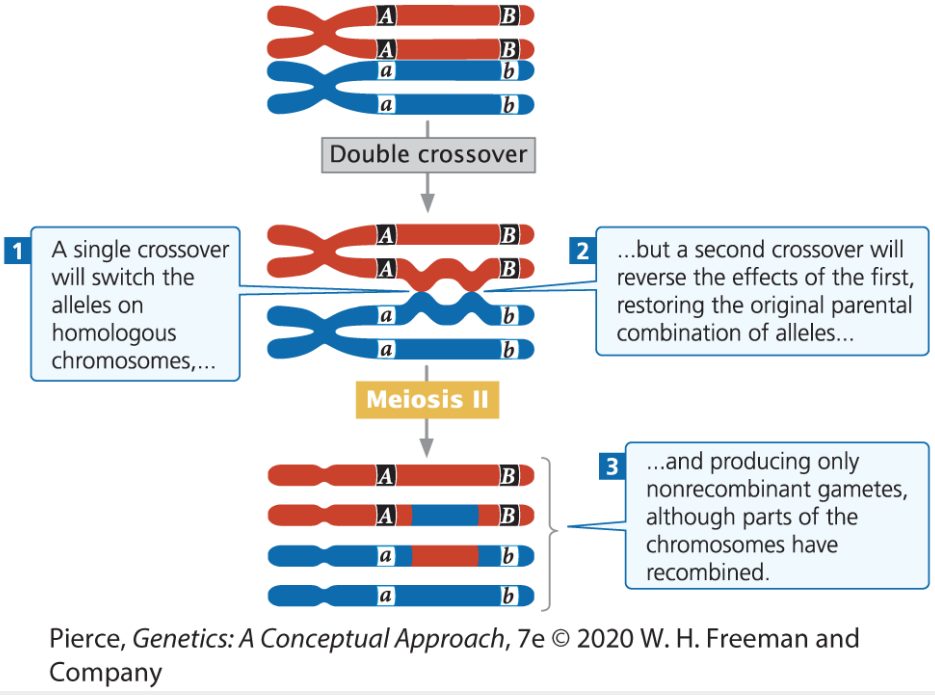
Description
From the left, their sequence is big D, big A, big B, and big C. Distance between big D and big A is 8 m u. Distance between big A and big B is 5 m u. Distance between big B and big C is 10 m u. Distance from big D to big B is 13 m u, from big A to big C is 15 m u, and total distance from big D to big C is 23 m u.

Thus, by doing a series of crosses between pairs of genes, we can construct genetic maps showing the linkage arrangements of a number of genes.

Two points about constructing chromosome maps from recombination frequencies should be emphasized. First, recall that we cannot distinguish between genes on different chromosomes and genes located far apart on the same chromosome. If genes exhibit 50% recombination, the most that can be said about them is that they belong to different linkage groups, either on different chromosomes or far apart on the same chromosome.

The second point is that a testcross for two genes that are far apart on the same chromosome tends to underestimate the true physical distance between them because the cross does not reveal double crossovers that might take place between the two genes (**Figure 7.11**). A double crossover arises when two separate crossover events take place between two loci. (For now, we will consider only double crossovers that take place between two of the four chromatids of a homologous pair—two-strand double crossovers. Double crossovers that take place among three and four chromatids will be considered later, in the section Effects of Multiple Crossovers.) Whereas a single crossover between two genes produces combinations of alleles that were not present on the original parental chromosomes, a second crossover between the same two genes reverses the effects of the first, thus restoring the original parental combination of alleles (see **Figure 7.11**). We therefore cannot distinguish between the progeny produced by two-strand double crossovers and the progeny produced when there is no crossing over at all. As we see in the next section, however, we can detect double crossovers if we examine a third gene that lies between the two crossovers. Because double

crossovers between two genes go undetected, map distances will be underestimated whenever double crossovers take place. Double crossovers are more frequent between genes that are far apart; therefore, genetic maps based on short distances are usually more accurate than those based on longer distances.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.11 A two-strand double crossover between two linked genes produces only nonrecombinant gametes.

Description

The diagram shows X-shaped red and blue chromosomes. On the red chromosome, the alleles are big A big B on both the chromatids. On the blue chromosome, the allele are small A small B on both the chromatids. Double crossover occurs and the red and blue chromatids of each chromosome that lie in the middle meet at two points. A caption reads, A single crossover will switch the alleles on homologous chromosomes, but a second crossover will reverse the effects of the first, restoring the original parental combination of allele and producing only nonrecombinant gametes, although parts of the chromosomes have recombined. Meiosis 2 occurs and the resultant chromosomes below are as follows:

Red chromosome with alleles big A and big B.

Red chromosome with alleles big A and big B where a part in between is blue.

Blue chromosome with alleles small A and small B where a part in between is red.

Blue chromosome with alleles small A and small B.

CONCEPTS

Recombination frequencies can be used to determine the order of the genes on a chromosome and calculate the approximate distances from one gene to another. In genetic maps, 1% recombination equals 1 map unit, or 1 centiMorgan. Double crossovers between two genes go undetected, so map distances between distant genes tend to underestimate genetic distances.

✔ CONCEPT CHECK 3

How does a genetic map differ from a physical map?

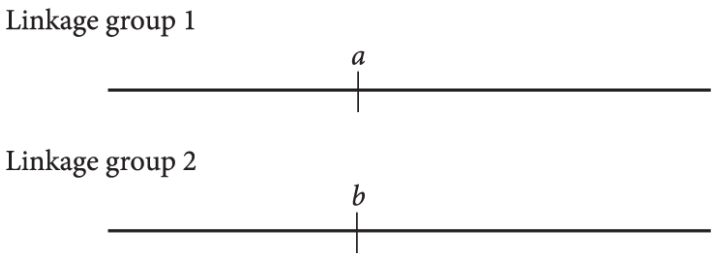
Constructing a Genetic Map with a Two-Point Testcross

Genetic maps can be constructed by conducting a series of testcrosses. In each testcross, one of the parents is heterozygous for a different pair of genes, and recombination frequencies are calculated for each pair of genes. A testcross between two genes is called a **two-point testcross**, or simply a two-point cross. Suppose

that we carried out a series of two-point crosses for four genes, *a*, *b*, *c*, and *d*, and obtained the following recombination frequencies:

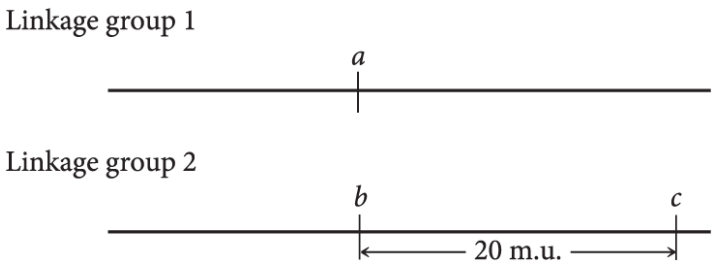
Gene loci in testcross	Recombination frequency (%)
a and *b*	50
a and *c*	50
a and *d*	50
b and *c*	20
b and *d*	10
c and *d*	28

We can begin constructing a genetic map for these genes by considering the recombination frequency for each pair of genes. The recombination frequency between *a* and *b* is 50%, which is the recombination frequency expected with independent assortment. Therefore, genes *a* and *b* may either be on different chromosomes or be very far apart on the same chromosome; we will place them in different linkage groups with the understanding that they may or may not be on the same chromosome:



Description
Linkage group 1 is a line with a notch in the middle labeled gene a. Linkage group 2 is a line with a notch in the middle labeled gene b.

The recombination frequency between *a* and *c* is 50%, indicating that they, too, are in different linkage groups. The recombination frequency between *b* and *c* is 20%, so these genes are linked and separated by 20 map units:

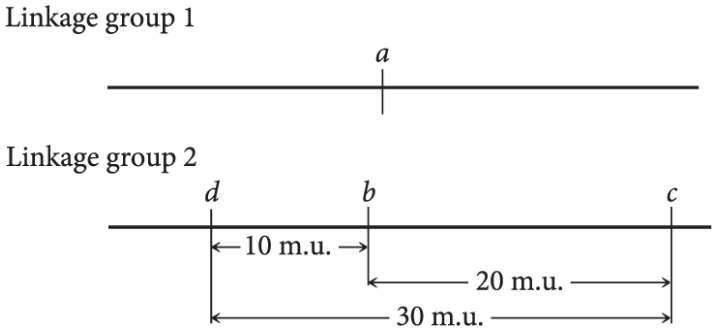


Description
Linkage group 1 is a line with a notch in the middle labeled gene a. Linkage group 2 is a line with a notch in the middle labeled gene b. 20 m u to the right of gene b is a notch labeled c.

The recombination frequency between *a* and *d* is 50%, indicating that these genes belong to different linkage groups, whereas genes *b* and *d* are linked, with a recombination frequency of 10%. To decide whether gene *d* is 10 m.u. to the left or to the right of gene *b*, we

must consult the *c-to-d* distance. If gene *d* is 10 m.u. to the left of gene *b*, then the distance between *d* and *c* should be approximately the sum of the distance between *b* and *c* and between *c* and *d*: 20 m.u.+10 m.u.=30 m.u. If, on the other hand, gene *d* lies to the right of gene *b*, then the distance between gene *d* and gene *c* will be much shorter, approximately 20 m.u.−10 m.u.=10 m.u. Again, the summed distances will be only approximate because any double crossovers between the two genes will be missed and the map distance will be underestimated.

By examining the recombination frequency between *c* and *d*, we can distinguish between these two possibilities. The recombination frequency between *c* and *d* is 28%, so gene *d* must lie to the left of gene *b*. Notice that the sum of the recombination frequency between *d* and *b* (10%) and between *b* and *c* (20%) is greater than the recombination frequency between *d* and *c* (28%). As already discussed, this discrepancy arises because double crossovers between the two outer genes go undetected, causing an underestimation of the true map distance. The genetic map of these genes is now complete:



Description

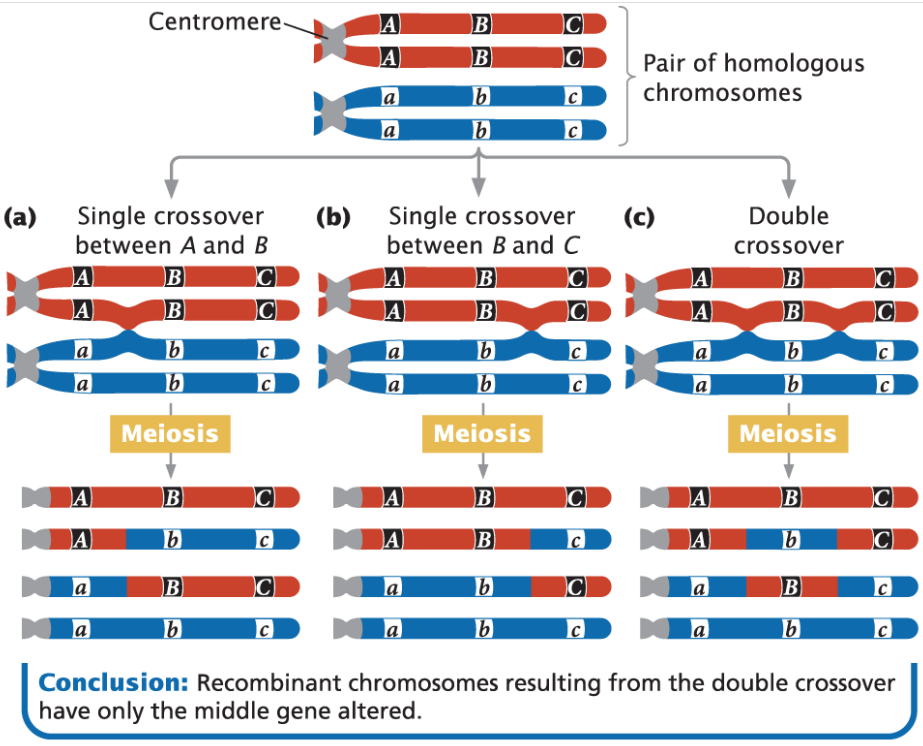
Linkage group 1 is a line with a notch in the middle labeled gene a. Linkage group 2 is a line with a notch in the middle labeled gene b. 20 m u to the right of gene b is gene c, and 10 m u to the left of gene b is gene d.

› **TRY PROBLEM 28**

7.3 A Three-Point Testcross Can Be Used to Map Three Linked Genes

While genetic maps can be constructed from a series of testcrosses for pairs of genes, this approach is not particularly efficient, because numerous two-point crosses must be carried out to establish the order of the genes and because double crossovers will be missed. A more efficient mapping technique is a testcross for three genes—a **three-point testcross**, or three-point cross. With a three-point cross, the order of the three genes can be established in a single set of progeny, and some double crossovers can usually be detected, providing more accurate map distances.

Consider what happens when crossing over takes place among three hypothetical linked genes. **Figure 7.12** illustrates a pair of homologous chromosomes of an individual that is heterozygous at three loci (*Aa Bb Cc*). Notice that the genes are in the coupling configuration: all the dominant alleles are on one chromosome ($\underline{A\ \ B\ \ C}$) and all the recessive alleles are on the other chromosome ($\underline{a\ \ b\ \ c}$). Three types of crossover events can take place between these three genes: two types of single crossovers (see Figure 7.12a and b) and a double crossover (see Figure 7.12c). In each type of crossover, two of the resulting chromosomes are recombinants and two are nonrecombinants.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.12 Three types of crossovers can take place among three linked loci.

Description

A pair of homologous chromosomes is at the top. The red chromosome has big A big B big C alleles on both the chromatids. The blue chromosome has small A small B small C alleles on both the chromatids. There are 3 arrows pointing downward showing three different types of crossovers.

Part a on the left shows single crossover between big A and big B, part b shows single crossover between big B and big C, and part c shows double crossover.

Part a shows the chromosomes crossing over at 1 point between big A and big B. Meiosis occurs and 4 resultant chromosomes are formed below as follows: red chromosome with big A big B big C; red chromosome with big A and blue part that has small B small C; blue chromosome with small A and red part that has big B big C; and a blue chromosome with small A small B small C.

Part b in the middle shows red and blue chromosomes crossing over at 1 point between big B and big C. Meiosis occurs and 4 resultant chromosomes are formed below as follows: red

chromosome with big A big B big C; red chromosome with big A big B and blue part that has small C; blue chromosome with small A small B and red part that has big C; and a blue chromosome with small A small B small C.

Part c on the right shows double crossover between red and blue chromosomes such that they are touching at 2 points between the three genes. Meiosis occurs and 4 resultant chromosomes are formed below as follows: red chromosome with big A big B big C; red chromosome with big A, blue part with small B, red part with big C; blue chromosome with small A, red part with big B, blue part with small C; and a blue chromosome with small A small B small C.

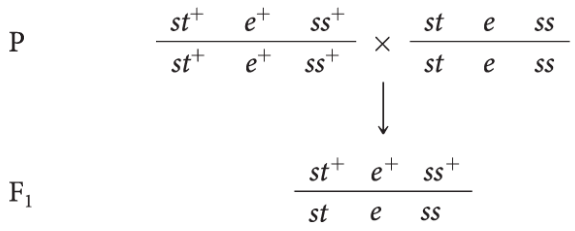
Notice that in the recombinant chromosomes resulting from the double crossover, the outer two alleles are the same as in the nonrecombinants, but the middle allele is different. This result provides us with an important clue about the order of the genes. In progeny that result from a double crossover, only the middle allele should differ from the alleles present in the nonrecombinant progeny.

Constructing a Genetic Map with a Three-Point Testcross

To examine gene mapping with a three-point testcross, let's consider three recessive mutations in the fruit fly *Drosophila melanogaster*. In this species, scarlet eyes (*st*) are recessive to wild-type red eyes (st^+), ebony body color (*e*) is recessive to wild-type gray body color (e^+), and spineless (*ss*)—that is, the presence of small bristles—is recessive to wild-type normal bristles (ss^+). The loci encoding these three characteristics are linked and located on chromosome 3.

We will refer to these three loci as *st*, *e*, and *ss*, but keep in mind that either the recessive alleles (*st*, *e*, and *ss*) or the dominant alleles (st^+, e^+, and ss^+) may be present at each locus. So when we say that there are 10 m.u. between *st* and *ss*, we mean that there are 10 m.u. between the loci at which mutations *st* and *ss* occur; we could just as easily say that there are 10 m.u. between st^+ and ss^+.

To map these genes, we need to determine their order on the chromosome and the genetic distances between them. First, we must set up a three-point testcross: a cross between a fly heterozygous at all three loci and a fly homozygous for recessive alleles at all three loci. To produce flies heterozygous for all three loci, we might cross a stock of flies that are homozygous for wild-type alleles at all three loci with flies that are homozygous for recessive alleles at all three loci:



Description
The P generation above shows one parent with alleles small S small T superscript positive, small E superscript positive, and small S small S superscript positive on the top and bottom of the line. The other parent has a small S small T, small E, and small S small S on the top and bottom of the line. The F subscript 1 progeny below has the following orientation: small S small T superscript positive, small E superscript positive, and small S small S superscript positive written on the top and a small S small T allele, small E allele, and a small S small S allele on the bottom.

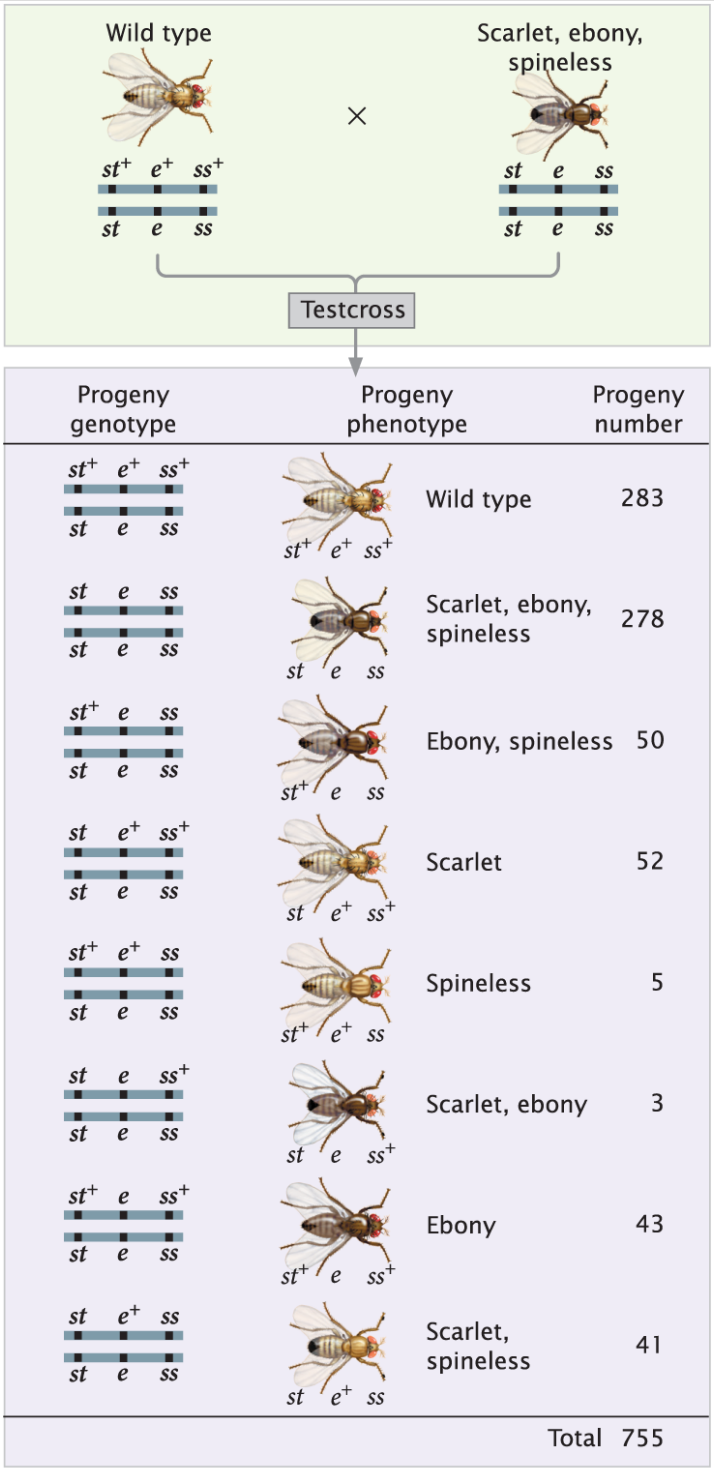
The order of the genes has been arbitrarily assigned because at this point, we do not know which one is the middle gene. Additionally, the alleles in the F_1 heterozygotes are in coupling configuration (because all the wild-type dominant alleles were inherited from one parent and all the recessive mutations from the other parent), although the testcross can also be done with alleles in repulsion.

In the three-point testcross, we cross the F_1 heterozygotes with flies that are homozygous for all three recessive mutations. In many organisms, it makes no difference whether the heterozygous parent in the testcross is male or female (provided that the genes are autosomal), but in *Drosophila*, no crossing over takes place in males. Because crossing over in the heterozygous parent is essential for determining recombination frequencies, the heterozygous flies in our testcross must be female. So we mate female F_1 flies that are heterozygous for all three traits with male flies that are homozygous for all the recessive traits:

$$\frac{st^+ \quad e^+ \quad ss^+}{st \quad e \quad ss}\ \text{Female} \times \frac{st \quad e \quad ss}{st \quad e \quad ss}\ \text{Male}$$

The progeny of this cross are listed in **Figure 7.13**. For each locus, two classes of progeny are produced: progeny that are heterozygous, displaying the dominant trait, and progeny that are homozygous, displaying the recessive trait. With two classes of progeny possible for each of the three loci, there will be $2^3 = 8$ classes of phenotypes possible in the progeny. In this example, all eight phenotypic classes are present, but in some three-point crosses, one or more of the

phenotypes may be missing if the number of progeny is limited. Nevertheless, the absence of a particular class can provide important information about which combination of traits is least frequent and, ultimately, about the order of the genes, as we will see.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.13 The results of a three-point testcross can be used to map linked genes. In this three-point testcross of *Drosophila melanogaster*, the recessive mutations leading to scarlet eyes (*st*), ebony body color (*e*), and spineless bristles (*ss*) are at three

linked loci. The order of the loci has been assumed arbitrarily. Each phenotypic class includes both male and female flies; the sex of the pictured flies is random.

Description

The figure shows P generation at the top. A wild type fly has genes small S small T superscript positive, small E superscript positive, and small S small S superscript positive on one top and small S small T, small E, and small S small S on the other chromosome. This fly is crossed with a scarlet, ebony, spineless fly, which has small S small T, small E, and small S small S on both the chromosomes.

Testcross occurs and F subscript 1 generation is obtained below. A table shows the results and has 8 rows and 3 columns. The column headers are as follows: progeny genotype, progeny phenotype, and progeny numbers. The row entries are as follows:

Row 1: small S small T superscript positive, small E superscript positive, and small S small S superscript positive on one chromosome and small S small T small E small S small S on other; wild type; 283.

Row 2: small S small T small E small S small S on both the chromosomes; All mutant; 278.

Row 3: small S small T superscript positive small E small S small S on one chromosome and small S small T small E small S small S on other; ebony, spineless; 50.

Row 4: small S small T small E superscript positive small S small S superscript positive on one chromosome and small S small T small E small S small S on other ; scarlet; 52.

Row 5: small S small T superscript positive small E superscript positive small S small S on one chromosome and small S small T small E small S small S on other; spineless; 5.

Row 6: small S small T small E small S small S superscript positive on one chromosome and small S small T small E small S small S on other; scarlet, ebony; 3.

Row 7: small S small T superscript positive small E small S small S superscript positive on one chromosome and small S small T small E small S small S on other; ebony; 43.

A text below reads, total equals 755.

To map the genes, we need information about where and how often crossing over has taken place. In the homozygous recessive parent, the two alleles at each locus are the same, and so crossing over will have no effect on the types of gametes produced: with or without crossing over, all gametes from this parent have a chromosome with three recessive alleles ($\underline{st\quad e\quad ss}$). In contrast, the heterozygous parent has different alleles on its two chromosomes, and so crossing over can be detected. The information that we need for mapping, therefore, comes entirely from the gametes produced by the heterozygous parent. Because chromosomes contributed by the homozygous parent carry only recessive alleles, whatever alleles are present on the chromosome contributed by the heterozygous parent will be expressed in the progeny.

As a shortcut, we often do not write out the complete genotypes of the testcross progeny, listing instead only the alleles expressed in the phenotype, which are the alleles inherited from the heterozygous parent. This convention is used in the discussion that follows.

CONCEPTS

To map genes, information about the location and number of crossovers in the gametes that produced the progeny of a cross is needed. An efficient way to obtain this information is to use a three-point testcross, in which an individual that is heterozygous at three linked loci is crossed with an individual that is homozygous recessive at the same three loci.

✔ CONCEPT CHECK 4

Write the genotypes of all recombinant and nonrecombinant progeny expected from the following three-point cross:

$$\frac{m^+ \quad p^+ \quad s^+}{m \quad p \quad s} \times \frac{m \quad p \quad s}{m \quad p \quad s}$$

Description
Each chromosome is represented by a straight, horizontal line. For first chromosome: the alleles above the line are small M superscript positive small P superscript positive small S superscript positive and alleles below the line are small M small P small S.

For second chromosome: the alleles above and below the line are small M small P small S. A cross sign is present between the chromosomes.

DETERMINING THE GENE ORDER

The first task in mapping the genes is to determine their order on the chromosome. In Figure 7.13, we arbitrarily listed the loci in the order *st*, *e*, *ss*, but we had no way of knowing which of the three loci was between the other two. We can now identify the middle locus by examining the double-crossover progeny.

First, determine which progeny are the nonrecombinants: they will be the two most numerous classes of progeny (even if crossing over takes place in every meiosis, the nonrecombinants will constitute at least 50% of the progeny). Among the progeny of the testcross in Figure 7.13, the most numerous are those with all three dominant traits ($\frac{st^+ \quad e^+ \quad ss^+}{}$) and those with all three recessive traits ($\frac{st \quad e \quad ss}{}$).

Next, identify the double-crossover progeny. These progeny should always have the two least numerous phenotypes because the probability of a double crossover is always less than the probability of a single crossover. The least common progeny among those listed in **Figure 7.13** are progeny with spineless bristles ($\underline{st^+ \quad e^+ \quad ss}$) and progeny with scarlet eyes and ebony body ($\underline{st \quad e \quad ss^+}$), so they are the double-crossover progeny.

Three orders of genes on the chromosome are possible: the eye-color locus could be in the middle ($\underline{e \quad st \quad ss}$), the body-color locus could be in the middle ($\underline{st \quad e \quad ss}$), or the bristle locus could be in the middle ($\underline{st \quad ss \quad e}$). To determine which gene is in the middle, we can draw the chromosomes of the heterozygous parent with all three possible gene orders and then see if a double crossover produces the combination of genes observed in the double-crossover progeny. The three possible gene orders and the types of progeny produced by their double crossovers are

Description

The diagram shows 3 pairs of original chromosomes, crossing over events, and chromosomes

after crossing over.

First pair has small E superscript positive, small S small T superscript positive, and small S small S superscript positive on the red chromosome and small E, small S small T, and small S small S on the blue chromosome. Crossing over takes place at 2 points. The resultant chromosome has red chromosome with small E superscript positive, blue part with small S small T, and red part small S small S superscript positive. Blue chromosome has small E, red part with small S small T superscript positive, and blue part with small S small S.

Second pair has small S small T superscript positive, small E superscript positive, and small S small S superscript positive on the red chromosome and small S small T, small E, and small S small S on the blue chromosome. Crossing over takes place at 2 points. The resultant chromosome has red chromosome with small S small T superscript positive, blue part with small E, and red part with small S small S superscript positive. Blue chromosome has small S small T, red part with small E superscript positive, and blue part with small S small S.

Third part has small S small T superscript positive, small S small S superscript positive, and small E superscript positive on the red chromosome and small S small T, small S small S,

and small E on the blue chromosome. Crossing over takes place at 2 points. The resultant chromosome has red chromosome with small S small T superscript positive, blue part with small S small S, and red part with small E superscript positive. Blue chromosome has small S small T, red part with small S small S superscript positive, and blue part with small E.

The only gene order that produces chromosomes with the set of alleles observed in the least numerous progeny or double crossovers ($\underline{st^+ \quad e^+ \quad ss}$ and $\underline{st \quad e \quad ss^+}$ in Figure 7.13) is the one in which the *ss* locus for bristles lies in the middle (gene order 3). Therefore, this order ($\underline{st \quad ss \quad e}$) must represent the correct sequence of genes on the chromosome.

With a little practice, we can quickly determine which locus is in the middle without writing out all the gene orders. The phenotypes of the progeny are expressions of the alleles inherited from the heterozygous parent. Recall that when we looked at the results of double crossovers (see Figure 7.12), only the alleles at the middle locus differed from those in the nonrecombinants. If we compare the nonrecombinant progeny with the double-crossover progeny, they should differ only in alleles at the middle locus (**Table 7.2**).

TABLE 7.2 Steps in determining gene order in a three-point cross

1. Identify the nonrecombinant progeny (two most numerous phenotypes).
2. Identify the double-crossover progeny (two least numerous phenotypes).
3. Compare the phenotypes of double-crossover progeny with the phenotypes of nonrecombinant progeny. They should be alike in two characteristics and differ in one.
4. The characteristic that differs between the double crossover and the nonrecombinant progeny is encoded by the middle gene.

Let's compare the alleles in the double-crossover progeny $\underline{st^+ \quad e^+ \quad ss}$ with those in the nonrecombinant progeny $\underline{st^+ \quad e^+ \quad ss^+}$. We see that both have an allele for red eyes (st^+) and both have an allele for gray body (e^+), but the nonrecombinants have an allele for normal bristles (ss^+), whereas the double crossovers have an allele for spineless bristles (ss). Because the bristle locus is the only one that differs between these two types of progeny, it must lie in the middle. We would obtain the same results if we compared the other class of double-crossover progeny ($\underline{st \quad e \quad ss^+}$) with the other class of nonrecombinant progeny ($\underline{st \quad e \quad ss}$). Again, the only locus that differs is the one for bristles. Don't forget that the nonrecombinants and the double crossovers should differ at only one locus; if they differ at two loci, the wrong classes of progeny are being compared. (A) **Animation 7.1** illustrates how to determine the order of three linked genes.

CONCEPTS

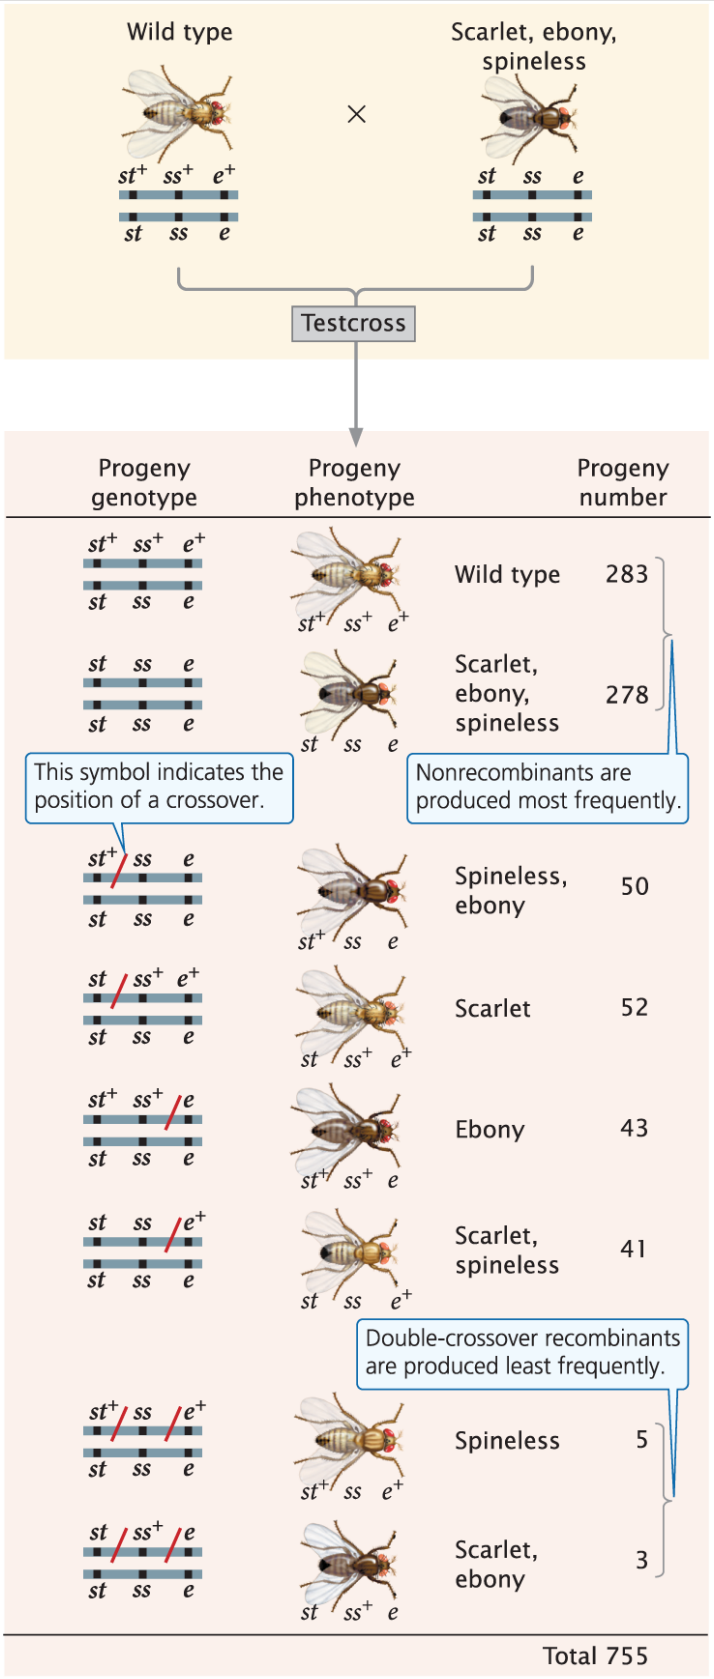
To determine the middle locus in a three-point cross, compare the double-crossover progeny with the nonrecombinant progeny. The double crossovers will be the two least common classes of phenotypes; the nonrecombinants will be the two most common classes of phenotypes. The double-crossover progeny should have the same alleles as the nonrecombinant types at two loci and different alleles at the locus in the middle.

✔ CONCEPT CHECK 5

A three-point testcross is carried out between three linked genes. The resulting nonrecombinant progeny are $s^+ r^+ c^+$ and $s\ r\ c$, and the double-crossover progeny are $s\ r\ c^+$ and $s^+ r^+ c$. Which is the middle locus?

DETERMINING THE LOCATIONS OF CROSSOVERS

When we know the correct order of the loci on the chromosome, we can rewrite the phenotypes of the testcross progeny in Figure 7.13 with the alleles in the correct order so that we can determine where crossovers have taken place (**Figure 7.14**).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020

W. H. Freeman and Company

7.14 Writing the results of a three-point testcross with the loci in the correct order allows the locations of crossovers to be determined. These results are from the testcross illustrated in Figure 7.13, with the loci shown in the correct order. The location of a crossover is indicated by a slash (/). Each phenotypic class includes both male and female flies; the sex of the pictured flies is random.

Description

The figure shows P generation. A wild type fly has alleles small S small T superscript positive, small S small S superscript positive, small E superscript positive on one chromosome and small S small T, small S small S, small E on the other chromosome. This fly is crossed with a scarlet, ebony, spineless fly, which has small S small T, small S small S, and small E on both the chromosomes. Testcross occurs and F subscript 1 generation is obtained. A table shows the results and has 8 rows and 3 columns. The column headers are as follows: progeny genotype, progeny phenotype, and progeny numbers. The row entries are as follows:

Row 1: small S small T superscript positive small S small S superscript positive small E superscript positive on one chromosome and small S small T small S small S small E on other; wild type; 283.

Row 2: small S small T small S small S small E on both the chromosomes; Scarlet,

ebony, spineless; 278.

A caption reads, Nonrecombinants are produced most frequently.

Row 3: small S small T superscript positive forward slash small S small S small E on one chromosome and small S small T small S small S small E on other; spineless, ebony; 50.

A caption pointing towards slash reads, This symbol indicates the position of a crossover.

Row 4: small S small T forward slash small S small S superscript positive small E superscript positive on one chromosome and small S small T small S small S small E on other; scarlet; 52.

Row 5: small S small T superscript positive small S small S superscript positive forward slash small E on one chromosome and small S small T small S small S small E on other; ebony; 43.

Row 6: small S small T small S small S forward slash small E superscript positive on one chromosome and small S small T small S small S small E on other; scarlet, spineless; 41.

Row 7: small S small T superscript positive forward slash small S small S forward slash small E superscript positive on one chromosome and small S small T small S small S small E on other; spineless; 5.

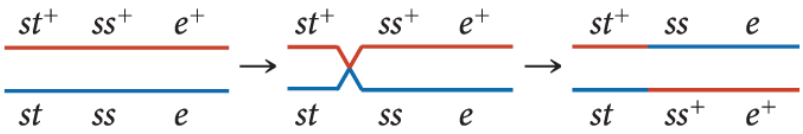
Row 8: small S small T forward slash small S small S superscript positive forward slash small E on one chromosome and small S small T small S small S small E on other chromosome; scarlet, ebony; 3.

A caption reads, Double-crossover recombinants are produced least frequently.

A text below reads, total 755.

Among the eight classes of progeny, we have already identified two classes as nonrecombinants ($\underline{st^+ \quad ss^+ \quad e^+}$ and $\underline{st \quad ss \quad e}$) and two classes as double crossovers ($\underline{st^+ \quad ss \quad e^+}$ and $\underline{st \quad ss^+ \quad e}$). The other four classes contain progeny that resulted from a chromosome that underwent a single crossover: two underwent single crossovers between *st* and *ss*, and two underwent single crossovers between *ss* and *e*.

To determine where the crossovers took place in these single-crossover progeny, we can compare the alleles found in these progeny with those found in the nonrecombinants, just as we did for the double crossovers. For example, consider the progeny with chromosome $\underline{st^+ \quad ss \quad e}$. The first allele ($st^+$) came from the nonrecombinant chromosome $\underline{st^+ \quad ss^+ \quad e^+}$, and the other two alleles (*ss* and *e*) must have come from the other nonrecombinant chromosome $\underline{st \quad ss \quad e}$ through crossing over:



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020

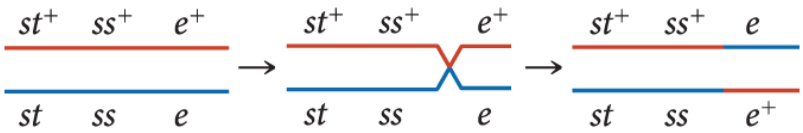
Description
The diagram shows a pair of chromosomes. Red chromosome has small S small T superscript positive, small S small S superscript positive, small E superscript positive. The blue chromosome has small S small T, small S small S, small E. Crossing over occurs at 1 point between the first two genes. The resultant chromosome has red chromosome with small S small T superscript positive, blue part with small S small S, and small E. Blue chromosome has small S small T, red part with small S small S superscript positive, and small E superscript positive.

This same crossover also produces the $st \quad ss^+ \quad e^+$ progeny.

This method can also be used to determine the location of crossing over in the other two types of single-crossover progeny. Crossing over between *ss* and *e* produces ($st^+ \quad ss^+ \quad e$ and $st \quad ss \quad e^+$) chromosomes:



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The diagram shows a pair of chromosome. Red chromosome has small S small T superscript positive, small S small S superscript positive, and small E superscript positive. Blue chromosome has small S small T, small S small S, and small E. Crossing over occurs at 1 point between the last two genes. The resultant chromosome has red chromosome

small S small T superscript positive, small S small S superscript positive, and blue part with small E. The blue chromosome has small S small T, small S small S, and red part with small E superscript positive.

We now know the locations of all the crossovers, which are marked with red slashes in Figure 7.14.

CALCULATING THE RECOMBINATION FREQUENCIES

Next, we can determine the map distances, which are based on the frequencies of recombination. We can calculate recombination frequency by adding up all the recombinant progeny, dividing this number by the total number of progeny from the cross, and multiplying the number obtained by 100%. To determine the map distances accurately, we must include all crossovers (both single and double) that take place between two genes.

Recombinant progeny that possess a chromosome that underwent crossing over between the eye-color locus (*st*) and the bristle locus (*ss*) include the single crossovers ($\underline{st^+ \;/\; ss \;/ e}$ and $\underline{st \;/\; ss^+ \quad e^+}$) and the two double crossovers ($\underline{st^+ \;/\; ss \;/\; e^+}$ and $\underline{st \;/\; ss^+ \;/\; e}$) (see Figure 7.14). There are a total of 755 progeny, so the recombination frequency between *ss* and *st* is:

$$st - ss \text{ recombination frequency} = \frac{50 + 52 + 5 + 3}{755} \times 100\% = 14.6\%$$

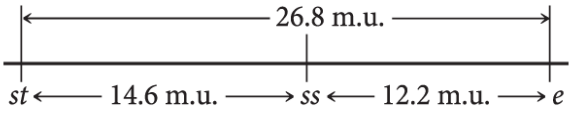
The distance between the *st* and *ss* loci can be expressed as 14.6 m.u.

The map distance between the bristle locus (*ss*) and the body-color locus (*e*) is determined in the same manner. The recombinant progeny that possess a crossover between *ss* and *e* are the single crossovers $\underline{st^+ \ ss^+ \ / \ e}$ and $\underline{st \ ss \ / \ e^+}$ and the double crossovers $\underline{st^+ \ / \ ss \ / \ e^+}$ and $\underline{st \ / \ ss^+ \ / \ e}$. The recombination frequency is

$$ss - e \text{ recombination frequency} = \frac{43 + 41 + 5 + 3}{755} \times 100\% = 12.2\%$$

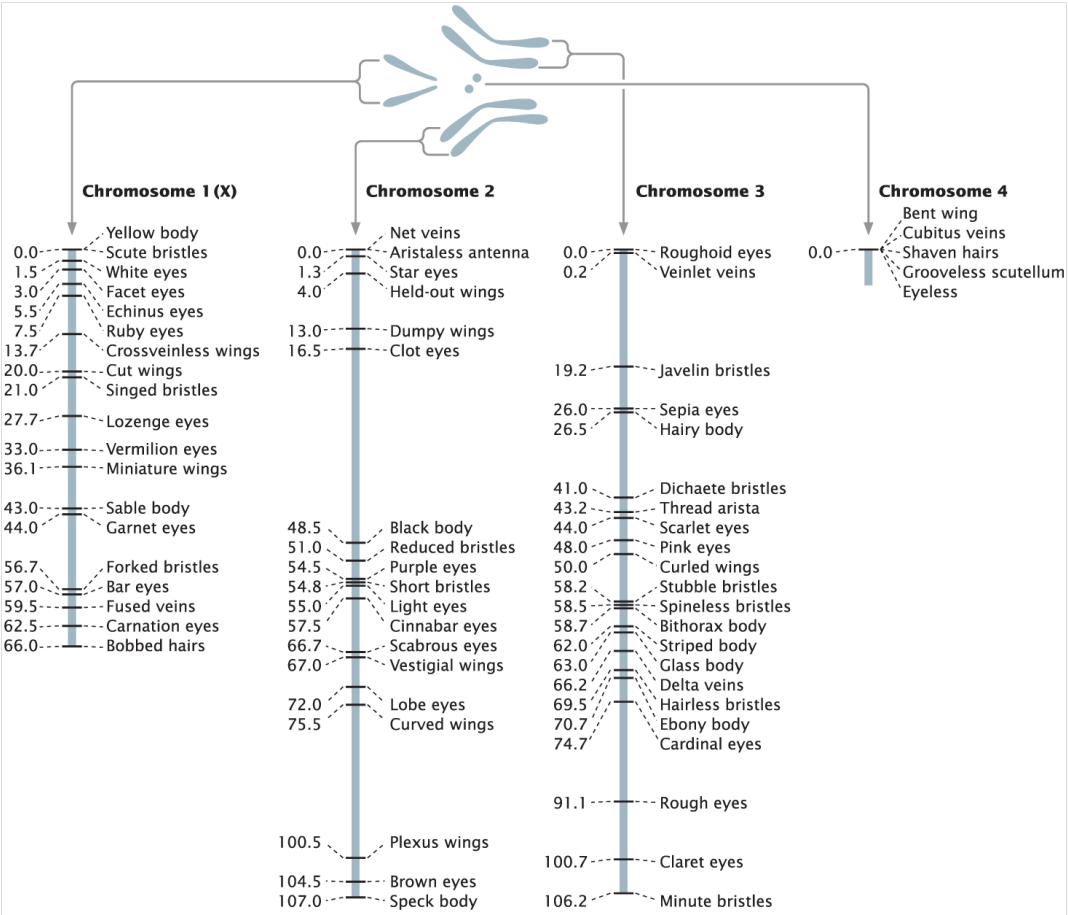
Thus, the map distance between *ss* and *e* is 12.2 m.u.

Finally, calculate the map distance between the outer two loci, *st* and *e*. This map distance can be obtained by summing the map distances between *st* and *ss* and between *ss* and *e* (14.6 m.u. + 12.2 m.u. = 26.8 m.u.). We can now use the map distances to draw a map of the three genes on the chromosome:



Description
Gene small S small T is on the extreme left and 14 point 6 m u to the right is gene small S small S. 12 point 2 m u to the right of gene small S small S is gene small E. The distance between gene small S small T to gene small E is 26 point 8 m u.

A genetic map of *D. melanogaster* is illustrated in Figure 7.15.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.15 *Drosophila melanogaster* has four linkage groups corresponding to its four pairs of chromosomes. These genes were mapped using recombination frequencies. Distances between genes within a linkage group are in map units. Note that the small chromosome 4 never undergoes recombination.

Description

The diagram shows the following information:

Chromosome 1 (X): gene at 0 point 0 m u, produces yellow body and scute bristles; 1 point 5, White eyes; 3 point 0, Facet eyes; 5 point 5, Echinus eyes; 7 point 5, Ruby eyes; 13 point 7, Cross vein less wings; 20 point 0, cut wings; 21 point 0, singled bristles; 27 point 7, Lozenge eyes; 33 point 0, Vermilion eyes; 36 point 1, Miniature wings; 43 point 0, Sable body; 44 point 0, Garnet eyes; 56 point 7, Forked bristles; 57 point 0, Bar eyes; 59 point 5, Fused veins; 62 point 5, Carnation eyes; and 66 point 0, Bobbed hairs.

Chromosome 2: 0 point 0, net veins and Aristaless antenna; 1 point 3, Star eyes; 4 point 0, Held-out wings; 13 point 0, Dumpy wings; 16 point 5, Clot eyes; 48 point 5, black body; 51 point 0, Reduced bristles; 54 point 5, Purple eyes; 54 point 8, Short bristles; 55 point 0, Light eyes; 57 point 5, Cinnabar eyes; 66 point 7, Scabrous eyes; 67 point 0, Vestigial wings; 72 point 0, Lobe eyes; 75 point 5, Curved wings; 100 point 5, Plexus wings; 104 point 5, Brown eyes; 107 point 0, Speck body.

Chromosome 3: 0 point 0, Roughoid eyes; 0 point 2, Veinlet veins; 19 point 2, Javelin bristles; 26 point 0, Sepia eyes; 26 point 5, Hairy body; 41 point 0, Dichaete bristles; 43 point 2, Thread arista; 44 point 0, Scarlet eyes; 48 point 0, Pink eyes; 50 point 0, Curled wings; 58 point 2, Stubble bristles; 58 point 5, Spineless bristles; 58 point 7, Bithorax body; 62 point 0, Striped body; 63 point 0, Glass body; 66 point 2, Delta veins; 69 point 5, Hairless bristles; 70 point 7, Ebony body; 74 point 7, Cardinal eyes; 91 point 1, Rough eyes; 100 point 7, Claret eyes; and 106 point 2, Minute bristles.

Chromosome 4: 0 point 0, Bent wing, Cubitus veins, Shaven hairs, Grooveless scutellum, and Eyeless.

INTERFERENCE AND THE COEFFICIENT OF COINCIDENCE

Map distances give us information not only about the distances that separate genes but also about the proportions of recombinant and nonrecombinant gametes that will be produced in a cross. For example, knowing that genes *st* and *ss* on chromosome 3 of *D. melanogaster* are separated by a distance of 14.6 m.u. tells us that 14.6% of the gametes produced by a fly heterozygous at these two loci will be recombinants. Similarly, 12.2% of the gametes from a fly heterozygous for *ss* and *e* will be recombinants.

Theoretically, we should be able to calculate the proportion of double-recombinant gametes by using the multiplication rule (see Chapter 3). Applying this rule, we should find that the proportion (probability) of gametes with double crossovers between *st* and *e* is equal to the probability of recombination between *st* and *ss* multiplied by the probability of recombination between *ss* and *e*, or 0.146 × 0.122 = 0.0178. Multiplying this probability by the total number of progeny gives us the *expected* number of double-crossover progeny from the cross: 0.0178 × 755 = 13.4. But only 8 double crossovers—considerably fewer than the 13 expected—were observed in the progeny of the cross (see Figure 7.14).

This phenomenon is common in eukaryotic organisms. The calculation assumes that each crossover event is independent and that the occurrence of one crossover does not influence the occurrence of another. But crossovers are frequently *not* independent events: the occurrence of one crossover tends to inhibit additional crossovers in the same region of the chromosome, so double crossovers are less frequent than expected.

The degree to which one crossover interferes with additional crossovers in the same region is termed the **interference**. To calculate the interference, we first determine the **coefficient of coincidence**, which is the ratio of observed double crossovers to expected double crossovers:

$$\text{coefficient of coincidence} = \frac{\text{number of observed double crossovers}}{\text{number of expected double crossovers}}$$

For the loci that we mapped on chromosome 3 of *D. melanogaster* (see Figure 7.14), we find that

$$\text{coefficient of coincidence} = \frac{5 + 3}{0.146 \times 0.122 \times 755} = \frac{8}{13.4} = 0.6$$

which indicates that we are actually observing only 60% of the double crossovers that we expected on the basis of the single-crossover frequencies. The interference is calculated as

$$\text{interference} = 1 - \text{coefficient of coincidence}$$

So the interference for our three-point cross is:

$$\text{interference} = 1 - 0.6 = 0.4$$

This interference value tells us that 40% of the double-crossover progeny expected will not be observed because of interference. When interference is complete and no double-crossover progeny are observed, the coefficient of coincidence is 0 and the interference is 1.

Sometimes a crossover *increases* the probability of another crossover taking place nearby, and we see *more* double-crossover progeny than expected. In this case, the coefficient of coincidence is greater than 1 and the interference is negative.

Most eukaryotic organisms exhibit interference, which causes crossovers to be more widely spaced than would be expected on a random basis. Interference was first observed in crosses of *Drosophila* in the early 1900s, yet despite years of study, the mechanism by which

interference occurs is still not well understood. One proposed model of interference suggests that crossovers occur when stress builds up along the chromosome. According to this model, a crossover releases stress for some distance along the chromosome. Because a crossover relieves the stress that causes crossovers, additional crossovers are less likely to occur in the same area. Recent research shows that an enzyme called topoisomerase II is required for crossover interference. Topoisomerase enzymes function to relieve stress along the chromosome, such as torsional stress that occurs during the unwinding of DNA (see Chapters 11 and 12). The fact that a topoisomerase enzyme is required for crossover interference supports the stress release model of crossover interference. **› TRY PROBLEM 31**

THINK-PAIR-SHARE Questions 5 and 6

CONCEPTS

The coefficient of coincidence equals the number of double crossovers observed divided by the number of double crossovers expected on the basis of single-crossover frequencies. The interference equals 1 minus the coefficient of coincidence; it indicates the degree to which one crossover interferes with additional crossovers.

✔ CONCEPT CHECK 6

In analyzing the results of a three-point testcross, a student determines that the interference is −0.23. What does this negative interference value indicate?

a. Fewer double crossovers took place than expected on the basis of single-crossover frequencies.

b. More double crossovers took place than expected on the basis of single-crossover frequencies.
c. Fewer single crossovers took place than expected.
d. A crossover in one region interferes with additional crossovers in the same region.

CONNECTING CONCEPTS

Stepping Through the Three-Point Cross

We have now examined the three-point cross in considerable detail, and we have seen how the information derived from it can be used to map a series of three linked genes. Let's briefly review the steps required to map genes using a three-point cross.

1. **Write out the phenotypes and numbers of progeny produced by the three-point cross.** The progeny phenotypes will be easier to interpret if you use allelic symbols for the traits (such as $st^+ e^+ ss$).
2. **Write out the genotypes of the original parents used to produce the triply heterozygous F_1 individual in the testcross and, if known, the arrangement (coupling or repulsion) of the alleles on their chromosomes.**
3. **Determine which phenotypic classes among the progeny of the testcross are the nonrecombinants and which are the double crossovers.** The nonrecombinants will be the two most common phenotypes; the double crossovers will be the two least common phenotypes.
4. **Determine which locus lies in the middle.** Compare the alleles present in the double crossovers with those present in the nonrecombinants; each class of double crossovers should be like one of the nonrecombinants at two loci and should differ at one locus. The locus that differs is the middle one.
5. **Rewrite the phenotypes with the genes in correct order.**
6. **Determine where crossovers must have taken place to give rise to the recombinant progeny phenotypes.** To do so, compare each phenotype with the phenotype of the nonrecombinant progeny.
7. **Determine the recombination frequencies.** Add the numbers of the progeny that possess a chromosome with a single crossover between a pair of loci. Add the double crossovers to this number. Divide this sum by the total number of progeny from the cross, and multiply by 100%; the result is the recombination frequency between the loci, which is the same as the map distance.
8. **Draw a map of the three loci.** Indicate which locus lies in the middle, and indicate the distances between them.

9. **Determine the coefficient of coincidence and the interference.** The coefficient of coincidence is the number of observed double-crossover progeny divided by the number of expected double-crossover progeny. The expected number can be obtained by multiplying the product of the two single-recombination probabilities by the total number of progeny from the cross.

WORKED PROBLEM

In *D. melanogaster*, cherub wings (*ch*), black body (*b*), and cinnabar eyes (*cn*) result from recessive alleles that are all located on chromosome 2. A homozygous wild-type fly was mated with a cherub, black, cinnabar-eyed fly, and the resulting F_1 females were test-crossed with cherub, black, cinnabar-eyed males. The following progeny were produced by the testcross:

ch	b^+	*cn*	105
ch^+	b^+	cn^+	750
ch^+	*b*	*cn*	40
ch^+	b^+	*cn*	4
ch	*b*	*cn*	753
ch	b^+	cn^+	41
ch^+	*b*	cn^+	102

ch	*b*	cn^+	5
Total			1800

a. Determine the linear order of the genes on the chromosome (which gene is in the middle?).
b. Calculate the map distances between the three loci.
c. Determine the coefficient of coincidence and the interference for these three loci.

Solution Strategy

What information is required in your answer to the problem?

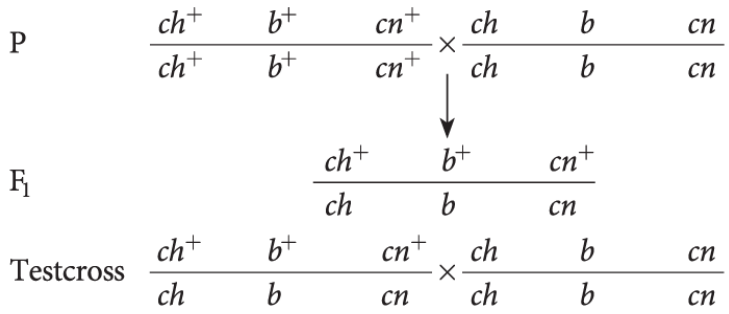
The order of the genes on the chromosome, the map distances among the genes, the coefficient of coincidence, and the interference.

What information is provided to solve the problem?

- A homozygous wild-type fly was mated with a cherub, black, cinnabar-eyed fly, and the resulting F_1 females were test-crossed with cherub, black, cinnabar-eyed males.
- The numbers of the different types of flies appearing among the progeny of the testcross.

Solution Steps

a. We can represent the crosses in this problem as follows:



Description
P generation at the top shows a parent with small C small H superscript positive, small B, and small C small N superscript positive alleles on both the chromosomes crossed with a parent with small C small H, small B, and small C small N on both the chromosomes. Fertilization occurs and F subscript 1 generation is obtained below. The F subscript 1 generation has small C small H superscript positive, small B, and small C small N superscript positive on the top chromosome and small C small H, small B, small C small N on the bottom chromosome. A test cross is done below between a parent with small C small H superscript positive, small B, and small C small N superscript positive alleles on the top chromosome and small C small H, small B, and small C small N on the bottom chromosome and a parent with small C small H, small B, and small C small N on both the chromosomes.

Note that at this point we do not know the order of the genes; we have arbitrarily put *b* in the middle.

The next step is to determine which of the testcross progeny are nonrecombinants and which are double crossovers. The nonrecombinants should be the most frequent phenotype, so they must be the progeny with phenotypes encoded by $\underline{ch^+ \ b^+ \ cn^+}$ and $\underline{\text{ch} \ \ b \ \ cn}$. These genotypes are consistent with the genotypes of the parents, given earlier. The double crossovers are the least frequent phenotypes and are encoded by $\underline{ch^+ \ b^+ \ cn}$ and $\underline{ch \ b \ cn^+}$.

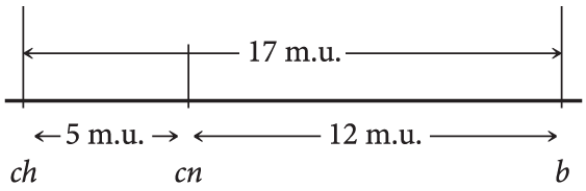
We can determine the gene order by comparing the alleles present in the double crossovers with those present in the nonrecombinants. The double-crossover progeny should be like one of the nonrecombinants at two loci and unlike it at one locus; the allele that differs should be in the middle. Compare the double-crossover progeny $\underline{ch\ b\ cn}^{+}$ with the nonrecombinant $\underline{\text{ch}\quad b\quad cn}$. Both have cherub wings (*ch*) and black body (*b*), but the double-crossover progeny have wild-type eyes (cn^{+}), whereas the nonrecombinants have cinnabar eyes (*cn*). The locus that determines cinnabar eyes must be in the middle.

b. To calculate the recombination frequencies among the genes, we first write the phenotypes of the progeny, with the genes encoding them, in the correct order. We have already identified the nonrecombinant and double-crossover progeny, so the other four progeny types must have resulted from single crossovers. To determine *where* single crossovers took place, we compare the alleles found in the single-crossover progeny with those in the nonrecombinants. Crossing over must have taken place where the alleles switch from those found in one nonrecombinant to those found in the other nonrecombinant. The locations of the crossovers are indicated with a slash:

ch		*cn*	/	b^{+}	105	single crossover
ch^{+}		cn^{+}		b^{+}	750	nonrecombinant
ch^{+}	/	*cn*		*b*	40	single crossover
ch^{+}	/	*cn*	/	b^{+}	4	double crossover
ch		*cn*		*b*	753	nonrecombinant
ch	/	cn^{+}		b^{+}	41	single crossover

ch^+		cn^+	/	b	102	single crossover
ch	/	cn^+	/	b	5	double crossover
Total					1800	

Next, we determine the recombination frequencies and draw a genetic map:



Description
The line drawing of a map shows small C small H gene on the extreme left and 5 m u to its right is gene small C small N, and 12 m u to its right is gene small B. The distance between gene small C small H and gene small B is 17 m u.

$$ch - cn \text{ recombination frequency} = \frac{40 + 4 + 41 + 5}{1800} \times 100\%$$

$$cn\text{-b recombination frequency} = \frac{105 + 4 + 102 + 5}{1800} \times 100\% = 12\%$$

$$ch - b \text{map distance} = 5\% + 12\% = 17\%$$

c. The coefficient of coincidence is the number of observed double crossovers divided by the number of expected double crossovers. The number of expected double crossovers is obtained by multiplying the probability of a crossover between *ch* and *cn* (0.05) by the probability of a crossover between *cn* and *b* (0.12),

then multiplying the product by the total number of progeny from the cross (1800):

$$\text{coefficient of coincidence} = \frac{4+5}{0.05 \times 0.12 \times 1800} = 0.83$$

Finally, the interference is equal to 1− the coefficient of coincidence:

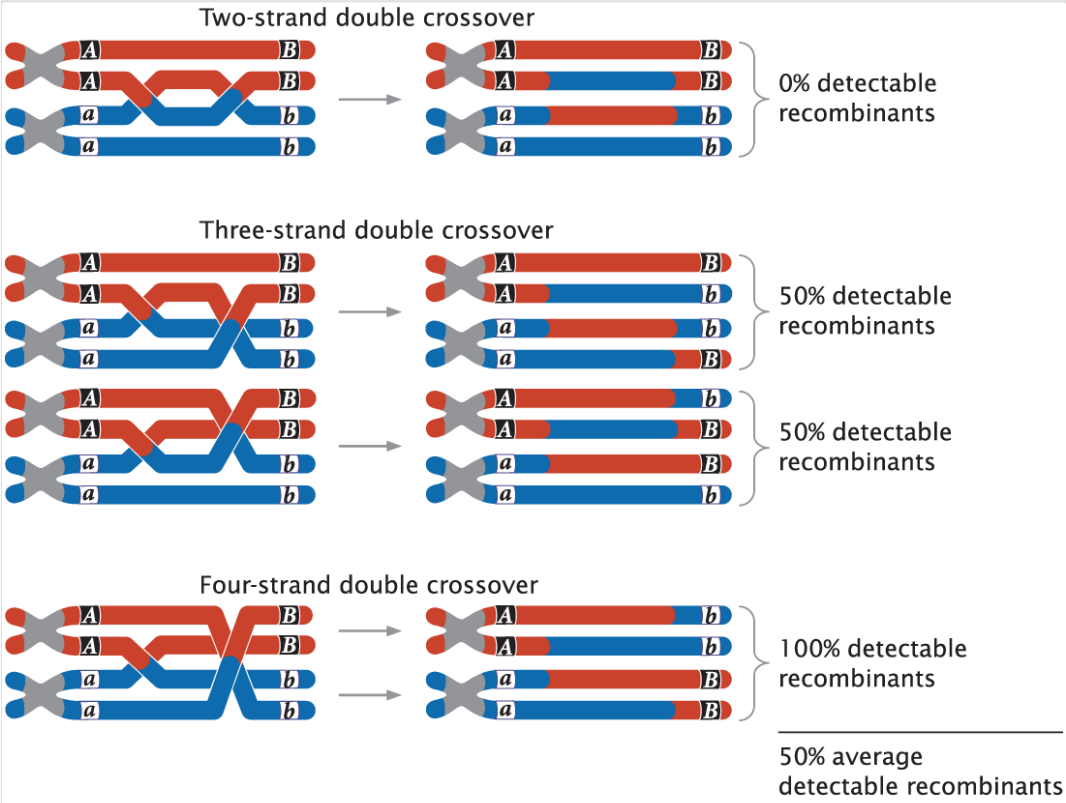
$$\text{interference} = 1 - 0.83 = 0.17$$

» To increase your skill with three-point crosses, try working **Problem 32** at the end of this chapter.

Effects of Multiple Crossovers

So far, we have examined the effects of double crossovers taking place between only two of the four chromatids (strands) of a homologous pair (two-strand double crossovers). Double crossovers that include three and even four of the chromatids of a homologous pair may also take place (**Figure 7.16**). As we have seen, if we examine only the alleles at loci on either side of both crossover events, two-strand double crossovers result in no new combinations of alleles, and no recombinant gametes are produced (see Figure 7.16). Three-strand

double crossovers result in two of the four gametes being recombinant, and four-strand double crossovers result in all four gametes being recombinant (see Figure 7.16). Thus, two-strand double crossovers produce 0% recombination, three-strand double crossovers produce 50% recombination, and four-strand double crossovers produce 100% recombination. The overall result is that all types of double crossovers, taken together, produce an average of 50% recombinant gametes.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.16 Effects of two-, three-, and four-strand double crossovers on recombination between two genes.

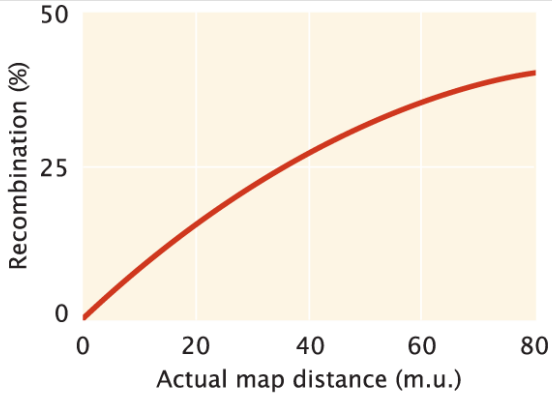
Description

The parent chromosome has red with big A big B on both chromatids and blue with small A and small B on both chromatids. The first part shows a two-strand double crossover where the chromosomes are crossing over at 2 points between the genes. In the progeny chromosomes, one arm of each chromosome is hybrid in color but the genes are not rearranged. A text reads, 0 percent detectable recombinants. The second part below shows a three-strand double crossover occurring and shows 2 examples. The first three-strand crossover shows a red chromosome where the bottom chromosome has blue part with small B allele. The second chromosome is a blue with a red part in between and again a blue part with small B, its bottom chromosome has a red part at the end with big B. A text reads, 50 percent detectable recombinants. The second example shows the first red chromosome with a blue part at the end with small B. Its bottom chromosome has a blue part in between but has same genes as in parent. The blue chromosome has a large red part of top chromosome with big B. The bottom chromosome has same genes as in the parent chromosome. A text reads, 50 percent detectable recombinants. The last part below shows a four-strand double crossover. In the resultant first red chromosome, the top chromosome has a small blue part at the end with small B. The bottom chromosome has a larger blue part with small B. The blue chromosome has large red part with big B and bottom chromosome has a small red part with big B at the end. A text reads, 100 percent detectable Recombinants.

A text below reads, 50 percent average detectable recombinants.

As we have also seen, two-strand double crossovers cause alleles on either side of the crossovers to remain the same and produce no recombinant progeny. Three-strand and four-strand crossovers produce recombinant progeny, but these progeny are the same types as those produced by single crossovers. Consequently, some multiple crossovers go undetected when the progeny of a genetic cross are observed. Therefore, map distances based on recombination rates underestimate the true physical distances between genes because some multiple crossovers are not detected among the progeny of a cross. When genes are very close together, multiple crossovers are

unlikely, and genetic distances based on recombination rates accurately correspond to the physical distances on the chromosome. But as the distance between genes increases, more multiple crossovers are likely, and the discrepancy between genetic distances (based on recombination rates) and physical distances increases. To correct for this discrepancy, geneticists have developed mathematical **mapping functions**, which relate recombination frequencies to actual physical distances between genes (**Figure 7.17**). Most of these functions are based on the Poisson distribution, which predicts the probability of multiple rare events. With the use of such mapping functions, map distances based on recombination rates can be more accurately estimated.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.17 Recombination rates underestimate the true physical distance between genes at higher map distances.

Description

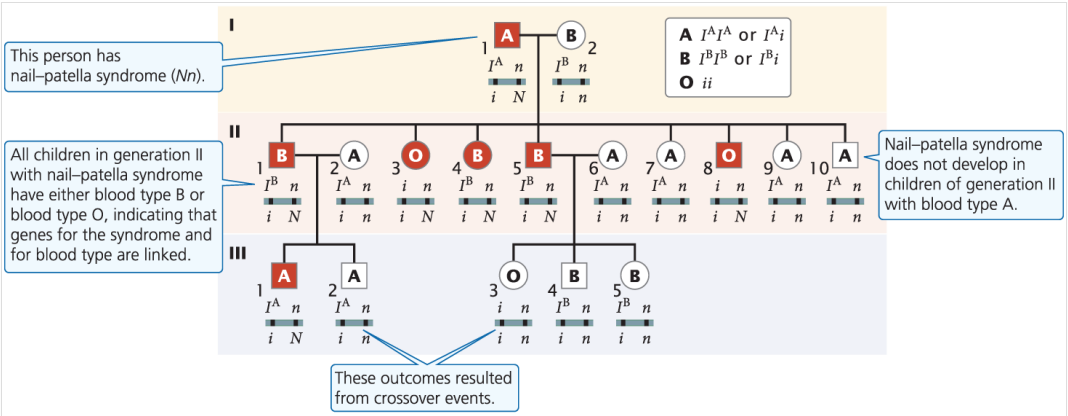
The horizontal axis is labeled as the actual map distance in m u from 0 to 80 with an interval of 20. The vertical axis shows recombination frequency from 0 to 50 percent with an interval of 25. The approximate data from the graph are as follows: the curve begins at the origin and

rises up to reach 27 percent recombination at 40 m u, and it eventually reaches 40 percent at 80 m u.

Mapping Human Genes

Efforts to map human genes are hampered by the inability to perform specific crosses and by the small number of progeny in most human families. Geneticists are often restricted to analyses of pedigrees, which may be incomplete and may provide limited information. Nevertheless, a large number of human traits have been successfully mapped with the use of pedigree data to analyze linkage. Because the number of progeny from any one mating is usually small, data from several families and pedigrees are usually combined to test for independent assortment. The methods used in these types of analyses are complex, but an example will illustrate how linkage can be detected from pedigree data.

One of the first documented demonstrations of linkage in humans was between the locus for nail–patella syndrome and the locus that determines the ABO blood types. Nail–patella syndrome is an autosomal dominant disorder characterized by abnormal fingernails and absent or rudimentary kneecaps. The ABO blood types are determined by an autosomal locus with multiple alleles (see Chapter 5). Linkage between the genes encoding these two traits was established in families in which both traits segregate. A pedigree for part of one such family is illustrated in **Figure 7.18**.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.18 Linkage between ABO blood type and nail–patella syndrome was established by examining families in which both traits segregate. The pedigree shown here is for one such family. The ABO blood type is indicated in each circle or square. The genotype, inferred from the phenotype, is given below each circle or square.

Description

Generation 1 shows parents where affected male has blood group A (big I superscript A small N small I big N). A caption reads, This person has nail–patella syndrome (big N small N). In same generation, an unaffected female has blood group B (big I superscript B small N small I small N). They mate and have 3 affected sons, 2 affected daughters, 2 unaffected daughters, and 1 unaffected son in generation 2. A caption reads, All children in generation 2 with nail–patella syndrome have either blood type B or blood type O, indicating that genes for the syndrome and for blood type are linked. The following chromosomes are obtained: First affected son has B blood group (big I superscript B small I big N). First affected daughter has O blood group (small I small N small I big N). The second affected daughter has B blood group (big I superscript B small N small I big N). The second affected son has B blood group (big I superscript B small N small I big N). The first unaffected daughter has A blood group (big I superscript A small N small I small N). The third affected son has O blood group (small I small N small I big N). The second unaffected daughter has A blood group (big I superscript A small N small I small N). The unaffected son has A blood group (big I superscript A small N small I small N). A caption reads, Nail–patella syndrome does not develop in children of generation 2 with blood type A. The first affected male from generation 2 who has B blood group (big I superscript B small I big N) mates with an unaffected female with A blood group (big I superscript A small N small I small N) and has an affected son and an unaffected son in generation 3. The affected son has A blood group (big I superscript A small N small I big N) and unaffected son has A blood group (big I superscript A small N small I small N). A caption

reads, These outcomes resulted from crossover events. The second affected male has B blood group (big I superscript B small N small I big N) mates with an unaffected female with blood group A (big I superscript A small N small I small N). They have 2 unaffected daughters and 1 affected son in generation 3. The first unaffected daughter has O blood group (small I small N small I small N). The unaffected son has B blood group (big I superscript B small N small I small N). The second unaffected daughter has B blood group (big I superscript B small N small I small N).

Nail–patella syndrome is rare, so we can assume that people who have this trait are heterozygous (*Nn*); unaffected people are homozygous (*nn*). The ABO genotypes of individuals can be inferred from their phenotypes and the types of offspring they produce. Female I-2 in Figure 7.18, for example, has blood type B, which has two possible genotypes: I^BI^B or I^Bi (see Figure 5.6). Because some of her offspring are blood type O (genotype *ii*) and must have therefore inherited an *i* allele from each parent, female I-2 must have genotype I^Bi. Similarly, the presence of blood type O offspring in generation II indicates that male I-1, with blood type A, must also carry an *i* allele and therefore has genotype I^Ai. The parents of this family are

$$I^Ai\ Nn \times I^Bi\ nn$$

In generation II, we can see that the genes for nail–patella syndrome and the blood types do not appear to assort independently. All children in generation II with nail–patella syndrome have either blood type B or blood type O; all those with blood type A have normal nails and kneecaps. If the genes encoding nail–patella syndrome and the ABO blood types assorted independently, we would expect that some children in generation II would have blood type A and nail–patella

syndrome, inheriting both the I^A and N alleles from their father. The observed outcome indicates that the arrangements of the alleles on the chromosomes of the crossed parents are

$$\frac{I^A \quad n}{i \quad N} \times \frac{I^B \quad n}{i \quad n}$$

Description
Each chromosome is represented by a straight, horizontal line. For first chromosome: the alleles above the line are big I superscript big A small N and alleles below the line are small I big N.

For second chromosome: the alleles above the line are big I superscript big B small N and alleles below the line are small I small N. A cross sign is present between the chromosomes.

The pedigree indicates that there is no recombination among the offspring (generation II) of these parents, but there are two instances of recombination among the offspring in generation III. Individuals II-1 and II-2 have the following genotypes:

$$\frac{I^B \quad n}{i \quad N} \times \frac{I^A \quad n}{i \quad n}$$

Description
Each chromosome is represented by a straight, horizontal line. For first chromosome: the alleles above the line are big I superscript big B small N and alleles below the line are small I big N. For second chromosome: the alleles above the line are big I superscript big A small N and alleles below the line are small I small N. A cross sign is present between the chromosomes.

Their child III-2 has blood type A and does not have nail–patella syndrome, so he must have genotype

$$\frac{I^{A} \quad n}{i \quad n}$$

Description
The chromosome is represented by a straight, horizontal line. The alleles above the line are big I superscript big A small N and alleles below the line are small I small N.

and must have inherited both the *i* and the *n* alleles from his father. These alleles are on different chromosomes in the father, so crossing over must have taken place. Crossing over must also have taken place to produce child III-3.

In the pedigree in Figure 7.18, thirteen children are offspring of matings in which the genes encoding nail–patella syndrome and ABO blood types segregate; two of the thirteen children are recombinant progeny. On this basis, we might assume that the loci for nail–patella syndrome and ABO blood types are linked, with a recombination frequency of $^{2}/_{13} = 0.154$. However, it is possible that the genes *are* assorting independently, and that the small number of children just makes it seem as though the genes are linked.

To determine the probability that genes are actually linked, geneticists often calculate **lod** (logarithm of odds) **scores**. To obtain a lod score, we calculate (1) the probability of obtaining the observed results under the assumption that the genes are linked with a specified degree of recombination and (2) the probability of obtaining

the observed results under the assumption of independent assortment. We then determine the ratio of these two probabilities, and the logarithm of this ratio is the lod score. Suppose that the probability of obtaining a particular set of observations under the assumption of linkage and a certain recombination frequency is 0.1, and that the probability of obtaining the same observations under the assumption of independent assortment is 0.0001. The ratio of these two probabilities is $^{0.1}/_{0.0001} = 1000$, the logarithm of which (the lod score) is 3. Thus, linkage with the specified recombination frequency is 1000 times as likely as independent assortment to produce what was observed. A lod score of 3 or higher is usually considered convincing evidence for linkage. › **TRY PROBLEM 38**

Mapping with Molecular Markers

For many years, gene mapping was limited in most organisms by the availability of **genetic markers**: variable genes with easily observable phenotypes whose inheritance could be studied. Traditional genetic markers include genes that encode easily observable characteristics, such as flower color, seed shape, blood types, or biochemical differences. The paucity of these types of characteristics in many organisms limited mapping efforts.

In the 1980s, new molecular techniques made it possible to examine variations in DNA itself, providing an almost unlimited number of genetic markers. The earliest of these molecular markers consisted of

restriction fragment length polymorphisms (RFLPs), which are variations in DNA sequence that can be detected by cutting the DNA with restriction enzymes. Later, methods were developed for detecting variable numbers of short DNA sequences repeated in tandem, called microsatellites. Now DNA sequencing allows the direct detection of individual variations in the DNA nucleotides. All of these methods have expanded the availability of genetic markers and greatly facilitated the creation of genetic maps.

Gene mapping with molecular markers is done in essentially the same manner as mapping performed with traditional phenotypic markers: the cosegregation of two or more markers is studied, and map distances are based on the rates of recombination between markers. These methods and their use in mapping are presented in more detail in Chapters 19 and 20.

Locating Genes with Genome-Wide Association Studies

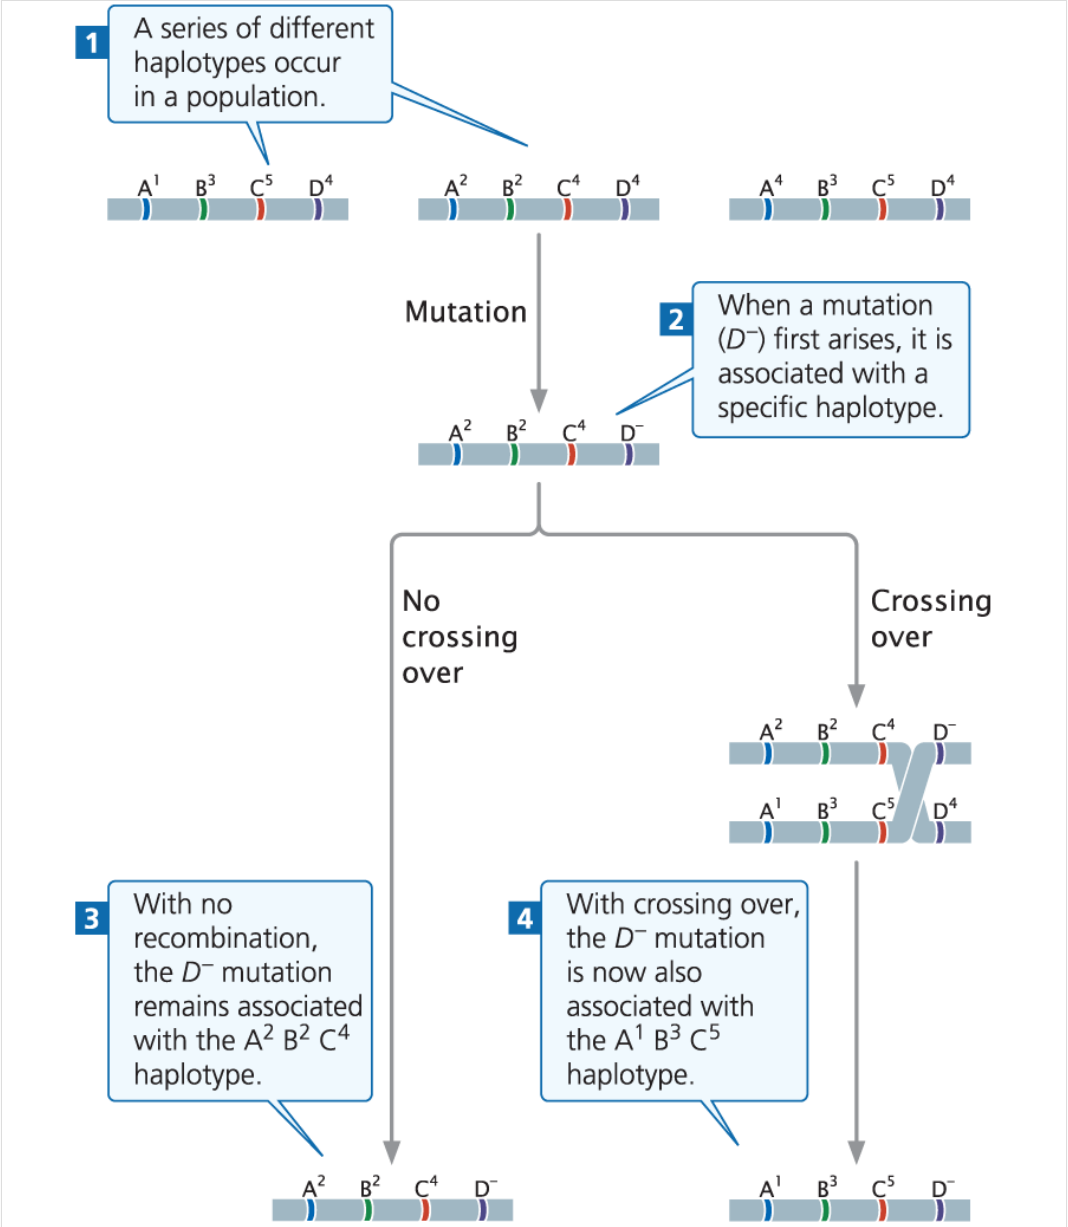
The traditional approach to mapping genes, which we have learned in this chapter, is to examine progeny phenotypes in genetic crosses or among individuals in a pedigree, looking for associations between the inheritance of a particular phenotype and the inheritance of alleles at other loci. This type of gene mapping is called **linkage analysis** because it is based on the detection of physical linkage between genes, as measured by the rate of recombination, in the progeny of a

cross. Linkage analysis has been a powerful tool in the genetic analysis of many different types of organisms, including fruit flies, corn, mice, and humans.

An alternative approach to mapping genes is to conduct **genome-wide association studies**, looking for nonrandom associations between the presence of a trait and alleles at many different loci scattered across the genome. Unlike linkage analysis, this approach does not trace the inheritance of genetic markers and traits in a genetic cross or family. Rather, it looks for associations between traits and particular suites of alleles in a *population*.

Imagine that we are interested in finding genes that contribute to bipolar disorder, a behavioral illness characterized by severe depression and mania. When a mutation that predisposes a person to bipolar disorder first arises in a population, it will occur on a particular chromosome and will be associated with a specific set of alleles on that chromosome. In the example illustrated in **Figure 7.19**, the D^- mutation first arises on a chromosome that has alleles A^2, B^2, and C^4, and therefore the D^- mutation is initially linked to the A^2, B^2, and C^4 alleles. A specific set of linked alleles such as this is called a **haplotype**, and the nonrandom association between alleles in a haplotype is called **linkage disequilibrium**. Because of the physical linkage between the bipolar mutation and the other alleles of the haplotype, bipolar disorder and the haplotype will tend to be inherited together. Crossing over, however, breaks up the association between the alleles of the haplotype (see Figure 7.19), reducing the linkage

disequilibrium between them. How long the linkage disequilibrium persists over evolutionary time depends on the frequency of recombination between alleles at different loci. When the loci are far apart, linkage disequilibrium breaks down quickly; when the loci are close together, crossing over is less common and linkage disequilibrium persists longer. The important point here is that linkage disequilibrium provides information about the distance between genes. A strong association between a trait such as bipolar disorder and a set of linked genetic markers indicates that one or more genes contributing to bipolar disorder are likely to be near the genetic markers.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

7.19 Genome-wide association studies are based on the nonrandom association of a mutation (D^-) that produces a trait with closely linked genes that constitute a haplotype.

Description

The diagram shows 3 different chromosomes. The first chromosome has the following alleles: A superscript 1, B superscript 3, C superscript 5, and D superscript 4. A caption

reads, A series of different haplotypes occur in a population. The second chromosome has following alleles: A superscript 2, B superscript 2, C superscript 4, and D superscript 4. The third chromosome has following alleles: A superscript 4, B superscript 3, C superscript 5, and D superscript 4. Mutation occurs in the chromosome 2. The D superscript 4 allele changes to D superscript negative. A caption reads, When a mutation (D superscript negative) first arises, it is associated with a specific haplotype. No crossing over occurs and the chromosome has same alleles. A caption reads, With no recombination, the D negative mutation remains associated with the A superscript 2 B superscript 2 C superscript 4 haplotype. Crossing over occurs between the mutated chromosome (A superscript 2, B superscript 2, C superscript 4, and D superscript negative) and a chromosome (A superscript 1, B superscript 3, C superscript 5, and D superscript 4). The resultant chromosome below is A superscript 1 B superscript 3 C superscript 5, and D superscript negative. A caption reads, With crossing over, the D negative mutation is now also associated with the A superscript 1 B superscript 3 C superscript 5 haplotype.

In recent years, geneticists have mapped millions of **single-nucleotide polymorphisms (SNPs)**, which are positions in the genome where individuals vary in a single nucleotide base (see the introduction to this chapter and Chapter 20). Recall that human SNPs were used to map genes associated with fear and aggression in dogs, as discussed in the introduction to this chapter. It is now possible to quickly and inexpensively genotype people for hundreds of thousands or millions of SNPs. This genotyping has provided the genetic markers needed for conducting genome-wide association studies in which SNP haplotypes of people who have a particular disease, such as bipolar disorder, are compared with the haplotypes of healthy people. Nonrandom associations between SNPs and the disease suggest that one or more genes that contribute to the disease are closely linked to the SNPs. Genome-wide association studies do not usually locate specific genes: rather, they associate the inheritance of a trait or

disease with a specific chromosomal region. After such an association has been established, geneticists can examine the chromosomal region for genes that might be responsible for the trait. Genome-wide association studies have been instrumental in the discovery of genes or chromosomal regions that affect a number of genetic diseases and important human traits, including bipolar disorder, height, skin pigmentation, eye color, body weight, coronary artery disease, blood-lipid concentrations, diabetes, heart attacks, bone density, and glaucoma. Genome-wide association studies are also being used to locate and study genes that affect traits in numerous other organisms.

THINK-PAIR-SHARE Question 7

CONCEPTS

The development of molecular techniques for examining variation in DNA sequences has provided a large number of genetic markers that can be used to create genetic maps and study linkage relations. Genome-wide association studies examine the nonrandom association of genetic markers and phenotypes to locate genes that contribute to the expression of traits.

7.4 Physical-Mapping Methods Are Used to Determine the Physical Positions of Genes on Particular Chromosomes

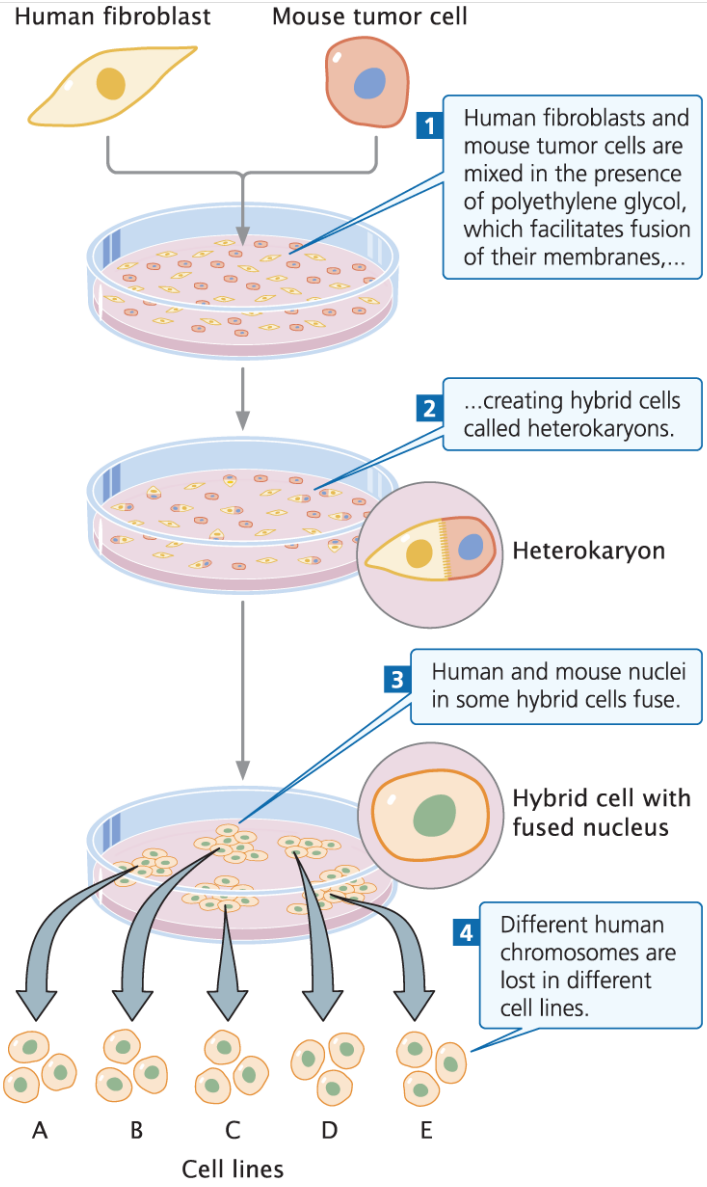
Genetic maps reveal the relative positions of genes on a chromosome, but they do not provide information that allows us to place groups of linked genes on particular chromosomes. Furthermore, the units of a genetic map do not always precisely correspond to physical distances on the chromosome, because a number of factors other than physical distances between genes (such as the type and sex of the organism) can influence recombination. Because of these limitations, physical-mapping methods that do not rely on recombination frequencies have been developed.

Somatic-Cell Hybridization

One method used for positioning genes on chromosomes is **somatic-cell hybridization**, which requires the fusion of different types of cells. Most mature somatic (nonsex) cells can undergo only a limited number of divisions and therefore cannot be grown continuously. However, cells that have been altered by viruses or derived from tumors that have lost the normal constraints on cell division will

divide indefinitely; this type of cell can be cultured in the laboratory to produce a **cell line**.

Cells from two different cell lines can be fused by treating them with polyethylene glycol or other agents that alter their plasma membranes. The resulting cell possesses two nuclei and is called a **heterokaryon**. The two nuclei of a heterokaryon eventually also fuse, generating a hybrid cell that contains chromosomes from both cell lines. If human and mouse cells are mixed in the presence of polyethylene glycol, their fusion results in human–mouse somatic-cell hybrids (**Figure 7.20**). The hybrid cells tend to lose chromosomes as they divide, and for reasons that are not understood, chromosomes from one of the species are lost preferentially. In human–mouse somatic-cell hybrids, the human chromosomes tend to be lost, whereas the mouse chromosomes are retained. Eventually, the chromosome number stabilizes when all but a few of the human chromosomes have been lost. Chromosome loss is random and differs among cell lines. The presence of these "extra" human chromosomes in the mouse genome makes it possible to assign human genes to specific chromosomes.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

7.20 Somatic-cell hybridization can be used to determine which chromosome contains a gene of interest.

Description

A spindle-shaped human fibroblast and a round mouse tumor cell fuse in a petri dish below to give hybrid cells. A caption reads, Human fibroblasts and mouse tumor cells are mixed in the presence of polyethylene glycol, which facilitates fusion of their membranes creating hybrid cells called heterokaryons. The resultant hybrid cells have fused membrane with

two distinct nuclei. This leads to the formation of hybrid cells with fused nucleus. Five clusters of cells are obtained below. A caption reads, Human and mouse nuclei in some hybrid cells fuse. These clusters are marked as different cell lines named A, B, C, D, and E. A caption reads, Different human chromosomes are lost in different cell lines.

Mapping genes by using somatic-cell hybridization requires a panel of different hybrid cell lines. Each cell line is examined microscopically, and the human chromosomes that it contains are identified. The cell lines of the panel are chosen so that they differ in the human chromosomes that they have retained. For example, one hybrid cell line might possess human chromosomes 2, 4, 7, and 8, whereas another might possess chromosomes 4, 19, and 20. Each cell line in the panel is examined for evidence of a particular human gene. The human gene can be detected by looking either for the gene itself (as discussed in Chapter 19) or for the protein that it produces. Correlation of the presence of the gene with the presence of specific human chromosomes often allows the gene to be assigned to the correct chromosome. For example, if a gene is detected in both of the aforementioned cell lines, the gene must be on chromosome 4 because it is the only human chromosome common to both cell lines (**Figure 7.21**). Somatic-cell hybridization is used less often today because DNA sequencing and mapping with molecular markers can often establish the chromosomal locations of linkage groups.

		Human chromosomes present																						
Cell line	Gene product present	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	X
A	+		+		+			+	+															
B	+	+	+		+				+	+	+	+	+	+										
C	–															+		+		+			+	
D	+		+		+		+	+	+															
E	–												+								+			
F	+				+															+	+			

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.21 Somatic-cell hybridization is used to assign a gene to a particular human chromosome. A panel of six hybrid cell lines, each containing a different subset of human chromosomes, is examined for the presence of the gene product (such as an enzyme). Four of the cell lines (A, B, D, and F) express the gene product. The only chromosome common to all four of these cell lines is chromosome 4, indicating that the gene is located on this chromosome.

Description

The column headers are as follows: cell line, gene product present, and the numbers 1 to 22, and X.

The row entries are as follows:

Row 1: A; gene product present, positive; then columns numbered 2, 4, 7, and 8 show positive.

Row 2: B; gene product present, positive; then columns numbered 1, 2, 4, and 8 to 13 show positive.

Row 3: C; gene product present, negative; then columns numbered 15, 17, 19, and 22 show positive.

Row 4: D; gene product present, positive; then columns numbered 2, 4, and 6 to 8 show positive.

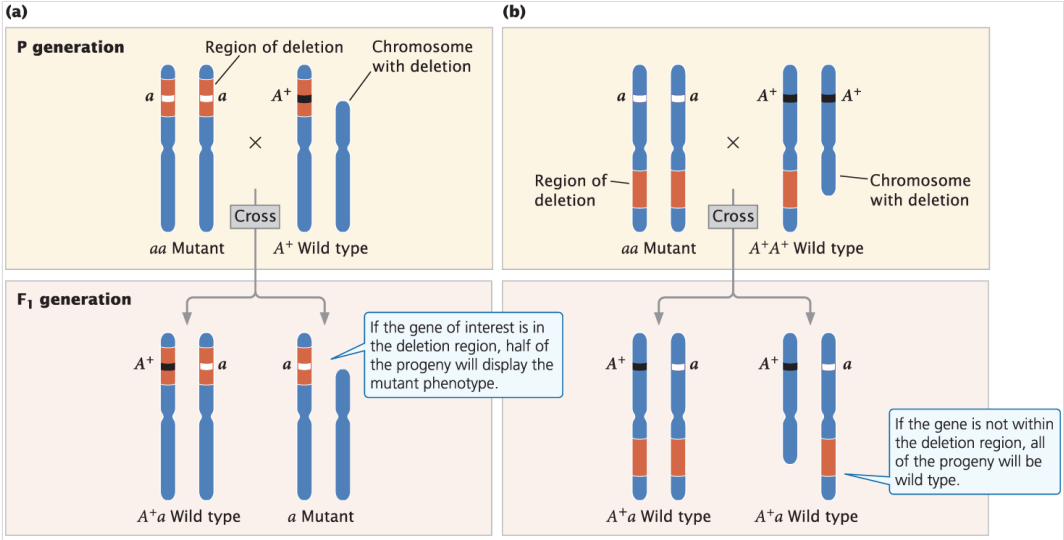
Row 5: E; gene product present, negative; then columns numbered 12 and 20 show positive.

Row 6: F; gene product present, positive; then columns numbered 4, 19, and 20 show positive.

Deletion Mapping

Another method for determining the chromosomal location of a gene is **deletion mapping**. Special staining methods have been developed that reveal characteristic banding patterns on chromosomes (see Chapter 8). The absence of one or more of the bands that are normally seen on a chromosome reveals the presence of a chromosomal *deletion* (loss of a chromosome segment). We can assign genes to regions of chromosomes by studying the association between a phenotype or product encoded by a gene and particular chromosomal deletions.

In deletion mapping, an individual that is homozygous for a recessive mutation in the gene of interest is crossed with an individual that is heterozygous for a deletion (**Figure 7.22**). If the gene of interest is in the region of the chromosome represented by the deletion (the red part of the chromosomes in Figure 7.22), then approximately half of the progeny will display the mutant phenotype (see Figure 7.22a). If the gene is not within the deleted region, then all of the progeny will be wild type (see Figure 7.22b).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

7.22 Deletion mapping can be used to determine the chromosomal location of a gene. An individual homozygous for a recessive mutation in the gene of interest (*aa*) is crossed with an individual heterozygous for a deletion.

Description

Part a on the left shows P generation at the top where a cross between an individual with genotype small A small A (small A small A mutant) and an individual with genotype big A superscript positive and a chromosome with deletion is done (big A superscript positive wild type). These chromosomes are crossed and the F subscript 1 generation obtained below has two progenies: a heterozygote with big A superscript positive on one chromosome and small A on other (big A superscript positive small A wild type), and a mutant progeny with genotype small A on one chromosome. A caption reads, If the gene of interest is in the deletion region, half of the progeny will display the mutant phenotype. Part b on the right shows P generation at the top. An individual has genotype homozygous small A on one chromosome and small A on other. The region of deletion is present on the both the chromosome below the centromere (small A small A mutant). Another individual has big A superscript positive on both the chromosomes above the centromere and has second chromosome has a deletion (big A superscript positive big A superscript positive wild type). These 2 individuals cross and yield an F subscript 1 generation below. The big A superscript positive small A wild type progeny has big A superscript positive allele on the first chromosome and small A on the other chromosome. Both chromosomes have a region of deletion below respective centromeres. Another big A superscript positive small A wild type progeny has first chromosome with big A superscript positive and short arm

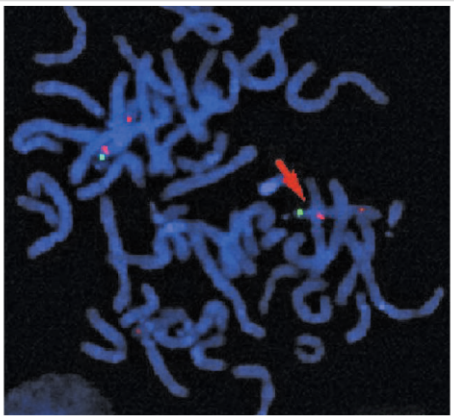
below centromere and second chromosome has small A with a region of deletion below its centromere. A caption reads, If the gene is not within the deletion region all of the progeny will be wild type.

Deletion mapping has been used in the past to reveal the chromosomal locations of a number of human genes. For example, Duchenne muscular dystrophy is a disease that causes progressive weakening and degeneration of the muscles (see introduction to Chapter 19). From its X-linked pattern of inheritance, the mutant allele causing this disorder was known to be on the X chromosome, but its precise location was uncertain. Examination of a number of patients with the disease who also possessed small deletions allowed researchers to position the gene on a small segment of the short arm of the X chromosome. Like somatic-cell hybridization, deletion mapping is used less often today because of the widespread availability of DNA sequencing. › **TRY PROBLEM 41**

Physical Chromosome Mapping Through Molecular Analysis

So far, we have explored methods that determine the chromosomal location of a gene indirectly. Researchers now have the information and technology to see where a gene actually lies. Described in more detail in Chapter 19, fluorescence in situ hybridization (FISH) is a method for determining the chromosomal location of a particular gene through molecular analysis. This method requires the creation

of a probe for the gene, which is a single-stranded DNA complement to the gene of interest. The probe fluoresces under high-frequency light so that it can be visualized. The probe binds to the DNA sequence of the gene of interest on the chromosome. The presence of fluorescence from the bound probe reveals the location of the gene on a particular chromosome (**Figure 7.23**).



Prader Willi & Angelman syndromes - FISH. Wessex Reg. Genetics Centre. CC BY.

7.23 In situ hybridization is another technique for determining the chromosomal location of a gene. The red and green fluorescence spots are produced by probes that are specific to different DNA sequences on chromosome 15.

In addition to allowing us to see where a gene is located on a chromosome, modern laboratory techniques now allow researchers to identify the precise location of a gene at the nucleotide level. For example, with DNA sequencing (described fully in Chapter 19), physical distances between genes can be determined in numbers of base pairs.

CONCEPTS

Physical-mapping methods determine the physical locations of genes on chromosomes. They include somatic-cell hybridization, deletion mapping, in situ hybridization, and direct DNA sequencing.

7.5 Recombination Rates Exhibit Extensive Variation

Geneticists have studied variation in rates of recombination and have found that they vary widely—among species, among and along chromosomes of a single species, and even between males and females of the same species. For example, about twice as much recombination takes place in humans as in mice and rats. Within the human genome, recombination rates vary among chromosomes, with chromosomes 21 and 22 having the highest rates and chromosomes 2 and 4 having the lowest rates. Researchers have also detected differences between male and female humans in rates of recombination: the autosomal chromosomes of females undergo about 50% more recombination than do the autosomal chromosomes of males.

Geneticists have found numerous recombination *hotspots*, where recombination is at least 10 times as high as the average elsewhere in the genome. The human genome contains an estimated 25,000 to 50,000 such recombination hotspots, and approximately 60% of all crossovers take place in them. For humans, recombination hotspots tend to be found near, but not within, active genes. Recombination hotspots have been detected in the genomes of other organisms as well. Other chromosomal regions, such as those near centromeres, often display reduced rates of recombination.

CONCEPTS

Rates of recombination vary among species, among and along chromosomes, and even between males and females.

Chapter 7 Review

CHAPTER SUMMARY

Section 7.1 Learning Objective: Be able to explain how the inheritance of linked genes is different from those that are not linked.

- Linked genes do not assort independently.

Section 7.2 Learning Objective: Be able to analyze crosses involving linked genes.

- In a testcross for two completely linked genes (with no crossing over), only nonrecombinant progeny are produced. When two genes assort independently, recombinant progeny and nonrecombinant progeny are produced in equal proportions. When two genes are linked with some crossing over between them, more nonrecombinant progeny than recombinant progeny are produced.
- Recombination frequency is calculated by summing the number of recombinant progeny, dividing by the total number of progeny produced in the cross, and multiplying by 100%. The frequency of recombinant gametes is half the frequency of crossing over, and the maximum frequency of recombinant gametes is 50%.
- Coupling and repulsion refer to the arrangement of alleles on a chromosome. Whether alleles are in coupling or in repulsion determines which combination of phenotypes will be most frequent in the progeny of a testcross.
- Interchromosomal recombination takes place among genes located on different chromosomes through the random segregation of

chromosomes in meiosis. Intrachromosomal recombination takes place among genes located on the same chromosome through crossing over.
- A chi-square test of independence can be used to determine whether genes are linked.
- Recombination rates can be used to determine the relative order of genes and distances between them on a chromosome. One percent recombination equals one map unit. Maps based on recombination rates are called genetic maps; maps based on physical distances are called physical maps.
- Genetic maps can be constructed by examining recombination rates from a series of two-point crosses.

Section 7.3 Learning Objective: Using data from a three-point testcross, be able to map a series of three linked genes, including determination of the order of the genes, the recombination frequencies, and the interference.

- Genetic maps can be constructed by examining the progeny of a three-point testcross.
- Interference is the degree to which one crossover interferes with additional crossovers in the same area. The interference equals 1 minus the coefficient of coincidence, which is the observed number of double crossovers divided by the expected number of double crossovers.
- Some multiple crossovers go undetected; thus, genetic maps based on recombination rates underestimate the true physical distances between genes.
- Human genes can be mapped by examining the cosegregation of traits in pedigrees.
- A lod score is the logarithm of the ratio of the probability of obtaining the observed progeny with the assumption of linkage to the probability of obtaining the observed progeny with the assumption of independent

assortment. A lod score of 3 or higher is usually considered evidence for linkage.
- Molecular techniques that allow the detection of differences in DNA sequence have greatly facilitated gene mapping.
- Genome-wide association studies locate genes that affect particular traits by examining the nonrandom association of a trait with sets of genetic markers from across the genome.

Section 7.4 Learning Objective: Be able to describe the methods used in physical gene mapping, including somatic cell hybridization, deletion mapping, and fluorescence in situ hybridization (FISH).

- Physical mapping methods are used to determine the chromosomal locations of genes.
- Nucleotide sequencing is another method of physically mapping genes.

Section 7.5 Learning Objective: Be able to describe variation in recombination rates.

- Rates of recombination vary widely, differing among species, among and along chromosomes within a single species, and even between males and females of the same species.

WORKED PROBLEMS

Problem 1

In guinea pigs, white coat (*w*) is recessive to black coat (*W*), and wavy hair (*v*) is recessive to straight hair (*V*). A breeder crosses a guinea pig that is homozygous for white coat and wavy hair with a guinea pig that is black with straight hair. The F_1 are then crossed with guinea pigs having white

coats and wavy hair in a series of testcrosses. The following progeny are produced from these testcrosses:

black, straight	30
black, wavy	10
white, straight	12
white, wavy	31
Total	83

a. Are the genes that determine coat color and hair type assorting independently? Carry out chi-square tests to test your hypothesis.
b. If the genes are not assorting independently, what is the recombination frequency between them?

» Solution Strategy

What information is required in your answer to the problem?

a. Whether the genes are assorting independently, along with a chi-square value, degrees of freedom, and P value to evaluate your hypothesis.
b. If the genes are not assorting independently, the recombination frequency between them.

What information is provided to solve the problem?

- White coat is recessive to black coat, and wavy hair is recessive to straight hair.

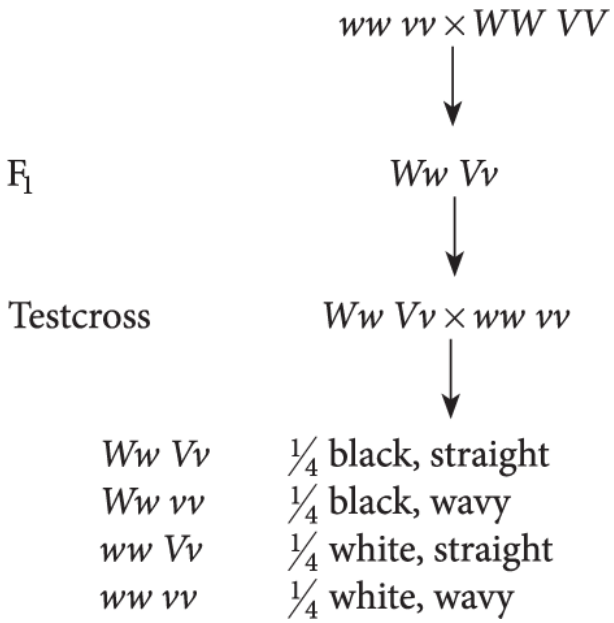
- The numbers of different types of progeny from a series of testcrosses.

For help with this problem, review:

Crossing Over Between Linked Genes, Calculating Recombination Frequency, and Testing for Independent Assortment in Section 7.2.

» Solution Steps

a. Assuming independent assortment, outline the crosses conducted by the breeder:



Description
P generation at the top shows a guinea pig with small W small W small V small V crossed with big W big W big V big V. F subscript 1 generation below shows genotype big W small W big V small V. A test cross is conducted between big W small W big V small V and small W small W small V small V. The genotypes obtained below are:

big W small W big V small V (one-fourth black, straight).

big W small W small V small V (one-fourth black, wavy).

small W small W big V small V (one-fourth white, straight).

small W small W small V small V (one-fourth white, wavy).

A caption reads, Recall: With independent assortment, we expect equal numbers of nonrecombinant and recombinant offspring.

Recall: With independent assortment, we expect equal numbers of nonrecombinant and recombinant offspring.

Because a total of 83 progeny were produced in the testcrosses, we expect $^1/_4 \times 83 = 20.75$ of each. The observed numbers of progeny from the testcross (30, 10, 12, 31) do not appear to fit the expected numbers (20.75, 20.75, 20.75, 20.75) well, so independent assortment may not have taken place.

Hint: See Figure 7.10 for a review of how to carry out a chi-square test of independence.

To test the hypothesis, carry out a chi-square test of independence. Construct a table with the genotypes of the first locus along the top and the genotypes of the second locus along the side. Compute the totals for the rows and columns and the grand total.

	Ww	*ww*	Row totals
Vv	30	12	42
vv	10	31	41
Column totals	40	43	83 ← Grand total

The expected value for each cell of the table is calculated with the following formula:

$$\text{expected number} = \frac{\text{row total} \times \text{column total}}{\text{grand total}}$$

Using this formula, we find the expected values (given in parentheses) to be

	Ww	*ww*	Row totals
Vv	30 (20.24)	12 (21.76)	42
vv	10 (19.76)	31 (21.24)	41
Column totals	40	43	83 ← Grand total

Using these observed and expected numbers, we find the calculated chi-square value to be

$$\begin{aligned}
\chi^2 &= \sum \frac{(\text{observed} - \text{expected})^2}{\text{expected}} \\
&= \frac{(30 - 20.24)^2}{20.24} + \frac{(10 - 19.76)^2}{19.76} + \frac{(12 - 21.76)^2}{21.76} + \frac{(31 - 21.24)^2}{21.24} \\
&= 4.71 + 4.82 + 4.38 + 4.48 = 18.39
\end{aligned}$$

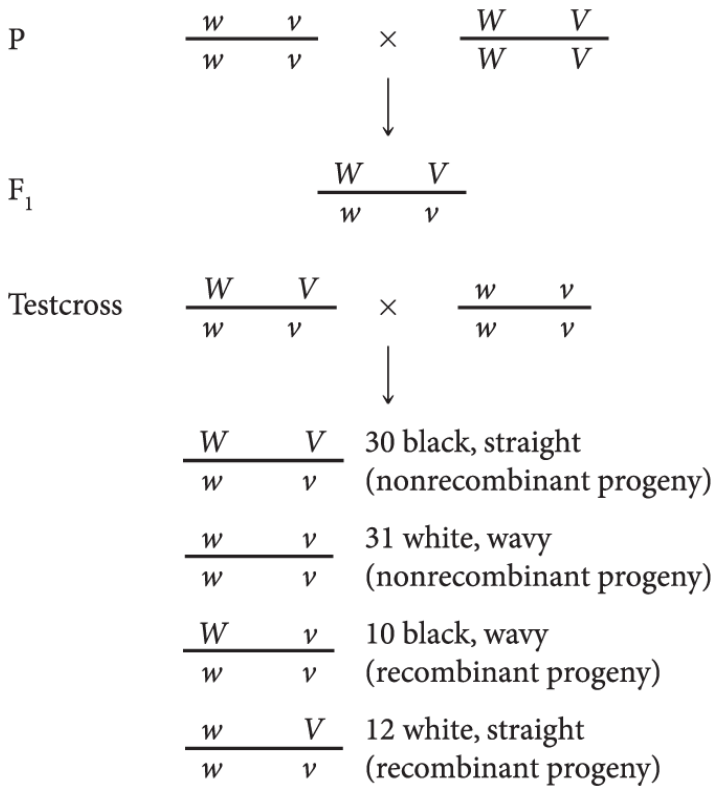
The degrees of freedom for the chi-square test of independence are df = (number of rows − 1) × (number of columns − 1) . There are two rows and two columns, so the degrees of freedom are

$$\text{df} = (2 - 1) \times (2 - 1) = 1 \times 1 = 1$$

In Table 3.5, the probability associated with a chi-square value of 18.39 and 1 degree of freedom is less than 0.005, indicating that chance is very unlikely to be responsible for the differences between the observed numbers and the numbers expected with independent assortment. The genes for coat color and hair type have therefore not assorted independently.

> **Recall:** The probability associated with the chi-square value is the probability that the difference between observed and expected values is due to chance.

b. To determine the recombination frequencies, identify the recombinant progeny. Using the notation for linked genes, write the crosses:



Description

The P generation has a guinea pig with small W and small V on both the chromosomes and another has big W and big V on both the chromosomes. The F subscript 1 progeny below has big W big V on the top chromosome and small W small V on the bottom chromosome. The testcross is between the F subscript 1 progeny and a guinea pig with small W small V on both the chromosomes. The resultant progeny obtained below is as follows: Progeny 1 has big W big V on the top chromosome and small W small V on the bottom chromosome. These are 30 and are black straight. The second progeny listed is small W small V on both the chromosomes.

These are 31 and are white wavy. The third progeny has big W small V on the top chromosome and small W small V on the bottom chromosome. These are 10 and are black wavy. The fourth progeny has small big V on the top chromosome and small W small V on the bottom chromosome. These are 12 and are white straight. The first 2 are nonrecombinant progeny, and the last 2 are recombinant progeny.

$$\text{The recombination frequency} = \frac{10+12}{30+31+10+12} \times 100\% = \frac{22}{83} \times 100\% = 26.5$$

Recall: $\text{The recombination frequency} = \frac{\text{number of recombinant progeny}}{\text{total number of progeny}} \times 100\%.$

Problem 2

A series of two-point crosses were carried out among seven loci (*a*, *b*, *c*, *d*, *e*, *f*, and *g*), producing the following recombination frequencies. Using these recombination frequencies, map the seven loci, showing their linkage groups, the order of the loci in each linkage group, and the distances between the loci of each group:

Loci	Recombination frequency (%)	Loci	Recombination frequency (%)
a and *b*	10	*c* and *d*	50
a and *c*	50	*c* and *e*	8
a and *d*	14	*c* and *f*	50
a and *e*	50	*c* and *g*	12
a and *f*	50	*d* and *e*	50
a and *g*	50	*d* and *f*	50

b and *c*	50	*d* and *g*	50
b and *d*	4	*e* and *f*	50
b and *e*	50	*e* and *g*	18
b and *f*	50	*f* and *g*	50
b and *g*	50		

» Solution Strategy

What information is required in your answer to the problem?

The linkage groups for the seven loci, the order of the loci within each linkage group, and the map distances between the loci.

What information is provided to solve the problem?

Recombination frequencies for each pair of loci.

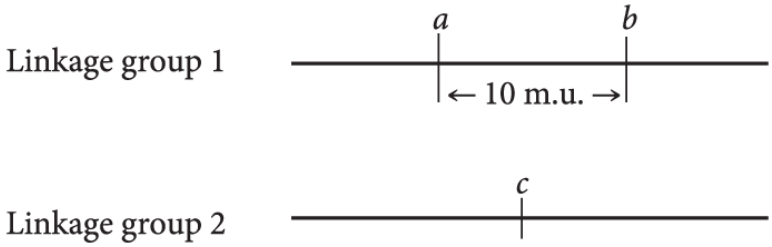
For help with this problem, review:

Constructing a Genetic Map with a Two-Point Testcross in Section 7.2.

» Solution Steps

To work this problem, remember that 1% recombination equals 1 map unit. The recombination frequency between *a* and *b* is 10%, so these two loci are in the same linkage group, approximately 10 m.u. apart.

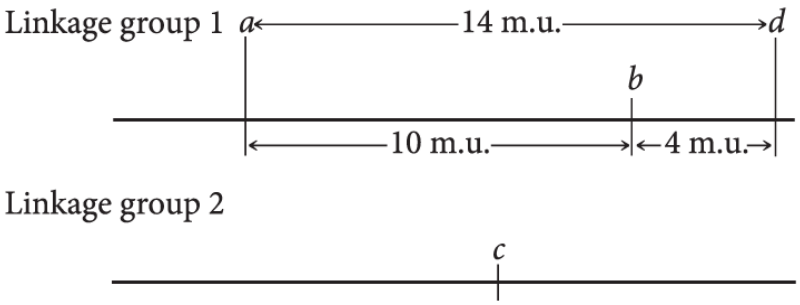
The recombination frequency between *a* and *c* is 50%, so *c* must lie in a second linkage group.



Description
The linkage group 1 shows distance between genes small A and small B is 10 m u. The linkage group 2 shows gene small C in the center.

Hint: A recombination frequency of 50% means that genes at the two loci are assorting independently (located in different linkage groups).

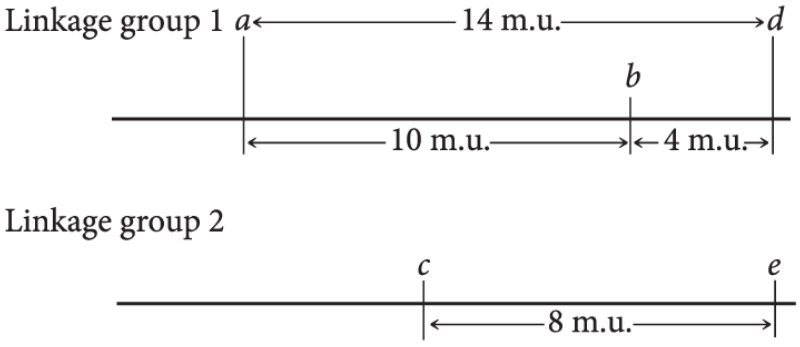
The recombination frequency between *a* and *d* is 14%, so *d* is located in linkage group 1. Is locus *d* 14 m.u. to the right or to the left of locus *a*? If *d* is 14 m.u. to the left of *a*, then the *b*-to-*d* distance should be 10 m.u. + 14 m.u. = 24 m.u. On the other hand, if *d* is to the right of *a*, then the distance between *b* and *d* should be 14 m.u. − 10 m.u. = 4 m.u. The *b*–*d* recombination frequency is 4%, so *d* is 14 m.u. to the right of *a*. The updated map is



Description
The first line is labeled linkage group 1 and shows genes small A and small B 10 m u away from each other. Gene small D is 4 m u to the right of gene small B. The distance between gene small A and small D is 14 m u. The second line is labeled linkage group 2 and shows gene small C in the center.

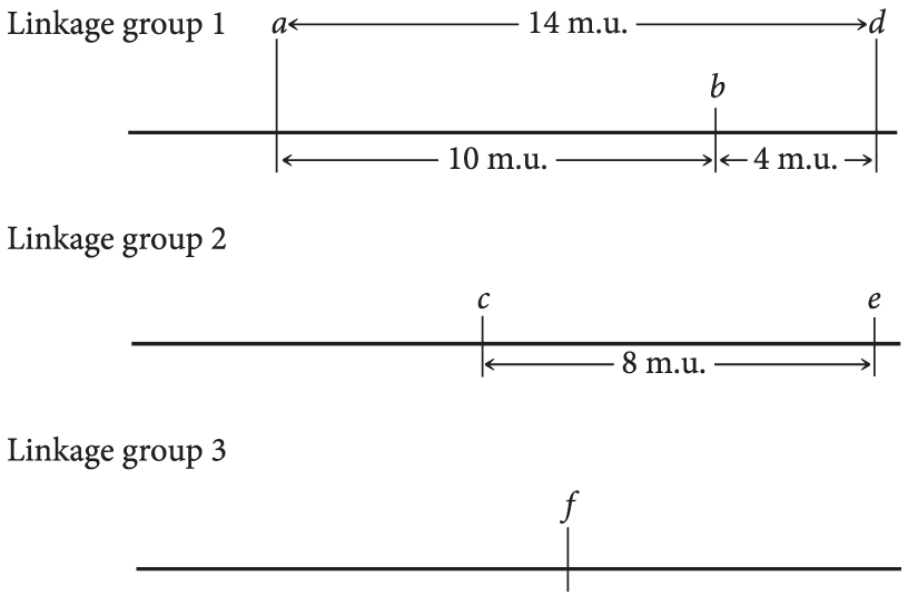
Hint: To determine whether locus *d* is to the right or the left of locus *a*, look at the *b*-to-*d* distance.

The recombination frequencies between each of loci *a*, *b*, and *d* and locus *e* are all 50%, so *e* is not in linkage group 1 with *a*, *b*, and *d*. The recombination frequency between *e* and *c* is 8%, so *e* is in linkage group 2:



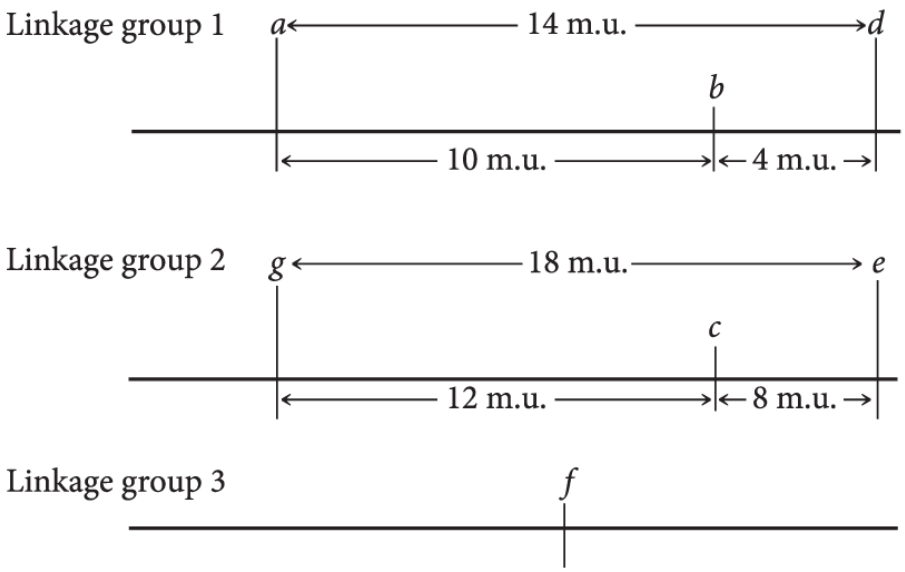
Description
The first line is labeled linkage group 1 and shows genes small A and small B 10 m u away from each other. Gene small D is an additional 4 m u to the right of gene small B. The distance between gene small A and small D is 14 m u. The second line is labeled linkage group 2 and shows gene small C in the middle and 8 m u to the right is gene small E.

There is 50% recombination between *f* and all the other genes, so *f* must belong to a third linkage group:



Description
The first line is labeled linkage group 1 and shows genes small A and small B 10 m u away from each other. Gene small D is 4 m u to the right of small B. The distance between gene small A and small D is 14 m u. The second line is labeled linkage group 2 and shows that gene small C in the middle and 8 m u to the right is gene small E. The third line is labeled linkage group 3 and has gene small F in the middle.

Finally, position locus *g* with respect to the other genes. The recombination frequencies between *g* and loci *a*, *b*, and *d* are all 50%, so *g* is not in linkage group 1. The recombination frequency between *g* and *c* is 12%, so *g* is a part of linkage group 2. To determine whether *g* is 12 m.u. to the right or left of *c*, consult the *g*–*e* recombination frequency. Because this recombination frequency is 18%, *g* must lie to the left of *c*:



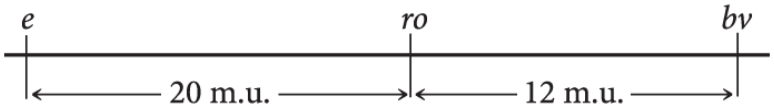
Description
The first line is labeled linkage group 1 and shows genes small A and small B 10 m u away from each other. Gene small D is 4 m u to the right of small B. The distance between gene small A and small D is 14 m u. The second line is labeled linkage group 2 and shows that gene small G is in extreme left, 12 m u to the right is gene small C and 8 m u to the right is gene small E. The distance between gene small G and small E is 18 m u. The third line is labeled linkage group 3 and has gene small F in the middle.

Note that the *g-to-e* distance (18 m.u.) is shorter than the sum of the *g-to-c* (12 m.u.) and *c-to-e* distances (8 m.u.) because of undetectable double crossovers between *g* and *e*.

Recall: Because some double crossovers may go undetected, the distance between two distant genes (such as *g* and *e*) may be less than the sum of shorter distances (such as *g* to *c* and *c* to *e*).

Problem 3

Ebony body color (*e*), rough eyes (*ro*), and brevis bristles (*bv*) are three recessive mutations that occur in fruit flies. The loci for these mutations have been mapped and are separated by the following map distances:



Description
The genes are from left to right are follows: gene small E is on extreme left, 20 m u to the right is gene small R small O, and 12 m u to the right is gene small B small V.

The interference between these genes is 0.4.

A fly with ebony body, rough eyes, and brevis bristles is crossed with a fly that is homozygous for the wild-type traits. The resulting F_1 females are test-crossed with males that have ebony body, rough eyes, and brevis bristles; 1800 progeny are produced. Give the expected numbers of phenotypes in the progeny of the testcross.

» Solution Strategy

What information is required in your answer to the problem?

The expected numbers of different progeny phenotypes produced by the testcross.

What information is provided to solve the problem?

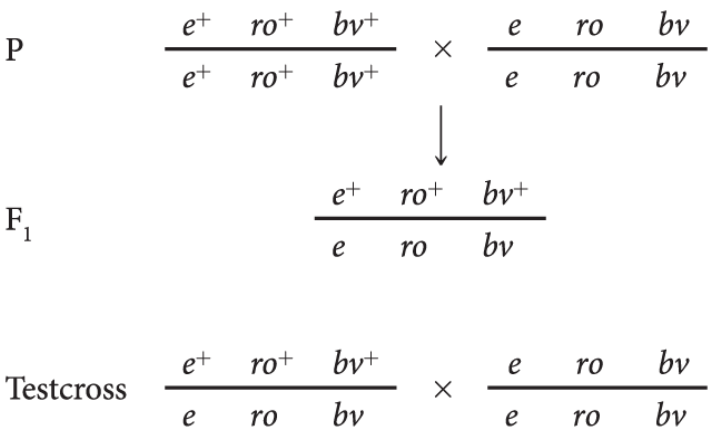
- The map distances among the three loci.
- The interference among the loci.
- A testcross is carried out and 1800 progeny are produced.

For help with this problem, review:

Constructing a Genetic Map with a Three-Point Testcross and the Worked Problem in Section 7.3.

» Solution Steps

The crosses are



Description
The P generation shows an individual with small E superscript positive small R small O superscript positive small B small V superscript positive on both the chromosomes crossed with an individual with small E small R small O small B small V on both the chromosomes. The F subscript 1 generation obtained below has small E superscript positive small R small O superscript positive small B small V superscript positive on one chromosome and small E small R small O small B small V on the other chromosome. A test cross below shows the F subscript 1 progeny crossed with an individual with small E small R small O small B small V on both the chromosomes.

In this case, we know that *ro* is the middle locus because the genes have been mapped. Eight classes of progeny will be produced by this cross:

e^+		ro^+	bv^+	nonrecombinant
e		*ro*	*bv*	nonrecombinant
e^+	/	*ro*	*bv*	single crossover between *e* and *ro*
e	/	ro^+	bv^+	single crossover between *e* and *ro*

e^+		ro^+	/	bv	single crossover between *ro* and *bv*
e		ro	/	bv^+	single crossover between *ro* and *bv*
e^+	/	ro	/	bv^+	double crossover
E	/	ro^+	/	bv	double crossover

Hint: The order of the genes is provided by the genetic map.

To determine the numbers of each type, use the map distances, starting with the double crossovers. The expected number of double crossovers is equal to the product of the single-crossover probabilities:

$$\begin{aligned} \text{expected number of double crossovers} &= 0.20 \times 0.12 \times 1800 \\ &= 43.2 \end{aligned}$$

However, there is some interference, so the observed number of double crossovers will be less than the expected. The interference is 1 – coefficient of coincidence, so the coefficient of coincidence is

$$\text{coefficient of coincidence} = 1 - \text{interference}$$

Recall: The presence of interference means that not all expected double crossovers will be observed.

The interference is given as 0.4, so the coefficient of coincidence equals 1 − 0.4 = 0.6. Recall that the coefficient of coincidence is

$$\text{coefficient of coincidence} = \frac{\text{number of observed double crossovers}}{\text{number of expected double crossovers}}$$

Rearranging this equation, we obtain

$$\begin{aligned}\text{number of observed double crossovers} &= \text{coefficient of coincidence} \times \text{number of expected double crossovers} \\ &= 0.6 \times 43.2 = 26\end{aligned}$$

A total of 26 double crossovers should be observed. Because there are two classes of double crossovers ($\underline{e^+ \ / \ ro \ / \ bv^+}$ and $\underline{e \ / \ ro^+ \ / \ bv}$,) we expect to observe 13 of each class.

Next, we determine the number of single-crossover progeny. The genetic map indicates that the distance between *e* and *ro* is 20 m.u., so 360 progeny (20% of 1800) are expected to have resulted from recombination between these two loci. Some of them will be single-crossover progeny, and some will be double-crossover progeny. We have already determined that the number of double-crossover progeny is 26, so the number of progeny resulting from a single crossover between *e* and *ro* is 360 − 26 = 334, which will be divided equally between the two single-crossover phenotypes ($\underline{e \ / \ ro^+ \ \ bv^+}$ and $\underline{e^+ \ / \ ro \ bv}$).

Hint: To obtain the number of single-crossover progeny, subtract the number of double crossover progeny from the total number that resulted from recombination.

The distance between *ro* and *bv* is 12 m.u., so the number of progeny resulting from recombination between these two genes is 0.12 × 1800 = 216. Again, some of these recombinants will be single-crossover progeny, and some will be double-crossover progeny. To determine the number of progeny resulting from a single crossover, subtract the double crossovers: 216 − 26 = 190. These single-crossover progeny will be divided between the two single-crossover phenotypes ($\underline{e^+ \ ro^+ \ / \ bv}$ and $\underline{e \ ro \ / \ bv^+}$), so there will be $^{190}/_{2} = 95$ of each of these phenotypes. The remaining progeny will be

nonrecombinants, and they can be obtained by subtraction: 1800 − 26 − 334 − 190 = 1250; there are two nonrecombinants ($e^+ \quad ro^+ \quad bv^+$ and $e \quad ro \quad bv$), so there will be ${}^{1250}/_{2}/625$ of each. The numbers of the various phenotypes are listed here:

e^+		ro^+		bv^+	625	nonrecombinant
e		ro		bv	625	nonrecombinant
e^+	/	ro		bv	167	single crossover between *e* and *ro*
e	/	ro^+		bv^+	167	single crossover between *e* and *ro*
e^+		ro^+	/	bv	95	single crossover between *ro* and *bv*
e		ro	/	bv^+	95	single crossover between *ro* and *bv*
e^+	/	ro	/	bv^+	13	double crossover
e	/	ro^+	/	bv	13	double crossover
Total					1800	

Hint: Don't forget to subtract the double crossovers from the total number of recombinants.

Hint: The number of nonrecombinants can be obtained by subtraction.

IMPORTANT TERMS

ANSWERS TO CONCEPT CHECKS

1. c
2. Repulsion
3. Genetic maps are based on rates of recombination; physical maps are based on physical distances.

4. 
Description
Each chromosome is represented by a straight, horizontal line. For first chromosome: the alleles above the line are small M superscript positive small P superscript positive small S superscript positive and alleles below the line are small M small P small S;

For second chromosome: the alleles above the line are small M superscript positive small P small S and alleles below the line are small M small P small S;

For third chromosome: the alleles above the line are small M small P superscript positive small S superscript positive and alleles below the line are small M small P small S;

For fourth chromosome: the alleles above the line are small M superscript positive small P superscript positive small S and alleles below the line are small M small P small S;

For fifth chromosome: the alleles above the line are small M small P small S superscript positive and alleles below the line are small M small P small S;

For sixth chromosome: the alleles above the line are small M superscript positive small P small S superscript positive and alleles below the line are small M small P small S;

For seventh chromosome: the alleles above the line are small M small P superscript positive small S and alleles below the line are small M small P small S;

For eighth chromosome: the alleles above and below the line are small M small P small S.

Chapter 7 Assessment

COMPREHENSION QUESTIONS

Section 7.1

1. What does the term *recombination* mean? What are two causes of recombination?

Section 7.2

2. In a testcross for two genes, what types of gametes are produced with (a) complete linkage, (b) independent assortment, and (c) incomplete linkage?

3. What effect does crossing over have on linkage?

4. Why is the frequency of recombinant gametes always half the frequency of crossing over?

5. What is the difference between genes in coupling configuration and genes in repulsion? How does the arrangement of linked genes (whether they are in coupling or repulsion) affect the results of a genetic cross?

6. CONNECT Explain how Creighton and McClintock's experiments involving a strain of corn with an abnormal chromosome 9

demonstrated the chromosome theory of inheritance (see Chapter 3).

7. How would you test to see if two genes are linked?
8. What is the relationship between recombination frequency and a centiMorgan?
9. Why do calculated recombination frequencies between pairs of loci that are located far apart underestimate the true genetic distances between loci?

Section 7.3

10. Explain how to determine, using the numbers of progeny from a three-point cross, which of three linked loci is the middle locus.
11. What does the interference tell us about the effect of one crossover on another?
12. What is a lod score, and how is it calculated?

Section 7.4

13. List some of the methods for physically mapping genes, and explain how they are used to position genes on chromosomes.

APPLICATION QUESTIONS AND PROBLEMS

Section 7.2

14. CONNECT In the snail *Cepaea nemoralis*, an autosomal allele causing a banded shell (B^B) is recessive to the allele for an unbanded shell (B^O). Genes at a different locus determine the background color of the shell; here, yellow (C^Y) is recessive to brown (C^{Bw}). A banded, yellow snail is crossed with a homozygous brown, unbanded snail. The F_1 are then crossed with banded, yellow snails (a testcross).

a.

Picture Press/Getty Images.

What will the results of the testcross be if the loci that control banding and color are linked with no crossing over?

b. What will the results of the testcross be if the loci assort independently (see Chapter 3)?

c. What will the results of the testcross be if the loci are linked and 20 m.u. apart?

15. *In silkmoths (*Bombyx mori*), red eyes (*re*) and white-banded wings (*wb*) are encoded by two mutant alleles that are recessive to those that produce wild-type traits (re^+ and wb^+); these two genes are on the same chromosome. A moth homozygous for red eyes and white-banded wings is crossed with a moth homozygous for the wild-type traits. The F_1 have wild-type eyes and wild-type wings. The F_1 are crossed with moths that have red eyes and white-banded wings in a testcross. The progeny of this testcross are

wild-type eyes, wild-type wings	418
red eyes, wild-type wings	19
wild-type eyes, white-banded wings	16
red eyes, white-banded wings	426

a. What phenotypic proportions would be expected if the genes for red eyes and for white-banded wings were located on different chromosomes?

b. What is the rate of recombination between the gene for red eyes and the gene for white-banded wings?

16. CONNECT *In 1916, Dorothy Osborn suggested that pattern baldness (the common type of baldness seen in most males) is a sex-influenced trait (see Chapter 5) that is dominant in males and recessive in females. Other research has found that pattern baldness is influenced by genes on the X chromosome. Would

you expect to see independent assortment between genetic markers on the X chromosome and pattern baldness if (a) pattern baldness is sex-influenced and (b) if pattern baldness is X-linked recessive? Explain your answer. (Research has also identified variation at autosomal genes that is associated with pattern baldness.)

17. *A geneticist discovers a new mutation in *D. melanogaster* that causes the flies to shake and quiver. She calls this mutation *quiver* (*qu*) and determines that it is due to an autosomal recessive gene. She wants to determine whether the gene encoding the quiver phenotype is linked to the recessive gene encoding vestigial (reduced) wings (*vg*). She crosses a fly homozygous for quiver and vestigial traits with a fly homozygous for the wild-type traits and then uses the resulting F_1 females in a testcross. She obtains the following flies from this testcross:

vg^+	qu^+	230
vg	*qu*	224
vg	qu^+	97
vg^+	*qu*	99
Total		650

Are the genes that cause vestigial wings and the quiver phenotype linked? Do a chi-square test of independence to determine whether the genes have assorted independently.

18. *In cucumbers, heart-shaped leaves (*hl*) are recessive to normal leaves (*Hl*), and having numerous fruit spines (*ns*) is recessive to

having few fruit spines (*Ns*). The genes for leaf shape and for number of spines are located on the same chromosome; findings from mapping experiments indicate that they are 32.6 m.u. apart. A cucumber plant having heart-shaped leaves and numerous spines is crossed with a plant that is homozygous for normal leaves and few spines. The F_1 are crossed with plants that have heart-shaped leaves and numerous spines. What phenotypes and phenotypic proportions are expected in the progeny of this cross?

19. In tomatoes, tall (*D*) is dominant over dwarf (*d*), and smooth fruit (*P*) is dominant over pubescent fruit (*p*), which is covered with fine hairs. A farmer has two tall and smooth-fruit tomato plants, which we will call plant A and plant B. The farmer crosses plants A and B with the same dwarf and pubescent-fruitx plant and obtains the following numbers of progeny:

	Progeny of	
	Plant A	**Plant B**
Dd Pp	122	2
Dd pp	6	82
dd Pp	4	82
dd pp	124	4

a. What are the genotypes of plant A and plant B?

b. Are the loci that determine the height of the plant and pubescence linked? If so, what is the rate of recombination between them?

c. Explain why different proportions of progeny are produced when plant A and plant B are crossed with the same dwarf and pubescent-fruit plant.

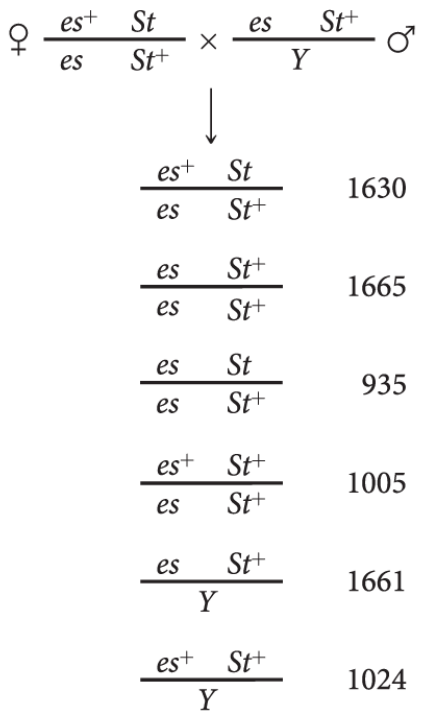
20. Alleles *A* and *a* reside at a locus on the same chromosome as a locus with alleles *B* and *b*. *Aa Bb* is crossed with *aa bb*, and the following progeny are produced:

Aa Bb	5
Aa bb	45
aa Bb	45
aa bb	5

What conclusion can be drawn about the arrangement of the genes on the chromosome in the *Aa Bb* parent?

21.

Daniel McDonald and Nancy Peer determined that eyespot (a clear spot in the center of the eye) in flour beetles is caused by an X-linked allele (*es*) that is recessive to the allele for the absence of eyespot (es^+). They conducted a series of crosses to determine the distance between the gene for eyespot and a dominant X-linked gene for striped (*St*), which causes white stripes on females and acts as a recessive lethal (is lethal when homozygous in females or hemizygous in males). The following cross was carried out (D. J. McDonald and N. J. Peer. 1961. *Journal of Heredity* 52:261–264).



Description

The female has small E small S superscript positive and big S small T on the top chromosome and small E small S and big S small T superscript positive on the bottom chromosome. The male has small E small S and big S small T superscript positive on the top chromosome and a Y on the bottom chromosome. The male and female are crossed and the numbers of progeny and their allele combinations obtained below are as follows: There are 1630 progenies with small E small S superscript positive and big S small T on the top chromosome and small E small S and big S small T superscript positive on the bottom chromosome. There are 1665 progenies with small E small S and big S small T superscript positive on the top chromosome and small E small S and big S small T superscript positive on the bottom chromosome. There are 935 progenies with small E small S and big S small T on the top chromosome and small E small S and big S small T superscript positive on the bottom chromosome. There are 1005 progenies with small E small S superscript positive and big S small T superscript positive on the top chromosome and small E small S and big S small T superscript positive on the bottom chromosome. There are 1661 progenies with small E small S and big S small T superscript positive on the top chromosome and big Y on the bottom chromosome. There are 1024 progenies with small E small S superscript positive and big S small T superscript positive on the top chromosome and big Y on the bottom chromosome.

a. Which progeny are the recombinants, and which progeny are the nonrecombinants?

b. Calculate the recombination frequency between *es* and *St*.

c. Are some potential genotypes missing among the progeny of the cross? If so, which ones, and why?

22. *Recombination frequencies between three loci in corn are shown in the following table:

Loci	Recombination frequency (%)
R and W_2	17
R and L_2	35
W_2 and L_2	18

What is the order of the genes on the chromosome?

23. In tomatoes, dwarf (*d*) is recessive to tall (*D*), and opaque (light-green) leaves (*op*) are recessive to green leaves (*Op*). The loci that determine height and leaf color are linked and separated by a distance of 7 m.u. For each of the following crosses, determine the phenotypes and proportions of progeny produced.

a. $\frac{D \quad Op}{d \quad op} \times \frac{d \quad op}{d \quad Op}$

b. $\frac{D \quad op}{d \quad Op} \times \frac{d \quad op}{d \quad op}$

c. $\frac{D \quad Op}{d \quad op} \times \frac{D \quad Op}{d \quad op}$

d. $\frac{D \quad op}{d \quad Op} \times \frac{D \quad op}{d \quad Op}$

24. In German cockroaches, bulging eyes (*bu*) are recessive to normal eyes (bu^+), and curved wings (*cv*) are recessive to straight wings (cv^+). These two traits are encoded by autosomal genes that are linked. A cockroach has genotype $bu^+bu\ cv^+cv$, and the genes are in repulsion. Which of the following sets of genes will be found in the most common gametes produced by this cockroach?

    a. $bu^+\ cv^+$

    b. *bu cv*

    c. bu^+bu

    d. cv^+cv

    e. $bu\ cv^+$

    Explain your answer.

25. In *D. melanogaster*, ebony body (*e*) and rough eyes (*ro*) are encoded by autosomal recessive genes found on chromosome 3; they are separated by 20 m.u. The gene that encodes forked bristles (*f*) is X-linked recessive and assorts independently of *e* and *ro*. Give the phenotypes of progeny and their expected proportions when a female of each of the following genotypes is test-crossed with a male.

    a. $\frac{e^+ \quad ro^+}{e \quad ro} \quad \frac{f^+}{f}$

b. $\frac{e^+ \quad ro}{e \quad ro^+} \quad \frac{f^+}{f}$

26. DATA ANALYSIS Honeybees have haplodiploid sex determination: queens (females) are diploid, developing from fertilized eggs, whereas drones (males) are haploid, developing from unfertilized eggs. Otto Mackensen studied linkage relations among eight mutations in honeybees (O. Mackensen. 1958. *Journal of Heredity* 49:99–102). The following table gives the results of two of Mackensen's crosses, including three recessive mutations: *cd* (cordovan body color), *h* (hairless), and *ch* (chartreuse eye color).

Queen genotype	Phenotypes of drone (male) progeny
$\frac{cd \quad h^+}{cd^+ \quad h}$	294 cordovan, 236 hairless, 262 cordovan and hairless, 289 wild type
$\frac{h \quad ch^+}{h^+ \quad ch}$	3131 hairless, 3064 chartreuse, 96 chartreuse and hairless, 132 wild type

a. Only the genotype of the queen is given. Why is the genotype of the male parent not needed for mapping these genes? Would the genotype of the male parent be required if we examined female progeny instead of male progeny?

b. Determine the nonrecombinant and recombinant progeny for each cross, and calculate the map distances between *cd*, *h*, and *ch*. Draw a linkage map illustrating the linkage arrangements among these three genes.

27. Perform a chi-square test of independence on the data provided in Figure 7.2 to determine if the genes for flower color and pollen shape in sweet peas are assorting independently. Give the chi-

square value, degrees of freedom, and associated probability. What conclusion would you draw about the independent assortment of these genes?

28. *A series of two-point crosses were carried out among seven loci (*a, b, c, d, e, f,* and *g*), producing the following recombination frequencies. Map the seven loci, showing their linkage groups, the order of the loci in each linkage group, and the distances between the loci of each group.

Loci	Recombination frequency (%)	Loci	Recombination frequency (%)
a and *b*	50	*c* and *d*	50
a and *c*	50	*c* and *e*	26
a and *d*	12	*c* and *f*	50
a and *e*	50	*c* and *g*	50
a and *f*	50	*d* and *e*	50
a and *g*	4	*d* and *f*	50
b and *c*	10	*d* and *g*	8
b and *d*	50	*e* and *f*	50
b and *e*	18	*e* and *g*	50
b and *f*	50	*f* and *g*	50
b and *g*	50		

29.

R. W. Allard and W. M. Clement determined recombination rates for a series of genes in lima beans (R. W. Allard and W. M. Clement. 1959. *Journal of Heredity* 50:63–67). The following table lists paired recombination frequencies for eight of the loci (*D, Wl, R, S,* L_1, *Ms, C,* and *G*) that they mapped. On the basis of these data, draw a series of genetic maps for the different linkage groups of the genes, indicating the distances between the genes. Keep in

mind that these frequencies are estimates of the true recombination frequencies and that some error is associated with each estimate. An asterisk beside a recombination frequency indicates that the recombination frequency is significantly different from 50%.

Recombination frequencies (%) among seven loci in lima beans

	Wl	*R*	*S*	L_1	*Ms*	*C*	*G*
D	2.1*	39.3*	52.4	48.1	53.1	51.4	49.8
Wl		38.0*	47.3	47.7	48.8	50.3	50.4
R			51.9	52.7	54.6	49.3	52.6
S				26.9*	54.9	52.0	48.0
L_1					48.2	45.3	50.4
Ms						14.7*	43.1
C							52.0

* *Significantly different from 50%.*

30. CONNECT A genetics student conducts some genetic crosses with *Drosophila* and finds that two phenotypes—purple eyes and dark body—tend to be inherited together. How could the student determine whether this association between dark eyes and dark body color is due to pleiotropy (see Chapter 5) or linkage?

Section 7.3

31. DATA ANALYSIS *Raymond Popp studied linkage among genes for pink eye (*p*), shaker-1 (*sh*-1, which causes circling behavior, head tossing, and

deafness), and hemoglobin (*Hb*) in mice (R. A. Popp. 1962. *Journal of Heredity* 53:73–80). He performed a series of testcrosses, in which mice heterozygous for pink eye, shaker-1, and hemoglobin 1 and 2 were crossed with mice that were homozygous for pink eye, shaker-1, and hemoglobin 2.

$$\frac{P\ Sh-1\ Hb^{1}}{p\ sh-1\ Hb^{2}} \times \frac{p\ sh-1\ Hb^{2}}{p\ sh-1\ Hb^{2}}$$

The following progeny were produced:

Progeny genotype	Number
$\frac{p\ sh-1\ Hb^{2}}{p\ sh-1\ Hb^{2}}$	274
$\frac{P\ Sh-1\ Hb^{1}}{p\ sh-1\ Hb^{2}}$	320
$\frac{P\ sh-1\ Hb^{2}}{p\ sh-1\ Hb^{2}}$	57
$\frac{p\ Sh-1\ Hb^{1}}{p\ sh-1\ Hb^{2}}$	45
$\frac{P\ Sh-1\ Hb^{1}}{p\ sh-1\ Hb^{2}}$	6
$\frac{p\ sh-1\ Hb^{2}}{p\ sh-1\ Hb^{2}}$	5

$\frac{p\ Sh - 1\ Hb^2}{p\ sh - 1\ Hb^2}$	0
$\frac{P\ sh - 1\ Hb^1}{p\ sh - 1\ Hb^2}$	1
Total	708

a. Determine the order of these genes on the chromosome.

b. Calculate the map distances between the genes.

c. Determine the coefficient of coincidence and the interference among these genes.

32. *Waxy endosperm (*wx*), shrunken endosperm (*sh*), and yellow seedlings (*v*) are encoded by three recessive genes in corn that are linked on chromosome 5. A corn plant homozygous for all three recessive alleles is crossed with a plant homozygous for all the dominant alleles. The resulting F_1 are then crossed with a plant homozygous for the recessive alleles in a three-point testcross. The progeny of the testcross are

wx	*sh*	*V*	87
Wx	*Sh*	*v*	94
Wx	*Sh*	*V*	3,479
wx	*sh*	*v*	3,478
Wx	*sh*	*V*	1,515
wx	*Sh*	*v*	1,531
wx	*Sh*	*V*	292
Wx	*sh*	*v*	280

Total	10,756

a. Determine the order of these genes on the chromosome.

b. Calculate the map distances between the genes.

c. Determine the coefficient of coincidence and the interference among these genes.

33.

Priscilla Lane and Margaret Green studied the linkage relations of three genes affecting coat color in mice: mahogany (*mg*), agouti (*a*), and ragged (*Rg*). They carried out a series of three-point crosses, mating mice that were heterozygous at all three loci with mice that were homozygous for the recessive alleles at these loci (P. W. Lane and M. C. Green. 1960. *Journal of Heredity* 51:228–230). The following table lists the progeny of the testcrosses:

a	*Rg*	+	1
+	+	*mg*	1
a	+	+	15
+	*Rg*	*mg*	9
+	+	+	16
a	*Rg*	*mg*	36
a	+	*mg*	76
+	*Rg*	+	69
Total			223

Note: + represents a wild-type allele.

a. Determine the order of the loci that encode mahogany, agouti, and ragged on the chromosome; the map distances between

them; and the coefficient of coincidence and the interference among these genes.

b. Draw a picture of the two chromosomes in the triply heterozygous mice used in the testcrosses, indicating which of the alleles are present on each chromosome.

34. Fine spines (*s*), smooth fruit (*tu*), and uniform fruit color (*u*) are three recessive traits in cucumbers, the genes for which are linked on the same chromosome. A cucumber plant heterozygous for all three traits is used in a testcross, and the following progeny are produced by this testcross:

S	*U*	*Tu*	2
s	*u*	*Tu*	70
S	*u*	*Tu*	21
s	*u*	*tu*	4
S	*U*	*tu*	82
s	*U*	*tu*	21
s	*U*	*Tu*	13
S	*u*	*tu*	17
Total			230

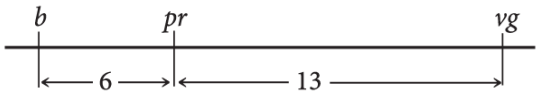
a. Determine the order of these genes on the chromosome.

b. Calculate the map distances between the genes.

c. Determine the coefficient of coincidence and the interference among these genes.

d. List the genes found on each chromosome in the parents used in the testcross.

35. In *D. melanogaster*, black body (*b*) is recessive to gray body (b^+), purple eyes (*pr*) are recessive to red eyes (pr^+), and vestigial wings (*vg*) are recessive to normal wings (vg^+). The loci encoding these traits are linked, with the following map distances:



Description
The gene map shows gene small B on the extreme left side. Gene small P small R is 6 m u to the right of gene small B, and gene small V small G is 13 m u to the right of gene small P small R.

The interference among these genes is 0.5. A fly with a black body, purple eyes, and vestigial wings is crossed with a fly homozygous for a gray body, red eyes, and normal wings. The female progeny are then crossed with males that have a black body, purple eyes, and vestigial wings. If 1000 progeny are produced by this testcross, what will be the phenotypes and proportions of the progeny?

36. *Sepia eyes*, *spineless bristles*, and *striped body* are three recessive mutations in *Drosophila* found on chromosome 3. A genetics student crosses a fly homozygous for the alleles encoding sepia eyes, spineless bristles, and striped body with a fly homozygous for the wild-type alleles—encoding red eyes, normal bristles, and solid body. The female progeny are then test-crossed with males that have sepia eyes, spineless bristles, and striped body. Assume that the interference between these genes is 0.2 and that 400 progeny

flies are produced by the testcross. Based on the map distances provided in Figure 7.15, predict the phenotypes and proportions of the progeny resulting from the testcross.

37. Shown below are eight DNA sequences from different individuals.

	Nucleotide position														
	1				5				10				15		
Sequence 1	T	C	T	G	G	A	T	C	A	T	C	A	C	A	T . . .
Sequence 2	A	C	A	G	C	A	T	C	A	T	T	A	C	G	T . . .
Sequence 3	T	C	A	G	G	A	T	C	A	T	T	A	C	T	A . . .
Sequence 4	T	C	A	G	G	A	T	C	A	T	T	A	C	A	T . . .
Sequence 5	A	C	A	G	C	A	T	C	A	T	T	A	C	G	T . . .
Sequence 6	T	C	T	G	G	A	T	C	A	T	C	A	C	A	T . . .
Sequence 7	T	C	A	G	G	A	T	C	A	T	T	A	C	A	T . . .
Sequence 8	A	C	A	G	C	A	T	C	A	T	T	A	C	G	T . . .

Description
The illustration shows the following information from top to bottom:

Sequence 1: T (Position 1), C, T, G, G (Position 5), A, T, C, A, T (Position 10), C, A, C, A, T (Position 15).

Sequence 2: A (Position 1), C, A, G, C (Position 5), A, T, C, A, T (Position 10), T, A, C, G, T (Position 15).

Sequence 3: T (Position 1), C, A, G, G (Position 5), A, T, C, A, T (Position 10), T, A, C, T, A (Position 15).

Sequence 4: T (Position 1), C, A, G, G (Position 5), A, T, C, A, T (Position 10), T, A, C, A, T (Position 15).

Sequence 5: A (Position 1), C, A, G, C (Position 5), A, T, C, A, T (Position 10), T, A, C, G, T (Position 15).

Sequence 6: T (Position 1), C, T, G, G (Position 5), A, T, C, A, T (Position 10), C, A, C, A, T (Position 15).

Sequence 7: T (Position 1), C, A, G, G (Position 5), A, T, C, A, T (Position 10), T, A, C, A, T (Position 15).

Sequence 8: A (Position 1), C, A, G, C (Position 5), A, T, C, A, T (Position 10), T, A, C, G, T (Position 15).

a. Give the nucleotide positions of all single-nucleotide polymorphisms (SNPs; nucleotide positions where individuals vary in a single nucleotide base) in these sequences.

b. How many different haplotypes (sets of linked variants) are found in these eight sequences?

c. Give the haplotype of each sequence by listing the specific bases at each variable position in that particular haplotype. (Hint: See **Figure 20.8**.)

38. *A group of geneticists are interested in identifying genes that may play a role in susceptibility to asthma. They study the inheritance of genetic markers in a series of families that have two or more asthmatic children. They find an association between the presence or absence of asthma and a genetic marker on the short arm of chromosome 20 and calculate a lod score of 2 for this association. What does this lod score indicate about genes that may influence asthma?

Section 7.4

39. A panel of cell lines was created by human–mouse somatic-cell hybridization. Each line was examined for the presence of human chromosomes and for the production of an enzyme. The following results were obtained:

		Human chromosomes											
Cell line	**Enzyme**	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**17**	**22**
A	−	+	−	−	−	+	−	−	−	−	−	+	−
B	+	+	+	−	−	−	−	−	+	−	−	+	+
C	−	+	−	−	−	+	−	−	−	−	−	−	+
D	−	−	−	−	+	−	−	−	−	−	−	−	−
E	+	+	−	−	−	−	−	−	+	−	+	+	−

Description
The column headers are as follows: cell line, enzyme, the numbers 1 to 10, 17, and 22.

The row entries are as follows:

Row 1: A, negative, positive, negative, negative, negative, positive, negative, negative, negative, negative, negative, positive, and negative.

Row 2: B, positive, positive, positive, negative, negative, negative, negative, negative, positive, negative, negative, positive, and positive.

Row 3: C, negative, positive, negative, negative, negative, positive, negative, negative, negative, negative, negative, negative, and positive.

Row 4: D, negative, negative, negative, negative, positive, negative, negative, negative, negative, negative, negative, negative, and negative.

Row 5: E, positive, positive, negative, negative, negative, negative, negative, negative, positive, negative, negative, positive, and negative.

On the basis of these results, which chromosome has the gene that encodes the enzyme?

40. *A panel of cell lines was created by human–mouse somatic-cell hybridization. Each cell line was examined for the presence of human chromosomes and for the production of three enzymes. The following results were obtained:

Cell line	Enzyme			Human chromosomes							
	1	2	3	4	8	9	12	15	16	17	22	X
A	+	−	+	−	−	+	−	+	+	−	−	+
B	+	−	−	−	−	+	−	−	+	+	−	−
C	−	+	+	+	−	−	−	−	−	+	−	+
D	−	+	+	+	+	−	−	−	+	−	−	+

Description
The column headers are as follows: cell line, the numbers 1 to 9, 12, 15 to 17, 22, and X; where headers 1 to 4 are enzymes and the rest from 8 to X are human chromosomes.

Row entries are as follows:

Row 1: A, positive, negative, positive, negative, negative, positive, negative, positive, positive, negative, negative, and positive.

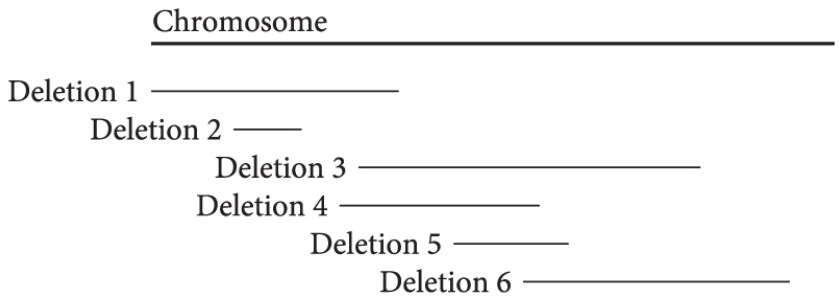
Row 2: B, positive, negative, negative, negative, negative, positive, negative, negative, positive, positive, negative, and negative.

Row 3: C, negative, positive, positive, positive, negative, negative, negative, negative, negative, positive, negative, and positive.

Row 4: D, negative, positive, positive, positive, positive, negative, negative, negative, positive, negative, negative, and positive.

On the basis of these results, give the chromosomal locations of the genes encoding enzyme 1, enzyme 2, and enzyme 3.

41. *The locations of six deletions have been mapped to a *Drosophila* chromosome, as shown in the following deletion map. Recessive mutations *a*, *b*, *c*, *d*, *e*, and *f* are known to be located in the same region as the deletions, but the order of the mutations on the chromosome is not known.



When flies homozygous for the recessive mutations are crossed with flies heterozygous for the deletions, the following results are obtained, in which "m" represents a mutant phenotype and a plus sign (+) represents the wild type. On the basis of these data, determine the relative order of the six mutant genes on the chromosome.

	Mutations					
Deletion	***a***	***b***	***c***	***d***	***e***	***f***
1	m	+	m	+	+	m
2	m	+	+	+	+	+
3	+	m	m	m	m	+
4	+	+	m	m	m	+
5	+	+	+	m	m	+
6	+	m	+	m	+	+

CHALLENGE QUESTIONS

Section 7.5

42. Transferrin is a blood protein that is encoded by the transferring locus (*Trf*). In house mice, the two alleles at this locus (Trf^a and Trf^b) are codominant and encode three types of transferrin:

Genotype	Phenotype
Trf^a/Trf^a	Trf-a
Trf^a/Trf^b	Trf-ab
Trf^b/Trf^b	Trf-b

The dilution locus, found on the same chromosome, determines whether the color of a mouse is diluted or full; an allele for dilution (d) is recessive to an allele for full color (d^+):

Genotype	Phenotype
d^+d^+	d^+ (full color)
d^+d	d^+ (full color)
Dd	d (dilution)

Donald Shreffler conducted a series of crosses to determine the map distance between the transferrin locus and the dilution locus (D. C. Shreffler. 1963. *Journal of Heredity* 54:127–129). The following table presents a series of crosses carried out by Shreffler and the progeny resulting from these crosses.

		Progeny phenotypes				
		d^+	d^+	d	d	
Cross	♂ ♀	**Trf-ab**	**Trf-b**	**Trf-ab**	**Trf-b**	**Total**

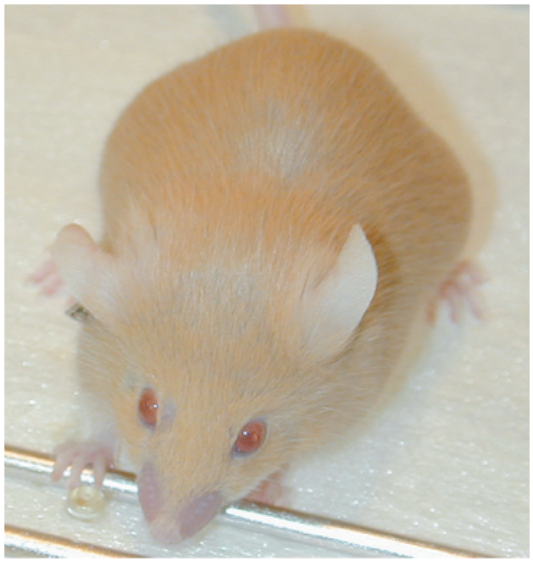
1	$\frac{d^{+}Trf^{a}}{d\ Trf^{b}} \times \frac{d\ Trf^{b}}{d\ Trf^{b}}$	32	3	6	21	62
2	$\frac{d\,Trf^{b}}{d\,Trf^{b}} \times \frac{d^{+}\,Trf^{a}}{d\ Trf^{b}}$	16	0	2	20	38
3	$\frac{d^{+}\,Trf^{a}}{d\,Trf^{b}} \times \frac{d\ Trf^{b}}{d\ Trf^{b}}$	35	9	4	30	78
4	$\frac{d\,Trf^{b}}{d\,Trf^{b}} \times \frac{d^{+}\ Trf^{a}}{d\ Trf^{b}}$	21	3	2	19	45
5	$\frac{d^{+}\,Trf^{b}}{d\,Trf^{a}} \times \frac{d\ Trf^{b}}{d\ Trf^{b}}$	8	29	22	5	64
6	$\frac{d\,Trf^{b}}{d\,Trf^{b}} \times \frac{d^{+}\,Trf^{b}}{d\ Trf^{a}}$	4	14	11	0	29

a. Calculate the recombination frequency between the *Trf* and the *d* loci by using the pooled data from all the crosses.

b. Which crosses represent recombination in male gamete formation, and which crosses represent recombination in female gamete formation?

c. On the basis of your answer to part *b*, calculate the frequency of recombination among male parents and female parents separately.

d. Are the rates of recombination in males and females the same? If not, what might produce the difference?



L. Montoliu, W. S. Oetting, D. C. Bennett. Color Genes. March 2010. European Society for Pigment Cell Research. (http:// www.espcr.org/ micemut) 03/2013

A mouse with the dilution trait.

ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Section 7.1

1. Species A has $2n = 10$ chromosomes. Species B has $2n = 40$ chromosomes. On average, will two randomly selected genes from species A be more likely, less likely, or equally likely to assort independently than two randomly selected genes from species B? Explain your reasoning.

Section 7.2

2. The recombination frequency between genes *a* and *b* is 20%. What is the frequency of crossing over between genes *a* and *b*? Explain your reasoning.

3. Is it possible to have a recombination frequency of 80% between two genes? Is it possible for two genes to be separated by 80 map units? Why or why not?

4. The rate of crossing over between two linked genes (*r* and *w*) is 0.44. The following cross is carried out: *Rr Ww* × *rr ww*. What proportion of the gametes of the *Rr Ww* parent were recombinant gametes? Explain your reasoning, and state any assumptions you made.

Section 7.3

5. Why is interference important? Why do we calculate it in a three-point cross? Why don't we calculate interference in a two-point cross?

6. Three recessive mutations in *D. melanogaster—roughoid* (*ru*, small rough eyes), *javelin* (*jv*, cylindrical bristles), and *sepia eyes* (*se*, dark brown eyes)—are linked. A three-point cross was carried out and the following progeny obtained:

jv^+	ru^+	se^+	37
jv^+	ru^+	*se*	2
jv^+	*ru*	*se*	14

jv^+	*ru*	se^+	146
jv	*ru*	se^+	2
jv	*ru*	*se*	35
jv	ru^+	*se*	154
jv	ru^+	se^+	10

a. Determine the order of the genes on the chromosome.

b. Determine which progeny contain single crossovers and which contain double crossovers, and indicate where among the genes the crossovers occurred.

c. Calculate the map distances among the genes.

d. Calculate the coefficient of coincidence and interference among the genes.

7. Compare and contrast linkage analysis and genome-wide association studies. How are they similar? How are they different?

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Introduction

1. Create a concept map that outlines the results obtained from the genome-wide association study of fear and aggression in dogs.

Section 7.1

2. What differences are expected in the outcomes of crosses involving linked genes and crosses involving genes that assort independently? Draw a concept map to illustrate these differences.

Section 7.2

3. Create a concept map that outlines the use of recombination to map genes. Include the following terms: crossing over, linked genes, unlinked genes, recombination, independent assortment, gene mapping, recombination frequency, and linkage group.

Section 7.3

4. Draw a concept map that outlines the procedure for mapping genes using a three-point cross.

5. Create a concept map that illustrates the concept of crossover interference. Include at least the following terms in your concept map: single crossover frequency, observed number of double crossovers, expected number of double crossovers, coefficient of coincidence, interference, positive interference, and negative interference.

Section 7.4

6. What are the different physical methods used for mapping genes, and what are their methodologies? Create a map that includes the three physical methods outlined in this chapter (somatic cell hybridization, deletion mapping, and in situ hybridization), the

information each method provides, and how each differs in the methodology employed in mapping.

Self-study tools that will help you practice what you've learned and reinforce this chapter's concepts are available online. Go to www.saplinglearning.com.

CHAPTER 8

Chromosome Variation

S_Photo/Shutterstock.

Wheat, the most widely grown food crop on Earth, has a genome consisting of chromosomes from three different species. The complete genome of wheat was sequenced in 2017.

The Complex Genome of Wheat

Nothing is more pleasing than the aroma and taste of freshly baked bread. Indeed, cooking, sharing, and eating bread has cultural and religious significance for billions of people around the world. The

primary constituent of bread—wheat—is the most widely grown crop on Earth, and foods made from wheat provide almost 20% of all calories consumed by humans worldwide.

Wheat has a highly complex genome that is a product of its unique evolutionary history. Most eukaryotic organisms are diploid ($2n$), consisting of two copies of genetic information, one inherited from each parent. Other organisms, such as fungi, are haploid (n), with a single copy of genetic information. But wheat is hexaploid ($6n$), with six copies of genetic information derived from three different species (**Figure 8.1**).

8.1 Modern bread wheat, *Triticum aestivum*, is a hexaploid with genes derived from three different species. Two diploid species, *T. urartu* ($2n = 14$) and probably *Aegilops speltoides* or a related species ($2n = 14$), originally crossed to produce a diploid hybrid ($2n = 14$) that underwent chromosome doubling to create *T. turgidum* ($4n = 28$). A cross between *T. turgidum* and *A. tauschii* ($2n = 14$) produced a triploid hybrid ($3n = 21$) that then underwent chromosome doubling to eventually produce *T. aestivum*, which is a hexaploid ($6n = 42$).

Description
In the P generation at the top, Einkorn wheat (Triticum uratu) is crossed with the wild grass (Aegilops speltoides or related species). Einkorn wheat has genome big A big A (2 n equals 14) and the wild grass has genome big B big B (2 n equals 14). The gametes from these 2 plants fuse and an arrow points to the F subscript 1 generation hybrid below with genome big A big B (2 n equals 14). An arrow labeled mitotic nondisjunction points from the hybrid to a picture of the Emmer wheat (Triticum turgidum) with genome big A big A big B big B (4 n equals 28) crossed with wild grass (Aegilops tauschii) having genome big D big D (2 n equals 14). The gametes from these two plants fuse and form the F subscript 2 generation hybrid below with genome big A big B big D (3 n equals 21). An arrow labeled mitotic nondisjunction points from the hybrid to a picture of the bread wheat (Triticum aestivum) having genome big A big A big B big B big D big D (6 n equals 42).

Some 10,000 years ago, two diploid grasses crossed, producing a hybrid with 14 chromosomes. The chromosomes of this hybrid then doubled, creating Emmer wheat (*Triticum turgidum*) with 28 chromosomes, which was domesticated by early farmers and is still cultivated in some parts of the world. Several thousand years later, Emmer wheat crossed with a third diploid species (Figure 8.1), giving rise to a new hybrid with 21 chromosomes. In the final step, this hybrid underwent yet another mitotic nondisjunction, doubling the

chromosomes to produce modern wheat (*Triticum aestivum*) with 42 chromosomes.

Over the ages, wheat has been subjected to selective breeding and genetic manipulation. Genetic modification of wheat in recent years, however, has been limited by the absence of detailed information about its genetic makeup. In 2005, a group of wheat farmers in Kansas saw the potential benefits of more genetic information and initiated an effort to sequence the wheat genome. This led to a large effort known as the International Wheat Genome Sequencing Consortium.

Sequencing the genome of wheat turned out to be a huge task. Wheat has a large genome, consisting of about 17 billion base pairs of DNA, compared to the human genome, with 3.2 billion base pairs. In addition, 85% of wheat's genome is made up of short, repeated DNA sequences, which are difficult to assemble into a full genome. Wheat's genome sequencing ultimately required 13 years to complete and the efforts of more than 200 scientists from 20 countries. The entire wheat genome was finally sequenced in 2017, and a fully annotated and assembled genome was published in 2018. The researchers identified 107,891 protein-encoding genes, over five times as many as in humans.

The completed genome sequence of wheat will allow researchers and plant breeders to more rapidly identify key genes involved in yield, nutrition, disease resistance, and stress tolerance. It will

undoubtedly aid in the breeding of new varieties that can be used to help feed the world's growing population. Already, researchers have used the genome sequence to find new genes that affect grain size, plant architecture, and the length of the wheat breeding cycle. Other researchers have identified a number of genes for proteins that cause immune responses in humans, which may help in the creation of new wheat varieties that are less allergenic.

THINK-PAIR-SHARE

- Modern wheat's genome consist of six sets of chromosomes derived from three different species. Can you think of any advantage to having a genome with genetic information from multiple species?

Most species have a characteristic number of chromosomes, each with a distinct size and structure, and all the tissues of an organism (except for gametes) generally have the same set of chromosomes. Nevertheless, variations in chromosome number—such as the extra sets of chromosomes seen in wheat—do periodically arise. Variations may also arise in chromosome structure: individual chromosomes may lose or gain parts, and the order of genes within a chromosome may be altered. These variations in the number and structure of chromosomes are termed **chromosome mutations**, and they frequently play an important role in agriculture and evolution.

We begin this chapter by reviewing some of the basic concepts of chromosome structure. We then consider the different types of

chromosome mutations and their features, phenotypic effects, and influences on evolution.

8.1 Chromosome Mutations Include Rearrangements, Aneuploidy, and Polyploidy

Before we consider the different types of chromosome mutations, their effects, and how they arise, it may be helpful to review and expand on the basics of chromosome structure that we learned in Chapter 2.

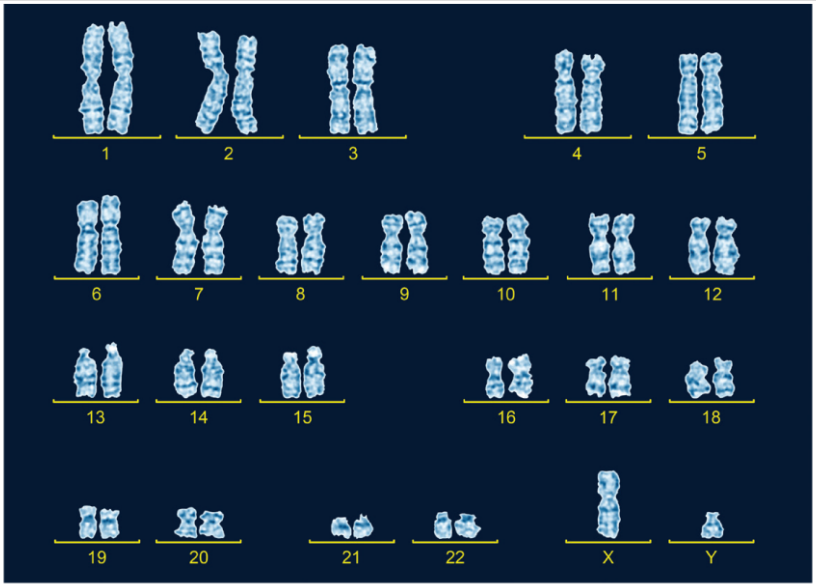
Chromosome Morphology

Each functional eukaryotic chromosome has a centromere, to which spindle microtubules attach, and two telomeres, which stabilize the chromosome ends (see Figure 2.7). Chromosomes are classified into four basic types:

1. **Metacentric**. The centromere is located approximately in the middle, so the chromosome has two arms of equal length.
2. **Submetacentric**. The centromere is displaced toward one end, creating a long arm and a short arm. (On human chromosomes, the short arm is designated by the letter *p* and the long arm by the letter *q*.)
3. **Acrocentric**. The centromere is near one end, producing a long arm and a knob, or satellite, at the other end.

4. **Telocentric**. The centromere is at or very near the end of the chromosome (see Figure 2.8).

The complete set of chromosomes possessed by an organism is called its *karyotype*. An organism's karyotype is usually presented as a picture of metaphase chromosomes lined up in descending order of their size (**Figure 8.2**). Karyotypes are prepared from actively dividing cells, such as white blood cells, bone-marrow cells, or cells from meristematic tissues of plants. After treatment with a chemical (such as colchicine) that prevents them from entering anaphase, the cells are chemically preserved. They are then burst open to release the chromosomes onto a microscope slide, and the chromosomes are stained and photographed. The photograph is then enlarged, and the individual chromosomes are cut out and arranged in a karyotype. For human chromosomes, karyotypes are routinely prepared by automated machines, which scan a slide using a video camera attached to a microscope, looking for a chromosome spread (a group of chromosomes that are well separated). When a spread has been located, the camera takes a picture of the chromosomes, the image is digitized, and the chromosomes are sorted and arranged electronically by a computer.



ISM/Pr. Philippe Vago/Medical Images.

8.2 A human karyotype consists of 46 chromosomes.

Description

Each chromosome pair is shown and its number is labeled below. The twenty third pair has 1 larger X chromosome and 1 relatively smaller Y chromosome.

Preparation and staining techniques help to distinguish among chromosomes of similar size and shape. For instance, special preparation and staining of chromosomes with a dye called Giemsa reveals G bands, which distinguish areas of DNA that are rich in adenine–thymine (A–T) base pairs (**Figure 8.3**; see also Chapter 10). Q bands are revealed by staining chromosomes with quinacrine mustard and viewing the chromosomes under ultraviolet light; variation in the brightness of Q bands results from differences in the relative numbers of cytosine–guanine (C–G) and adenine–thymine base pairs. Other techniques reveal C bands, which are regions of

DNA occupied by centromeric heterochromatin, and R bands, which are rich in cytosine–guanine base pairs.

Leonard Lessin/Science Source.

8.3 Chromosome banding is revealed by special staining techniques. These chromosomes have undergone Giemsa staining to produce G banding.

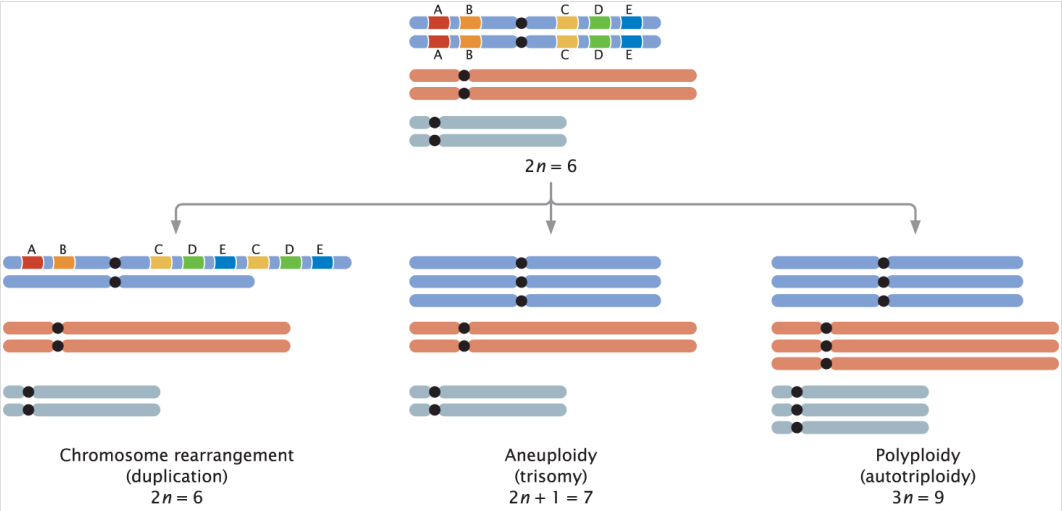
Description
This karyotype shows the chromosomes lined up and clustered in groups. The chromosomes have several bands of light gray.

Types of Chromosome Mutations

Chromosome mutations can be grouped into three basic categories: chromosome rearrangements, aneuploidy, and polyploidy (Figure 8.4). Chromosome rearrangements alter the *structure* of

chromosomes: for example, a piece of a chromosome may be duplicated, deleted, or inverted. In aneuploidy, the *number* of chromosomes is altered: one or more individual chromosomes are added or deleted. In polyploidy, one or more complete *sets* of chromosomes are added. A polyploid is any organism that has more than two sets of chromosomes (3*n*, 4*n*, 5*n*, or more).

THINK-PAIR-SHARE Question 1



8.4 The three basic categories of chromosome mutations are chromosome rearrangements, aneuploidy, and polyploidy. Duplication, trisomy, and autotriploidy, respectively, are examples of these categories of mutations.

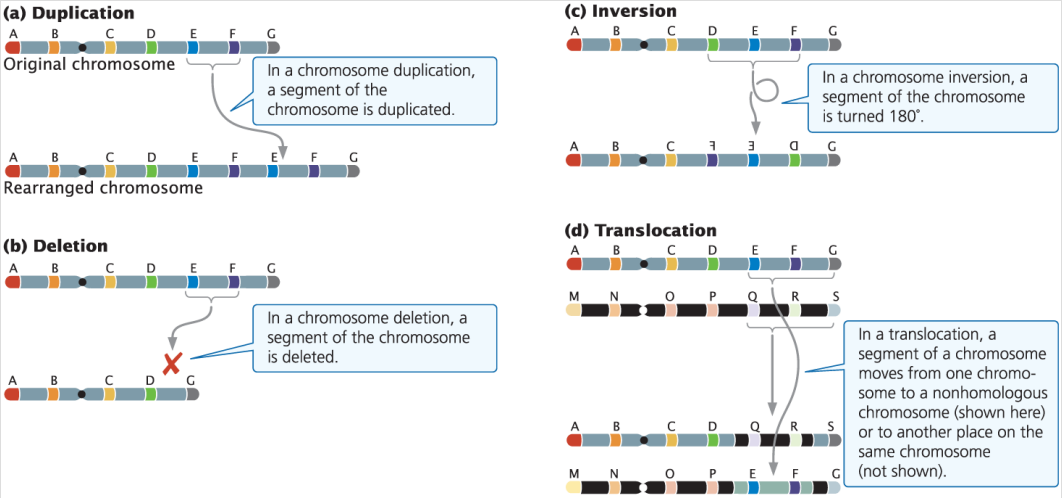
Description

The diagram shows 3 sets of chromosomes. The first has genes big A and big B on both the chromosomes above the centromere and big C, big D, and big E on both the chromosomes below the centromere. Second set of chromosomes has longer arm below the centromere and the third set also has the longer arm below the centromere but is relatively shorter (as compared to the second set). A text below reads, 2 n equals 6.

Chromosome rearrangement (duplication) occurs at left below and the first set of chromosome gets the genes big C, big D, and big E duplicated on one of its chromosomes. The chromosome set now has genes big and big B on one chromosome above the centromere and big C, big D, big E, big C, big D, and big E on that chromosome below the centromere. The long arm of the chromosome with these genes is relatively longer than the other chromosome in the set. The other two sets of chromosomes remain the same as original. A text below reads, 2 n equals 6. Aneuploidy (trisomy) occurs at center below and the first set of chromosome gets one extra chromosome while other 2 sets remain same as original. A text below reads, 2 n plus 1 equals 7. Polyploidy (Autotriploid) occurs at right below and each set gets one similar extra chromosome. A text below reads, 3 n equals 9.

8.2 Chromosome Rearrangements Alter Chromosome Structure

Chromosome rearrangements are chromosome mutations that change the structure of individual chromosomes. The four basic types of rearrangements are duplications, deletions, inversions, and translocations (**Figure 8.5**). Many of these chromosome rearrangements originate when double-stranded breaks occur in the DNA molecule found within a chromosome. Double-stranded breaks in DNA often cause cell death, so organisms have evolved elaborate mechanisms to repair breaks by reconnecting the broken ends of DNA (see Repair of Double-Strand Breaks in Chapter 18). If the two broken ends are rejoined correctly, the original chromosome is restored, and no chromosome rearrangement results. Sometimes the wrong ends are connected, however, leading to a chromosome rearrangement. Chromosome rearrangements can also arise through errors in crossing over or when crossing over occurs between repeated DNA sequences.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

8.5 The four basic types of chromosome rearrangements are duplications, deletions, inversions, and translocations.

Description

Each part begins with a chromosome containing genes big A through big G.

In the first part at the top left, the caption reads: In chromosome duplication, a segment of the chromosome is duplicated. In the picture, the genes big E and big F are duplicated. On the new strand, there is a second set of genes big E and big F between genes big F and big G.

In the second part at the bottom left, the caption reads: in chromosome deletion, a segment of the chromosome is deleted. In the picture, the genes e and f are deleted. On the new strand, there are only 5 genes: big A, big B, big C, big D, and big G.

In the third part at the top right, the caption reads: in chromosome inversion, a segment of the chromosome is turned 180 degrees. In the picture, genes big D, big E, and big F are flipped in alignment. On the new strand, there are genes big A, big B, big C, backwards big F, backwards big E, backwards big D, and big G.

The fourth part at the bottom right begins with an additional chromosome containing genes big M through big S, and the caption reads: In translocation, a segment of a chromosome moves from one chromosome to a non-homologous chromosome (shown here) or to another place on the same chromosome (not shown). In this picture, genes big E, big F, and big G on the one chromosome switch places with big Q, big R, and big S on the other.

Duplications

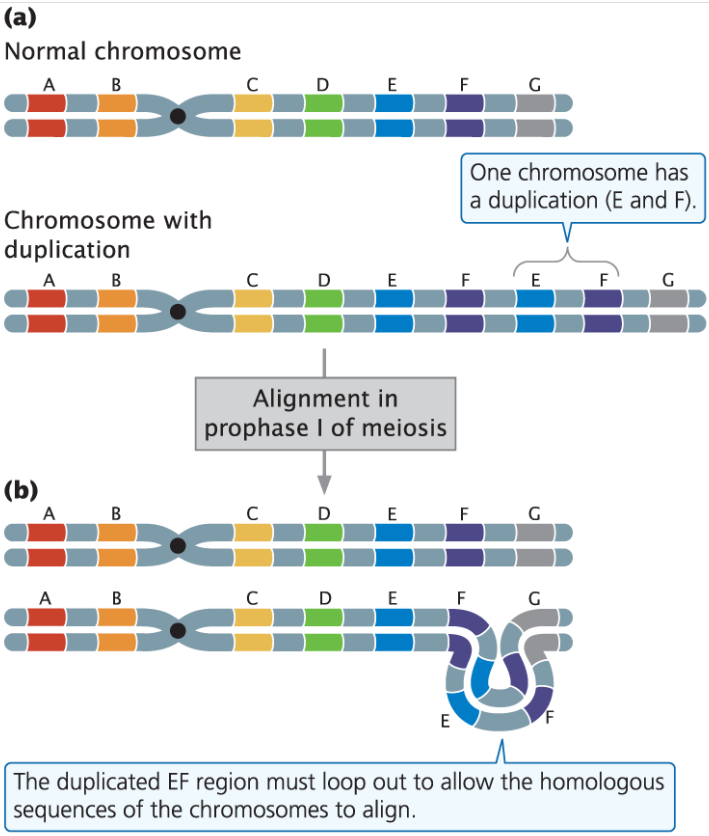
A **chromosome duplication** is a mutation in which part of the chromosome has been doubled (see Figure 8.5a). Consider a chromosome with segments AB•CDEFG, in which • represents the centromere. A duplication might include the EF segments, giving rise to a chromosome with segments AB•CDEFEFG (where the underlined letters represent the part of the chromosome that has changed). This type of duplication, in which the duplicated segment is immediately adjacent to the original segment, is called a **tandem duplication**. If the duplicated segment is located some distance from the original segment, either on the same chromosome or on a different one, the chromosome rearrangement is called a **displaced duplication**. An example of a displaced duplication would be AB•CDEFGEF. A duplication can have the same orientation as the original sequence, as in the two preceding examples, or it can be inverted: AB•CDEFFEG. When the duplication is inverted, it is called a **reverse duplication**.

The human genome contains numerous duplicated sequences called **segmental duplications**, which are defined as duplications greater than a thousand base pairs (bp) in length. Most segmental duplications are *intrachromosomal* duplications (i.e., the two copies are found on the same chromosome), but others are

interchromosomal duplications (the two copies are found on different chromosomes).

EFFECTS OF CHROMOSOME DUPLICATIONS

An individual that is homozygous for a duplication carries that duplication on both homologous chromosomes, and an individual that is heterozygous for a duplication has one normal chromosome and one chromosome with the duplication. In heterozygotes (**Figure 8.6a**), problems in chromosome pairing arise at prophase I of meiosis because the two chromosomes are not homologous throughout their length. The pairing and synapsis of homologous regions require that one or both chromosomes loop and twist so that these regions are able to line up (**Figure 8.6b**). The appearance of this characteristic loop structure in meiosis is one way to detect duplications.

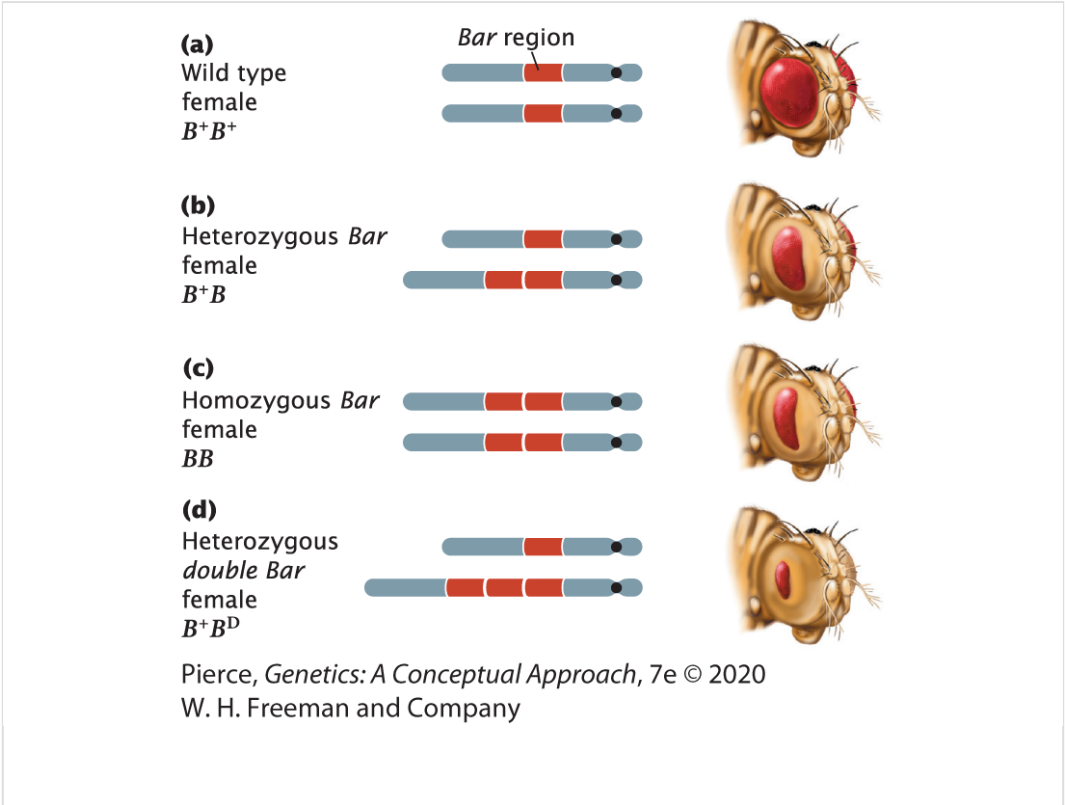


8.6 In an individual heterozygous for a duplication, the duplicated region loops out during pairing in prophase I.

Description

Part a at the top shows a normal chromosome with genes big A and big B on the short arms of both the chromatids and big C, big D, big E, big F, and big G on the long arms of both the chromatids. The chromosome with duplication has genes big A and big B on both the chromatids on the short arms and big C, big D, big E, big F, big E (duplicated gene), big F (duplicated gene), and big G on both the chromatids on the long arms. A caption reads, One chromosome has a duplication (big E and big F). Alignment occurs in prophase 1 of meiosis and leads to part b below which shows the chromosomes after alignment. The Normal chromosome has genes with the same alignment as part a. The chromosome below or the chromosome with duplication has the duplicated region looped out with genes big E big F. A caption pointing towards the looped out region reads, The duplicated big E big F region must loop out to allow the homologous sequences of the chromosomes to align.

Duplications may have major effects on the phenotype. Among fruit flies, for example, a fly with the *Bar* mutation has a reduced number of facets in the eye, making the eye smaller and bar shaped instead of oval (**Figure 8.7**). The *Bar* mutation results from a small duplication on the X chromosome that is inherited as an incompletely dominant, X-linked trait: heterozygous female flies have somewhat smaller eyes (the number of facets is reduced; see Figure 8.7b), whereas in homozygous female and hemizygous male flies, the number of facets is greatly reduced (see Figure 8.7c). Occasionally, a fly carries three copies of the *Bar* duplication on its X chromosome; in flies with this mutation, termed *double Bar*, the number of facets is extremely reduced (Figure 8.7d).



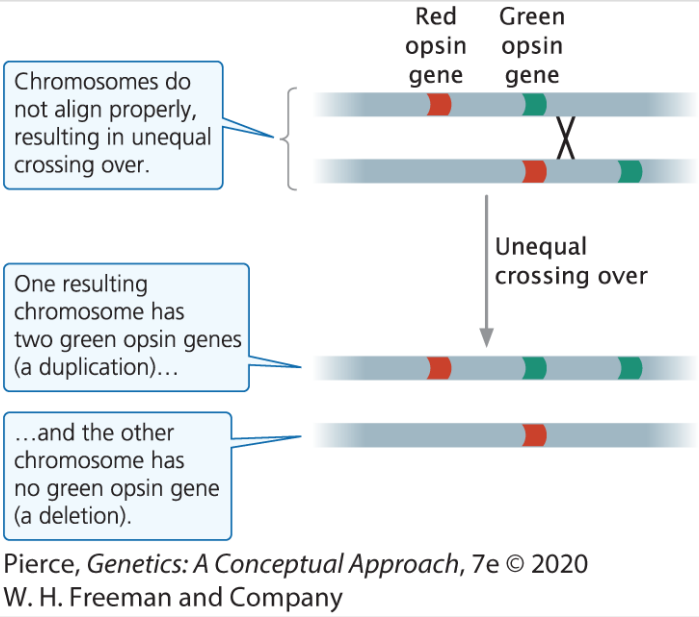
Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

8.7 The Bar phenotype in *Drosophila melanogaster* results from an X-linked duplication. (a) Wild-type fruit flies have normal-sized eyes. (b) Flies that are heterozygous and (c) homozygous for the *Bar* mutation have smaller, bar-shaped eyes. (d) Flies with *double Bar* have three copies of the duplication and much smaller bar-shaped eyes.

Description
Part a at the top shows a wild type female fly with genes big B superscript positive big B superscript positive. Both the chromosomes contain 1 copy each of bar gene. The fly has large, round red-colored eyes. Part b below shows a heterozygous bar female with genes big B superscript positive big B. The top chromosome has 1 copy of bar gene and the bottom chromosome has 2 copies of bar gene. The fly has thick bar eyes. Part c below shows a homozygous bar female with genes big B big B. Both the chromosomes have 2 copies each of bar gene. The fly has relatively thinner bar eyes. Part d below shows a heterozygous double bar female with genes big B superscript positive big B superscript D. The top chromosome has 1 copy of bar gene and the bottom chromosome has 3 copies of bar gene. The fly has the thinnest and shortest bar eyes.

Duplications and deletions often arise from **unequal crossing over**, in which chromosomes misalign during crossing over. Unequal crossing over is frequently the cause of red–green color blindness in humans. Perception of color is affected by red and green opsin genes, which are found on the X chromosome and are 98% identical in their DNA sequence. Most people with normal color vision have one red opsin gene and one green opsin gene (although some people have more than one copy of each). Occasionally, two paired X chromosomes in a female do not align properly in prophase I, and unequal crossing over takes place. The unequal crossing over produces one chromosome with an extra opsin gene and one chromosome that is missing an opsin gene (**Figure 8.8**; see also

Figure 18.14). When a male inherits the chromosome that is missing one of the opsin genes, red–green color blindness results.



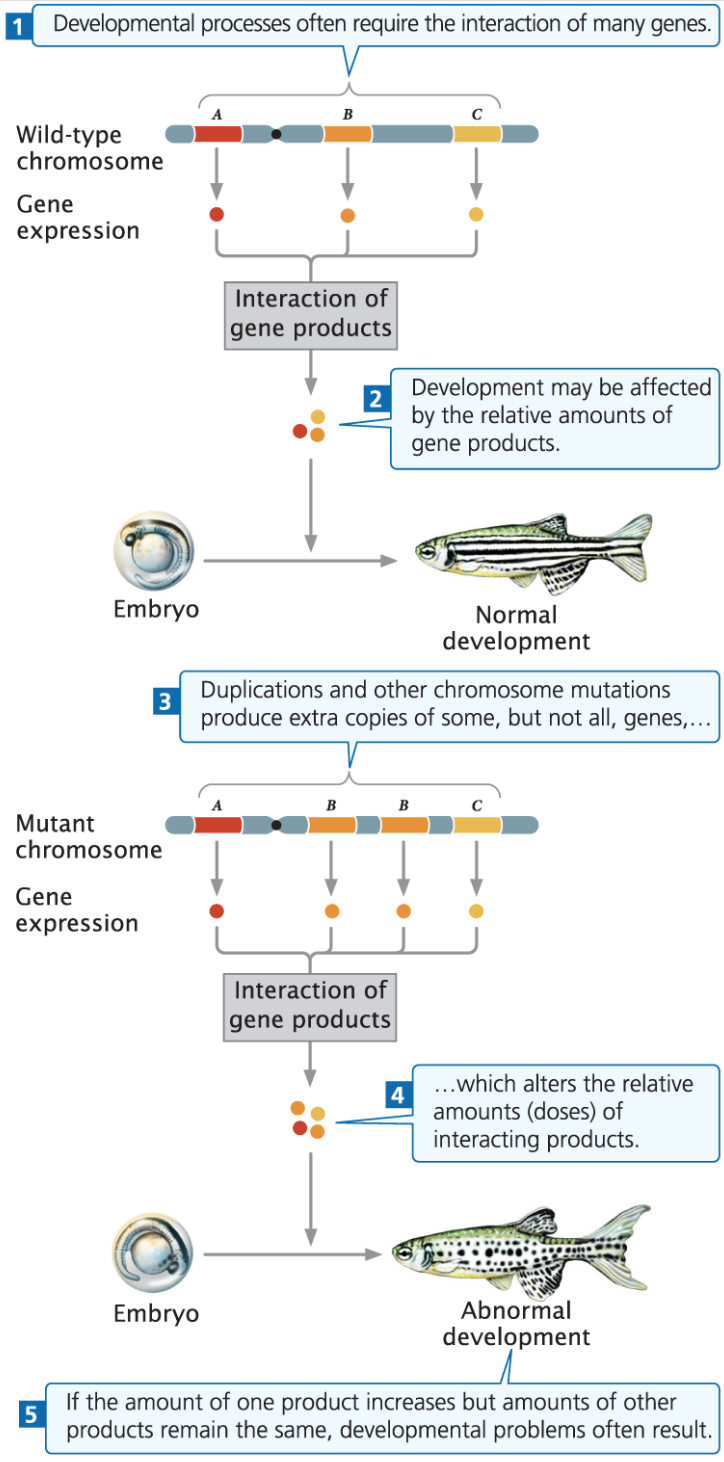
8.8 Unequal crossing over produces duplications and deletions.

Description

A chromosome has a red opsin gene and a green opsin gene. Below this chromosome, a chromosome has the same genes but its red gene is aligned below the green gene of the above chromosome. A caption reads, Chromosomes do not align properly, resulting in unequal crossing over. Unequal crossing over occurs and resulting chromosomes are obtained below. The resulting top chromosome has 1 red opsin gene and 2 green opsin genes (a duplication) and the bottom chromosome has only red opsin gene and green opsin gene is missing (a deletion). A caption reads, One resulting chromosome has two green opsin genes (a duplication) and the other chromosome has no green opsin gene (a deletion).

UNBALANCED GENE DOSAGE

How does chromosome duplication alter the phenotype? After all, gene sequences are not altered by duplications, and no genetic information is missing; the only change is the presence of additional copies of normal sequences. The answer to this question is not well understood, but the effects are most likely due to imbalances in the amounts of gene products (abnormal gene dosage). The amount of a particular protein synthesized by a cell is often directly related to the number of copies of its corresponding gene: an individual organism with three functional copies of a gene often produces 1.5 times as much of the protein encoded by that gene as an individual with two copies. Because developmental processes require the interaction of many proteins, they often depend critically on proper gene dosage. If the amount of one protein increases while the amounts of others remain constant, problems can result (**Figure 8.9**). Duplications can have severe consequences when the precise balance of gene products is critical to cell function (**Table 8.1**).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

8.9 Unbalanced gene dosage leads to developmental abnormalities.

Description
The diagram shows a wild-type chromosome with genes big A, big B, and big C at the top. A caption reads, Developmental processes often require the interaction of many genes. Below the chromosome, the individual genes are expressed and the gene products interact. A caption reads, Development may be affected by the relative amounts of gene products. An embryo below is influenced by the interaction of gene products which leads to normal development of a fish. This fish has stripes running horizontally over the body.

A mutant chromosome below shows genes big A, big B, big B, and big C. A caption reads, Duplications and other chromosome mutations produce extra copies of some, but not all, genes, which alters the relative amounts (doses) of interacting products. The individual genes are expressed and the gene products interact. An embryo below is influenced by the interaction of gene products which leads to abnormal development of a fish. It has a different appearance than the normal fish and has spots rather than stripes. A caption below reads, If the amount of one product increases but amount of other products remain the same, developmental problems often result.

TABLE 8.1 Effects of some human chromosome rearrangements

Type of Rearrangement	Chromosome	Disorder	Symptoms
Duplication	4, short arm	—	Small head, short neck, low hairline, reduced growth, intellectual disability
Duplication	4, long arm	—	Small head, sloping forehead, hand abnormalities
Duplication	7, long arm	—	Delayed development, asymmetry of the head, fuzzy scalp, small nose, low-set ears
Duplication	9, short arm	—	Characteristic facial features, variable intellectual disability, high and broad forehead, hand abnormalities
Deletion	5, short arm	*Cri-du-chat* syndrome	Small head, distinctive cry, widely spaced eyes, round face, intellectual disability
Deletion	4, short arm	Wolf–	Small head with high forehead, wide nose,

		Hirschhorn syndrome	cleft lip and palate, severe intellectual disability
Deletion	4, long arm	—	Small head, mild to moderate intellectual disability, cleft lip and palate, hand and foot abnormalities
Deletion	7, long arm	Williams–Beuren syndrome	Distinctive facial features, heart defects, cognitive impairment
Deletion	15, long arm	Prader–Willi syndrome	Feeding difficulty at early age but becoming obese after one year of age, mild to moderate intellectual disability
Deletion	18, short arm	—	Round face, large and low-set ears, mild to moderate intellectual disability
Deletion	18, long arm	—	Distinctive mouth shape, small hands, small head, intellectual disability

IMPORTANCE OF DUPLICATIONS IN EVOLUTION

Duplications have arisen frequently throughout the evolution of many eukaryotic organisms. Chromosome duplications are one way in which new genes evolve. In many cases, existing copies of a gene are not free to vary because they encode a product that is essential to development or function. However, after a chromosome undergoes duplication, extra copies of genes within the duplicated region are present. The original copy can provide the essential function, whereas an extra copy from the duplication is free to undergo mutation and change. Over evolutionary time, the extra copy may acquire enough mutations to assume a new function that benefits the organism. For example, humans have a series of genes that encode different globin chains, which function as oxygen

carriers. Some of these globin chains function during adult stages, and others function during embryonic and fetal development. The genes encoding all of these globins arose from an original primordial globin gene that underwent a series of duplications (see Figure 26.19). Segmental duplications have played an important role in the evolution of human chromosomes; about 4% of the human genome consists of segmental duplications.

CONCEPTS

A chromosome duplication is a mutation that doubles part of a chromosome. In individuals heterozygous for a chromosome duplication, the duplicated region of the chromosome loops out when homologous chromosomes pair in prophase I of meiosis. Duplications often have major effects on the phenotype, possibly by altering gene dosage. Segmental duplications are common within the human genome.

✔ CONCEPT CHECK 1

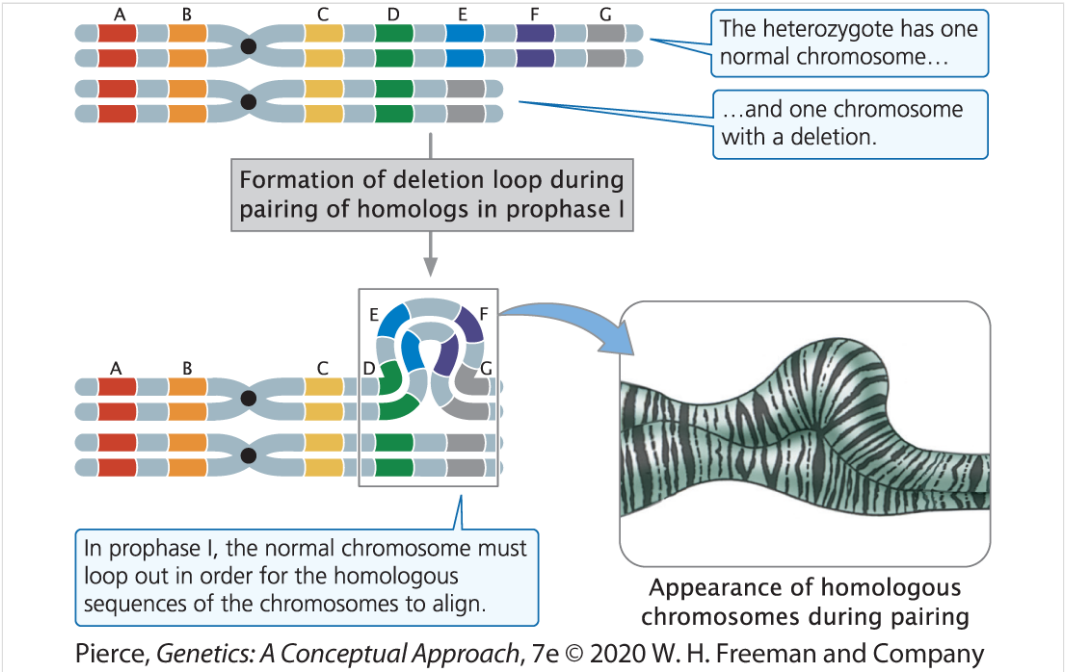
Chromosome duplications often result in abnormal phenotypes because

a. developmental processes depend on the relative amounts of proteins encoded by different genes.
b. extra copies of the genes within the duplicated region do not pair in meiosis.
c. the chromosome is more likely to break when it loops in meiosis.
d. extra DNA must be replicated, which slows down cell division.

Deletions

A second type of chromosome rearrangement is a **chromosome deletion**: the loss of a chromosome segment (see Figure 8.5b). A chromosome with segments AB•CDEFG that undergoes a deletion of segment EF would generate the mutated chromosome AB•CDG.

A large deletion can be easily detected because the chromosome is noticeably shortened. In individuals heterozygous for deletions, the normal chromosome must loop out during the pairing of homologs in prophase I of meiosis (**Figure 8.10**) to allow the homologous regions of the two chromosomes to align and undergo synapsis. This looping out generates a structure that looks very much like that seen in individuals heterozygous for duplications.



8.10 In an individual heterozygous for a deletion, the normal chromosome loops out during chromosome pairing in prophase I.

Description
The diagram shows 2 homologous chromosomes. The top chromosome has genes big A, big B, big C, big D, big E, big F, and big G. The bottom chromosome has genes big A, big B, big C, big D, and big G. A caption reads, The heterozygote has one normal chromosome and one chromosome with a deletion. Formation of deletion loop during pairing of homologs in prophase 1 occurs. The resultant chromosmes are shown below. Both the homologous chromosomes are aligned but the genes big E and big F are looping out from the top chromosome. A caption reads, In prophase 1, the normal chromosome must loop out in order for the homologous sequences of the chromosomes to align. The illustration also shows a close-up of homologous chromosomes during pairing where the top chromosome is looped out from a region. The other regions are aligned and vertical stripes are present all over the aligned chromosomes.

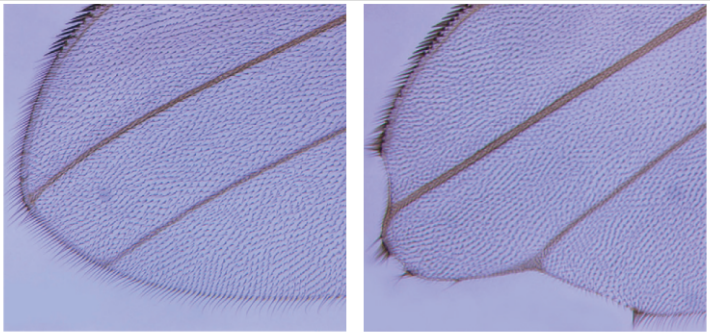
EFFECTS OF DELETIONS

The phenotypic consequences of a deletion depend on which genes are located in the deleted region. If the deletion includes the centromere, then the chromosome will not segregate in meiosis or mitosis and will usually be lost. Many deletions are lethal in the homozygous state because all copies of any essential genes located in the deleted region are missing.

Even individuals heterozygous for a deletion may have multiple defects for three reasons. First, the heterozygous condition may produce imbalances in the amounts of gene products similar to those produced by extra gene copies. Second, normally recessive mutations on the homologous chromosome lacking the deletion may be expressed when the wild-type allele has been deleted (and is no longer present to mask the recessive allele's expression). The

expression of a normally recessive mutation is referred to as **pseudodominance**, and it is an indication that one of the homologous chromosomes has a deletion.

Third, some genes must be present in two copies for normal function. When a single copy of a gene is not sufficient to produce a wild-type phenotype, that gene is said to be **haploinsufficient**. A series of X-linked wing mutations in *Drosophila* are known as *Notch* mutations. These mutations often result from chromosome deletions. *Notch* deletions behave in a dominant manner: when heterozygous for a *Notch* deletion, a fly has wings that are notched at the tips and along the edges (**Figure 8.11**). The *Notch* gene is therefore haploinsufficient. Females that are homozygous for a *Notch* deletion (or males that are hemizygous) die early in embryonic development. The *Notch* gene, which is deleted in *Notch* mutants, encodes a receptor that normally transmits signals received from outside the cell to the cell's interior and is important in fly development. The deletion acts as a recessive lethal because the loss of all copies of the *Notch* gene prevents normal development.



Spyros Artavanis-Tsakonas, Kenji Matsuno, and Mark E. Fortini.

8.11 The Notch phenotype is produced by a chromosome deletion that includes the *Notch* gene. (Left) Normal wing venation. (Right) Wing venation produced by a *Notch* mutation.

Description
The photo on the left shows a normal wing venation with a round outer edge. The photo on the rights shows wing venation with notches at the edges and tips in the wing as a result of Notch mutation.

CHROMOSOME DELETIONS IN HUMANS

In humans, a deletion on the short arm of chromosome 5 is responsible for *cri-du-chat* syndrome. The name (French for "cry of the cat") derives from the peculiar, catlike cry of infants with this syndrome. A child who is heterozygous for this deletion has a small head, widely spaced eyes, and a round face, and is intellectually disabled. Deletion of part of the short arm of chromosome 4 results in another human disorder, Wolf–Hirschhorn syndrome, which is characterized by seizures, severe intellectual disability, and delayed growth. A deletion of a tiny segment of chromosome 7 causes haploinsufficiency of the gene encoding elastin and a few other genes and leads to a condition known as Williams–Beuren syndrome, which is characterized by distinctive facial features, heart defects, high blood pressure, and cognitive impairments. The effects of some deletions in human chromosomes are summarized in Table 8.1.

CONCEPTS

A chromosome deletion is a mutation in which a part of a chromosome is lost. In individuals heterozygous for a deletion, the normal chromosome loops out during prophase I of meiosis. Deletions cause recessive genes on the homologous chromosome to be expressed and may cause imbalances in gene products.

✔ CONCEPT CHECK 2

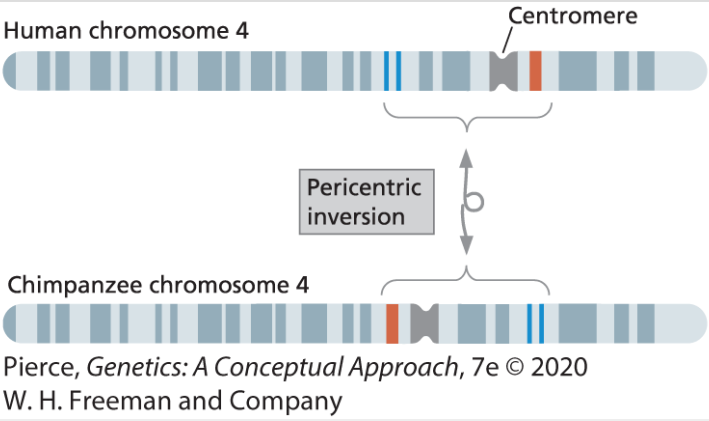
What is pseudodominance, and how is it produced by a chromosome deletion?

Inversions

A third type of chromosome rearrangement is a **chromosome inversion**, in which a chromosome segment is inverted—turned 180 degrees (see Figure 8.5c). If a chromosome originally had segments AB•CDEFG, then chromosome AB•CFEDG represents an inversion that includes segments DEF. For an inversion to take place, the chromosome must break in two places. Inversions that do not include the centromere, such as AB•CFEDG, are termed **paracentric inversions** (*para* meaning "next to"), whereas inversions that include the centromere, such as ADC•BEFG, are termed **pericentric inversions** (*peri* meaning "around").

Inversion heterozygotes are common in many organisms, including a number of plants, some species of *Drosophila*, mosquitoes, and

grasshoppers. Inversions may have played an important role in human evolution: G-banding patterns reveal that several human chromosomes differ from those of chimpanzees by only a pericentric inversion (Figure 8.12).



8.12 Chromosome 4 in humans and in chimpanzees differs by a pericentric inversion.

Description
Human chromosome 4 shown at the top has same genes as that in chimpanzee chromosome 4 shown below, except a small region around centromere that is inversed in the chimpanzee chromosome 4. This inversion is marked as pericentric inversion.

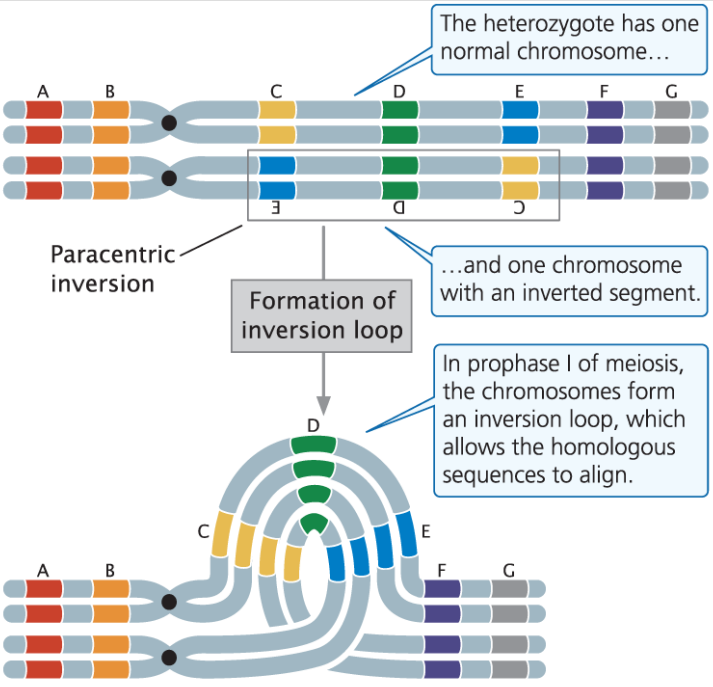
EFFECTS OF INVERSIONS

Individual organisms with inversions have neither lost nor gained any genetic material; only the DNA sequence has been altered. Nevertheless, these mutations often have pronounced phenotypic effects. An inversion may break a gene into two parts, with one part moving to a new location and destroying the function of that gene.

Even when the chromosome breaks lie between genes, phenotypic effects may arise from the inverted gene order. Many genes are regulated in a position-dependent manner; if their positions are altered by an inversion, their expression may be altered, an outcome referred to as a **position effect**. For example, when an inversion moves a wild-type allele (which normally encodes red eyes) at the *white* locus in *Drosophila* to a chromosomal region that contains highly condensed and inactive chromatin, the wild-type allele is not expressed in some cells, resulting in an eye consisting of red and white spots.

INVERSIONS IN MEIOSIS

When an individual is homozygous for a particular inversion, no special problems arise in meiosis, and the two homologous chromosomes can pair and separate normally. However, when an individual is heterozygous for an inversion, the gene order of the two homologs differs, and the homologous sequences can align and pair only if the two chromosomes form an inversion loop (**Figure 8.13**).



8.13 In an individual heterozygous for a paracentric inversion, the chromosomes form an inversion loop during pairing in prophase I.

Description

The diagram shows a pair of homologous chromosomes. The top chromosome has the genes big A, big B, big C, big D, big E, big F, and big G. The bottom chromosome has paracentric inversion involving genes big C, big D, and big E that are highlighted in a box. A caption reads, The heterozygote has one normal chromosome and one chromosome with an inverted segment. Formation of inversion loop occurs and the resultant chromosomes are shown below. The top chromosome forms a bump involving genes big C, big D, and big E, while the bottom chromosome rises upwards, turns down and eventually lies parallel to the top chromosome. Genes big C, big D, and big E on both the chromosomes are aligned in the loop. A caption reads, In prophase 1 of meiosis, the chromosomes form an inversion loop, which allows the homologous sequences to align.

Individuals heterozygous for inversions also exhibit reduced recombination among genes located in the inverted region. When

crossing over takes place, the outcome is abnormal gametes that do not give rise to viable offspring, and thus no recombinant progeny are observed. Let's see why this happens.

Figure 8.14 illustrates the results of crossing over within a paracentric inversion. Suppose that an individual is heterozygous for an inversion (see Figure 8.14a), with one wild-type, nonmutated chromosome (AB•CDEFG) and one inverted chromosome (AB•EDCFG). In prophase I of meiosis, an inversion loop forms, allowing the homologous sequences to pair up (see Figure 8.14b). If a single crossover takes place in the inverted region (between segments C and D in Figure 8.14), an unusual structure results (see Figure 8.14c). The two outer chromatids, which did not participate in crossing over, contain original, nonrecombinant gene sequences. The two inner chromatids, which did participate in crossing over, are highly abnormal: each has two copies of some genes and no copies of others. Furthermore, one of the four chromatids now has two centromeres, and is therefore referred to as a **dicentric chromatid**; the other lacks a centromere and is an **acentric chromatid**.

8.14 In a heterozygous individual, a single crossover within a paracentric inversion leads to abnormal gametes.

Description

Part a at the top shows 2 homologous chromosomes. The first chromosome has genes big A, big B, big C, big D, big E, big F, and big G and the bottom chromosome has the same genes with an inverted portion containing big C, big D, big E. A caption reads, The heterozygote possesses one wild type chromosome and one with a paracentric inversion.

Part b below shows the chromosomes aligned and forming an inversion loop with genes big C, big D, and big E. A caption reads, In prophase 1, an inversion loop forms and a single crossover within the inverted region results in an unusual structure. Crossing over occurs within the inversion. The crossing over is outlined in a semi-circular shaped box.

Part c below shows the results of a crossover at the inversion. The two X-shaped chromosomes, instead of being separated, are connected at one of their arms involving gene big D. So, these X-shaped chromosomes are now fused. Also, the remaining part of the arm where the crossover occurred is now fused, but a chromosome has no centromere. A caption reads, One of the four chromatids now has two centromeres, and one lacks a centromere. Genes big C, big D, and big E on the bottom chromosome are outlined in a rectangular box.

Part d below shows the fused chromosome and the chromatid without the centromere. A dicentric bridge between the arms that are fused is formed. This bridge has gene big D. The chromatid without centromere is separated now. A caption reads, In anaphase 1, the centromeres separate, stretching the dicentric chromatid, which breaks. The chromosome lacking a centromere is lost. Genes big C, big D, and big E on the bottom chromosome are outlined in a rectangular box. Anaphase 2 occurs.

Part e below shows the resulting gametes. A caption reads, Two gametes contain non-recombinant chromosomes: one wild type (normal) and one with the inversion. The 2 normal, nonviable recombinant gametes are shorter and do not contain all of the genes present in the original. One gamete here has big C gene and other gamete has big D and big E gene which are highlighted in a box. A caption reads, The other two contain recombinant chromosomes that are missing some genes; these gametes will not produce viable offspring. A normal non recombinant gamete has all the genes that are in original and one Non recombinant gamete has all the genes involved in the paracentric inversion; big C, big D, and big E. These genes are highlighted in a rectangular box.

A caption below reads, Conclusion: The resulting recombinant gametes are nonviable because they are missing some genes.

In anaphase I of meiosis, the centromeres are pulled toward opposite poles, and the two homologous chromosomes separate. This action stretches the dicentric chromatid across the center of the nucleus, forming a structure called a **dicentric bridge** (see Figure 8.14d). Eventually, the dicentric bridge breaks as the two centromeres are pulled farther apart. Spindle microtubules do not attach to the acentric fragment, so that fragment does not segregate to a spindle pole and is usually lost when the nucleus re-forms.

In the second division of meiosis, the sister chromatids separate, and four gametes are produced (see Figure 8.14e). Two of the gametes contain the original, nonrecombinant chromosomes (AB•CDEFG and AB•EDCFG). The other two gametes contain recombinant chromosomes that are missing some genes; these gametes will not produce viable offspring. Thus, no recombinant progeny result when crossing over takes place within a paracentric inversion. The key is to recognize that when crossing over takes

place, the resulting recombinant gametes are not viable, so no recombinant progeny are observed.

Recombination is also reduced within a pericentric inversion (**Figure 8.15**). No dicentric bridges or acentric fragments are produced, but the recombinant chromosomes have too many copies of some genes and no copies of others, so gametes that receive the recombinant chromosomes cannot produce viable progeny.

8.15 In a heterozygous individual, a single crossover within a pericentric inversion leads to abnormal gametes.

Description

The diagram shows a pair of chromosomes at the top. The top chromosome has genes big A, big B, big C, big D, big E, big F, and big G and the bottom chromosome has the same genes with pericentric inversion of genes big C, big D, big E. A caption reads, The heterozygote possesses one wild-type chromosome and one chromosome with a pericentric inversion. Formation of inversion loop involving genes big C, big D, and big E occurs below. The genes are highlighted in a semi-circular box to indicate crossing over. A caption reads, In prophase 1, an inversion loop forms. Another caption reads, If crossing over takes place within the inverted region, two of the resulting chromatids have too many copies of some genes and no copies of others. Crossing over within inversion occurs below. The two X-shaped chromosomes, instead of being separated, are connected at one of their arms involving gene big D, fusing the X-shaped chromosomes. Also, the remaining part of the arm where the crossover occurred is now fused. Genes big C, big D, and big E on the bottom chromosome and big G genes involved in fusing are outlined in a box. Anaphase 1 occurs and a caption reads, The chromosomes separate in anaphase 1. The top chromosomes obtained has big F, and big G and bottom chromosome has big C, big D and big E (outlined in a rectangular box), and big B, big A. Anaphase 2 occurs and a caption reads, The sister chromatids separate in anaphase 2, forming four gametes. The gametes obtained below are: One normal non-recombinant gamete with the genes same as original. Two non-viable recombinant gametes where one has a copy of big G instead of big A gene. Another has big C, big D, and big E outlined in a rectangular box, while other genes are big A and big B. One non-recombinant gamete with pericentric inversion has big C, big D, and big E outlined in a rectangular box while other genes are big A, big B, big F, and big G. A caption below reads, Conclusion: Recombinant gametes are nonviable because genes are either missing or present in too many copies.

Figures 8.14 and 8.15 illustrate the results of single crossovers within inversions. Double crossovers in which both crossovers are on the same two strands (two-strand double crossovers) result in functional recombinant chromosomes. (To see why functional gametes are produced by double crossovers, try drawing the results of a two-strand double crossover.) Thus, even though the overall rate of recombination is reduced within an inversion, some viable recombinant progeny may still be produced through two-strand double crossovers. › **TRY PROBLEM 27**

IMPORTANCE OF INVERSIONS IN EVOLUTION

Inversions can play important evolutionary roles by suppressing recombination among a set of genes. As we have seen, crossing over within an inversion in an individual that is heterozygous for a pericentric or paracentric inversion leads to unbalanced gametes and no recombinant progeny. This suppression of recombination allows alleles adapted to a specific environment to remain together, unshuffled by recombination.

CONCEPTS

In an inversion, a segment of a chromosome is turned 180 degrees. Inversions cause breaks in some genes and may move others to new locations. In individuals heterozygous for a chromosome inversion, the homologous chromosomes form an inversion loop in prophase I of meiosis. When crossing over takes place within the inverted region, nonviable gametes are usually produced, resulting in a reduction in the recombination frequency observed.

✔ CONCEPT CHECK 3

A dicentric chromosome is produced when crossing over takes place in an individual heterozygous for which type of chromosome rearrangement?

a. Duplication
b. Deletion
c. Paracentric inversion
d. Pericentric inversion

Translocations

A **translocation** entails the movement of genetic material between nonhomologous chromosomes (see Figure 8.5d) or within the same chromosome. Translocation should not be confused with crossing over, in which there is an exchange of genetic material between *homologous* chromosomes.

In a **nonreciprocal translocation**, genetic material moves from one chromosome to another without any reciprocal exchange. Consider the following two nonhomologous chromosomes: AB•CDEFG and MN•OPQRS. If chromosome segment EF moves from the first chromosome to the second without any transfer of segments from the second chromosome to the first, a nonreciprocal translocation has taken place, producing chromosomes AB•CDG and MN•OPEFQRS. More commonly, there is a two-way exchange of segments between the chromosomes, resulting in a **reciprocal**

translocation. A reciprocal translocation between chromosomes AB•CDEFG and MN•OPQRS might give rise to chromosomes AB•CDQRS and MN•OPEFG.

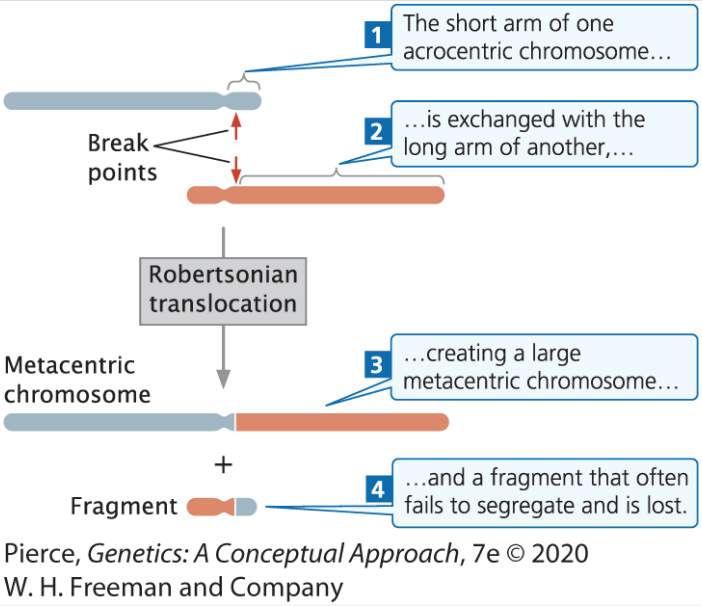
EFFECTS OF TRANSLOCATIONS

Translocations can affect a phenotype in several ways. First, they can physically link genes that were formerly located on different chromosomes. These new linkage relations may affect gene expression (a position effect), as genes translocated to new locations may come under the control of different regulatory sequences or other genes that affect their expression.

Second, the chromosome breaks that bring about translocations may take place within a gene and disrupt its function. Molecular geneticists have used these types of effects to map human genes. Neurofibromatosis, a genetic disease characterized by numerous fibrous tumors of the skin and nervous tissue, results from an autosomal dominant mutation. Linkage studies first placed the locus that, when mutated, causes neurofibromatosis on chromosome 17, but its precise location was unknown. Geneticists later narrowed down the location when they identified two patients with neurofibromatosis who possessed a translocation affecting chromosome 17. They assumed that these patients had developed neurofibromatosis because one of the chromosome breaks that occurred in the translocation disrupted a particular gene. Sequencing of DNA from the regions around the breaks eventually

led to the identification of the gene responsible for neurofibromatosis.

Deletions frequently accompany translocations. In a **Robertsonian translocation**, for example, the long arms of two acrocentric chromosomes become joined to a common centromere through a translocation, generating a metacentric chromosome with two long arms and another chromosome with two very short arms (**Figure 8.16**). The smaller chromosome is often lost because very small chromosomes do not have enough mass to segregate properly during mitosis and meiosis. The result is an overall reduction in chromosome number. As we will see, Robertsonian translocations are the cause of some cases of Down syndrome, a chromosome disorder discussed later in this chapter.

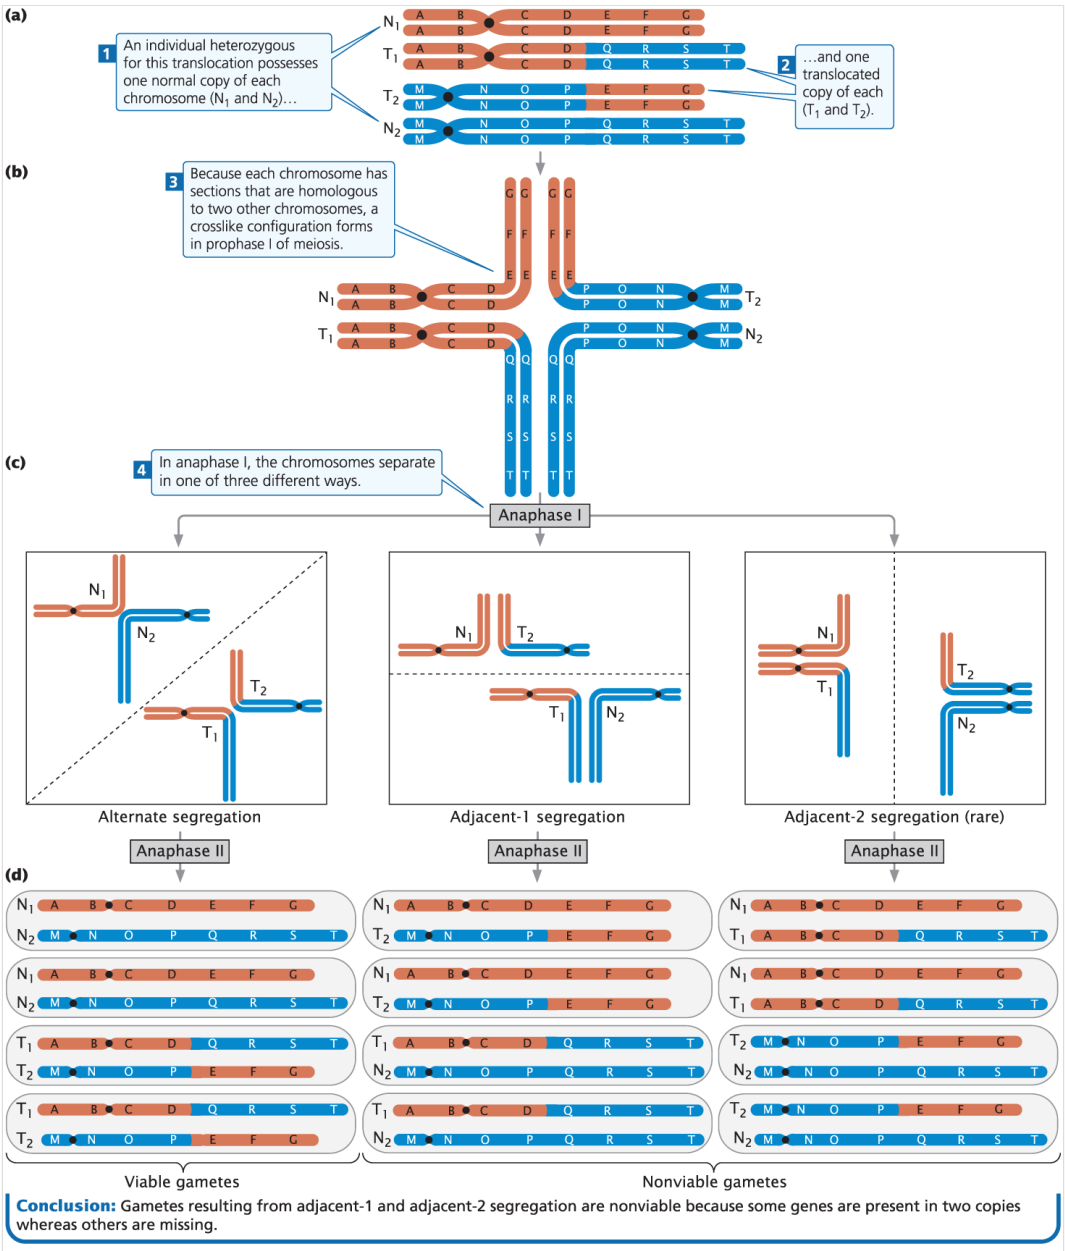


8.16 In a Robertsonian translocation, the short arm of one acrocentric chromosome is exchanged with the long arm of another.

Description
The diagram shows 2 acrocentric chromosomes arranged opposite to each other. The short arm of the top chromosome is above the long arm of bottom chromosome. Both these arms are labeled as break points. A caption reads, The short arm of one acrocentric chromosome is exchanged with the long arm of another creating a large metacentric chromosome and a fragment that often fails to segregate and is lost. Robertsonian translocation occurs and a large metacentric chromosome is obtained below. This large chromosome has larger arms on both sides of the centromere. The fragments join together as well.

TRANSLOCATIONS IN MEIOSIS

The effect of a translocation on chromosome segregation in meiosis depends on the nature of the translocation. Let's consider what happens in an individual heterozygous for a reciprocal translocation. Suppose that the original chromosomes are AB•CDEFG and M•NOPQRST (designated N_1 and N_2, respectively, for normal chromosomes 1 and 2) and that a reciprocal translocation takes place, producing chromosomes AB•CDQRST and M•NOPEFG (designated T_1 and T_2, respectively, for translocated chromosomes 1 and 2). An individual heterozygous for this translocation would possess one normal copy and one translocated copy of each chromosome (Figure 8.17a). Each of these chromosomes contains segments that are homologous to segments of two other chromosomes. Thus, when the homologous segments pair in prophase I of meiosis, crosslike configurations consisting of all four chromosomes form (Figure 8.17b).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

8.17 In an individual heterozygous for a reciprocal translocation, crosslike structures form in homologous pairing.

Description

Part a at the top shows 2 sets of 2 homologous chromosomes. For pair 1, the top chromosome named N subscript 1 is red and has genes big A, big B, big C, big D, big E, big F, and big G. Bottom chromosome named T subscript 1 is red has genes big A, big B, big C, big D, and a blue part with big Q, big R, big S, and big T. For pair 2, the top

chromosome named T subscript 2 is blue and has genes big M, big N, big O, big P and red part with big E, big F, and big G. The bottom chromosome named N subscript 2 has all blue part and has genes big M, big N, big O, big P, big Q, big R, big S, and big T. A caption reads, An individual heterozygous for this translocation possesses one normal copy of each chromosome, called N subscript 1 and N subscript 2, and one translocated copy of each, called T subscript 1 and T subscript 2.

Part b below shows the red chromosome N subscript 1 forming the shape of a bookend. One side of this chromosome is aligned with the red portion from the T subscript 1 chromosome, and the other side is aligned with red portion of the T subscript 2 chromosome. The blue chromosome is forming the same type of structure in inverse. This results in the shape of a cross. A caption reads, Because each chromosome has sections that are homologous to two other chromosomes, a cross-like configuration forms in prophase 1 of meiosis. Anaphase 1 occurs and leads to illustration c below. A caption reads, In anaphase 1, the chromosomes separate in one of three different ways.

Part c below shows three different ways of chromosome separation: 1, Alternate segregation where N subscript 1 and N subscript 2 are paired opposite T subscript 1 and T subscript 2. 2, Adjacent-1 segregation where N subscript 1 and T subscript 2 are together and T subscript 1 and N subscript 2 are together. 3, Adjacent-2 segregation (rare) where N subscript 1 and T subscript 1 are together and T subscript 2 and N subscript 2 are together.

Part d below shows viable gametes formed by alternate segregation and non-viable gametes formed by adjacent-1 and adjacent 2 segregations.

There are 4 viable gametes from alternate segregation as follows: N subscript 1, N subscript 2; N subscript 1, N subscript 2; T subscript 1, T subscript 2; and T subscript 1, T subscript 2.

4 non-viable gametes from adjacent-1 segregation are: N subscript 1, T subscript 2; N subscript 1, T subscript 2; T subscript 1, N subscript 2; and T subscript 1, N subscript 2.

4 non-viable gametes from adjacent-2 segregation are: N subscript 1, T subscript 1; N subscript 1, T subscript 1; T subscript 2, N subscript 2; and T subscript 2, N subscript 2.

A caption below reads, Conclusion: Gametes resulting from adjacent-I and adjacent-2 segregation are nonviable because some genes are present in two copies

whereas others are missing.

Notice that N_1 and T_1 have homologous centromeres (in both chromosomes, the centromere is between segments B and C); similarly, N_2 and T_2 have homologous centromeres (between segments M and N). Normally, homologous centromeres separate and move toward opposite poles in anaphase I of meiosis. With a reciprocal translocation, the chromosomes may segregate in three different ways. In **alternate segregation** (**Figure 8.17c**), N_1 and N_2 move toward one pole, and T_1 and T_2 move toward the opposite pole. In **adjacent-1 segregation**, N_1 and T_2 move toward one pole, and T_1 and N_2 move toward the other pole. In both alternate and adjacent-1 segregation, homologous centromeres segregate to opposite poles. **Adjacent-2 segregation**, in which N_1 and T_1 move toward one pole and T_2 and N_2 move toward the other, is rare because the two homologous chromosomes usually separate in meiosis.

The products of the three segregation patterns are illustrated in **Figure 8.17d**. As you can see, each of the gametes produced by alternate segregation possesses one complete set of the chromosome segments. These gametes are therefore functional and can produce viable progeny. In contrast, gametes produced by adjacent-1 and adjacent-2 segregation are not viable because some chromosome segments are present in two copies, whereas others are missing. Because adjacent-2 segregation is rare, most gametes are produced by alternate or adjacent-1 segregation. Therefore, approximately half of the gametes from an individual heterozygous

for a reciprocal translocation are expected to be functional. **› TRY PROBLEM 28**

THINK-PAIR-SHARE Question 2

CONCEPTS

In translocations, parts of chromosomes move to other nonhomologous chromosomes or to other regions of the same chromosome. Translocations can affect the phenotype by causing genes to move to new locations, where they come under the influence of new regulatory sequences, or by breaking genes and disrupting their function.

✔ CONCEPT CHECK 4

What is the outcome of a Robertsonian translocation?

a. Two acrocentric chromosomes
b. One large metacentric chromosome and one very small chromosome with two very short arms
c. One large metacentric chromosome and one large acrocentric chromosome
d. Two large metacentric chromosomes

Fragile Sites

Some chromosomes contain **fragile sites** (**Figure 8.18**), which are sites that develop constrictions or gaps when the cells are grown in culture and that are prone to breakage under certain conditions.

More than 100 fragile sites have been identified on human chromosomes.

Courtesy of
Dr. Christine Harrison.

8.18 Fragile sites are chromosomal regions susceptible to breakage under certain conditions. Shown here is a fragile site on the human X chromosome.

One of the most intensively studied rare fragile sites is located on the human X chromosome and is associated with **fragile-X syndrome**, a disorder that includes intellectual disability. Fragile-X syndrome, which exhibits X-linked inheritance and arises with a frequency of about 1 in 5000 male births, has been shown to result from an increase in the number of repeats of a CGG trinucleotide, a type of mutation known as expanding nucleotide repeats (see Chapter 18). In the case of fragile-X syndrome, the increased copies of the CGG trinucleotide occur within and disrupt a gene that encodes fragile X mental retardation protein (FMRP), which regulates the translation of other proteins and plays a role in the development of neural synapses.

Molecular studies of fragile sites have shown that many of these sites are more than 100,000 bp in length and include one or more genes. Fragile sites are often replicated late in S phase. At these sites, the enzymes that replicate DNA may stall while unwinding of the DNA continues (see Chapter 12), leading to long stretches of DNA that are unwound and vulnerable to breakage. In spite of recent advances in our understanding of fragile sites, their nature is not completely understood.

Copy-Number Variations

Chromosome rearrangements have traditionally been detected by examining chromosomes with a microscope. Visual examination identifies chromosome rearrangements on the basis of changes in the overall size of a chromosome, alteration of banding patterns revealed by chromosome staining, or the behavior of chromosomes in meiosis. Microscopy, however, can detect only large chromosome rearrangements, typically those that are at least 5 million base pairs in length.

With the completion of the Human Genome Project (see Chapter 20), detailed information about DNA sequences found on individual human chromosomes became available. Using this information, geneticists can now examine the number of copies of specific DNA sequences present in a cell and detect duplications, deletions, and other chromosome rearrangements that cannot be observed with microscopy alone. Because these methods measure the number of copies of particular DNA sequences, the variations that they detect are called **copy-number variations (CNVs)**. They include duplications and deletions that range in length from thousands of base pairs to several million base pairs. Many of these variants include at least one gene and may encompass several. Recently developed techniques for rapidly sequencing the genome now make it possible to detect not only copy-number variations but also other chromosome rearrangements, such as inversions and translocations. Chromosome rearrangements and copy-number variations are collectively referred to as **structural variants**.

Recent studies of copy-number variations have revealed that submicroscopic chromosome duplications and deletions are quite common: research suggests that each person may possess as many as a thousand copy-number variations. Many of these variations probably have no observable phenotypic effects, but some have now been implicated in a number of diseases and disorders. For example, Janine Wagenstaller and her colleagues studied copy-number variation in 67 children with unexplained intellectual disability and found that 11 (16%) of them had duplications or deletions. Copy-number variations have also been associated with osteoporosis, autism, schizophrenia, and a number of other diseases and disorders. › **TRY PROBLEM 20**

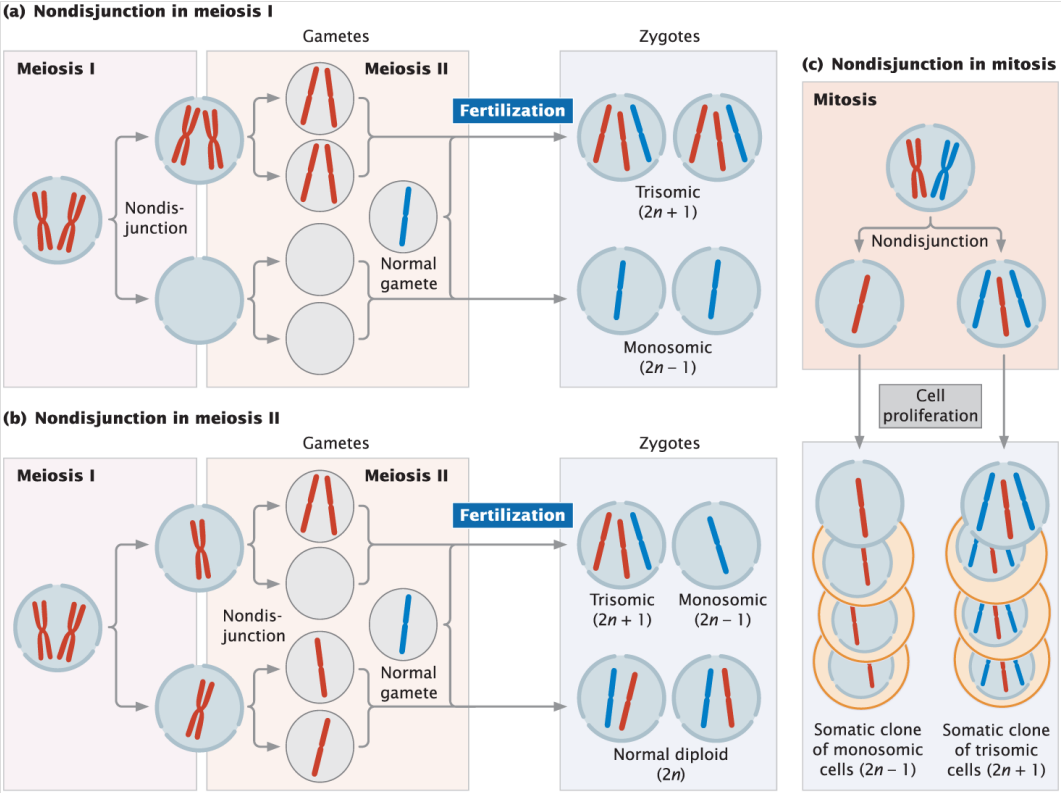
CONCEPTS

Variations in the number of copies of particular DNA sequences (copy-number variations) are surprisingly common in the human genome.

8.3 Aneuploidy Is an Increase or a Decrease in the Number of Individual Chromosomes

In addition to chromosome rearrangements, chromosome mutations include changes in the number of chromosomes. Variations in chromosome number can be classified into two basic types: **aneuploidy**, which is a change in the number of individual chromosomes, and **polyploidy**, which is an increase in the number of chromosome sets.

Aneuploidy can arise in several ways. First, a chromosome may be lost in the course of mitosis or meiosis if, for example, its centromere is deleted. Loss of the centromere prevents the spindle microtubules from attaching, so the chromosome fails to move to the spindle pole and does not become incorporated into a nucleus after cell division. Second, the small chromosome generated by a Robertsonian translocation may be lost in mitosis or meiosis. Third, aneuploidy may arise through nondisjunction, the failure of homologous chromosomes or sister chromatids to separate in meiosis or mitosis (see Chapter 4). Nondisjunction leads to some gametes or cells that contain an extra chromosome and other gametes or cells that are missing a chromosome (**Figure 8.19**).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

8.19 Aneuploids can be produced through nondisjunction in meiosis I, meiosis II, or mitosis. The gametes that result from meioses with nondisjunction may combine with a gamete (with blue chromosome) that results from normal meiosis to produce aneuploid zygotes.

Description

Part a at the top left shows non-disjunction during meiosis 1. In a box labeled meiosis 1, a nucleus has 2 X-shaped red chromosomes. Non-disjunction occurs and a nucleus with these 2 chromosomes and a nucleus with no chromosomes are produced. Meiosis 2 occurs and gametes are produced. Two gametes have 2 red chromatids each and 2 gametes contain no chromatids. A normal gamete has one blue chromatid. Normal gamete fertilizes with gametes with red chromatid and produces 2 trisomic (2 n plus 1) zygotes that have 2 red and one blue chromatid each. Normal gamete fertilizes with gametes with no chromatids and produces 2 monosomic zygotes (2 n minus 1) that have only one blue chromatid each.

Part b at the bottom left shows non-disjunction in meiosis 2. Here, normal separation of the 2 red X-shaped chromosomes occurs during meiosis 1. The gametes are as follows: one

gamete has 2 chromatids, one has no chromatid, while 2 gametes have 1 chromatid each. A normal gamete has blue chromatid. The normal gamete fertilizes with a gamete with two chromatids and other gamete with no chromatids. It produces 1 trisomic (2 n plus 1) zygote with 2 red and 1 blue chromatids and 1 monosomic zygote (2 n minus 1) with only 1 blue chromatid. The normal gamete fertilizes with gametes that have one chromatid each and produces 2 normal diploid (2 n) zygotes with one red and one blue chromatid each.

Part c at the top right shows non-disjunction in mitosis. A nucleus has 2 X-shaped chromosomes, one blue and one red. Non-disjunction occurs and a nucleus with 1 red chromatid and a nucleus with one red and 2 blue chromatids are produced. Cell proliferation occurs and a somatic clone of monosomic cells (2 n minus 1) and a somatic clone of trisomic cells (2 n plus 1) are produced.

Types of Aneuploidy

We consider four types of common aneuploid conditions in diploid organisms: nullisomy, monosomy, trisomy, and tetrasomy.

1. **Nullisomy** is the loss of both members of a homologous pair of chromosomes. It is represented as $2n - 2$, where n refers to the haploid number of chromosomes. Thus, among humans, who normally possess $2n = 46$ chromosomes, a nullisomic zygote has 44 chromosomes.
2. **Monosomy** is the loss of a single chromosome, represented as $2n - 1$. A human monosomic zygote has 45 chromosomes.
3. **Trisomy** is the gain of a single chromosome, represented as $2n + 1$. A human trisomic zygote has 47 chromosomes. The gain of a chromosome means that there are three homologous copies of

one chromosome. Most cases of Down syndrome, discussed later in this section, result from trisomy of chromosome 21.

4. **Tetrasomy** is the gain of two homologous chromosomes, represented as $2n + 2$. A human tetrasomic zygote has 48 chromosomes. Tetrasomy is not the gain of *any* two extra chromosomes but rather the gain of two homologous chromosomes, so that there are four homologous copies of a particular chromosome.

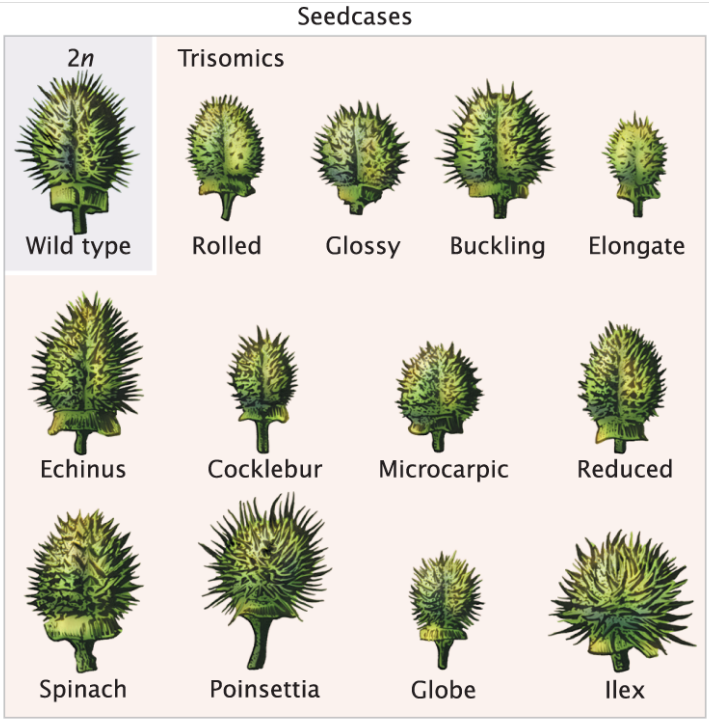
More than one aneuploid mutation may occur in the same individual. An individual that has an extra copy of each of two different (nonhomologous) chromosomes is referred to as being double trisomic; this condition is represented as $2n + 1 + 1$. Similarly, a double monosomic individual has two fewer nonhomologous chromosomes than normal ($2n - 1 - 1$), and a double tetrasomic individual has two extra pairs of homologous chromosomes ($2n + 2 + 2$).

THINK-PAIR-SHARE Question 3

Effects of Aneuploidy

One of the first aneuploids to be recognized was a fruit fly with a single X chromosome and no Y chromosome, discovered by Calvin Bridges in 1913 (see Chapter 4). Another early study of aneuploidy

focused on mutants in the Jimson weed (*Datura stramonium*). A. Francis Blakeslee began breeding this plant in 1913, and he observed that crosses with several Jimson-weed mutants produced unusual ratios of progeny. For example, the *globe* mutation (which produces a globe-shaped seedcase) was dominant but was inherited primarily from the female parent. When *globe* mutants self-fertilized, only 25% of the progeny had the globe phenotype. If the *globe* mutation were strictly dominant, Blakeslee should have seen 75% of the progeny with the trait (see Chapter 3), so the 25% that he observed was unusual. Blakeslee isolated 12 different mutants (**Figure 8.20**) that exhibited peculiar patterns of inheritance. Eventually, John Belling demonstrated that these 12 mutants were in fact trisomics. *D. stramonium* has 12 pairs of chromosomes ($2n = 24$), and each of the 12 mutants was trisomic for a different chromosome pair. The aneuploid nature of the mutants explained the unusual ratios that Blakeslee had observed in the progeny. Many of the extra chromosomes in the trisomics were lost in meiosis, so fewer than 50% of the gametes carried the extra chromosome, and the proportion of trisomics in the progeny was low. Furthermore, the pollen containing an extra chromosome was not as successful in fertilization, and trisomic zygotes were less viable.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

8.20 Mutant seedcases in Jimson weed (*Datura stramonium*) result from different trisomies. Each seedcase phenotype results from trisomy of a different chromosome.

Description

The wild type case seed is labeled as 2 n. The 12 different seed case mutants have different heights, widths, and levels of spikiness. These are labeled as trisomics and are as follows: Rolled, Glossy, Buckling, Elongate, Echinus, Cocklebur, Microcarpic, Reduced, Spinach, Poinsettia, Globe, and Ilex.

Aneuploidy usually alters the phenotype drastically. In most animals and many plants, aneuploidies are lethal. Because aneuploidy affects the number of gene copies but not their nucleotide sequences, the effects of aneuploidy are most likely due to abnormal gene dosage. Aneuploidy alters the dosage for some, but not all, genes, disrupting

the relative concentrations of gene products and often interfering with normal development.

A major exception to the relation between gene number and gene dosage pertains to genes on the mammalian X chromosome. In mammals, X-chromosome inactivation ensures that males (who have a single X chromosome) and females (who have two X chromosomes) receive the same functional dosage for X-linked genes (see Chapter 4 for further discussion of X-chromosome inactivation). Because additional X chromosomes in mammals are inactivated, we might expect that aneuploidy of the sex chromosomes would be less detrimental in these animals. Indeed, this is the case for mice and humans, for whom aneuploidy of the sex chromosomes is the most common form of aneuploidy seen in living organisms. Y-chromosome aneuploidy is probably relatively common because there is so little information in the Y chromosome.

THINK-PAIR-SHARE Question 4

CONCEPTS

Aneuploidy, the loss or gain of one or more individual chromosomes, may arise from the loss of a chromosome subsequent to translocation or from nondisjunction in meiosis or mitosis. It disrupts gene dosage and often has severe phenotypic effects.

✔ CONCEPT CHECK 5

A diploid organism has $2n = 36$ chromosomes. How many chromosomes will be found in a trisomic member of this species?

Aneuploidy in Humans

A high percentage of all human embryos that are conceived possess chromosome abnormalities. Findings from studies of women who are attempting pregnancy suggest that more than 30% of all conceptions are spontaneously aborted (miscarried), usually so early in development that the woman is not even aware of her pregnancy. Chromosome mutations are present in at least 50% of spontaneously aborted human fetuses, with aneuploidy accounting for most of them. This rate of chromosome abnormality in humans is higher than in other organisms that have been studied; in mice, for example, aneuploidy is found in no more than 2% of fertilized eggs. Most aneuploids in humans are due to missegregation of chromosomes in meiosis I during oogenesis, the formation of eggs in females.

In Chapter 2, we discussed the importance of crossovers for proper segregation of homologous chromosomes in meiosis I. Generally, each pair of homologous chromosomes must undergo at least one crossover for the two homologous chromosomes to segregate properly during meiosis. Crossovers connect the two chromosomes, creating tension when the homologs are pulled in opposite

directions during metaphase I (see Figure 2.19c). This tension is necessary for the two homologs to separate properly in anaphase I. Research of crossover formation in humans demonstrates that the process of crossover maturation in females is often inefficient compared to that in males, leading to fewer mature crossovers in females and, among those that do occur, more crossovers that are likely to lead to missegregation of chromosomes during meiosis. This may account for the high levels of aneuploidy seen in human conceptions that originate in oogenesis. Furthermore, researchers have identified a genetic variant at the *Polo-like Kinase 4* (*PLK4*) gene that increases the frequency of aneuploidy in humans. The *PLK4* gene plays a role in regulating the centriole (see Chapter 2), the disruption of which can lead to failure of the chromosomes to separate properly in mitosis. Interestingly, this genetic variant occurs at high frequencies in many human populations, and some evidence suggests it has been favored by natural selection, but why it might have been favored by natural selection is still unclear.

Aneuploidy in humans usually produces such serious developmental problems that spontaneous abortion results. Only about 2% of all fetuses with a chromosome mutation survive to birth.

THINK-PAIR-SHARE Question 5

SEX-CHROMOSOME ANEUPLOIDIES

The most common aneuploidies seen in living humans are those that involve the sex chromosomes. As is true of all mammals, aneuploidy of the human sex chromosomes is better tolerated than aneuploidy of autosomes. Both Turner syndrome and Klinefelter syndrome (see Figures 4.8 and 4.9) result from aneuploidy of the sex chromosomes.

AUTOSOMAL ANEUPLOIDIES

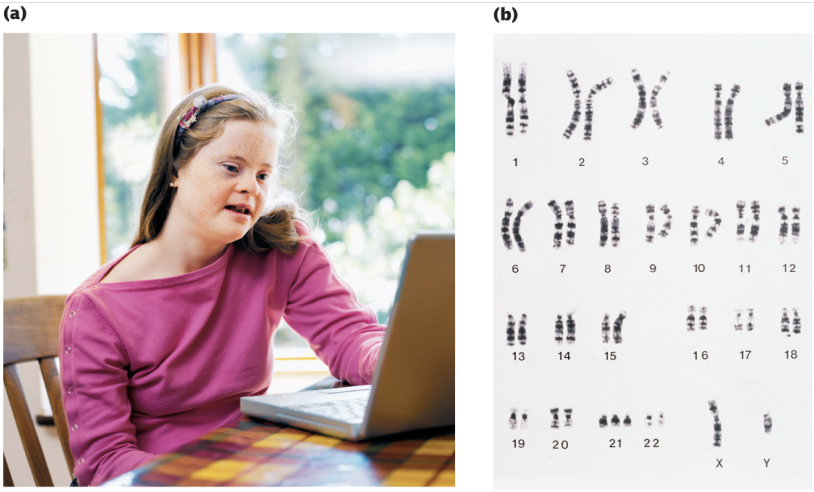
Autosomal aneuploidies resulting in live births are less common than sex-chromosome aneuploidies in humans, probably because there is no mechanism of dosage compensation for autosomes. Most embryos with autosomal aneuploidies are spontaneously aborted, though occasionally fetuses with aneuploidies of some of the small autosomes, such as chromosome 21, complete development. Because these chromosomes are small and carry relatively few genes, the presence of extra copies is less detrimental than it is for larger chromosomes.

DOWN SYNDROME

In 1866, John Langdon Down, physician and medical superintendent of the Earlswood Asylum in Surrey, England, noticed a remarkable resemblance among a number of his patients who were intellectually disabled: all of them possessed a broad, flat face, a small nose, and oval-shaped eyes. Their features were so similar, in

fact, that he felt that they might easily be mistaken for children from the same family. Down did not understand the cause of their intellectual disability, but his original description faithfully records the physical characteristics of people with this genetic form of intellectual disability. In his honor, the disorder is today known as Down syndrome.

Down syndrome, also known as **trisomy 21**, is the most common autosomal aneuploidy in humans (**Figure 8.21a**). The incidence of Down syndrome in the United States is similar to that worldwide—about 1 in 700 human births—although the incidence increases among children born to older mothers. Approximately 92% of those who have Down syndrome have three full copies of chromosome 21 (and therefore a total of 47 chromosomes), a condition termed **primary Down syndrome** (**Figure 8.21b**). Primary Down syndrome usually arises from spontaneous nondisjunction during egg formation: about 75% of the nondisjunction events that cause Down syndrome are maternal in origin, most arising in meiosis I. Most children with Down syndrome are born to unaffected parents, and the failure of the chromosomes to divide has little hereditary tendency. Therefore, a couple who has conceived one child with primary Down syndrome has only a slightly higher risk of conceiving a second child with Down syndrome (compared with other couples of similar age who have not had any children with Down syndrome). Similarly, the couple's relatives are not more likely to have a child with primary Down syndrome.



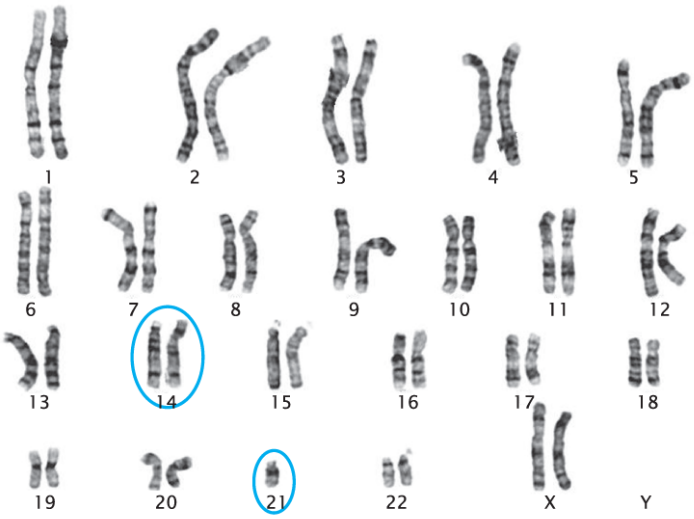
Part a: George Doyle/Getty Images. Part b: L. Wilatt, East Anglian Regional Genetics Service/ Science Photo Library/Science Source.

8.21 Down syndrome (a) is caused by trisomy of chromosome 21 (b).

About 4% of people with Down syndrome are not trisomic for a complete chromosome 21. Instead, they have 46 chromosomes, but an extra copy of part of chromosome 21 is attached to another chromosome through a translocation. This condition is termed **familial Down syndrome** because it has a tendency to run in families. The phenotypic characteristics of familial Down syndrome are the same as those of primary Down syndrome.

Familial Down syndrome arises in offspring whose parents are carriers of chromosomes that have undergone a Robertsonian translocation, most commonly between chromosome 21 and chromosome 14: the long arm of 21 and the short arm of 14 exchange places (Figure 8.22). This exchange produces one chromosome that includes the long arms of chromosomes 14 and 21 and another, very small chromosome that consists of the short arms of chromosomes 21 and 14. The small chromosome is generally lost after several cell

divisions. Although exchange between chromosomes 21 and 14 is the most common cause of familial Down syndrome, the condition can also be caused by translocations between 21 and other chromosomes, such as 15.



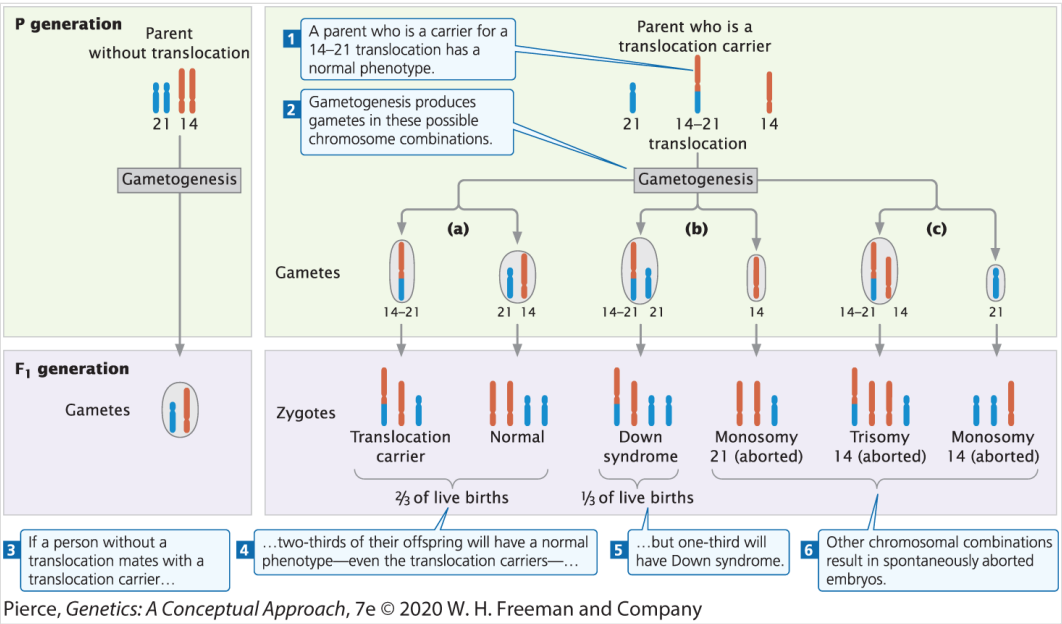
© Centre for Genetics Education for and on behalf of the Crown in right of the State of New South Wales.

8.22 The translocation of part of chromosome 21 to another chromosome results in familial Down syndrome. Here, the long arm of chromosome 21 is attached to chromosome 14. This karyotype is from a translocation carrier, who is phenotypically normal but is at increased risk for producing children with Down syndrome.

People with this type of translocation, called **translocation carriers**, do not have Down syndrome. Although they possess only 45 chromosomes, their phenotypes are normal because they have two copies of the long arms of chromosomes 14 and 21, and apparently the short arms of these chromosomes (which are lost) carry no essential genetic information. Although translocation carriers have a

completely normal phenotype, they have an increased chance of producing children with Down syndrome.

When a translocation carrier produces gametes, the translocation chromosome segregates in one of three different ways. First, it may separate from the normal chromosomes 14 and 21 in anaphase I of meiosis (Figure 8.23a). In this type of segregation, half of the gametes produced will have the translocation chromosome and no other copies of chromosomes 21 and 14; the fusion of such a gamete with a normal gamete will give rise to a translocation carrier. The other half of the gametes produced by this first type of segregation will be normal, each with a single copy of chromosomes 21 and 14, and will result in offspring with a normal set of chromosomes.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

8.23 Translocation carriers are at increased risk for producing children with familial Down syndrome.

Description

The diagram shows P generation at the top with a parent without translocation who has normal chromosomes 21 and 14. Gametogenesis occurs and in F subscript 1 generation obtained below, a gamete produced has one 14 chromatid and one 21 chromatid. The illustration also shows a P generation at the top where parent is translocation carrier with one chromatid 21, one chromatid 14, and a hybrid chromatid 14-21. A caption reads, A parent who is a carrier for a 14 21 translocation has a normal phenotype. Gametogenesis occurs. A caption reads, Gametogenesis produces gametes in these possible chromosome combinations. Pair a obtained below has a gamete with 14-21 chromatid and a gamete with two chromatids 21 and 14. Pair b obtained below has a gamete with 14-21 chromatid and a 21 chromatid; another gamete has 14 chromatid. Pair c obtained below has a gamete with 14-21 chromatid and a 21 chromatid; another gamete has 21 chromatid.

Zygotes formed in the F subscript 1 generation below are as follows:

From Pair a:

A gamete with 14-21 chromatid produces a translocation carrier. A gamete with two chromatids 21 and 14 produces a normal zygote. These form two-third of a live birth.

From Pair b:

A gamete with 14-21 chromatid and a 21 chromatid produces a zygote with down syndrome. This forms one-third of live births. Another gamete has 14 chromatid and produces a zygote with monosomy 21 (aborted).

From Pair c:

A gamete with 14-21 chromatid and a 21 chromatid produces a zygote with trisomy 14 (aborted). Another gamete has 21 chromatid produces a zygote with monosomy 14 (aborted).

A caption reads, If a person without a translocation mates with a translocation carrier, two-thirds of their offspring will have a normal phenotype—even the translocation carriers, but one-third will have Down syndrome. Other chromosomal combinations result in spontaneously aborted embryos.

Alternatively, the translocation chromosome may separate from chromosome 14 and pass into the same cell with the normal chromosome 21 (**Figure 8.23b**). This type of segregation produces abnormal gametes only; half will have two functional copies of chromosome 21 (one normal and one attached to chromosome 14) and the other half will lack chromosome 21. If a gamete with the two functional copies of chromosome 21 fuses with a normal gamete carrying a single copy of chromosome 21, the resulting zygote will have familial Down syndrome. If a gamete lacking chromosome 21 fuses with a normal gamete, the resulting zygote will have monosomy 21 and will be spontaneously aborted.

In the third type of segregation, the translocation chromosome and the normal copy of chromosome 14 segregate together (**Figure 8.23c**). This pattern is presumably rare because the two centromeres are both derived from chromosome 14 and usually separate from each other. All the gametes produced by this process are abnormal: half result in monosomy 14 and the other half result in trisomy 14. All are spontaneously aborted.

Thus, only three of the six types of gametes that can be produced by a translocation carrier will result in the birth of a baby, and theoretically, these gametes should arise with equal frequency. One-third of the offspring of a translocation carrier should be translocation carriers like their parent, one-third should have familial Down syndrome, and one-third should have a normal set of chromosomes. In reality, however, fewer than one-third of the

children born to translocation carriers have Down syndrome, which suggests that some of the embryos with Down syndrome are spontaneously aborted. ❯ **TRY** **PROBLEM 33**

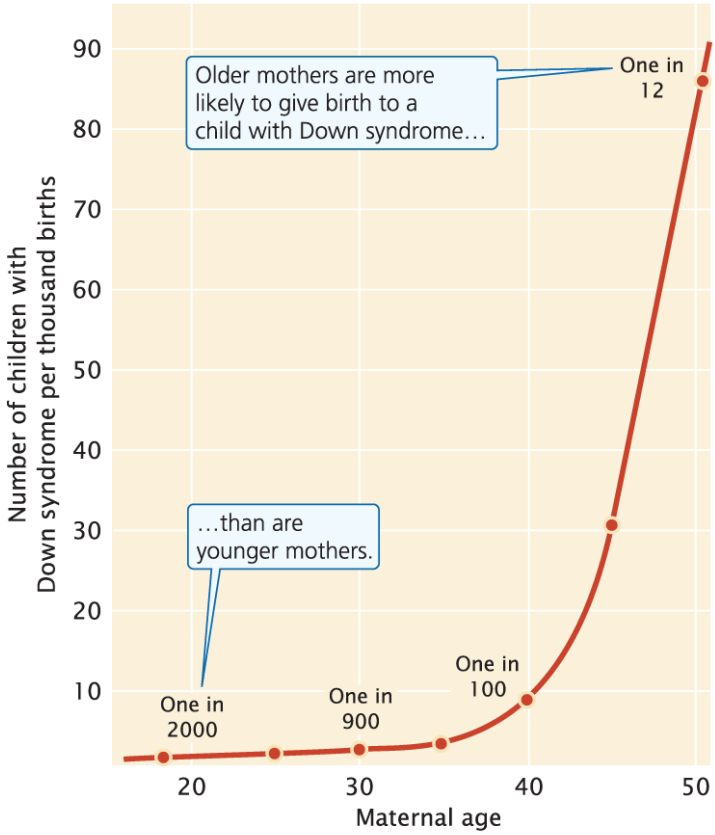
OTHER HUMAN TRISOMIES

Few autosomal aneuploidies in humans besides trisomy 21 result in live births. **Trisomy 18**, also known as **Edwards syndrome**, arises with a frequency of approximately 1 in 8000 live births. Babies with Edwards syndrome have severe intellectual disability, low-set ears, a short neck, deformed feet, clenched fingers, heart problems, and other disabilities. Few live for more than a year after birth. **Trisomy 13** has a frequency of about 1 in 15,000 live births and produces features that are collectively known as **Patau syndrome**. Characteristics of this condition include severe intellectual disability, a small head, a sloping forehead, small eyes, a cleft lip and palate, extra fingers and toes, and numerous other problems. About half of the children with trisomy 13 die within the first month of life, and 95% die by the age of three. Rarer still is **trisomy 8**, which arises with a frequency ranging from about 1 in 25,000 to 1 in 50,000 live births. This aneuploidy is characterized by intellectual disability, contracted fingers and toes, low-set malformed ears, and a prominent forehead. Most individuals born with this condition are mosaics, having some cells with three copies of chromosome 8 and other cells with the usual two copies (see the following discussion on genetic mosaicism). Complete trisomy 8, in which all cells in the

body have three copies of chromosome 8, usually results in spontaneous abortion.

ANEUPLOIDY AND MATERNAL AGE

Most cases of Down syndrome and other types of aneuploidy in humans arise from maternal nondisjunction, and the frequency of aneuploidy increases with maternal age (**Figure 8.24**). Why maternal age is associated with nondisjunction is not known for certain. Female mammals are born with primary oocytes suspended in the diplotene substage of prophase I of meiosis. Just before ovulation, meiosis resumes and the first division is completed, producing a secondary oocyte. At this point, meiosis is suspended again and remains so until the secondary oocyte is penetrated by a sperm. The second meiotic division takes place immediately before the nuclei of egg and sperm unite to form a zygote.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

8.24 The incidence of primary Down syndrome and other aneuploidies increases with maternal age.

Description

The horizontal axis represents maternal age from 20 to 50 with an interval of 10. The vertical axis represents number of children with Down syndrome per 1000 births and ranges from 0 to 90 with intervals of 10. The curve in the graph remains near the horizontal axis and starts to slope up at around age 35 and from age 40 to 50, there is a steep rise in the curve. The approximate data from graph are as follows:

For 20 years, 1 child in 2000 suffers from Down syndrome; for 30 years, 1 child in 900 suffers from Down syndrome; for 40 years, 1 child in 100 suffers from Down syndrome; and for 50 years, 1 child in 12 suffers from Down syndrome. A caption in the graph reads: Older mothers are more likely to give birth to a child with Down syndrome than are younger mothers.

Thus, primary oocytes may remain suspended in diplotene for many years before ovulation takes place and meiosis recommences. Cohesin (see Chapter 2) components of the spindle and other structures required for proper chromosome segregation may break down during the long arrest of meiosis, leading to more aneuploidy in children born to older mothers. No similar age effect is seen in males because sperm are produced continuously after puberty, with no long suspension of the meiotic divisions.

ANEUPLOIDY AND CANCER

Many tumor cells have extra chromosomes or missing chromosomes, or both; some types of tumors are consistently associated with specific chromosome mutations, including aneuploidy and chromosome rearrangements. The role of chromosome mutations in cancer will be explored in Chapter 23.

CONCEPTS

In humans, sex-chromosome aneuploidies are more common than autosomal aneuploidies. X-chromosome inactivation prevents problems of gene dosage for X-linked genes. Down syndrome results from three functional copies of chromosome 21, either through trisomy (primary Down syndrome) or a Robertsonian translocation (familial Down syndrome).

✔ CONCEPT CHECK 6

Briefly explain why, in humans and other mammals, sex-chromosome aneuploidies are more common than autosomal aneuploidies.

Uniparental Disomy

Normally, the two chromosomes of a homologous pair are inherited from two different parents—one from the father and one from the mother. The development of molecular techniques that facilitate the identification of specific DNA sequences (see Chapter 19) has made the determination of the parental origins of chromosomes possible. Surprisingly, these techniques have revealed that sometimes both chromosomes are inherited from the same parent, a condition termed **uniparental disomy**.

Many cases of uniparental disomy probably originate as trisomies. Although most autosomal trisomies are lethal, a trisomic embryo can survive if one of the three chromosomes is lost early in development. If, just by chance, the two remaining chromosomes are both from the same parent, uniparental disomy results.

Uniparental disomy violates the rule that children affected with a recessive disorder appear only in families in which both parents are carriers. For example, cystic fibrosis is an autosomal recessive disease; typically, both parents of an affected child are heterozygous for a cystic fibrosis mutation on chromosome 7. However, for a small proportion of people with cystic fibrosis, only one of the parents is heterozygous for a cystic fibrosis mutation. In these cases, cystic fibrosis is due to uniparental disomy: the person with cystic fibrosis has inherited two copies of the chromosome 7 that carries

the defective cystic fibrosis allele from the heterozygous parent and no copy of the normal allele from the other parent.

Uniparental disomy has also been observed in Prader–Willi syndrome, a rare condition that arises when a paternal copy of a gene on chromosome 15 is missing. Although most cases of Prader–Willi syndrome result from a chromosome deletion that removes the paternal copy of the gene (see Genomic Imprinting in Chapter 5), 20% to 30% of the cases arise when both copies of chromosome 15 are inherited from the mother and no copy is inherited from the father.

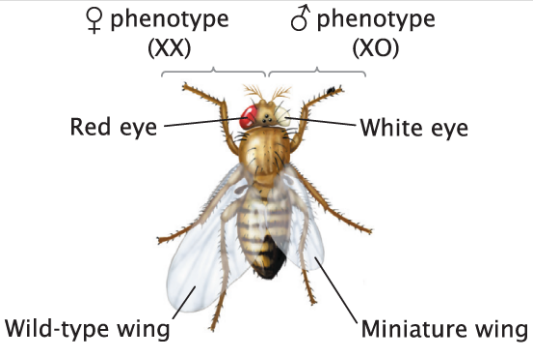
Genetic Mosaicism

Nondisjunction in a mitotic division may generate patches of cells in which every cell has a chromosome abnormality and other patches in which every cell has a normal karyotype. This type of nondisjunction leads to regions of tissue with different chromosome constitutions, a condition known as **genetic mosaicism** (see Chapter 6). Growing evidence suggests that genetic mosaicism is more common than is often recognized. For example, about 50% of those diagnosed with Turner syndrome (individuals with a single X chromosome) are actually mosaics, possessing some 45,X cells and some normal 46,XX cells. A few may even be mosaics for two or more abnormal karyotypes. The 45,X/46,XX mosaic usually arises

when an X chromosome is lost soon after fertilization in an XX embryo.

Fruit flies that are XX/XO mosaics (O designates the absence of a homologous chromosome; XO means that the cell has a single X chromosome and no Y chromosome) develop a mixture of male and female traits because the presence of two X chromosomes produces female traits, and the presence of a single X chromosome produces male traits (Figure 8.25). In fruit flies, sex is determined independently in each cell in the course of development. Those cells that are XX express female traits; those that are XO express male traits. Such sexual mosaics are called **gynandromorphs**. Normally, X-linked recessive genes are masked in heterozygous females, but in XX/XO mosaics, any X-linked recessive genes present in the cells with a single X chromosome will be expressed.

THINK-PAIR-SHARE Question 6



Pierce, *Genetics: A Conceptual Approach*, 7e
© 2020 W. H. Freeman and Company

8.25 Genetic mosaicism for the sex chromosomes produces a gynandromorph.
This XX/XO gynandromorph fruit fly carries one wild-type X chromosome and one

X chromosome with recessive alleles for white eyes and miniature wings. The left side of the fly has a normal female phenotype because the cells are XX and the recessive alleles on one X chromosome are masked by the presence of wild-type alleles on the other. The right side of the fly has a male phenotype with white eyes and miniature wings because the cells are missing the wild-type X chromosome (are XO), allowing the white and miniature alleles to be expressed.

Description

The gynandromorph fruit fly has female phenotype big X big X on the left side and male phenotype big X big O on the right side. On the left side, it has red eye and wild-type wing and on the right side, it has white eye and miniature wing.

CONCEPTS

In uniparental disomy, an individual organism has two copies of a chromosome from one parent and no copy from the other. Uniparental disomy may arise when a trisomic embryo loses one of the triplicate chromosomes early in development. In genetic mosaicism, different cells within the same individual organism have different chromosome constitutions.

8.4 Polyploidy Is the Presence of More Than Two Sets of Chromosomes

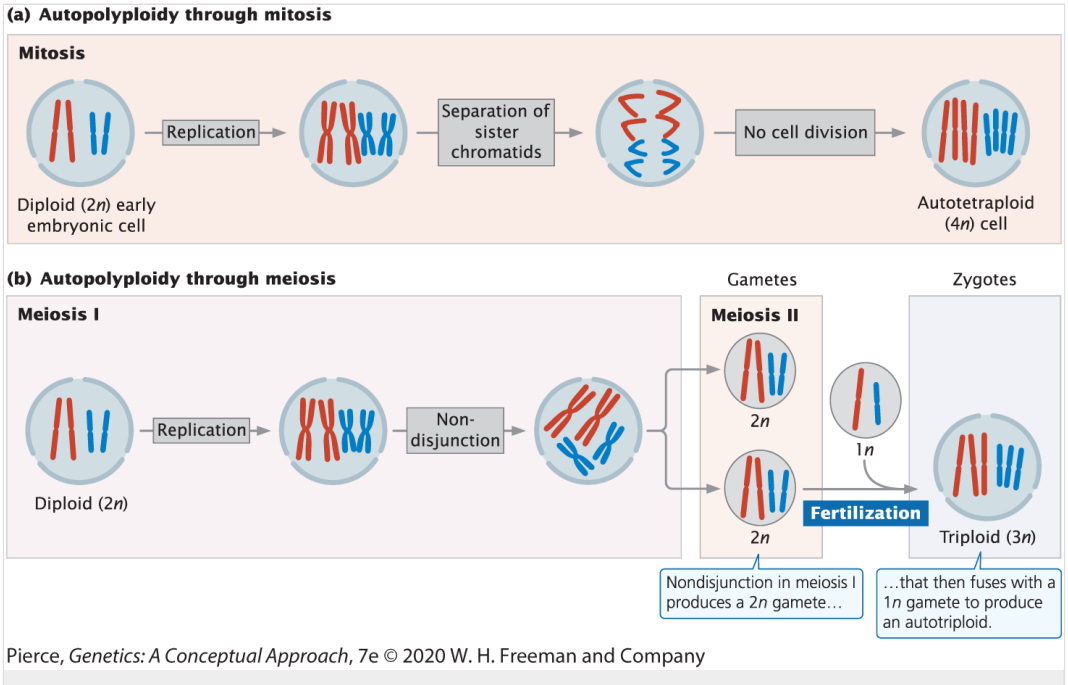
As discussed in the introduction to this chapter, some organisms (such as wheat) possess more than two sets of chromosomes—they are polyploid. Polyploids include *triploids* (3*n*), *tetraploids* (4*n*), *pentaploids* (5*n*), *hexaploids* (6*n*), and organisms with even higher numbers of chromosome sets.

Polyploidy is common in plants and is a major mechanism by which new plant species have evolved. Approximately 40% of all flowering-plant species and 70% to 80% of grasses are polyploids. A number of agriculturally important plants are polyploid, including wheat, oats, cotton, potatoes, and sugarcane. Polyploidy is less common in animals but is found in some invertebrates, fishes, salamanders, frogs, and lizards. No naturally occurring, viable polyploids are known in birds or mammals.

We consider two major types of polyploidy: **autopolyploidy**, in which all chromosome sets are from a single species, and **allopolyploidy**, in which chromosome sets are from two or more species.

Autopolyploidy

Autopolyploidy is caused by accidents of mitosis or meiosis that produce extra sets of chromosomes, all derived from a single species. Nondisjunction of all chromosomes in mitosis in an early 2*n* embryo, for example, doubles the chromosome number and produces an autotetraploid (4*n*), as depicted in Figure 8.26a. An autotriploid (3*n*) may arise when nondisjunction in meiosis produces a diploid gamete that then fuses with a normal haploid gamete to produce a triploid zygote (Figure 8.26b). Alternatively, triploids may arise from a cross between an autotetraploid that produces 2*n* gametes and a diploid that produces 1*n* gametes. Nondisjunction can be artificially induced by colchicine, a chemical that disrupts spindle formation. Colchicine is often used to induce polyploidy in agriculturally and ornamentally important plants.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

8.26 Autopolyploidy can arise through nondisjunction in mitosis or meiosis.

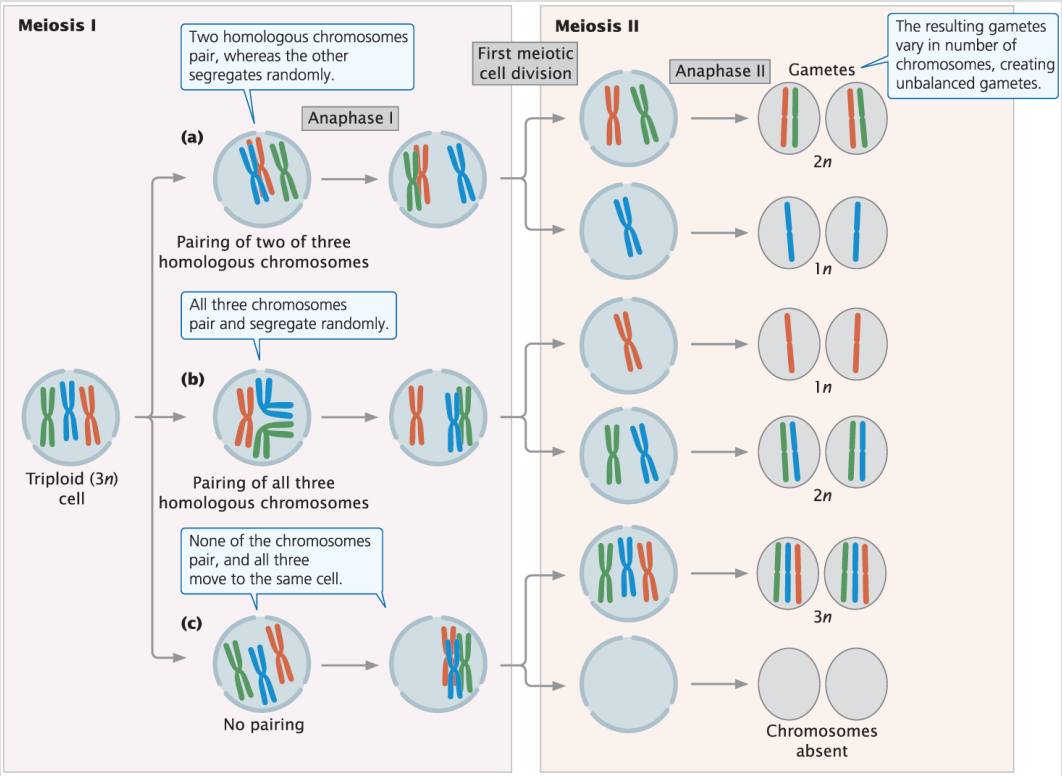
Description

Part a at the top shows autopolyploidy through mitosis. The illustration shows a diploid (2 n) early embryonic cell with 2 longer red and 2 relatively short blue chromatids. Replication occurs and the cell has 2 red large chromosomes and 2 blue smaller chromosomes. Separation of sister chromatids occurs and 4 chromatids move towards the right and 4 move towards the left of the cell. No cell division occurs and an autotetraploid (4 n) cell is produced. This cell has 4 longer red chromatids and 4 blue short chromatids.

Part b below shows a diploid (2 n) cell with 2 red longer and 2 blue short chromatids. Replication occurs and the cell has 2 red large chromosomes and 2 blue smaller chromosomes. Non-disjunction occurs and the chromosomes arrange randomly in the cell. Meiosis 2 occurs and gametes are produced. Each gamete is diploid (2 n) and has 2 red longer chromatids and 2 blue short chromatids each. A caption reads, Non-disjunction in meiosis I produces a 2 n gamete that then fuses with 1 n gamete to produce an autotriploid. One of these gametes is fertilized with a 1 n cell that has 1 red longer and 1 blue short chromatid. The zygote produced is a triploid (3 n) cell with 3 red longer and 3 blue short chromatids.

Because all the chromosome sets in autopolyploids are from the same species, they are homologous and attempt to align in prophase I of meiosis, which usually results in sterility. Consider meiosis in an autotriploid (**Figure 8.27**). In meiosis in a diploid cell, two homologs pair and align, but in autotriploids, three homologs are present. One of the three homologs may fail to align with the other two, and this unaligned chromosome will segregate randomly (see Figure 8.27a). Which gamete gets the extra chromosome will be determined by chance and will differ for each homologous trio of chromosomes. The resulting gametes will have two copies of some chromosomes and one copy of others. Even if all three chromosomes align, two

chromosomes must segregate to one gamete and one chromosome to the other (see Figure 8.27b). Occasionally, the presence of a third chromosome interferes with normal alignment, and all three chromosomes move to the same gamete (see Figure 8.27c).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

8.27 In meiosis in an autotriploid, homologous chromosomes can pair, or fail to pair, in three ways. This example illustrates the pairing and segregation of a single homologous set of chromosomes.

Description

In meiosis 1 at the left, the illustration shows a triploid cell (3 n) with three almost similar sized X-shaped chromosomes that are green, blue, and red. The illustration shows 3 different ways these chromosomes can segregate that are labeled as part a, b, and c.

Part a below shows pairing of two of three homologous chromosomes in meiosis 1 where the cell has red and blue pairing together while the green is aligned at a distance. A caption

reads, Two homologous chromosomes pair, whereas the other segregates randomly. Anaphase 1 occurs where a green and red pair together and blue remains at other end of the cell. First meiotic cell division occurs and next stage meiosis 2 is shown at the right. A cell has red and green chromosomes and another cell has only the blue chromosome. Anaphase 2 occurs and gametes are produced. The cell with the red and green chromosome produces 2 diploid (2 n) gametes with 1 red and 1 green chromatid each. The cell with blue chromosome produces 2 haploid (1 n) gametes with 1 blue chromatid each. A caption reads, The resulting gametes vary in number of chromosomes, creating unbalanced gametes.

Part b below shows pairing of all three homologous chromosomes in meiosis 1 where the cell has red, blue, and green chromosomes in close proximity with each other. This leads to cell where red chromosome is at one end while blue and green are paired together after anaphase 1. A caption reads, All three chromosomes pair and segregate randomly. First meiotic cell division occurs and next stage meiosis 2 is reached is shown at the right. One cell has only the red chromosome and another cell has blue and green chromosomes. Anaphase 2 occurs and gametes are produced. The cell with a red chromosome produces 2 haploid (1 n) gametes with 1 red chromatid each. The cell with blue and green chromosomes produces 2 diploid (2 n) gametes with 1 blue and 1 green chromatid each.

Part c below shows no pairing in meiosis 1where the cell has red, blue, and green chromosomes at a distance from each other. This leads to a cell where all the chromosomes move to the same side in the cell during anaphase 1. A caption reads, None of the chromosomes pair and all three move to the same cell. First meiotic cell division occurs and next stage meiosis 2 is reached is shown at the right. A cell has all three chromosomes and a cell has no chromosome. Anaphase 2 occurs and gametes are produced. The cell with all three chromosomes produces 2 (3 n) gametes with 1 blue, 1 red, and 1 green chromatid each. The cell with no chromosome produces 2 gametes with no chromosomes.

No matter how the three homologous chromosomes align, their random segregation will create **unbalanced gametes**, with various numbers of chromosomes. A gamete produced by meiosis in such an autotriploid might receive, say, two copies of chromosome 1, one

copy of chromosome 2, three copies of chromosome 3, and no copies of chromosome 4. When the unbalanced gamete fuses with a normal gamete (or with another unbalanced gamete), the resulting zygote has different numbers of the four types of chromosomes. This difference in number creates unbalanced gene dosage in the zygote, which is often lethal. For this reason, triploids do not usually produce viable offspring.

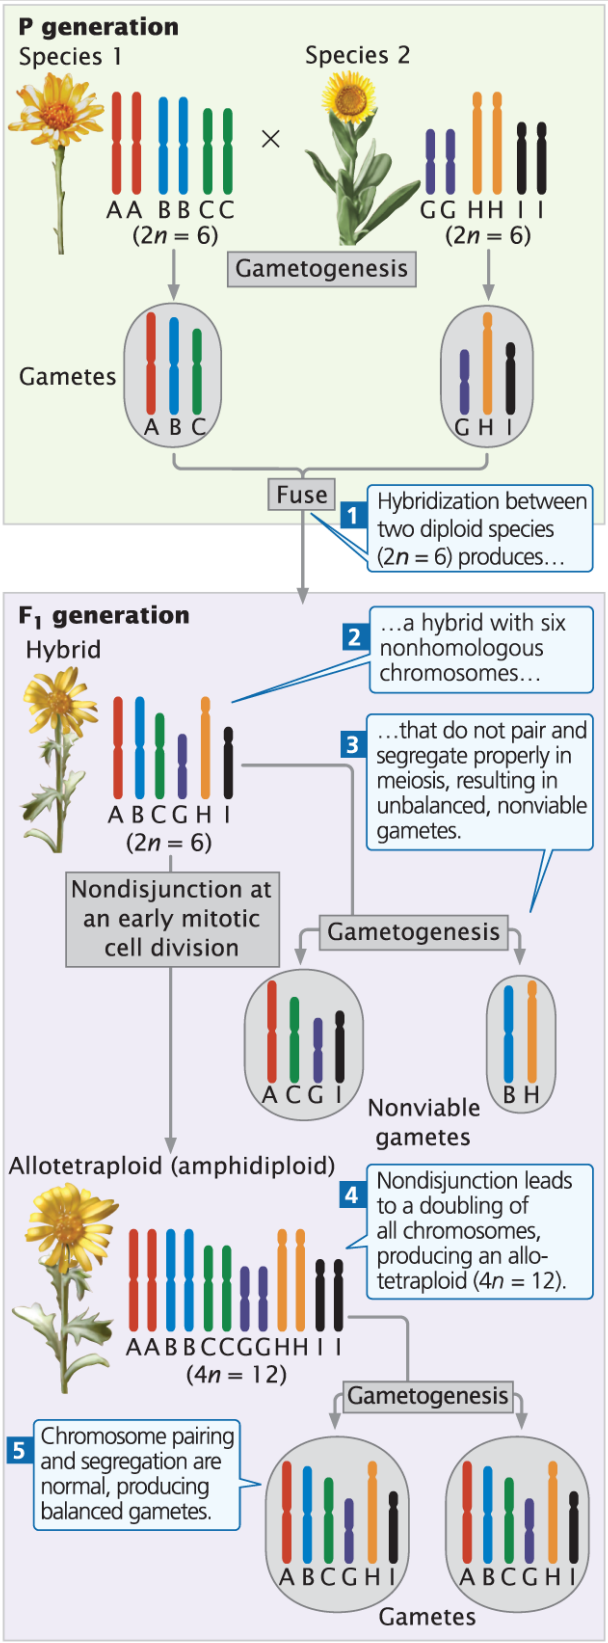
In even-numbered autopolyploids, such as autotetraploids, the homologous chromosomes can theoretically form pairs and divide equally. Equal division rarely takes place, however, so these types of autotetraploids also produce unbalanced gametes.

The sterility that usually accompanies autopolyploidy has been exploited in agriculture. Triploid bananas ($3n = 33$) are sterile and seedless. Similarly, seedless triploid watermelons have been created and are now widely sold.

Allopolyploidy

Allopolyploidy arises from hybridization between two species; the resulting polyploid carries chromosome sets derived from two or more species. **Figure 8.28** shows one mechanism for how allopolyploidy can arise from two species that are sufficiently related that hybridization takes place between them. Species I (AABBCC, $2n = 6$) produces haploid gametes with chromosomes ABC, and species

II (GGHHII, $2n = 6$) produces haploid gametes with chromosomes GHI. If gametes from species I and II fuse, a hybrid with six chromosomes (ABCGHI) is created. The hybrid has the same number of chromosomes as both diploid species, so the hybrid is considered diploid. However, because the hybrid chromosomes are not homologous, they will not usually pair and segregate properly in meiosis; thus, this hybrid is functionally haploid and sterile.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

8.28 Allopolyploids may arise from hybridization between two species followed by chromosome doubling.

Description
The diagram shows P generation at the top where species 1 is crossed with species 2. Species 1 has 3 pairs each of rod-shaped chromosomes big A, big B, and big C of varying lengths. A text reads, 2 n equals 6. Species 2 has 3 pairs each of rod-shaped chromosomes big G, big H, and big I of varying lengths. A text reads, 2 n equals 6. Gametogenesis occurs and the gametes are obatined below. The gametes produced by species 1 has one chromatid each of big A, big B, and big C. Gamete produced by species 2 has one chromatid each of big G, big H, and big I. These gametes fuse. A caption reads, Hybridization between two diploid species (2 n equals 6) produces a hybrid with six non-homologous chromosomes that do not pair and segregate properly in meiosis, resulting in unbalanced, non-viable gametes. A hybrid is obtained in F subscript 1 generation. The hybrid has one chromatid each of big A, big B, big C, big G, big H, and big I. A text reads, 2 n equals 6. This stage can progress in 2 conditions: gametogenesis and non-disjunction. First, gametogenesis occurs and 2 non-viable gametes are produced below. First gamete has one chromatid each of big A, big C, big G, and big I. Second gamete has one chromatid each of big B and big H. Second, non-disjunction at an early mitotic cell division occurs and an allotetraploid (amphidiploid) is produced below. This allotetraploid has a pair of each of chromosomes big A, big B, big C, big G, big H, and big I. A text reads, 4 n equals 12. A caption reads, Non-disjunction leads to a doubling of all chromosomes, producing an allotetraploid (4 n equals 12). Gametogenesis occurs and 2 gametes are produced. Both gametes have one chromatid each of big A, big B, big C, big G, big H, and big I. A caption reads, Chromosome pairing and segregation are normal, producing balanced gametes.

The sterile hybrid cannot produce viable gametes through meiosis, but it may be able to perpetuate itself through mitosis (asexual reproduction). On rare occasions, nondisjunction takes place in a mitotic division, which leads to a doubling of chromosome number and an allotetraploid with chromosomes AABBCCGGHHII. This type

of allopolyploid, consisting of two combined diploid genomes, is sometimes called an **amphidiploid**. Although the chromosome number has doubled compared with what was present in each of the parental species, the amphidiploid is functionally diploid: every chromosome has one and only one homologous partner, which is exactly what is required for proper segregation in meiosis. The amphidiploid can now undergo normal meiosis to produce balanced gametes with six chromosomes each. Allopolyploidy may also arise when nondisjunction during meiosis leads to a $2n$ gamete, which then fuses with a $1n$ or $2n$ gamete from a different species to produce a polyploid individual.

Georgii Karpechenko created polyploids experimentally in the 1920s. Cabbages (*Brassica oleracea*, $2n = 18$) and radishes (*Raphanus sativus*, $2n = 18$) are agriculturally important plants now, as they were then, but only the leaves of the cabbage and the roots of the radish are normally consumed. Karpechenko wanted to produce a plant that had cabbage leaves and radish roots so that no part of the plant would go to waste. Because both cabbages and radishes possess 18 chromosomes, Karpechenko was able to cross them successfully, producing a hybrid with $2n = 18$, but unfortunately the hybrid was sterile. After several crosses, Karpechenko noticed that one of his hybrid plants produced a few seeds. When planted, these seeds grew into plants that were viable and fertile. Analysis of their chromosomes revealed that the plants were allotetraploids, with $2n$

= 36 chromosomes. To Karpechenko's great disappointment, the new plants possessed the roots of a cabbage and the leaves of a radish.

WORKED PROBLEM

Species I has $2n = 14$ and species II has $2n = 20$. Give all possible chromosome numbers that may be found in the following individuals:

a. An autotriploid of species I.
b. An autotetraploid of species II.
c. An allotriploid formed from species I and species II.
d. An allotetraploid formed from species I and species II.

Solution Strategy

What information is required in your answer to the problem?

All possible chromosome numbers for individuals with the type of polyploidy indicated.

What information is provided to solve the problem?

- Species I has $2n = 14$ and species II has $2n = 20$.
- The type of polyploidy the individual possesses.

Solution Steps

The haploid number of chromosomes (n) for species I is 7, and that for species II is 10.

a. A triploid individual is $3n$. A common mistake is to assume that $3n$ means three times as many chromosomes as in a normal individual, but remember that normal individuals are $2n$. Because n for species I is 7 and all the chromosome sets of an autopolyploid are from the same species, $3n = 3 \times 7 = 21$.
b. An autotetraploid is $4n$ with all chromosome sets from the same species. The n for species II is 10, so $4n = 4 \times 10 = 40$.
c. A triploid is $3n$. By definition, an allopolyploid must have chromosome sets from two different species. An allotriploid could have $1n$ from species I and $2n$ from species II, or $(1 \times 7) + (2 \times 10) = 27$. Alternatively, it could have $2n$ from species I and $1n$ from species II, or $(2 \times 7) + (1 \times 10) = 24$. Thus, the number of chromosomes in an allotriploid could be 24 or 27.
d. A tetraploid is $4n$. By definition, an allotetraploid must have chromosome sets from at least two different species. An allotetraploid could have $3n$ from species I and $1n$ from species II, or $(3 \times 7) + (1 \times 10) = 31$; or $2n$ from species I and $2n$ from species II, or $(2 \times 7) + (2 \times 10) = 34$; or $1n$ from species I and $3n$ from species II, or $(1 \times 7) + (3 \times 10) = 37$. Thus, the number of chromosomes could be 31, 34, or 37.

» For additional practice, try **Problem 39** at the end of this chapter.

The Significance of Polyploidy

In many organisms, cell volume is correlated with nuclear volume, which in turn is determined by genome size. Thus, the increase in chromosome number in polyploidy is often associated with an increase in cell size, and many polyploids are physically larger than diploids. Breeders have used this effect to produce plants with larger leaves, flowers, fruits, and seeds. For example, as discussed in the introduction to the chapter, modern wheat is hexaploid ($6n = 42$) with chromosomes derived from three different wild species (Figure 8.1). As a result, the seeds of modern wheat are larger than those of its ancestors. Cultivated bananas are often polyploid. Most strains were created by crossing plants within and between two diploid species: *Musa acuminata* (genome = AA) and *Musa balbisiana* (genome = BB). Many cultivated strains are triploid, with three sets of chromosomes (AAA, AAB, or ABB), and others are tetraploid (AAAA, AAAB, AABB, or ABBB). Polyploid bananas generally have larger fruits than diploid bananas and many are seedless, making them more edible. Many other cultivated plants are also polyploid (**Table 8.2**).

TABLE 8.2 Examples of polyploid crop plants

Plant	Type of Polyploidy	Chromosome Sets	Chromosome Number
Potato	Autopolyploid	4*n*	48
Banana	Autopolyploid	3*n*	33
Peanut	Autopolyploid	4*n*	40
Sweet potato	Autopolyploid	6*n*	90

Tobacco	Allopolyploid	4*n*	48
Cotton	Allopolyploid	4*n*	52
Wheat	Allopolyploid	6*n*	42
Oats	Allopolyploid	6*n*	42
Sugarcane	Allopolyploid	8*n*	80
Strawberry	Allopolyploid	8*n*	56

Data from F. C. Elliot, *Plant Breeding and Cytogenetics* (New York: McGraw-Hill, 1958).

Polyploidy is less common in animals than in plants for several reasons. As discussed, allopolyploids require hybridization between different species, which happens less frequently in animals than in plants. Animal behavior often prevents interbreeding among species, and the complexity of animal development causes most interspecific hybrids to be nonviable. Many of the polyploid animals that do arise are in groups that reproduce through parthenogenesis (a type of reproduction in which the animal develops from an unfertilized egg). Thus, asexual reproduction may facilitate the development of polyploids, perhaps because the perpetuation of hybrid individuals through asexual reproduction provides greater opportunities for nondisjunction than does sexual reproduction. Only a few human polyploid babies have been reported, and most died within a few days of birth. Polyploidy—usually triploidy—is seen in about 10% of all spontaneously aborted human fetuses.

Although complete polyploidy, in which all cells are polyploid, is lethal in humans, significant numbers of autopolyploid cells do occur in some human tissues. For example, some liver cells and

heart cells are polyploid. Although the reason for polyploidy in these cells is unknown, the large cell size that results from polyploidy might be advantageous under certain circumstances. Polyploid cells are also found in many cancers. One study suggested that extra sets of chromosomes occur in 37% of all cancers.

THINK-PAIR-SHARE Question 7

IMPORTANCE OF POLYPLOIDY IN EVOLUTION

Polyploidy, particularly allopolyploidy, often gives rise to new species and has been particularly important in the evolution of flowering plants. Occasional genome doubling through polyploidy has been a major contributor to evolutionary success in several groups. For example, *Saccharomyces cerevisiae* (yeast) is a tetraploid, having undergone whole-genome duplication about 100 million years ago. The vertebrate genome has duplicated twice, once in the common ancestor of jawed vertebrates and again in the ancestor of fishes. Certain groups of vertebrates, such as some frogs and some fishes, have undergone additional duplications. Cereal plants have undergone several genome-duplication events.

The types of chromosome mutations we have discussed in this chapter are summarized in Table 8.3.

TABLE 8.3 Different types of chromosome mutations

Chromosome Mutation	Definition
Chromosome rearrangement	Change in chromosome structure
Chromosome duplication	Duplication of a chromosome segment
Chromosome deletion	Deletion of a chromosome segment
Inversion	Chromosome segment inverted 180 degrees
Paracentric inversion	Inversion that does not include the centromere in the inverted region
Pericentric inversion	Inversion that includes the centromere in the inverted region
Translocation	Movement of a chromosome segment to a nonhomologous chromosome or to another region of the same chromosome
Nonreciprocal translocation	Movement of a chromosome segment to a nonhomologous chromosome or to another region of the same chromosome without reciprocal exchange
Reciprocal translocation	Exchange between segments of nonhomologous chromosomes or between regions of the same chromosome
Aneuploidy	Change in number of individual chromosomes
Nullisomy	Loss of both members of a homologous pair
Monosomy	Loss of one member of a homologous pair
Trisomy	Gain of one chromosome, resulting in three homologous chromosomes
Tetrasomy	Gain of two homologous chromosomes, resulting in four homologous chromosomes
Polyploidy	Addition of entire chromosome sets
Autopolyploidy	Polyploidy in which extra chromosome sets are derived from the same species
Allopolyploidy	Polyploidy in which extra chromosome sets are derived from two or more species

CONCEPTS

Polyploidy is the presence of extra chromosome sets. Autopolyploids possess extra chromosome sets from the same species; allopolyploids possess extra chromosome sets from two or more species. Problems in chromosome pairing and segregation often lead to sterility in autopolyploids, but many allopolyploids are fertile.

✔ CONCEPT CHECK 7

Species A has $2n = 16$ and species B has $2n = 14$. How many chromosomes would be found in an allotriploid of these two species?

a. 21 or 24
b. 42 or 48
c. 22 or 23
d. 45

Chapter 8 Review

CHAPTER SUMMARY

Section 8.1 Learning Objective: Be able to define the major types of chromosome mutations.

- The three basic categories of chromosome mutations are: (1) chromosome rearrangements, which are changes in the structures of chromosomes; (2) aneuploidy, which is an increase or decrease in chromosome number; and (3) polyploidy, which is the presence of extra chromosome sets.

Section 8.2 Learning Objective: Be able to describe the major types of chromosome rearrangements and their effects.

- Chromosome rearrangements include duplications, deletions, inversions, and translocations.
- In individuals heterozygous for a duplication, the duplicated region forms a loop when homologous chromosomes pair in meiosis. Duplications often have pronounced effects on the phenotype owing to unbalanced gene dosage. Segmental duplications are common in the human genome.
- In individuals heterozygous for a deletion, one of the chromosomes loops out during pairing in meiosis. Deletions

may cause recessive alleles to be expressed.

- Pericentric inversions include the centromere; paracentric inversions do not. In individuals heterozygous for an inversion, the homologous chromosomes form inversion loops in meiosis, and reduced recombination is observed within the inverted region.
- In translocation heterozygotes, the chromosomes form crosslike structures in meiosis, and the segregation of chromosomes produces unbalanced gametes.
- Fragile sites are constrictions or gaps that appear at particular regions on the chromosomes of cells grown in culture and are prone to breakage under certain conditions.
- Copy-number variations (CNVs) are differences in the number of copies of DNA sequences and include duplications and deletions. These variants are common in the human genome; some are associated with diseases and disorders.

Section 8.3 Learning Objective: Be able to describe the different types of aneuploidy and their effects in humans.

- Nullisomy is the loss of two homologous chromosomes, monosomy is the loss of a single chromosome, trisomy is the addition of a single chromosome, and tetrasomy is the addition of two homologous chromosomes.
- Aneuploidy usually causes drastic phenotypic effects because it leads to unbalanced gene dosage.
- Primary Down syndrome is caused by the presence of three full copies of chromosome 21. Familial Down syndrome is caused

by the presence of two normal copies of chromosome 21 and a third copy that is attached to another chromosome through a translocation.
- Uniparental disomy is the presence of two copies of a chromosome from one parent and no copy from the other. Genetic mosaicism is caused by nondisjunction in an early mitotic division that leads to different chromosome constitutions in different cells of a single individual.

Section 8.4 Learning Objective: Be able to describe the different types of polyploidy and how they arise.

- All the chromosomes in an autopolyploid derive from one species; chromosomes in an allopolyploid come from two or more species.

WORKED PROBLEMS

Problem 1

A chromosome has the following segments, where • represents the centromere:

A B C D E • F G

What types of chromosome mutations are required to change this chromosome into each of the following chromosomes? (In some

cases, more than one chromosome mutation may be required.)

a. A B E • F G
b. A E D C B • F G
c. A B A B C D E • F G
d. A F • E D C B G
e. A B C D E E D C • F G

» Solution Strategy

What information is required in your answer to the problem?

The types of chromosome mutations that would lead to the chromosome shown.

What information is provided to solve the problem?

- The original segments found on the chromosome.
- The segments that are present after the mutations.

For help with this problem, review:

Section 8.2.

» Solution Steps

a. The mutated chromosome (A B E • F G) is missing segment CD, so this mutation is a deletion.

b. The mutated chromosome (A E D C B • F G) has one and only one copy of each original segment, but segment B C D E has been inverted 180 degrees. Because the centromere has not changed its location and is not in the inverted region, this chromosome mutation is a paracentric inversion.
c. The mutated chromosome (A B A B C D E • F G) is longer than normal, and we see that segment AB has been duplicated. This mutation is a tandem duplication.
d. The mutated chromosome (A F • E D C B G) is normal in length, but the order of the segments and the location of the centromere have changed; this mutation is therefore a pericentric inversion of region (B C D E • F).
e. The mutated chromosome (A B C D E E D C • F G) contains a duplication (C D E) that is also inverted, so this chromosome has undergone a duplication and a paracentric inversion.

Problem 2

Species I is diploid ($2n = 4$) with chromosomes AABB; related species II is diploid ($2n = 6$) with chromosomes MMNNOO. Give the chromosomes that would be found in individuals with the following chromosome mutations:

a. Autotriploidy in species I.
b. Allotetraploidy including species I and II.
c. Monosomy in species I.
d. Trisomy in species II for chromosome M.
e. Tetrasomy in species I for chromosome A.

f. Allotriploidy including species I and II.
g. Nullisomy in species II for chromosome N.

» Solution Strategy

What information is required in your answer to the problem?

The chromosomes found in individuals with each type of chromosome mutation.

What information is provided to solve the problem?

- Species I is diploid with $2n = 4$.
- Species I has chromosomes AABB.
- Species II is diploid with $2n = 6$.
- Species II has chromosomes MMNNOO.

For help with this problem, review:

Sections 8.3 and 8.4.

» Solution Steps

a. An autotriploid is $3n$, with all the chromosomes coming from a single species, so an autotriploid of species I would have chromosomes AAABBB ($3n = 6$).

Hint: First determine the haploid genome complement for each species. For species I, $n = 2$ with chromosomes AB, and for species II, $n = 3$ with chromosomes MNO.

b. An allotetraploid is $4n$, with the chromosomes coming from more than one species. An allotetraploid could consist of $2n$ from species I and $2n$ from species II, giving the allotetraploid ($4n = 2 + 2 + 3 + 3 = 10$) chromosomes AABBMMNNOO. An allotetraploid could also possess $3n$ from species I and $1n$ from species II ($4n = 2 + 2 + 2 + 3 = 9$; AAABBBMNO) or $1n$ from species I and $3n$ from species II ($4n = 2 + 3 + 3 + 3 = 11$; ABMMMNNNOOO).
c. A monosomic individual is missing a single chromosome, so monosomy in species I would result in $2n - 1 = 4 - 1 = 3$. The monosomy might include either of the two chromosome pairs, giving chromosomes ABB or AAB.
d. Trisomy requires an extra chromosome, so trisomy in species II for chromosome M would result in $2n + 1 = 6 + 1 = 7$ (MMMNNOO).
e. A tetrasomic individual has two extra homologous chromosomes, so tetrasomy in species I for chromosome A would result in $2n + 2 = 4 + 2 = 6$ (AAAABB).
f. An allotriploid is $3n$, with the chromosomes coming from two different species, so an allotriploid could be $3n = 2 + 2 + 3 = 7$ (AABBMNO) or $3n = 2 + 3 + 3 = 8$ (ABMMNNOO).
g. A nullisomic individual is missing both chromosomes of a homologous pair, so a nullisomy in species II for chromosome N would result in $2n - 2 = 6 - 2 = 4$ (MMOO).

ANSWERS TO CONCEPT CHECKS

1. a
2. Pseudodominance is the expression of a normally recessive mutation. It is produced when the dominant wild-type allele in a heterozygous individual is absent due to a deletion on one chromosome.
3. c
4. b
5. 37
6. Dosage compensation prevents the expression of additional copies of X-linked genes in mammals, and there is little information in the Y chromosome, so extra copies of the X and Y chromosomes do not have major effects on development. In contrast, there is no mechanism of dosage compensation for autosomes, and so extra copies of autosomal genes are expressed, upsetting developmental processes and causing the spontaneous abortion of aneuploid embryos.
7. c

Chapter 8 Assessment

COMPREHENSION QUESTIONS

Section 8.1

1. List the three basic categories of chromosome mutations, and define each one.

Section 8.2

2. Why do extra copies of genes sometimes cause drastic phenotypic effects?

3. Draw a pair of chromosomes as they would appear during synapsis in prophase I of meiosis in an individual heterozygous for a chromosome duplication.

4. What is haploinsufficiency?

5. What is the difference between a paracentric and a pericentric inversion?

6. How can inversions in which no genetic information is lost or gained cause phenotypic effects?

7. Explain, with the aid of a drawing, how a dicentric bridge is produced when crossing over takes place in an individual

heterozygous for a paracentric inversion.

8. Explain why recombination is suppressed in individuals heterozygous for paracentric and pericentric inversions.

9. How do translocations in which no genetic information is lost or gained produce phenotypic effects?

10. Sketch the chromosome pairing and the different segregation patterns that can arise in an individual heterozygous for a reciprocal translocation.

11. What is a Robertsonian translocation?

Section 8.3

12. List four major types of aneuploidy.

13. What is the difference between primary Down syndrome and familial Down syndrome? How does each type arise?

14. What is uniparental disomy, and how does it arise?

15. What is genetic mosaicism, and how does it arise?

Section 8.4

16. What is the difference between autopolyploidy and allopolyploidy? How does each arise?

17. Explain why autopolyploids are usually sterile, whereas allopolyploids are often fertile.

APPLICATION QUESTIONS AND PROBLEMS

Section 8.1

18. Examine the karyotypes shown in **Figure 8.2** and **Figure 8.3**. Are the individuals from whom these karyotypes were made males or females?

19. *Which types of chromosome mutations

    a. increase the amount of genetic material in a particular chromosome?

    b. increase the amount of genetic material in all chromosomes?

    c. decrease the amount of genetic material in a particular chromosome?

    d. change the position of DNA sequences in a single chromosome without changing the amount of genetic material?

    e. move DNA from one chromosome to a nonhomologous chromosome?

Section 8.2

20. *A chromosome has the following segments, where • represents the centromere:

    A B • C D E F G

What types of chromosome mutations are required to change this chromosome into each of the following chromosomes? (In some cases, more than one chromosome mutation may be required.)

a. A B A B • C D E F G

b. A B • C D E A B F G

c. A B • C F E D G

d. A • C D E F G

e. A B • C D E

f. A B • E D C F G

g. C • B A D E F G

h. A B • C F E D F E D G

i. A B • C D E F C D F E G

21. A chromosome initially has the following segments:

A B • C D E F G

Draw the chromosome, identifying its segments, that would result from each of the following mutations.

a. Tandem duplication of DEF

b. Displaced duplication of DEF

c. Deletion of FG

d. Paracentric inversion that includes DEFG

e. Pericentric inversion of BCDE

22. The following diagram represents two nonhomologous chromosomes:

A B • C D E F G

R S • T U V W X

What type of chromosome mutation would produce each of the following groups of chromosomes?

a. A B • C D

R S • T U V W X E F G

b. A U V B • C D E F G

R S • T W X

c. A B • T U V F G

R S • C D E W X

d. A B • C W G

R S • T U V D E F X

23. CONNECT *The *Notch* mutation is a deletion on the X chromosome of *Drosophila melanogaster*. Female flies heterozygous for *Notch* have an indentation on the margins of their wings; *Notch* is

lethal in the homozygous and hemizygous conditions. The *Notch* deletion covers the region of the X chromosome that contains the locus for white eyes, an X-linked recessive trait (see Chapter 4). Give the phenotypes and proportions of progeny produced in the following crosses.

a. A red-eyed Notch female is mated with a white-eyed male

b. A white-eyed Notch female is mated with a red-eyed male

c. A white-eyed Notch female is mated with a white-eyed male

24. The green-nose fly normally has six chromosomes: two metacentric and four acrocentric. A geneticist examines the chromosomes of an odd-looking green-nose fly and discovers that it has only five chromosomes; three of them are metacentric, and two are acrocentric. Explain how this change in chromosome number might have taken place.

25. *A wild-type chromosome has the following segments:

A B C • D E F G H I

Researchers have found individuals that are heterozygous for each of the following chromosome mutations. For each mutation, sketch how the wild-type and mutated chromosomes would pair in prophase I of meiosis, showing all chromosome strands.

a. A B C • D E F D E F G H I

b. A B C • D H I

c. A B C • D G F E H I

d. A B E D • C F G H I

26. For the chromosomes shown in **Figure 8.13**, draw the chromatids that would result from a two-strand double crossover: one crossover between C and D and the other crossover between D and E.

27.

*As discussed in this chapter, crossing over within a pericentric inversion produces chromosomes that have extra copies of some genes and no copies of other genes. The fertilization of gametes containing chromosomes with duplications or deletions often result in children with syndromes characterized by developmental delay, intellectual disability, abnormal development of organ systems, and early death. Maarit Jaarola and colleagues examined individual sperm cells of a male who was heterozygous for a pericentric inversion on chromosome 8 and determined that crossing over took place within the pericentric inversion in 26% of the meiotic divisions (M. Jaarola, R. H. Martin, and T. Ashley. 1998. *American Journal of Human Genetics* 63:218–224).

Assume that you are a genetic counselor (see Chapter 6) and that a couple seeks counseling from you. Both the man and the woman are phenotypically normal, but the woman is heterozygous for a pericentric inversion on chromosome 8. The man is karyotypically normal. What is the probability that

this couple will produce a child with a debilitating syndrome as the result of crossing over within the pericentric inversion?

28. *An individual heterozygous for a reciprocal translocation possesses the following chromosomes:

A B • C D E F G

A B • C D V W X

R S • T U E F G

R S • T U V W X

a. Draw the pairing arrangement of these chromosomes in prophase I of meiosis.

b. Diagram the alternate, adjacent-1, and adjacent-2 segregation patterns in anaphase I of meiosis.

c. Give the products that result from alternate, adjacent-1, and adjacent-2 segregation.

Section 8.3

29. CONNECT *Red–green color blindness is a human X-linked recessive disorder (see Chapter 4). A young man with a 47,XXY karyotype (Klinefelter syndrome) is color blind. His 46,XY brother is also color blind. Both parents have color vision. In which parent and where in meiosis did the nondisjunction that gave rise to the young man with Klinefelter syndrome take

place? Assume that no crossing over took place in prophase I of meiosis (see Chapter 2).

30.

Junctional epidermolysis bullosa (JEB) is a severe skin disorder that results in blisters over the entire body. The disorder is caused by autosomal recessive mutations at any one of three loci that help to encode laminin 5, a major component in the dermal–epidermal basement membrane. Leena Pulkkinen and colleagues described a male newborn who was born with JEB and died at 2 months of age (L. Pulkkinen et al. 1997. *American Journal of Human Genetics* 61:611–619); the child had healthy, unrelated parents. Chromosome analysis revealed that the infant had 46 normal-appearing chromosomes. Analysis of DNA showed that his mother was heterozygous for a JEB-causing allele at the *LAMB3* locus, which is on chromosome 1. The father had two normal alleles at this locus. DNA fingerprinting demonstrated that the male assumed to be the father had, in fact, conceived the child.

a. Assuming that no new mutations occurred in this family, explain the presence of an autosomal recessive disease in the child when the mother is heterozygous and the father is homozygous normal.

b. How might you go about proving your explanation? Assume that a number of genetic markers are available for each chromosome.

31.

In contrast to the fact that older women give birth to more children with Down syndrome, a few studies have demonstrated that children of *young* fathers are more likely to

have Down syndrome than those of older males. Other research has observed that the spermatocytes of juvenile mice have fewer crossovers (see Chapter 2) than the spermatocytes of adult male mice (M. J. Zelazowski et al. 2017. *Cell* 171:601–614). How might fewer crossovers in younger males result in higher rates of children with aneuploidy?

32.

Some people with Turner syndrome (see Chapter 4) are 45,X/46,XY mosaics. Explain how this mosaicism could arise.

33. *Bill and Betty have had two children with Down syndrome. Bill's brother has Down syndrome, and his sister has two children with Down syndrome. On the basis of these observations, indicate which of the following statements are most likely correct and which are most likely incorrect. Explain your reasoning.

a. Bill has 47 chromosomes.

b. Betty has 47 chromosomes.

c. Bill and Betty's children each have 47 chromosomes.

d. Bill's sister has 45 chromosomes.

e. Bill has 46 chromosomes.

f. Betty has 45 chromosomes.

g. Bill's brother has 45 chromosomes.

34. In mammals, sex-chromosome aneuploids are more common than autosomal aneuploids, but in fishes, sex-chromosome aneuploids and autosomal aneuploids are found with equal frequency. Offer a possible explanation for these differences between mammals and fishes. (Hint: Think about why sex-chromosome aneuploids are more common than autosomal aneuploids in mammals.)

35. *A young couple is planning to have children. Knowing that there have been a substantial number of stillbirths, miscarriages, and fertility problems on the husband's side of the family, they see a genetic counselor. A chromosome analysis reveals that whereas the woman has a normal karyotype, the man possesses only 45 chromosomes and is a carrier of a Robertsonian translocation between chromosomes 22 and 13.

    a. List all the different types of gametes that might be produced by the man.

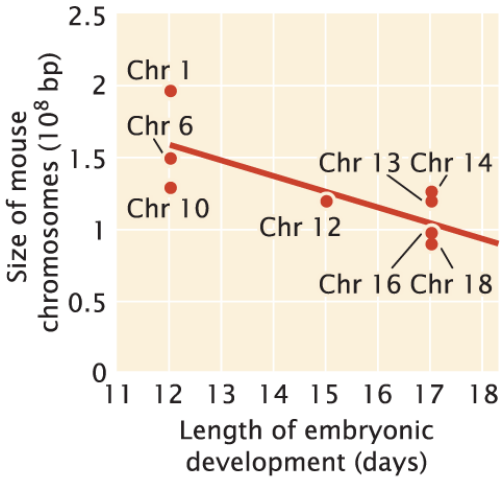
    b. What types of zygotes will develop when each of the gametes produced by the man fuses with a normal gamete produced by the woman?

    c. If trisomies and monosomies entailing chromosomes 13 and 22 are lethal, approximately what proportion of the surviving offspring are expected to be carriers of the translocation?

36.

Using breeding techniques, Andrei Dyban and V. S. Baranov (*Cytogenetics of Mammalian Embryonic Development*. Oxford: Oxford University Press, Clarendon Press; New York: Oxford University Press, 1987) created mice that were trisomic for each of the different mouse chromosomes. They found that only mice with

trisomy 19 developed. Mice that were trisomic for all other chromosomes died in the course of development. For some of these trisomics, the researchers plotted the length of development (number of days after conception before the embryo died) as a function of the size of the mouse chromosome that was present in three copies (see the adjoining graph). Summarize their findings, and provide a possible explanation for the results.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

[E. Torres, B. R. Williams, and A. Amon. 2008. *Genetics* 179:737–746, Fig. 2B.]

Description

The horizontal axis represents length of embryonic development in days from 11 to 18 with an interval of 1. The vertical axis represents size of mouse chromosomes in 10 to the power of 8 base pairs from 0 to 2 point 5 with an interval of 0 point 5. Dots on the graph represent chromosomes 1, 6, 10, 12, 13, 14, 16, and 18. The approximate data from the graph are as follows: Chromosome 1 corresponds to 12 days and size 2. Chromosome 6 corresponds to 12 days and size 1 point 5. Chromosome 10 corresponds to 12 days and size 1 point 3. Chromosome 12 corresponds to 15 days and size 1 point 2. Chromosome 13 and 14 corresponds to 17 days and size 1 point 2, and Chromosomes 16 and 18 corresponds to 17 days and size 1. A line starts from (12, 1 point 6) and ends at (18, 1).

Section 8.4

37. Species I has $2n = 16$ chromosomes. How many chromosomes will be found per cell in each of the following mutants in this species?

    a. Monosomic

    b. Autotriploid

    c. Autotetraploid

    d. Trisomic

    e. Double monosomic

    f. Nullisomic

    g. Autopentaploid

    h. Tetrasomic

38. Species I is diploid ($2n = 8$) with chromosomes AABBCCDD; related species II is diploid ($2n = 8$) with chromosomes MMNNOOPP. What types of chromosome mutations do individuals with the following sets of chromosomes have?

    a. AAABBCCDD

    b. MMNNOOOOPP

    c. AABBCDD

    d. AAABBBCCCDDD

e. AAABBCCDDD

f. AABBDD

g. AABBCCDDMMNNOOPP

h. AABBCCDDMNOP

39. *Species I has $2n = 8$ chromosomes and species II has $2n = 14$ chromosomes. What would the expected chromosome numbers be in individuals with the following chromosome mutations? Give all possible answers.

    a. Allotriploidy including species I and II

    b. Autotetraploidy in species II

    c. Trisomy in species I

    d. Monosomy in species II

    e. Tetrasomy in species I

    f. Allotetraploidy including species I and II

40. Suppose that species I in **Figure 8.28** had $2n = 10$ and species II in that figure had $2n = 12$. How many chromosomes would be present in the allotetraploid at the bottom of the figure?

41. Consider a diploid cell that has $2n = 4$ chromosomes: one pair of metacentric chromosomes and one pair of acrocentric chromosomes. Suppose that this cell undergoes nondisjunction, giving rise to an autotriploid cell ($3n$). The triploid cell then

undergoes meiosis. Draw the different types of gametes that could result from meiosis in the triploid cell, showing the chromosomes present in each type. To distinguish between the different metacentric and acrocentric chromosomes, use a different color to draw each metacentric chromosome; similarly, use a different color to draw each acrocentric chromosome. (Hint: See **Figure 8.27**.)

42. Assume that the autotriploid cell in **Figure 8.27** has $3n = 30$ chromosomes. For each of the gametes produced by this cell, give the chromosome number of the zygote that would result if the gamete fused with a normal haploid gamete.

43.

Nicotiana glutinosa ($2n = 24$) and *Nicotiana tabacum* ($2n = 48$) are two closely related plants that can be intercrossed, but the F_1 hybrid plants that result are usually sterile. In 1925, Roy Clausen and Thomas Goodspeed crossed *N. glutinosa* and *N. tabacum* and obtained one fertile F_1 plant (R. E. Clausen and T. H. Goodspeed. 1925. *Genetics* 10:278–284). They were able to self-pollinate the flowers of this plant to produce an F_2 generation. Surprisingly, the F_2 plants were fully fertile and produced viable seeds. When Clausen and Goodspeed examined the chromosomes of the F_2 plants, they observed 36 pairs of chromosomes in metaphase I and 36 individual chromosomes in metaphase II. Explain the origin of the F_2 plants obtained by Clausen and Goodspeed and the numbers of chromosomes observed.

44. What would be the chromosome number of progeny resulting from the following crosses in wheat (see **Figure 8.1**)? What type of

polyploid (allotriploid, allotetraploid, etc.) would result from each cross?

a. Einkorn wheat and Emmer wheat

b. Bread wheat and Emmer wheat

c. Einkorn wheat and bread wheat

45.

Karl and Hally Sax crossed *Aegilops cylindrica* ($2n = 28$), a wild grass found in the Mediterranean region, with *Triticum vulgare* ($2n = 42$), a type of wheat (K. Sax and H. J. Sax. 1924. *Genetics* 9:454–464). The resulting F_1 plants from this cross had 35 chromosomes. Examination of metaphase I in the F_1 plants revealed the presence of 7 pairs of chromosomes (bivalents) and 21 unpaired chromosomes (univalents).

a. If the unpaired chromosomes segregate randomly, what possible chromosome numbers will appear in the gametes of the F_1 plants?

b. What does the appearance of the bivalents in the F_1 hybrids suggest about the origin of *T. vulgare* wheat?

Left: Sam Brinker, MNR-NHIC, 2008/Canadian Food Inspection Agency.; right: Michael Hieber/ 123RF.com.

Aegilops cylindrica, jointed goatgrass. and *Triticum vulgare*, a type of wheat.

CHALLENGE QUESTIONS

Section 8.3

46. CONNECT Red–green color blindness is a human X-linked recessive disorder (see Chapter 4). Jill has normal color vision, but her father is color blind. Jill marries Tom, who also has normal color vision. Jill and Tom have a daughter who has Turner syndrome (Chapter 4) and is color blind.

    a. How did the daughter inherit color blindness?

    b. Did the daughter inherit her X chromosome from Jill or from Tom?

47. Progeny of triploid tomato plants often contain parts of an extra chromosome, in addition to the normal complement of 24 chromosomes (J. W. Lesley and M. M. Lesley. 1929. *Genetics* 14:321–336). Mutants with a part of an extra chromosome are referred to as secondaries. James and Margaret Lesley observed that secondaries arise from triploid ($3n$), trisomic ($3n + 1$), and double trisomic ($3n + 1 + 1$) parents, but never from diploids ($2n$). Give one or more possible reasons that secondaries arise from parents that have unpaired chromosomes but not from parents that are normal diploids.

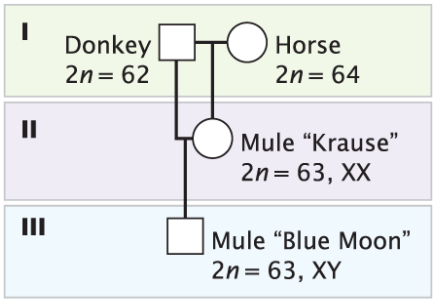
48. Mules result from a cross between a horse ($2n = 64$) and a donkey ($2n = 62$), have 63 chromosomes, and are almost always sterile. However, in the summer of 1985, a female mule named Krause, who was pastured with a male donkey, gave birth to a male foal (O. A. Ryder et al. 1985. *Journal of Heredity* 76:379–381). Blood tests established that the foal, appropriately named Blue Moon, was the offspring of Krause and that Krause was indeed a mule. Both Blue Moon and Krause were fathered by the same donkey (see the accompanying pedigree). The foal, like his mother, had 63 chromosomes—half of them horse chromosomes and the other half donkey chromosomes. Analyses of genetic markers showed that, remarkably, Blue Moon seemed to have inherited a complete set of horse chromosomes from his mother, instead of the random mixture of horse and donkey chromosomes that would be expected with normal meiosis. Thus, Blue Moon and Krause were not only mother and son but also brother and sister.

a. With the use of a diagram, show how, if Blue Moon inherited only horse chromosomes from his mother, Krause and Blue

Moon are mother and son as well as sister and brother.

b. Although rare, additional cases of fertile mules giving birth to offspring have been reported. In these cases, when a female mule mates with a male horse, the offspring is horselike in appearance, but when a female mule mates with a male donkey, the offspring is mulelike in appearance. Is this observation consistent with the idea that the offspring of fertile female mules inherit only a set of horse chromosomes from their mule mothers? Explain your reasoning.

c. Can you suggest a possible mechanism for how fertile female mules might pass on a complete set of horse chromosomes to their offspring?



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description
Generation 1 shows a male donkey (2 n equals 62) crossed with a female horse (2 n equals 64). They have a female mule progeny named Krause in generation 2 (2 n equals 63, big X big X). The male donkey from generation 1 mates with Krause from generation 2 to have a male mule named Blue Moon in generation 3 (2 n equals 63, big X big Y).

Section 8.4

49. Humans and many other complex organisms are diploid, possessing two sets of genes, one inherited from the mother and one from the father. However, a number of eukaryotic organisms spend most of their life cycles in a haploid state. Many of these eukaryotes, such as *Neurospora* and yeast, still undergo meiosis and sexual reproduction, but most of the cells that make up the organism are haploid.

    Considering that haploid organisms are fully capable of sexual reproduction and generating genetic variation, why are most complex eukaryotes diploid? In other words, what might be the evolutionary advantage of existing in a diploid state instead of a haploid state? And why might a few organisms, such as *Neurospora* and yeast, exist as haploids?

ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Section 8.1

1. Why do species usually have a characteristic number of chromosomes? Why don't we see many species in which chromosome number varies within the species, with some individuals having, say, $2n = 20$ and others having $2n = 24$?

Section 8.2

2. An individual is heterozygous for a reciprocal translocation, with the following chromosomes:
   A • B C D E F
   A • B C V W X
   R S T • U D E F
   R S T • U V W X

   a. Draw a picture of these chromosomes pairing in prophase I of meiosis.

   b. Draw the products of alternate, adjacent-1, and adjacent-2 segregations.

   c. Explain why the fertility of this individual is likely to be less than the fertility of an individual without a translocation.

Section 8.3

3. Monozygotic (identical) twins arise when a single egg, fertilized by a single sperm, divides early in development, giving rise to two genetically identical embryos (see Chapter 6). A recent study examined a pair of monozygotic twins in which one of the twins had trisomy 21 and the other twin had two normal copies of chromosome 21. Explain how two identical twins could differ in their number of chromosomes.

4. The human X chromosome is about the same size as human chromosomes 4 and 5. Trisomy of the X chromosome occurs about once in every thousand human female births, and yet trisomy 4 and trisomy 5 are almost never seen among living humans. Why do

these differences in the frequency of trisomic individuals occur, in spite of similar chromosome size?

5. Humans, compared to other organisms, exhibit a high level of chromosome nondisjunction resulting in aneuploid embryos, most of which are spontaneously aborted. Most of the nondisjunction occurs during oogenesis and is related to deficient crossover maturation in females. A specific genetic variant that increases the frequency of aneuploidy in humans has been discovered, and this variant occurs in high frequency in some human populations (see Aneuploidy in Humans in Section 8.3). These observations have led some researchers to speculate that the high frequency of chromosome nondisjunction observed in human females was adaptive in the past and was favored by natural selection. This might seem counterintuitive, because most aneuploids in humans are spontaneously aborted and result in lower fertility. Propose one or more explanations for why nondisjunction leading to aneuploidy might have been adaptive and favored by natural selection during human evolution.

6. In Chapter 2, we learned that the two chromosomes of a homologous pair carry information for the same characteristics but are not identical, having different alleles. Would you ever expect the two chromosomes of a homologous pair to be identical? If so, how might that occur? If not, why not?

Section 8.4

7. Trisomics often have more developmental problems than triploids. Can you suggest a reason why?

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Introduction

1. Draw a concept map that illustrates the origins of modern wheat.

Section 8.2

2. Draw a concept map that compares and contrasts the results of chromosome pairing in individuals heterozygous for paracentric and pericentric inversions.

Section 8.3

3. Show the relationships among the different types of human aneuploidy by creating a concept map that includes at least the following terms: Klinefelter syndrome, sex-chromosome aneuploids, aneuploidy in humans, autosomal aneuploids, Down syndrome, Edwards syndrome, Turner syndrome, Patau syndrome, trisomy 8.

Sections 8.1, 8.2, and 8.3

4. Create a concept map that outlines the major types of chromosome mutations, including their differences and similarities. Include at least the following terms: autopolyploidy, chromosome mutation, monosomy, chromosome rearrangements, aneuploidy, duplication, deletion, inversion, allopolyploidy

translocation, paracentric inversion, pericentric inversion, reciprocal translocation, nonreciprocal translocation, trisomy, polyploidy, nullisomy, tetrasomy.

CHAPTER 9

Bacterial and Viral Genetic Systems

REUTERS/Rupak de Chowdhuri (INDIA).

Woman with leprosy, a disease caused by the bacterium *Mycobacterium leprae*. The study of *M. leprae* DNA isolated from ancient skeletons of medieval Europeans with leprosy has provided information about the evolution of this bacterium.

The Genetics of Medieval Leprosy

Leprosy, one of the most feared diseases in history, was well known in ancient times, and people with leprosy were frequently ostracized from society. Although leprosy is successfully treated today with antibiotics, it remains a major public health problem: from 2 million to 3 million people worldwide are disabled by leprosy, and over 200,000 new cases are reported each year. In its severest form, leprosy causes paralysis, blindness, and disfigurement. Leprosy is caused by the bacterium *Mycobacterium leprae*, which infects cells of the nervous system—although human genes do play a role in susceptibility to this disease.

In 2013, geneticists isolated DNA of *M. leprae* from five skeletons of medieval Europeans who exhibited signs of leprosy. Their comparisons of the gene sequences of these ancient bacteria with those of modern strains provided insight into the evolution of this organism. Scientists had previously determined the genome sequence of *M. leprae* and found that it contains 3,268,203 base pairs of DNA, 1 million base pairs fewer than the genomes of other mycobacteria. In most bacterial genomes, the vast majority of the DNA encodes proteins—little DNA lies between the protein-encoding genes. In contrast, only 50% of the DNA of *M. leprae* encodes proteins. *M. leprae* also has 2300 fewer genes than its close relative *M. tuberculosis*. An incredible 27% of *M. leprae*'s genome consists of nonfunctional copies of genes (called pseudogenes) that have been inactivated by mutations. Its reduced DNA content, fewer functional genes, and large number of pseudogenes suggest

that evolutionarily, the genome of *M. leprae* has undergone massive decay over time, losing DNA and acquiring mutations that have inactivated many of its genes. Although the reasons for this decay are not known, it helps account for *M. leprae*'s long generation time —14 days in humans, an incredibly long replication time for a bacterium—and the inability of scientists to culture the bacteria in the laboratory.

Leprosy was common in Europe until the Middle Ages, when it disappeared from the population. Why did it disappear from Europe, despite remaining common in many other parts of the world? To address this question, geneticists extracted DNA from the bones and teeth of five medieval skeletons (dating from the eleventh to the fourteenth centuries) exhumed from cemeteries in Denmark, Sweden, and the United Kingdom. They separated out the DNA of *M. leprae* and determined whole-genome sequences for the bacteria. They then compared the DNA sequences of these medieval strains of *M. leprae* with those of modern strains from India, Thailand, the United States, Brazil, and other locations.

This analysis revealed that the ancient strains of *M. leprae* were remarkably similar to modern strains. Three of the ancient strains were most closely related to modern strains from Iran and Turkey, suggesting a Middle Eastern–European connection to the disease. Some of the ancient strains were closely related to modern *M. leprae* currently found in the United States, suggesting that these North

American bacteria originated in Europe. The close similarity between ancient European strains and a modern virulent strain from North America suggests that leprosy did not disappear from Europe because it lost its virulence. More likely, improved social conditions, changes in the immunity of Europeans, or the presence of other infectious diseases brought about the demise of leprosy in Europe. This study of leprosy illustrates the importance of genetic studies of bacteria to human health and shows how modern tools of evolutionary and molecular genetics are being applied to our understanding of bacterial biology.

THINK-PAIR-SHARE

- In the ancient world, leprosy was greatly feared, and people with the disease were often ostracized from society. Why was leprosy so feared? Are there modern diseases that evoke similar fears and for which infected people are ostracized? If so, give some examples. What characteristics of a disease produce this response on the part of society? Are any of these modern diseases caused by bacteria or viruses?
- Genetic analysis of *M. leprae*, the bacterium that causes leprosy, reveals that its genome has undergone decay over time, losing DNA and acquiring mutations that make some of its genes nonfunctional. What might be some potential reasons for this evolutionary decay of its genome?

In this chapter, we examine some of the genetic properties of bacteria and viruses, and the mechanisms by which they exchange and recombine their genes.

9.1 Bacteria and Viruses Have Important Roles in Human Society and the World Ecosystem

The genetic systems of bacteria and viruses are studied because these organisms play critically important roles in human society and the world ecosystem. Viruses infect all living organisms and are, by far, the most common biological entity on Earth. They are the cause of many important diseases. Bacteria in the oceans produce 50% of the oxygen in the air and remove roughly 50% of the carbon dioxide. Bacteria and viruses also play critical roles in agriculture, serving as economically important pathogens of crops and domesticated animals, but also providing nitrogen, phosphorus, and other essential nutrients to our food plants. Bacteria are found naturally in the mouth, in the gut, and on the skin, where they are essential to human function and ecology. These complex communities of bacteria protect us from disease and are essential for digestion and other physiological functions.

Bacteria and viruses have immense medical significance because they cause many human diseases. Infectious diseases are one of the leading causes of death worldwide, although many of these diseases can be controlled through antibiotics and vaccines. Bacteria have also been harnessed to produce a number of economically important substances, including drugs, hormones, food additives,

and other chemicals and compounds. And viruses are now being used in gene therapies.

Bacteria and viruses are also important in the study of genetics because they possess a number of characteristics that make them suitable for genetic analysis (Table 9.1). Their simple genetic systems have a number of features in common with the genetic systems of humans and other more complex organisms, so information gleaned from the genetic study of bacteria and viruses often provides important insight into genetic principles that are applicable to many other organisms.

TABLE 9.1 Advantages of using bacteria and viruses for genetic studies

1. Reproduction is rapid.
2. Many progeny can be produced.
3. The haploid genome allows all mutations to be expressed directly.
4. Asexual reproduction simplifies the isolation of genetically pure strains.
5. Growth in the laboratory is easy and requires little space.
6. Genomes are small.
7. Techniques are available for isolating and manipulating their genes.
8. They have medical importance.
9. They can be genetically engineered to produce substances of commercial value.

Life in a Bacterial World

Humans like to think that we rule the world, but we are clearly in a minor position compared with bacteria. Bacteria first evolved some 3.5 billion years ago, 2 billion years before the first eukaryotes appeared (or perhaps even earlier, as suggested by some evidence). Today, bacteria are found in every conceivable environment, including boiling springs, highly saline lakes, and beneath more than 2 miles of ice in Antarctica. They are found at the top of Mount Everest and at the bottom of the deepest oceans. They are also present on and in *us*—in astounding numbers! Within the average human gut, there are approximately 10 trillion bacteria, ten times the total number of cells in the entire human body. No one knows how many bacteria populate the world, but an analysis conducted by scientists in 1998 estimated that the total number of living bacteria on Earth exceeded 5 million trillion trillion (5×10^{30}).

Bacteria are not only numerically vast but also constitute the majority of life's diversity. The total number of *described* species of bacteria is less than 10,000, compared with about 1.4 million plants, animals, fungi, and single-celled eukaryotes. But the number of described species of bacteria falls far short of the true microbial diversity.

Species of bacteria are typically described only after they have been cultivated and studied in the laboratory. Because only a few species are amenable to laboratory culture, it was impossible for many years to identify and study most bacteria. Then, in the 1970s,

molecular techniques for analyzing DNA became available and opened up a whole new vista on microbial diversity. These techniques revealed several important facts about bacteria. First, many of the relations among bacteria that microbiologists had worked out on the basis of their physical and biochemical traits turned out to be incorrect. Bacteria once thought to be related were in fact genetically quite different. Second, molecular analysis showed that members of one group of microbes—now called the archaea—are as different from other bacteria as they are from eukaryotes. Third, molecular analysis revealed that the number of different types of bacteria is astounding.

In 2007, Luiz Roesch and his colleagues set out to determine exactly how many types of bacteria exist in a gram of soil. They obtained soil samples from four locations: Brazil, Canada, and Florida and Illinois in the United States. From these soil samples, they extracted and purified bacterial DNA. Using this DNA, they determined the sequences of a gene present in all bacteria, the 16S rRNA gene. Each bacterial species has a unique 16S rRNA gene sequence, so the researchers could determine how many species of bacteria existed in each soil sample by counting the different DNA sequences.

Roesch's results were amazing. The number of different types of bacterial DNA in each gram of soil ranged from 26,140 for samples from Brazil to 53,533 for Canadian samples. Many unusual bacteria were detected, which appeared dissimilar to any previously described groups of bacteria. Another interesting finding was that

soil from agricultural fields harbored considerably fewer species than did soil from forests.

This study and others demonstrate that bacterial diversity far exceeds that of multicellular organisms, and undoubtedly, numerous groups of bacteria have yet to be discovered. In 2010, researchers founded the Earth Microbiome Project, the focus of which is to sample microbial communities in diverse environments across the globe, with the aim of increasing our understanding of the microbial world and how it is organized. Like it or not, we truly live in a bacterial world. ❯ **TRY PROBLEM 18**

THINK-PAIR-SHARE Question 1

Bacterial Diversity

Prokaryotes, as we saw in Chapter 2, are unicellular organisms that lack nuclear membranes and membrane-bounded organelles. For many years, biologists considered all prokaryotes to be related, but in recent years scientists have developed methods to isolate the DNA from bacteria that cannot be cultured in the laboratory and sequence their entire genome. This genome sequence information has revolutionized our understanding of microbial diversity. It is now clear that prokaryotes are divided into at least two distinct groups: the archaea and the eubacteria. The archaea are a group of

diverse prokaryotes that are found in almost all environments, including extreme environments such as hot springs and the bottom of oceans. The archaea are a very diverse group of microbes, consisting of at least four major groups and numerous phyla. The eubacteria (usually referred to simply as *bacteria*, as we generally do in this book) include most of the familiar bacterial species. Although superficially similar in their cell structure, bacteria and archaea are distinct in their genetic makeup, and the differences between them are as great as those between bacteria and eukaryotes. In fact, examination of their DNA sequences, as well as other evidence, indicates that archaea are more closely related to eukaryotes than to eubacteria. Some experts are now challenging the long-held idea that life consists of three major groups (eubacteria, archaea, and eukaryotes), suggesting instead that there are only two domains of life—eubacteria and archaea—and that eukaryotes are just a branch within the archaeal domain.

Bacteria are extremely diverse and come in a variety of shapes and sizes. Some are rod-shaped, whereas others are spherical or helical. Most are much smaller than eukaryotic cells, but at least one species isolated from the guts of fish is almost 1 mm long and can be seen with the naked eye. Some bacteria are photosynthetic. Others produce stalks and spores, superficially resembling fungi.

Bacteria have long been considered simple organisms that lack much of the cellular complexity of eukaryotes. However, evidence

now points to a number of similarities and parallels in bacterial and eukaryotic structure. For example, a bacterial protein termed FtsZ, which plays an integral part in bacterial cell division, is structurally similar to eukaryotic tubulin proteins, which are subunits of microtubules and help segregate chromosomes in mitosis and meiosis (see Chapter 2). Like eukaryotes, bacteria have proteins that help condense DNA. Other bacterial proteins function much as cytoskeletal proteins do in eukaryotes, helping give bacterial cells shape and structure. And although bacteria don't undergo mitosis and meiosis, replication of the bacterial chromosome precedes binary fission, and there are bacterial processes that ensure that one copy of the chromosome is allocated to each daughter cell.

CONCEPTS

Bacteria and viruses play important roles in human health and society and in the world ecosystem. They are extremely abundant and make up the majority of life's diversity. Analysis of DNA sequences allow study of bacteria that cannot be cultured in the laboratory.

9.2 Genetic Analysis of Bacteria Requires Special Methods

Heredity in bacteria is fundamentally similar to heredity in more complex organisms. However, the bacterial haploid genome and the small size of bacteria (which makes observation of their phenotypes difficult) necessitate different approaches and methods.

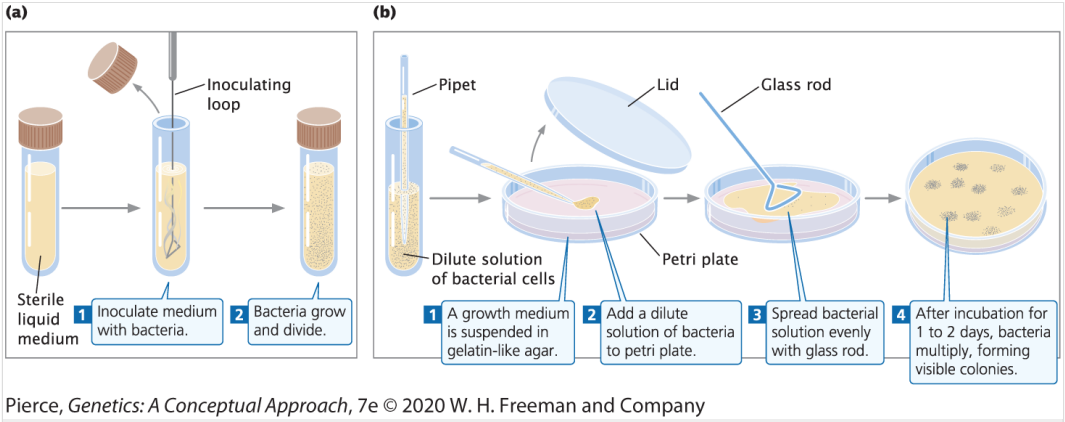
Techniques for the Study of Bacteria

Microbiologists have defined the nutritional needs of a number of bacteria and developed culture media for growing them in the laboratory. These culture media typically contain a carbon source, essential elements such as nitrogen and phosphorus, certain vitamins, and other required ions and nutrients. Wild-type, or **prototrophic**, bacteria can use these simple ingredients to synthesize all the compounds that they need for growth and reproduction. A medium that contains only the nutrients required by prototrophic bacteria is termed a **minimal medium**.

Mutant strains called **auxotrophs** lack one or more enzymes necessary for synthesizing essential compounds and will grow only on a medium supplemented with those essential molecules. For example, auxotrophic strains that are unable to synthesize the amino acid leucine will not grow on a minimal medium but *will*

grow on a medium to which leucine has been added. A **complete medium** contains all the substances, such as the amino acid leucine, required by bacteria for growth and reproduction.

Cultures of bacteria are often grown in test tubes that contain a sterile liquid medium, or *broth* (**Figure 9.1a**). A few bacteria are added to a broth tube, in which they grow and divide until all the nutrients are used up or—more commonly—until the concentration of their waste products becomes toxic to them. Bacteria can also be grown on agar plates (**Figure 9.1b**), in which melted agar is suspended in a growth medium and poured into the bottom half of a petri plate. The agar solidifies when cooled and provides a solid, gelatin-like base for bacterial growth. In a process called *plating*, a dilute solution of bacteria is spread over the surface of the agar. As each bacterium grows and divides, it gives rise to a visible clump of genetically identical cells (a **colony**). Genetically pure strains can be isolated by collecting bacteria from a single colony and transferring them to a new broth tube or agar plate. The chief advantage of this method is that it allows one to isolate and count bacteria, which individually are too small to see without a microscope.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

9.1 Growing bacteria in the laboratory. Bacteria can be grown (a) in a liquid medium (broth) or (b) on a solid medium.

Description

Illustration a on the left shows a capped test tube with sterile liquid media inside. The cap of the test tube is removed and an inoculating loop is put inside the media and a caption reads, Inoculate medium with bacterium. The test tube is capped again and the liquid media shows dots inside and a caption reads, Bacteria grow and divide.

Illustration b on the right shows a test tube with bacteria in liquid media and a pipet is inserted into the test tube. The liquid media in the test tube is labeled dilute solution of bacterial cells. From the pipet, bacterial solution is inoculated on solid media in a petri plate. A caption pointing towards the petri plate reads, A growth medium is suspended in gelatin-like agar. Another caption pointing towards the bacterial suspension reads, Add a dilute solution of bacteria to petri plate. A lid is shown above the petri plate. Glass rod is used to stir the suspension onto the media. A caption reads Spread bacterial solution evenly with glass rod. Next petri plate shows several colonies of bacteria on the petri plate in circular pattern. A caption reads, After incubation for 1 to 2 days, bacteria multiply, forming visible colonies.

Microbiologists often study phenotypes that affect the appearance of the colony (Figure 9.2) or that can be detected by simple chemical tests. Auxotrophs are commonly studied phenotypes. Suppose we want to detect auxotrophs that cannot synthesize leucine (*leu*$^-$

mutants). We first spread bacteria on a petri plate containing a medium that includes leucine; both prototrophs that have the *leu*$^+$ allele and auxotrophs that have the *leu*$^-$ allele will grow on it (**Figure 9.3**). Next, using a technique called *replica plating*, we transfer a few cells from each of the colonies on the original plate to two new plates: one plate contains a medium to which leucine has been added; the other plate contains a medium lacking leucine. A medium that lacks an essential nutrient, such as the medium lacking leucine, is called a *selective* medium. The *leu*$^+$ bacteria will grow on both media, but the *leu*$^-$ mutants will grow only on the selective medium supplemented by leucine because they cannot synthesize their own leucine. Any colony that grows on a medium that contains leucine but not on a medium that lacks leucine consists of *leu*$^-$ bacteria. The auxotrophs that grow only on the supplemented medium can then be cultured for further study. Auxotrophic mutants are often used to study the results of genetic crosses and other genetic manipulations.

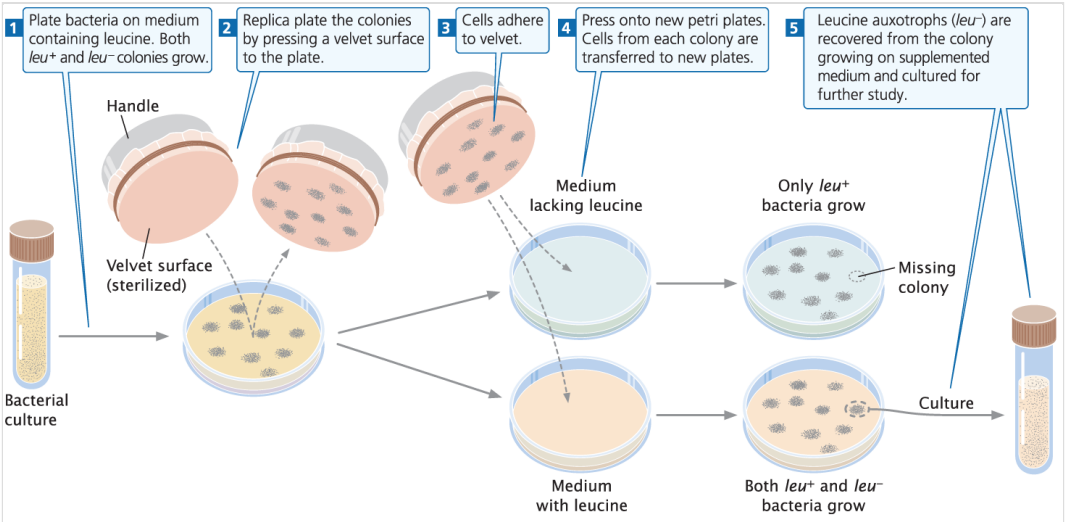
9.2 Bacterial colonies have a variety of phenotypes. (a) *Serratia marcescens* with color variation. (b) *Bacillus cereus*; colony shape varies among different strains of this species.

Description

The photo a on the left shows bacterial growth in a petri plate with color variation ranging from white to dark orange. The photo b on the right shows round-shaped colonies of white color but different sizes.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

9.3 Mutant bacterial strains can be isolated on the basis of their nutritional requirements.

Description

The illustration shows bacteria grown on petri plates transferred to other plates via a velvet cloth that is tied to a circular handle almost the same size as the petri plate. The illustration starts with a bacterial culture in a capped test tube. The first caption reads, Plate bacteria on medium containing leucine. Both l e u superscript positive and l e u superscript negative colonies grow. Bacteria from the test tube are cultured on a petri plate and are transferred to a velvet cloth attached to a handle. The second caption reads, Replica plate the colonies by pressing a velvet surface to the plate. Third caption reads, Cells adhere to velvet. From the handle, bacteria are transferred to two petri-plates; one containing medium lacking leucine and one containing medium with leucine. The fourth caption reads, Press onto new petri plates. Cells from each colony are transferred to new plates. From these two petri-plates, two cultures are produced. The first has only l e u superscript positive bacterial colonies and the other has both l e u superscript positive and l e u superscript negative

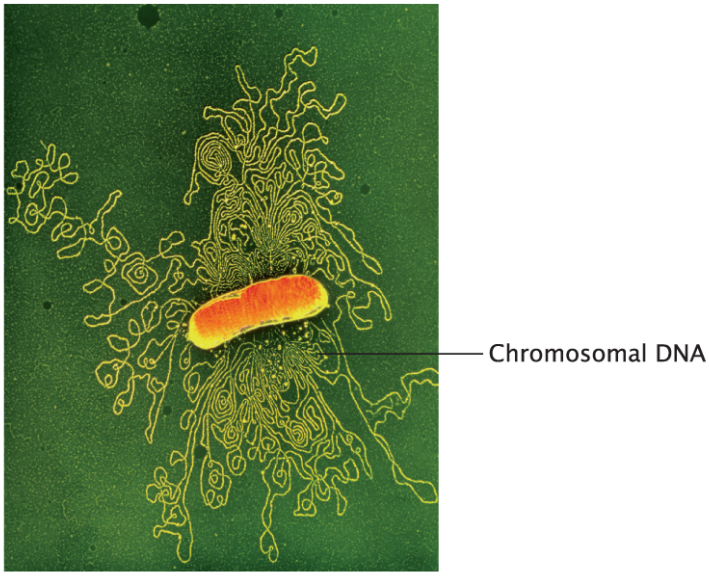
colonies. Missing colony is labeled in the first petri plate. From the second petri plate, the colony that was missing in first petri plate is cultured in a test tube. The fifth caption reads, Leucine auxotrophs, which are l e u superscript negative, are recovered from the colony growing on supplemented medium and cultured for further study. Text at the bottom reads, Conclusion: A colony that grows only on the supplemented medium has a mutation in a gene that encodes the synthesis of an essential nutrient.

Today, bacteria are often studied using genomic methods, which involve isolating and analyzing DNA sequences from bacteria (see Chapters 19 and 20). These methods make it possible to detect and study bacteria that cannot be cultured in the laboratory. They are providing insight into bacterial diversity, bacterial evolution, how genes are organized on the bacterial chromosome, and gene function.

The Bacterial Genome

Most bacterial genomes that have been studied consist of a circular chromosome that contains a single double-stranded DNA molecule, often several million base pairs (bp) in length (**Figure 9.4**). For example, the *Escherichia coli* genome has approximately 4.6 million base pairs of DNA. However, some bacteria contain multiple chromosomes. *Vibrio cholerae*, which causes cholera, has two circular chromosomes, and *Rhizobium meliloti* has three chromosomes. There are even a few bacteria that have linear chromosomes. Most bacterial chromosomes consist largely of sequences that encode proteins. For example, more than 90% of the

DNA in *E. coli* encodes proteins. In contrast, only about 1% of human DNA encodes proteins.



Dr. Gopal Murti/Science Source.

9.4 Most bacterial cells possess a single circular chromosome. The chromosome shown here is emerging from a ruptured bacterial cell.

Some newly discovered bacteria are smaller in size and have smaller genomes than bacteria that have been traditionally studied. The CPR (candidate phyla radiation) is a newly discovered group of bacteria that have been detected largely through culture-independent methods of DNA isolation and sequencing. The group is highly diverse and may contain as many as 90 different phyla. Species in CPR typically have a small genome, averaging about 1 million bp in length, and many are missing genes usually found in other bacteria. Based on their small cell size and reduced genomes, many bacteria in this group may be symbionts living on or in other bacteria or archaea.

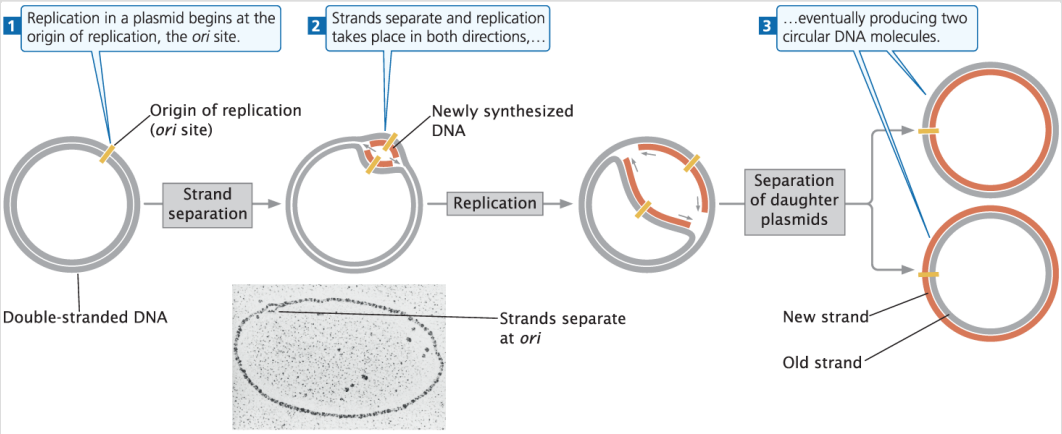
THINK-PAIR-SHARE Question 2

Plasmids

In addition to having a chromosome, many bacteria possess **plasmids**: small, usually circular DNA molecules that are distinct from the bacterial chromosome. Some plasmids are present in many copies per cell, whereas others are present in only one or two copies. In general, plasmids carry genes that are not essential to bacterial function but may play important roles in the life cycle and growth of their bacterial hosts. There are many different types of plasmids; *E. coli* alone is estimated to have more than 270 different types of naturally occurring plasmids. Some plasmids promote gene transfer between bacteria; others contain genes that kill other bacteria. Of importance to human health, plasmids are responsible for the spread of antibiotic resistance among bacteria. Plasmids are also used extensively in genetic engineering (see Chapter 19).

Most plasmids are circular and several thousand base pairs in length, although plasmids as large as several hundred thousand base pairs have also been found. Each plasmid possesses an origin of replication, a specific DNA sequence where DNA replication is initiated (see Chapter 2). The origin of replication allows a plasmid to replicate independently of the bacterial chromosome (**Figure 9.5**). **Episomes** are plasmids that are capable of replicating freely and are

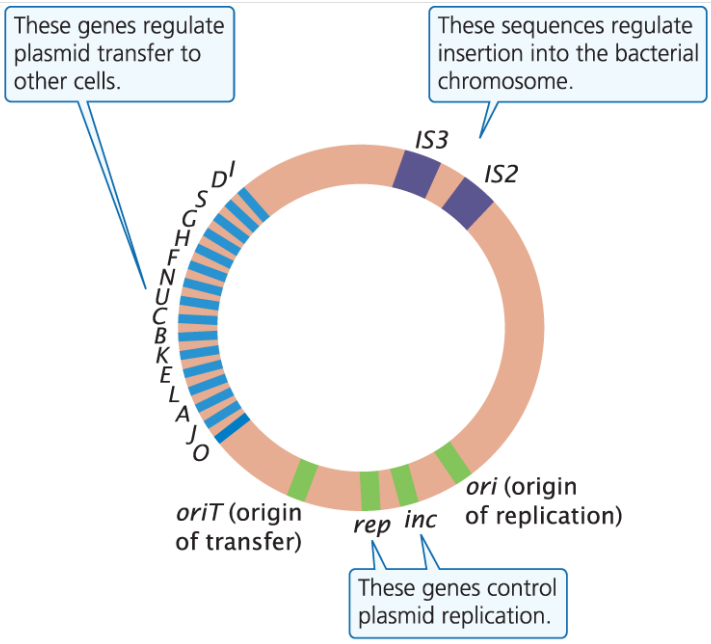
able to integrate into bacterial chromosomes. The F (fertility) factor of *E. coli* (Figure 9.6) is an episome that controls mating and gene exchange between *E. coli* cells, a process we will discuss shortly.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company
Photograph: Biology Pics/Science Source.

9.5 A plasmid replicates independently of its bacterial chromosome.
Replication begins at the origin of replication (*ori*) and continues around the circle. In this diagram, replication is taking place in both directions; in some plasmids, replication is in one direction only.

Description
The illustration shows a circular double-stranded D N A on which the origin of replication is marked with a yellow line. A caption pointing towards the ori reads, Replication in a plasmid begins at the origin of replication, the ori site. A forward arrow labeled strand separation points to the circular D N A with a bubble created at the ori. The second caption reads, Strands separate and replication takes place in both directions, eventually producing 2 circular D N A molecules. Another forward arrow labeled replication points to the D N A with its strands open up at the ori and newly synthesized D N A is shown next to the template D N A. Another forward arrow labeled separation of daughter plasmids points to two double-stranded circular daughter D N A molecules, each with a new strand and an old strand.



F factor

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

9.6 The F factor, a circular episome of *E. coli*, contains a number of genes that regulate its transfer into a bacterial cell, replication, and insertion into the bacterial chromosome. Replication is initiated at *ori*. Insertion sequences (see Chapter 18) *IS3* and *IS2* control insertion into the bacterial chromosome and excision from it.

Description

A group of 16 genes named O, J, A, L, E, K, B, C, U, N, F, H, G, S, D, and I are labeled as genes that regulate plasmid transfer to other cells. The I S 3 and I S 2 genes are labeled as sequences that regulate insertion into the bacterial chromosome. The rep and inc genes are labeled as genes that control plasmid replication. There are also 2 ori's: one is an origin of replication and the other is an origin of transfer.

CONCEPTS

Bacteria can be studied in the laboratory by growing them on liquid or solid media. A typical bacterial genome consists of a single circular chromosome that contains several million base

pairs, although some bacteria have smaller genomes. Bacterial genes may be present on plasmids, which are small, circular DNA molecules that replicate independently of the bacterial chromosome.

✔ CONCEPT CHECK 1

Which of the following statements is true of plasmids?

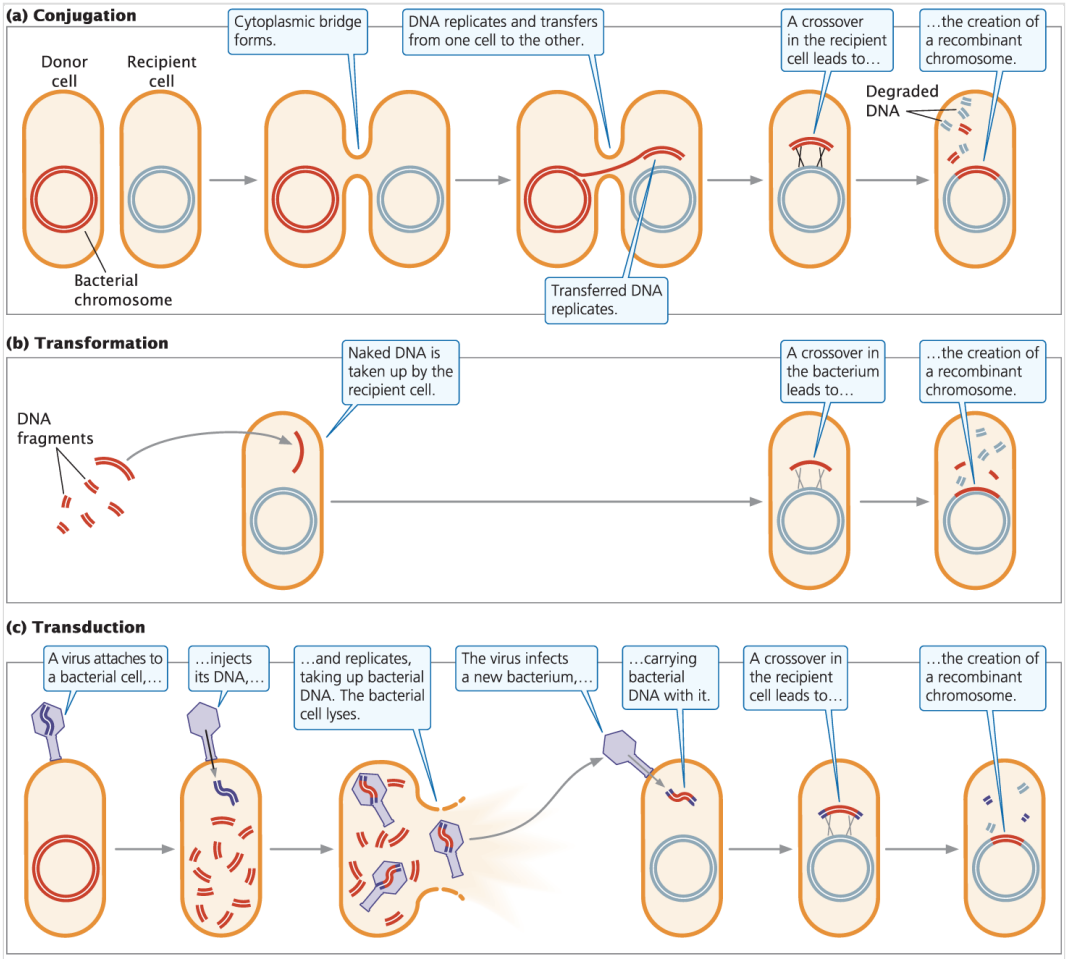
a. They are composed of RNA.
b. They normally exist outside bacterial cells.
c. They possess only a single strand of DNA.
d. They contain an origin of replication.

9.3 Bacteria Exchange Genes Through Conjugation, Transformation, and Transduction

Exchange of genetic information is widespread and common among bacteria and has played an important role in their evolution. Bacteria exchange genetic material by three different mechanisms, all entailing some type of DNA transfer and recombination between the transferred DNA and the bacterial chromosome.

1. **Conjugation** takes place when genetic material passes directly from one bacterium to another (**Figure 9.7a**). In conjugation, two bacteria lie close together and a connection forms between them. A plasmid or a part of the bacterial chromosome passes from one cell (the donor) to the other (the recipient). After conjugation, crossing over may take place between homologous sequences in the transferred DNA and the chromosome of the recipient cell. In conjugation, DNA is transferred only from donor to recipient, with no reciprocal exchange of genetic material.
2. **Transformation** takes place when a bacterium takes up DNA from the medium in which it is growing (**Figure 9.7b**). After transformation, recombination may take place between the introduced genes and those of the bacterial chromosome.
3. **Transduction** takes place when bacterial viruses (bacteriophages) carry DNA from one bacterium to another

(Figure 9.7c). Inside the bacterium, the newly introduced DNA may undergo recombination with the bacterial chromosome.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

9.7 Conjugation, transformation, and transduction are the three processes of gene transfer in bacteria. For the transferred DNA to be stably inherited, all three processes require the transferred DNA to undergo recombination with the bacterial chromosome.

Description

Illustration a at the top shows the process of conjugation. A donor cell with a red bacterial chromosome and a recipient cell with a green chromosome are shown. A forward arrow leads to the fusion of both these cells in the middle section of the cell. A caption reads, Cytoplasmic bridge forms. Another forward arrow leads to the bacterial chromosome that

replicates and migrates to the recipient cell. A caption pointing towards the migrating D N A reads, Transferred D N A replicates. Another caption from the fusion point reads, D N A replicates and transfers from one cell to the other. A forward arrow leads to recipient cell with crossing over occurring between the donor and recipient chromosome. A caption reads, a crossover in the recipient cell leads to the creation of a recombinant chromosome. A forward arrow leads to the recipient cell with a recombinant chromosome and some pieces of degraded D N A.

Illustration b below shows the process of transformation. D N A fragments are present outside the cell. An arrow from one such fragments leads to inside a bacterial cell and a fragment is shown here. A caption reads, Naked D N A is taken up by the recipient cell. Crossing over between the outside D N A fragments and bacterial chromosome occurs. The next picture shows a bacterial cell with recombinant D N A and some smaller D N A fragments. A caption reads, A crossover in the bacterium leads to the creation of a recombinant chromosome.

Illustration c below shows the process of transduction. The process starts with a viral cell attaching to bacterial cell surface. A caption reads, a virus attaches to a bacterial cell, injects its D N A, and replicates taking up bacterial D N A. The bacterial cell lyses. The next picture shows fragments of bacterial D N A along with a fragment of viral D N A inside the bacterium. The bacterial cell is lysed and viral cells take up the bacterial chromosome. This viral cell infects another bacterial cell. A caption reads, The virus infects a new bacterium, carrying bacterial D N A with it. Crossing over between the viral and bacterial D N A occurs. A caption reads, A crossover in the recipient cell leads to the creation of a recombinant chromosome. The last picture shows a bacterial cell recombinant D N A and some fragments of D N A left over.

Not all bacterial species exhibit all three types of DNA transfer. Conjugation takes place more frequently in some species than in others. Transformation takes place to a limited extent in many species of bacteria, but laboratory techniques can increase the rate of DNA uptake. Most bacteriophages have a limited host range, so

transduction normally takes place between bacteria of the same or closely related species only.

These processes of genetic exchange in bacteria differ from diploid eukaryotic sexual reproduction in two important ways. First, DNA exchange and reproduction are not coupled in bacteria; bacteria often undergo reproduction (binary fission) without receiving any DNA from another cell. Second, donated genetic material that is not recombined into the host DNA is usually degraded, so the recipient cell remains haploid. Each type of DNA transfer has been used to map genes.

CONCEPTS

DNA may be transferred between bacterial cells through conjugation, transformation, or transduction. Each type of DNA transfer consists of a one-way movement of genetic information to the recipient cell, sometimes followed by recombination. These processes are not connected to reproduction in bacteria.

✔ CONCEPT CHECK 2

Which process of DNA transfer in bacteria requires a virus?

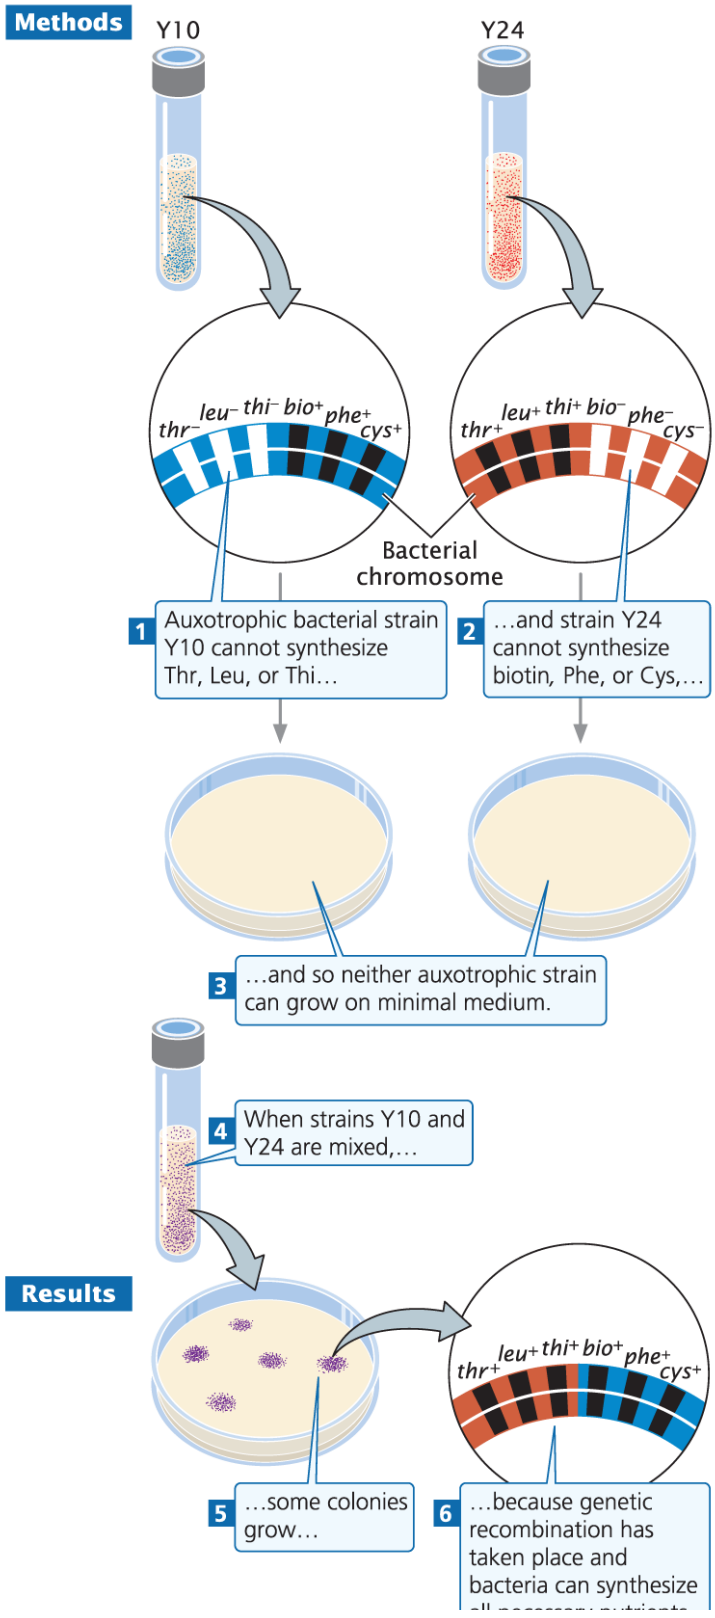
a. Conjugation
b. Transduction
c. Transformation
d. All of the above

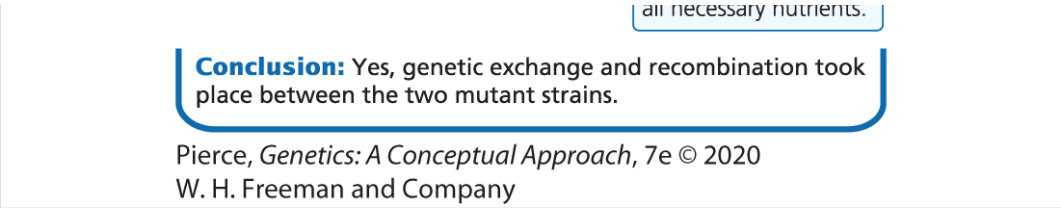
Conjugation

In 1946, Joshua Lederberg and Edward Tatum demonstrated that bacteria can transfer and recombine genetic information, paving the way for the use of bacteria in genetic studies. In the course of their research, Lederberg and Tatum studied auxotrophic strains of *E. coli*. The Y10 strain required the amino acids threonine (and was thus genotypically thr^-) and leucine (leu^-) and the vitamin thiamine (thi^-) for growth, but it did not require the vitamin biotin (bio^+) or the amino acids phenylalanine (phe^+) and cysteine (cys^+); the genotype of this strain can be written as $thr^-\ leu^-\ thi^-\ bio^+\ phe^+\ cys^+$. The Y24 strain had the opposite set of alleles: it required biotin, phenylalanine, and cysteine in its medium, but it did not require threonine, leucine, or thiamine; its genotype was $thr^+\ leu^+\ thi^+\ bio^-\ phe^-\ cys^-$. In one experiment, Lederberg and Tatum mixed Y10 and Y24 bacteria together and plated them on a minimal medium (**Figure 9.8**). Each strain was also plated separately on a minimal medium.

Experiment

Question: Do bacteria exchange genetic information?





9.8 Lederberg and Tatum's experiment demonstrated that bacteria undergo genetic exchange.

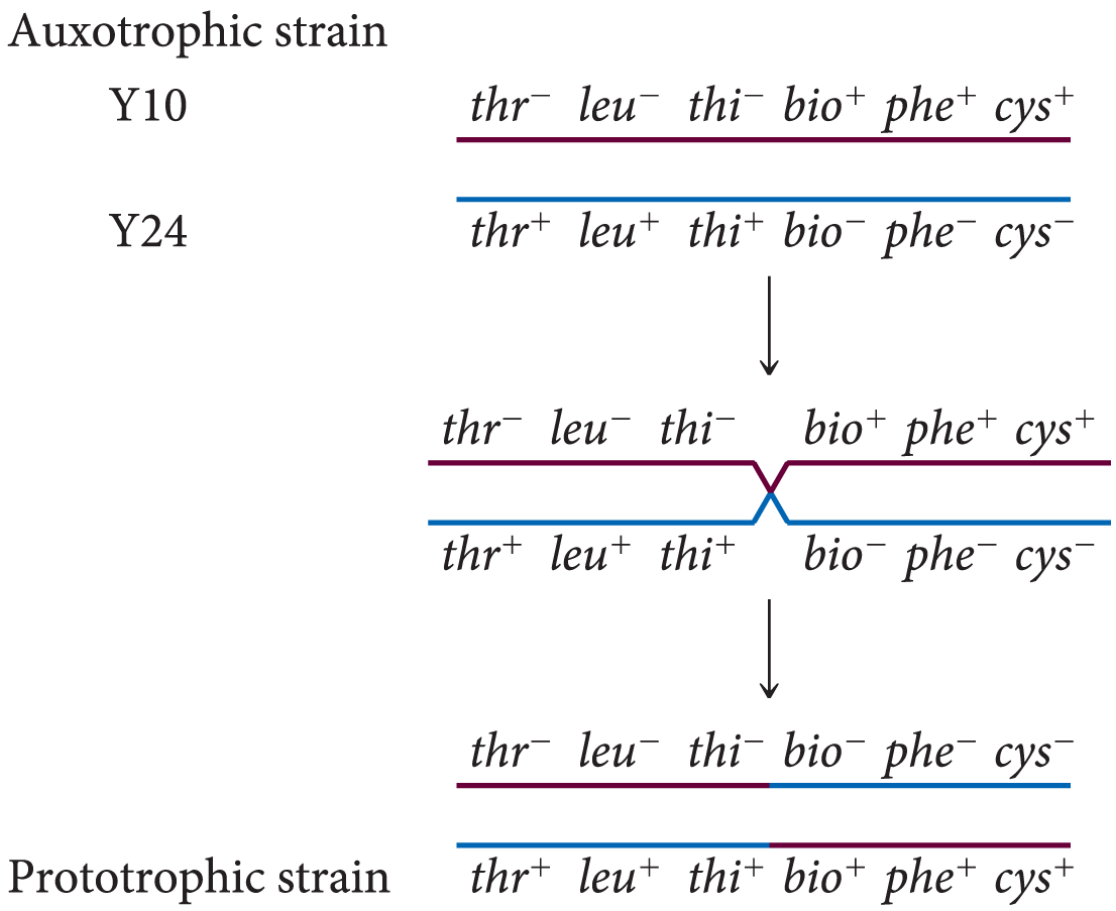
Description

The illustration shows question for the experiment: Do bacteria exchange genetic information? The methods below show the Y 10 and Y 24 strains in two different test tubes and a zoomed in image of their bacterial chromosomes with genes involved. Functional genes are represented by black color and non-functional genes by white color. A picture of petriplate with no colony is present below each strain. Three captions pointing towards the bacterial chromosome of Y 10 strain, strain Y 24, and the petriplates read, auxotrophic bacterial strain Y 10 cannot synthesize Thr, Leu, or t h i and strain Y 24 cannot synthesize biotin, phe, or cys, and so neither auxotrophic strain can grow on minimal medium. The results below start with pictures of a test tube of bacteria, a petri plate with colonies, and a zoomed in image of the bacterial chromosome with all of the genes blacked in. Three captions pointing towards the test tube, a bacterial colony, and the bacterial chromosome read, When strains Y 10 and Y 24 are mixed, some colonies grow because genetic recombination has taken place and bacteria can synthesize all necessary nutrients. A caption below reads, Conclusion: Yes, genetic exchange and recombination took place between the two mutant strains.

Alone, neither Y10 nor Y24 grew on a minimal medium: each strain required nutrients that were absent. Strain Y10 was unable to grow because it required threonine, leucine, and thiamine, which were absent in the minimal medium; strain Y24 was unable to grow because it required biotin, phenylalanine, and cysteine, which were also absent from the minimal medium. When Lederberg and Tatum mixed the two strains, however, a few colonies did grow on the

minimal medium. These prototrophic bacteria must have had genotype thr^+ leu^+ thi^+ bio^+ phe^+ cys^+. Where had they come from?

If mutations were responsible for the prototrophic colonies, then some colonies should also have grown on the plates containing Y10 or Y24 alone, but no bacteria grew on those plates. Multiple simultaneous mutations ($thr^- \rightarrow thr^+$, $leu^- \rightarrow leu^+$, and $thi^- \rightarrow thi^+$ in strain Y10 or $bio^- \rightarrow bio^+$, $phe^- \rightarrow phe^+$, and $cys^- \rightarrow cys^+$ in strain Y24) would have been required for either strain to become prototrophic by mutation, which was very improbable. Lederberg and Tatum concluded that some type of genetic transfer and recombination had taken place:

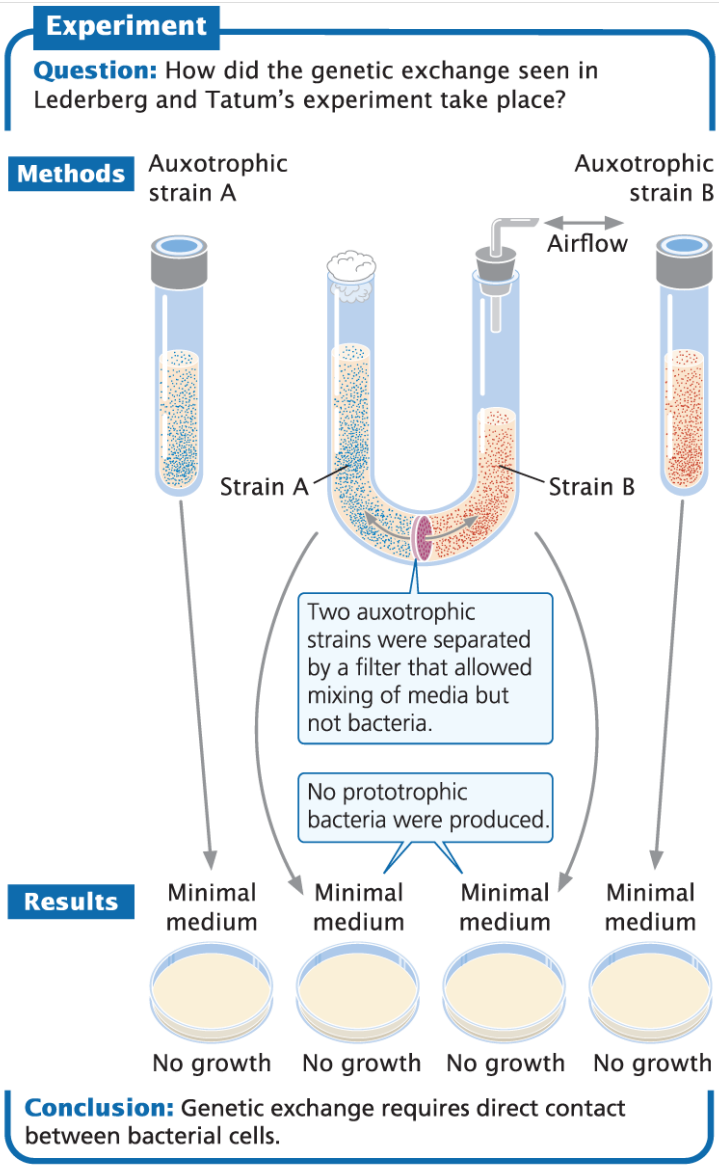


Description

The genes present on the Y 10 strain are t h r superscript negative, l e u superscript negative, and t h i superscript negative and b i o superscript positive, p h e superscript positive, and c y s superscript positive. The genes present on the Y 24 strain are t h r superscript positive, l e u superscript positive, and t h i superscript positive and b i o superscript negative, p h e superscript negative, and c y s superscript negative. The next pair of lines show a crossover event in the middle. An arrow pointing down shows the results of the recombination. The strand above is all negative and the other strand below is all positive with same gene sequence and labeled a prototrophic strain.

What they did not know was *how* it had taken place.

To study this problem, Bernard Davis constructed a U-shaped tube (Figure 9.9) that was divided into two compartments by a filter with fine pores. This filter allowed a liquid medium to pass from one side of the tube to the other, but the pores of the filter were too small to allow the passage of bacteria. Two auxotrophic strains of bacteria were placed on opposite sides of the filter, and suction was applied alternately to the ends of the U-tube, causing the medium to flow back and forth between the two compartments. Despite hours of incubation in the U-tube, bacteria plated on the minimal medium did not grow; there had been no genetic exchange between the strains. The exchange of bacterial genes clearly required direct contact, or conjugation, between the bacterial cells.



9.9 Davis's U-tube experiment.

Description

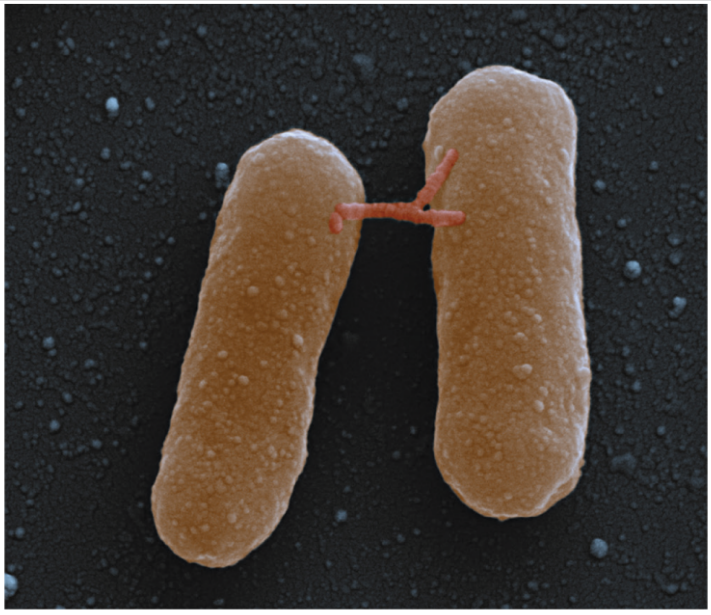
The illustration shows question as follows: How did the genetic exchange seen in Lederberg and Tatum's experiment take place? The methods below show two auxotrophic strains A and B. Both of these strains are put into a U-shaped tube that has a filter in between physically separating the two bacteria. A caption pointing towards the filter reads, Two auxotrophic strains were separated by a filter that allowed mixing of medium but not bacteria. The results below show four petriplates having minimal media. Bacteria in the

first petriplate are cultured directly from the test tube containing auxotrophic strain A. Bacteria in the second petriplate are cultured from strain A in the U-shaped tube. Bacteria in the third petriplate are cultured from strain B in the U-shaped tube. All the four petriplates show no growth. A caption below reads, Conclusion: Genetic exchange requires direct contact between bacterial cells.

F^+ AND F^- CELLS

In many bacterial species, conjugation depends on a plasmid or DNA element that is present in the donor cell and absent in the recipient cell. In *E. coli*, this plasmid is known as the fertility (F) factor. Cells that contain the F factor are referred to as F^+, and cells lacking the F factor are F^-.

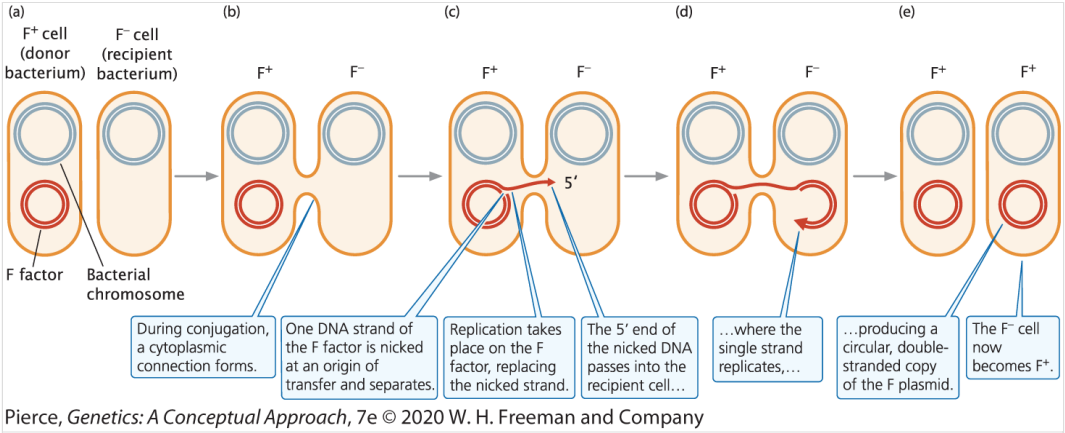
The F factor is an episome that contains an origin of replication and a number of genes required for conjugation (see Figure 9.6). For example, some of the genes in this plasmid encode sex **pili** (singular, pilus), slender extensions of the cell membrane. A cell containing the F factor produces sex pili, one of which makes contact with a receptor on an F^- cell (**Figure 9.10**) and pulls the two cells together. DNA is then transferred from the F^+ cell to the F^- cell. Conjugation can take place only between a cell that possesses the F factor and a cell that lacks the F factor.



Eye of Science/Science Source.

9.10 Sex pili connect F^+ and F^- cells during bacterial conjugation.

In most cases, the only genes transferred during conjugation between an F^+ and an F^- cell are those on the F factor (**Figure 9.11a** and b). Transfer is initiated when one of the DNA strands on the F factor is nicked at an origin of transfer (*oriT*). One end of the nicked DNA separates from the circular F plasmid and passes into the recipient cell (**Figure 9.11c**). Replication takes place on the F factor, proceeding around the circular plasmid in the F^+ cell and replacing the transferred strand. Because the F factor in the F^+ donor cell is always nicked at the *oriT* site, this site always enters the recipient cell first, followed by the rest of the plasmid. Thus, the transfer of genetic material has a defined direction. Inside the recipient cell, the single strand replicates, producing a circular, double-stranded copy of the F plasmid (**Figure 9.11d** and e). If the entire F factor is transferred to the recipient F^- cell, that cell becomes an F^+ cell.



9.11 The F factor is transferred during conjugation between an F^+ and an F^- cell.

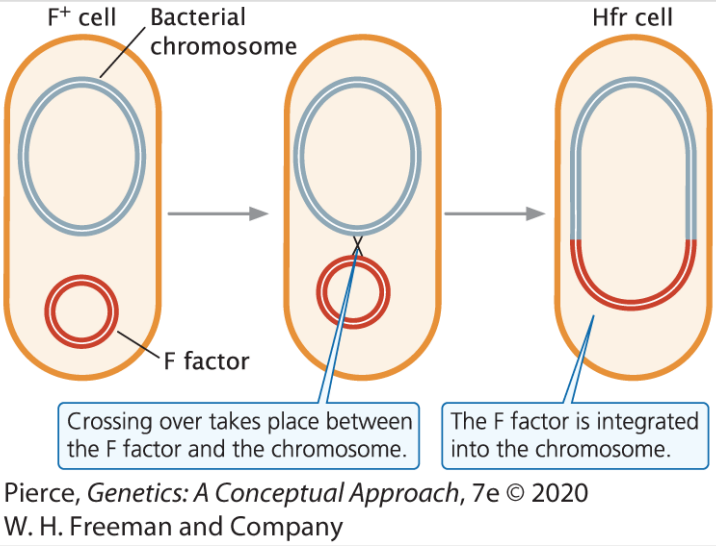
Description

The illustration shows five pictures of bacterial cells labeled a through e. Picture a at the left shows an F superscript positive donor cell and an F superscript negative recipient cell. Both cells have a double stranded bacterial chromosome, but only the F superscript positive cell has a red, double-stranded circular D N A complex labeled F factor. The captions in the illustration describe how the red D N A complex migrates from donor to recipient. The captions read as follows: During conjugation, a cytoplasmic connection forms. One D N A strand of the F factor is nicked at an origin and separates. Replication takes place on the F factor, replacing the nicked strand. The 5 prime end of the nicked D N A passes into the recipient cell where the single strand replicates, producing a circular, double-stranded copy of the F factor. The F superscript negative cell now becomes F superscript positive.

Hfr CELLS

Conjugation transfers genetic material in the F plasmid from F^+ to F^- cells, but it does not account for the transfer of chromosomal genes observed by Lederberg and Tatum. In Hfr (high-frequency

recombination) bacterial strains, the F factor is integrated into the bacterial chromosome (Figure 9.12). Hfr cells behave like F^+ cells, forming sex pili and undergoing conjugation with F^- cells.



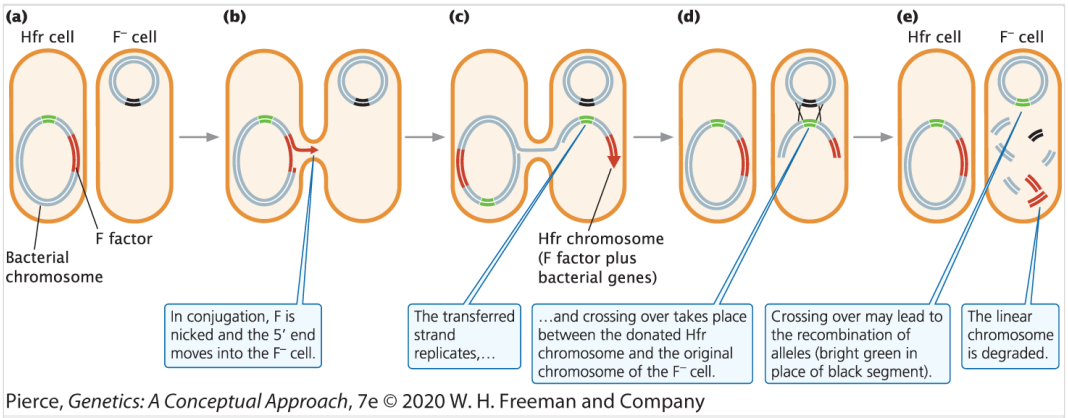
9.12 The F factor is integrated into the bacterial chromosome in an Hfr cell.

Description

The F superscript positive cell has a circular bacterial chromosome and an relatively smaller, circular red F factor plasmid. Crossing over occurs between the chromosome and the F factor. A caption reads, Crossing over takes place between the F factor and chromosome. The cell shows a continuous chromosome with both the F factor and bacterial chromosome fused together and the cell is labeled as H f r cell. Another caption reads, The F factor is integrated into the chromosome.

In conjugation between Hfr and F^- cells (Figure 9.13a), the integrated F factor is nicked, and the end of the nicked strand moves into the F^- cell (Figure 9.13b), just as it does in conjugation between F^+ and F^- cells. But because in an Hfr cell, the F factor has been integrated into the bacterial chromosome, the chromosome follows

the F factor into the recipient cell. How much of the bacterial chromosome is transferred depends on the length of time that the two cells remain in conjugation.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

9.13 Bacterial genes may be transferred from an Hfr cell to an F⁻ cell in conjugation.

Description

The illustration a shows an H f r cell and an F superscript negative cell. The H f r cell has a bacterial chromosome including the regular genome in gray, the F factor portion in red, and one stretch of the chromosome is bright green. The F superscript negative cell next to it has a gray genome with a small double-stranded portion that is black. The illustration a leads to next illustration. In the illustration b, the bacterial cells are fused in between and the red portion of the strand is nicked and starts to begin the transfer. A caption reads, In conjugation, F is nicked and the 5 prime end moves into the F superscript negative cell. In the illustration c, the transferred strand starts the replication and a caption reads, The transferred strand replicates, and crossing over takes place between the donated H f r chromosome and the original chromosome of the F superscript negative cell. In the illustration d, the bridge between the two bacterial cells is not present and crossing over is taking place in the F superscript negative cell. The illustration e shows two cells as before, H f r cell and F superscript negative cell. H f r cell is exactly the same, but the F superscript negative cell has a green portion in its genome with some degraded fragments of gray, red, and black color. Captions read, Crossing over may lead to the recombination of alleles, or bright green in place of black segment. The linear chromosome is degraded.

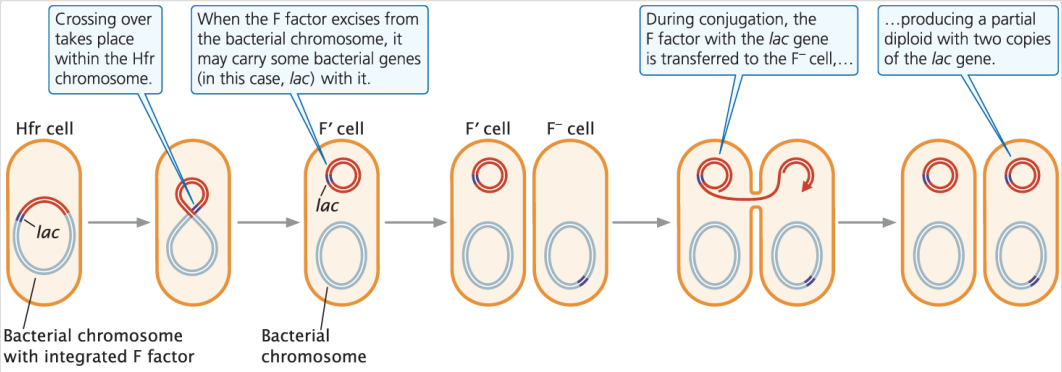
Inside the recipient cell, the donor DNA strand replicates (Figure 9.13c), and crossing over between it and the original chromosome of the F^- cell (Figure 9.13d) may take place. This chromosomal gene transfer between Hfr and F^- cells explains how the recombinant prototrophic cells observed by Lederberg and Tatum were produced. After crossing over has taken place in the recipient cell, the donated strand is degraded and the recombinant recipient chromosome remains (Figure 9.13e), to be replicated and passed on to later generations by binary fission.

In a mating between an Hfr and an F^- cell, the F^- cell almost never becomes F^+ or Hfr because the F factor is nicked in the middle at the initiation of strand transfer, which places part of the F factor at the beginning and part at the end of the strand that is transferred. To become F^+ or Hfr, the recipient cell must receive the entire F factor, which requires that the entire donor chromosome be transferred. This event happens rarely because most conjugating cells break apart before the entire chromosome has been transferred.

The F plasmid in an F^+ cell integrates into the bacterial chromosome, causing the F^+ cell to become Hfr, at a frequency of only about 1 in 10,000. This low frequency accounts for the low rate of recombination observed by Lederberg and Tatum in their F^+ cells. The F factor is excised from the bacterial chromosome at a similarly low rate, causing a few Hfr cells to become F^+.

F′ CELLS

When an F factor is excised from the bacterial chromosome, a small amount of the bacterial chromosome may be removed with it, and these chromosomal genes will then be carried with the F plasmid (Figure 9.14). Cells containing an F plasmid with some bacterial genes are called F prime (F′) cells. For example, if an F factor integrates into a chromosome at a position adjacent to the *lac* genes (genes that enable a cell to metabolize the sugar lactose), the F factor may pick up *lac* genes when it is excised, becoming F′*lac*. F′ cells can conjugate with F⁻ cells because F′ cells possess the F plasmid, with all the genetic information necessary for conjugation and DNA transfer. Characteristics of different mating types of *E. coli* (cells with different types of F) are summarized in Table 9.2.



9.14 An Hfr cell may be converted into an F′ cell when the F factor is excised from the bacterial chromosome and carries bacterial genes with it.

Conjugation between an F′ cell and an F⁻ cell produces a partial diploid.

Description

The illustration starts with an H f r cell having a circular bacterial chromosome with integrated F factor and l a c gene. Crossing over occurs within the chromosome and F prime cell is produced with two circular D N A; one is the bacterial chromosome and the

other have F factor and l a c gene. The captions read as follows: Crossing over takes place within the H f r chromosome. When the F factor is excised from the bacterial chromosome, it may carry some chromosomal genes, in this case, l a c, with it. This leads to two cells; one with the F factor and l a c gene and bacterial chromosome labeled F prime cell and other with only bacterial chromosome labeled F superscript negative cell. The F factor transfers from the F prime to the F superscript negative cell. Both the cells have F factor and l a c gene now. The captions here read: During conjugation, the F factor with the l a c gene is transferred to the F superscript negative cell, producing a partial diploid with 2 copies of the l a c gene.

TABLE 9.2 Characteristics of *E. coli* cells with different types of F factor

Type	F Factor Characteristics	Role in Conjugation
F^+	Present as separate circular plasmid	Donor
F^-	Absent	Recipient
Hfr	Present, integrated into bacterial chromosome	High-frequency donor
F'	Present as separate circular plasmid, carrying some bacterial genes	Donor

During conjugation between an F' cell and an F^- cell, the F plasmid is transferred to the F^- cell, which means that any genes on the F plasmid, including those from the bacterial chromosome, may be transferred to the F^- recipient cell (see Figure 9.14). This process produces partial diploids, or merozygotes, which are cells with two copies of some genes, one on the bacterial chromosome and one on the newly introduced F plasmid. The outcomes of conjugation between different mating types of *E. coli* are summarized in **Table 9.3**.

TABLE 9.3 Results of conjugation between *E. coli* cells with different F factor

Conjugating Cells	Cell Types Present after Conjugation
$F^+ \times F^-$	Two F^+ cells (F^- cell becomes F^+)
Hfr × F^-	One Hfr cell and one F^- cell (no change)*
$F' \times F^-$	Two F' cells (F^- cell becomes F')

*Rarely, the F^- cell becomes F^+ in an Hfr × F^- conjugation if the entire chromosome is transferred during conjugation.

CONCEPTS

Conjugation in *E. coli* is controlled by an episome called the F factor. Cells containing the F factor (F^+ cells) are donors of DNA; cells lacking the F factor (F^- cells) are recipients. In Hfr cells, the F factor is integrated into the bacterial chromosome; these cells donate DNA to F^- cells at a high frequency. F' cells contain a copy of the F plasmid with some bacterial genes.

✔ CONCEPT CHECK 3

Conjugation between an F^+ and an F^- cell usually results in

a. two F^+ cells.
b. two F^- cells.
c. an F^+ and an F^- cell.
d. an Hfr cell and an F^+ cell.

MAPPING BACTERIAL GENES WITH INTERRUPTED CONJUGATION

The transfer of DNA that takes place during conjugation between Hfr and F^- cells has been used to map bacterial genes, although it is not commonly employed today. (Most genes in bacteria are mapped today using DNA sequencing; see Chapter 19.) Conjugation mapping used conjugation between Hfr cells and F^- cells. Transfer of the entire *E. coli* chromosome from the Hfr donor to the F^- recipient requires about 100 minutes; if conjugation is interrupted before 100 minutes have elapsed, only part of the donor chromosome will have passed into the F^- cell and had an opportunity to recombine with the recipient chromosome. Chromosome transfer always begins within the integrated F factor and proceeds in a defined direction, so genes are transferred according to their sequence on the chromosome. The times required for individual genes to be transferred indicate their relative positions on the chromosome. View (A) **Animation 9.1** to see how genes are mapped using interrupted conjugation.

CONCEPTS

Conjugation can be used to map bacterial genes by mixing Hfr and F^- cells of different genotypes and interrupting conjugation at regular intervals. The amounts of time required for individual genes to be transferred from the Hfr to the F^- cells indicate the relative positions of the genes on the bacterial chromosome.

✔ CONCEPT CHECK 4

Interrupted conjugation was used to map three genes in *E. coli*. The donor genes first appeared in the recipient cells at the following times: *gal*, 10 minutes; *his*, 8 minutes; *pro*, 15 minutes. Which gene is in the middle?

Natural Gene Transfer and Antibiotic Resistance

Antibiotics are substances that kill bacteria. Their development and widespread use have greatly reduced the threat of infectious disease and saved countless lives. But many pathogenic bacteria have developed resistance to antibiotics, particularly in environments where antibiotics are routinely used, such as hospitals, livestock operations, and fish farms. In these environments, where antibiotics are continually present, the only bacteria to survive are those that possess antibiotic resistance. No longer in competition with other bacteria, resistant bacteria multiply quickly and spread. In this way, the presence of antibiotics selects for resistant bacteria and reduces the effectiveness of antibiotic treatment for infections.

Antibiotic resistance in bacteria frequently results from the action of genes located on *R plasmids,* small circular plasmids that can be transferred by conjugation. Some drug-resistant R plasmids convey resistance to several antibiotics simultaneously. Ironic but plausible sources of some of the resistance genes found in R plasmids are the microbes that produce antibiotics in the first place.

Widespread use of antibiotics not only increases the frequency of resistant pathogenic bacteria it also affects nonpathogenic bacteria. The community of bacteria associated with humans—in our mouth, in our gut, and on our skin—is collectively referred to as the **human**

microbiome. Much research indicates that the microbiome is essential to human digestion, pathogen resistance, weight control, and physiology. It is clear that in developed countries, the human microbiome has changed significantly over the past hundred years, probably as a result of widespread antibiotics but perhaps also due to cleaner and chlorinated drinking water, better sanitation, and use of infant formula. Some studies have suggested that modern societies may have lost more than half of their microbial diversity. What effect this erosion of our microbiome will have on our health and function isn't yet clear.

THINK-PAIR-SHARE Question 3

Transformation in Bacteria

A second way in which DNA can be transferred between bacteria is through transformation (see Figure 9.7b). Transformation played an important role in the initial identification of DNA as the genetic material, as we will see in Chapter 10.

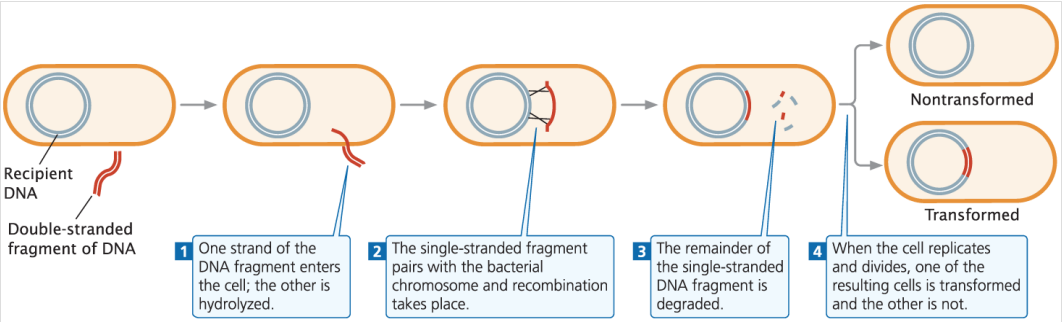
Transformation requires both the uptake of DNA from the surrounding medium and its incorporation into a bacterial chromosome or a plasmid. It may occur naturally when dead bacteria break down and release DNA fragments into the environment. In soil and marine environments, transformation may

be an important route of genetic exchange for some bacteria. Transformation is also an important technique for transferring genes to bacteria in the laboratory.

MECHANISM OF TRANSFORMATION

Cells that can take up DNA through their cell membranes are said to be **competent**. Some species of bacteria take up DNA more easily than others: competence is influenced by growth stage, the concentration of available DNA in the environment, and other environmental factors. The DNA that a competent cell takes up need not be bacterial: virtually any type of DNA (bacterial or otherwise) can be taken up by competent cells under the appropriate conditions.

As a DNA fragment enters the cell in the course of transformation (**Figure 9.15**), one of the strands is broken up, whereas the other strand moves across the membrane and may pair with a homologous region and become integrated into the bacterial chromosome. Its integration into the recipient chromosome requires two crossover events, after which the remaining single-stranded DNA is degraded by bacterial enzymes. In some bacteria, double-stranded DNA moves across the cell membrane and is integrated into the bacterial chromosome. Cells that receive genetic material through transformation are called **transformants**.



9.15 Genes can be transferred between bacteria through transformation.

Description

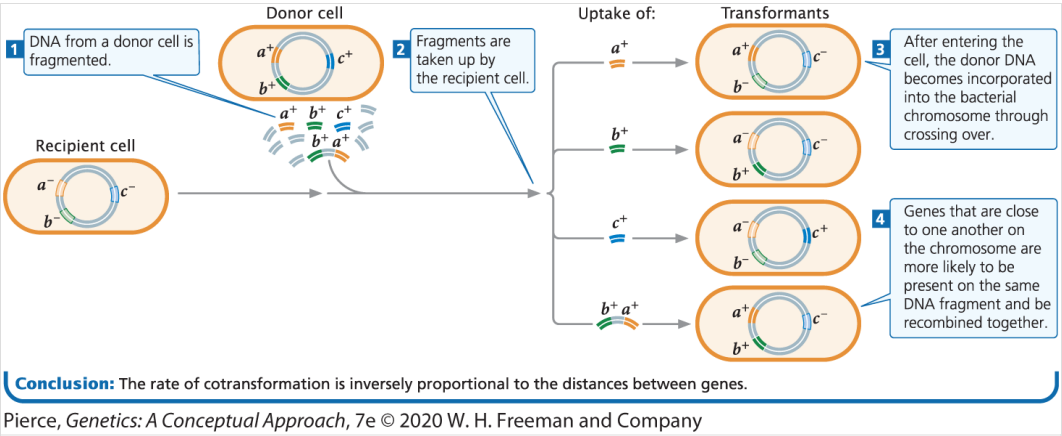
The illustration shows a bacterial cell on the left side with a naked doubled-stranded D N A from the outside integrating into the cell. Only a single strand red in color enters the cell. A caption reads, One strand of the D N A fragment enters the cell; the other is hydrolyzed. Crossing over occurs between the recipient D N A and the single-stranded fragment. A caption reads, The single-stranded fragment pairs with the bacterial chromosome and recombination takes place. Now the bacterial cell has the single-stranded D N A incorporated into one of its strands of recipient D N A. Some fragments of both the outside D N A and the bacterial D N A are present in the cell. A caption reads, The remainder of the single-stranded D N A fragment is degraded. Cell division occurs and two daughter cells are produced. One has only the bacterial chromosome and is labeled non-transformed, while the other has outside D N A incorporated into its genome and is labeled transformed. A caption reads, When the cell replicates and divides, one of the resulting cells is transformed and the other is not.

Bacterial geneticists have developed techniques for increasing the frequency of transformation in the laboratory to introduce particular DNA fragments or whole plasmids into cells. They have also developed strains of bacteria that are more competent than wild-type cells. Treatment with calcium chloride, heat shock, or an electrical field makes bacterial membranes more porous and permeable to DNA. The efficiency of transformation can also be

increased by using high concentrations of DNA. These techniques enable researchers to transform bacteria such as *E. coli*, which are not naturally competent.

GENE MAPPING WITH TRANSFORMATION

Transformation, like conjugation, has been used in the past to map bacterial genes. Transformation mapping requires two strains of bacteria that differ in several genetic traits; for example, the recipient strain might be $a^- b^- c^-$ (auxotrophic for three nutrients), and the donor strain might be $a^+ b^+ c^+$ (prototrophic for the same three nutrients) (Figure 9.16). DNA from the donor strain is isolated, purified, and fragmented. The recipient strain is treated to increase its competence, and DNA from the donor strain is added to the medium. Fragments of the donor DNA enter the recipient cells and undergo recombination with homologous DNA sequences on the bacterial chromosome.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

9.16 Transformation can be used to map bacterial genes.

Description
The illustration shows a recipient with a chromosome that is negative for genes a, b, and c. The donor cell is positive for genes a, b, and c. D N A fragments and genes positive for a, b, and c are also present outside the donor cell. A caption reads, D N A from a donor cell is fragmented. A second caption reads, Fragments are taken up by the recipient cell. An arrow from the recipient cell points to 4 different types of transformants for the uptake of a superscript positive, b superscript positive, c superscript positive, and b superscript positive a superscript positive respectively: First transformant has a superscript positive, b superscript negative, and c superscript negative genes. A caption reads, After entering the cell, the donor D N A becomes incorporated into the bacterial chromosome through crossing over. The second transformant has a superscript negative, b superscript positive, and c superscript negative genes. The third transformant has a superscript negative, b superscript negative, and c superscript positive genes. The fourth transformant has a superscript positive, b superscript positive, and c superscript negative genes. A caption reads, Genes that are close to one another on the chromosome are more likely to be present on the same D N A fragment and be recombined together. A caption below reads, Conclusion: The rate of cotransformation is inversely proportional to the distances between genes.

Bacterial genes can be mapped by observing the rate at which two or more genes are transferred to the recipient chromosome together, or **cotransformed**. When the donor DNA is fragmented before transformation, genes that are physically closer together on the bacterial chromosome are more likely to be present on the same DNA fragment and transferred together, as shown for genes a^+ and b^+ in Figure 9.16. Genes that are far apart are unlikely to be present on the same DNA fragment and are rarely cotransformed. Therefore, the frequency of cotransformation can be used to map bacterial genes. If genes *a* and *b* as well as genes *b* and *c* are frequently cotransformed, but genes *a* and *c* are rarely cotransformed, then

gene *b* must be between *a* and *c*—the gene order is *a*, *b*, *c*. **› TRY PROBLEM 23**

CONCEPTS

Genes can be mapped in bacteria by taking advantage of transformation—the ability of bacteria to take up DNA from the environment and incorporate it into their chromosomes through crossing over. The relative rates at which pairs of genes are cotransformed indicate the distance between them: the higher the rate of cotransformation, the closer the genes are on the bacterial chromosome.

✔ CONCEPT CHECK 5

A bacterial strain with genotype his^- leu^- thr^- is transformed with DNA from a strain that is his^+ leu^+ thr^+. A few leu^+ thr^+ cells and a few his^+ thr^+ cells are found, but no his^+ leu^+ cells are observed. Which genes are farthest apart?

Bacterial Genome Sequences

Genetic maps serve as the foundation for the more detailed information provided by DNA sequencing, such as gene content and organization (see Chapter 19 for a discussion of gene sequencing). Geneticists have now determined the complete nucleotide sequences of more than two thousand bacterial genomes (see Table 20.3), and many additional microbial sequencing projects are under way.

Most bacterial genomes contain from 1 million to 4 million base pairs of DNA, but a few are much smaller (e.g., 580,000 bp in *Mycoplasma genitalium*) and some are considerably larger (e.g., more than 7 million bp in *Mesorhizobium loti*). The small size of bacterial genomes (relative to those found in multicellular eukaryotes, which often have billions of base pairs of DNA) is thought to be an adaptation for rapid cell division, because the rate of cell division is limited by the time required to replicate the DNA. On the other hand, the lack of mobility in most bacteria requires metabolic and environmental flexibility, so genome size and content are likely to reflect a balance between the opposing evolutionary forces of gene loss to maintain rapid reproduction and gene acquisition to ensure flexibility.

The functions of a substantial proportion of genes in all bacteria have not been determined. Certain genes, particularly those with related functions, tend to reside next to one another, but these clusters are in very different locations in different species, suggesting that bacterial genomes are constantly being reshuffled. Comparisons of the gene sequences of pathogenic and benign bacteria are helping identify genes implicated in disease and may suggest new targets for antibiotics and other antimicrobial agents.

Horizontal Gene Transfer

The availability of bacterial genome sequences has provided evidence that many bacteria have acquired genetic information from other species of bacteria—and sometimes even from eukaryotic organisms—in a process called **horizontal gene transfer**. In most eukaryotes, genes are passed only among members of the same species through reproduction (a process called vertical transmission); that is, genes are passed from one generation to the next. In horizontal gene transfer, genes can be passed between individual members of different species by nonreproductive mechanisms, such as conjugation, transformation, and transduction. Evidence suggests that horizontal gene transfer has taken place repeatedly among bacteria. For example, as much as 17% of *E. coli*'s genome has been acquired from other bacteria through horizontal gene transfer. Of medical significance, some pathogenic bacteria have acquired the genes necessary for infection, whereas others have acquired genes that confer resistance to antibiotics.

Because of the widespread occurrence of horizontal gene transfer, many bacterial chromosomes are a mixture of genes inherited through vertical transmission and genes acquired through horizontal gene transfer. This observation has caused some biologists to question whether the species concept is appropriate for bacteria. A *species* is often defined as a group of organisms that are reproductively isolated from other groups, have a set of genes in common, and evolve together (see Chapter 26). Because of horizontal gene transfer, the genes of one bacterial species are not

isolated from the genes of other species, making the traditional species concept difficult to apply. Horizontal gene transfer also muddies the determination of the ancestral relationships among bacteria. The reconstruction of ancestral relationships is usually based on genetic similarities and differences: organisms that are genetically similar are assumed to have descended from a recent common ancestor, whereas organisms that are genetically distinct are assumed to be more distantly related. Through horizontal gene transfer, however, even distantly related bacteria may share some genes and thus appear to have descended from a recent common ancestor. The nature of species and how to classify bacteria are currently controversial topics within the field of microbiology.

9.4 Bacterial Defense Mechanisms

As discussed earlier, we live in a microbial world. Bacteria and archaea are found in almost every conceivable environment, often in very large numbers, and thrive where other organisms perish. In spite of their abundance, being a microbe is not easy. Bacteria and archaea face significant challenges, the most serious of which are viruses. Scientists have estimated that there are ten times as many viruses as bacteria and archaea, so viruses are a constant threat. Not surprisingly, bacteria and archaea have evolved a number of mechanisms to prevent the entry and reproduction of viruses and other forms invading DNA.

To invade a cell, a virus must first attach to the cell wall or membrane and inject its DNA or RNA into the cell. Many bacteria and archaea have evolved mechanisms to prevent viral attachment and injection of the viral DNA or RNA into the cell. Some bacteria turn off the expression of receptors to which viruses attach; other bacteria secrete polysaccharide coats that limit the access of viruses to those receptors. Bacteria can also produce proteins on the cell membrane that prevent viruses from injecting their nucleic acids into the cell. In other cases, a bacterium that has been infected self-destructs, so that the virus within it is unable to replicate and spread to other bacteria. Other defense mechanisms block virus replication.

Restriction-Modification Systems

Another type of bacterial defense consists of **restriction-modification systems**. Bacteria produce enzymes called restriction endonucleases that recognize and cleave double-stranded DNA at specific nucleotide sequences (see Chapter 19). These enzymes cut up viral DNA, destroying the viral genome before it can replicate. Bacteria protect their own DNA from cleavage by modifying the recognition sequences on their DNA, usually by the addition of methyl groups. Restriction enzymes have been extensively used by geneticists in genetic engineering (see Chapter 19).

CRISPR-Cas Systems

A powerful set of defense mechanisms in bacteria and archaea are **CRISPR-Cas systems**. These have been compared to the immune systems of vertebrates in that they recognize and "remember" DNA from specific pathogens. CRISPR-Cas systems combine small RNA molecules known as CRISPR RNAs (crRNAs) with Cas (CRISPR-associated) proteins to provide defense against specific foreign DNA molecules originating from viruses, plasmids, and transposable elements. CRISPR-Cas systems are widespread in prokaryotes, occurring in 50% of bacterial species and 87% of archaea.

Bacteria and archaea have evolved a diverse set of CRISPR-Cas systems; these are divided into two major classes, 6 types, and 19

subtypes. These different CRISPR-Cas systems vary in the details of their components and mechanisms. In spite of these differences, all CRISPR-Cas systems have two major components: (1) a DNA sequence called the CRISPR array and (2) a set of genes encoding Cas proteins.

CRISPR ARRAY

The **CRISPR array** (**Figure 9.17a**) is located in the bacterial or archaeal chromosome and consists of a series of repeated DNA sequences called clustered regularly interspaced short palindromic repeats (CRISPR). Palindromic sequences are sequences that read the same forward and backward on two complementary DNA strands. A CRISPR array consists of a series of repeated palindromic sequences, separated by spacers that are derived from the DNA of viruses or plasmid genomes. For example, in the bacterium *Pseudomonas aeruginosa*, CRISPR palindromic repeats are 28 base pairs (bp) in length, separated by 32 bp spacers. Adjacent to the CRISPR array is a series of genes that encode **Cas proteins**, which are essential to the functioning of the CRISPR-Cas system.

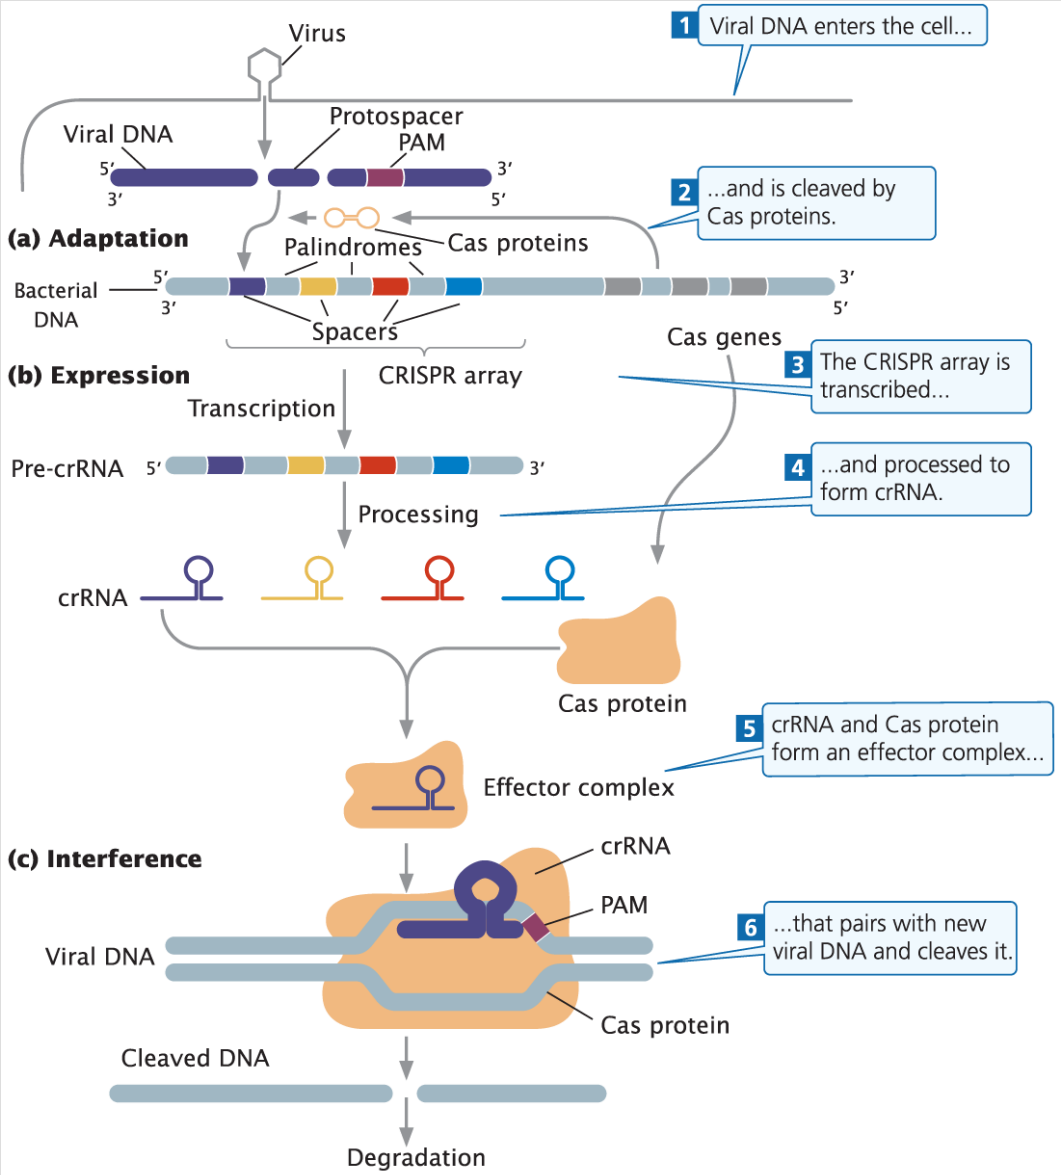
CRISPR-CAS FUNCTION

The action of a CRISPR-Cas system takes place in three stages: adaptation, expression, and interference. Adaptation (Figure 9.17a) occurs when foreign DNA from a virus, plasmid, or other element

enters the cells. The foreign DNA is identified and cleaved by Cas proteins into fragments called protospacers. The protospacers are then processed and incorporated into the CRISPR array as spacers, which serve as a memory of the foreign DNA and can trigger the CRISPR-Cas reaction if the foreign DNA ever enters the cell again. New spacers are preferentially integrated at the 5′ end of the CRISPR array, where they enhance immunity against recent invaders.

In the second stage—expression—the CRISPR array is transcribed into a long CRISPR precursor RNA (**Figure 9.17b**), which is then cleaved by Cas proteins and processed into crRNAs, each of which contains a spacer sequence that is homologous to the foreign DNA. The crRNA combines with a Cas protein to form an effector complex.

Interference, the final stage of the process, occurs when foreign DNA from the same bacteriophage or plasmid enters the cell again. The effector complex binds to the foreign DNA through base pairing between the crRNA and the foreign DNA sequence. The Cas protein cleaves the foreign DNA, which is then degraded (**Figure 9.17c**). In this way, CRISPR-Cas serves as an adaptive defense system against foreign invaders. Because the bacterial cell carries the inserted pieces of foreign DNA in its own chromosome, it can "remember" previously encountered pathogens and quickly destroy their DNA. When bacterial cells divide, they pass on their CRISPR array to progeny cells, so the acquired immunity becomes inherited by future generations of bacteria.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

9.17 CRISPR-Cas immunity takes place in three steps: adaptation, expression, and interference.

Description

The process chart starts with the entry of foreign D N A from a virus into the bacterial cell. Viral D N A consists of complementary strands from 5 prime to 3 prime and from 3 prime to 5 prime respectively, protospacer, and P A M. An arrow points to (a) adaptation where foreign viral D N A is incorporated into the C R I S P R array of bacterial D N A as spacers. Palindromes are embedded between these spacers and Cas proteins. An arrow from the

Cas proteins points to the arrow from the virus to the bacterial D N A. An arrow from the C R I S P R array of adaptation points to (b) expression, where C R I S P R array transcription takes place forming a 5 prime to 3 prime single stranded pre-c r R N A that undergoes processing resulting in the formation of 4 sickle shaped c r R N A. This c r R N A is then incorporated into Cas protein and forms effector complex. After that the process (c) interference takes place where the effector complex binds to the foreign D N A through base pairing between the c r R N A and the foreign D N A sequence along with PAM after that Cas protein cleaves the foreign D N A resulting in degradation of the D N A.

PAM SEQUENCES

Integral to the functioning of most CRISPR-Cas systems is a requirement that foreign DNA that makes up the protospacers possess a short adjacent DNA sequence called a **protospacer-adjacent motif (PAM)**. During interference, the CRISPR-Cas effector complex first associates with a PAM and then unwinds the DNA nearby. The requirement of a PAM for interference solves a dilemma that bacteria face in the use of CRISPR-Cas: how to recognize and cleave foreign DNA without destroying the spacer DNA within its own CRISPR array. To solve this dilemma, many bacteria species have evolved the requirement of an adjacent PAM. Although a PAM is adjacent to the protospacer in the foreign DNA, the PAM sequences themselves are not integrated into the CRISPR array as part of the spacer. In this way, the CRISPR-Cas system cleaves foreign DNA (which has a PAM) but avoids cleaving DNA in the CRISPR array of the bacterial genome (where PAM is absent).

In recent years, researchers have adapted and modified natural CRISPR-Cas systems to serve as powerful gene-editing tools in genetic engineering. We will discuss this use of CRISPR-Cas in Chapter 19.

An Evolutionary Arms Race Between Bacteria and Viruses

As we have seen, bacteria have evolved a number of mechanisms to avoid infection by and reproduction of viruses, but viruses have, in turn, evolved countermeasures to avoid bacterial defenses. This has generated an evolutionary "arms race," in which bacteria and phages are constantly changing in response to evolutionary changes in each other.

One way that viruses can avoid CRISPR-Cas immunity in bacteria is by constantly mutating their sequences so that the bacteria cannot recognize viruses that have previously infected the cell. Viral mutations that are effective in avoiding detection by CRISPR-Cas often occur in the PAM sequence or in the part of the protospacer recognized by the CRISPR-Cas effector complex. In addition, some viruses have evolved small proteins called anti-CRISPRs, which directly interfere with the CRISPR-Cas machinery.

CRISPR-Cas systems are found in many bacteria, but they are missing from almost 50% of all bacterial species. Why do many

bacterial species lack what appears to be a very effective defense against viruses and other foreign DNA? One possibility is that other defense mechanisms are sufficiently effective that CRISPR-Cas immunity provides no additional advantage. There are also likely to be significant costs to having CRISPR-Cas immunity. It may limit the ability of bacteria to take up potentially beneficial DNA that might provide antibiotic resistance or other adaptive traits. It is possible that CRISPR-Cas may sometimes erroneously attack the bacteria's own DNA, creating a type of autoimmunity that disrupts normal function. And there are energetic costs to maintaining the CRISPR-Cas system. All of these factors may make it too costly for some bacteria to evolve CRISPR-Cas immunity.

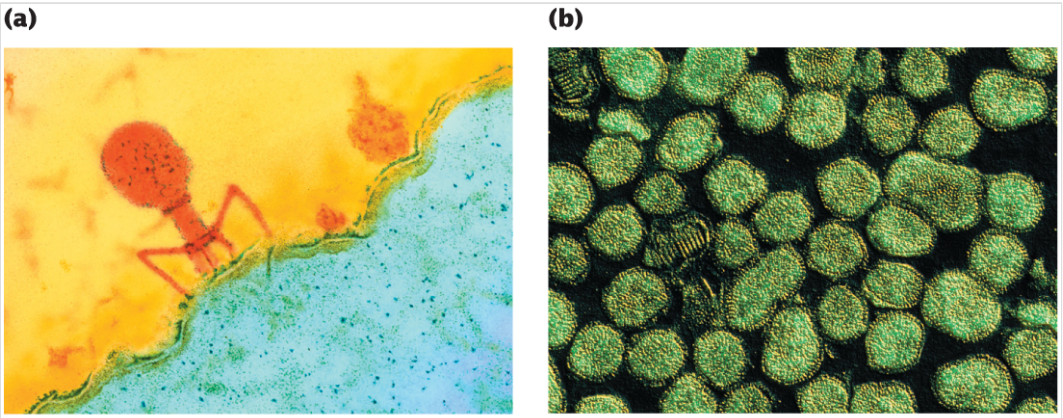
THINK-PAIR-SHARE Question 4

CONCEPTS

Bacteria and archaea have evolved mechanisms to prevent the entry and reproduction of viruses and other forms of invading DNA. These include systems to prevent viral attachment and injection of the viral DNA or RNA into the cell, restriction-modification systems, and CRISPR-Cas immunity. CRISPR-Cas systems are powerful defense mechanisms that provide adaptive immunity: the ability to recognize and remember DNA from specific pathogens. In response, viruses have evolved a number of adaptations to avoid bacterial defenses.

9.5 Viruses Are Simple Replicating Systems Amenable to Genetic Analysis

All organisms—plants, animals, fungi, and bacteria—are infected by viruses. A **virus** is a simple replicating structure made up of nucleic acid surrounded by a protein coat (see Figure 2.4). Viruses come in a great variety of shapes and sizes (**Figure 9.18**). Enveloped viruses have an outer lipid envelope that is derived from the host's cell membrane. Some viruses have DNA as their genetic material, whereas others have RNA; the nucleic acid may be double stranded or single stranded, linear or circular.

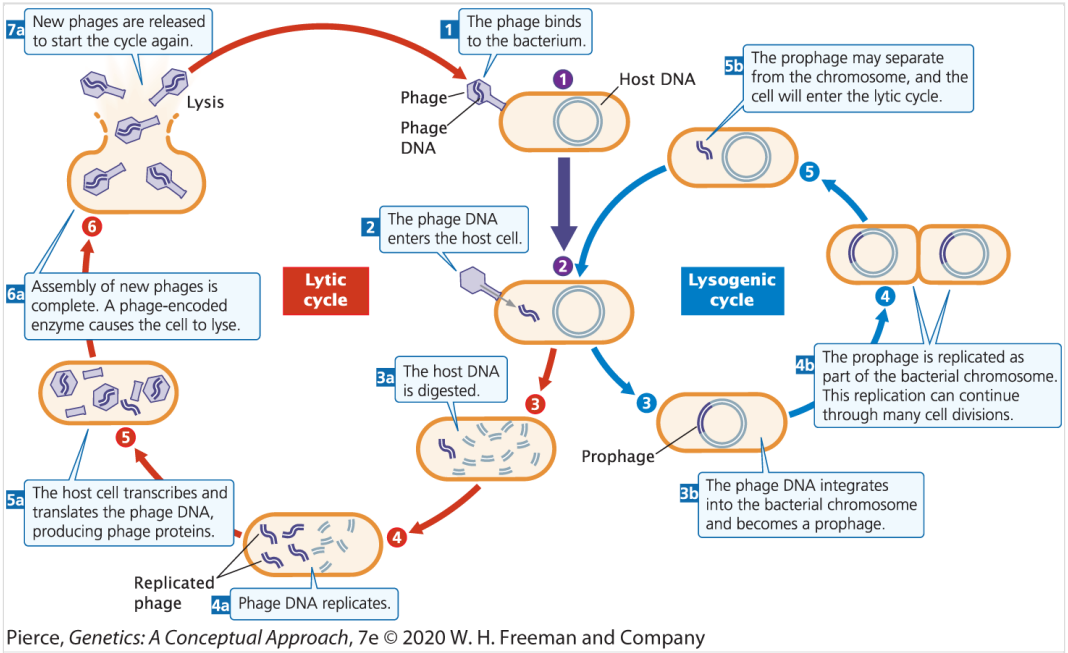


Part a: Biozentrum, University of Basel/Science Source. Part b: Eye of Science/Science Source.

9.18 Viruses have a variety of structures and sizes. (a) Bacteriophage T4 (bright orange). (b) Influenza A virus (green structures).

Viruses that infect bacteria (bacteriophages, or phages for short) have played a central role in genetic research since the late 1940s.

They are ideal for many types of genetic research because they have small and easily manageable genomes, reproduce rapidly, and produce large numbers of progeny. Bacteriophages have two alternative life cycles: the *lytic* cycle and the *lysogenic* cycle. In the lytic cycle, a phage attaches to a receptor on the bacterial cell wall and injects its DNA into the cell (Figure 9.19). Inside the host cell, the host DNA is degraded, and phage DNA is replicated, transcribed, and translated, producing more phage DNA and phage proteins. New phage particles are assembled from these components. The phages then produce an enzyme that breaks open the host cell, releasing the new phages. **Virulent phages** reproduce strictly through the lytic cycle and always kill their host cells.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

9.19 Bacteriophages have two alternative life cycles: lytic and lysogenic.

Description

On the right is the lysogenic cycle, and on the left is the lytic cycle. The host cell has a gray circular chromosome and the phage has a purple double stranded chromosome. The cycles are connected in the middle because they share stages 1 and 2, where the phage binds and enters the host cell. The lytic cycle starts when a phage having phage D N A attaches to bacterial cell containing host D N A. The phage D N A enters the cell. The captions read, 1, The phage binds to the bacterium. 2, The phage D N A enters the host cell. From this point, the phage can either remain in the lytic cycle or can enter lysogenic cycle. In the lytic cycle on the left side, the host D N A is lysed and a caption reads, The host D N A is digested. The next picture shows multiple phage D N A and host D N A fragments and a caption reads, Phage D N A replicates. The next picture of bacterial cell shows phage D N A with phage proteins and then these are assembled and the bacterial cell is lysed. The captions read, Assembly of new phages is complete. A phage-encoded enzyme causes the cell to lyse. New phages are released to start the cycle again. From step 2 in the lytic cycle where phage D N A enters the host cell, the phage can enter a lysogenic cycle. A picture of host cell shows a bacterial chromosome with phage D N A incorporated. A caption reads, The phage D N A integrates into the bacterial chromosome and becomes a prophage. The next picture shows two bacterial cells with phage D N A incorporated into their genome. A caption reads, The prophage is replicated as part of the bacterial chromosome. This replication can continue through many cell divisions. The next picture shows host cell with bacterial chromosome and a separate phage D N A. A caption reads, The prophage may separate and the cell will enter the lytic cycle.

Temperate phages can undergo either the lytic or the lysogenic cycle. The lysogenic cycle begins like the lytic cycle (see Figure 9.19), but inside the cell, the phage DNA integrates into the bacterial chromosome, where it remains as an inactive **prophage**. The prophage is replicated along with the bacterial DNA and is passed on when the bacterium divides. While the prophage is integrated into the bacterial chromosome, it inhibits subsequent infection by the same type of phage. Certain stimuli, such as ultraviolet light and some chemicals, can cause the prophage to dissociate from the

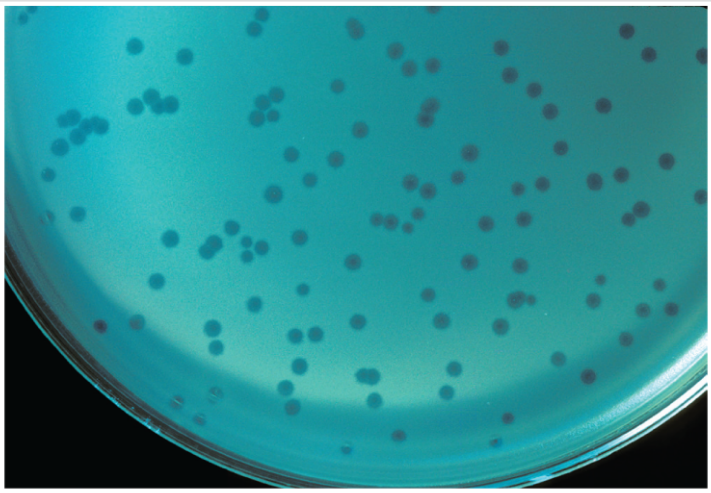
bacterial chromosome and enter the lytic cycle, producing new phage particles and lysing the cell.

THINK-PAIR-SHARE Question 5

Techniques for the Study of Bacteriophages

Viruses reproduce only within host cells, so bacteriophages must be cultured in bacterial cells. Phages can be grown in large liquid cultures of bacteria to generate large numbers of offspring, but to study the characteristics of individual phages, we must isolate them on petri plates. To do so, we can mix phages and bacteria together and plate them on a solid medium. A high concentration of bacteria is used so that the colonies will grow into one another and produce a continuous layer of bacteria, or *lawn*, on the agar. As the bacteria grow, an individual phage infects a single bacterial cell and goes through its lytic cycle. Many new phages are released from the lysed cell and infect additional cells, and the cycle is repeated. Because the bacteria are growing on a solid medium, the diffusion of the phages is restricted, so only nearby cells are infected. After several rounds of phage reproduction, a clear patch of lysed cells, called a **plaque**, appears on the plate (Figure 9.20). Each plaque represents a single phage that multiplied and lysed many cells. Plating of a known volume of a dilute solution of phages on a bacterial lawn and

counting the number of plaques that appear is a way to determine the original concentration of phages in the solution.



Carolina Biological/Medical Images.

9.20 Plaques are clear patches of lysed cells on a lawn of bacteria.

CONCEPTS

Viral genomes may be DNA or RNA, circular or linear, and double or single stranded. Bacteriophages are used in many types of genetic research.

✔ CONCEPT CHECK 6

In which bacteriophage life cycle does the phage DNA become incorporated into the bacterial chromosome?

a. Lytic
b. Lysogenic
c. Both lytic and lysogenic
d. Neither lytic nor lysogenic

Transduction

In our discussion of bacterial genetics in Section 9.3, three mechanisms of gene transfer were identified: conjugation, transformation, and transduction (see Figure 9.7). Let's take a closer look at transduction, in which genes are transferred between bacteria by viruses. In **generalized transduction**, any gene may be transferred. In **specialized transduction**, only a few genes are transferred.

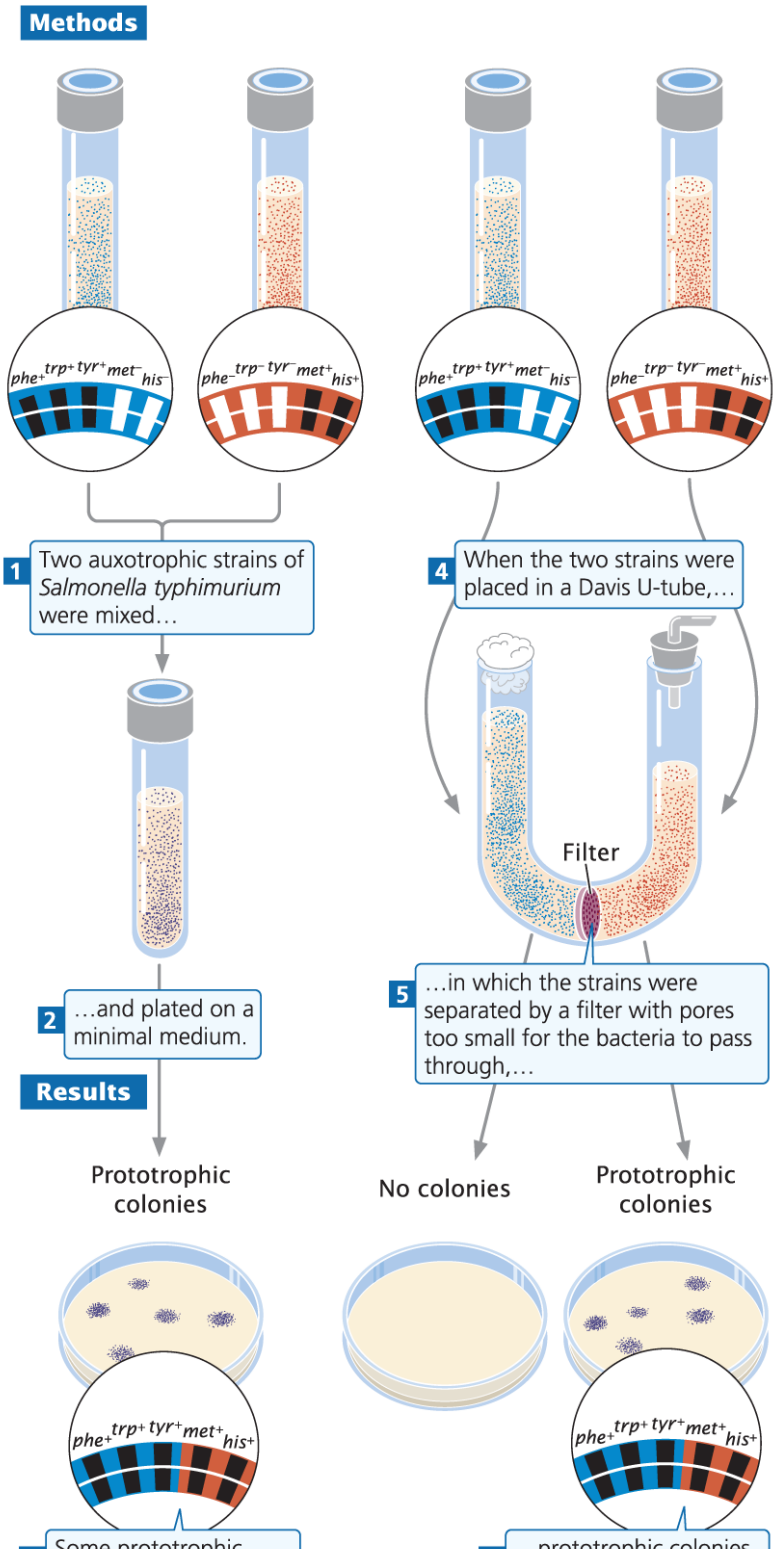
GENERALIZED TRANSDUCTION

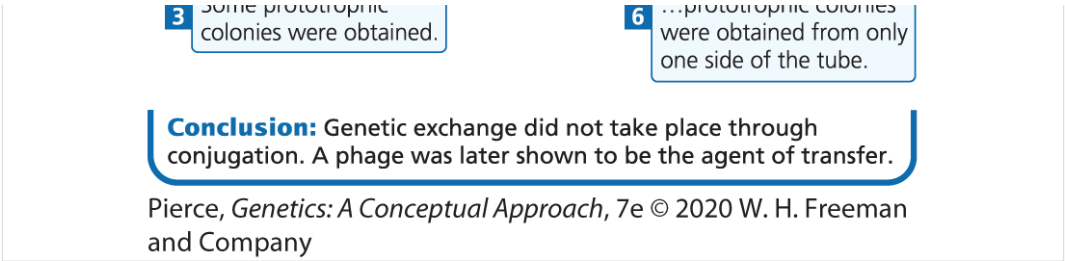
Joshua Lederberg and Norton Zinder discovered generalized transduction in 1952 while trying to produce recombination in the bacterium *Salmonella typhimurium* by conjugation. They mixed a strain of *S. typhimurium* that was phe^+ trp^+ tyr^+ met^- his^- with a strain that was phe^- trp^- tyr^- met^+ his^+ (**Figure 9.21**) and plated the mixture on a minimal medium. A few prototrophic recombinants (phe^+ trp^+ tyr^+ met^+ his^+) appeared, suggesting that conjugation had taken place. However, when they tested the two strains in a U-shaped tube similar to the one used by Davis, some phe^+ trp^+ tyr^+ met^+ his^+ prototrophs were obtained on one side of the tube (compare Figure 9.21 with Figure 9.9). In this apparatus, the two strains were separated by a filter with pores too small for the passage of bacteria, so how were genes being transferred between bacteria in the

absence of conjugation? The results of subsequent studies revealed that the agent of transfer was a bacteriophage.

Experiment

Question: Does genetic exchange between bacteria always require cell-to-cell contact?





9.21 The Lederberg and Zinder experiment.

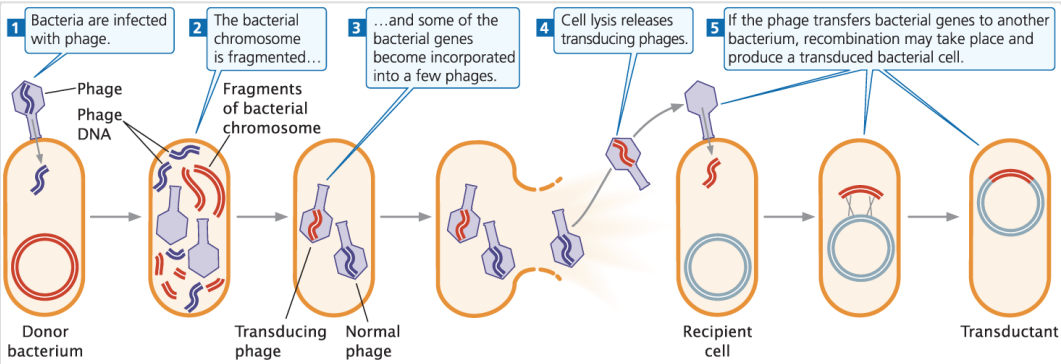
Description

The experiment starts with a question, Does genetic exchange between bacteria always require cell-to-cell contact? The methods below show two auxotrophic strains of Salmonella typhimurium in two separate test tubes and a zoomed in image of their bacterial chromosome. A caption reads, Two auxotrophic strains of Salmonella typhimurium were mixed and plated on minimal medium. Next test tube shows mixed strains. The results section below shows a petriplate with colonies labeled prototrophic colonies and a zoomed in image of their chromosome. A caption reads, Some prototrophic colonies were obtained. In another method, the two strains are not mixed. A caption reads, When the 2 strains were placed in a Davis U-tube, in which the strains were separated by a filter with pores too small for the bacteria to pass through, prototrophic colonies were obtained from only one side of the tube. The two strains are put into a U-shaped tube that has a filter in between physically separating the two bacteria. Two petriplates are shown below in the results section. The first has no colonies and the second has some colonies labeled prototrophic colonies. A caption below reads, Conclusion: Genetic exchange did not take place through

conjugation. A phage was later shown to be the agent of transfer.

In the lytic cycle of phage reproduction, the phage degrades the bacterial chromosome into random fragments (Figure 9.22). In some types of bacteriophages, a piece of the bacterial chromosome, instead of phage DNA, occasionally gets packaged into a phage coat; these phage particles are called **transducing phages**. If a transducing phage infects a new cell and releases the bacterial DNA, the

introduced genes may then become integrated into the bacterial chromosome by a double crossover. Some transducing phages insert viral DNA, along with the bacterial DNA, into the bacterial chromosome. In either case, bacterial genes can be moved from one bacterial strain to another, producing recombinant bacteria called **transductants**.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

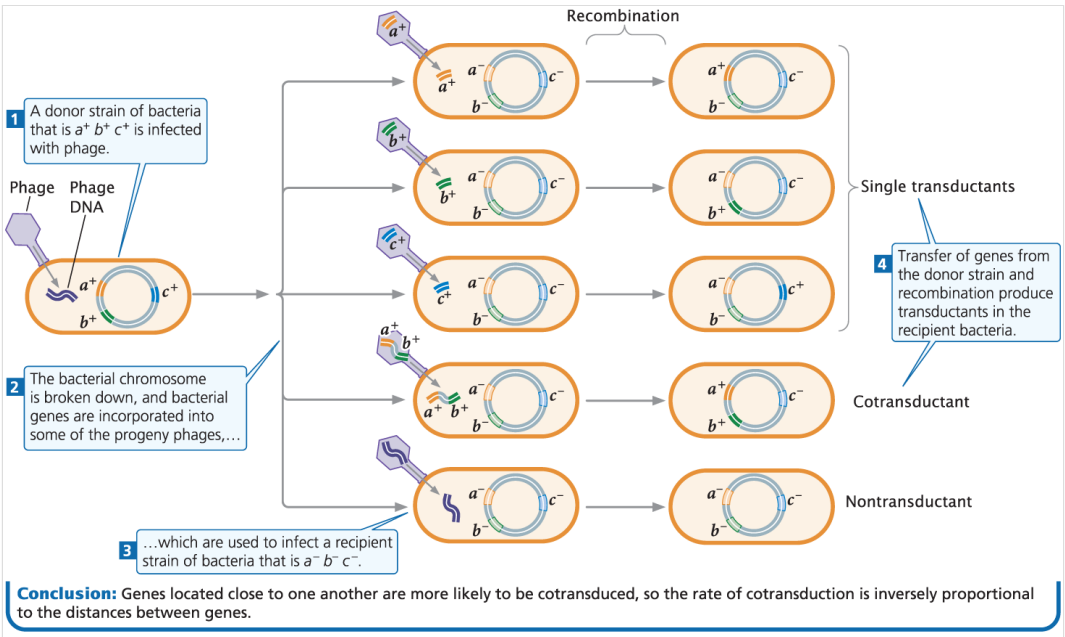
9.22 Genes can be transferred from one bacterium to another through generalized transduction.

Description

The illustration shows a bacterium with a phage infecting it at the left. The bacterial chromosome is red, circular and the phage D N A is purple double stranded. A caption reads, Bacteria are infected with phage. This leads to the next image that shows the bacterial cell with D N A fragments of both the phage and the bacterium and new phages with no D N A. A caption reads, The bacterial chromosome is fragmented and some of the bacterial genes become incorporated into a few phages. This leads to the next image that shows assembled phages inside the host cell. One is transducing phage having bacterial chromosome and the other is normal phage having its own D N A. Bacterial cell is then lysed and the phage particles are released. A caption reads, cell lysis releases transducing phages. The transducing phage infects another host cell and its D N A enters the bacterial cell. Crossing over occurs and a caption reads If the phage transfers bacterial genes to another bacterium, recombination may take place and produce a transduced bacterial cell. This leads to the next image that shows transductant with recombinant D N A.

Not all phages are capable of transduction, a rare event that requires that (1) the phage degrade the bacterial chromosome, (2) the process of packaging DNA into the phage coat not be specific for phage DNA, and (3) the bacterial genes transferred by the virus recombine with the chromosome in the recipient cell. The overall rate of transduction ranges from only about 1 in 100,000 to 1 in 1,000,000 phage particles.

Because of the limited size of a phage particle, only about 1% of the bacterial chromosome can be transduced. Only genes located close together on the bacterial chromosome will be transferred together, or **cotransduced**. Because the chance of a cell undergoing transduction by two separate phages is exceedingly small, we can assume that any cotransduced genes are located close together on the bacterial chromosome. Thus, rates of cotransduction, like rates of cotransformation, provide an indication of the physical distances between genes on a bacterial chromosome, and transduction has been used in the past to map genes in bacteria (**Figure 9.23**). **› TRY PROBLEM 29**



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

9.23 Generalized transduction can be used to map genes.

Description

The illustration shows a phage with purple D N A and a bacterial chromosome with genes a superscript positive, b superscript positive, and c superscript positive. A caption reads, A donor strain of bacteria that is a superscript positive b superscript positive c superscript positive is infected with phage. The second caption reads, The bacterial chromosome is broken down, and bacterial genes are incorporated into some of the progeny phages, which are used to infect a recipient strains of bacteria that is a superscript negative b superscript negative c superscript negative. 5 forward arrows show 5 different phage infecting 5 different bacterial cells. One has gene, a, packaged; one has gene, b; one has gene, c; one has genes a and b; and one has phage D N A. Recombination occurs and the resulting bacterial chromosomes are as follows: 1, bacterium with gene a superscript positive, b superscript negative, and c superscript negative; 2, bacterium with gene a superscript negative, b superscript positive, and c superscript negative; 3, bacterium with gene a superscript negative, b superscript negative, and c superscript positive; 4, bacterium with gene a superscript positive, b superscript positive, and c superscript negative; 5, bacterium with gene a superscript negative, b superscript negative, and c superscript negative. The first to third bacterium are labeled single transductants. The fourth is labeled co-transductant and fifth is labeled non-tranductant. A caption reads,

Transfer of genes from the donor strain and recombination produce transductants in the recipient bacteria.

CONCEPTS

In transduction, bacterial genes are packaged into a phage coat, transferred to another bacterium by the virus, and incorporated into the recipient bacterial chromosome by crossing over. Bacterial genes can be mapped with the use of generalized transduction.

✔ CONCEPT CHECK 7

In gene mapping using generalized transduction, bacterial genes that are cotransduced are

a. far apart on the bacterial chromosome.
b. on different bacterial chromosomes.
c. close together on the bacterial chromosome.
d. on a plasmid.

SPECIALIZED TRANSDUCTION

Like generalized transduction, specialized transduction involves gene transfer from one bacterium to another by a phage, but here, only genes near particular sites on the bacterial chromosome are transferred. This process requires temperate bacteriophages that use specific prophage integration sites on the bacterial chromosome. When the lysogenic cycle ends, the prophage may be imperfectly excised from the bacterial chromosome, carrying with it a small part of the bacterial DNA adjacent to the integration site. A

phage carrying this DNA then injects it into another bacterial cell in the next round of infection. This process resembles conjugation in F′ cells, in which the F plasmid carries genes from one bacterium into another (see Figure 9.14). Specialized transduction requires phages that use specific integration sites; many phages integrate randomly and exhibit only generalized transduction.

CONCEPTS

Specialized transduction transfers only those bacterial genes located near the site of prophage integration.

Gene Mapping in Phages

The mapping of genes in bacteriophages depends on homologous recombination between phage chromosomes and therefore requires the application of the same principles that are applied to mapping genes in eukaryotic organisms (see Chapter 7). Crosses are made between viruses that differ in two or more genes, and recombinant progeny phages are identified and counted. The proportion of recombinant progeny is then used to estimate the distances between the genes and to determine their linear order on the chromosome.

In 1949, Alfred Hershey and Raquel Rotman examined rates of recombination in the bacteriophage T2, which has single-stranded

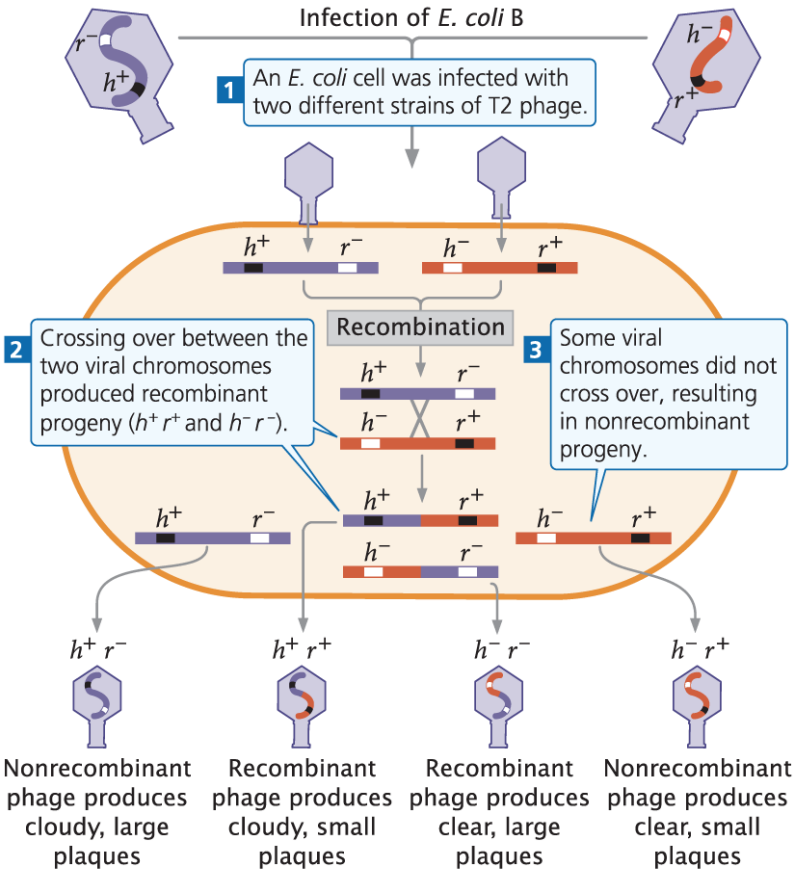
DNA. They studied recombination between genes in two strains that differed in plaque appearance and host range (the bacterial strains that the phages could infect). One strain was able to infect and lyse type B *E. coli* cells but not type B/2 cells (making this strain of phage wild type with a normal host range, or h^+), and produced abnormal plaques that were large with distinct borders (r^-). The other strain was able to infect and lyse both B and B/2 cells (mutant host range, h^-) and produced wild-type plaques that were small with fuzzy borders (r^+).

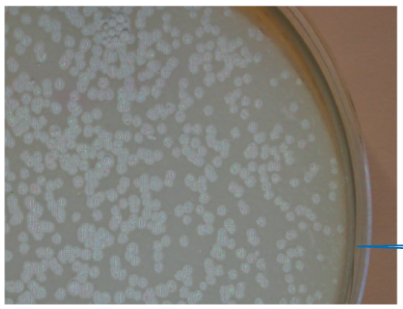
Hershey and Rotman crossed the $h^+ r^-$ and $h^- r^+$ strains of T2 by infecting type B *E. coli* cells with a mixture of the two strains. They used a high concentration of phages so that most cells could be simultaneously infected by both strains (**Figure 9.24**). Within the bacterial cells, homologous recombination occasionally took place between the chromosomes of the different bacteriophage strains, producing $h^+ r^+$ and $h^- r^-$ chromosomes, which were then packaged into new phage particles. When the cells lysed, the recombinant phages were released, along with nonrecombinant $h^+ r^-$ phages and $h^- r^+$ phages.

Experiment

Question: How can we determine the position of a gene on a phage chromosome?

Method





4 Progeny phages were then plated on a mixture of *E. coli* B and *E. coli* B/2 cells,...

Results

Genotype	Plaques	Designation
$h^- r^+$	42	Parental progeny 76%
$h^+ r^-$	34	
$h^+ r^+$	12	Recombinant progeny 24%
$h^- r^-$	12	

5 ...which allowed all four genotypes of progeny to be identified.

6 The percentage of recombinant progeny allowed the h^- and r^- mutations to be mapped.

recombinant plaques $(h^+ r^+) + (h^- r^-)$

9.24 Hershey and Rotman developed a technique for mapping viral genes.

Description

The illustration starts with a question that reads, How can we determine the position of a gene on a phage chromosome? The illustration below has a methods and a results section. In the methods section, there is a picture of a phage with purple linear D N A and a phage with red linear D N A. One of them is r superscript negative and h superscript positive, and the other phage has the opposite genotype, r superscript positive h superscript negative. A caption reads, An E coli cell was infected with 2 different strains of T 2 phage. Both the phages infect a bacterial cell and inject their D N A into the same cell. The phage D N A recombines inside the host cell. Two captions read as follows: Crossing over between the 2 viral chromosomes produced recombinant progeny, h superscript positive r superscript positive and h superscript negative r superscript negative and Some viral chromosomes did not cross over, resulting in non-recombinant progeny. Arrows beneath the bacterial cell show 4 different combinations of genes assembled into phage genomes followed by a text as follows: 1, h superscript positive r superscript negative, non-recombinant phage produces cloudy, large plaques; 2, h superscript positive r superscript positive, recombinant phage produces cloudy, small plaques; 3, h superscript negative r superscript negative, recombinant phage produces clear, large plaques; and 4, h superscript negative r superscript positive, non-recombinant phage produces clear, small plaques. Below this, an image of bacteria in a petri plate with different types of plaques. A caption reads, Progeny phages were then plated on a mixture of E coli B and E coli B over 2 cells, which allowed all four genotypes of progeny to be identified. In the results section below, is a table showing the number of plaques of each phage genotype and designation. The table has 3 columns and 4 rows. The column headers are as follows: Genotype, plaques, and designation. For genotype h superscript negative r superscript positive, there are 42 plaques. For genotype h superscript positive r superscript negative, there are 34 plaques. Designation for both is parental progeny 76 percent. For genotype h superscript positive r superscript positive, there are 12 plaques. For genotype h superscript negative r

superscript negative, there are 12 plaques. Designation for both is recombinant progeny 24 percent. A formula for calculating the R F, is given below: R F equals start fraction recombinant plaques over total plaques end fraction equals start fraction left parenthesis h superscript positive r superscript positive right parenthesis plus left parenthesis h superscript negative r superscript negative right parenthesis over total plaques end fraction. A caption reads, The percentage of recombinant progeny allowed the h superscript negative and r superscript negative mutants to be mapped. A caption reads, Conclusion: The recombination frequency indicates that the distance between h and r genes is 24 percent.

Hershey and Rotman diluted the progeny phages and plated them on a bacterial lawn that consisted of a *mixture* of B and B/2 cells. Phages carrying the h^+ allele (which conferred the ability to infect only B cells) produced a cloudy plaque because the B/2 cells were not lysed. Phages carrying the h^- allele produced a clear plaque because all the cells within the plaque were lysed. The r^+ phages produced small plaques, whereas the r^- phages produced large plaques. The genotypes of the progeny phages could therefore be determined by the appearance of the plaques (see Figure 9.24 and **Table 9.4**).

TABLE 9.4 Progeny phages produced from $h^- r^+ \times h^+ r^-$

Phenotype	Genotype
Clear and small	$h^- r^+$
Cloudy and large	$h^+ r^-$
Cloudy and small	$h^+ r^+$
Clear and large	$h^- r^-$

In this type of phage cross, the recombination frequency (*RF*) between the two genes can be calculated by using the following formula:

$$RF = \frac{\text{recombinant plaques}}{\text{total plaques}}$$

In Hershey and Rotman's cross, the recombinant plaques were $h^+ r^+$ and $h^- r^-$, so the recombination frequency was

$$RF = \frac{(h^+r^+) + (h^-r^-)}{\text{total plaques}}$$

Recombination frequencies can be used to determine the distances between genes and their order on the phage chromosome, just as they are used to map genes in eukaryotes. Today, most phage genes are mapped by DNA sequencing. **› TRY PROBLEMS 28 AND 32**

CONCEPTS

To map phage genes, bacterial cells are infected with viruses that differ in two or more traits. Recombinant plaques are counted, and rates of recombination are used to determine the linear order of the genes on the chromosome and the distances between them.

Plant and Animal Viruses

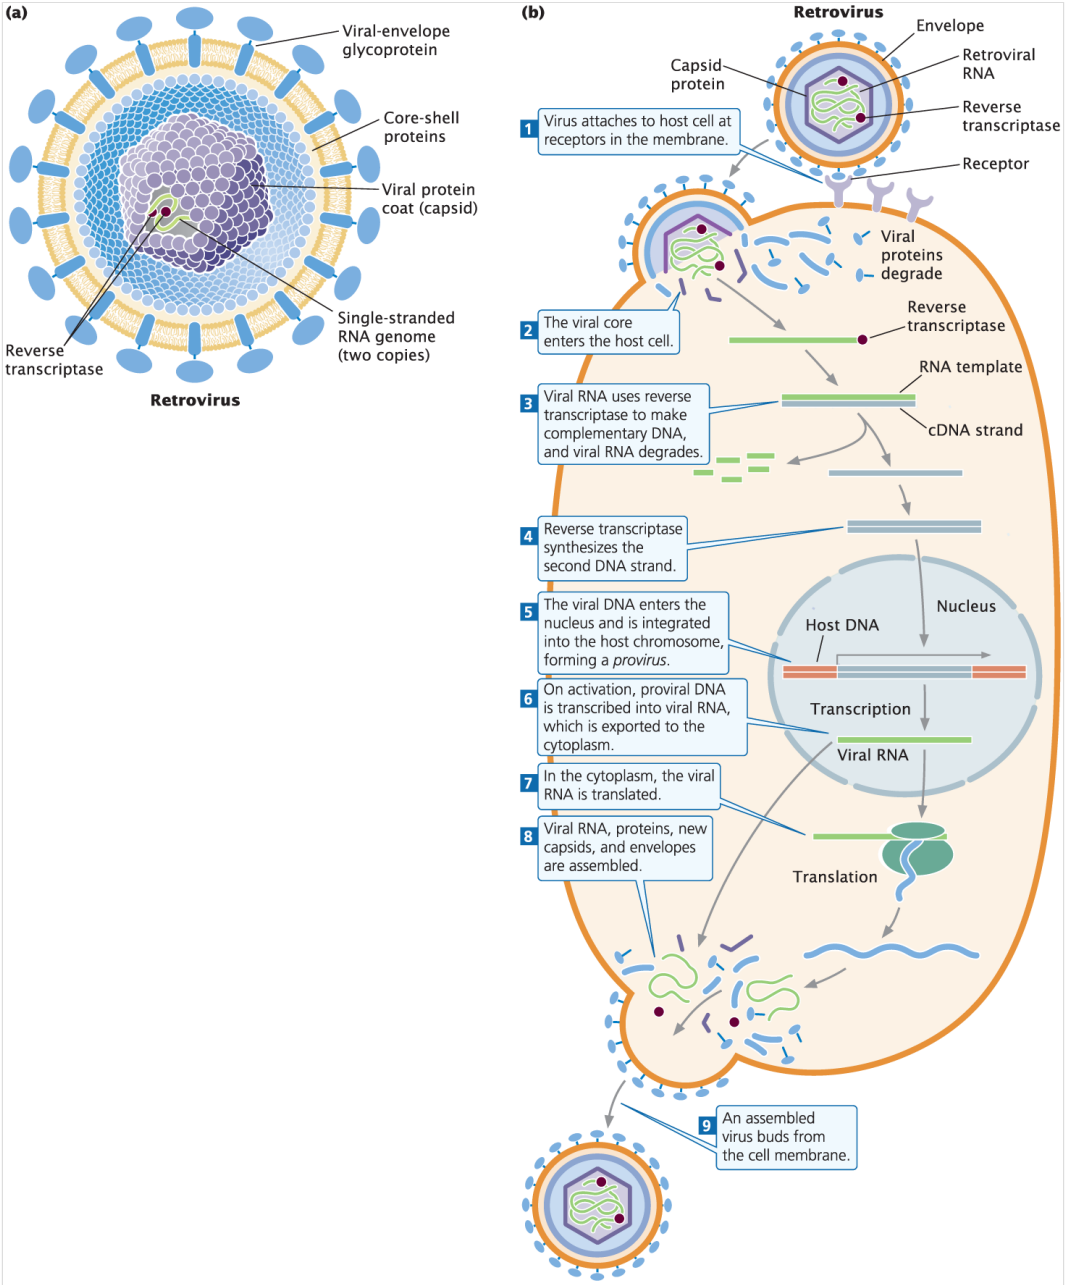
Thus far, we have primarily considered viruses that infect bacteria. Viruses also infect protists, fungi, plants, humans, and other animals, and some are important pathogens in these organisms. About 263 different viruses are known to infect humans, although there are undoubtedly many that have not been characterized. What we have learned about bacteriophages has important implications for the study of viruses that infect these complex organisms.

Viral genomes may be encoded in either DNA or RNA and may be double stranded or single stranded. Double-stranded DNA viruses include adenoviruses, which are responsible for gastroenteritis and some types of pneumonia; herpesviruses, which cause genital herpes and cold sores; papillomaviruses, which are associated with some cases of cervical cancer (see Chapter 23); and numerous viruses that infect other vertebrate and invertebrate animals. Single-stranded DNA viruses include parvovirus (parvo), which is highly infectious and sometimes lethal in dogs.

RNA viruses are found in a wide range of host organisms, including plants, invertebrates, and vertebrates. Almost all viruses that infect both plants and all major groups of vertebrates have RNA genomes. RNA is also the genetic material of some human viruses, including those that cause colds, influenza, polio, and AIDS. The medical and economic importance of RNA viruses has encouraged their study.

RNA viruses capable of integrating into the genomes of their hosts, much as temperate phages insert themselves into bacterial

chromosomes, are called **retroviruses** (**Figure 9.25a**). Because the retroviral genome is RNA, whereas that of the host is DNA, a retrovirus must produce **reverse transcriptase**, an enzyme that can synthesize complementary DNA (cDNA) from either an RNA or a DNA template. A retrovirus uses reverse transcriptase to copy its RNA genome into a single-stranded DNA molecule. The reverse transcriptase enzyme—or sometimes the host DNA polymerase—then copies this single-stranded DNA, creating a double-stranded DNA molecule that is integrated into a host chromosome. A viral genome incorporated into a host chromosome is called a **provirus**. The provirus is replicated by host enzymes when the host chromosome is duplicated (**Figure 9.25b**).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

9.25 A retrovirus uses reverse transcription to incorporate its RNA into the host DNA. (a) Structure of a typical retrovirus. Two copies of the single-stranded RNA genome and the reverse transcriptase enzyme are shown enclosed within a protein capsid. The capsid is surrounded by a viral envelope that is studded with viral glycoproteins. (b) The retrovirus life cycle.

Description

Illustration a on the left shows the typical structure of a retrovirus. Two copies of single-stranded R N A molecule is present with reverse transcriptase on it. R N A is enclosed within an octahedral viral protein coat, also known as capsid. Circular core-shell proteins are present above it, enclosing the whole structure. Viral-envelope glycoprotein lie on top of that in a radial manner.

Illustration b on the right shows how a retrovirus uses reverse transcription to incorporate its R N A into the host D N A. The illustration starts with a retrovirus docking on a cell receptor of a bacterial cell and then fusing with the cell. The first caption reads, Virus attaches to host cell at receptors in the membrane. Viral R N A with reverse transcriptase enzyme and viral proteins enters the host cell. The proteins are labeled viral proteins degrade. The second caption reads, The viral core enters the host cell. Reverse transcriptase on R N A makes c D N A strand complementary to the R N A. The third caption reads, Viral R N A uses reverse transcriptase to make complementary D N A, and viral R N A degrades. From this c D N A, a second complementary strand is formed. The fourth caption reads, Reverse transcriptase synthesizes the second D N A strand. This D N A now enters the host nucleus and incorporates itself within the host D N A. Transcription occurs and viral R N A is produced. This R N A leaves the nucleus and produces viral protein in the cell through translation. Assembly of virus takes place and a new virus is produced. The next captions read as follows: The viral D N A enters the nucleus and is integrated into the host chromosome, forming a provirus. On activation, proviral D N A is transcribed into viral R N A, which is exported to the cytoplasm. In the cytoplasm, the viral R N A is translated. Viral R N A, proteins, new capsids, and envelopes are assembled. An assembled virus buds from the cell membrane.

When conditions are appropriate, the provirus undergoes transcription to produce numerous copies of the original viral RNA genome. This RNA encodes viral proteins and serves as genomic RNA for new viral particles. As these new viruses escape the cell, they collect patches of the cell membrane to use as their envelopes.

All known retroviral genomes have three genes in common: *gag*, *pol*, and *env*, each encoding a precursor protein that is cleaved into two

or more functional proteins. The *gag* gene encodes proteins that make up the viral protein coat. The *pol* gene encodes reverse transcriptase and an enzyme called **integrase**, which inserts the viral DNA into a host chromosome. The *env* gene encodes the glycoproteins that appear on the surface of the viral envelope.

Some retroviruses contain **oncogenes** (see Chapter 23), which may stimulate cell division and cause the formation of tumors. The first retrovirus to be isolated, the Rous sarcoma virus, was originally recognized by its ability to produce connective-tissue tumors (sarcomas) in chickens.

THINK-PAIR-SHARE Question 6

Human Immunodeficiency Virus and AIDS

An example of a retrovirus is the human immunodeficiency virus (HIV), which causes acquired immune deficiency syndrome (AIDS). Although research now indicates that HIV entered the United States around 1970 and was present in Africa much earlier, AIDS was not recognized as a disease until 1982, when a number of homosexual males in the United States began to exhibit symptoms of a new immune-system-deficiency disease. In that year, Robert Gallo proposed that AIDS was caused by a retrovirus; eventually, research

by Gallo, Luc Montagnier, Françoise Barré-Sinoussi, Jay Levy, and others identified HIV as the causative agent of AIDS. Between 1983 and 1984, as the AIDS epidemic became widespread, the HIV retrovirus was isolated from people with the disease. AIDS is now known to be caused by two different immunodeficiency viruses, HIV-1 and HIV-2, which together have infected more than 70 million people worldwide since the beginning of the epidemic. Of those infected, 35 million have died. At the end of 2017, there were almost 37 million people around the globe living with HIV, including 2 million children. Most cases of AIDS are caused by HIV-1, which now has a global distribution; HIV-2 is found primarily in western Africa.

HIV illustrates the importance of genetic recombination in viral evolution. Studies of the DNA sequences of HIV and other retroviruses reveal that HIV-1 is closely related to the simian immunodeficiency virus found in chimpanzees (SIV_{cpz}). Many wild chimpanzees in Africa are infected with SIV_{cpz}, although it doesn't cause AIDS-like symptoms in these animals. SIV_{cpz} is itself a hybrid that resulted from recombination between a retrovirus found in the red-capped mangabey (a monkey) and a retrovirus found in the greater spot-nosed monkey (**Figure 9.26**). Apparently, one or more chimpanzees became infected with both viruses; recombination between the viruses produced SIV_{cpz}, which was then transmitted to humans through contact with infected chimpanzees. In humans, SIV_{cpz} underwent significant evolution to become HIV-1, which then spread throughout the world to produce the AIDS epidemic. Several independent transfers of SIV_{cpz} to humans gave rise to different

groups (strains) of HIV-1. In the case of HIV-1 groups O and P, SIV_{cpz} first jumped to gorillas, then passed from gorillas to humans. The M group of HIV-1 has spread throughout the world and is responsible for most cases of HIV worldwide. The O group has infected about 100,000 people in west central Africa. Groups N and P have infected only a small number of people in Africa. HIV-2 evolved from a different retrovirus, SIV_{sm}, found in sooty mangabeys.

9.26 HIV-1 evolved from a similar virus SIV_{cpz} found in chimpanzees and was transmitted to humans. SIV_{cpz} arose from recombination between retroviruses from red-capped mangabeys and from greater spot-nosed monkeys.

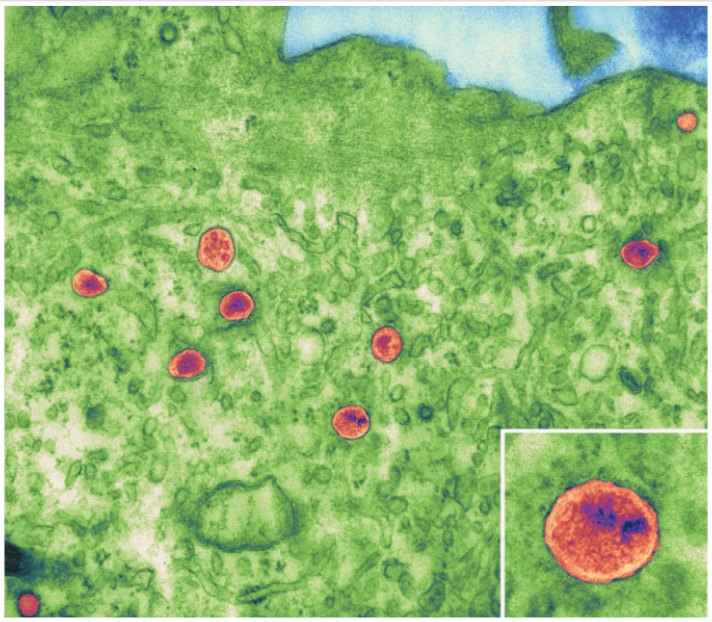
Description

The illustration shows outlines of different human and non-human primates with a drawing of their respective S I V or H I V viruses. At the bottom of the illustration, is the red-capped mangabey wth S I V subscript r c m and greater spot-nosed monkey with S I V subscript g s n. An upward arrow points to a doubly infected chimpanzee with S I V subscript r c m and S I V subscript g s n. Recombination occurs and an upward arrow shows an outline of a chimpanzee with a virus called S I V subscript c p z. From this chimpanzee, three arrows pointing up show three chimpanzees with the same virus, S I V c p z. From the first chimpanzee, an upward arrow points to a human outline with H I V-1 group M. From the second chimpanzee, an upward arrow points to a human outline with H I V-1 group N. An arrow from the third chimpanzee leads to a gorilla outline with S I V g o r. From this gorilla, two upward arrows point to two individual human outlines; one with H I V-1 group O and the other with H I V-1 group P.

HIV is transmitted between humans by sexual contact and through any type of blood-to-blood contact, such as that caused by the sharing of dirty needles by drug users. HIV can also be transmitted between mother and child during pregnancy or in breast milk. Until screening tests were developed to identify HIV-infected blood, transfusions and clotting factors used to treat hemophilia were sources of infection as well.

HIV principally attacks a class of blood cells called helper T lymphocytes, or simply helper T cells (Figure 9.27). HIV enters a

helper T cell, undergoes reverse transcription, and integrates into the chromosome. The virus reproduces rapidly, destroying the T cell as new virus particles escape from the cell. Because helper T cells are central to immune function, people with AIDS have a diminished immune response; most deaths among AIDS patients are caused by secondary infections that develop because they have lost the ability to fight off pathogens.



Thomas Deerinck, NCMIR/Science Source.

9.27 HIV principally attacks helper T lymphocytes. This electron micrograph shows a T cell (green) infected with HIV (orange).

The HIV genome is 9749 nucleotides long and carries *gag*, *pol*, *env*, and six other genes that regulate the life cycle of the virus. HIV's reverse transcriptase is very error prone, giving the virus a high mutation rate and allowing it to evolve rapidly, even within a single host. This rapid evolution makes the development of an effective

vaccine against HIV particularly difficult. Genetic variation within the human population also affects the virus. To date, more than 10 loci in humans that affect HIV infection and the progression of AIDS have been identified.

CONCEPTS

A retrovirus is an RNA virus that integrates into a host chromosome by using reverse transcription to make a DNA copy of its RNA genome. Human immunodeficiency virus, the causative agent of AIDS, is a retrovirus. It evolved from related retroviruses found in other primates.

✔ CONCEPT CHECK 8

What enzyme is used by a retrovirus to make a DNA copy of its genome?

Influenza

Influenza demonstrates how rapidly changes in a pathogen can arise through recombination of its genetic material. Influenza, commonly called flu, is a respiratory disease caused by influenza viruses. In the United States, from 5% to 20% of the population is infected with influenza annually, and though most cases are mild, an estimated 36,000 people die from influenza-related causes each year. At certain times, particularly when new strains of influenza virus enter the human population, there are worldwide epidemics (called

pandemics); for example, in 1918, the Spanish flu virus killed an estimated 20 million to 100 million people worldwide.

Influenza viruses are RNA viruses that infect birds and mammals. The three main types are influenza A, influenza B, and influenza C. Most cases of the common flu are caused by influenza A and B. Influenza A is divided into subtypes on the basis of two proteins, hemagglutinin (HA) and neuraminidase (NA), found on the surface of the virus. The HA and NA proteins affect the ability of the virus to enter host cells and the host organism's immune response to infection. There are 16 types of HA and 9 types of NA, which can exist in a virus in different combinations. For example, common subtypes of influenza A circulating in humans today are H1N1 and H3N2 (Table 9.5), along with several types of influenza B.

TABLE 9.5 Strains of influenza virus responsible for major flu pandemics

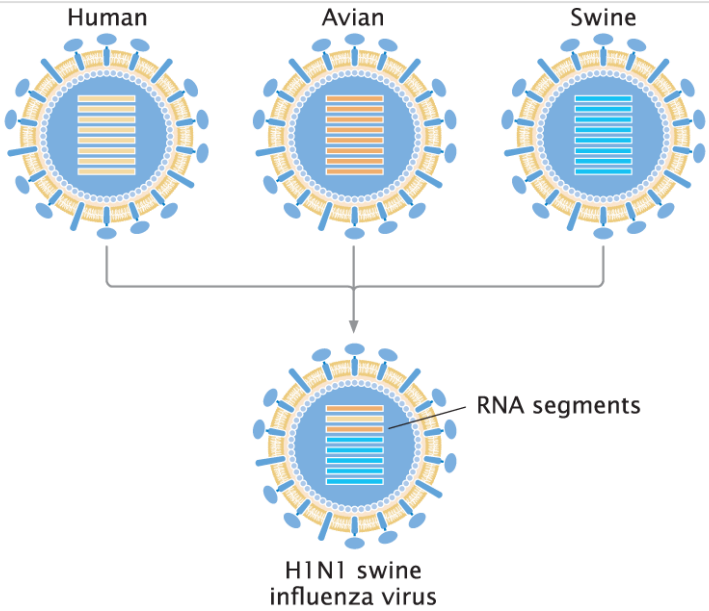
Year	Influenza Pandemic	Strain
1918	Spanish flu	H1N1
1957	Asian flu	H2N2
1968	Hong Kong flu	H3N2
2009	Swine flu	H1N1

Although the influenza virus is an RNA virus, it is not a retrovirus: its genome is not copied into DNA and incorporated into a host chromosome. The influenza viral genome consists of seven or eight pieces of RNA enclosed in a viral envelope. Each piece of RNA

encodes one or two of the virus's proteins. The virus enters a host cell by attaching to specific receptors on the cell membrane. After the viral particle has entered the cell, the viral RNA is released, copied, and translated into viral proteins. Viral RNA molecules and viral proteins are then assembled into new viral particles, which exit the cell and infect additional cells.

One of the dangers of the influenza virus is that it evolves rapidly, so that new strains appear frequently. The virus evolves in two ways. First, the enzyme that copies the viral RNA is especially prone to making mistakes, so new mutations are continually introduced into the genome of each viral strain. This type of continual change is called **antigenic drift**. Second, major changes in the viral genome occasionally take place through **antigenic shift**, in which genetic material from different strains is combined in a process called reassortment. Reassortment may take place when a host is simultaneously infected with two different strains. When the RNAs of both strains are replicated within the cell, RNA segments from two different strains may be incorporated into the same viral particle, creating a new strain. For example, in 2002, reassortment occurred between the H1N1 and H3N2 subtypes, creating a new H1N2 strain that contained the HA from H1N1 and the NA from H3N2. New strains produced by antigenic shift are responsible for most pandemics because no one has immunity to the radically different virus that is produced.

Birds harbor the most different strains of influenza A, but humans are not easily infected with bird influenza. New strains in humans are thought to arise most often from viruses that reassort in pigs, which can be infected by viruses from both humans and birds. In 2009, a new strain of H1N1 influenza (called swine flu) emerged in Mexico and quickly spread throughout the world. This virus arose from a series of reassortment events that combined gene sequences from human, bird, and pig influenza viruses (Figure 9.28). Farming practices that raise pigs and birds in close proximity may facilitate reassortment among avian, swine, and human strains of influenza.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

9.28 New strains of influenza virus are created by reassortment of genetic material from different strains. A new H1N1 virus (swine flu) that appeared in 2009 contained genetic material from avian, swine, and human viruses.

Description

The illustration shows images of viruses with different colored R N A segments inside. The swine virus has 8 blue-colored R N A segments inside. The human strain's segments are yellow, while the avian's segments are orange. In the H 1 N 1 swine influenza virus below, there are 5 blue segments, 2 orange segments, and 1 yellow segment inside the virus.

Rhinoviruses

Rhinoviruses are very small RNA viruses that infect epithelial cells of the respiratory tract and are responsible for respiratory infections, including the common cold. Although the symptoms of rhinovirus infections are usually mild, they constitute a serious public health burden: colds force many people to miss work, make millions of people miserable, and occasionally lead to medical complications, such as pneumonia or exacerbation of asthma and cystic fibrosis. Respiratory infections caused by rhinoviruses remain resistant to treatment, even in the era of modern medicine.

Rhinoviruses have a genome of single-stranded RNA, consisting of approximately 7200 nucleotides, that encodes only 11 proteins. Rhinoviruses have considerable genetic diversity and evolve rapidly. These viruses have a high mutation rate, caused by the inability of their RNA polymerase enzymes (which copy the RNA genome of the virus) to detect and correct mistakes made during the copying process. In addition, multiple viral strains may simultaneously infect the same cell and recombine, leading to the emergence of new rhinovirus strains.

Rhinoviruses that cause colds in humans are highly specialized and are adapted to the human ecosystem. Curiously, they evolved from enteroviruses—viruses that inhabit the gut and can cause acute intestinal infections. Research suggests that rhinoviruses evolved long ago and are adapted to replicate and spread between human cells efficiently without killing their host, leading to relatively mild effects on the humans they infect. Genetic analysis demonstrates that there are three species of human rhinoviruses, called rhinovirus A, rhinovirus B, and rhinovirus C. Within each species, there are numerous variants, called serotypes. Recombination within and between species constantly generates new types of rhinoviruses.

Zika Virus

Zika virus is an RNA flavivirus, a group that includes a number of viruses that cause human disease, including West Nile virus, dengue virus, tick-borne encephalitis virus, and yellow fever virus. Zika virus has recently spread rapidly around the world and is transmitted to humans by *Aedes* mosquitoes. Outbreaks of Zika virus in Brazil during the 2016 Olympics in Rio de Janeiro focused worldwide attention on the disease.

Infection with Zika virus usually causes mild or no symptoms but can lead to several neurological conditions, including microcephaly (small head) in newborns. The virus was isolated in 1947 from a monkey in Africa and was found in humans in 1952, but prior to

2007, only a few cases of Zika virus infection were recorded. Major epidemics occurred in the Pacific Islands in 2013. In 2015, epidemics of Zika virus infection erupted in Brazil and then spread to other parts of South America, Central America, the Caribbean, and North America. Although transmitted primarily by mosquito vectors, the virus is present in human body fluids and can be transmitted sexually.

The Zika virus genome consists of one single-stranded RNA molecule consisting of about 10,800 nucleotides. It contains a single gene, which is translated and processed into 10 different proteins. A characteristic of Zika virus is a high rate of recombination within its genome, which is uncommon in other flaviviruses and has perhaps contributed to its rapid spread around the globe. The virus has undergone multiple recombination events since it was first discovered. Zika virus undergoes rapid evolution, and a number of different strains have evolved.

Our understanding of Zika origin and spread has been greatly facilitated by studies that have isolated, sequenced, and analyzed the genomes of Zika viruses from around the world. For example, studies of Zika genomes indicate that the virus first evolved into two different lineages, one from Africa and another from Asia. Based on the number of genetic differences between them, researchers have estimated that the African and Asian strains diverged sometime in the seventeenth century. The outbreaks in the Pacific Islands and the Americas emerged from the Asian lineage. Genetic analysis

demonstrated that hundreds of infections in Florida originated from at least 4 and perhaps as many as 40 separate introductions, mostly from countries and territories in the Caribbean.

CONCEPTS

Influenza is caused by RNA viruses. New strains of influenza viruses appear through antigenic shift, in which new viral genomes are created through the reassortment of RNA molecules of different strains. Rhinoviruses are small RNA viruses that often cause respiratory infections. Zika virus is an RNA virus that has spread rapidly around the world in recent years.

Chapter 9 Review

CHAPTER SUMMARY

Section 9.1 Learning Objective: Be able to list some of the reasons that the study of bacteria and viruses is important.

- Bacteria and viruses play important roles in human health and society and in the world ecosystem. They are extremely abundant and make up the majority of life's diversity. Analysis of DNA sequences allow study of bacteria that cannot be cultured in the laboratory.

Section 9.2 Learning Objective: Be able to describe how bacteria are cultured and studied in the laboratory.

- Bacteria and viruses are well suited to genetic studies: they are small, have a small haploid genome, undergo rapid reproduction, and produce large numbers of progeny through asexual reproduction.
- The bacterial genome normally consists of a single circular molecule of double-stranded DNA. Plasmids are small pieces of bacterial DNA that can replicate independently of the bacterial chromosome.

Section 9.3 Learning Objective: Be able to summarize the primary mechanisms by which bacteria exchange genes.

- DNA can be transferred between bacteria by conjugation, transformation, or transduction.
- Conjugation is the transfer of genetic material from one bacterial cell to another by direct contact between the two cells. Conjugation is controlled by an episome called the F factor. The time it takes for individual genes to be transferred during conjugation provides information about the order of the genes, and the distances between them, on the bacterial chromosome.
- Bacteria take up DNA from the environment through the process of transformation. Frequencies of cotransformation provide information about the physical distances between chromosomal genes.
- Complete genome sequences of many bacterial species have been determined. This sequence information indicates that horizontal gene transfer—the movement of DNA between species—is common in bacteria.

Section 9.4 Learning Objective: Be able to describe the different ways that bacteria avoid infection by viruses and other foreign DNA elements.

- Bacteria and archaea have evolved mechanisms to prevent the entry and reproduction of viruses and other invading DNA. These include systems that prevent viral attachment and injection of the viral DNA or RNA into the cell, restriction-modification systems, and CRISPR-Cas immunity.

- CRISPR-Cas systems provide adaptive immunity, the ability to recognize and remember DNA from specific pathogens. In response, viruses have evolved mechanisms to avoid bacterial defenses.

Section 9.5 Learning Objective: Be able to describe the genetic systems of viruses.

- Viruses are replicating structures with DNA or RNA genomes that may be double stranded or single stranded and linear or circular.
- Bacterial genes may be incorporated into phage coats and transferred to other bacteria by phages in a process called transduction. Rates of cotransduction can be used to map bacterial genes.
- Phage genes can be mapped by infecting bacterial cells with two different phage strains and counting the recombinant plaques produced by the progeny phages.
- A number of viruses have RNA genomes. Retroviruses encode reverse transcriptase, an enzyme used to make a DNA copy of the viral genome, which then integrates into the host genome as a provirus. HIV is a retrovirus that is the causative agent for AIDS.
- Influenza is caused by RNA viruses. These viruses evolve both through small changes that take place by mutation (antigenic drift) and through major changes that take place via the reassortment of genetic material from different strains within a host (antigenic shift).

- Rhinoviruses are small RNA viruses that often cause respiratory infections.
- Zika virus is an RNA virus that has rapidly spread around the world.

WORKED PROBLEMS

Problem 1

DNA from a strain of bacteria with genotype $a^+ b^+ c^+ d^+ e^+$ was isolated and used to transform a strain of bacteria that was $a^- b^- c^- d^- e^-$. The transformants were tested for the presence of donated genes. The following genes were cotransformed:

a^+ and d^+
b^+ and e^+
c^+ and d^+
c^+ and e^+

What is the order of genes *a*, *b*, *c*, *d*, and *e* on the bacterial chromosome?

» Solution Strategy

What information is required in your answer to the problem?

The order of genes *a*, *b*, *c*, *d*, and *e* on the bacterial chromosome.

What information is provided to solve the problem?

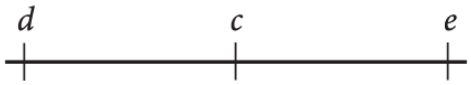
- The donor cells were a^+ b^+ c^+ d^+ e^+ and the recipient cells were a^- b^- c^- d^- e^-.
- The combinations of genes that were cotransformed.

For help with this problem, review:

Transformation in Bacteria in Section 9.3.

» Solution Steps

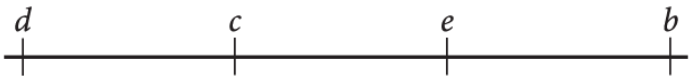
In this transformation experiment, gene c^+ is cotransformed with both gene e^+ and gene d^+, but genes e^+ and d^+ are not cotransformed; therefore, the *c* locus must be between loci *d* and *e*:



Recall: The rate at which genes are cotransformed is inversely proportional to the distance between them: genes that are close together are frequently cotransformed, whereas genes that are far apart are rarely cotransformed.

Gene e^+ is also cotransformed with gene b^+, so the *e* and *b* loci must be located close together. Locus *b* could be on either side of locus *e*. To determine whether locus *b* is on the same side of *e* as locus *c*, we

look to see whether genes b^+ and c^+ are cotransformed. They are not, so locus *b* must be on the opposite side of *e* from *c*:



Gene a^+ is cotransformed with gene d^+, so the *a* and *d* loci must be located close together. If locus *a* were located on the same side of *d* as locus *c*, then genes a^+ and c^+ would be cotransformed. Because these genes display no cotransformation, locus *a* must be on the opposite side of locus *d*:

Problem 2

Consider three genes in *E. coli*: thr^+, ara^+, and leu^+ (which give the cell the ability to synthesize threonine, arabinose, and leucine, respectively). All three of these genes are close together on the *E. coli* chromosome. Phages are grown in a thr^+ ara^+ leu^+ strain of bacteria (the donor strain). The phage lysate is collected and used to infect a strain of bacteria that is thr^- ara^- leu^-. The recipient bacteria are then tested on a selective medium lacking leucine. Bacteria that grow and form colonies on this medium (leu^+ transductants) are then replica-plated on a medium lacking threonine and on a medium lacking arabinose to see which are thr^+ and which are ara^+.

Another group of the recipient bacteria are tested on a medium lacking threonine. Bacteria that grow and form colonies on this medium (*thr*$^+$ transductants) are then replica-plated on a medium lacking leucine and on a medium lacking arabinose to see which are *ara*$^+$ and which are *leu*$^+$. Results from these experiments are as follows:

Selected gene	Cells with cotransduced genes (%)
leu$^+$	3 *thr*$^+$
	76 *ara*$^+$
thr$^+$	3 *leu*$^+$
	0 *ara*$^+$

How are the loci arranged on the chromosome?

» Solution Strategy

What information is required in your answer to the problem?

The order of genes *thr, ara,* and *leu* on the bacterial chromosome.

What information is provided to solve the problem?

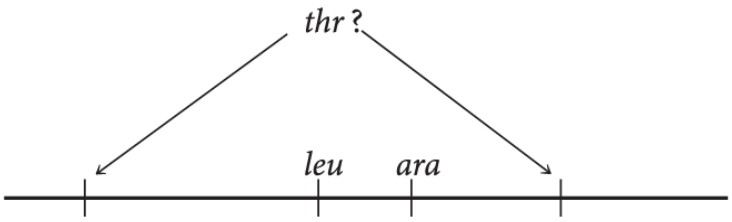
- The genes are located close together on the *E. coli* chromosome.
- The donor strain is *thr*$^+$ *ara*$^+$ *leu*$^+$ and the recipient strain is *hr*$^-$ *ara*$^-$ *leu*$^-$.
- The percentage of cells with cotransduced genes.

For help with this problem, review:

Transduction in Section 9.5.

» Solution Steps

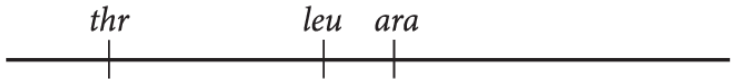
Notice that when we select for *leu*$^+$ (the top half of the table), most of the selected cells are also *ara*$^+$. This finding indicates that the *leu* and *ara* genes are usually cotransduced and are therefore located close together. In contrast, *thr*$^+$ is only rarely cotransduced with *leu*$^+$, indicating that *leu* and *thr* are much farther apart. On the basis of these observations, we know that *leu* and *ara* are closer together than are *leu* and *thr*, but we don't yet know the order of the three genes—whether *thr* is on the same side of *ara* as *leu* or on the opposite side:



Description
Genes l e u and a r a are in the middle of the map, but on the right and left sides are 2 blank notches. Above the line map is a t h r and a question mark. From this point, 2 arrows are drawn down pointing to the 2 blank notches in the map.

Hint: Genes located close together are more likely to be cotransduced than are genes located far apart.

Notice that although the cotransduction frequency for *thr* and *leu* is 3%, no thr^+ ara^+ cotransductants are observed. This finding indicates that *thr* is closer to *leu* than to *ara*, and therefore *thr* must be on the opposite side of *leu* from *ara*:



Hint: We can determine the position of *thr* with respect to the other two genes by looking at the cotransduction frequencies when thr^+ is selected.

Chapter 9 Assessment

COMPREHENSION QUESTIONS

Section 9.1

1. What are some advantages of using bacteria and viruses for genetic studies?

Section 9.2

2. Explain how auxotrophic bacteria are isolated.
3. What is the difference between a complete medium and a minimal medium? How are complete media and minimal media to which one or more nutrients have been added (selective media) used to isolate auxotrophic mutants of bacteria?

Section 9.3

4. Briefly explain the differences between F^+, F^-, Hfr, and F' cells.
5. What types of matings are possible between F^+, F^-, Hfr, and F' cells? What outcomes do these matings produce? What is the role of the F factor in conjugation?

6. Explain how interrupted conjugation, transformation, and transduction can be used to map bacterial genes. How are these methods similar, and how are they different?
7. What is horizontal gene transfer, and how might it take place?

Section 9.4

8. What are the three stages by which CRISPR-Cas immunity occurs? What takes place in each stage?
9. What problem is solved by the requirement that a PAM sequence be adjacent to a protospacer in order to be recognized by CRISPR-Cas systems?

Section 9.5

10. List some of the characteristics that make bacteriophages ideal organisms for many types of genetic studies.
11. What types of genomes do viruses have?
12. Briefly describe the differences between the lytic cycle of virulent phages and the lysogenic cycle of temperate phages.
13. Briefly explain how genes in phages are mapped.
14. Briefly describe the genetic structure of a typical retrovirus.
15. Explain how a retrovirus, which has an RNA genome, is able to integrate its genetic material into that of a host having a DNA genome.
16. What are the evolutionary origins of HIV-1 and HIV-2?
17. Most humans are not easily infected by avian influenza. How, then, do DNA sequences from avian influenza become incorporated into human influenza?

APPLICATION QUESTIONS AND PROBLEMS

Section 9.1

18. *Suppose you want to compare the species of bacteria that exist in a polluted stream with the species that exist in an unpolluted stream. Traditionally, bacteria have been identified by growing them in the laboratory and comparing their physical and biochemical properties. You recognize that you will be unable to culture most of the bacteria that reside in the streams. How might you go about identifying the species in the two streams without culturing them in the laboratory?

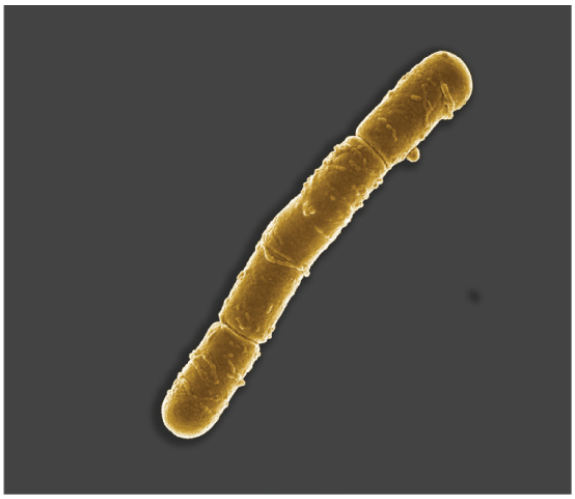
Section 9.3

19. John Smith is a pig farmer. For the past five years, Smith has been adding vitamins and low doses of antibiotics to his pig food; he says that these supplements enhance the growth of the pigs. Within the past year, however, several of his pigs died from infections of common bacteria, which failed to respond to large doses of antibiotics. Can you explain the increased rate of mortality due to infection in Smith's pigs? What advice might you offer Smith to prevent this problem in the future?
20. Rarely, the conjugation of Hfr and F^- cells produces two Hfr cells. Explain how this event takes place.

21. In **Figure 9.8**, what do the red and blue parts of the DNA labeled by balloon 6 represent?
22. DNA from a strain of *Bacillus subtilis* with the genotype trp^+ tyr^+ was used to transform a recipient strain with the genotype trp^- tyr^-. The following numbers of transformed cells were recovered:

Genotype	Number of transformed cells
trp^+ tyr^-	**154**
trp^- tyr^+	**312**
trp^+ tyr^+	**354**

What do these results suggest about the linkage of the *trp* and *tyr* genes?



Nano Creative/Science Source.

B. subtilis.

23. *DNA from a strain of *B. subtilis* with genotype $a^+ b^+ c^+ d^+ e^+$ is used to transform a strain with genotype $a^- b^- c^- d^- e^-$. Pairs of genes are checked for cotransformation, and the following results are obtained:

Pair of genes	Cotransformation	Pair of genes	Cotransformation
a^+ and b^+	No	b^+ and d^+	No
a^+ and c^+	No	b^+ and e^+	Yes
a^+ and d^+	Yes	c^+ and d^+	No
a^+ and e^+	Yes	c^+ and e^+	Yes
b^+ and c	Yes	d^+ and e^+	No

On the basis of these results, what is the order of the genes on the bacterial chromosome?

24.

Rollin Hotchkiss and Julius Marmur studied transformation in the bacterium *Streptococcus pneumoniae* (R. D. Hotchkiss and J. Marmur. 1954. *Proceedings of the National Academy of Sciences of the United States of America* 40:55–60). They examined four mutations in this bacterium: penicillin resistance (*P*), streptomycin resistance (*S*), sulfanilamide resistance (*F*), and the ability to use mannitol (*M*). They extracted DNA from strains of bacteria with different combinations of different mutations and used this DNA to transform wild-type bacterial cells ($P^+ S^+ F^+ M^+$). The results from one of their transformation experiments are shown here:

Donor DNA	Recipient DNA	Transformants	Percentage of all cells
$M\ S\ F$	$M^+\ S^+\ F^+$	$M^+\ S\ F^+$	4.0
		$M^+\ S^+\ F$	4.0
		$M\ S^+\ F^+$	2.6
		$M\ S\ F^+$	0.41
		$M^+\ S\ F$	0.22
		$M\ S^+\ F$	0.0058
		$M\ S\ F$	0.0071

a. Hotchkiss and Marmur noted that the percentage of cotransformation was higher than would be expected on a random basis. For example, the results show that 2.6% of the cells were transformed into *M* and 4% were transformed into *S*. If the *M* and *S* traits were inherited independently, the expected probability of cotransformation of *M* and *S* (*M S*) would be 0.026 × 0.04 = 0.001, or 0.1%. However, they observed 0.41% *M S* cotransformants, four times more than they expected. What accounts for the relatively high frequency of cotransformation of the traits they observed?
b. On the basis of the results, what conclusion can you draw about the order of the *M*, *S*, and *F* genes on the bacterial chromosome?
c. Why is the rate of cotransformation for all three genes (*M S F*) almost the same as the rate of cotransformation for *M F* alone?

25. In the course of a study on the effects of the mechanical shearing of DNA, Eugene Nester, A. T. Ganesan, and Joshua Lederberg studied the transfer, by transformation, of sheared DNA from a wild-type strain of *B. subtilis* (his_2^+ aro_3^+ tyr_2^+ $aro1^+$ $tyr1^+$ $aro2^+$) to strains of bacteria carrying a series of mutations (E. W. Nester, A. T. Ganesan, and J. Lederberg. 1963. *Proceedings of the National Academy of Sciences of the United States of America* 49:61–68). They reported the following rates of cotransformation between his_2^+ and the other genes (expressed as cotransfer rate):

Genes	Rate of cotransfer
his_2^+ and aro_3^+	0.015
his_2^+ and tyr_2^+	0.10
his_2^+ and aro_1^+	0.12
his_2^+ and tyr_1	0.23
his_2^+ and aro_2^+	0.05

On the basis of these data, which gene is farthest from his_2^+? Which gene is closest?

Section 9.4

26. Place the following components of CRISPR-Cas systems in the order in which they function during generation of CRISPR-Cas immunity.
a. Effector complex binds to the foreign DNA

b. Transcription of CRISPR array into a long CRISPR precursor RNA
c. crRNA combines with a Cas protein to form an effector complex
d. Incorporation of spacers into CRISPR array
e. Cas protein in the effector complex cleaves the foreign DNA
f. CRISPR precursor RNA (pre-crRNA) is cleaved and processed into crRNAs

27. CONNECT In Chapter 1, we discussed the theory of the inheritance of acquired characteristics, an idea that was later discredited. Recently some researchers have claimed that the CRISPR-Cas system represents a form of inheritance of acquired characteristics. How might the CRISPR-Cas system be considered a type of inheritance of acquired characteristics? Do you think CRISPR-Cas represents inheritance of acquired characteristic? Why or why not?

Section 9.5

28. *Two mutations that affect plaque morphology in phages (a^- and b^-) have been isolated. Phages carrying both mutations a^- b^- are mixed with wild-type phages (a^+ b^+) and added to a culture of bacterial cells. Once the phages have infected and lysed the bacteria, samples of the phage lysate are collected

and cultured on plated bacteria. The following number of plaques are observed:

Plaque phenotype	Number
$a^+ b^+$	2043
$a^+ b^-$	320
$a^- b^+$	357
$a^- b^-$	2134

What is the frequency of recombination between the *a* and *b* genes?

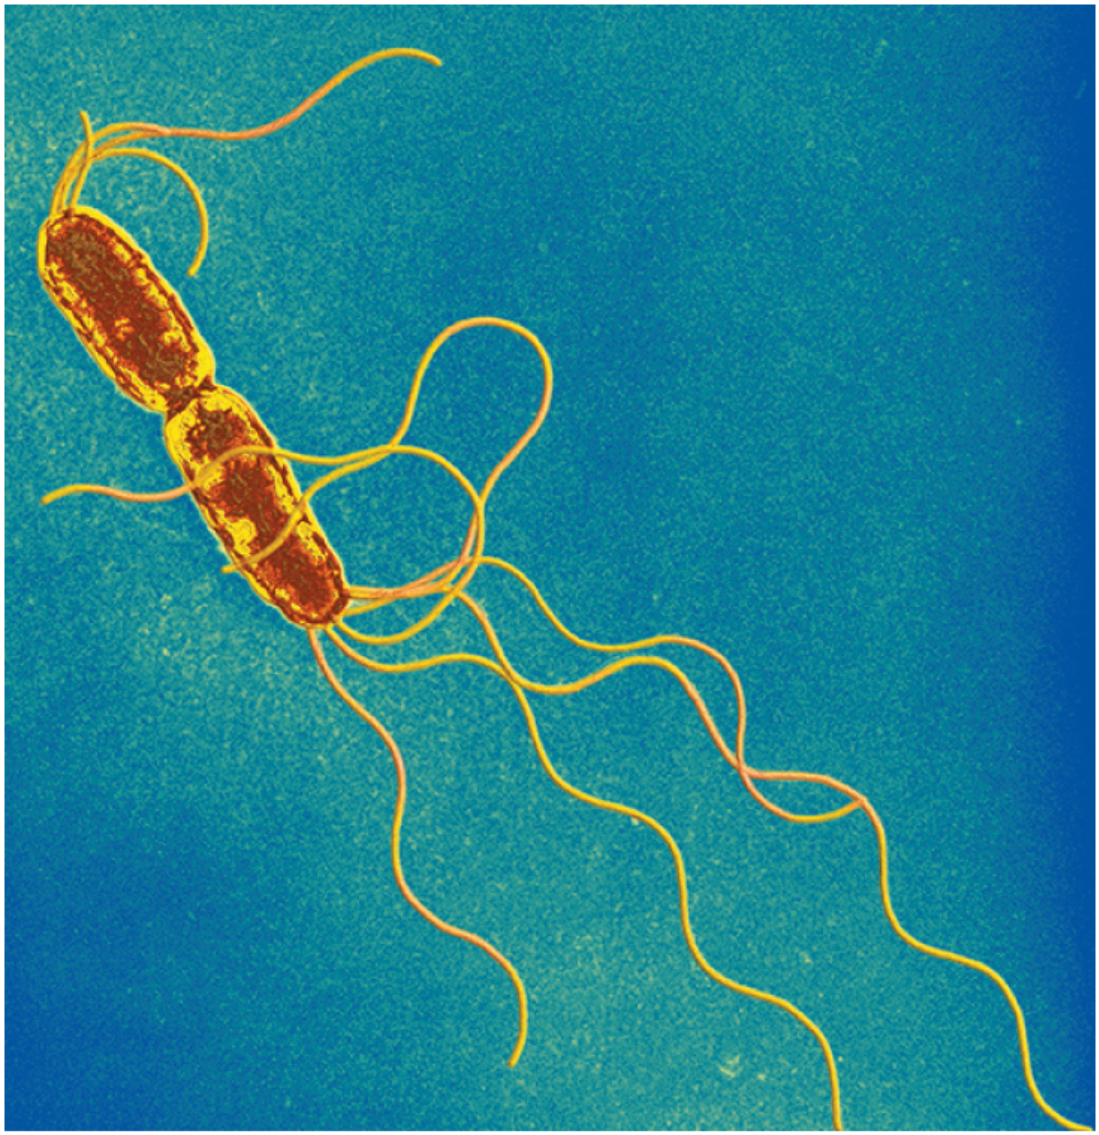
29. *

T. Miyake and M. Demerec examined proline-requiring mutations in the bacterium *S. typhimurium* (T. Miyake and M. Demerec. 1960. *Genetics* 45:755–762). On the basis of complementation testing, they found four proline auxotrophs: *proA*, *proB*, *proC*, and *proD*. To determine whether *proA*, *proB*, *proC*, and *proD* loci were located close together on the bacterial chromosome, they conducted a transduction experiment. Bacterial strains that were $proC^+$ and had mutations at *proA*, *proB*, or *proD* were used as donors. The donors were infected with bacteriophages, and progeny phages were allowed to infect recipient bacteria with genotype $proC^- proA^+ proB^+ proD^+$. The recipient bacteria were then plated on a selective medium that allowed only $proC^+$ bacteria to grow. After this, the $proC^+$ transductants were plated on selective media to reveal their

genotypes at the other three *pro* loci. The following results were obtained:

Donor genotype	Transductant genotype	Number
$proC^{+}\ proA^{-}\ proB^{+}\ proD^{+}$	proC+ proA+ proB+ proD+	2765
	$proC^{+}\ proA^{-}\ proB^{+}\ proD^{+}$	3
$proC^{+}\ proA^{+}$ proB− $proD^{+}$	$proC^{+}\ proA^{+}\ proB^{+}\ proD^{+}$	1838
	$proC^{+}\ proA^{+}$ proB− $proD^{+}$	2
$proC^{+}\ proA^{+}\ proB^{+}\ proD^{-}$	$proC^{+}\ proA^{+}\ proB^{+}\ proD^{+}$	1166
	$proC^{+}\ proA^{+}\ proB^{+}\ proD^{-}$	0

a. Why are there no proC− genotypes among the transductants?
b. Which genotypes represent single transductants, and which represent cotransductants?
c. Is there evidence that *proA*, *proB*, and *proD* are located close to *proC*? Explain your answer.



Kwangshin Kim/Science Source.

S. typhimurium.

30. *A geneticist isolates two mutations in a bacteriophage. One mutation causes clear plaques (*c*), and the other produces minute plaques (*m*). Previous mapping experiments have established that the genes responsible for these two mutations are 8 map units apart. The geneticist mixes phages with

genotype $c^+ m^+$ and genotype $c^- m^-$ and uses the mixture to infect bacterial cells. She collects the progeny phages and cultures a sample of them on plated bacteria. A total of 1000 plaques are observed. What numbers of the different types of plaques ($c^+ m^+$, $c^- m^-$, $c^+ m^-$, $c^- m^+$) should she expect to see?

31. CONNECT The geneticist carries out the same experiment described in Problem 30, but this time she mixes phages with genotypes $c^+ m^-$ and $c^- m^+$. Are the mutations in coupling or repulsion (see Chapter 7)? What results are expected from *this* cross?

32. *A geneticist isolates two bacteriophage *r* mutants (r_{13} and r_2) that cause rapid lysis. He carries out the following crosses and counts the number of plaques listed here:

Genotype of parental phage	Progeny	Number of plaques
$h^+ r_{13}^- \times h^- r_{13}^+$	$h^+ r_{13}^+$	1
	$h^- r_{13}^+$	104
	$h^+ r_{13}^-$	110
	$h^- r_{13}^-$	2
Total		217
$h^+ r_2^- \times h^- r_2^+$	$h^+ r_2^+$	6
	$h^- r_2^+$	86
	$h^+ r_2^-$	81

	$h^- r_2^-$	7
Total		180

a. Calculate the recombination frequencies between r_2 and h and between r_{13} and h.
b. Draw all possible linkage maps for these three genes.

33. CONNECT **E. coli* cells are simultaneously infected with two strains of phage λ. One strain has a mutant host range, is temperature sensitive, and produces clear plaques (genotype *h st c*); another strain carries the wild-type alleles (genotype h^+ st^+ c^+). Progeny phages are collected from the lysed cells and are plated on bacteria. The following number of different progeny phages are obtained:

Progeny phage genotype	Number of plaques
$h^+ c^+ st^+$	321
h c st	338
h^+ c st	26
h c^+ st^+	30
h^+ c st^+	106
h c^+ st	110
h^+ c^+ st	5
h c st^+	6

a. Determine the order of the three genes on the phage chromosome.
b. Determine the map distances between the genes.
c. Determine the coefficient of coincidence and the interference (see pp. 199–201 in Chapter 7).

34. A donor strain of bacteria with alleles $a^+ b^+ c^+$ is infected with phages to map the donor chromosome using generalized transduction. The phage lysate from the bacterial cells is collected and used to infect a second strain of bacteria that are $a^- b^- c^-$. Bacteria with the a^+ allele are selected, and the percentage of cells with cotransduced b^+ and c^+ alleles are recorded.

Donor	Recipient	Selected allele	Cells with cotransduced allele (%)
$a^+ b^+ c^+$	$a^- b^- c^-$	a^+	25 b^+
		a^+	3 c^+

Is gene *b* or gene *c* closer to gene *a*? Explain your reasoning.

35. A donor strain of bacteria with genotype $leu^+ gal^- pro^+$ is infected with phages. The phage lysate from the bacterial cells is collected and used to infect a second strain of bacteria that are $leu^- gal^+ pro^-$. The second strain is selected for leu^+, and the following cotransduction data are obtained:

Donor	Recipient	Selected allele	Cells with cotransduced allele (%)
$leu^+ gal^-$	$leu^- gal^+$	leu^+	47 pro^+

pro$^+$	*pro*$^-$		
		leu$^+$	26 *gal*–

Which genes are closest, *leu* and *gal* or *leu* and *pro*?

36. Viruses from which organism contributed the most RNA to the H1N1 influenza virus shown at the bottom of **Figure 9.28**?

CHALLENGE QUESTION

Section 9.3

37. A group of genetics students mix two auxotrophic strains of bacteria: one is *leu*$^+$ *trp*$^+$ *his*– *met*$^-$ and the other is *leu*$^-$ *trp*$^-$ *his*$^+$ *met*$^+$. After mixing the two strains, they plate the bacteria on a minimal medium and observe a few prototrophic colonies (*leu*$^+$ *trp*$^+$ *his*$^+$ *met*$^+$). They assume that some gene transfer has taken place between the two strains. How can they determine whether the transfer of genes is due to conjugation, transduction, or transformation?

ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Section 9.1

1. Luiz Roesch and colleagues (Roesch L. F., R. R. Fulthorpe, A. Riva, et al. 2007. *ISME Journal* 1:283–290) conducted a study to determine how many types of bacteria exist in a gram of soil at different locations around the world. They found that soil from agricultural fields harbored considerably fewer types of bacteria than did soil from forests (see Life in a Bacterial World). Propose some possible reasons that agricultural fields might have less bacterial diversity than forests.

Section 9.2

2. One advantage of using bacteria and viruses for genetic study is the fact that they have haploid genomes. Explain why a haploid genome facilitates genetic analysis.

Section 9.3

3. Antibiotic resistance genes are often found on R plasmids (see Natural Gene Transfer and Antibiotic Resistance). A likely source of the R plasmids is bacteria that produce the antibiotic. Why would some bacteria produce antibiotics (chemicals that kill bacteria), and why would they carry R plasmids?
4. Bacteria have evolved numerous mechanisms to prevent the invasion of foreign viral DNA (see Bacterial Defense Mechanisms). Yet clearly many bacteria have evolved competence, the ability to take up foreign DNA from the environment. Why do bacteria take up naked DNA from the environment and yet exclude DNA from viruses?

Section 9.5

5. Researchers have recently discovered giant viruses that are 1 μm in length, the same size as some bacterial cells. The genomes of these viruses contain over 2 million base pairs of DNA, which is more DNA than is found in many bacterial genomes, and their genomes contain hundreds—in some cases, thousands—of genes. Given these observations and what you know about viruses, should viruses be considered living or nonliving? Give arguments for and against considering viruses as living organisms.
6. RNA viruses often undergo rapid evolution. What aspects of their biology contribute to their high rate of evolution? What are some consequences of their rapid evolution?

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Introduction

1. Draw a concept map that outlines the relationship of leprosy and the bacterium *Mycobacterium leprae*. Include how genome sequences of medieval *M. leprae* are related to those in modern strains of *M. leprae*.

Sections 9.3 and 9.5

2. Create a concept map that displays the interrelationships among the following terms: bacterial gene exchange, conjugation, transduction, transformation, F factor, sex pilus, F^+ cells, F^- cells, Hfr cells, F' cells, competent, transformants, horizontal gene transfer, generalized transduction, specialized transformation, transducing phage, transductants.

Section 9.4

3. Draw a concept map that outlines the different components and functions of CRISPR-Cas systems.

Section 9.5

4. Create a concept map that outlines the relationships among the following terms: retrovirus, reverse transcriptase, cDNA, provirus, integrase, oncogenes, *gag, pol*, and *env* genes.

SaplingPlus Self-study tools that will help you practice what you've learned and reinforce this chapter's concepts are available online. Go to www.saplinglearning.com.

CHAPTER 10

DNA: The Chemical Nature of the Gene

Eddie Gerald/Alamy Stock Photo.

The Denisova cave in Siberia, where scientists found 90,000-year-old bones from an ancient human. Analysis of DNA from these bones revealed that the woman was a hybrid between a Neanderthal mother and a Denisovan father.

Hominin History in Ancient DNA

Deep in the Altai mountains of Siberia lies the Denisova cave, famous for its accumulation of fossils and animal remains. In 2018, scientists extracted DNA from a 90,000-year-old human bone found in the cave and sequenced its owner's genome. Analysis revealed that there were two copies of sequences located on the X chromosome, indicating that the bone came from a female. The thickness of the bone suggested that she was at least 13 years old at the time of her death. Researchers named this ancient woman Denny. Remarkably, Denny's DNA showed that she was a hybrid between two now-extinct groups of early humans (hominins), the result of a mating between a Neanderthal woman and a Denisovan man.

Denisovans were first discovered in 2009, when scientists found a single 40,000-year-old finger bone in the Denisova cave. Although the bone was too fragmentary to draw any conclusion about its origin based on anatomy, scientists successfully extracted DNA from it. They were able to sequence and reconstruct the person's entire genome from that extracted DNA. Study of this genome revealed that the bone came from a new hominin, related to Neanderthals but distinct from Neanderthals and other known hominins. These people were given the name Denisovans, after the cave from which the bone came. Researchers have since found traces of Denisovan DNA in some present-day humans in Southeast Asia, suggesting that early *Homo sapiens* and Denisovans also interbred. Both Neanderthals and Denisovans have long since

disappeared, perhaps outcompeted or exterminated by *Homo sapiens* some 40,000 years ago.

The researchers who examined Denny's genome found that 39% of her DNA came from Neanderthals and 42% came from Denisovans, demonstrating that both species contributed equally to her ancestry. Further analysis revealed that Denny possessed a level of heterozygosity expected if she had inherited one set of chromosomes from a Neanderthal mother and the other set from a Denisovan father. The data were unequivocal: Denny was an F_1 hybrid between the two species. Examination revealed that Denny's Denisovan father possessed some Neanderthal DNA himself, indicating that earlier matings between Denisovans and Neanderthals took place in Denny's distant ancestors.

DNA, with its double-stranded spiral, is among the most elegant of all biological molecules, but the double helix is not just a beautiful structure; it also gives DNA incredible stability and permanence, as evidenced by our ability to extract and sequence DNA from a 90,000-year-old bone, revealing startlingly intimate details of ancient family life. In an even more incredible feat, geneticists in 2013 sequenced the genome of a long-extinct ancestral horse from DNA extracted from a 700,000-year-old bone fragment recovered from the permafrost of Yukon, Canada.

THINK-PAIR-SHARE

What do you think might be some of the problems associated with isolating and sequencing DNA from ancient samples, such as that of the 90,000-year-old bone from the Denisova cave?

This chapter focuses on how DNA was identified as the source of genetic information and on how it encodes the genetic instructions for all life. We begin by considering the basic requirements for the genetic material and the history of the study of DNA—how its relation to genes was uncovered and its structure determined. The history of DNA illustrates several important points about the nature of scientific research. As with so many important scientific advances, the structure of DNA and its role as the genetic material were not discovered by any single person but were gradually revealed over a period of almost 100 years, thanks to the work of many investigators. Our understanding of the relation between DNA and genes was enormously enhanced in 1953, when James Watson and Francis Crick, analyzing data provided by Rosalind Franklin and Maurice Wilkins, proposed a three-dimensional structure for DNA that brilliantly illuminated its role in genetics.

After reviewing the discoveries that led to our current understanding of DNA, we examine DNA structure. While the structure of DNA is important in its own right, the key genetic concept is the relation between the structure and the function of DNA—that is, how its structure allows it to serve as the genetic material.

10.1 Genetic Material Possesses Several Key Characteristics

Life is characterized by tremendous diversity, but the coding instructions for all living organisms are written in the same genetic language—that of nucleic acids. Surprisingly, the idea that genes are made of nucleic acids was not widely accepted until after 1950. This skepticism was due in part to a lack of knowledge about the structure of deoxyribonucleic acid (DNA). Until the structure of DNA was understood, no one knew how DNA could store and transmit genetic information.

Even before nucleic acids were identified as the genetic material, biologists recognized that whatever the nature of the genetic material, it must possess four important characteristics:

1. **The genetic material must contain complex information.** First and foremost, the genetic material must be capable of storing large amounts of information—instructions for the traits and functions of an organism.
2. **The genetic material must replicate faithfully.** Every organism begins life as a single cell. To produce a complex multicellular organism like yourself, this single cell must undergo billions of cell divisions. At each cell division, the genetic instructions must be accurately transmitted to descendant cells. And when

organisms reproduce and pass genes to their progeny, the genetic instructions must be copied with fidelity.

3. **The genetic material must encode the phenotype.** The genetic material (the genotype) must have the capacity to be expressed as a phenotype—to code for traits. The product of a gene is often a protein or an RNA molecule, so there must be a mechanism for genetic instructions in the DNA to be copied into RNAs and proteins.
4. **The genetic material must have the capacity to vary.** Genetic information must have the ability to vary, because different species—and even individual members of the same species—differ in their genetic makeup.

THINK-PAIR-SHARE Question 1

CONCEPTS

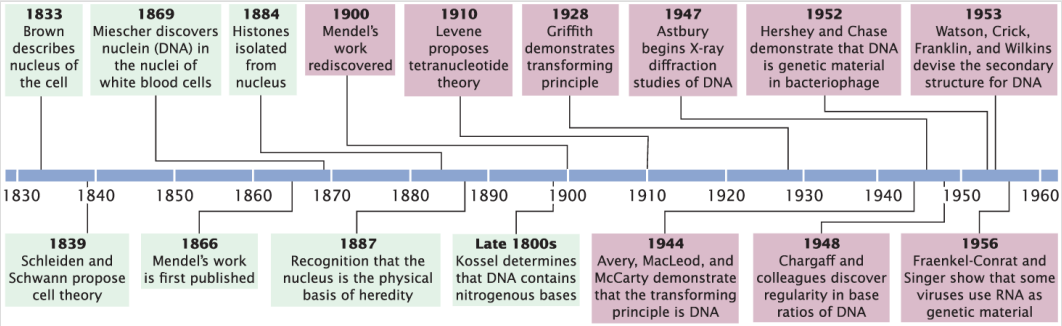
The genetic material must carry large amounts of information, replicate faithfully, express its coding instructions as phenotypes, and have the capacity to vary.

✔ CONCEPT CHECK 1

Why was the discovery of the structure of DNA so important for understanding genetics?

10.2 All Genetic Information Is Encoded in the Structure of DNA or RNA

Although our understanding of how DNA encodes genetic information is relatively recent, the study of DNA structure stretches back more than 100 years (Figure 10.1).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

10.1 Many people have contributed to our understanding of the structure of DNA.

Description

Data from the timeline is as follows from left to right:

18 33, Brown describes nucleus of the cell.

18 39, Schleiden and Schwann propose cell theory.

18 66, Mendel's work is first published.

18 69, Miescher discovers nuclein (D N A) in the nuclei of white blood cells.

18 84, histones isolated from the nucleus.

18 87, recognition that the nucleus is the physical basis of heredity.

Late 18 80's, Kossel determines that D N A contains nitrogenous bases.

19 00, Mendel's work rediscovered.

19 10, Levene proposes tetranucleotide theory.

19 28, Griffith demonstrates transforming principle.

19 44, Avery, MacLeod, and McCarty demonstrate that the transforming principle is D N A.

19 47, Ashbury begins X-ray diffraction studies of D N A.

19 48, Chargaff and colleagues discover regularity in base ratios of D N A.

19 52, Hershey and Chase demonstrate that D N A is genetic material in bacteriophage.

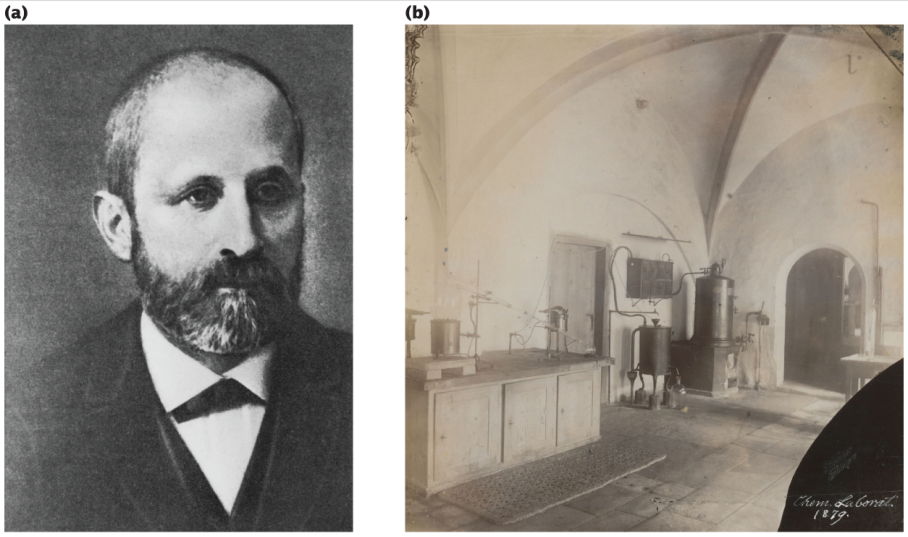
19 53, Watson and Crick devise the secondary structure for D N A.

19 56, Fraenkel-Conrat and Singer show that some viruses use R N A as their genetic material.

Early Studies of DNA

In 1868, Johann Friedrich Miescher (Figure 10.2) graduated from medical school in Switzerland. Influenced by an uncle who believed that the key to understanding disease lay in the chemistry of tissues, Miescher traveled to Tübingen, Germany, to study under Ernst Felix Hoppe-Seyler, an early leader in the emerging field of biochemistry. Under Hoppe-Seyler's direction, Miescher turned his attention to the chemistry of pus, a substance of clear medical importance. Pus contains white blood cells, which have large nuclei, and Miescher developed a method for isolating these nuclei. The minute amounts of nuclear material that he obtained were insufficient for a thorough

chemical analysis, but he did establish that the nuclear material contained a novel substance that was slightly acidic and high in phosphorus. This material, which we now know must have consisted of DNA and protein, Miescher called *nuclein*. The substance was later renamed *nucleic acid* by one of his students.

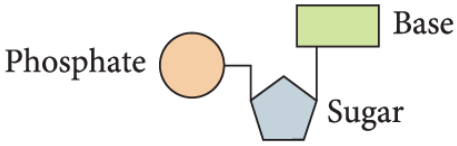


Part a: SPL/Science Source. Part b: Courtesy of the University of Tübingen Library Image Database, Tübingen, Federal Republic of Germany.

10.2 Johann Friedrich Miescher performed the first chemical analysis of DNA.
(a) Portrait of Miescher. (b) Miescher's laboratory in Tübingen, Germany.

By 1887, several researchers had independently concluded that the physical basis of heredity lies in the nucleus. Chromatin was shown to consist of nucleic acid and proteins, but which of these substances was actually the genetic information was not clear. In the late 1800s, Albrecht Kossel carried out further work on the chemistry of DNA and determined that it contains four nitrogenous bases: adenine, cytosine, guanine, and thymine (abbreviated A, C, G, and T).

In the early twentieth century, the Rockefeller Institute in New York City became a center for nucleic acid research. Phoebus Aaron Levene joined the Institute in 1905 and spent the next 40 years studying the chemistry of DNA. He discovered that DNA consists of a large number of linked, repeating units, called **nucleotides**; each nucleotide contains a sugar, a phosphate, and a base.



Nucleotide

Description
The sugar is represented by a pentagon. A line emerges from C 1 of the sugar and is bonded to a rectangle labeled base. A line emerges from C 4 of the sugar and is bonded to a circle labeled phosphate.

Levene incorrectly proposed that DNA consists of a series of four-nucleotide units, each containing all four bases—adenine, guanine, cytosine, and thymine—in a fixed sequence. This concept, known as the tetranucleotide hypothesis, implied that the structure of DNA was not variable enough to make it the genetic material. The tetranucleotide hypothesis contributed to the idea that protein is the genetic material because the structure of protein, with its 20 different amino acids, could be highly variable.

As additional studies of the chemistry of DNA were completed in the 1940s and 1950s, the notion of DNA as a simple, invariant molecule

began to change. Erwin Chargaff and his colleagues carefully measured the amounts of the four bases in DNA from a variety of organisms, and they found that DNA from different organisms varies greatly in base composition. This finding disproved the tetranucleotide hypothesis. They discovered that within each species, there is some regularity in the ratios of the bases: the amount of adenine is always equal to the amount of thymine (A = T), and the amount of guanine is always equal to the amount of cytosine (G = C) (Table 10.1). These findings became known as Chargaff's rules. However, the cause of these ratios among the bases was unknown at the time.

TABLE 10.1 Base composition (percent*) of DNA from different sources and ratios of bases

					Ratio		
Source of DNA	**A**	**T**	**G**	**C**	**A/T**	**G/C**	**(A + G)/(T + C)**
E. coli	26.0	23.9	24.9	25.2	1.09	0.99	1.04
Yeast	31.3	32.9	18.7	17.1	0.95	1.09	1.00
Sea urchin	32.8	32.1	17.7	18.4	1.02	0.96	1.00

*Percent in moles of nitrogenous constituents per 100 g-atoms of phosphate in hydrolysate corrected for 100% recovery. Data from: E. Chargaff and J. Davidson eds., *The Nucleic Acids,* vol 1. (New York: Academic Press, 1955)

CONCEPTS

Details of the composition of DNA were worked out by a number of scientists. At first, DNA was interpreted as being too regular in structure to carry genetic information, but by the 1940s, DNA from different organisms was shown to vary in its base composition.

✔ CONCEPT CHECK 2

What contribution did Levene make to our understanding of DNA structure?

a. He determined that the nucleus contains DNA.
b. He determined that DNA contains four nitrogenous bases.
c. He determined that DNA consists of nucleotides.
d. He determined that the nitrogenous bases of DNA are present in regular ratios.

DNA as the Source of Genetic Information

While chemists were working out the structure of DNA, biologists were attempting to identify the carrier of genetic information. Mendel identified the basic rules of heredity in 1866, but he had no idea about the physical nature of hereditary information. By the early 1900s, biologists had concluded that genes resided on chromosomes, which were known to contain both DNA and protein. Two sets of experiments, one conducted on bacteria and the other on viruses, provided pivotal evidence that DNA, rather than protein, was the genetic material.

THE DISCOVERY OF THE TRANSFORMING PRINCIPLE

An initial step in identifying DNA as the source of genetic information came with the discovery of a phenomenon called *transformation* (described in Section 9.3). This phenomenon was first observed in 1928 by Fred Griffith, an English physician whose special interest was the bacterium that causes pneumonia: *Streptococcus pneumoniae*. Griffith had succeeded in isolating several different strains of *S. pneumoniae* (type I, II, III, and so forth). In the virulent (disease-causing) forms of a strain, each bacterium is surrounded by a polysaccharide coat, which makes the bacterial colony appear smooth (S) when grown on an agar plate. Griffith found that these virulent forms occasionally mutated to nonvirulent forms, which lack a polysaccharide coat and produce a rough-appearing colony (R).

Griffith observed that small amounts of living type IIIS bacteria injected into mice caused the mice to develop pneumonia and die; when he examined the dead mice, he found large amounts of type IIIS bacteria in their blood (**Figure 10.3a**). When Griffith injected type IIR bacteria into mice, the mice lived, and no bacteria were recovered from their blood (**Figure 10.3b**). Griffith knew that boiling killed all bacteria and destroyed their virulence; when he injected large amounts of heat-killed type IIIS bacteria into mice, the mice lived, and no type IIIS bacteria were recovered from their blood (**Figure 10.3c**).

10.3 Griffith's experiments demonstrated transformation in bacteria.

Description

The illustration shows the question as follows: Can an extract from dead bacterial cells genetically transform living cells? The methods section below shows part a where a conical flask has Type 3 S (virulent) bacteria. These bacteria are injected into mice. The results below show that the mouse dies. Eventually, type 3 S (virulent) bacteria are recovered. Part b shows a method where a conical flask has type 2 R (nonvirulent) bacteria. These bacteria are injected into mice. The results below show that the mouse

lives. No bacteria are recovered. Part c shows a method where a conical flask has heat-killed type 3 S bacteria. These bacteria are injected into mice. The results below show that the mouse lives. No bacteria are recovered. Part d shows a method where a conical flask has a mixture of type 2 R bacteria and heat-killed type 3 S bacteria. These bacteria are injected into mice. The results show that the mouse dies. Eventually, type 3 S (virulent) bacteria are recovered. A caption below reads, Conclusion: A substance in the heat-killed virulent bacteria genetically transformed the type 2 R bacteria

into live, virulent type 3 S bacteria.

The results of these experiments were not unusual. However, Griffith got a surprise when he injected his mice with a small amount of living type IIR bacteria along with a large amount of heat-killed type IIIS bacteria. Because both the type IIR bacteria and the heat-killed type IIIS bacteria were nonvirulent, he expected these mice to live. Surprisingly, 5 days after the injections, the mice developed pneumonia and died (**Figure 10.3d**). When Griffith examined blood from the hearts of these mice, he observed live type IIIS bacteria. Furthermore, these bacteria retained their type IIIS characteristics through several generations: their virulence was heritable.

Griffith considered all the possible interpretations of his results. First, there was a possibility that he had not sufficiently sterilized the type IIIS bacteria and thus a few live bacteria had remained in the culture. Any live bacteria injected into the mice would have multiplied and caused pneumonia. Griffith knew that this possibility was unlikely because he had used only heat-killed type IIIS bacteria

in the control experiment, and they never produced pneumonia in the mice.

A second interpretation was that the live type IIR bacteria had mutated to the virulent S form. Such a mutation would cause pneumonia in the mice, but it would produce type IIS bacteria, not the type IIIS that Griffith found in the dead mice. Because type II and type III bacteria differ in a number of traits, many mutations would be required for type II bacteria to mutate to type III bacteria, and the chance of all the mutations occurring simultaneously was impossibly low.

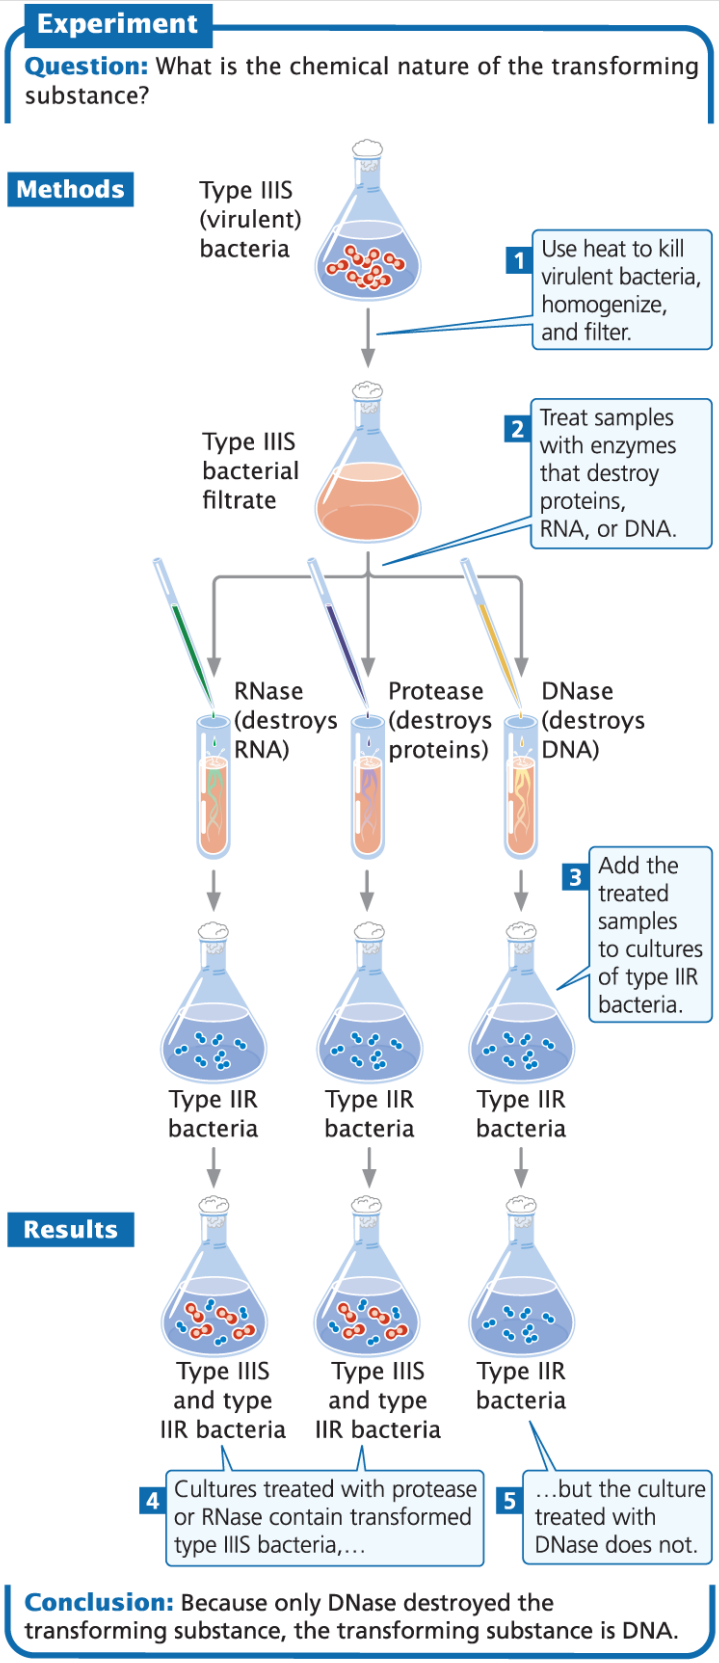
Griffith concluded that the type IIR bacteria had somehow been transformed, acquiring the genetic virulence of the dead type IIIS bacteria, and that this transformation had produced a permanent genetic change in the bacteria. Although Griffith didn't understand the nature of this transformation, he theorized that some substance in the dead bacteria might be responsible. He called this substance the **transforming principle**. › **TRY PROBLEM 19**

IDENTIFICATION OF THE TRANSFORMING PRINCIPLE

At the time of Griffith's report, Oswald Avery (see Figure 10.1) was a microbiologist at the Rockefeller Institute. At first, Avery was skeptical of Griffith's results, but after other microbiologists successfully repeated Griffith's experiments with other bacteria,

Avery set out to understand the nature of the transforming substance.

After 10 years of research, Avery, Colin MacLeod, and Maclyn McCarty succeeded in isolating and partially purifying the transforming substance. They showed that it had a chemical composition closely matching that of DNA and quite different from that of proteins. Enzymes such as trypsin and chymotrypsin, known to break down proteins, had no effect on the transforming substance. Ribonuclease, an enzyme that destroys RNA, also had no effect. Enzymes capable of destroying DNA, however, eliminated the biological activity of the transforming substance (**Figure 10.4**). Avery, MacLeod, and McCarty showed that the transforming substance precipitated at about the same rate as purified DNA and that it absorbed ultraviolet light at the same wavelengths as DNA. These results, published in 1944, provided compelling evidence that the transforming principle—and therefore genetic information—resides in DNA. However, new theories in science are rarely accepted on the basis of a single experiment, and many biologists continued to prefer the hypothesis that the genetic material is protein.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

10.4 Avery, MacLeod, and McCarty's experiment revealed the chemical nature of the transforming principle.

Description
The illustration shows a question that reads, What is the chemical nature of the transforming substance? The methods are shown below where a conical flask has Type 3 S (virulent) bacteria. A caption reads, Use heat to kill virulent bacteria, homogenize, and filter. This leads to a flask containing type 3 S bacterial filtrate. A caption reads, Treat samples with enzymes that destroy proteins, R N A, or D N A. This bacterial filtrate is then poured into 3 separate test tubes. RNase (destroys R N A) is added to the first test tube, type 2 R bacteria is obtained in a conical flask. Results below show that type 3 S and type 2 R bacteria is obtained in a conical flask. A caption reads, Cultures treated with protease or RNase contain transformed type 3 S bacteria, but the culture treated with DNase does not. Protease (destroys proteins) is added to the second test tube, type 2 R bacteria is obtained in a conical flask. Results show that type 3 S and type 2 R bacteria is obtained in a conical flask. DNase (destroys D N A) is added to third test tube, type 2 R bacteria is obtained in a conical flask. A caption reads, add the treated samples to cultures of type 2 R bacteria. Results show that type 2 R bacteria is obtained in a conical flask. A caption below reads, Conclusion: Because only DNase destroyed the transforming substance, the transforming substance is D N A.

CONCEPTS

The process of transformation indicates that some substance—the transforming principle—is capable of genetically altering bacteria. Avery, MacLeod, and McCarty demonstrated that the transforming principle is DNA, providing the first evidence that DNA is the genetic material.

✔ CONCEPT CHECK 3

If Avery, MacLeod, and McCarty had found that samples of heat-killed bacteria treated with RNase and DNase transformed bacteria but that samples treated with protease did not, what conclusion would they have drawn?

a. Protease carries out transformation.
b. RNA and DNA are the genetic materials.
c. Protein is the genetic material.
d. RNase and DNase are necessary for transformation.

THE HERSHEY–CHASE EXPERIMENT

A second piece of evidence that indicated DNA was the genetic material resulted from a study of the T2 bacteriophage conducted by Alfred Hershey and Martha Chase. The T2 bacteriophage is a virus that infects the bacterium *Escherichia coli* (**Figure 10.5a**). As we saw in Section 9.5, a phage reproduces by attaching to the outer wall of a bacterial cell and injecting its DNA into the cell, where it replicates and directs the cell to synthesize phage proteins. The phage DNA becomes encapsulated within the phage proteins, producing progeny phages that lyse (break open) the cell and escape (**Figure 10.5b**).

10.5 T2 is a bacteriophage that infects *E. coli*. (a) T2 phage. (b) Its life cycle.

Description
Illustration a on the left shows multiple T 2 phages over a cell surface along with a diagram that shows structure of a phage. The phage has an icosahedral head with thread-like D N A. A caption reads, Phage genome is D N A. The phage has a tube-shaped body. Another caption reads, All other parts of the bacteriophage are protein. Below the body are 6 legs at its base.

Illustration b on the right shows a virus attaching to an E coli cell with a grey-colored circular chromosome and injecting its red-colored phage chromosome. A caption reads, Phage attaches to E coli and injects its chromosome. This leads to breaking down of the bacterial chromosome and replication of the phage chromosome. A caption reads, Bacterial chromosome breaks down and the phage chromosome replicates. This leads to formation of phage looking structures inside the cell. A caption reads, Expression of phage genes produces phage structural components. This leads to assembling of progeny phages in the cell. A caption reads, Progeny phage particles assemble. This eventually leads to the bacterial wall lyses and release of progeny phages. A caption reads, Bacterial wall lyses, releasing progeny phages.

At the time of the Hershey–Chase study (their paper was published in 1952), biologists did not understand exactly how phages reproduce. What they did know was that the T2 phage is approximately 50% protein and 50% DNA, that a phage infects a bacterial cell by first attaching to the cell wall, and that progeny phages are ultimately produced within the cell. Because the progeny

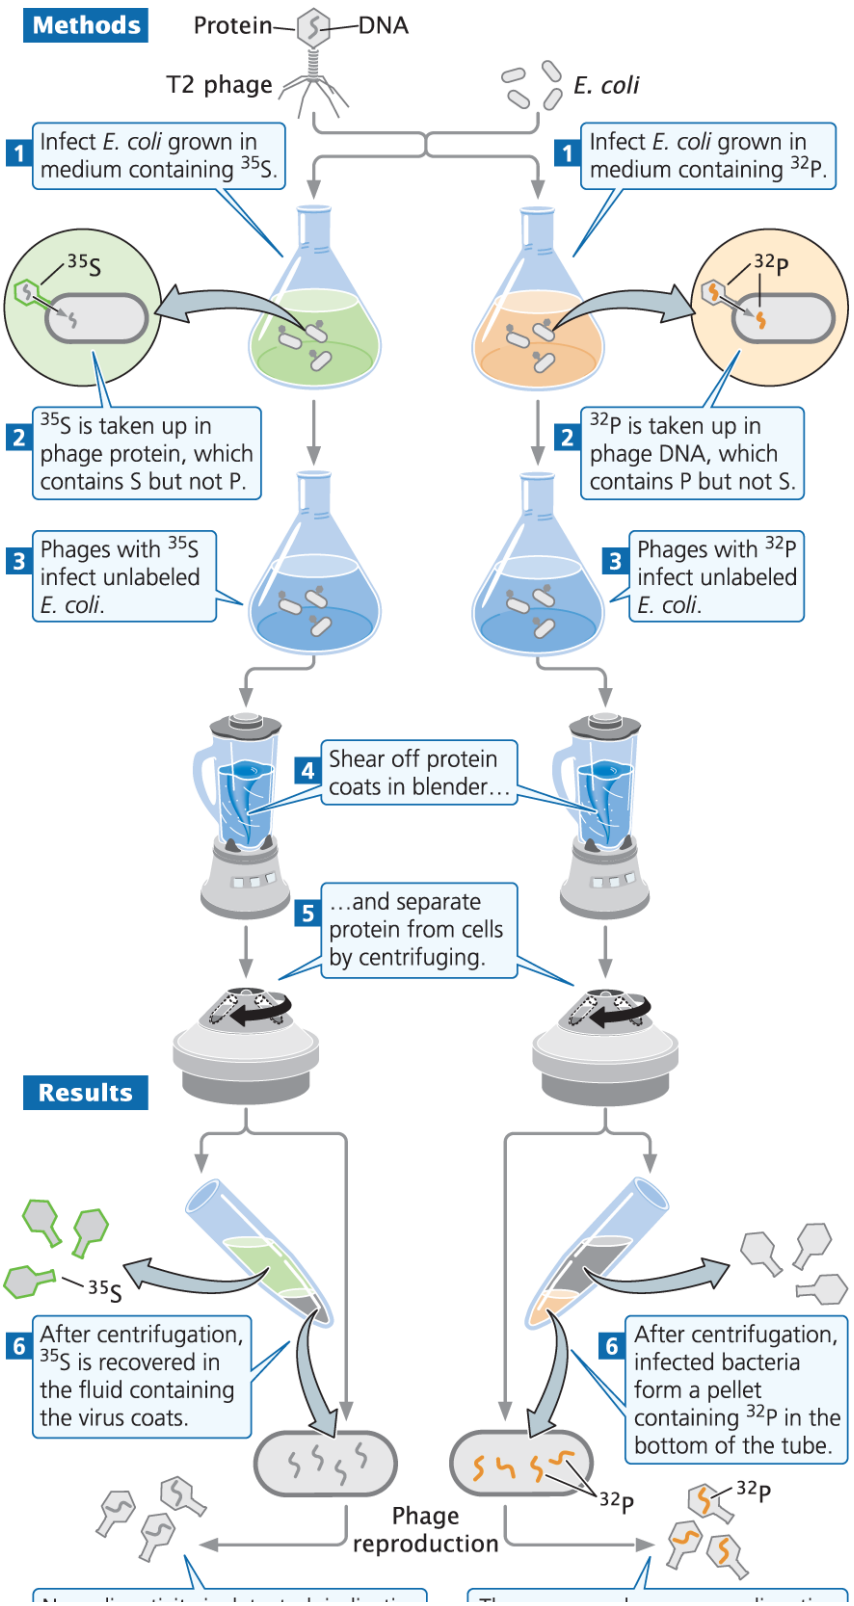
carry the same traits as the infecting phage, genetic material from the infecting phage must be transmitted to the progeny, but how this genetic transmission takes place was unknown.

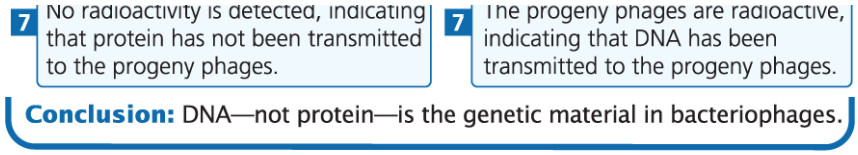
Hershey and Chase designed a series of experiments to determine whether the phage *protein* or the phage *DNA* is transmitted in phage reproduction. To follow the fates of protein and DNA, they used radioactive forms, or **isotopes**, of phosphorus and sulfur. A radioactive isotope can be used as a tracer to identify the location of a specific molecule, because any molecule containing the isotope will be radioactive and therefore easily detected. DNA contains phosphorus but not sulfur, so Hershey and Chase used a radioactive isotope of phosphorus (^{32}P) to follow phage DNA during reproduction. Protein contains sulfur but not phosphorus, so they used a radioactive isotope of sulfur (^{35}S) to follow the protein.

Hershey and Chase grew one batch of *E. coli* in a medium containing ^{32}P and infected the bacteria with the T2 phage so that all the progeny phages would have DNA labeled with ^{32}P (**Figure 10.6**). They grew a second batch of *E. coli* in a medium containing ^{35}S and infected these bacteria with T2 phage so that all the progeny phages would have proteins labeled with ^{35}S. Hershey and Chase then infected separate batches of unlabeled *E. coli* with the ^{35}S- and ^{32}P-labeled progeny phages. After allowing time for the phages to infect the *E. coli* cells, they placed the cells in a blender and sheared off the now-empty phage protein coats from the cell walls. They separated out the protein coats and cultured the infected bacterial cells.

Experiment

Question: Which part of the phage—its DNA or its protein—serves as the genetic material and is transmitted to phage progeny?





Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

10.6 Hershey and Chase demonstrated that DNA carries the genetic information in bacteriophages.

Description

The illustration begins with the question, Which part of the phage—its D N A or its protein—serves as the genetic material and is transmitted to phage progeny? The methods below show a T 2 phage with its D N A inside the icosahedral head. Two flasks contain E coli and T 2 phage grown in different radioactive materials. A caption pointing to left conical flask reads, Infect E coli in medium containing radioactive sulfur or S left superscript 35. The phage proteins take up the radioactive sulfur. A caption reads, S left superscript 35 is taken up in phage protein, which contains S but not P. On the right side, infect E coli is grown in medium containing P left superscript 32. A caption pointing to the right conical flask reads, Infect E coli grown in medium containing P left superscript 32. Now, the radioactive phosphate is taken up in phage D N A. A caption reads, P left superscript 32 is taken up in phage D N A, which contains P but not S.

On the left side, phages that have S left superscript 35 infect the unlabeled E coli. A caption reads, Phages with S left superscript 35 infect unlabeled E coli. On the right side, phages that have P left superscript 32 infect the unlabeled E coli. A caption reads, Phages with P left superscript 32 infect unlabeled E coli.

The next set of pictures on both left and right show that the labeled phage and unlabeled bacteria are put in a blender to shear off protein coats. Centrifugation is done after the blending. A caption reads, Shear off protein coats in blender and separate protein from cells by centrifugation.

In the results section below, are 2 tubes with pellets and liquid layers. The tube on the left contains radioactive S left superscript 35 in the liquid. An arrow from the bacteria indicates virus coats are radioactive. A caption reads, After centrifugation, S left superscript 35 is recovered in the fluid containing the virus coats. The tube on the right pellet contains radioactive P left superscript 32 bacterial cells. An arrow from the bacteria indicates virus

coat is not radioactive. A caption reads, After centrifugation, infected bacteria form a pellet containing P left superscript 32 in the bottom of the tube.

An arrow pointing down from the left pellet shows a bacterial cell without radiolabeled content. After phage reproduction, progeny phages are obtained. A caption reads, No radioactivity is detected, indicating that protein has not been transmitted to the progeny phages. An arrow pointing down from the right pellet shows a bacterial cell with radiolabeled content. After phage reproduction, progeny phages are obtained. A caption reads, The progeny phages are radioactive, indicating that D N A has been transmitted to progeny phages. A caption below reads, Conclusion: D N A—not protein—is the genetic material in bacteriophages.

In the case of the bacteria infected by phages labeled with ^{35}S, most of the radioactivity was detected in the phage protein coats, and little was detected in the cells. Furthermore, when new phages emerged from the cells, they contained almost no ^{35}S (see Figure 10.6). This result indicated that the protein component of a phage does not enter the cell and is not transmitted to progeny phages.

In contrast, when Hershey and Chase infected bacteria with ^{32}P-labeled phages and then removed the phage protein coats, the bacteria were radioactive. Most significantly, after the bacterial cells were lysed and new progeny phages emerged, many of those phages emitted radioactivity, demonstrating that DNA from the infecting phages had been passed on to the progeny phages (see Figure 10.6). These results confirmed that DNA, not protein, is the genetic material of phages. › **TRY PROBLEM 24**

CONCEPTS

Using radioactive isotopes, Hershey and Chase traced the movement of DNA and protein during phage infection of bacteria. They demonstrated that DNA, not protein, enters the bacterial cell during phage reproduction and that only DNA is passed on to progeny phages.

✔ CONCEPT CHECK 4

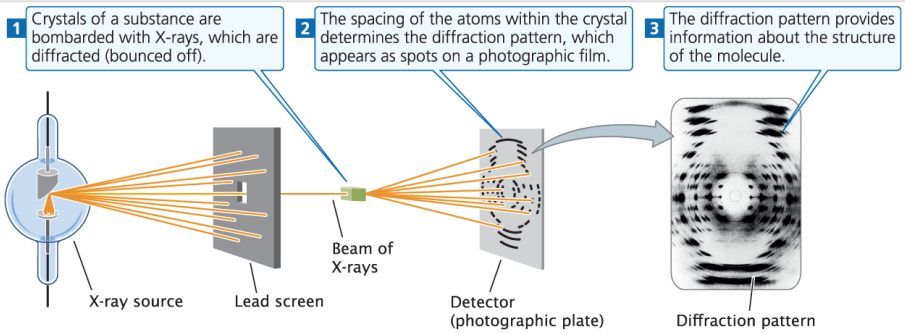
Could Hershey and Chase have used a radioactive isotope of carbon instead of ^{32}P? Why or why not?

Watson and Crick's Discovery of the Three-Dimensional Structure of DNA

These experiments on the nature of the genetic material set the stage for one of the most important advances in the history of biology: the discovery of the three-dimensional structure of DNA by James Watson and Francis Crick in 1953.

Before Watson and Crick's breakthrough, much of the basic chemistry of DNA had already been determined by Miescher, Kossel, Levene, Chargaff, and others, who had established that DNA consists of nucleotides and that each nucleotide contains a sugar, a nitrogenous base, and a phosphate group. However, how the nucleotides fit together in the three-dimensional structure of the molecule was not at all clear.

In 1947, William Astbury began studying the three-dimensional structure of DNA by using a technique called **X-ray diffraction** (**Figure 10.7**), in which X-rays beamed at a molecule are reflected in specific patterns that reveal aspects of the structure of the molecule. However, his diffraction images did not provide enough resolution to reveal the structure. A research group at King's College in London, led by Maurice Wilkins, also used X-ray diffraction to study DNA. Working in Wilkins's laboratory, Rosalind Franklin obtained strikingly better images of the molecule. Rosalind Franklin was an excellent X-ray crystallographer, and her images were critical in the eventual elucidation of the structure of DNA by Watson and Crick.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company
Science Source.

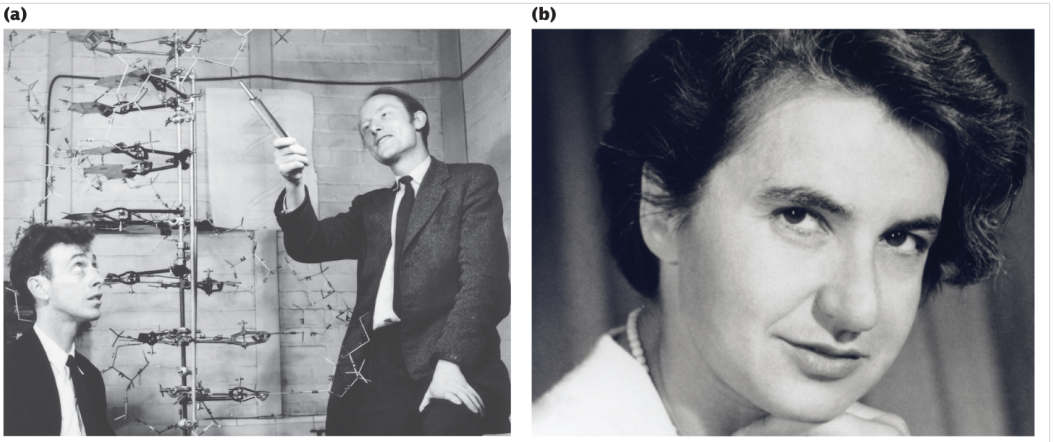
10.7 X-ray diffraction provides information about the structure of molecules.

Description

The illustration shows a circular tube placed on the left. The tube is the source of X-rays that scatter an array of rays towards the surface of the flat lead screen placed on the right. A square hole in the middle of the lead screen allows a beam of X-ray to pass through. This beam hits a square substance and is scattered. A caption reads, Crystals of a substance are bombarded with X-rays, which are diffracted or bounce off. The scattered X-rays then fall on a detector (photographic plate). A caption reads, The spacing of the atoms within the crystal determines the diffraction pattern, which appears as spots on a

photographic film. Finally, a diffraction pattern is obtained on the right side. A caption reads, The diffraction pattern provides information about the structure of the molecule.

Watson and Crick investigated the structure of DNA not by collecting new data but by using all available information about the chemistry of DNA to construct molecular models (Figure 10.8a). By using the excellent X-ray diffraction images taken by Rosalind Franklin (Figure 10.8b) and by applying the laws of structural chemistry, they were able to limit the number of possible structures that DNA could assume. They tested various structures by building models made of wire and metal plates. With their models, they were able to see whether a structure was compatible with chemical principles and with the X-ray images.



Part a: A. Barrington/Science Photo Library/Science Source. Part b: National Library of Medicine/Science Source.

10.8 James Watson and Francis Crick (a) developed a three-dimensional model of the structure of DNA based in part on X-ray diffraction images taken by Rosalind Franklin (b).

The key to solving the structure came when Watson recognized that an adenine base could bond with a thymine base and that a guanine base could bond with a cytosine base; these pairings accounted for the base ratios that Chargaff had discovered earlier. The model developed by Watson and Crick showed that DNA consists of two strands of nucleotides that run in opposite directions (are antiparallel) and wind around each other to form a right-handed helix, with the sugars and phosphates on the outside and the bases in the interior. They recognized that the double-stranded structure of DNA, with its specific base pairing, provided an elegant means by which DNA could be replicated. Watson and Crick published an electrifying description of their model in *Nature* in 1953. At the same time, Franklin and Wilkins each published their X-ray diffraction data, which demonstrated that DNA was helical in structure.

Many have called the solving of DNA's structure the most important biological discovery of the twentieth century. For their discovery, Watson and Crick, along with Maurice Wilkins, were awarded the Nobel Prize in chemistry in 1962. Rosalind Franklin had died of cancer in 1958 and thus could not be considered a candidate for the shared prize, but many scholars and historians believe that she should receive equal credit for solving the structure of DNA.

Following the discovery of DNA's structure, much research was focused on how genetic information is encoded within the base sequence and how this information is copied and expressed. Even

today, the details of DNA structure and function continue to be the subject of active research.

THINK-PAIR-SHARE Questions 2 and 3

CONCEPTS

Using data collected by Rosalind Franklin, Maurice Wilkins, and others, and building molecular models, Watson and Crick were able to discover the three-dimensional structure of the DNA molecule.

✔ CONCEPT CHECK 5

What did Watson and Crick use to help solve the structure of DNA?

a. X-ray diffraction images
b. Laws of structural chemistry
c. Models of DNA
d. All of the above

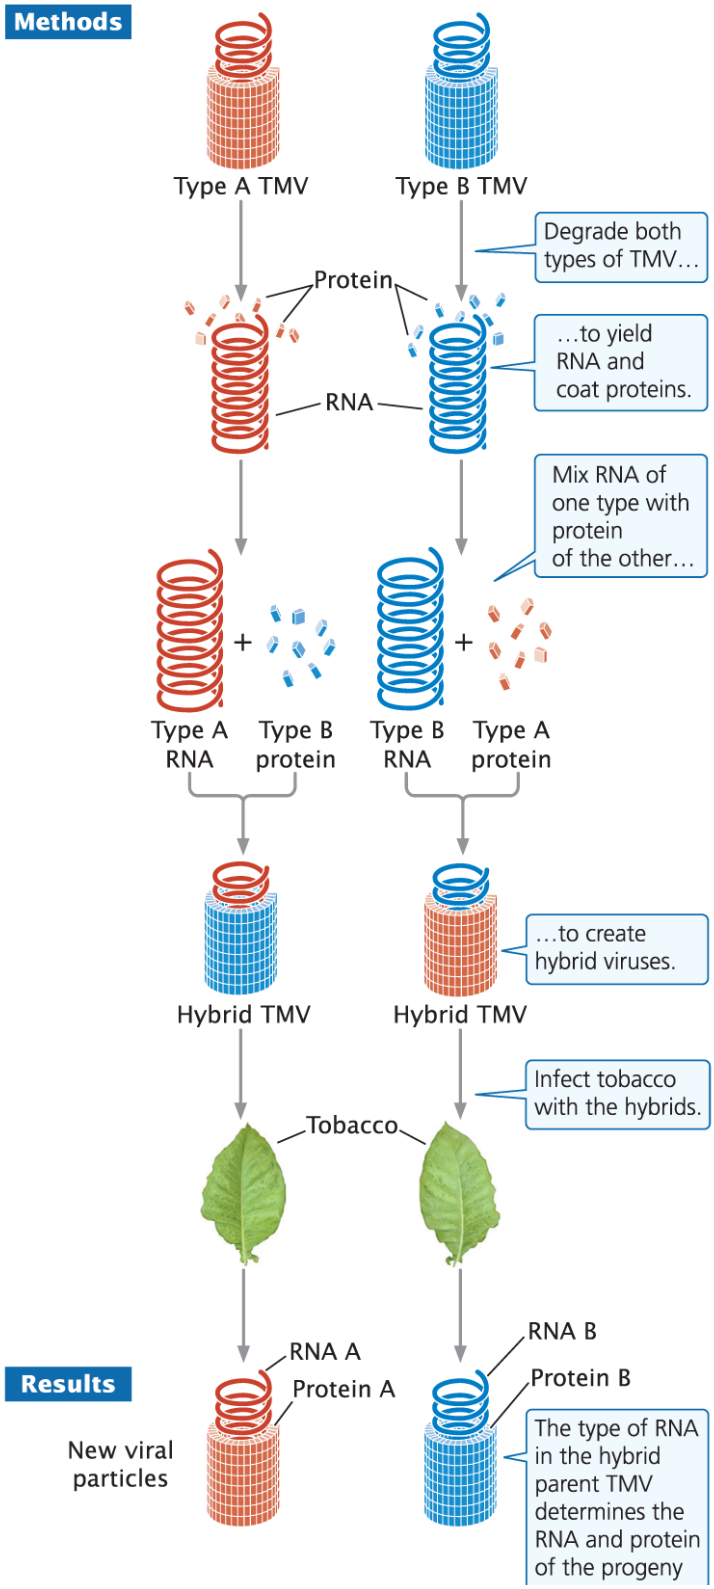
RNA as Genetic Material

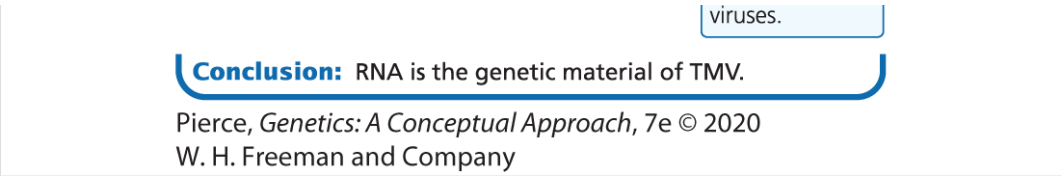
In most organisms, DNA carries the genetic information. A few viruses, however, use RNA, not DNA, as their genetic material. This was demonstrated in 1956 by Heinz Fraenkel-Conrat and Bea Singer, who worked with the tobacco mosaic virus (TMV), which infects and causes disease in tobacco plants (Figure 10.9). The tobacco mosaic

virus possesses a single molecule of RNA surrounded by a helically arranged cylinder of protein molecules. Fraenkel-Conrat found that after separating the RNA and the protein of TMV, he could remix the RNA and protein of different strains of TMV and obtain intact, infectious viral particles.

Experiment

Question: What substance—RNA or protein—carries the genetic material in tobacco mosaic virus (TMV)?





10.9 Fraenkel-Conrat and Singer's experiment demonstrated that RNA carries the genetic information in tobacco mosaic virus.

Description

The illustration shows the question at the top which reads, What substance—R N A or protein—carries the genetic material in tobacco mosaic virus (T M V)? The methods section below shows a red tobacco mosaic virus labeled as T M V type A on the left and a blue tobacco mosaic virus labeled as T M V type B on the right. The virus is cylindrical and its R N A is shaped like a coiled spring. The viruses are degraded to obtain coat proteins and their respective R N A. A caption reads, Degrade both types of T M V to yield R N A and coat proteins. Red type A-R N A is now mixed with type B protein and blue type B-R N A is mixed with type A protein. A caption reads, Mix R N A of one type with protein of the other to create hybrid viruses. The blue virus has a red R N A inside and the red virus has a blue R N A inside. Both viruses are labeled as hybrid T M V. Two tobacco leaves are infected with one each of these hybrid T M V's. A caption reads, Infect tobacco with the hybrids.

The results below show new viral particles. The tobacco leaf infected with hybrid T M V that has blue protein and red R N A eventually produces a virus with red protein and red R N A type A. The tobacco leaf infected with hybrid T M V with red protein and blue R N A eventually produces a virus with blue protein and blue R N A type B. A caption reads, The type of R N A in the hybrid parent T M V determines the R N A and protein of the progeny viruses. A caption below reads, Conclusion: RNA is the genetic material of T M V.

With Singer, Fraenkel-Conrat then created hybrid viruses by mixing RNA and protein from different strains of TMV. When these hybrid viruses infected tobacco leaves, new viral particles were produced. The new viral progeny were identical to the strain from which the RNA had been isolated and did not exhibit the characteristics of the

strain that donated the protein. These results showed that RNA carries the genetic information in TMV.

Also in 1956, Alfred Gierer and Gerhard Schramm demonstrated that RNA isolated from TMV is sufficient to infect tobacco plants and direct the production of new TMV particles. This finding confirmed that RNA carries the genetic instructions in this virus. › **TRY PROBLEM 18**

CONCEPTS

RNA serves as the genetic material in some viruses.

10.3 DNA Consists of Two Complementary and Antiparallel Nucleotide Strands That Form a Double Helix

DNA, though relatively simple in structure, has an elegance and beauty unsurpassed by other large molecules. It is useful to consider the structure of DNA at three levels of increasing complexity, known as the primary, secondary, and tertiary structures of DNA. The primary structure of DNA refers to its nucleotide structure and how the nucleotides are joined together. The secondary structure refers to DNA's stable three-dimensional configuration, the helical structure worked out by Watson and Crick. In Chapter 11, we will consider DNA's tertiary structures, which are the complex packing arrangements of double-stranded DNA in chromosomes.

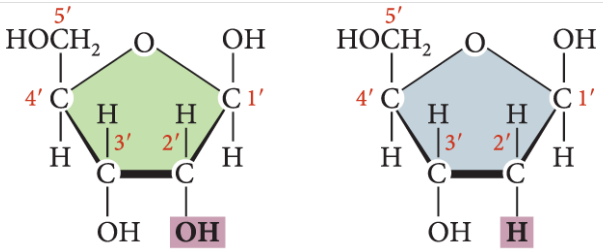
The Primary Structure of DNA

The primary structure of DNA consists of a string of nucleotides joined together by phosphodiester linkages.

NUCLEOTIDES

DNA is typically a very long molecule and is therefore termed a macromolecule. For example, the DNA in each human chromosome is a single molecule that, if stretched out straight, would be several centimeters in length, thousands of times longer than a human cell. In spite of its large size, DNA has quite a simple structure: it is a polymer—that is, a chain made up of many repeating units linked together. The repeating units of DNA are nucleotides, each comprising three parts: (1) a sugar, (2) a phosphate group, and (3) a nitrogen-containing base.

The sugars of nucleic acids—called pentose sugars—have five carbon atoms, numbered $1'$, $2'$, $3'$, $4'$, and $5'$ (**Figure 10.10**). The sugars of DNA and RNA are slightly different in structure. RNA's sugar, called **ribose**, has a hydroxyl group (OH) attached to the $2'$-carbon atom, whereas DNA's sugar, or **deoxyribose**, has a hydrogen atom (H) at this position and therefore contains one oxygen atom fewer overall. This difference gives rise to the names ribonucleic acid (RNA) and *deoxy*ribonucleic acid (DNA). This minor chemical difference is recognized by most of the cellular enzymes that interact with DNA or RNA, thus providing specific functions for each nucleic acid. Furthermore, the additional oxygen atom in the RNA nucleotide makes it more reactive and less chemically stable than DNA. For this reason, DNA is better suited to serve as the long-term carrier of genetic information.



Ribose **Deoxyribose**

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

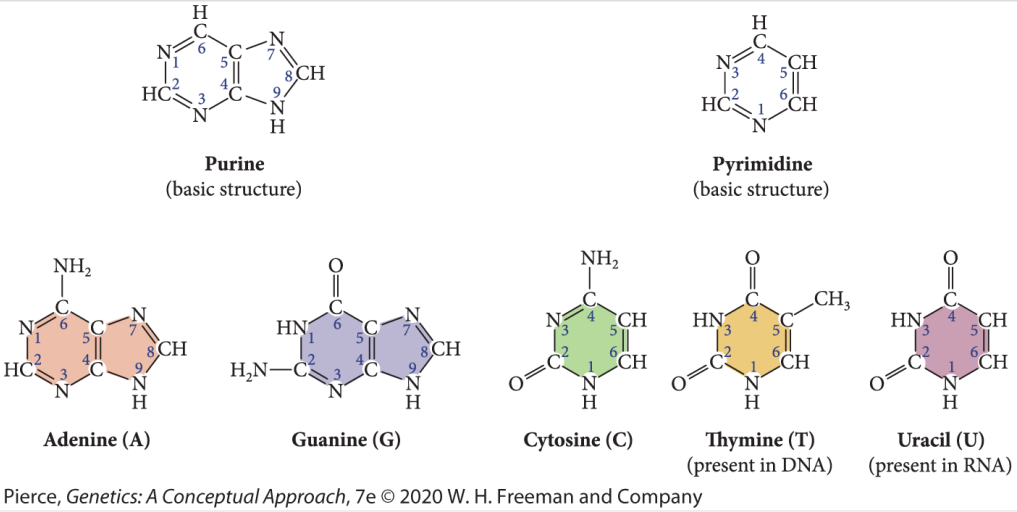
10.10 A nucleotide contains either a ribose sugar (in RNA) or a deoxyribose sugar (in DNA). The carbon atoms of the sugars are assigned primed numbers.

Description

The illustration shows both the sugar molecules have pentagonal rings. The top of the ring is occupied by an O and the other vertices of the pentagon have C atoms. The carbon on the right is designated as 1 prime, and moving clockwise, they are labeled as 2, 3, and 4 prime. For ribose sugar, the carbon atoms 1 through 3 have one hydroxyl group and one hydrogen atom each. For deoxyribose, carbon 2 prime has both hydrogen atoms instead. For both ribose and deoxyribose sugars, 4 prime carbon is bound to one hydrogen atom and to a C atom labeled as 5 prime. The 5 prime C atom has 2 hydrogen bonds and one hydroxyl bond.

The second component of a nucleotide is its **nitrogenous base**, which may be either of two types—a **purine** or a **pyrimidine** (**Figure 10.11**). Each purine consists of a six-member ring attached to a five-member ring, whereas each pyrimidine consists of a six-member ring only. Both DNA and RNA contain two purines, **adenine** and **guanine** (A and G), which differ in the positions of their double bonds and in the groups attached to the six-member ring. Three pyrimidines are common in nucleic acids: **cytosine** (C), **thymine** (T), and **uracil** (U). Cytosine is present in both DNA and RNA; however,

thymine is restricted to DNA, and uracil is found only in RNA. The three pyrimidines differ in the groups or atoms attached to the carbon atoms of the ring and in the number of double bonds in the ring. In a nucleotide, the nitrogenous base always forms a covalent bond with the 1′-carbon atom of the sugar (see Figure 10.10). A deoxyribose or a ribose sugar and a base together are referred to as a **nucleoside**.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

10.11 A nucleotide contains either a purine or a pyrimidine base. The atoms of the rings in the bases are assigned unprimed numbers.

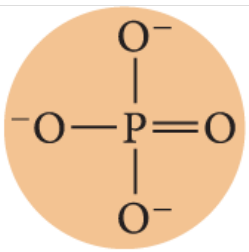
Description

The structure of purine contains a pentagon bound to a hexagon. The numbering of the rings starts with one of the nitrogens on the hexagon. The atoms from positions 2 to 6 are C 2, N 3, C 4, C 5, and C 6 which is double bonded to N 1. Every alternate bond in the hexagonal ring is a double bond. In other words, there is a double bond between positions 2 and 3, 4 and 5, and 6 and 1. The C 4 C 5 double bond of the hexagon is shared with the pentagon. Positions 7 through 9 are in the pentagon. N 7 is bonded to the C 5 carbon. The next 2 atoms are C 8 and N 9, which is then bonded with the hexagon at position C 4. Between N 7 and C 8 is another double bond. C 2, C 6, C 8, and N 9 are each bonded to a hydrogen atom. Below this purine structure, are the structures of bases, adenine and

guanine. The adenine structure is identical to that of the purine, with the exception that the hydrogen at C 6 is replaced by an amine group (N H subscript 2). The structure of guanine is identical to that of the purine, with the exception that the hydrogen at C 2 is replaced by an amine group (N H subscript 2).

On the right side, is the basic structure of pyrimidine. It has the shape of a hexagon and is almost identical to the structure of the hexagonal ring in the purine. The only difference between the two is the orientation of the double bonds, which are drawn in the opposite orientation. In other words, between positions 1 and 2, 3 and 4, and 5 and 6. Below the basic structure of pyrimidine, are the structures of cytosine, thymine, and uracil. The structure of cytosine is identical to the basic pyrimidine, except there are differences at carbons 2 and 4. The double bond between C 2 and N 1 is absent, the hydrogen at C 2 is replaced with a double bond to an oxygen atom. The hydrogen at the C 4 of cytosine is replaced with an amine group (N H subscript 2). Next is the structure of thymine, which is only present in D N A. Thymine is identical to cytosine, except at carbons 4 and 5. C 4 is no longer double bonded with N 3 and now has a double bond with an oxygen atom. C 5's hydrogen atom is replaced with a methyl group (C H subscript 3). Next is the structure of uracil, which is only found in R N A. The structure of uracil is identical with that of thymine, except that the methyl group on carbon 5 is replaced with a hydrogen atom.

The third component of a nucleotide is its **phosphate group**, which consists of a phosphorus atom bonded to four oxygen atoms (**Figure 10.12**). Phosphate groups are found in every nucleotide and frequently carry a negative charge, which makes DNA acidic. The phosphate group is always bonded to the 5′-carbon atom of the sugar (see Figure 10.10) in a nucleotide.

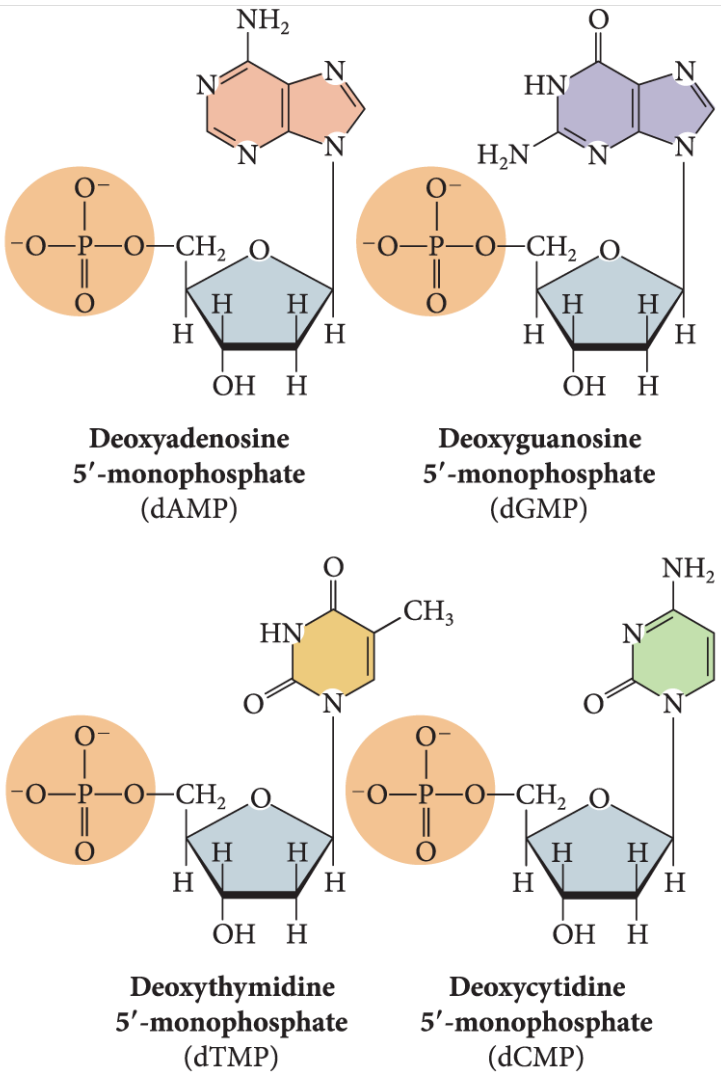


Phosphate

10.12 A nucleotide contains a phosphate group.

Description
The phosphate group has one central P atom bonded to 4 oxygen atoms at right angles. One of the oxygen atoms is double bonded, and the remaining three are single-bonded and have single negative charges associated with them.

The DNA nucleotides are properly known as **deoxyribonucleotides**, or deoxyribonucleoside 5′-monophosphates. Because there are four types of bases, there are four different kinds of DNA nucleotides (**Figure 10.13**). The equivalent RNA nucleotides are termed **ribonucleotides**, or ribonucleoside 5′-monophosphates. RNA molecules sometimes contain additional rare bases, which are modified forms of the four common bases. These modified bases will be discussed in more detail when we examine the function of RNA molecules in Chapter 14. The names for DNA bases, nucleotides, and nucleosides are shown in **Table 10.2**. **› TRY PROBLEM 26**



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

10.13 There are four types of DNA nucleotides. These nucleotides are deoxyribonucleoside 5′-monophosphates.

Description

The phosphate group at the top has one central P atom bonded to 4 oxygen atoms at right angles. One of the oxygen atoms is double bonded, and the remaining three are single-bonded and have single negative charges associated with them.

The illustration also shows four types of D N A nucleotides below. Each of the four D N A nucleotides is drawn as a central deoxyribose sugar with a single phosphate group attached to the 5 prime carbon and with the base pair on top attached through the C 1

prime carbon. For Deoxyadenosine 5 prime monophosphate or d A M P shown at top left, the hydroxyl group at C 1 of the deoxyribose is removed and is bound to the adenine structure through the N 9 position. Deoxyguanosine 5 prime monophosphate or d G M P shown at top right, also has the hydroxyl group at C 1 removed and is bound to guanine through the N 9 position. Deoxythymidine 5 prime monophosphate or d T M P shown at bottom left, has the thymine base pair attached to the C 1 through the N 1 position of the thymine. Deoxycytidine 5 prime monophosphate or d C M P shown at bottom right, is also attached to the C 1 position of the deoxyribose through the N 1 of the cytosine.

TABLE 10.2 Names of DNA bases, nucleotides, and nucleosides

	Adenine	Guanine	Thymine	Cytosine
Base symbol	A	G	T	C
Nucleotide	deoxyadenosine 5′-monophosphate	deoxyguanosine 5′-monophosphate	deoxythymidine 5′-monophosphate	deoxycytidine 5′-monophosphate
Nucleotide symbol	dAMP	dGMP	dTMP	dCMP
Nucleoside	deoxyadenosine	deoxyguanosine	deoxythymidine	deoxycytidine
Nucleoside symbol	dA	dG	dT	dC

CONCEPTS

The primary structure of DNA consists of a string of nucleotides. Each nucleotide consists of a five-carbon sugar, a phosphate group, and a nitrogenous base. There are two types of DNA bases: purines (adenine and guanine) and pyrimidines (thymine and cytosine).

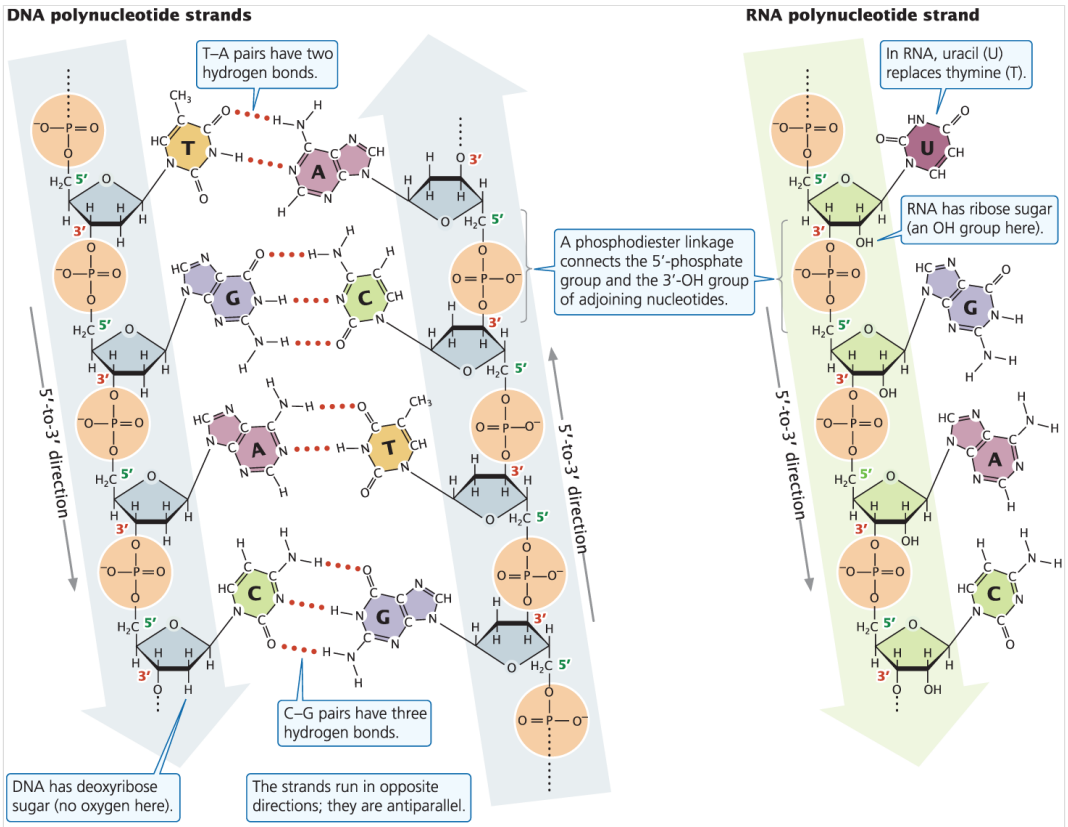
✔ CONCEPT CHECK 6

How do the sugars of RNA and DNA differ?

a. RNA has a six-carbon sugar; DNA has a five-carbon sugar.
b. The sugar of RNA has a hydroxyl group that is not found in the sugar of DNA.
c. RNA contains uracil; DNA contains thymine.
d. DNA's sugar has a phosphorus atom; RNA's sugar does not.

POLYNUCLEOTIDE STRANDS

DNA is made up of many nucleotides connected by covalent bonds, which join the 5′-phosphate group of one nucleotide to the 3′-hydroxyl group of the next nucleotide (**Figure 10.14**). The structures shown in Figure 10.14 are flattened into two dimensions, although the molecule itself is three-dimensional, as shown in Figure 10.15a. Note that Figure 10.14 shows only a portion of the DNA and RNA molecules; each strand continues at its 5′ and 3′ ends, as indicated by ••••. The bonds that connect nucleotides, called **phosphodiester linkages**, are strong covalent bonds; a series of nucleotides linked in this way constitutes a **polynucleotide strand**. The backbone of the polynucleotide strand is composed of alternating sugars and phosphate groups; the bases project away from the long axis of the strand. The negative charges of the phosphate groups are frequently neutralized by their association with positive charges on proteins, metals, or other molecules.



10.14 DNA and RNA are composed of polynucleotide strands. DNA is usually composed of two polynucleotide strands, although single-stranded DNA is found in some viruses. This figure shows only a portion of larger DNA and RNA molecules; each strand continues at its 5′ and 3′ ends.

Description

The D N A strand on the left has nucleotides T, G, A, and C in a chain (from 5 prime at top to 3 prime at bottom) with the A, C, T, and G pairing respectively with them on the opposite strand (from 3 prime at top to 5 prime at bottom). In the sugar molecule, the C 3 prime atom's hydroxyl groups are replaced with the next nucleotide in the chain, joined through one of the oxygen atoms in the phosphate group. A caption reads, T-A pairs have 2 hydrogen bonds and C-G pairs have 3 hydrogen bonds. The double bonded oxygen, N 3, and a hydrogen atom from the amine group of deoxycytosine interacts with the hydrogen, N atom and oxygen atoms from deoxyguanosine. The N 2 and hydrogen atom from the amine group of deoxyadenosine, interact with the double bonded oxygen and hydrogen atom from deoxythymidine. A caption reads, The strands run in opposite directions; they are antiparallel. Another caption reads, A phosphodiester linkage connects the 5 prime

phosphate group and the 3 prime O H group of adjoining nucleotides. Another caption reads, D N A has a deoxyribose sugar, which has no oxygen on the C 2 atom. The illustration also shows an R N A strand on the right from 5 prime (top) to 3 prime (bottom) in which nucleotides U, G, A, and C are present. In the sugar molecule, the C 3 prime atom's hydroxyl groups are replaced with the next nucleotide in the chain, joined through one of the oxygen atoms in the phosphate group. A caption reads, In R N A, uracil (U) replaces the thymine (T). R N A has ribose sugar and has one O H group on the C 2 atom. A caption reads, R N A has ribose sugar (an O H group here).

An important characteristic of the polynucleotide strand is its direction, or polarity. At one end of the strand, a free phosphate group (unattached on one side) is attached to the 5′-carbon atom of the sugar in the nucleotide. This end of the strand is therefore referred to as the **5′ end**. The other end of the strand, referred to as the **3′ end**, has a free hydroxyl group attached to the 3′-carbon atom of the sugar. RNA nucleotides are also connected by phosphodiester linkages to form similar polynucleotide strands (see Figure 10.14).

CONCEPTS

The nucleotides of DNA are joined into polynucleotide strands by phosphodiester bonds that connect the 3′-carbon atom of one nucleotide to the 5′-phosphate group of the next. Each polynucleotide strand has polarity, with a 5′ end and a 3′ end.

Secondary Structures of DNA

The secondary structure of DNA refers to its three-dimensional configuration—its fundamental helical structure. DNA's secondary structure can assume a variety of configurations, depending on its base sequence and the conditions in which it is placed.

THE DOUBLE HELIX

A fundamental characteristic of DNA's secondary structure is that it consists of two polynucleotide strands wound around each other—it's a *double* helix. The sugar–phosphate linkages are on the outside of the helix, and the bases are stacked in the interior of the molecule (see Figure 10.14). The two polynucleotide strands run in opposite directions—they are **antiparallel**, which means that the 5′ end of one strand is opposite the 3′ end of the other strand.

The two strands are held together by two types of molecular forces. Hydrogen bonds link the bases on opposite strands (see Figure 10.14). These bonds are relatively weak compared with the covalent phosphodiester bonds that connect the sugars and phosphate groups of adjoining nucleotides on the same strand. As we will see, several important functions of DNA require the separation of its two nucleotide strands, and this separation can be readily accomplished because of the relative ease of breaking and reestablishing the hydrogen bonds.

The nature of the hydrogen bond imposes a limitation on the types of bases that can pair. Adenine normally pairs only with thymine through two hydrogen bonds, and cytosine normally pairs only with guanine through three hydrogen bonds (see Figure 10.14). Because three hydrogen bonds form between C and G and only two hydrogen bonds form between A and T, C–G pairing is stronger than A–T pairing. The specificity of the base pairing means that wherever there is an A on one strand, there must be a T in the corresponding position on the other strand, and wherever there is a G on one strand, a C must be on the other. The two polynucleotide strands of a DNA molecule are therefore not identical but rather **complementary DNA strands**. The complementary nature of the two nucleotide strands provides for efficient and accurate DNA replication, as we will see in Chapter 12.

The second force that holds the two DNA strands together is the interaction between the stacked base pairs in the interior of the molecule. Stacking means that adjacent bases are aligned so that their rings are parallel and stack on top of one another. The stacking interactions stabilize the DNA molecule but do not require that any particular base follow another. Thus, the base sequence of the DNA molecule is free to vary, allowing DNA to carry genetic information.

› TRY PROBLEMS 32 AND 38

THINK-PAIR-SHARE QUESTION 4

CONCEPTS

DNA consists of two polynucleotide strands. The sugars and phosphate groups of each polynucleotide strand are on the outside of the molecule, and the bases are in the interior. Hydrogen bonding joins the bases of the two strands: guanine pairs with cytosine, and adenine pairs with thymine. The two polynucleotide strands of a DNA molecule are complementary and antiparallel.

✔ CONCEPT CHECK 7

The antiparallel nature of DNA refers to

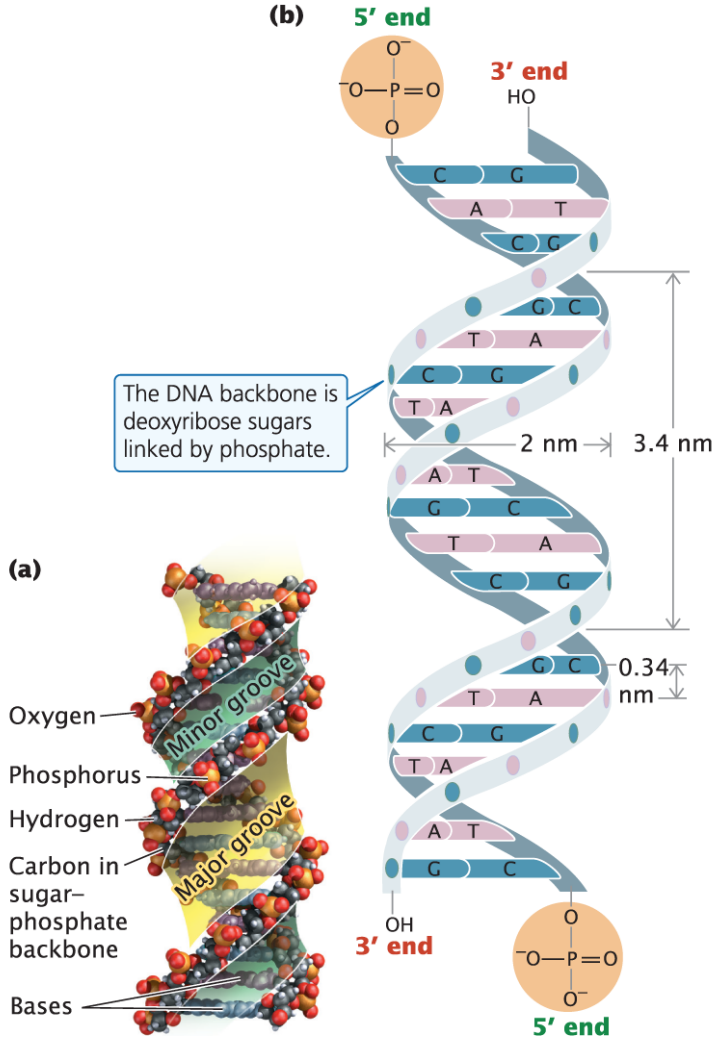
a. its charged phosphate groups.
b. the pairing of bases on one strand with bases on the other strand.
c. the formation of hydrogen bonds between bases from opposite strands.
d. the opposite direction of the two strands of nucleotides.

DIFFERENT SECONDARY STRUCTURES

As we have seen, DNA normally consists of two polynucleotide strands that are antiparallel and complementary (exceptions are the single-stranded DNA molecules found in a few viruses). The precise three-dimensional shape of the molecule can vary, however, depending on the conditions in which the DNA is placed and, in some cases, on the base sequence itself.

The three-dimensional structure of DNA described by Watson and Crick is termed the **B-DNA** structure (**Figure 10.15**). This structure exists when plenty of water surrounds the molecule and there are no

unusual base sequences in the DNA—conditions that are likely to be present in cells. The B-DNA structure is the most stable configuration for a random sequence of nucleotides under physiological conditions, and most evidence suggests that it is the predominant structure in the cell.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

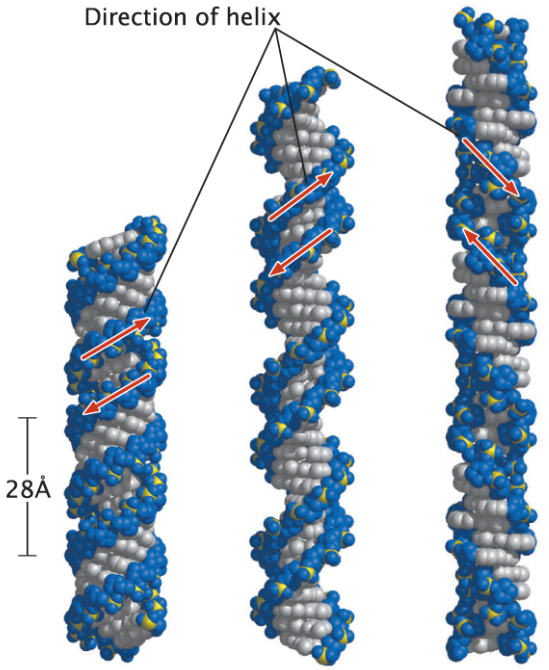
10.15 B-DNA consists of a right-handed helix with approximately 10 bases per turn. (a) Space-filling model of B-DNA showing major and minor grooves. (b) Diagrammatic representation.

Description
Illustration a, the space model on the left, has several round circles of different colors labeled as oxygen, phosphorus, hydrogen, and carbon in sugar-phosphate backbone. Base pairs are also labeled. The major groove is labeled where the backbones are far apart in the helix and the minor groove is marked where they are close together. Illustration b on the right shows one strand of the helix with a phosphate group and is labeled as the 5 prime end, and on the opposing strand an O H group is present and is labeled the 3 prime end. A caption reads, The D N A backbone has deoxyribose sugars linked by phosphate. The illustrations also show the dimensions of double helix. The width is 2 nanometers. From minor groove to minor groove, the distance is 3 point 4 nanometers. From base pair to base pair, the distance is 0 point 3 4 nanometers.

B-DNA is a right-handed helix, meaning that it has a clockwise spiral. There are approximately 10 base pairs (bp) per 360-degree rotation of the helix, so each base pair is twisted 36 degrees relative to the adjacent bases (see **Figure 10.15b**). The base pairs are 0.34 nanometers (nm) apart, so each complete rotation of the molecule encompasses 3.4 nm. The diameter of the helix is 2 nm, and the bases are perpendicular to the long axis of the DNA molecule. A space-filling model shows that B-DNA has a slim and elongated structure (see **Figure 10.15a**). The spiraling of the nucleotide strands creates major and minor grooves in the helix, features that are important for the binding of some proteins that regulate the expression of genetic information (see Chapter 16).

Another secondary structure that DNA can assume is the **A-DNA** structure, which exists if less water is present. Like B-DNA, A-DNA is a right-handed helix (**Figure 10.16a**), but it is shorter and wider than B-DNA (**Figure 10.16b**), and its bases are tilted away from the main

axis of the molecule. A-DNA has been detected in some DNA–protein complexes and in spores of some bacteria.



After J. M. Berg, J. L. Tymoczko, and L. Stryer, *Biochemistry*, 6th ed. (New York: W. H. Freeman and Company, 2002), pp. 785 and 787.

10.16 DNA can assume several different secondary structures.

Description

Illustration a on the left shows A form which is relatively smaller than the B form and measures 28 angstroms from minor groove to minor groove. The direction of first groove is upwards at almost an angle of 30 degrees and the second groove is downwards at an angle of almost 30 degrees. Illustration b in the center shows B form which is a little longer than the A form and its grooves are oriented in the same direction as A form. Illustration c on the right shows Z form which is relatively longer than the B form and the grooves are oriented in opposite direction.

A radically different secondary structure, called Z-DNA (Figure 10.16c), forms a left-handed helix. In this structure, the sugar–phosphate backbone zigzags back and forth, giving rise to its name. A Z-DNA structure can result if the molecule contains particular base sequences, such as stretches of alternating C and G nucleotides. Researchers have found that Z-DNA-specific antibodies bind to regions of the DNA that are being transcribed into RNA, suggesting that Z-DNA may play some role in gene expression. Additional secondary structures of DNA (C-DNA, D-DNA, etc.) can form under specialized laboratory conditions or in DNA with specific base sequences.

THINK-PAIR-SHARE Question 5

CONCEPTS

DNA can assume different secondary structures, depending on the conditions in which it is placed and on its base sequence. B-DNA is thought to be the most common configuration in the cell.

✔ CONCEPT CHECK 8

How does Z-DNA differ from B-DNA?

CONNECTING CONCEPTS CONNECT

Genetic Implications of DNA Structure

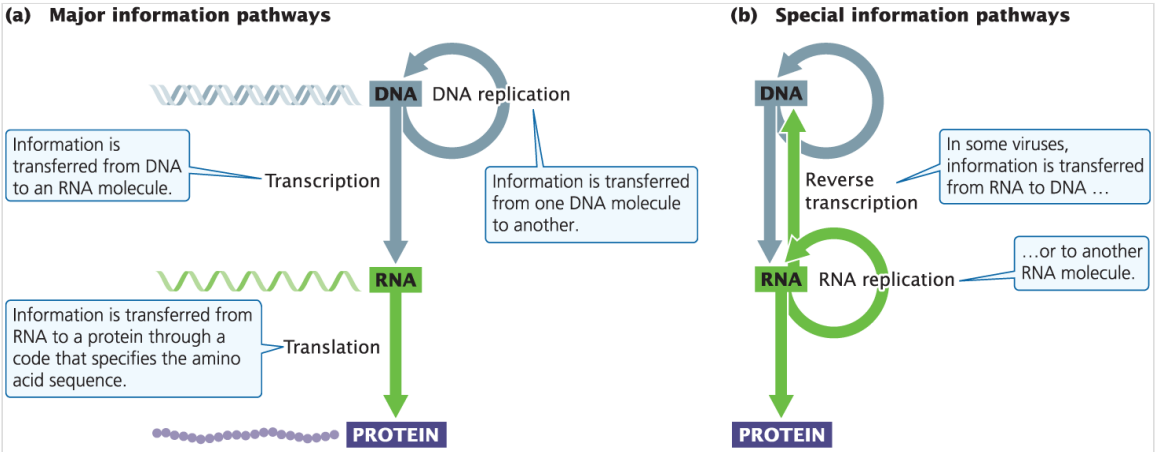
Watson and Crick's great contribution was their elucidation of the genotype's chemical structure, which made it possible for geneticists to begin to examine genes directly, instead of looking only at the phenotypic consequences of gene action. The determination of the structure of DNA led to the birth of molecular genetics—the study of the chemical and molecular nature of genetic information.

Watson and Crick's structure did more than create the potential for molecular genetic studies, however; it was an immediate source of insight into key genetic processes. At the beginning of this chapter, four fundamental requirements for genetic material were identified. Watson and Crick's structure showed how DNA met those requirements.

1. First, genetic material must be capable of carrying large amounts of information. Watson and Crick's model suggested that genetic instructions are encoded in the base sequence of DNA, the only variable part of the molecule.
2. A second necessary property of genetic material is its ability to replicate faithfully. The complementary polynucleotide strands of DNA make this replication possible. Watson and Crick proposed that in replication, the two polynucleotide strands unzip, breaking the weak hydrogen bonds between them, and each strand serves as a template on which a new strand is synthesized. The specificity of the base pairing means that only one possible sequence of bases—the complementary sequence—can be synthesized from each template strand. Newly replicated double-stranded DNA molecules are therefore identical with the original double-stranded DNA molecule (see Chapter 12 on DNA replication).
3. A third essential property of genetic material is the ability to be expressed as a phenotype. DNA expresses its genetic instructions by first transferring its information to an RNA molecule in a process termed **transcription** (see Chapter 13). The term *transcription* is appropriate because although the information is transferred from DNA to RNA, the information remains in the language of nucleic acids. In some cases, the RNA molecule then transfers the genetic information to a protein by specifying its amino acid sequence. This process is termed **translation** (see Chapter 15) because the information must be *translated* from the language of nucleotides into the language of amino acids.
4. A fourth essential property of genetic material is the capacity to vary. The variation in DNA, as we have seen, consists of differences in the sequence of bases found among different individuals.

We can now identify three major pathways of information flow in the cell (**Figure 10.17a**): in **replication**, information passes from one DNA molecule to other DNA molecules; in transcription, information passes from DNA to RNA; and in translation, information passes

from RNA to protein. This concept of information flow was formalized by Francis Crick in a concept that he called the **central dogma** of molecular biology. The central dogma states that genetic information passes from DNA to protein in a one-way information pathway. We now realize, however, that the central dogma is an oversimplification. In addition to the three general information pathways of replication, transcription, and translation, other transfers may take place in certain organisms or under special circumstances. Retroviruses (see Chapter 9) and some transposable elements (see Chapter 18) transfer information from RNA to DNA (in **reverse transcription**), and some RNA viruses transfer information from RNA to RNA (in **RNA replication**; **Figure 10.17b**).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

10.17 Pathways of information transfer within the cell.

Description

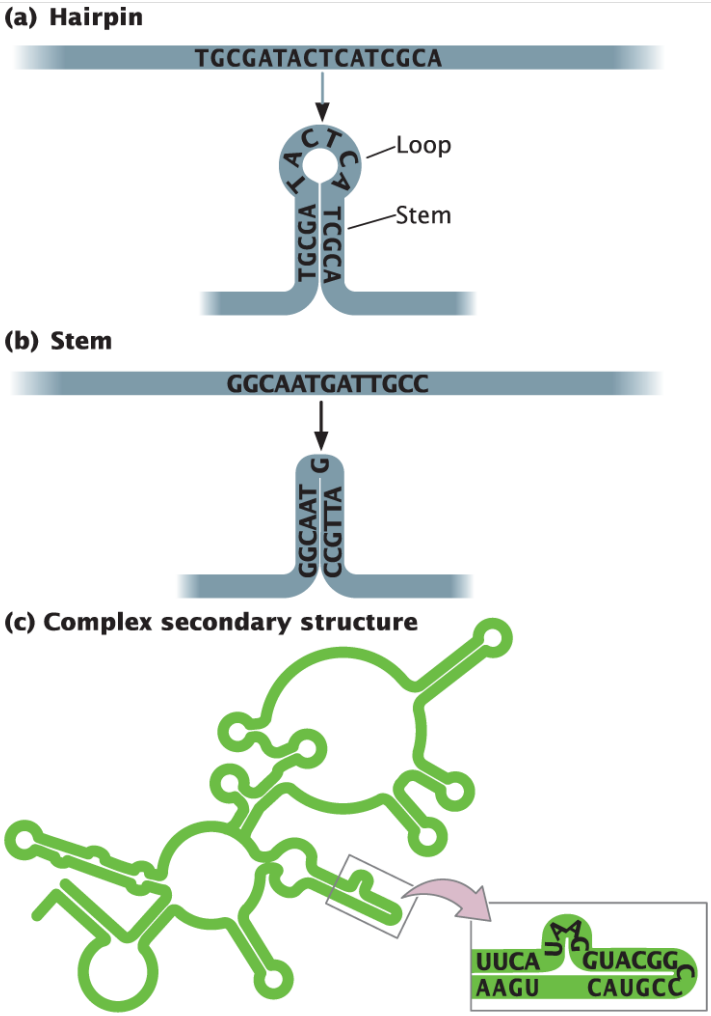
Illustration a on the left shows major information pathways. It shows a D N A helix undergoing replication to form D N A again. A caption reads, Information is transferred from one D N A molecule to another. D N A also undergoes transcription to produce an R N A strand. A caption reads, Information is transferred from D N A to an R N A molecule. Then, this R N A strand undergoes translation to form a protein. A caption reads, Information is transferred from R N A to a protein through a code that specifies the amino acid sequence.

Illustration b on the right shows special information pathways. It shows a D N A helix undergoing replication to form D N A again. D N A also undergoes transcription to produce an R N A strand. Then, this R N A strand undergoes reverse transcription to form D N A. A caption reads, In some viruses, information is transferred from R N A

to D N A or to another R N A molecule. This R N A strand further undergoes R N A replication to form R N A again. R N A strand also undergoes translation to form a protein.

10.4 Special Structures Can Form in DNA and RNA

Sequences *within* a single strand of nucleotides may be complementary to each other and able to pair by forming hydrogen bonds, producing double-stranded regions (**Figure 10.18**). This internal base pairing imparts a secondary structure to a single-stranded molecule. One common type of secondary structure found in single strands of nucleotides is a **hairpin**, which forms when sequences of nucleotides on the same strand are inverted complements (see **Figure 10.18a**). A hairpin consists of a region of paired bases (the stem) and intervening unpaired bases (a loop). When the complementary sequences are contiguous, a stem is formed with no loop (see **Figure 10.18b**). RNA molecules may contain numerous hairpins, which allow them to fold up into complex structures (see **Figure 10.18c**). Secondary structures play important roles in the functions of many RNA molecules, as we will see in Chapters 14 and 15.



10.18 Both DNA and RNA can form special secondary structures. (a) A hairpin consisting of a region of paired bases (which form the stem) and a region of unpaired bases between the complementary sequences (which form a loop at the end of the stem). (b) A stem with no loop. (c) Secondary structure of the RNA component of RNase P of *E. coli*. RNA molecules often have complex secondary structures.

Description

Illustration a at the top shows a D N A strand forming a hairpin loop structure. In the stem, the base pairs starting from 5 prime are T, G, C, G, A, and they pair with T, C, G, C, A, that start 6 base pairs away. The 6 base pairs intervening form the loop and are as follows: T, A, C, T, C, and A.

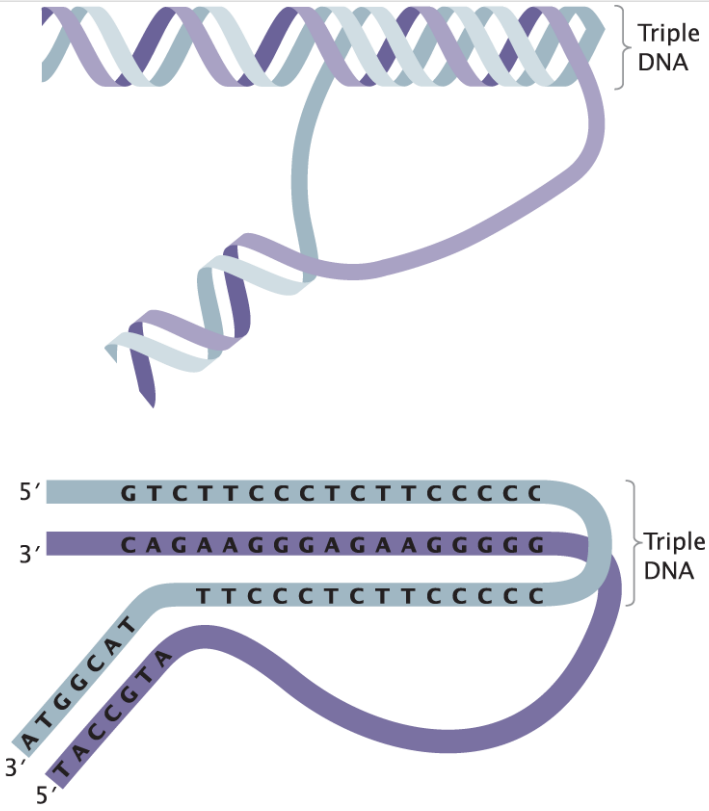
Illustration b below shows a D N A strand forming a stem structure. In the stem, 6 base pairs, starting from 5 prime G, G, C, A, A, T base pair with A, T, T, G, C, C. Only 1 base pair, G, intervenes these 2 complementary strands and sits on the top of the stem. This forms the stem.

Illustration c below shows a strand of R N A forming a complex secondary structure. The strand has 3 stems that have large loops, 9 stems with small loops, and 1 stem. Some of the stem loops have regions where a section does not base pair complement the other side of the stem and this section forms a small bump within the stem. One of these sections is magnified to show the base pairs U, U, C, A base pairing with A, A, G, U on the other side of the stem. 4 base pairs without a complement on the other side form a small bump in the stem and are as follows: U, A, A, G. The stem continues with base pairs G, U, A, C, G, G pairing with C, A, U, G, C, C with C at the top of stem.

DNA sequences can also sometimes form three-stranded (triplex) structures, called **H-DNA**, when some of the DNA unwinds and a single polynucleotide strand from one part of the molecule pairs with double-stranded DNA from another part of the molecule (**Figure 10.19**). This is possible because under certain conditions, one base can simultaneously pair with two other bases. H-DNA often occurs in long sequences containing only purine bases or only pyrimidine bases. Some triplex structures consist of one strand of purines paired with two strands of pyrimidines; other triplex structures consist of one strand of pyrimidines paired with two strands of purines. Sequences capable of adopting an H-DNA conformation are common in mammalian genomes, and evidence suggests that H-DNA occurs under natural conditions. Research has demonstrated that H-DNA breaks more readily than double-stranded DNA, which then leads to higher rates of mutation in regions where H-DNA structures occur. Quadruplex structures involving four

strands of DNA can also occur under certain conditions. ❯ **TRY PROBLEM 40**

THINK-PAIR-SHARE Question 6



10.19 H-DNA arises when three polynucleotide strands pair.

Description

The illustration shows two D N A duplexes that have a purple and grey strand. The purple strand in the first D N A duplex is continuous with the purple strand in the second duplex. The grey strand in the first duplex remains a part of the D N A strand. The grey strand from the second D N A duplex invades the first duplex for about 3 turns forming the triple D N A

strand section and replaces the purple strand in the duplex as it dissociates from that duplex.

The illustration below shows 2 grey strands sandwiching a purple strand and representing the triple D N A. The grey strands have the same D N A nucleotide sequence going left to right in the diagram. Both complement the sequence on the purple strand.

CONCEPTS

In DNA and RNA, base pairing between nucleotides on the same strand produces special secondary structures, such as hairpins. Triple-stranded DNA structures can arise when a single strand of DNA pairs with double-stranded DNA.

✔ CONCEPT CHECK 9

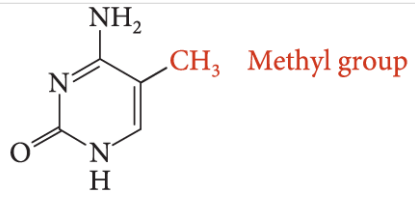
Hairpins are formed in DNA as a result of

a. sequences on the same strand that are inverted and complementary.
b. sequences on the opposite strand that are complements.
c. sequences on the same strand that are identical.
d. sequences on the opposite strand that are identical.

The primary structure of DNA can also be modified in various ways. One such modification is **DNA methylation**, a process in which methyl groups (CH_3) are added by specific enzymes to certain positions on the nitrogenous bases. Bacterial DNA is frequently methylated to distinguish it from foreign, unmethylated DNA that may be introduced by viruses; bacteria use proteins called restriction enzymes to cut up any unmethylated viral DNA (see Chapter 19). In eukaryotic cells, methylation is often related to gene expression. Sequences that are methylated typically show low levels

of transcription, while sequences lacking methylation are actively being transcribed (see Chapter 17). Methylation can also affect the three-dimensional structure of the DNA molecule and is responsible for some epigenetic effects (see Chapter 21).

Adenine and cytosine are commonly methylated in bacteria. In eukaryotic DNA, cytosine bases are sometimes methylated to form **5-methylcytosine** (**Figure 10.20**). The extent of cytosine methylation varies among eukaryotic organisms: in most animal cells, about 5% of the cytosine bases are methylated, but there is no methylation of cytosine in yeast, and more than 50% of the cytosine bases in some plants are methylated. Why eukaryotic organisms differ so widely in their degree of methylation is not clear.



5-Methylcytosine

Pierce, *Genetics: A Conceptual Approach*, 7e
© 2020 W. H. Freeman and Company

10.20 In eukaryotic DNA, cytosine bases are often methylated to form 5-methylcytosine.

CONCEPTS

Methyl groups may be added to certain bases in DNA. Both prokaryotic and eukaryotic DNA can be methylated. In eukaryotes, cytosine bases are most often methylated to form 5-methylcytosine, and methylation is often related to gene expression.

Chapter 10 Review

CHAPTER SUMMARY

Section 10.1 Learning Objective: Be able to list key characteristics of genetic material.

- Genetic material must contain complex information, be replicated accurately, code for the phenotype, and have the capacity to vary.

Section 10.2 Learning Objective: Be able to describe how researchers identified DNA as the source of genetic information.

- Evidence that DNA is the source of genetic information came from the finding by Avery, MacLeod, and McCarty that transformation depends on DNA and from the demonstration by Hershey and Chase that viral DNA is passed on to progeny phages.
- James Watson and Francis Crick, using data provided by Rosalind Franklin and Maurice Wilkins, proposed a model for the three-dimensional structure of DNA in 1953.
- The results of experiments with tobacco mosaic virus showed that RNA carries genetic information in some viruses.

Section 10.3 Learning Objective: Be able to outline the primary and secondary structures of DNA.

- A DNA nucleotide consists of a deoxyribose sugar, a phosphate group, and a nitrogenous base. An RNA nucleotide consists of a ribose sugar, a phosphate group, and a nitrogenous base.
- The bases of a DNA nucleotide are of two types: purines (adenine and guanine) and pyrimidines (cytosine and thymine). RNA contains the pyrimidine uracil instead of thymine.
- Nucleotides are joined together by phosphodiester linkages to form a polynucleotide strand. Each polynucleotide strand has a free phosphate group at its $5'$ end and a free hydroxyl group at its $3'$ end.
- DNA consists of two nucleotide strands that wind around each other to form a double helix. The sugars and phosphates lie on the outside of the helix, and the bases are stacked in the interior. The two strands are joined together by hydrogen bonding between bases in each strand. The two strands are antiparallel and complementary.
- DNA molecules can form a number of different secondary structures, depending on the conditions in which the DNA is placed and on its base sequence.
- The structure of DNA has several important genetic implications. Genetic information resides in the base sequence of DNA, which ultimately specifies the amino acid sequence of proteins. Complementarity of the bases on DNA's two strands allows genetic information to be replicated.

- The central dogma of molecular biology proposes that information flows in a one-way direction, from DNA to RNA to protein. Exceptions to the central dogma are now known.

Section 10.4 Learning Objective: Be able to describe special structures that occur within DNA and RNA.

- Pairing between bases on the same nucleotide strand can lead to hairpins and other special secondary structures.
- DNA may be modified by the addition of methyl groups to the nitrogenous bases.

WORKED PROBLEMS

Problem 1

The percentage of cytosine in a double-stranded DNA molecule is 40%. What is the percentage of thymine?

» Solution Strategy

What information is required in your answer to the problem?

The percentage of thymine in the DNA molecule.

What information is provided to solve the problem?

- The DNA molecule is double stranded.
- The percentage of cytosine is 40%.

> **Recall:** In double-stranded DNA, A pairs with T, whereas G pairs with C; so the percentage of A equals the percentage of T, and the percentage of G equals the percentage of C.

For help with this problem, review:

The Primary Structure of DNA and Secondary Structures of DNA in Section 10.3.

» Solution Steps

If C=40%, then G also must be 40%. The total percentage of C + G is therefore 40% + 40% = 80%. All the remaining bases must be either A or T, so the total percentage of A + T = 100% − 80% = 20%; because the percentage of A equals the percentage of T, the percentage of T is 20% / 2 = 10%.

Problem 2

Which of the following relations will be true for the percentage of bases in double-stranded DNA?

a. C + T = A + G
b. $\frac{C}{A} = \frac{T}{G}$

» Solution Strategy

What information is required in your answer to the problem?

Whether C + T = A + G and $\frac{C}{A} = \frac{T}{G}$ are true.

What information is provided to solve the problem?

- The DNA is double stranded.
- Ratios of different groups of bases.

For help with this problem, review:

The Primary Structure of DNA and Secondary Structures of DNA in Section 10.3.

» Solution Steps

An easy way to determine whether the relations are true is to arbitrarily assign percentages to the bases, remembering that, in double-stranded DNA, A = T and G = C. For example, if the percentages of A and T are each 30%, then the percentages of G and C are each 20%. We can substitute these values into the equations to see if the relations are true.

a. 20 + 30 = 30 + 20. This relation is true.
b. $^{20}/_{30} \neq {}^{30}/_{20}$. This relation is not true.

COMPREHENSION QUESTIONS

Section 10.1

1. What four general characteristics must the genetic material possess?

Section 10.2

2. Briefly outline the history of our knowledge of the structure of DNA until the time of Watson and Crick. Which do you think were the principal contributions and developments?

3. What experiments demonstrated that DNA is the genetic material?

4. What is transformation? How did Avery and his colleagues demonstrate that the transforming principle is DNA?

5. How did Hershey and Chase show that DNA is passed to new phages in phage reproduction?

6. Why was the discovery of DNA structure so important?

Section 10.3

7. Draw and identify the three parts of a DNA nucleotide.

8. How does an RNA nucleotide differ from a DNA nucleotide?
9. How does a purine differ from a pyrimidine? What purines and pyrimidines are found in DNA and RNA?
10. Draw a short segment of a single polynucleotide strand, including at least three nucleotides. Indicate the polarity of the strand by identifying the $5'$ end and the $3'$ end.
11. Which bases are capable of forming hydrogen bonds with each other?
12. What different types of chemical bonds are found in DNA, and where are they found?
13. What are some of the important genetic implications of the DNA structure?
14. What are the three major pathways of information flow within the cell?

Section 10.4

15. What are hairpins and how do they form?
16. What is DNA methylation?

APPLICATION QUESTIONS AND PROBLEMS

Introduction

17. The introduction to this chapter, which describes the sequencing of 90,000-year-old DNA, emphasizes DNA's extreme stability. What aspects of DNA's structure contribute to the stability of the molecule? Why is RNA less stable than DNA?

Section 10.2

18. *Match the researchers (a–j) with the discoveries listed.

    a. Kossel

    b. Fraenkel-Conrat

    c. Watson and Crick

    d. Levene

    e. Miescher

    f. Hershey and Chase

    g. Avery, MacLeod, and McCarty

    h. Griffith

    i. Franklin and Wilkins

    j. Chargaff

    _____ Took X-ray diffraction pictures used in constructing the structure of DNA.
    _____ Determined that DNA contains nitrogenous bases.
    _____ Identified DNA as the genetic material in bacteriophages.

_____ Discovered regularity in the ratios of different bases in DNA.
_____ Determined that DNA is responsible for transformation in bacteria.
_____ Worked out the helical structure of DNA by building models.
_____ Discovered that DNA consists of repeating nucleotides.
_____ Determined that DNA is acidic and high in phosphorus.
_____ Conducted experiments showing that RNA can serve as the genetic material in some viruses.
_____ Demonstrated that heat-killed material from bacteria can genetically transform live bacteria.

19. *A student mixes some heat-killed type IIS *S. pneumoniae* bacteria with live type IIR bacteria and injects the mixture into a mouse. The mouse develops pneumonia and dies. The student recovers some type IIS bacteria from the dead mouse. If this is the only experiment conducted by the student, has the student demonstrated that transformation has taken place? What other explanations might explain the presence of the type IIS bacteria in the dead mouse?

20. Predict what would happen if Griffith had mixed some heat-killed type IIIS bacteria and some heat-killed type IIR bacteria and injected these into a mouse. Would the mouse have contracted pneumonia and died? Explain why or why not.

21. CONNECT Explain how heat-killed type IIIS bacteria in Griffith's experiment genetically altered the live type IIR bacteria. (Hint: See the discussion of transformation in Chapter 9.)

22. What results would you expect if the bacteriophage that Hershey and Chase used in their experiment had contained RNA instead of DNA?

23. Which of the processes of information transfer illustrated in **Figure 10.17** are required for the T2 phage reproduction illustrated in **Figure 10.5**?

24. *Imagine that you are a student in Alfred Hershey and Martha Chase's lab in the late 1940s. You are given five test tubes containing *E. coli* bacteria infected with T2 bacteriophages that have been labeled with either ^{32}P or ^{35}S. Unfortunately, you forget to mark the tubes and are now uncertain about which were labeled with ^{32}P and which with ^{35}S. You place the contents of each tube in a blender and turn it on for a few seconds to shear off the phage protein coats. You then centrifuge the contents to separate the protein coats from the cells. You check for the presence of radioactivity and obtain the following results. Which tubes contained *E. coli* infected with ^{32}P-labeled phage? Explain your answer.

Tube number	Radioactivity present in
1	Cells
2	Protein coats
3	Protein coats
4	Cells
5	Cells

25. **Figure 10.9** illustrates Fraenkel-Conrat and Singer's experiment on the genetic material of TMV. What results would you expect in this

experiment if protein carried the genetic information of TMV instead of RNA?

Section 10.3

26. *DNA molecules of different sizes are often separated with the use of a technique called electrophoresis (see Chapter 19). With this technique, DNA molecules are placed in a gel, an electrical current is applied to the gel, and the DNA molecules migrate toward the positive (+) pole of the current. What aspect of its structure causes a DNA molecule to migrate toward the positive pole?

27. *Each nucleotide pair of a DNA double helix weighs about 1×10^{-21}g. The human body contains approximately 0.5 g of DNA. How many nucleotide pairs of DNA are in the human body? If you assume that all the DNA in human cells is in the B-DNA form, how far would the DNA reach if stretched end to end?

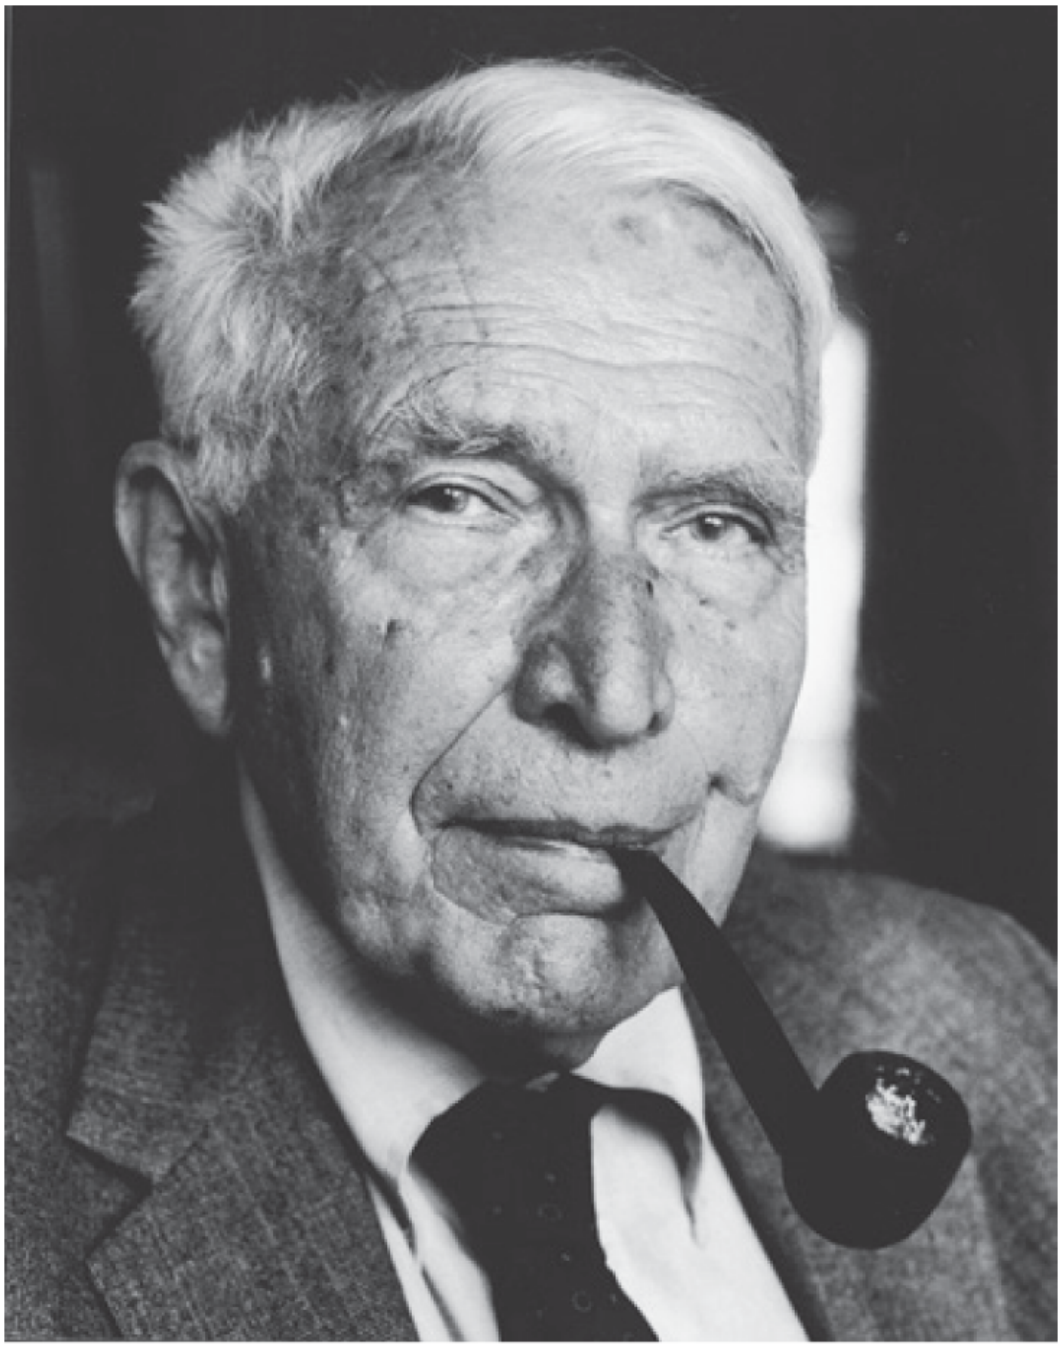
28. One nucleotide strand of a DNA molecule has the base sequence illustrated below.

    $5'$–ATTGCTACGG–$3'$

    Give the base sequence, and label the $5'$ and $3'$ ends of the complementary DNA nucleotide strand.

29.

*Erwin Chargaff collected data on the proportions of nitrogenous bases from the DNA of a variety of different organisms and tissues (E. Chargaff, in *The Nucleic Acids: Chemistry and Biology*, vol. 1, E. Chargaff and J. N. Davidson, Eds. New York: Academic Press, 1955). The following data are from the DNA of several organisms analyzed by Chargaff.



Horst Tappe/Getty Images.

Erwin Chargaff.

Percentage

Organism and tissue	A	G	C	T
Sheep thymus	29.3	21.4	21.0	28.3
Pig liver	29.4	20.5	20.5	29.7
Human thymus	30.9	19.9	19.8	29.4
Rat bone marrow	28.6	21.4	20.4	28.4
Hen erythrocytes	28.8	20.5	21.5	29.2
Yeast	31.7	18.3	17.4	32.6
E. coli	26.0	24.9	25.2	23.9
Human sperm	30.9	19.1	18.4	31.6
Salmon sperm	29.7	20.8	20.4	29.1
Herring sperm	27.8	22.1	20.7	27.5

a. For each organism, compute the ratio of (A + G)/(T + C) and the ratio of (A + T)/(C + G).

b. Are these ratios constant, or do they vary among the organisms? Explain why.

c. Is the (A + G)/(T + C) ratio different for the sperm samples? Would you expect it to be? Why or why not?

30. Boris Magasanik collected data on the amounts of the bases of RNA isolated from a number of sources, expressed relative to a value of 10 for adenine (B. Magasanik, in *The Nucleic Acids: Chemistry and Biology*, vol. 1, E. Chargaff and J. N. Davidson, Eds. New York: Academic Press, 1955).

	Amount			
Organism and tissue	**A**	**G**	**C**	**U**
Rat liver nuclei	10	14.8	14.3	12.9
Rabbit liver nuclei	10	13.6	13.1	14.0
Cat brain	10	14.7	12.0	9.5
Carp muscle	10	21.0	19.0	11.0
Yeast	10	12.0	8.0	9.8

a. For each organism, compute the ratio of (A + G)/(U + C).

b. How do these ratios compare with the (A + G)/(T + C) ratio found in DNA (see Problem 29)? Explain.

31. Which of the following relations or ratios would be true for a double-stranded DNA molecule?

a. A + T = G + C

b. A + G = T + C

c. A + C = G + T

d. $\frac{A + T}{C + G} = 1.0$

e. $\frac{A + G}{C + T} = 1.0$

f. $\frac{A}{C} = \frac{G}{T}$

g. $\frac{A}{G} = \frac{C}{T}$

h. $\frac{A}{T} = \frac{G}{C}$

32. *If a double-stranded DNA molecule is 15% thymine, what are the percentages of all the other bases?

33.

In pea plants, tall (*T*) is dominant to dwarf (*t*). Let us assume that the DNA sequence for the tall allele is TTTT and the sequence that codes for the dwarf allele is TGTT. A geneticist crosses a pea plant homozygous for tall with a dwarf plant to produce F_1 progeny (see Chapter 3 for a review of genetic crosses). Draw a picture that illustrates the DNA molecules that code for tall and dwarf alleles in a pair of chromosomes of the F_1 progeny from this cross at the following stages. Label the DNA sequences for the tall and dwarf alleles. To keep the diagram simple, you can use a straight line for each polynucleotide chain.

a. G_1 of interphase

b. Metaphase I of meiosis

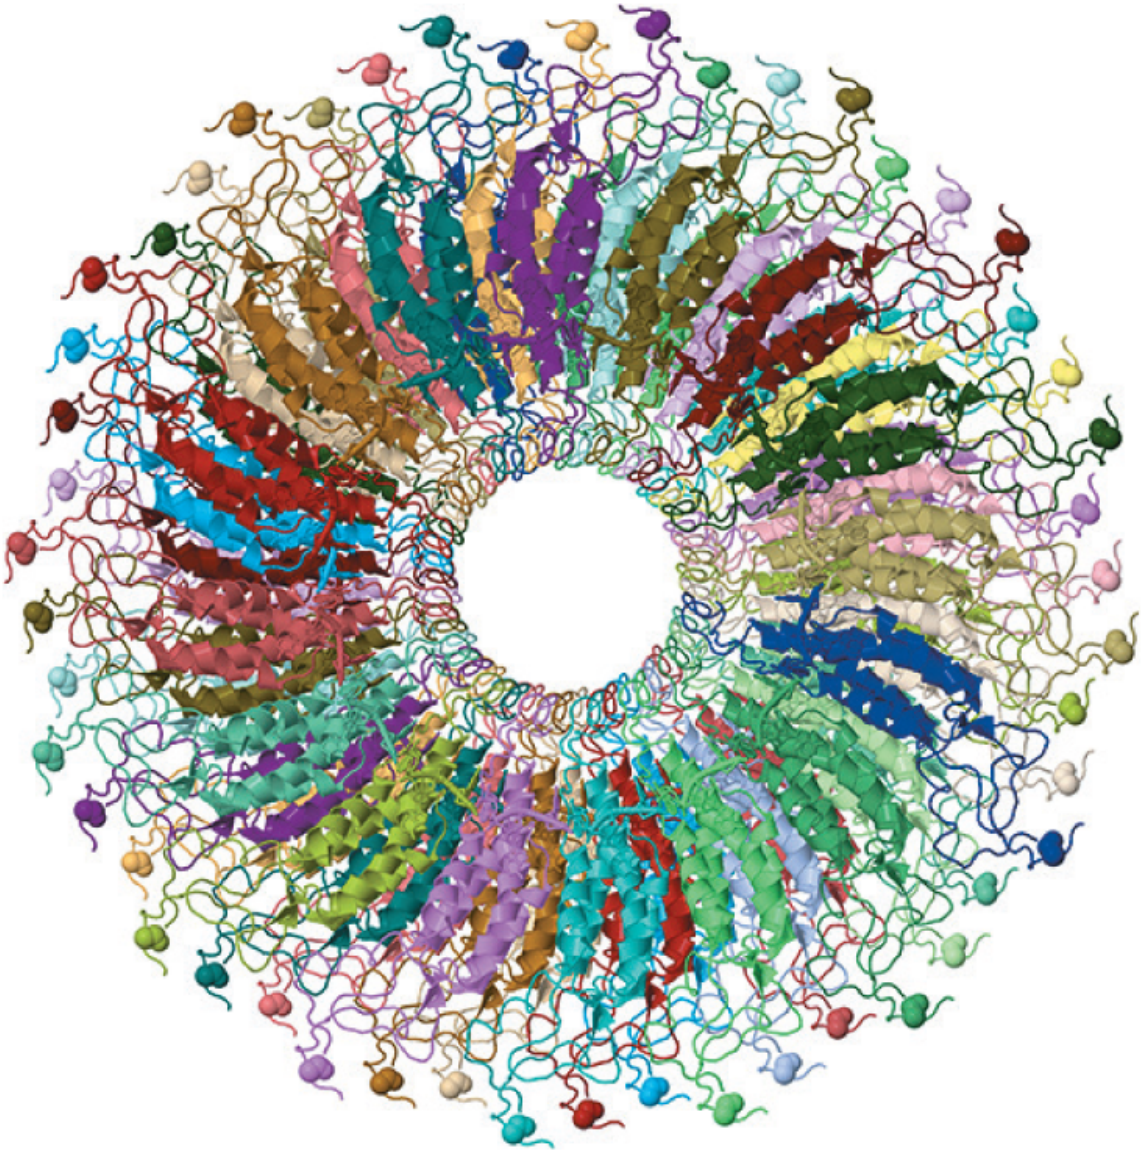
c. Anaphase II of meiosis

34. Suppose that each of the bases in DNA were capable of pairing with any other base. What effect would this capability have on DNA's capacity to serve as the source of genetic information?

35.

Heinz Shuster collected the following data on the base composition of ribgrass mosaic virus (H. Shuster, in *The Nucleic Acids: Chemistry and Biology*, vol. 3, E. Chargaff and J. N. Davidson, Eds. New York: Academic Press, 1955). On the basis of this information, is the hereditary information of the ribgrass mosaic virus RNA or DNA? Is it likely to be single stranded or double stranded?

	Percentage				
	A	**G**	**C**	**T**	**U**
Ribgrass mosaic virus	29.3	25.8	18.0	0.0	27.0



Leibniz Institute for Age Research, Fritz Lipmann-Institute.

Ribgrass mosaic virus.

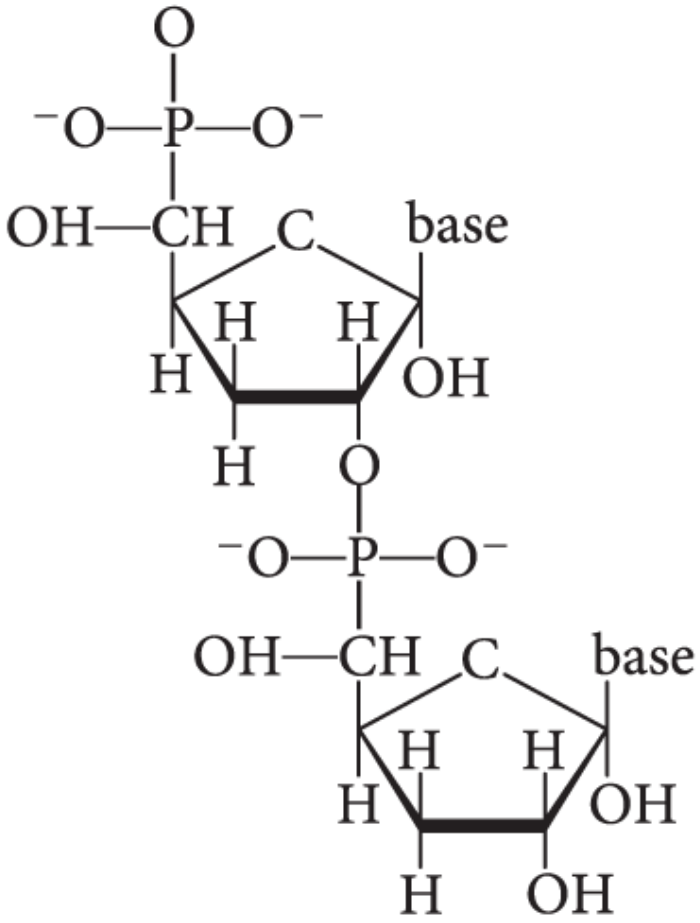
36. *The relative amounts of each nitrogenous base are tabulated here for four different viruses. For each virus listed in the following table, indicate whether its genetic material is DNA or RNA and

whether it is single stranded or double stranded. Explain your reasoning.

Virus	T	C	U	G	A
I	0	12	9	12	9
II	23	16	0	16	23
III	34	42	0	18	39
IV	0	24	35	27	17

37. *A B-DNA molecule has 1 million nucleotide pairs. How many complete turns of the helix are there in this molecule?

38. *For entertainment on a Friday night, a genetics professor proposed that his children diagram a polynucleotide strand of DNA. Having learned about DNA in preschool, his 5-year-old daughter was able to draw a polynucleotide strand, but she made quite a few mistakes. The daughter's diagram (represented here) contained at least 10 mistakes.



Description
The structure begins with a phosphate group that has a central P atom, having 2 O' negatives and one O atom. The P with 3 oxygen atoms is bound to a sugar molecule through the 5 prime C atom. The three other groups attached to 5 prime C are a hydroxyl group (O H), a hydrogen (H), and the 4 prime C of the pentagon. 4 prime and 3 prime C's are individually bonded to a hydrogen atom. C prime 1 is attached to a base and a hydroxyl group (O H). The 2 prime C is attached to the O atom of the adjoining phosphate group attached. This phosphate group is same as the above phosphate group C prime 1 is attached to a base and a hydroxyl group (O H).

a. Make a list of all the mistakes in the structure of this DNA polynucleotide strand.

b. Draw the correct structure for the polynucleotide strand.

39. CONNECT Chapter 1 considered the theory of the inheritance of acquired characteristics and noted that this theory is no longer accepted. Is the central dogma consistent with the theory of the inheritance of acquired characteristics? Why or why not?

Section 10.4

40. *Write a sequence of bases in an RNA molecule that will produce a hairpin structure.

CHALLENGE QUESTIONS

Section 10.1

41. *Suppose that an automated, unmanned probe is sent into deep space to search for extraterrestrial life. After wandering for many light-years among the far reaches of the universe, this probe arrives on a distant planet and detects life. The chemical composition of life on this planet is completely different from that of life on Earth, and its genetic material is not composed of nucleic acids. What predictions can you make about the chemical properties of the genetic material on this planet?

Section 10.2

42. How might ^{32}P and ^{35}S be used to demonstrate that the transforming principle is DNA? Briefly outline an experiment that

would show that DNA, rather than protein, is the transforming principle.

Section 10.3

43. Researchers have proposed that early life on Earth used RNA as its source of genetic information and that DNA eventually replaced RNA as the source of genetic information. What aspects of DNA structure might make it better suited than RNA to be the genetic material?

44. Scientists reportedly isolated short fragments of DNA from fossilized dinosaur bones hundreds of millions of years old. The technique used to isolate this DNA is the polymerase chain reaction, which is capable of amplifying very small amounts of DNA a millionfold (see Chapter 19). Critics claimed that the DNA isolated from dinosaur bones is not purely of ancient origin but instead has been contaminated by DNA from present-day organisms, such as bacteria, mold, or humans. What precautions, analyses, and control experiments could be carried out to ensure that DNA recovered from fossils is truly of ancient origin?

ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Section 10.1

1. Suppose that proteins, instead of nucleic acids, had evolved as the carriers of genetic information. How well would proteins satisfy the four requirements for the genetic material listed in Section 10.1?

Section 10.2

2. Isaac Newton said, "If I have seen further, it is by standing on the shoulders of giants." How does this statement apply to Watson and Crick?

3. Compare and contrast Gregor Mendel's scientific method and approach to science (see Chapter 3) with that of Watson and Crick. How did they differ? Were there any similarities?

Section 10.3

4. Draw a short section of DNA. Include both nucleotide strands and at least two nucleotides for each strand. Your drawing should include the structure of the nucleotides, as well as show how nucleotides are joined together to form a polynucleotide strand and how the two nucleotide strands are connected.

5. How does its structure enable DNA to function effectively as the genetic material? Give some specific examples.

6. Write out the sequence of a theoretical DNA molecule 50 bp in length that consists of 12% guanine and, when one strand is copied into RNA, produces an RNA molecule that has a 14 bp hairpin structure.

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Introduction

1. What was the genetic origin of Denny, a woman from the Denisova cave who lived 90,000 years ago? Create a concept map to explain Denny's origin and how scientists verified intimate details of Denny's family life using the extreme stability of DNA.

Section 10.2

2. Draw a concept map that summarizes the key discoveries that led to the conclusion that DNA was the genetic material.

Section 10.3

3. What is the structure of DNA? Create a concept map that outlines the basic structure of DNA using the following terms: DNA, polynucleotide strand, purine, pyrimidine, antiparallel, base, phosphate group, adenine, thymine, guanine, cytosine, nucleotides, nucleosides, complementary, deoxyribose sugar.

Section 10.4

4. Draw a concept map that summarizes the major information pathways and special information pathways in cells. In your map, compare and contrast the major information pathways with special information pathways.

SaplingPlus Self-study tools that will help you practice what you've learned and reinforce this chapter's concepts are available online. Go to www.saplinglearning.com.

CHAPTER 11

Chromosome Structure and Organelle DNA

Romano Cagnoni/Getty Images.

Children from a Romanian orphanage. Research demonstrated that children who lived in state-run orphanages had shorter telomeres than children raised in foster homes.

Telomeres and Childhood Adversity

Within each of our cells are 46 chromosomes, exquisitely complex structures of DNA and protein that carry the coding instructions for all of our traits. These chromosomes are passed down from our parents and constitute the basis of heredity, the passage of traits from one generation to the next. But chromosomes don't just carry a record of our genetic legacy. They also carry a record—in the lengths of their telomeres—of the stresses we encounter.

Telomeres are special protective structures found at the ends of each of our chromosomes. Like the small plastic tips that keep the ends of a shoelace from unraveling, telomeres prevent chromosomes from being degraded at their ends. In spite of the protection of the telomeres, chromosomes of most cells shorten progressively with each cell division. Due to a quirk of DNA replication, most cells are unable to copy the very end of each linear chromosome (see Chapter 12 for a full discussion of the end-replication problem). Hence, with each round of replication, a chromosome becomes shorter, until it is so reduced that the cell stops dividing, becomes inactive, and eventually dies. For most cells, this shortening of telomeres limits the number of divisions possible. Exceptions occur in the germ-line cells that produce future generations, certain stem cells, and—unfortunately—many cancer cells that have escaped normal constraints on cell division.

Because telomeres become shorter with each cell division, much research has focused on determining if telomere length is indicative of biological aging. Although the relation between telomere length

and aging is complex and not fully understood, considerable evidence suggests that telomeres do shorten with age, and that processes that lead to premature telomere shortening are associated with features of aging. In 2011, geneticists studying this phenomenon observed that hardships encountered early in life can play a part in shortening our telomeres.

To study the effects of early life experience on telomere length, geneticists studied 100 children living in state-run orphanages in Romania. At an early age, some of these children were placed in foster homes; others remained in the orphanages. Previous studies had demonstrated that children in such orphanages receive less individual attention and care compared with children growing up with natural or foster parents, and institutional care is assumed to be more stressful than foster care.

When the children were 6 to 10 years old, the researchers collected samples of their DNA and measured the length of their telomeres. The results were striking: children who remained in the orphanages had significantly shorter telomeres than those who spent time in foster care. The researchers concluded that telomere length is affected by childhood adversity: children reared in stressful environments are more likely to have shorter telomeres than those raised in less stressful environments. Several other studies have found a similar association between telomere length in adults and early childhood stresses, such as abuse and chronic illness. How stress affects telomeres and results in their shortening is not

known, but the research documents that chromosomes are more than just a repository of our genetic information: their structure is also affected by our environment.

THINK-PAIR-SHARE

- Most cells are unable to copy the ends of chromosomes, and therefore chromosomes shorten with each cell division. This limits the number of times a cell can divide. In germ cells and stem cells, however, an enzyme called telomerase lengthens the telomeres and prevents chromosome shortening. Thus, these cells are not limited in the number of times they can divide. All cells have the gene for telomerase, but most somatic cells don't express it, and they produce no telomerase. Why don't somatic cells express telomerase and have unlimited division?
- The introduction to this chapter discussed recent research showing that children who experience early childhood stresses have shorter telomeres. How might this information be used in a practical sense?

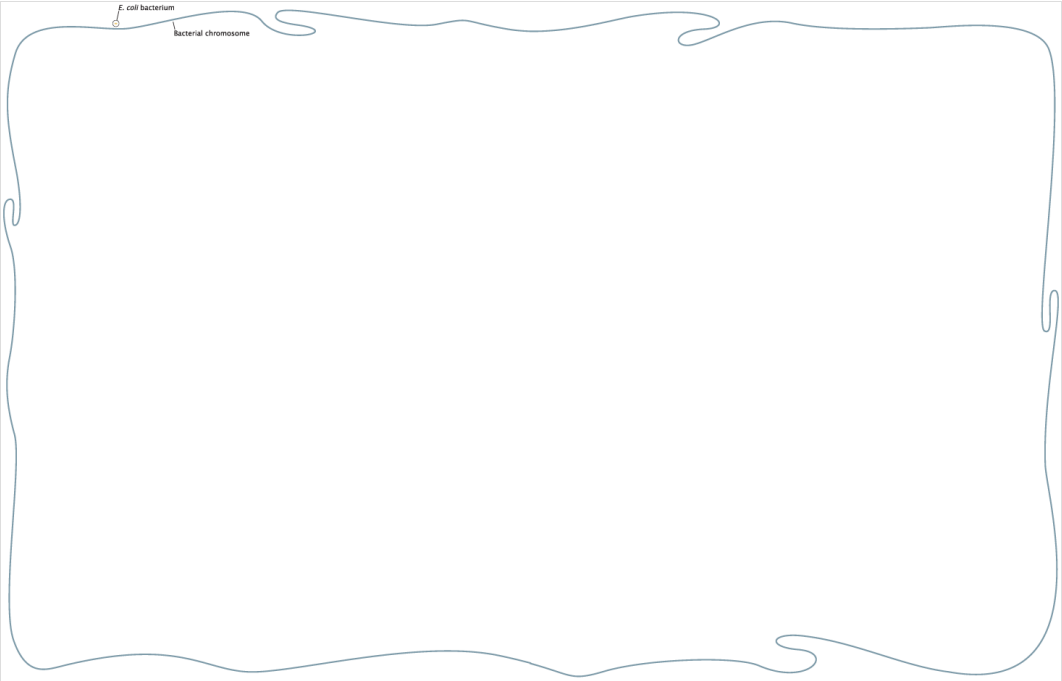
In this chapter, we examine the molecular structure of chromosomes and of the DNA found in cytoplasmic organelles. The first part of the chapter focuses on a storage problem: how to cram tremendous amounts of DNA into the limited confines of a cell. Even in those organisms that have the smallest amounts of DNA, the length of the genetic material far exceeds the length of the cell. Thus, cellular DNA must be highly folded and tightly packed. But this packing itself creates problems: it renders the DNA inaccessible, unable to be copied or read. Functional DNA must be capable of partly unfolding and expanding so that individual genes can undergo replication and transcription. The flexible, dynamic nature of DNA packing that allows it to meet these challenges is a

major theme of this chapter. We first consider supercoiling, an important tertiary structure of DNA found in both prokaryotic and eukaryotic cells. After a brief look at the bacterial chromosome, we examine the structure of eukaryotic chromosomes. We pay special attention to the working parts of a chromosome—specifically, centromeres and telomeres. We also consider the types of DNA sequences present in many eukaryotic chromosomes.

The second part of this chapter focuses on the organization of DNA sequences found in mitochondria and chloroplasts. The uniparental pattern of inheritance exhibited by genes found in these organelles was discussed in Chapter 5; here, we examine molecular aspects of organelle DNA. We briefly consider the structures of mitochondria and chloroplasts, the inheritance of traits encoded by their genes, and the evolutionary origin of these organelles. We then examine the general characteristics of **mitochondrial DNA (mtDNA)**, followed by a discussion of the organization and function of different types of mitochondrial genomes. Finally, we turn to **chloroplast DNA (cpDNA)** and examine its characteristics, organization, and function.

11.1 Large Amounts of DNA Are Packed into a Cell

The packaging of tremendous amounts of genetic information into the small space within a cell has been called the ultimate storage problem. Consider the chromosome of the bacterium *Escherichia coli*, a single molecule of DNA with approximately 4.6 million base pairs. Stretched out straight, this DNA would be about 1000 times as long as the cell it resides in (Figure 11.1). Human cells contain more than 6 billion base pairs of DNA, which would measure over 2 m (over 6 feet) stretched end to end. Even the DNA in the smallest human chromosome would stretch 14,000 times the length of the cell nucleus. Clearly, DNA molecules must be tightly packed to fit into such small spaces.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

11.1 The DNA in *E. coli* is about 1000 times as long as the cell itself.

Description
The bacterium is a small and circular shaped structure. The bacterial chromosome is a thin thread-like structure that is very long as compared to the size of E coli.

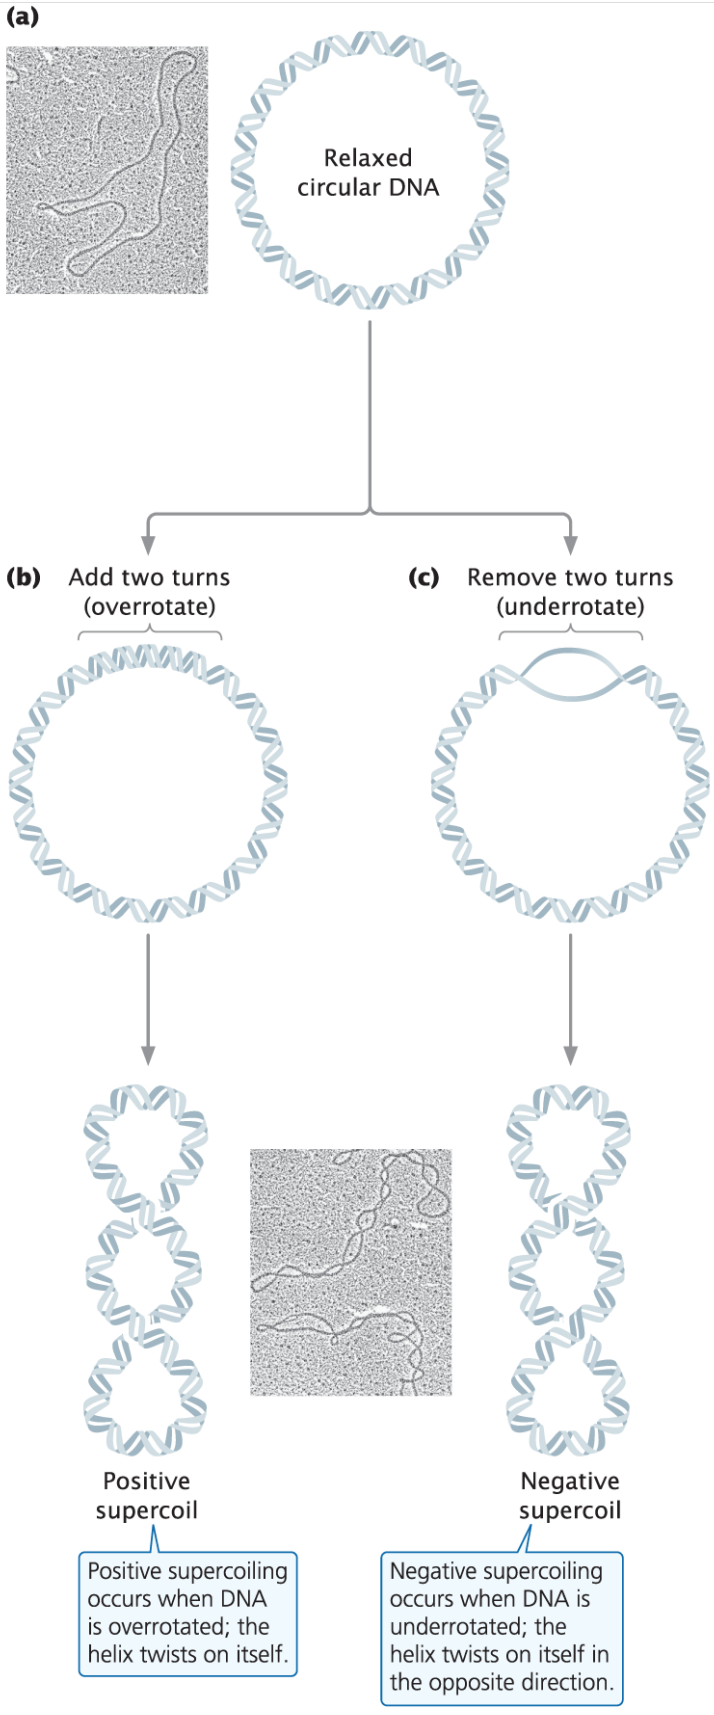
The structure of DNA can be considered at three hierarchical levels: the primary structure of DNA is its nucleotide sequence; the secondary structure is the double-stranded helix; and the tertiary structure is the higher-order folding that allows DNA to be packed into the confined space of a cell. The primary and secondary structures of DNA were described in Chapter 10; in this section, our focus is on its tertiary structure.

CONCEPTS

Chromosomal DNA exists in the form of very long molecules that are tightly packed to fit into the small confines of a cell.

Supercoiling

One type of DNA tertiary structure is **supercoiling**, which takes place when the DNA helix is subjected to strain by being overwound or underwound. B-DNA (see Chapter 10) is in its lowest-energy state when it has approximately 10 bp per turn of its helix. In this **relaxed state**, a stretch of 100 bp of DNA would assume about 10 complete turns (**Figure 11.2a**). If energy is used to add or remove any turns, strain is placed on the molecule, causing the helix to supercoil, or twist on itself. Molecules that are overrotated exhibit **positive supercoiling** (**Figure 11.2b**). Underrotated molecules exhibit **negative supercoiling** (**Figure 11.2c**). Supercoiling is a partial solution to the cell's DNA packing problem because supercoiled DNA occupies less space than relaxed DNA.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020

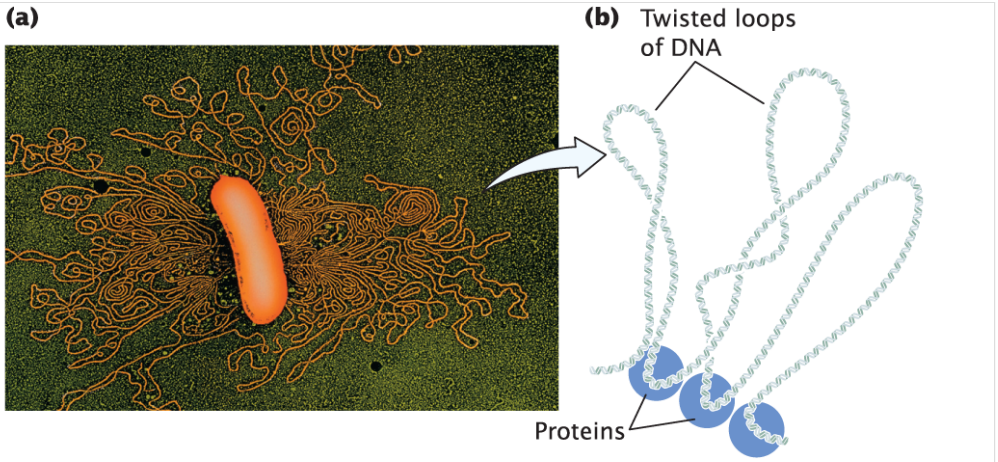
W. H. Freeman and Company
Photographs: Gopal Murti/Medical Images.

11.2 Supercoiled DNA is overwound or underwound, causing it to twist on itself.
Electron micrographs are of relaxed DNA (top) and supercoiled DNA (bottom).

Description
Illustration a at the top left shows an electron micrograph of a circular, relaxed circular D N A and a photo of a relaxed telephone cord at the top right. A caption reads, a telephone cord is like relaxed circular D N A. Illustration b at the bottom left shows the circular D N A after adding 2 turns (overrotate). This leads to the helix twisting onto itself. A caption reads, Positive supercoiling occurs when D N A is over-rotated; the helix twists on itself. An electron micrograph shows supercoiled D N A. Illustration c at the bottom right shows removing two turns or under-rotating the D N A. This leads to negative supercoiling where the helix twists onto itself but in the opposite direction. A caption reads, negative supercoiling occurs when D N A is under-rotated; the helix twists on itself in the opposite direction. A photo at the bottom right shows a telephone wire twisting on itself. A caption reads, if you turn the receiver when you hang up, you induce a negative supercoil in the cord.

Supercoiling takes place when the strain of overrotating or underrotating cannot be compensated by the turning of the ends of the double helix, which is the case if the DNA is circular—that is, there are no free ends. If the ends *can* turn freely, they will simply turn as extra rotations are added or removed, and the molecule will spontaneously revert to the relaxed state. Both bacterial and eukaryotic DNA usually fold into loops stabilized by proteins (which prevent free rotation of the ends; see Figure 11.3), and supercoiling takes place within the loops.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company
Part a: G. Murti/Science Source.

11.3 Bacterial DNA is highly folded into a series of twisted loops.

Description
The photo labeled a on the left shows a rod-shaped bacterium surrounded by twisted loops of bacterial D N A and an illustration labeled b on the right shows a magnified view of the twisted loops of D N A that are attached to three round proteins molecules at the bottom.

Supercoiling relies on **topoisomerases**, enzymes that add or remove rotations from the DNA helix by temporarily breaking the nucleotide strands, rotating the ends around each other, and then rejoining the broken ends. Thus, topoisomerases can both induce and relieve supercoiling, although not all topoisomerases do both.

Most DNA found in cells is negatively supercoiled. This state has two advantages over relaxed DNA. First, negative supercoiling makes the separation of the two strands of DNA easier during replication and transcription. Negatively supercoiled DNA is underrotated, so separation of the two strands during replication and transcription is

more rapid and requires less energy. Second, the supercoiled DNA can be packed into a smaller space than can relaxed DNA.

CONCEPTS

Overrotation or underrotation of a DNA double helix places strain on the molecule, causing it to supercoil. Supercoiling is controlled by topoisomerase enzymes. Most cellular DNA is negatively supercoiled, which eases the separation of nucleotide strands during replication and transcription and allows the DNA to be packed into small spaces.

✔ CONCEPT CHECK 1

A DNA molecule 300 bp long has 20 complete rotations. This DNA molecule is

a. positively supercoiled.
b. negatively supercoiled.
c. relaxed.

The Bacterial Chromosome

Most bacterial genomes consist of a single circular DNA molecule, although linear DNA molecules have been found in a few species. In circular bacterial chromosomes, the DNA does not exist in an open, relaxed circle; the 3 million to 4 million base pairs of DNA found in a typical bacterial genome would be much too large in this state to fit into a bacterial cell (see Figure 11.1). Unlike eukaryotic DNA, bacterial DNA is not attached to histone proteins, but bacterial DNA is associated with a number of proteins that help to compact it.

When a bacterial cell is viewed with an electron microscope, its DNA frequently appears as a distinct clump, called the **nucleoid**, which is confined to a definite region of the cytoplasm. If a bacterial cell is broken open gently, its DNA spills out in a series of twisted loops (**Figure 11.3a**). The ends of the loops are most likely held in place by proteins (**Figure 11.3b**). Many bacteria contain additional DNA in the form of small circular molecules called plasmids, which replicate independently of the chromosome (see Chapter 9).

CONCEPTS

A typical bacterial chromosome consists of a large circular molecule of DNA that forms a series of twisted loops. Within the cell, bacterial DNA appears as a distinct clump, called the nucleoid.

✔ CONCEPT CHECK 2

How does bacterial DNA differ from eukaryotic DNA?

Eukaryotic Chromosomes

Individual eukaryotic chromosomes contain enormous amounts of DNA. Each eukaryotic chromosome consists of a single extremely long linear molecule of DNA. For this DNA to fit into the nucleus, tremendous packing and folding are required, the extent of which must change in the course of the cell cycle. The chromosomes are in

an elongated, relatively uncondensed state during interphase (see Figure 2.10), but the term *relatively* is important here. Although the DNA of interphase chromosomes is less tightly packed than the DNA of mitotic chromosomes, it is still highly condensed; it's just *less* condensed. In the course of the cell cycle, the level of DNA packing changes: chromosomes progress from a highly packed state to a state of extreme condensation, which is necessary for chromosome movement in mitosis and meiosis. DNA packing also changes locally during replication and transcription, when the two nucleotide strands must unwind so that particular base sequences are exposed. Thus, the packing of eukaryotic DNA (its tertiary chromosomal structure) is not static but changes regularly in response to cellular processes.

CHROMATIN

Eukaryotic DNA in the cell is closely associated with proteins. This complex of DNA and proteins is called *chromatin*. The two basic types of chromatin are **euchromatin**, which undergoes the normal process of condensation and decondensation in the cell cycle, and **heterochromatin**, which remains in a highly condensed state throughout the cell cycle, even during interphase. Euchromatin constitutes the majority of the chromosomal material and is where most transcription takes place. All chromosomes have permanent heterochromatin (called *constitutive heterochromatin*) at the centromeres and telomeres; the Y chromosome also consists largely

of constitutive heterochromatin. Heterochromatin may also occur during certain developmental stages; this material is referred to as *facultative heterochromatin*. For example, facultative heterochromatin occurs along one entire X chromosome in female mammals when that X becomes inactivated (see Chapter 4). In addition to remaining condensed throughout the cell cycle, heterochromatin is characterized by a general lack of transcription, the absence of crossing over, and replication late in the S phase. Differences between euchromatin and heterochromatin are summarized in **Table 11.1**.

THINK-PAIR-SHARE Question 1

TABLE 11.1 Characteristics of euchromatin and heterochromatin

Characteristic	Euchromatin	Heterochromatin
Chromatin condensation	Less condensed	More condensed
Location	On chromosome arms	At centromeres, telomeres, and other specific places
Type of sequences	Unique sequences	Repeated sequences*

Presence of genes	Many genes	Few genes*
When replicated	Throughout S phase	Late S phase
Transcription	Often	Infrequent
Crossing over	Common	Uncommon

*Applies only to constitutive heterochromatin.

The most abundant proteins in chromatin are the *histones*, which are small positively charged proteins of five major types: H1, H2A, H2B, H3, and H4. All histones have a high percentage of arginine and lysine, positively charged amino acids that give the histones a net positive charge. These positive charges attract the negative charges on the phosphates of DNA; this attraction holds the DNA in contact with the histones. A heterogeneous assortment of **nonhistone chromosomal proteins** is also found in eukaryotic chromosomes. At times, variant histones, with somewhat different amino acid sequences, are incorporated into chromatin in place of one of the major histone types. These variants alter chromatin structure and influence its function. For example, some specific variant histones are associated with actively transcribed DNA; these variants are assumed to make the chromatin more open and accessible to the enzymes and proteins that carry out transcription. › **TRY PROBLEM 18**

CONCEPTS

Chromatin, which consists of DNA complexed with proteins, is the material that makes up eukaryotic chromosomes. The most abundant of these proteins are the five types of positively charged histone proteins: H1, H2A, H2B, H3, and H4. Variant histones may at times be incorporated into chromatin in place of the normal histone types.

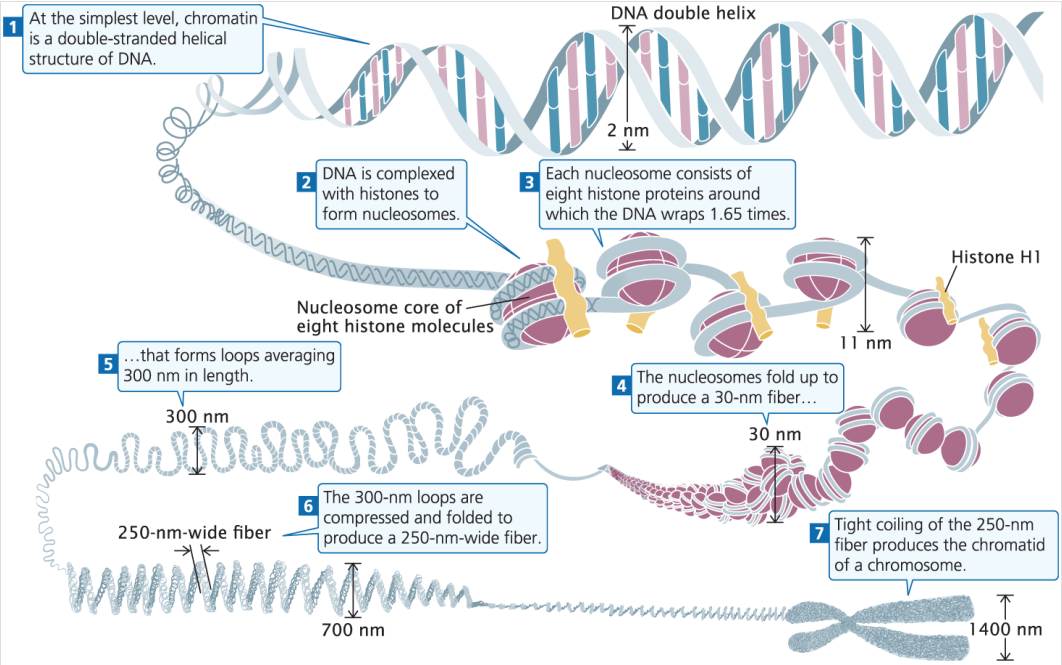
✔ CONCEPT CHECK 3

Neutralizing their positive charges would have which effect on the histone proteins?

a. They would bind the DNA tighter.
b. They would bind less tightly to the DNA.
c. They would no longer be attracted to each other.
d. They would cause supercoiling of the DNA.

THE NUCLEOSOME

Chromatin has a highly complex structure, with several levels of organization (**Figure 11.4**). The simplest level is the double-helical structure of DNA, discussed in Chapter 10. At a more complex level, the DNA molecule is closely associated with proteins and is highly folded to produce a chromosome.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

11.4 Chromatin has a highly complex structure, with several levels of organization.

Description

The illustration shows a D N A double helix with a width of 2 n m. A caption reads, at the simplest level, chromatin is a double-stranded helical structure of D N A. The D N A then coils around nucleosome cores that consist of 8 histone molecules. A caption reads, D N A is complexed with histones to form nucleosomes. Each nucleosome consists of eight histone proteins around which the D N A wraps 1 point 6 5 times. The diameter of the D N A-nucleosome complex is 11 n m. Histone 1 protein is bound to the outside of the D N A-nucleosome complex. These nucleosomes fold multiple times and become more and more condensed to eventually form a fiber-like structure. A caption reads, the nucleosomes fold up to produce a 30 n m fiber that forms loops averaging 300 n m in length. The 300 n m loops are then compressed and folded to produce a 250 n m wide fiber. The fiber produced is 700 n m in diameter. This fiber finally produces the chromatids of a chromosome. A caption reads, tight coiling of the 250 n m fiber produces the chromatid of a chromosome. The X shaped chromosome formed has a width of 1400 n m.

When chromatin is isolated from the nucleus of a cell and viewed with an electron microscope, it frequently looks like beads on a string (**Figure 11.5a**). If a small amount of nuclease is added to this structure, the enzyme cleaves the "string" between the "beads," leaving individual beads attached to about 200 bp of DNA (**Figure 11.5b**). If more nuclease is added, the enzyme chews up all of the DNA between the beads and leaves a core of proteins attached to a fragment of DNA (**Figure 11.5c**). Such experiments demonstrate that chromatin is not a random association of proteins and DNA but has a fundamental repeating structure.

11.5 The nucleosome is the fundamental repeating unit of chromatin. Part *d* shows a space-filling model of the core particle, which consists of two copies each of H2A, H2B, H3, and H4, around which DNA (white) coils.

Description
Illustration a at the top shows a beads-on-a-string view of chromatin where a D N A helix is wound around three nucleosomes with core histones. The D N A portion between two consecutive nucleosomes is labeled as linker D N A. This D N A-nucleosome complex is subjected to a nuclease action. A caption reads, a small amount of nuclease cleaves the string between the beads. Illustration b below shows the linkage D N A is cleaved by the nuclease such that three D N A-nucleosome molecules are formed. A caption reads, releasing individual beads attached to about 200 b p of D N A. More nuclease is added. Illustration c below shows D N A-nucleosome molecules where more unprotected D N A has been destroyed by nuclease. The diameter of these molecules is 11 n m. A caption reads, more nuclease destroys all of the unprotected D N A between the beads, leaving a core of proteins attached to 145 to 147 b p of D N A. Illustration d below shows a space-filling model with 2 copies of each of H 2 A, H 2 B, H 3, and H 4 surrounded by white-colored D N A coils.

The core of protein and DNA produced by digestion with nuclease enzymes is the simplest level of chromatin structure, the **nucleosome** (see Figure 11.4). The nucleosome is a core particle consisting of DNA wrapped about two times around an octamer of eight histone proteins (two copies each of H2A, H2B, H3, and H4), much like thread wound around a spool (**Figure 11.5d**). The DNA in direct contact with the histone octamer is between 145 and 147 bp in length.

Each of the histone proteins that make up the nucleosome core particle has a flexible “tail,” containing from 11 to 37 amino acids,

which extends out from the nucleosome. Positively charged amino acids in the tails of the histones interact with the negative charges of the phosphates on the DNA, keeping the DNA and histones tightly associated. The tails of one nucleosome may also interact with neighboring nucleosomes, which facilitates compaction of the nucleosomes themselves. Chemical modifications of the histone tails bring about changes in chromatin structure (discussed in the next section) that are necessary for gene expression.

The fifth type of histone, H1, is not a part of the nucleosome core particle but plays an important role in nucleosome structure. H1 binds to 20–22 bp of DNA where the DNA joins and leaves the histone octamer (see Figure 11.4) and helps lock the DNA into place, acting as a clamp around the nucleosome.

Each nucleosome encompasses about 167 bp of DNA. Nucleosomes are located at regular intervals along the DNA molecule and are separated from one another by **linker DNA**, which varies in size among cell types; in most cells, linker DNA comprises from about 30 to 40 bp. Nonhistone chromosomal proteins may be associated with this linker DNA, and a few also appear to bind directly to the core particle.

Although histone proteins are not present in bacteria, archaea have two types of histones that are similar to the H3 and H4 histones found in eukaryotes. These archaeal histones associate in groups of four, forming a tetramer instead of the octamers seen in eukaryotes.

The DNA of archaea wraps around the tetramers of histones to form structures similar to the nucleosomes of eukaryotes, each encompassing about 60 bp of DNA. The nucleosomes of archaea occupy specific positions along the DNA, much as they do in eukaryotes, which suggests that they may play a role in gene expression (see Chapter 17). ❯ **TRY PROBLEMS 19 AND 22**

HIGHER-ORDER CHROMATIN STRUCTURE

When chromatin is in a condensed form, nucleosomes fold on themselves to form a dense, tightly packed structure (see Figure 11.4) that makes up a fiber with a diameter of about 30 nm. Some recent research suggests that the 30-nm fiber consists of two interwound stacks of nucleosomes, with the linker DNA between successive nucleosomes crisscrossing back and forth in the interior of the fiber. However, other structures of the 30-nm fiber have also been proposed, and indeed, different structures may exist under different conditions within the nucleus.

The precise structure of chromatin above the level of the 30-nm fiber is poorly understood. The next level of chromatin structure is a series of loops of the 30-nm fiber (see Figure 11.4), each anchored at its base by proteins. On average, each loop encompasses some 20,000 to 100,000 bp of DNA and is about 300 nm in length, but the individual loops vary considerably. The 300-nm loops are packed and folded to produce a 250-nm-wide fiber. Tight helical coiling of the 250-nm fiber, in turn, produces the structure that appears in

metaphase: an individual chromatid approximately 700 nm in width. You can view the different levels of chromatin structure in **Animation 11.1**.

The traditional view of chromosome structure has been that nucleosomes and their packing arrangement lead to higher-order chromosome structure. However, some research has challenged this view. Researchers have reported that chromosomes can form even in the absence of nucleosomes, although chromosomes without nucleosomes were wider and more fragile than chromosomes with nucleosomes. The research indicates that condensins, molecules that are involved in chromosome formation during mitosis (see Chapter 2), are essential for higher-order chromosome structure. Nucleosomes are also important, but their primary role may be in DNA compaction and protection more than shaping the chromosome. How condensins might shape chromosomes is still being studied.

During interphase, different chromosomes and different parts of the same chromosome do not associate randomly within the nucleus. Instead, large regions of chromatin form spatially interacting regions called **topologically associated domains (TADs)**. These domains may encompass tens of thousands to millions of bp of DNA. Within a TAD, regions of chromatin lie in close proximity and interact with one another but are separated in space from other TADs. TADs are a consistent and important feature of eukaryotic genomes; they contribute to the control of gene expression by bringing genes and

distant regulatory elements (called enhancers, see Chapter 17) into close proximity.

CONCEPTS

The nucleosome consists of a core particle of eight histone proteins and the DNA that wraps around them. A single H1 histone associates with each core particle. Nucleosomes are separated by linker DNA. Nucleosomes fold to form a 30-nm chromatin fiber, which appears as a series of loops that pack to create a 250-nm fiber. Helical coiling of the 250-nm fiber produces a chromatid. Larger areas of chromatin form interacting regions called topologically associated domains.

✔ CONCEPT CHECK 4

How many copies of the H2B histone would be found in chromatin containing 50 nucleosomes?

a. 5
b. 10
c. 50
d. 100

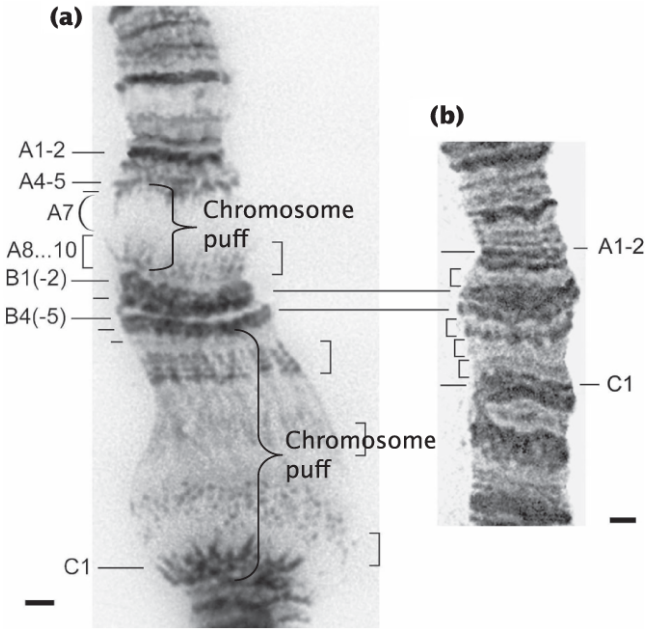
Changes in Chromatin Structure

Although eukaryotic DNA must be tightly packed to fit into the cell nucleus, it must also periodically unwind to undergo transcription and replication. Polytene chromosomes and DNase I sensitivity, discussed in the following sections, are visible evidence of the dynamic nature of chromatin structure.

POLYTENE CHROMOSOMES

Giant chromosomes called **polytene chromosomes** are found in certain tissues of *Drosophila* larvae and some other organisms (Figure 11.6). Polytene chromosomes have provided researchers with evidence of the changing nature of chromatin structure. These large, unusual chromosomes arise when repeated rounds of DNA replication take place without accompanying cell divisions, producing thousands of copies of DNA that lie side by side. When polytene chromosomes are stained with dyes, numerous bands are revealed. Under certain conditions, the bands may exhibit **chromosome puffs**—localized swellings of the chromosome. Each puff is a region of the chromatin that has a relaxed structure and, consequently, a more open state. Research indicates that chromosome puffs are regions of active transcription. This correlation between the occurrence of transcription and the relaxation of chromatin at a puff site indicates that chromatin structure undergoes dynamic change associated with gene activity.

THINK-PAIR-SHARE Question 2



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020

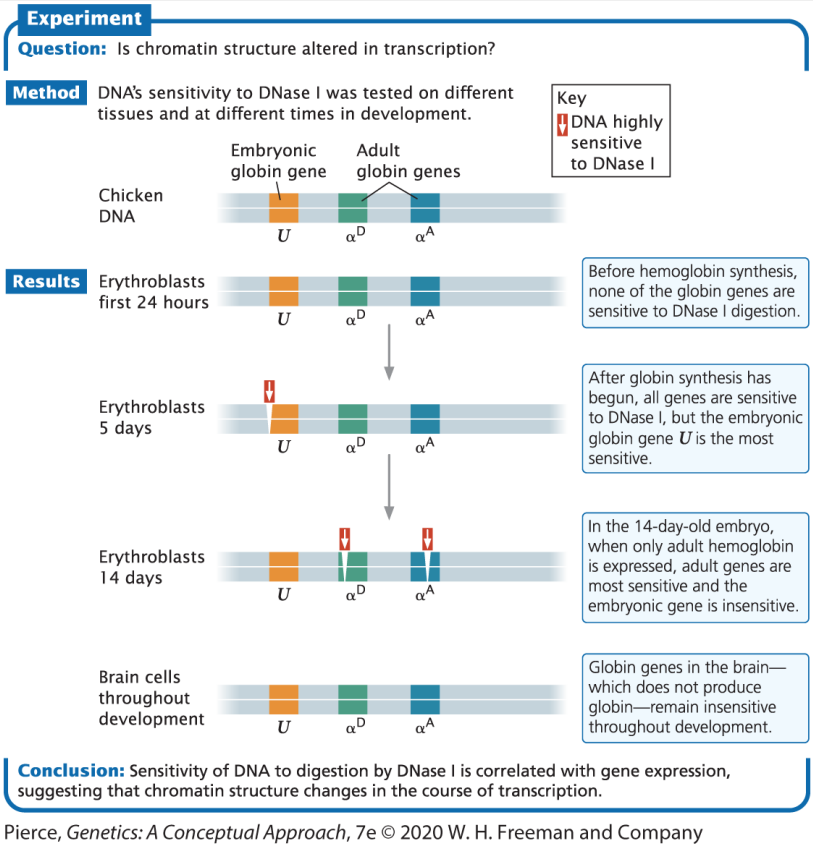
11.6 Chromosome puffs are regions of relaxed chromatin where active transcription is taking place. (a) Chromosome puffs on giant polytene chromosomes isolated from the salivary glands of larval *Drosophila*. (b) The corresponding region without chromosome puffs. The density of the stain correlates with the density of the chromatin.

Description
Illustration a at the left shows a giant polytene chromosomes with a chromosome puff between A 7, A 8, to 10 and another between B 4 (negative 5) to C 1. There are multiple dark bands while the chromosome puffs are light colored regions. Illustration b at the right shows the same chromosome compacted and without the chromosome puffs.

DNASE I SENSITIVITY

A second piece of evidence indicating that chromatin structure changes with gene activity is sensitivity to DNase I, an enzyme that

digests DNA. The ability of this enzyme to digest DNA depends on chromatin structure: when DNA is tightly bound to histone proteins, it is less sensitive to DNase I, whereas unbound DNA is more sensitive to DNase I. The results of experiments that examined the effect of DNase I on specific globin genes in chick embryos showed that DNase sensitivity is correlated with gene activity. Globin genes encode several types of hemoglobin, which are expressed in the erythroblasts (precursors of red blood cells) of chickens at different stages of development (Figure 11.7). These types of experiments demonstrate that transcriptionally active genes are sensitive to DNase I, indicating that the chromatin structure is more exposed during transcription.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

11.7 DNase I sensitivity is correlated with the transcription of globin genes in chick embryos. The *U* gene encodes embryonic hemoglobin; the α^{D} and α^{A} genes encode adult hemoglobin. The red arrows indicate sites of DNase I digestion.

Description
The illustration begins with a question that reads, Is chromatin structure altered in transcription? The illustration shows methods below where a chicken D N A has the following three genes: embryonic globin gene (U), adult globin genes (alpha superscript D and alpha superscript A). The results below show the following: Erythroblasts after first 24 hours show no sensitivity to DNase 1. Text reads, before hemoglobin synthesis, none of the globin genes are sensitive to DNase 1 digestion. Erythroblasts after 5 days show increased DNase 1 sensitivity at the beginning of embryonic globin gene (U). Text reads, after globin synthesis has begun, all genes are sensitive to DNase 1, but the embryonic globin gene U is the most sensitive. Erythroblasts after 14 days show increased DNase 1 sensitivity at the beginning of adult globin gene alpha superscript D and in the center of alpha superscript A. Text reads, in the 14-day old embryo, when only adult hemoglobin is expressed, adult genes are most sensitive and the embryonic gene is insensitive. Brain cells throughout development are not sensitive to DNase 1. Text reads, globin genes in the brain, which does not produce globin, remain insensitive throughout development. A caption below reads, Conclusion: Sensitivity of D N A to digestion by DNase 1 is correlated with gene expression, suggesting that chromatin structure changes in the course of transcription.

What is the nature of the change in chromatin structure that produces chromosome puffs and DNase I sensitivity? In both cases, the chromatin relaxes; presumably, the histones loosen their grip on the DNA. One process that alters chromatin structure is acetylation. Enzymes called acetyltransferases attach acetyl groups to lysine amino acids on the histone tails. This modification reduces the positive charges that normally exist on lysine and destabilizes the nucleosome structure, so the histones hold the DNA less tightly.

Other chemical modifications of the histone proteins, such as methylation and phosphorylation, also alter chromatin structure, as do special chromatin-remodeling proteins that bind to the DNA. ❯

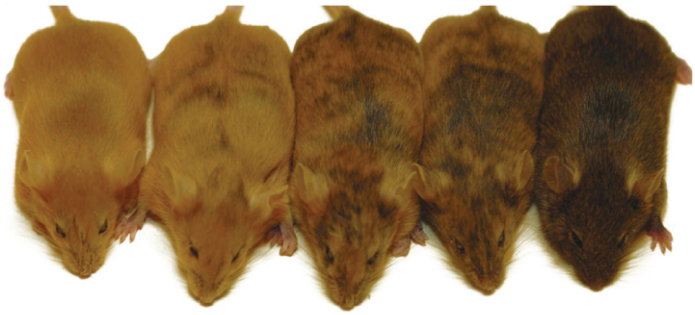
TRY PROBLEM 21

EPIGENETIC CHANGES ASSOCIATED WITH CHROMATIN MODIFICATIONS

We have now seen how chromatin structure can be altered by chemical modification of the histone proteins. A number of other changes can also affect chromatin structure, including the methylation of DNA (see Chapter 10), the use of variant histone proteins in the nucleosome, and the binding of nonhistone proteins to DNA and chromatin. Although these changes do not alter the DNA sequence, they often have major effects on the expression of genes, which will be discussed in more detail in Chapter 17.

Some changes in chromatin structure are retained through cell division, so that they are passed on to future generations of cells and even occasionally to future generations of organisms. Stable alterations of chromatin structure that may be passed on to descendant cells or individuals are frequently referred to as **epigenetic changes,** or simply *epigenetics* (see Chapter 5). For example, the *agouti* locus helps determine coat color in mice: parents that have identical DNA sequences but have different degrees of methylation on their DNA may give rise to offspring with

different coat colors (**Figure 11.8**). Such epigenetic changes have been observed in a number of organisms and are responsible for a variety of phenotypic effects. Unlike mutations, epigenetic changes do not alter the DNA sequence, are capable of being reversed, and are often influenced by environmental factors (see Chapter 21 for more details).



Cropley et al., 2006, Germ-line epigenetic modification of the murine A^{vy} allele by nutritional supplementation, *PNAS* November 14, 2006 vol. 103, no. 46 pp. 7308–17312. ©2006 National Academy of Sciences, U.S.A.

11.8 Variation in DNA methylation at the *agouti* locus produces different coat colors in mice.

CONCEPTS

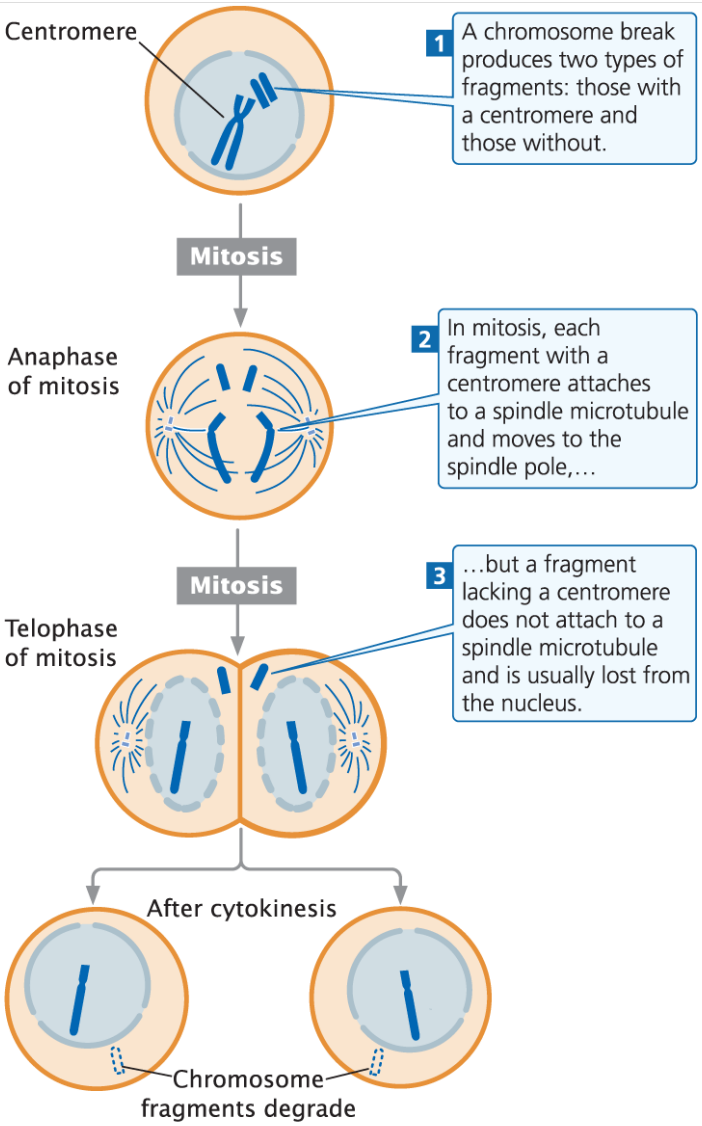
Epigenetic changes are alterations of chromatin or DNA structure that do not include changes in the base sequence but are stable and passed on to descendant cells or organisms. Some epigenetic changes result from alterations of chromatin structure.

11.2 Eukaryotic Chromosomes Possess Centromeres and Telomeres

Chromosomes, as we have seen, segregate in mitosis and meiosis and remain stable over many cell divisions. These properties of chromosomes arise in part from special structural features, including centromeres and telomeres.

Centromere Structure

The centromere, a constricted region of the chromosome, is the attachment site for the kinetochore and for spindle microtubules; this chromosome structure is necessary for proper chromosome movement in mitosis and meiosis (see Figure 2.7). The essential role of the centromere in chromosome movement was recognized by early geneticists, who observed the consequences of chromosome breakage. When a chromosome break produces two fragments, one with a centromere and one without, the chromosome fragment containing the centromere attaches to a spindle microtubule and moves to the spindle pole. The fragment lacking a centromere fails to connect to a spindle microtubule and is usually lost because it fails to move into the nucleus of a daughter cell during mitosis (**Figure 11.9**).



11.9 Chromosome fragments that lack centromeres are lost in mitosis.

Description

The illustration shows a cell with two fragments of chromosomes inside the nucleus. One of the fragments has a centromere while another has no centromere. A caption reads, a chromosome break produces 2 types of fragments, those with a centromere and those without. Mitosis occurs and the illustration shows anaphase of mitosis below where each fragment with centromere moves towards one of the cell poles after attaching to the spindle fiber. A caption reads, in mitosis, each fragment with a centromere attaches to a

spindle microtubule and moves to the spindle pole. Mitosis progresses and telophase below shows the cell membrane dividing into two compartments. A nuclear envelope starts developing around fragments with centromere, in both compartments. The other fragments without centromere remain outside the nuclear membranes. A caption reads, but a fragment lacking a centromere does not attach to a spindle microtubule and is usually lost from the nucleus. Cytokinesis occurs and two daughter cells are formed below. The fragment without a centromere degrades in both the daughter cells.

What are the key features of the centromere? In *Drosophila*, *Arabidopsis*, and humans, centromeres span hundreds of thousands of base pairs. Most of the centromere is made up of heterochromatin. Surprisingly, there are no specific sequences that are found in all centromeres, which raises the question of what exactly determines where the centromere is. Research suggests that most centromeres are not defined by DNA sequence but rather by changes in chromatin structure, referred to as epigenetic modifications (see Chapter 21). Nucleosomes in the centromeres of most eukaryotes have a variant histone protein called CENP-A (also referred to as CenH3), which takes the place of the usual H3 histone. The CENP-A variant histone is required for the assembly of proteins associated with the kinetochore; the presence of the CENP-A histone probably alters the nucleosome and chromatin structure, allowing kinetochore proteins to bind and spindle microtubules to attach.

CONCEPTS

The centromere is a region of the chromosome to which spindle microtubules attach. Centromeres display considerable variation in their DNA sequences and are distinguished by

epigenetic alterations to chromatin structure, including the use of a variant H3 histone in the nucleosome.

✔ CONCEPT CHECK 5

What happens to a chromosome that loses its centromere?

Telomere Structure

Telomeres are the natural ends of a chromosome (see Figure 2.7 and the introduction to this chapter). Pioneering work by Hermann Muller (in fruit flies) and Barbara McClintock (in corn) showed that chromosome breaks produce unstable ends that have a tendency to stick together and enable the chromosome to be degraded. Because attachment and degradation do not happen to the ends of a chromosome that has telomeres, the telomeres must serve as caps that stabilize the chromosome. Telomeres also provide a means of replicating the ends of a chromosome, as we will see in Chapter 12. In 2009, Elizabeth Blackburn, Carol Greider, and Jack Szostak were awarded the Nobel Prize in physiology or medicine for discovering the structure of telomeres and how they are replicated.

Telomeres have now been isolated from protozoans, plants, humans, and other organisms; most are similar in structure (**Table 11.2**). These **telomeric sequences** usually consist of repeated units of a series of adenine or thymine nucleotides followed by several guanine

nucleotides, taking the form 5′–(A or T)$_m$G$_n$–3′, where *m* ranges from 1 to 4 and *n* is 2 or more. For example, the repeating unit in human telomeres is 5′–TTAGGG–3′, which may be repeated from hundreds to thousands of times. The sequence is always oriented with the string of Gs and Cs toward the end of the chromosome, as shown here:

Toward centromere ← 5′–TTAGGGTTAGGGTTAGGG–3′ / 3′–AATCCCAATCCCAATCCC–5′ → end of chromosome

Description
The illustration shows two complementary strands. The first strand begins from 5 prime and the sequence is as follows: T; T; A; G; G; G; T; T; A; G; G; G; T; T; A; G; G; G. It ends at 3 prime. The second strand begins at 3 prime and the sequence is as follows: A; A; T; C; C; C; A; A; T; C; C; C; A; A; T; C; C; C. It ends at 5 prime. Text at the beginning of both reads, towards centromere, and text at the end of both reads, end of the chromosome.

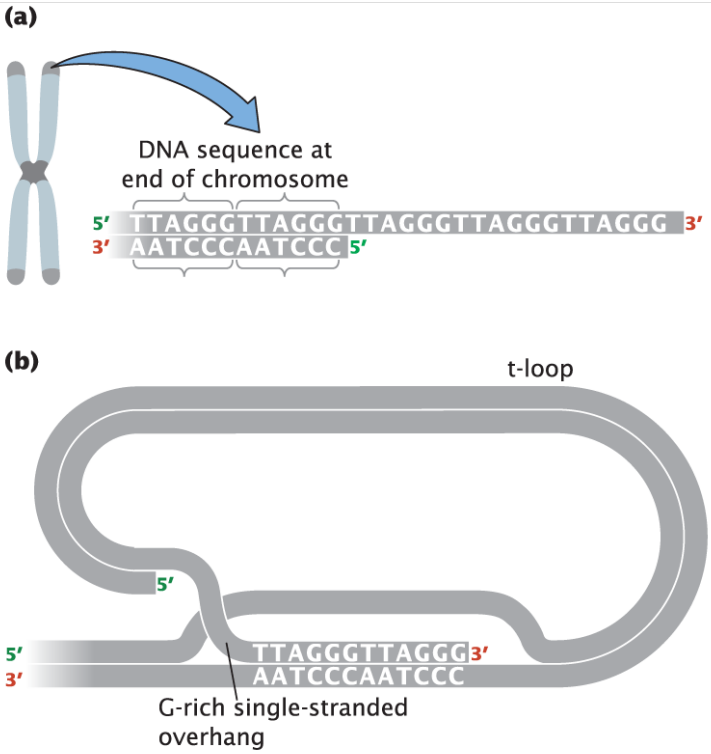
TABLE 11.2 DNA sequences typically found in telomeres of various organisms

Organism	Sequence
Tetrahymena (protozoan)	5′–TTGGGG–3′ 3′–AACCCC–5′
Saccharomyces (yeast)	5′–T1–6GTG2–3–3′ 3′–A1–6CAC2–3–5′
Caenorhabditis (nematode)	5′–TTAGGC–3′ 3′–AATCCG–5′

Vertebrate	5′–TTAGGG–3′ 3′–AATCCC–5′
Arabidopsis (plant)	5′–TTTAGGG–3′ 3′–AAATCCC–5′

Data from: V. A. Zakian, *Science* 270:1602, 1995.

The G-rich strand often protrudes beyond the complementary C-rich strand at the end of the chromosome (**Figure 11.10a**), in which case it is called the G-rich 3′ overhang. The G-rich 3′ overhang in the telomeres of mammals is from 50 to 500 nucleotides long. Special proteins bind to this G-rich single-stranded sequence, protecting the telomere from degradation and preventing the ends of chromosomes from sticking together. A multiprotein complex called **shelterin** binds to telomeres and protects the ends of the DNA from being inadvertently repaired as a double-stranded break in the DNA. In some cells, the G-rich 3′ overhang may fold over and pair with a short stretch of DNA to form a structure called a t-loop, which also functions in protecting the end of the telomere from degradation (**Figure 11.10b**).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

11.10 DNA at the ends of eukaryotic chromosomes consists of telomeric sequences. (a) The G-rich strand at the telomere is longer than the C-rich strand. (b) In some cells, the G-rich strand folds over and pairs with a short stretch of DNA to form a t-loop.

Description

Illustration “a” at the top shows an X-shaped chromosome with the telomeres in gray and an arrow pointing from the telomere to the D N A telomeric sequence. The 5 prime to 3 prime strand extends 18 nucleotides out from end of the other strand. The repeating sequence contains base pairs T T A G G G. Illustration “b” below shows the T T A G G G sequence pairing with the complementary sequence at an earlier part of the telomere and dislocating the D N A that was previously bound.

Because DNA polymerases (enzymes that synthesize DNA) cannot replicate the ends of chromosomes, telomeres in most somatic cells

shorten each time the cell divides (see section on Replication at the Ends of Chromosomes in Chapter 12). Single-cell eukaryotes, germ cells, and early embryonic cells produce an enzyme called telomerase, which lengthens telomeres and prevents chromosome shortening (see Chapter 12). Somatic cells have additional mechanisms that regulate the length of telomeres by trimming and elongating telomeric sequences.

CONCEPTS

A telomere is the stabilizing end of a chromosome. At the end of each telomere are many short telomeric sequences.

✔ CONCEPT CHECK 6

Which of the following is a characteristic of DNA sequences at the telomeres?

a. One strand consists of guanine and adenine (or thymine) nucleotides.
b. They consist of repeated sequences.
c. One strand protrudes beyond the other, creating some single-stranded DNA at the end.
d. All of the above

11.3 Eukaryotic DNA Contains Several Classes of Sequence Variation

Eukaryotic organisms vary dramatically in the amount of DNA per cell, a quantity termed an organism's **C-value** (Table 11.3). Each cell of a fruit fly, for example, contains about 35 times the amount of DNA found in a cell of the bacterium *E. coli*. In general, eukaryotic cells contain more DNA than prokaryotic cells do, but variation among eukaryotes in their C-values is huge. Human cells contain more than 10 times the amount of DNA found in *Drosophila* cells, whereas some salamander cells contain 20 times as much DNA as human cells. Clearly, these differences in C-value cannot be explained simply by differences in organismal complexity. So what is all of the extra DNA in eukaryotic cells doing? This question has been termed the **C-value paradox**. We do not yet have a complete answer to the C-value paradox, but analysis of eukaryotic DNA sequences has revealed a complexity that is absent from prokaryotic DNA.

TABLE 11.3 Genome sizes of various organisms

Organism	Approximate Genome Size (bp)
λ (bacteriophage)	50,000

Escherichia coli (bacterium)	4,640,000
Saccharomyces cerevisiae (yeast)	12,000,000
Arabidopsis thaliana (plant)	125,000,000
Drosophila melanogaster (insect)	170,000,000
Homo sapiens (human)	3,200,000,000
Zea mays (corn)	4,500,000,000
Amphiuma (salamander)	765,000,000,000

The Denaturation and Renaturation of DNA

The first clue that eukaryotic DNA contains several types of sequences not present in prokaryotic DNA came from studies in which double-stranded DNA was separated and then allowed to reassociate. When double-stranded DNA in solution is heated, the hydrogen bonds that hold the two nucleotide strands together are weakened, and with enough heat, the two strands separate completely, a process called **denaturation** or *melting*. The

temperature at which DNA denatures, called the **melting temperature (T_m)**, depends on the base sequence of the particular sample of DNA: G–C base pairs have three hydrogen bonds, whereas A–T base pairs have only two, so the separation of G–C pairs requires more heat (energy) than does the separation of A–T pairs.

The denaturation of DNA by heating is reversible: if single-stranded DNA is slowly cooled, single strands will collide and hydrogen bonds will form again between complementary base pairs, producing double-stranded DNA. This reaction is called **renaturation** or *reannealing*.

Two single-stranded molecules of DNA from different sources, such as different organisms, will anneal if they are complementary; this process is termed **hybridization**. For hybridization to take place, the two strands from the different sources do not have to be complementary at all their bases—just at enough bases to hold the two strands together. The extent of hybridization between DNA from two species can be used to measure the similarity of their nucleic acid sequences and to assess their evolutionary relationship. The rate at which hybridization takes place also provides information about the sequence complexity of DNA. **› TRY PROBLEM 27**

Types of DNA Sequences in Eukaryotes

Eukaryotic DNA consists of at least three classes of sequences: unique-sequence DNA, moderately repetitive DNA, and highly repetitive DNA. **Unique-sequence DNA** consists of sequences that are present only once or, at most, a few times in the genome. This DNA includes sequences that encode proteins, as well as a great deal of DNA whose function is unknown. Genes that are present in a single copy constitute roughly 25% to 50% of the protein-encoding genes in most multicellular eukaryotes. Other genes within unique-sequence DNA are present in several similar but not identical copies and are collectively referred to as a **gene family**. Most gene families arose through duplication of an existing gene and include just a few member genes, but some, such as those that encode immunoglobulin proteins in vertebrates, contain hundreds of members. The genes that encode β-like globins are another example of a gene family. In humans, there are six β-globin genes, clustered together on chromosome 11. The polypeptides encoded by these genes join with α-globin polypeptides to form hemoglobin molecules, which transport oxygen in the blood.

Other sequences, called **repetitive DNA**, exist in many copies. Some eukaryotic organisms have large amounts of repetitive DNA; for example, almost half of the human genome consists of repetitive DNA. A major class of repetitive DNA is **moderately repetitive DNA**,

which typically consists of sequences from 150 to 300 bp in length (although they may be longer) that are repeated many thousands of times. Some of these sequences perform important functions for the cell; for example, multiple copies of the genes for ribosomal RNAs (rRNAs) and transfer RNAs (tRNAs) make up a part of the moderately repetitive DNA. However, the function of much moderately repetitive DNA is unknown, and indeed, it may have no function.

Moderately repetitive DNA itself can be divided into two types of repeats. **Tandem repeats** appear one after another and tend to be clustered at particular locations on the chromosomes. **Interspersed repeats** are scattered throughout the genome. An example of an interspersed repeat is the *Alu* sequence, an approximately 300-bp sequence that is present more than a million times and constitutes 11% of the human genome, although it has no obvious cellular function. Short repeats such as the *Alu* sequence are called **SINEs (short interspersed elements)**. Longer interspersed repeats consisting of several thousand base pairs are called **LINEs (long interspersed elements)**. One class of LINEs, called LINE1, constitutes about 17% of the human genome. Most interspersed repeats are the remnants of transposable elements, sequences that can multiply and move (see Chapter 18).

The other major class of repetitive DNA is **highly repetitive DNA**. These short sequences, often less than 10 bp in length, are present

in hundreds of thousands to millions of copies that are repeated in tandem and clustered in certain regions of the chromosome, especially in centromeres and telomeres. Highly repetitive DNA is sometimes called *satellite DNA* because its proportions of the four bases differ from those of other DNA sequences, and therefore it separates as a satellite fraction when centrifuged at high speeds in a density gradient (see Figure 12.2). Highly repetitive DNA is rarely transcribed into RNA. Although it may contribute to centromere and telomere function, most highly repetitive DNA has no known function.

Organization of Genetic Information in Eukaryotes

DNA-hybridization reactions and, more recently, direct sequencing of eukaryotic genomes have not only revealed the types of sequences we have just described but also told us a lot about how genetic information is organized within chromosomes. We now know that the density of genes varies greatly among and within chromosomes. For example, human chromosome 19 has a high density of genes, with about 26 genes per million base pairs. Chromosome 13, on the other hand, has only about 6.5 genes per million base pairs. Gene density can also vary among different regions of the same chromosome: some parts of the long arm of chromosome 13 have only 3 genes per million base pairs, whereas

other parts have almost 30 genes per million base pairs. And the short arm of chromosome 13 contains almost no genes, consisting entirely of heterochromatin.

CONCEPTS

Eukaryotic DNA comprises three major classes: unique-sequence DNA, moderately repetitive DNA, and highly repetitive DNA. Unique-sequence DNA consists of sequences that exist in one or a few copies; moderately repetitive DNA consists of sequences that may be several hundred base pairs in length and are present in thousands to hundreds of thousands of copies. Highly repetitive DNA consists of very short sequences repeated in tandem and is present in hundreds of thousands to millions of copies. The density of genes varies greatly among and even within chromosomes.

✔ CONCEPT CHECK 7

Most of the genes that encode proteins are found in

a. unique-sequence DNA.
b. moderately repetitive DNA.
c. highly repetitive DNA.
d. All of the above

11.4 Organelle DNA Has Unique Characteristics

As we have seen, eukaryotic chromosomes reside within the nucleus and have a complex structure consisting of DNA and associated histone proteins. However, some DNA found in eukaryotic cells occurs outside the nucleus, has a very different organization, and exhibits a different pattern of inheritance from nuclear DNA. This DNA occurs in mitochondria and chloroplasts, which are membrane-bounded organelles located in the cytoplasm of eukaryotic cells (Figure 11.11).

11.11 Comparison of the structures of mitochondria and chloroplasts.

Description

The electron micrograph on the left shows red-colored mitochondria against blue background with randomly present circular structures. The diagram on the left shows all the parts of mitochondria. The outermost layer is labeled as outer membrane. The inner membrane is folded inside forming zig-zag pattern. The inside of the inner membrane is labeled as matrix. The matrix has a large number of small, round structures spread throughout and labeled as ribosomes. Two D N A strands are present in the center and

bottom of the mitochondria respectively and are nearly arranged in a circular manner. Its length is 0 point 5 to 1 point 0 m. The illustration on the right shows a chloroplast. The outermost layer is labeled as outer membrane and a layer inside is labeled as inner membrane. The inside of the chloroplast is labeled as stroma. Circular disc shaped structures are stacked and are labeled as grana. The layer covering the circular disc shaped structures is labeled as thylakoid membrane. D N A strands are present randomly in the mitochondria and are nearly arranged in a circular manner. Its length is 4 to 6 m. The electron micrograph on the right shows green-colored chloroplast against yellow background.

Mitochondrion and Chloroplast Structure

Mitochondria are present in almost all eukaryotic cells, whereas chloroplasts are found in plants, algae, and some protists. Both organelles generate ATP, the universal energy carrier of cells.

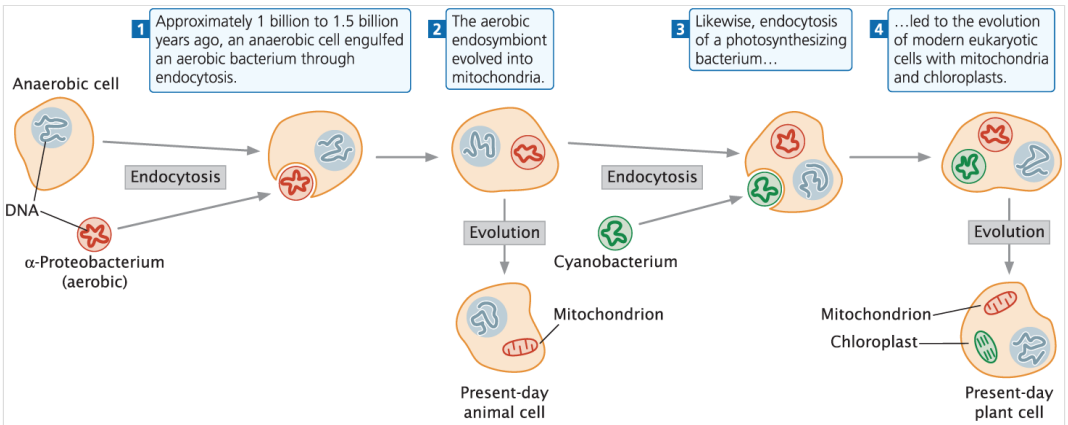
Mitochondria are tubular structures that are from 0.5 to 1.0 micrometer (μm) in diameter, about the size of a typical bacterium, whereas chloroplasts are typically from about 4 to 6 μm in diameter. Both are surrounded by two membranes enclosing a region (called the matrix in mitochondria and the stroma in chloroplasts) that contains enzymes, ribosomes, RNA, and DNA. In mitochondria, the inner membrane is highly folded; embedded within it are the enzymes that catalyze electron transport and oxidative phosphorylation. Chloroplasts have a thylakoid membrane, which is highly folded and stacked to form aggregates called grana. This

membrane bears the pigments and enzymes required for photophosphorylation. New mitochondria and chloroplasts arise by the division of existing organelles; these divisions take place throughout the cell cycle and are independent of mitosis and meiosis.

Mitochondria and chloroplasts possess DNA that encodes some polypeptides used by the organelles, as well as rRNAs found in the ribosomes and the tRNAs needed for the translation of these proteins. The genes for most of the 900 or so structural proteins and enzymes found in mitochondria, however, are actually encoded by nuclear DNA; the mitochondrial genome typically encodes only a few proteins and a few rRNA and tRNA molecules needed for mitochondrial protein synthesis.

The Endosymbiotic Theory

Chloroplasts and mitochondria are similar to bacteria in many ways. This resemblance is not superficial; indeed, there is compelling evidence that these organelles evolved from bacteria. The **endosymbiotic theory** (**Figure 11.12**) proposes that mitochondria and chloroplasts were once free-living bacteria that became internal inhabitants (endosymbionts) of early eukaryotic cells. It is assumed that over evolutionary time, many of the endosymbionts' original genes were subsequently lost (because nuclear genes existed that provided the same function) or were transferred to the nucleus.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

11.12 The endosymbiotic theory proposes that mitochondria and chloroplasts in eukaryotic cells arose from bacteria.

Description

The illustration shows an anaerobic cell on the left with D N A strand in its nucleus and an alpha proteobacterium (aerobic) with a nearly star-shaped D N A. Endocytosis occurs and the anaerobic cells engulf aerobic bacterium. Text reads, approximately 1 billion to 1.5 billion years ago, an anaerobic cell engulfed an aerobic bacterium through endocytosis. The cell which engulfed the bacterium undergoes evolution and produces the present-day animal cell with a mitochondrion. Text reads, the aerobic endosymbiont evolved into mitochondria. The cell which engulfed bacterium also engulfs a cyanobacterium with almost circular D N A strand, through endocytosis. Evolution occurs and the present day plant cell is produced below. The plant cell has a chloroplast and mitochondria. Text reads, likewise, endocytosis of a photosynthesizing bacterium led to the evolution of modern eukaryotic cells with mitochondria and chloroplasts.

A great deal of evidence supports the idea that mitochondria and chloroplasts originated as bacterial cells. Many modern single-celled eukaryotes (protists) are hosts to endosymbiotic bacteria. Mitochondria and chloroplasts are similar in size to present-day bacteria and possess their own DNA, which shares many characteristics with bacterial DNA. Mitochondria and chloroplasts

possess ribosomes, some of which are similar in size and structure to bacterial ribosomes. In addition, antibiotics that inhibit protein synthesis in bacteria but do not affect protein synthesis in eukaryotic cells do inhibit protein synthesis in these organelles.

The strongest evidence for the endosymbiotic theory comes from studies of DNA sequences, which demonstrate that sequences in mtDNA and cpDNA are more closely related to sequences in the genes of bacteria than they are to those found in the eukaryotic nucleus. All of this evidence indicates that mitochondria and chloroplasts are more closely related to bacterial cells than they are to the eukaryotic cells in which they are now found.

CONCEPTS

Mitochondria and chloroplasts are membrane-bounded organelles of eukaryotic cells that generally possess their own DNA. The well-supported endosymbiotic theory proposes that these organelles began as free-living bacteria that developed stable endosymbiotic relations with early eukaryotic cells.

✔ CONCEPT CHECK 8

What evidence supports the endosymbiotic theory?

Uniparental Inheritance of Organelle-Encoded Traits

Mitochondria and chloroplasts are present in the cytoplasm and are usually inherited from a single parent. Thus, traits encoded by mtDNA and cpDNA exhibit uniparental inheritance (see Chapter 5). In animals, mtDNA is inherited almost exclusively from the female parent, although occasional male transmission of mtDNA has been documented. In 2018, researchers demonstrated that paternal transmission of mtDNA also occasionally occurs in humans, although it appears to be very rare. Maternal inheritance of animal mtDNA may be partly a function of gamete size: sperm are much smaller than eggs and hold fewer mitochondria. However, in many animals, paternal mitochondria are selectively eliminated by autophagy, a process in which mitochondria are digested by the cell. In these cases, paternal mitochondria are marked for destruction, whereas maternal mitochondria are not; the mechanism that produces this difference is not known. Paternal inheritance of chloroplast DNA is common in gymnosperms (conifers) and in a few angiosperms (flowering plants). Some plants even exhibit biparental inheritance of mtDNA and cpDNA.

REPLICATIVE SEGREGATION

Individual cells may contain from dozens to hundreds of mitochondria and chloroplasts, each with numerous copies of the organelle genome, so each cell typically possesses from hundreds to thousands of copies of mitochondrial and chloroplast genomes (**Figure 11.13**). A mutation arising within one DNA molecule within one organelle generates a mixture of organelles within the cell, some

with a mutant DNA sequence and others with a wild-type DNA sequence. The occurrence of two distinct varieties of DNA within the cytoplasm of a single cell is termed **heteroplasmy**. When a heteroplasmic cell divides, the organelles segregate randomly into the two progeny cells in a process called **replicative segregation** (**Figure 11.14**), and chance determines the proportion of mutant organelles in each cell. Although most progeny cells inherit a mixture of mutant and wild-type organelles, some cells, just by chance, may receive organelles with only mutant or only wild-type sequences; the result, in which all organelles are genetically identical, is known as **homoplasmy**. Fusion of mitochondria also takes place frequently.

11.14 Organelles in a heteroplasmic cell segregate randomly into the progeny cells. This diagram illustrates replicative segregation in mitosis; the same process also takes place in meiosis.

Description

The illustration shows a dividing heteroplasmic cell at the top. A caption reads, a heteroplasmic cell has two distinct varieties of D N A contained in its organelles. Cell division occurs and the cell divides into two daughter cells below: one has 3 red mitochondria and 1 blue mitochondria while other has 3 blue and 1 red mitochondria. A caption reads, the organelles segregate randomly in cell division. Replication of mitochondria occurs and each daughter cell starts dividing into two daughters cells. A caption reads, replicate. Cell division occurs. The first cell gives two daughter cells: both with 3 red and 1 blue mitochondria. The second cell gives two daughter cells: one with 4 blue mitochondria and one with 2 blue and 3 red mitochondria. A caption reads, and again segregate randomly in cell division. Replication of mitochondria occurs and each daughter cell starts dividing into two daughters cells as a furrow starts developing. The first cell has two compartments: 4 red mitochondria; 2 blue and 2 red mitochondria.

The second cell has two compartments: 3 red and 1 blue mitochondria; 3 red and 1 blue mitochondria.

The third cell has two compartments: 2 blue and 2 red mitochondria; 2 blue and 2 red mitochondria.

The fourth cell has two compartments: 4 blue mitochondria; 4 blue mitochondria. A caption reads, the organelles replicate again and randomly segregate. The first cell produces two cells below with: 4 red mitochondria (homoplasmic cell); 2 blue and 2 red mitochondria (heteroplasmic cell).

The second cell produces two cells below with: 3 red and 1 blue mitochondria (heteroplasmic cell); 3 red and 1 blue mitochondria (heteroplasmic cell).

The third cell produces two cells below with: 2 blue and 2 red mitochondria (heteroplasmic cell); 2 blue and 2 red mitochondria (heteroplasmic cell).

The fourth cell produces two cells below with: 4 blue mitochondria (homoplasmic cell); 4 blue mitochondria (homoplasmic cell).

A caption below reads, Conclusion: Most of the resulting cells are heteroplasmic, but just by chance, some cells may receive only one type of organelle (e.g., they may receive all normal or all mutant).

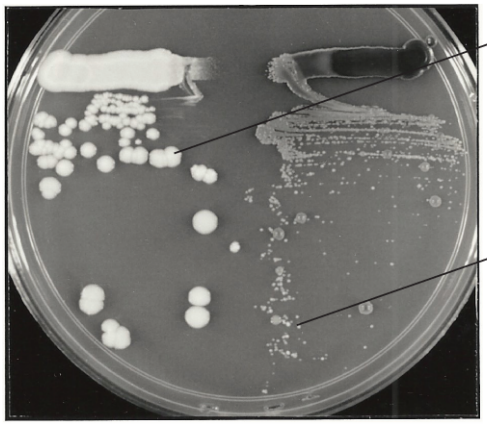
When replicative segregation takes place in somatic cells, it may create phenotypic variation within a single organism: different cells of the organism may possess different proportions of mutant and wild-type sequences, resulting in different degrees of phenotypic expression in different tissues. When replicative segregation takes place in the germ cells of a heteroplasmic cytoplasmic donor, there may be different phenotypes among the offspring.

The disease known as myoclonic epilepsy and ragged-red fiber (MERRF) syndrome is caused by a mutation in an mtDNA gene. In one case, a 20-year-old person who carried this mutation in 85% of his mtDNA sequences displayed a normal phenotype, whereas a cousin who had the mutation in 96% of his mtDNA sequences was severely affected. In diseases caused by mutations in mtDNA, the severity of the disease is frequently related to the proportion of mutant mtDNA sequences inherited at birth. › **TRY** PROBLEM 29

TRAITS ENCODED BY mtDNA

A number of traits affected by organelle DNA have been studied. One of the first to be examined in detail was the phenotype produced by *petite* mutations in yeast (Figure 11.15). In the late 1940s, Boris Ephrussi and his colleagues noticed that when they grew yeast on a solid medium, some colonies were much smaller than normal. Examination of these *petite* colonies revealed that the growth rates of the cells within the colonies were greatly reduced. The results of

biochemical studies demonstrated that the *petite* mutants were unable to carry out aerobic respiration; they obtained all their energy from anaerobic metabolism (glycolysis and fermentation), which is much less efficient than aerobic respiration and results in a smaller colony size.



Reprinted by permission of Genetics Society of America, from Xin Jie Chen and G. Desmond Clark-Walker, The mitochondrial genome integrity gene, *MGI1*, of *Kluyveromyces lactis* encodes the β-subunit of F1-ATPase," *Genetics* 1997, 144 (4): 1445–1454, Figure 1. Courtesy of Xin Jie Chen, Department of Biochemistry and Molecular Biology, SUNY Upstate Medical University. Permission conveyed through Copyright Clearance Center, Inc.

11.15 *Petite* mutations are deletions in mtDNA. Colonies of normal yeast cells and colonies of *petite* mutants are shown here. The *petite* mutants have large deletions in their mtDNA and are unable to carry out oxidative phosphorylation.

Some *petite* mutations are defects in nuclear DNA, but most *petite* mutations occur in mtDNA. Mitochondrial *petite* mutants often have large deletions in mtDNA or, in some cases, are missing mtDNA entirely. Much of the mtDNA sequence encodes enzymes that catalyze aerobic respiration; therefore, the *petite* mutants are unable

to carry out aerobic respiration and cannot produce normal quantities of ATP, which inhibits their growth.

Another group of mtDNA mutations occurs in *Neurospora* (see Chapter 15). Isolated by Mary Mitchell in 1952, *poky* mutants grow slowly, display cytoplasmic inheritance, and have abnormal amounts of cytochromes. Cytochromes are protein components of the electron-transport chain of the mitochondria and play an integral role in the production of ATP. Most organisms have three primary types of cytochromes: cytochrome *a*, cytochrome *b*, and cytochrome *c*. *Poky* mutants have cytochrome *c*, but no cytochrome *a* or *b*. Like *petite* mutants, *poky* mutants are defective in ATP synthesis and therefore grow more slowly than do normal, wild-type cells. **› TRY PROBLEM 33**

A number of genetic diseases that result from mutations in mtDNA (in addition to MERRF syndrome, mentioned earlier) have been identified in humans. Leber hereditary optic neuropathy (LHON) results from mutations in the mtDNA genes that encode electron-transport proteins. LHON typically leads to sudden loss of vision in middle age. Another disease caused by mtDNA mutations is neurogenic muscle weakness, ataxia, and retinitis pigmentosa (NARP), which is characterized by seizures, dementia, and developmental delay. Other mitochondrial diseases include Kearns–Sayre syndrome (KSS) and chronic external ophthalmoplegia (CEOP), both of which result in paralysis of the eye muscles; droopy eyelids; and, in severe cases, vision loss, deafness, and dementia. All of these

diseases exhibit cytoplasmic inheritance and variable expression (see Chapter 5).

A trait in plants that is produced by mutations in mitochondrial genes is cytoplasmic male sterility, a mutant phenotype found in more than 140 different plant species and inherited only from the maternal parent. These mutations inhibit pollen development but do not affect female fertility.

A number of cpDNA mutants have also been discovered. One of the first to be recognized was the mutation responsible for leaf variegation in the four o'clock plant, *Mirabilis jalapa*, which was studied by Carl Correns in 1909 (see pp. 131–132 in Chapter 5). In the green alga *Chlamydomonas*, streptomycin-resistant mutations occur in cpDNA, and in higher plants, a number of mutants exhibiting altered pigmentation and growth have been traced to defects in cpDNA.

CONCEPTS

In most organisms, genes encoded by mtDNA and cpDNA are inherited from a single parent. A cell may contain more than one distinct type of mtDNA or cpDNA; in these cases, replicative segregation of the organelle DNA may produce phenotypic variation within a single organism, or it may produce different degrees of phenotypic expression among progeny.

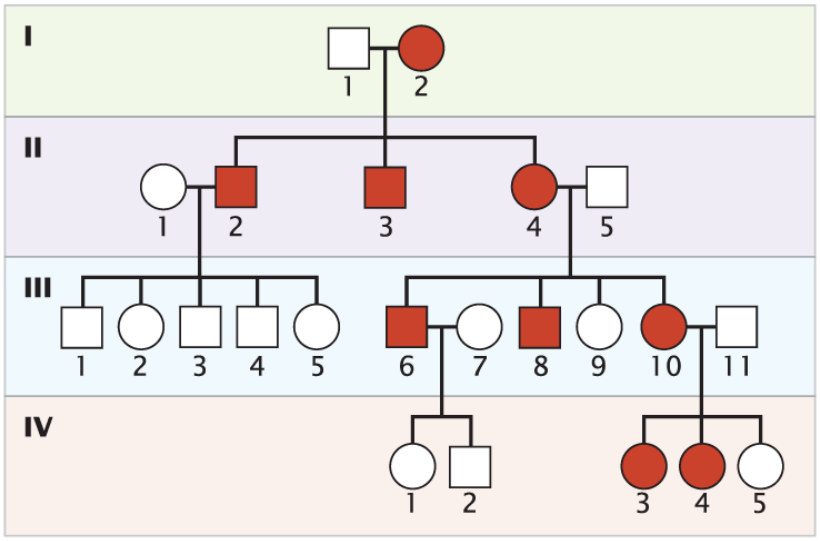
✔ CONCEPT CHECK 9

In a few organisms, traits encoded by mtDNA can be inherited from either parent. This observation suggests that in these organisms,

a. mitochondria do not exhibit replicative segregation.
b. heteroplasmy is present.
c. both sperm and eggs contribute mitochondria to the zygote.
d. there are multiple copies of mtDNA in each cell.

WORKED PROBLEM

A physician examines a young man who has a progressive muscle disorder and visual abnormalities. A number of the patient's relatives have the same condition, as shown in the following pedigree. The degree of expression of the trait is highly variable among members of the family: some are only slightly affected, whereas others developed severe symptoms at an early age. The physician concludes that this disorder is due to a mutation in the mitochondrial genome. Do you agree with the physician's conclusion? Why or why not? Could the disorder be due to a mutation in a nuclear gene? Explain your reasoning.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
In generation 1, the female parent is affected and the male parent is unaffected. They mate and have 2 affected sons and 1 affected daughter in generation 2. One affected male from generation 2 mates with an unaffected female, and have 3 unaffected sons and 2 unaffected daughters in generation 3. The affected female from generation 2 mates with an unaffected male and has 2 affected sons, 1 unaffected daughter, and 1 affected daughter in generation 3. One affected male from generation 3 mates with an unaffected female and has 1 unaffected daughter and 1 unaffected son in generation 4. The affected female from generation 3 mates with an unaffected male and has 2 affected daughters and 1 unaffected daughter in generation 4.

Solution Strategy

What information is required in your answer to the problem?

An explanation of whether and how a mutation in the mitochondrial genome could have caused the patient's disorder, as well as an

explanation of whether and how the disorder could have been caused by a mutation in a nuclear gene.

What information is provided to solve the problem?

- The patient has a progressive muscle disorder and visual abnormalities.
- A pedigree for the patient's family.
- The trait exhibits variable expression among members of the family.

Solution Steps

The conclusion that the disorder is caused by a mutation in the mitochondrial genome is supported by the pedigree and by the observation of variable expression in affected members of the same family. The disorder is passed only from affected mothers to both their male and their female offspring; when fathers are affected, none of their children have the trait (as seen in the children of II-2 and III-6). This outcome is expected of traits determined by mutations in mtDNA because mitochondria are located in the cytoplasm and are usually inherited from a single parent (in humans, the mother). The trait cannot be X-linked recessive because in that case, a cross between a female with the trait (X^aX^a) and a male without the trait (X + Y) would *not* produce daughters with the trait (X^aX^a) which we see in II-4, III-10, IV-3, and IV-4. It cannot be X-linked dominant, because in that case, II-2 and III-6 would have

passed it to their daughters, who are unaffected (unless the trait exhibited incomplete penetrance).

The facts that some offspring of affected mothers do not show the trait (III-9 and IV-5) and that expression varies from one person to another suggest that the affected family members are heteroplasmic, with both mutant and wild-type mitochondria. Replicative segregation of mitochondria in meiosis may produce gametes having different proportions of mutant and wild-type mtDNA sequences, resulting in different degrees of phenotypic expression of the disorder among the offspring. Most likely, symptoms of the disorder develop when some minimum proportion of the mitochondria are mutant. Just by chance, some of the gametes produced by an affected mother contain few mutant mitochondria and result in offspring who lack the disorder.

Another possible explanation for the disorder is that it results from an autosomal dominant allele. When an affected (heterozygous) person mates with an unaffected (homozygous) person, about half of the offspring are expected to have the trait, but just by chance, some affected parents will have no affected offspring. Affected individuals II-2 and III-6 in the pedigree could have just happened to be male, and their sex could be unrelated to the mode of transmission. The variable expression could be explained by variable expressivity (see Chapter 5).

» For more experience with the inheritance of organelle-encoded traits, try working **Problem 30** at the end of the chapter.

The Mitochondrial Genome

In most animals and fungi, the entire mitochondrial genome exists on a single double-stranded, highly coiled, circular DNA molecule, although there may be many copies of this genome in each cell. This circular mitochondrial DNA molecule is similar in structure to a bacterial chromosome. Plant mitochondrial genomes often exist as a complex collection of multiple circular DNA molecules. In some species, the mitochondrial genome consists of a single linear DNA molecule.

Each mitochondrion contains multiple copies of the mitochondrial genome, and a cell may contain many mitochondria. A typical rat liver cell, for example, has from 5 to 10 mtDNA molecules in each of about 1000 mitochondria, so each cell possesses from 5000 to 10,000 copies of the mitochondrial genome. Mitochondrial DNA constitutes about 1% of the total cellular DNA in a rat liver cell. Like bacterial chromosomes, mtDNA lacks the histone proteins normally associated with eukaryotic nuclear DNA, although it is complexed with other proteins that have some histone-like properties. The guanine–cytosine (G–C) content of mtDNA is often sufficiently

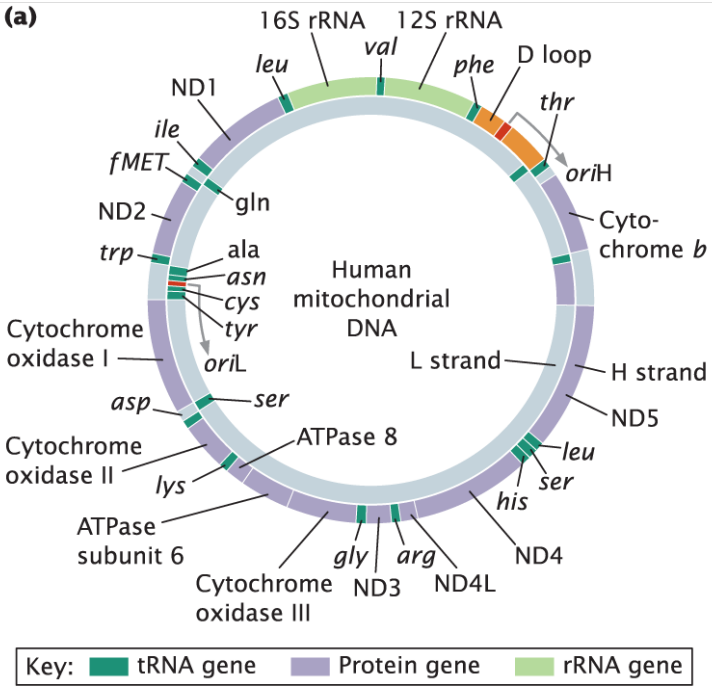
different from that of nuclear DNA that mtDNA can be separated from nuclear DNA by density-gradient centrifugation.

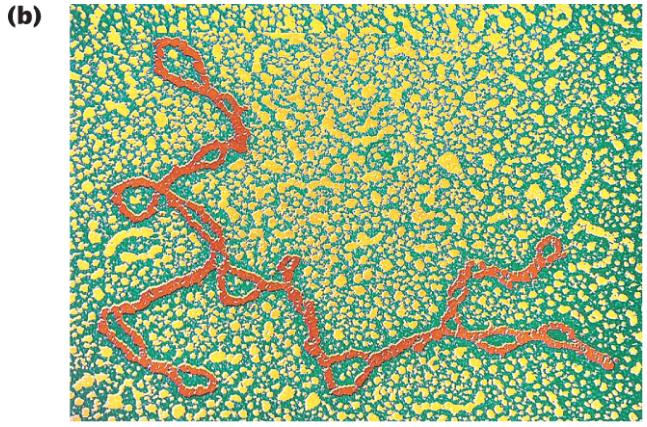
Mitochondrial genomes are small compared with nuclear genomes and vary greatly in size among different organisms. The sizes of mitochondrial genomes of most species range from 15,000 bp to 65,000 bp, but those of a few species are much smaller (e.g., the genome of *Plasmodium falciparum*, the parasite that causes malaria, is only 6000 bp), while those of some plants are several million base pairs. There is no correlation, however, between genome size and number of genes. The number of genes is more constant than genome size: most species have only 40 to 50 genes. These genes encode five basic functions: respiration and oxidative phosphorylation, translation, transcription, RNA processing, and the import of proteins into mitochondria. Most of the variation in the size of mitochondrial genomes is due to differences in noncoding DNA sequences. As mentioned earlier, genes for most of the proteins and enzymes found in mitochondria are actually encoded by nuclear DNA.

HUMAN mtDNA

Human mtDNA is a circular molecule encompassing 16,569 bp that encode 2 rRNAs, 22 tRNAs, and 13 proteins. The two nucleotide strands of the molecule differ in their base composition: the heavy (H) strand has more guanine nucleotides, whereas the light (L)

strand has more cytosine nucleotides. The H strand is the template for both rRNAs, 14 of the 22 tRNAs, and 12 of the 13 proteins, whereas the L strand serves as the template for only 8 of the tRNAs and 1 protein. The **D loop** (**Figure 11.16**) is a region of the mtDNA that contains sites where replication and transcription of the mtDNA is initiated. Human mtDNA is highly economical in its organization: there are few noncoding nucleotides between the genes, and almost all the mRNA transcribed from it encodes proteins. Human mtDNA also contains very little repetitive DNA. The one region of human mtDNA that does contain some noncoding nucleotides is the D loop.





Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company
Part b: CNRI/Science Source.

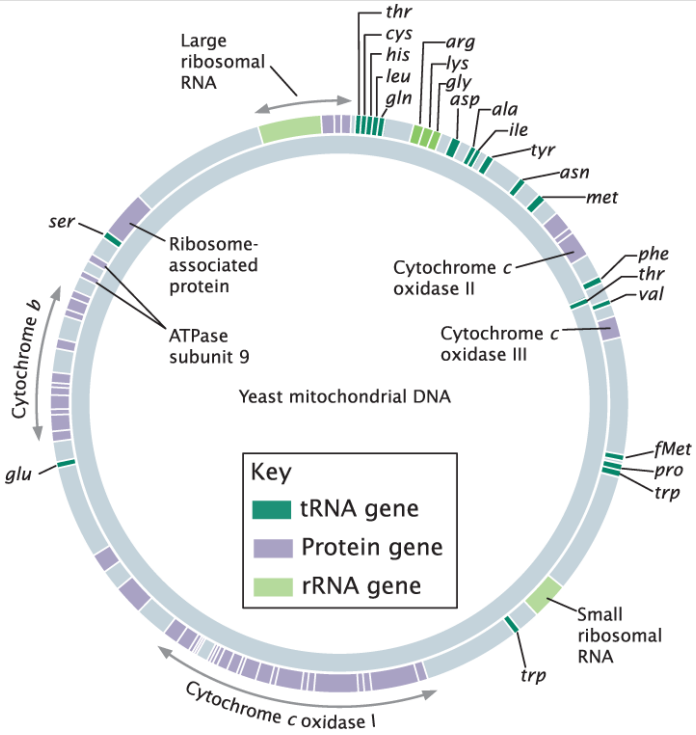
11.16 The human mitochondrial genome, consisting of 16,569 bp, is highly economical in its organization, with few sequences that do not code for RNA or protein. (a) The outer circle represents the heavy (H) strand, and the inner circle represents the light (L) strand. The origins of replication for the H and L strands are *ori*H and *ori*L, respectively. ND identifies genes that encode subunits of NADH dehydrogenase. (b) Electron micrograph of isolated mtDNA.

Description

The diagram “a” shows the protein encoding regions that are colored in purple and the r R N A and t R N A genes are colored in different shades of green. Almost the entire D N A encodes for a gene. The outside of the circle is known as heavy (H) strand and has the majority of the genes, and the light (L) strand encodes very few genes. The origins for the heavy and light strands are on opposite sides of the plasmid. Genes N D 1, 2, 3, 4, 4 L, and 5 are labeled in the diagram. The electron micrograph below labeled “b”, shows isolated mitochondrial D N A (m t D N A).

YEAST mtDNA

The organization of yeast (*Saccharomyces cerevisiae*) mtDNA is quite different from that of human mtDNA. Although the yeast mitochondrial genome, with its 78,000 bp, is nearly five times as large, it encodes only six additional genes, for a total of 2 rRNAs, 25 tRNAs, and 16 proteins (**Figure 11.17**). Most of the extra DNA in the yeast mitochondrial genome consists of noncoding sequences found within and between genes.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

11.17 The yeast mitochondrial genome, consisting of 78,000 bp, contains much noncoding DNA.

Description
The D N A shows regions for the protein gene, r R N A gene, and t R N A gene. The outer strand shows most of the coding regions, such as: a s n, m e t, v a l, t r p. The inner strand has most of the noncoding regions.

FLOWERING-PLANT mtDNA

Flowering plants (angiosperms) have the largest and most complex mitochondrial genomes known: their mitochondrial genomes range in size from 186,000 bp in white mustard to 2,400,000 bp in

muskmelon. Even closely related plant species may differ greatly in the sizes of their mtDNA. Part of the extensive size variation in the mtDNA of flowering plants can be explained by the presence of long sequences that are direct repeats. Crossing over between these repeats can generate multiple circular chromosomes of different sizes.

CONCEPTS

The mitochondrial genome consists of circular DNA with no associated histone proteins, although it is complexed with other proteins that have some histone-like properties. The sizes and structures of mtDNA differ greatly among organisms. Human mtDNA exhibits extreme economy, but mtDNAs found in yeast and flowering plants contain many noncoding nucleotides and repetitive sequences. In most flowering plants, mitochondrial DNA is large and typically has one or more large direct repeats that can recombine to generate smaller or larger molecules.

The Evolution of Mitochondrial DNA

As already mentioned, comparisons of mitochondrial DNA sequences with DNA sequences in bacteria strongly support a common bacterial origin for all mtDNA. Nevertheless, patterns of evolution seen in mtDNA vary greatly among different groups of organisms.

The sequences of vertebrate mtDNA exhibit an accelerated rate of evolution: the sequences in mammalian mtDNA, for example, typically change from 5 to 10 times faster than those in mammalian nuclear DNA. The accelerated rate of evolution seen in vertebrate mtDNA is due to its high mutation rate, which allows sequences to change more quickly. In spite of this high rate of sequence evolution, the numbers of genes present and the organization of vertebrate mitochondrial genomes are relatively constant. In contrast, the sequences of plant mtDNA evolve slowly, at a rate only one-tenth that of the nuclear genome, but their gene content and organization change rapidly. The reason for these basic differences in rates of evolution is not yet known.

Mitochondrial DNA has been studied extensively to reconstruct patterns of evolution in humans and many other organisms. Some of the advantages of mtDNA for studying evolution include (1) the small size of mtDNA and its abundance in the cell; (2) the rapid evolution of mtDNA sequences in some organisms, which facilitates study of closely related groups; and (3) the maternal inheritance of mtDNA and lack of recombination, which makes it possible to trace female lines of descent. Samples of human mtDNA from thousands of people belonging to hundreds of different ethnic groups throughout the world have been analyzed. These mtDNA samples are helping unravel many aspects of human evolution and history. For example, initial studies on mtDNA sequences led to the proposal that small groups of humans migrated out of Africa about 85,000 years ago and populated the rest of the world. This proposal, called

the Out of Africa hypothesis or the African replacement hypothesis, has now gained wide acceptance. The Out of Africa hypothesis is supported by additional studies of DNA sequences from the Y chromosome and nuclear genes. The use of mtDNA in evolutionary studies will be described in more detail in Chapter 26.

At conception, a mammalian zygote inherits approximately 100,000 copies of mtDNA from the egg. Because of the large number of mtDNA molecules in each cell and the high rate of mutation in mtDNA, most cells would be expected to contain a mixture of wild-type and mutant mtDNA molecules (heteroplasmy). However, heteroplasmy is rarely present: the copies of mtDNA in most individuals are genetically identical (homoplasmy). To account for the uniformity of mtDNA within individual mammals, geneticists hypothesize that at some point in early development or gamete formation, mtDNA goes through some type of bottleneck, during which the mtDNAs within a cell are reduced to just a few copies, which then replicate and give rise to all subsequent copies of mtDNA. Through this process, genetic variation in mtDNA within a cell is eliminated.

THINK-PAIR-SHARE Question 3

CONCEPTS

All mtDNA appears to have evolved from a common bacterial ancestor, but the patterns of evolution seen in different mitochondrial genomes vary greatly. Vertebrate mtDNA exhibits

rapid change in sequence but little change in gene content and organization, whereas the mtDNA of plants exhibits little change in sequence but much variation in gene content and organization. Mitochondrial DNA sequences are frequently used to study patterns of evolution.

Damage to Mitochondrial DNA Associated with Aging

The symptoms of many human genetic diseases caused by defects in mtDNA first appear in middle age or later and increase in severity as people age. One hypothesis to explain this pattern is related to the decline in oxidative phosphorylation with aging.

Oxidative phosphorylation is the process that generates ATP, the primary carrier of energy in the cell. This process takes place on the inner membrane of the mitochondrion and requires a number of different proteins, some encoded by mtDNA and others encoded by nuclear genes. Oxidative phosphorylation normally declines with age, and if it falls below a critical threshold, tissues do not make enough ATP to sustain vital functions and disease symptoms appear. Most people start life with an excess capacity for oxidative phosphorylation; this capacity decreases with age, but most people reach old age or die before the critical threshold is passed. People who are born with mitochondrial diseases carry mutations in their mtDNA that lower their capacity for oxidative phosphorylation. At birth, their capacity may be sufficient to support their ATP needs,

but as their oxidative phosphorylation capacity declines with age, they cross the critical threshold and begin to experience disease symptoms.

The mechanism of age-related increases in mtDNA damage is not yet known. Oxygen radicals—highly reactive compounds that are natural by-products of oxidative phosphorylation—are known to damage DNA (see p. 541 in Chapter 18). Because mtDNA is physically close to the enzymes taking part in oxidative phosphorylation, mtDNA may be more prone to oxidative damage than is nuclear DNA. When mtDNA has been damaged, the cell's capacity to produce ATP drops.

Mitochondrial Replacement Therapy

A number of severe genetic disorders result from mutations in mtDNA, and 1 out of every 5000 babies is born with a mitochondrial disease. Geneticists have developed methods that allow a woman carrying an mtDNA mutation to give birth to a healthy child. Called **mitochondrial replacement therapy (MRT)**, these methods combine the nuclear DNA of a female who carries a mitochondrial mutation with that of a sperm and the egg cytoplasm of a healthy donor, creating a "three-parent baby."

One type of MRT, termed pronuclear transfer, starts with an egg from a woman with an mtDNA mutation. The egg is fertilized in vitro (in the laboratory). After penetrating the egg, the sperm releases its

nucleus into the egg, resulting in two nuclei (called pronuclei), one from the father and one from the mother. Using a very fine pipette, a technician removes the pronuclei and transfers them to an egg cell from a healthy donor from which the nucleus has been previously removed. Inside the donor egg, the pronuclei fuse, and the resulting embryo begins development. The developing embryo is then implanted into the uterus of the affected female.

In a related technique, called maternal spindle transfer, the nuclear material is removed from the unfertilized oocyte of an affected female and transferred to an enucleated donor egg. The resulting oocyte, containing nuclear genetic material from the affected mother and cytoplasm from the healthy donor, is fertilized in vitro. The resulting embryo is then implanted into the affected female.

Mitochondrial replacement therapy is legally permissible for preventing mitochondrial disorders in the United Kingdom and a few other countries, but its use is not currently allowed in the United States. Because it combines genetic material from three parents in the conception of a child, MRT has raised a number of ethical and safety issues. Some mutated mitochondrial DNAs may be carried over when the nuclear material is transferred to a healthy egg; although this is usually a very small fraction of all the mtDNA in the cell, the long-term consequences are unknown. There have also been concerns about the possible developmental consequences of combining nuclear DNA and mtDNA from different people.

THINK-PAIR-SHARE Question 4

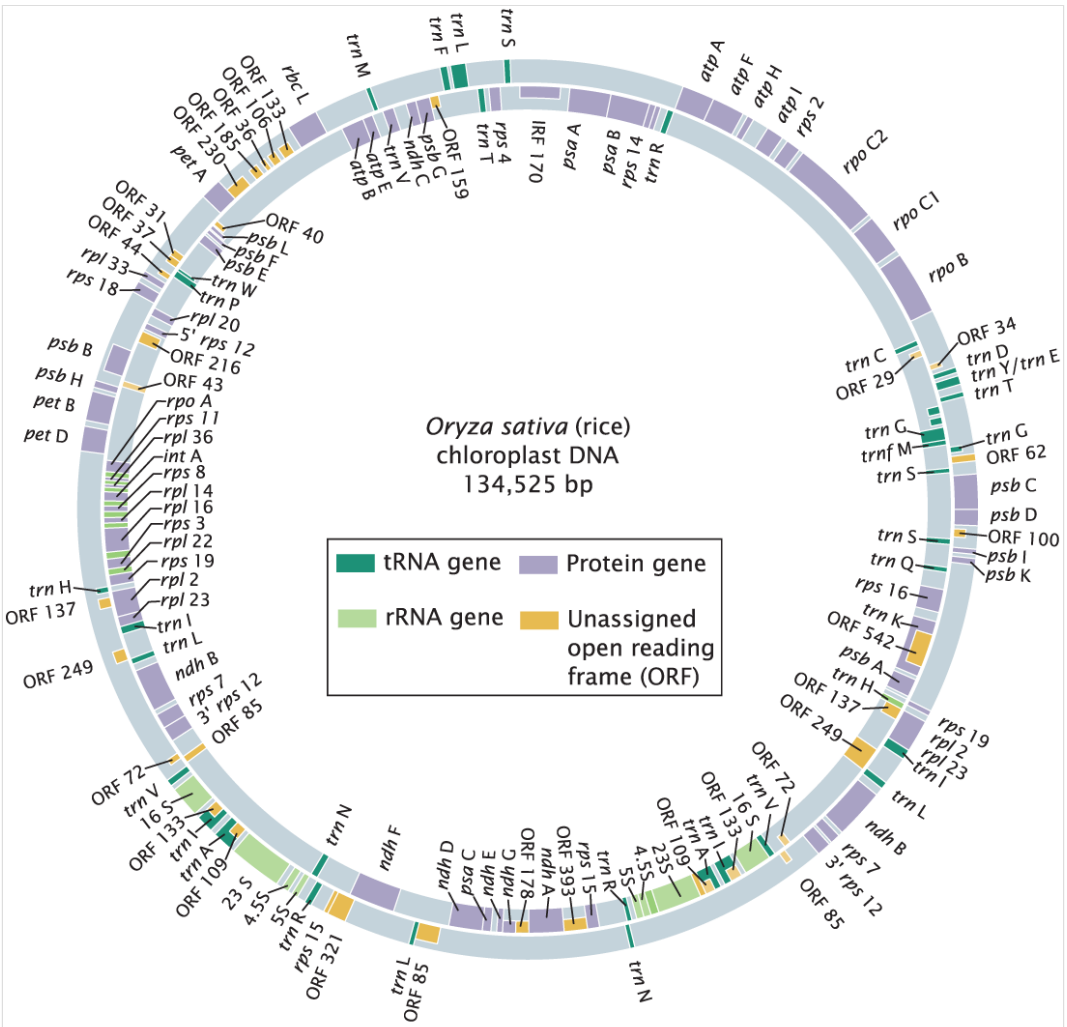
The Chloroplast Genome

Among plants, the chloroplast genome ranges in size from 80,000 to 600,000 bp, but most chloroplast genomes range from 120,000 to 160,000 bp. Chloroplast DNA is usually a single double-stranded DNA molecule that is circular, highly coiled, and lacks associated histone proteins. As in mtDNA, multiple copies of the chloroplast genome are found in each chloroplast, and there are multiple organelles per cell, so there are several hundred to several thousand copies of cpDNA in a typical plant cell.

The chloroplast genomes of a number of plant and algal species have been sequenced, and cpDNA is now recognized to be basically bacterial in its organization: the order of some groups of genes is the same as that observed in *E. coli*, and many chloroplast genes are organized into clusters similar to those found in bacteria. Many of the gene sequences in cpDNA are quite similar to those found in homologous bacterial genes.

Among vascular plants, chloroplast genomes are similar in gene content and gene order. A typical chloroplast genome encodes 4 rRNA genes, from 30 to 35 tRNA genes, a number of ribosomal proteins, many proteins engaged in photosynthesis, and several

proteins with roles in nonphotosynthetic processes (Figure 11.18). A key protein encoded by cpDNA is ribulose-1,5-bisphosphate carboxylase-oxygenase (abbreviated RuBisCO), which participates in the fixation of carbon in photosynthesis. RuBisCO makes up about 50% of the protein found in green plants and is therefore considered the most abundant protein on Earth. It is a complex protein consisting of eight identical large subunits and eight identical small subunits. The large subunit is encoded by chloroplast DNA, whereas the small subunit is encoded by nuclear DNA. Much of cpDNA consists of noncoding sequences.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

11.18 Chloroplast DNA of rice. An unassigned open reading frame (ORF) refers to an apparent protein-encoding gene—a sequence with a translation start and stop signal in the same reading frame—for which the protein has not yet been identified.

Description

The D N A shows regions for protein genes, t R N A genes, r R N A genes, and unassigned open reading frame (O R F's). There are a large number of genes labeled on the outer strand while remaining regions are non-coding. Some of the outer strand genes are: a t p A, r p o C 1, t r n N, and p e t B. A large number of genes are also labeled on the inner strand while remaining regions are noncoding. Some of the inner strand genes are: t r n C, n d h F, i n t A, and r p o A.

THE EVOLUTION OF CHLOROPLAST DNA

The DNA sequences of chloroplasts are very similar to those found in cyanobacteria (a group of photosynthetic bacteria), so chloroplast genomes clearly have a bacterial ancestry. Overall, cpDNA sequences evolve slowly compared with sequences in nuclear DNA and some mtDNA. For most chloroplast genomes, size and gene organization are similar, although there are some notable exceptions. Because it evolves slowly and, like mtDNA, is inherited from only one parent, cpDNA is often useful for determining the evolutionary relationships among different plant species.

CONCEPTS

Most chloroplast genomes consist of a single circular DNA molecule not complexed with histone proteins. Although there is considerable size variation among species, the chloroplast genomes found in most plants range from 120,000 to 160,000 bp. Chloroplast DNA sequences are most similar to DNA sequences in cyanobacteria, which supports the endosymbiotic theory of chloroplast origin.

✔ CONCEPT CHECK 10

In its organization, chloroplast DNA is most similar to

a. bacteria.
b. archaea.
c. nuclear DNA of plants.
d. nuclear DNA of primitive eukaryotes.

Movement of Genetic Information Between Nuclear, Mitochondrial, and Chloroplast Genomes

As we have seen, many of the proteins found in modern mitochondria and chloroplasts are encoded by nuclear genes, which suggests that much of the genetic material in the original endosymbionts has been transferred to the nucleus over evolutionary time. This assumption is also supported by the observation that some DNA sequences normally found in mtDNA have been detected in the nuclear DNA of some strains of yeast and corn. Likewise, chloroplast sequences have been found in the nuclear DNA of spinach. Furthermore, the sequences of those nuclear genes that encode organelle proteins are most similar to their bacterial counterparts.

There is also evidence that during evolution, genetic material has moved from chloroplasts to mitochondria. For example, DNA fragments from some rRNA genes that are normally found in cpDNA have been found in the mtDNA of corn. Sequences from the gene that encodes the large subunit of RuBisCO, which is normally encoded by cpDNA, are duplicated in corn mtDNA. And there is even evidence that some nuclear genes have moved into mitochondrial genomes. The exchange of genetic material between the nuclear, mitochondrial, and chloroplast genomes over evolutionary time has given rise to the term “promiscuous DNA” to describe this

phenomenon. The mechanism by which this exchange takes place is not entirely clear.

Chapter 11 Review

CHAPTER SUMMARY

Section 11.1 Learning Objective: Be able to explain how large amounts of DNA are packed into a cell.

- Chromosomes contain very long DNA molecules that are tightly packed.
- Supercoiling results from strain produced when rotations are added to a relaxed DNA molecule or removed from it. Overrotation produces positive supercoiling; underrotation produces negative supercoiling. Supercoiling is controlled by topoisomerase enzymes.
- A bacterial chromosome consists of a single circular DNA molecule that is bound to proteins and exists as a series of large loops. It usually appears in the cell as a distinct clump known as the nucleoid.
- Each eukaryotic chromosome contains a single long linear DNA molecule that is bound to histone and nonhistone chromosomal proteins. Euchromatin undergoes the normal cycle of decondensation and condensation in the cell cycle. Heterochromatin remains highly condensed throughout the cell cycle.

- The nucleosome is a core particle of eight histone proteins and the DNA that wraps around them. Nucleosomes are folded into a 30-nm fiber that forms a series of 300-nm-long loops; these loops are anchored at their bases by proteins. The 300-nm loops are condensed to form a fiber that is itself tightly coiled to produce a chromatid.
- Topologically associated domain (TADs) are areas of chromatin that form regions of spatial association within the interphase nucleus.
- Chromosome regions that are undergoing active transcription are sensitive to digestion by DNase I, indicating that DNA is more exposed during transcription.
- Epigenetic changes are stable alterations of gene expression that do not require changes in DNA sequences. Epigenetic changes can take place through alterations of chromatin structure.

Section 11.2 Learning Objective: Be able to describe the special features of centromeres and telomeres.

- Centromeres are chromosomal regions where spindle microtubules attach; chromosomes without centromeres are usually lost in the course of cell division. Most centromeres are defined by epigenetic changes to chromatin structure. Telomeres stabilize the ends of chromosomes.

Section 11.3 Learning Objective: Be able to describe different types of sequences found in eukaryotic chromosomes.

- Eukaryotic DNA comprises three classes of sequences. Unique-sequence DNA exists in very few copies. Moderately repetitive DNA consists of moderately long sequences that are repeated from hundreds to thousands of times. Highly repetitive DNA consists of very short sequences that are repeated in tandem from many thousands to millions of times.

Section 11.4 Learning Objective: Be able to explain how DNA in mitochondria and chloroplasts differs from nuclear DNA.

- Mitochondria and chloroplasts are eukaryotic organelles that possess their own DNA. The endosymbiotic theory proposes that mitochondria and chloroplasts originated as free-living bacteria that entered into a beneficial association with eukaryotic cells.
- Traits encoded by mtDNA and cpDNA are usually inherited from a single parent, most often the mother. Replicative segregation of organelles in cell division may produce phenotypic variation among cells within an individual organism and among the offspring of a single female.
- The mitochondrial genome usually consists of a single circular DNA molecule that lacks histone proteins. Mitochondrial DNA varies in size among different groups of organisms. Human mtDNA is highly economical, with few noncoding nucleotides. Fungal and plant mtDNAs contain much noncoding DNA between genes.
- Comparisons of mtDNA sequences suggest that mitochondria evolved from a bacterial ancestor. Vertebrate mtDNA exhibits

rapid change in sequence but little change in gene content and organization. Plant mtDNA exhibits little change in sequence but much variation in gene content and organization.

- Mitochondrial DNA sequences are widely used to study evolution. Damage to mtDNA has been associated with aging in humans.
- Mitochondrial replacement therapy can be used to transfer nuclear DNA from a woman with a mitochondrial disorder and from a sperm into an egg cell from a healthy donor, giving rise to a baby with genetic material from three parents. This procedure has raised ethical issues and safety concerns.
- Chloroplast genomes consist of a single circular DNA molecule that lacks histone proteins and varies little in size. Each plant cell contains multiple copies of cpDNA. Chloroplast DNA sequences are most similar to those in cyanobacteria and tend to evolve slowly.
- Through evolutionary time, many mitochondrial and chloroplast genes have moved to nuclear chromosomes. In some plants, there is evidence that copies of chloroplast genes have moved to the mitochondrial genome.

WORKED PROBLEMS

Problem 1

A diploid plant cell contains 2 billion base pairs of DNA.

a. How many nucleosomes are present in the cell?
b. Give the number of molecules of each type of histone protein associated with the genomic DNA.

» Solution Strategy

What information is required in your answer to the problem?

The number of nucleosomes per cell and the number of molecules of each type of histone protein associated with the DNA.

What information is provided to solve the problem?

The cell contains 2 billion base pairs of DNA.

For help with this problem, review:

The Nucleosome in Section 11.1.

» Solution Steps

Each nucleosome encompasses about 200 bp of DNA: 145–147 bp of DNA wrapped around the histone core, 20–22 bp of DNA associated with the H1 protein, and another 30–40 bp of linker DNA.

> **Recall:** The repeating unit of the chromosome is a nucleosome, which consists of DNA complexed with histone proteins.

a. To determine how many nucleosomes are present in the cell, we simply divide the total number of base pairs of DNA (2×10^9 bp) by the number of base pairs per nucleosome:

$$\frac{2\times10^9 \text{ base pairs}}{2\times10^2 \text{ base pairs/nucleosome}} = 1 \times 10^7 \text{ nucleosomes}$$

Thus, there are approximately 10 million nucleosomes in the cell.

b. Each nucleosome includes two molecules each of H2A, H2B, H3, and H4 histones. Therefore, there are 2×10^7 molecules each of H2A, H2B, H3, and H4 histones. Each nucleosome has one copy of the H1 histone associated with it, so there are 1×10^7 molecules of H1.

Problem 2

Suppose that a new organelle is discovered in an obscure group of protists. This organelle contains a small DNA genome, and some scientists are arguing that like chloroplasts and mitochondria, this organelle originated as a free-living eubacterium that entered into an endosymbiotic relation with the protist. Outline a research plan to determine whether the new organelle evolved from a free-living eubacterium. What kinds of data would you collect, and what predictions would you make if the theory were correct?

» Solution Strategy

What information is required in your answer to the problem?

A research plan with the types of data you would collect as well as predictions.

What information is provided to solve the problem?

- The newly discovered organelle contains a small DNA genome.
- Other organelles have probably evolved through an endosymbiotic relationship.

For help with this problem, review:

The Endosymbiotic Theory, The Mitochondrial Genome, and The Chloroplast Genome in Section 11.4.

» Solution Steps

We should examine the structure, organization, and sequences of the organelle genome. If the organelle shows only characteristics of eukaryotic DNA, then it most likely has a eukaryotic origin, but if it displays some characteristics of bacterial DNA, those observations support the theory of a bacterial origin.

> **Recall:** The endosymbiotic theory proposes that organelles evolved from bacteria.

We could start by examining the overall characteristics of the organelle DNA. If it has a bacterial origin, we might expect that the organelle genome will consist of a circular molecule and will lack

histone proteins. We could compare the DNA sequences found in the organelle genome with homologous sequences from bacterial and eukaryotic genomes. If the theory of an endosymbiotic origin is correct, then the organelle sequences should be most similar to homologous sequences found in bacteria.

IMPORTANT TERMS

mitochondrial DNA (mtDNA)
chloroplast DNA (cpDNA)
supercoiling
relaxed state
positive supercoiling
negative supercoiling
topoisomerase
nucleoid
euchromatin
heterochromatin
nonhistone chromosomal protein

renaturation
hybridization
unique-sequence DNA
gene family
repetitive DNA
moderately repetitive DNA
tandem repeat
interspersed repeat
short interspersed element (SINE)
long interspersed element (LINE)
highly repetitive DNA
endosymbiotic theory
heteroplasmy
replicative segregation
homoplasmy
D loop
mitochondrial replacement therapy

ANSWERS TO CONCEPT CHECKS

1. b
2. Bacterial DNA is not complexed with histone proteins and is circular.

3. b
4. d
5. A chromosome that loses its centromere will not segregate into the nucleus in mitosis and is usually lost.
6. d
7. a
8. Many modern protists are hosts to endosymbiotic bacteria. Mitochondria and chloroplasts are similar in size to bacteria and have their own DNA, as well as ribosomes that are similar in size and shape to bacterial ribosomes. Antibiotics that inhibit protein synthesis in bacteria also inhibit protein synthesis in mitochondria and chloroplasts. Gene sequences in mtDNA and cpDNA are most similar to bacterial DNA sequences.
9. c
10. a

Chapter 11 Assessment

COMPREHENSION QUESTIONS

Section 11.1

1. How does supercoiling arise? What is the difference between positive and negative supercoiling?

2. What functions does supercoiling serve for the cell?

3. Describe the composition and structure of the nucleosome.

4. Describe in steps how the double helix of DNA, which is 2 nm in width, gives rise to a chromosome that is 700 nm in width.

5. What are polytene chromosomes and chromosome puffs?

6. What are epigenetic changes, and how are they brought about?

Section 11.2

7. Describe the function of the centromere. How are centromeres different from other regions of the chromosome?

8. Describe the function and molecular structure of a telomere.

9. What is the difference between euchromatin and heterochromatin?

Section 11.3

10. What is the C-value of an organism?

11. Describe the different classes of DNA sequence variation that exist in eukaryotes.

Section 11.4

12. Explain why many traits encoded by mtDNA and cpDNA exhibit considerable variation in their expression, even among members of the same family.

13. What is the endosymbiotic theory? How does it help to explain some of the characteristics of mitochondria and chloroplasts?

14. What evidence supports the endosymbiotic theory?

15. Briefly describe the organization of genes on the chloroplast genome.

16. What is meant by the term *promiscuous* DNA?

APPLICATION QUESTIONS AND PROBLEMS

Introduction

17. The introduction to this chapter discussed a study of telomere length in Romanian children. The study demonstrated that children raised in orphanages had shorter telomeres than children raised in foster homes. What effect, if any, do you think having shorter telomeres in childhood might have on adult life?

Section 11.1

18. *Compare and contrast bacterial and eukaryotic chromosomes. How are they alike, and how do they differ?

19. *In a typical eukaryotic cell, would you expect to find more molecules of the H1 histone or more molecules of the H2A histone? Would you expect to find more molecules of H2A or more molecules of H3? Explain your reasoning.

20. CONNECT Archaea are prokaryotes, lacking a nucleus and possessing a circular DNA similar to bacteria. However, they have histones and nucleosome-like structures similar to those found in eukaryotes. Why are the archaea more similar to eukaryotes than bacteria in how their DNA is packaged? (Hint: See the discussion of bacteria, archaea, and eukaryotes in Section 2.1 in Chapter 2.)

21. *Based on the sensitivity of DNA to DNase I, as illustrated in **Figure 11.7**, which type of chicken hemoglobin (embryonic or

adult) is likely to be produced in the highest quantity in the following tissues and developmental stages?

a. Erythroblasts during the first 24 hours
b. Erythroblasts at day 5
c. Erythroblasts at day 14
d. Brain cells throughout development

22. *A diploid human cell contains approximately 6.4 billion base pairs of DNA.
    a. How many nucleosomes are present in such a cell? (Assume that the linker DNA encompasses 40 bp.)
    b. How many histone proteins are complexed with this DNA?

23. *Would you expect to see more or less acetylation in regions of DNA that are sensitive to digestion by DNase I? Why?

24.

Gunter Korge examined several proteins that are secreted from the salivary glands of *Drosophila melanogaster* during larval development (G. Korge. 1975. *Proceedings of the National Academy of Sciences of the United States of America* 72:4550–4554). One protein, called protein fraction 4, was encoded by a gene found by deletion mapping to be located on the X chromosome at position 3C. Korge observed that about 5 hours before the first synthesis of protein fraction 4, an expanded and puffed-out region formed on the X chromosome at position 3C. This chromosome puff disappeared before the end of the third larval instar stage, when the synthesis of protein fraction 4 ceased. He observed that there was no puff at position 3C in a special strain of flies that lacked secretion of protein fraction 4. Explain these

results. What is the chromosome puff at region 3, and why does its appearance and disappearance roughly coincide with the secretion of protein fraction 4?

25. Suppose a chemist develops a new drug that neutralizes the positive charges on the tails of histone proteins. What would be the most likely effect of this new drug on chromatin structure? Would this drug have any effect on gene expression? Explain your answers.

Section 11.2

26. CONNECT What would be the likely consequences of a large deletion in the gene that encoded CENP-A, so that no functional CENP-A was produced? (Hint: See Chapters 2 and 8).

Section 11.3

27. *Which of the following two molecules of DNA has the lower melting temperature? Why?

AGTTACTAAAGCAATACATC
TCAATGATTTCGTTATGTAG

AGGCGGGTAGGCACCCTTA
TCCGCCCATCCGTGGGAAT

Description

The first nucleotide pair at the top has the following top strand sequence: A G T T A C T A A A G C A A T A C A T C.

The bottom strand below has the following sequence: T C A A T G A T T T C G T T A T G T A G.

The second nucleotide pair at the bottom has the following top strand sequence: A G G C G G G T A G G C A C C C T T A.

The bottom strand below has the following sequence: T C C G C C C A T C C G T G G G A A T.

28. In a DNA-hybridization study, DNA was isolated from wheat, labeled with ^{32}P, and sheared into small fragments (S. K. Dutta et al. 1967. *Genetics* 57:719–727). Hybridizations between these labeled fragments and denatured DNA from different plant species were then compared. The following table gives the percentages of labeled wheat DNA that hybridized to DNA molecules of wheat, corn, radish, and cabbage.

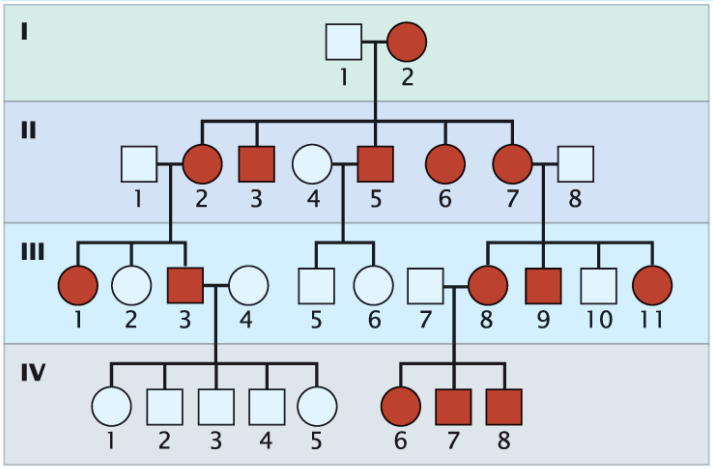
Species	Percentage of wheat DNA hybridized relative to wheat
Wheat	100
Corn	63
Radish	30
Cabbage	23

What do these results indicate about the evolutionary differences among these plants?

Section 11.4

29. *A wheat plant that is light green in color is found growing in a field. Biochemical analysis reveals that chloroplasts in this plant produce only 50% of the chlorophyll normally found in wheat chloroplasts. Propose a set of crosses to determine whether the light-green phenotype is caused by a mutation in a nuclear gene or in a chloroplast gene.

30. CONNECT *The following pedigree illustrates the inheritance of a rare neurological disease (see Chapter 6 for a discussion of pedigrees). What is the most likely mode of inheritance for this disorder? Explain your reasoning.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description

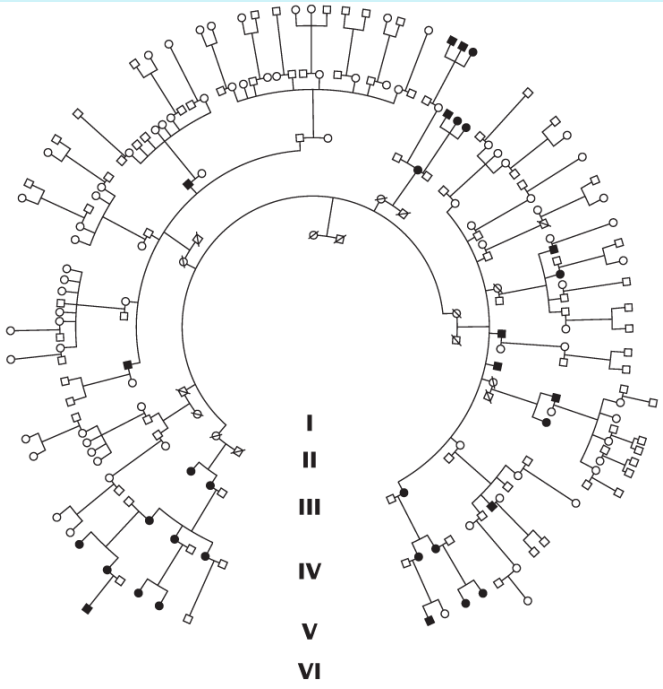
In generation one, the female is affected and the male is unaffected. They mate and have 1 affected daughter and 2 affected sons in generation 2. The affected male from generation 2 mates with an unaffected female and has 3 unaffected sons and 2 unaffected daughters in generation 3. The affected female from generation 2 mates with an unaffected male and has 2 affected sons (one of which is a proband), 1 unaffected daughter, and 1 affected daughter in generation 3. The proband from generation 3 mated with an unaffected daughter and has 1 unaffected son and 1 unaffected daughter in generation 4. The affected female from generation 3 mates with an unaffected male and has 2 affected daughters and 1 unaffected daughter in generation 4.

31. Assume that the muscle disorder whose inheritance is illustrated in the pedigree in the Worked Problem on p. 332 is a rare disease that results from a defect in mitochondrial DNA. If individual III-8 has a daughter, what is the probability that the daughter will inherit the muscle disorder from her affected parent?

32.

Fredrick Wilson and his colleagues studied members of a large family who had low levels of magnesium in their blood (see the pedigree below). They argued that this disorder (and associated high blood pressure and high cholesterol) is caused by a mutation in mtDNA (F. H. Wilson et al. 2004. *Science* 306:1190–1194).
    a. What evidence suggests that a mutation in mtDNA is causing this disorder?
    b. Could this disorder be caused by an autosomal dominant gene? (see Chapter 6 for characteristics of

autosomal dominant traits in pedigrees.) Why or why not?



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

[Data from F. H. Wilson et al. 2004. *Science* 306:1190–1194.]

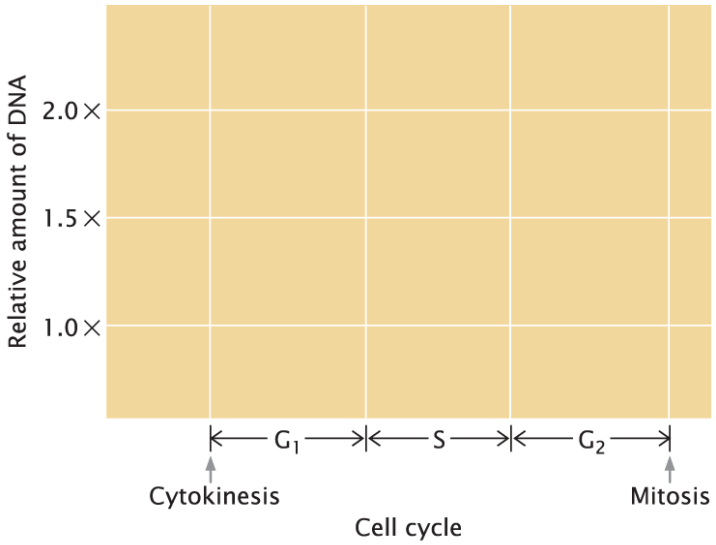
Description

The male crossed out and female crossed out in generation 1 have five female offspring (all crossed out) who all mate with males (all crossed out) and have offspring. None of these individuals are known to be affected with the disorder. Generation 3 has 19 members (9 females and 10 males). Of these 8 are affected (4 males and 4 females). Most of the unaffected members do not pass on the disorder, but 3 of them who are female have offspring that are affected. One female has only unaffected male offspring, one female crossed out has 2 affected offspring, and the other female crossed out has 2 offspring, one affected male and one affected female. No other offspring in these 3 family lineages has the disease. 3 of the 4 males affected with the disease

have children. None of their children are affected. Of the affected females in generation 3, they all mate with unaffected males and have 9 offspring in total, 7 affected females, 1 affected male, and 1 unaffected female. The one affected female mates with an unaffected male and has 3 afflicted offspring. Only 5 of the 7 affected females mate and have offspring. In total, they have 9 offspring: 6 affected females, 1 affected male, 1 unaffected male, and 1 unaffected female. Only one of the females from this generation mates and has children, and they have only one affected male offspring.

33. *In a particular strain of *Neurospora*, a *poky* mutation exhibits biparental inheritance, whereas *poky* mutations in other strains are inherited only from the maternal parent. Explain these results.

34. CONNECT *A scientist collects cells at various points in the cell cycle (see Chapter 2) and isolates DNA from them. Using density-gradient centrifugation, she separates the nuclear DNA and mtDNA. She then measures the amounts of mtDNA and nuclear DNA present at different points in the cell cycle. On the following graph, draw a line to represent the relative amounts of nuclear DNA that you expect her to find per cell throughout the cell cycle. Then draw a dotted line on the same graph to indicate the relative amounts of mtDNA that you would expect to see at different points throughout the cell cycle.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description

The horizontal axis is labeled as cell cycle. On the left side of the axis, an arrow points to the first line labeled as cytokinesis and on the right end, there is a line labeled mitosis. Between these 2 spots are evenly spaced sections labeled G subscript 1, S, and G subscript 2. The vertical axis is labeled relative amount of D N A and has 3 equally spaced lines labeled as follows: 1 point 0 X, 1 point 5 X and 2 point 0 X.

35. In 1979, bones found outside Ekaterinburg, Russia, were shown to be those of Tsar Nicholas and his family, who were executed in 1918 by a Bolshevik firing squad in the Russian Revolution (see the introduction to Chapter 14). To prove that the skeletons were those of the royal family, mtDNA was extracted from the bone samples, amplified by PCR, and compared with mtDNA from living relatives of the tsar's family.
    a. Why was DNA from the mitochondria analyzed instead of nuclear DNA? What are some of the advantages of using

mtDNA for this type of study?

b. Mitochondrial DNA from which living relatives would provide useful information for verifying that the skeletons were those of the royal family?

36.

Antibiotics such as chloramphenicol, tetracycline, and erythromycin inhibit protein synthesis in bacteria but have no effect on the synthesis of proteins encoded by eukaryotic nuclear genes (see Section 15.4 in Chapter 15 for a discussion of the effects of antibiotics on protein synthesis). Cycloheximide inhibits the synthesis of proteins encoded by nuclear genes but has no effect on bacterial protein synthesis. How might these compounds be used to determine which proteins are encoded by mitochondrial and chloroplast genomes?

CHALLENGE QUESTIONS

Section 11.1

37. An explorer discovers a strange new species of plant and sends some of the plant tissue to a geneticist to study. The geneticist isolates chromatin from the plant and examines it with an electron microscope. She observes what appear to be beads on a string. She then adds a small amount of nuclease, which cleaves the string into individual beads that each contain 280 bp of

DNA. After digestion with more nuclease, a 120-bp fragment of DNA remains attached to a core of histone proteins. Analysis of the histone core reveals histones in the following proportions:

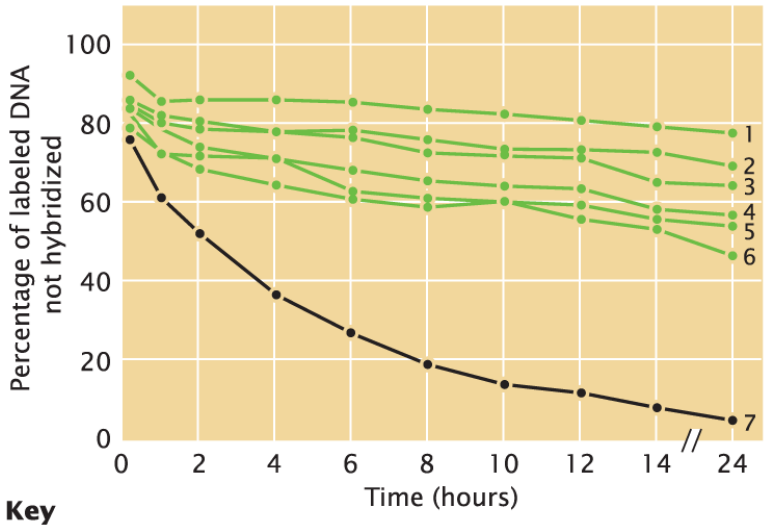
H1	12.5%
H2A	25%
H2B	25%
H3	0%
H4	25%
H7 (a new histone)	12.5%

On the basis of these observations, what conclusions could the geneticist make about the probable structure of the nucleosome in the chromatin of this plant?

Section 11.3

38.

In DNA-hybridization experiments on six species of plants in the genus *Vicia*, DNA was isolated from each of the six species, denatured by heating, and sheared into small fragments (W. Y. Chooi. 1971. *Genetics* 68:213–230). In one experiment, DNA from each species and from *E. coli* was allowed to renature. The graph shows the results of this renaturation experiment.



Key

1 = *V. melanops*, 2 = *V. sativa*, 3 = *V. benghalensis*,
4 = *V. atropurpurea*, 5 = *V. faba*, 6 = *V. narbonensis*, 7 = *E. coli*

Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

[Data from W. V. Choi. 1971. *Genetics* 68:213–230.]

Description

The horizontal axis represents time in hours ranging from 0 to 14 with an interval of 2. Then there is a break in the axis and the next point is 24 hours. The vertical axis shows percentage of labeled D N A not hybridized ranging from 0 to 100 with an interval of 20. The graph shows 7 lines, the first six lines represents species of Vicia as follows: 1, V melanops; 2, V sativa; 3, V benghalensis; 4, V atropurpurea; 5, V faba; and 6, V narbonensis. Line 7 represents E coli. The first 6 parallel lines representing Vicia species have a similar downward progression on the line graph. They all start between 80 and 95 percent and gradually decrease to around 50 to 80 percent. At 24 hours, line 1 ends at 79 percent, line 2 at 75 percent, line 3 at 65 percent, line 4 at 58 percent, line 5 at 55 percent, and line 6 at 48 percent. Line 7 is starts at 79 percent, falls steeply, and ends at 5 percent. All data are approximate.

Bob Gibbons/Alamy.

Fodder vetch (*Vicia sativa*).

a. Can you explain why the *E. coli* DNA renatures at a much faster rate than does DNA from any of the *Vicia* species?
b. Notice that for the *Vicia* species, the rate of renaturation is much faster in the first hour and then slows down. What might cause this initial rapid renaturation and the subsequent slowdown?

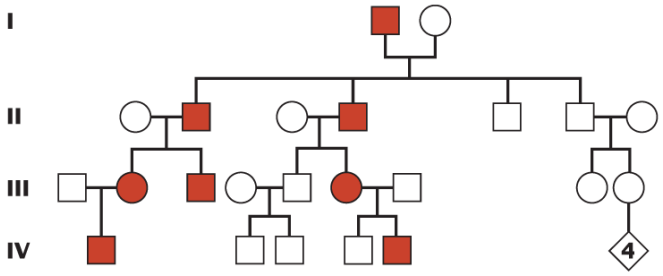
Section 11.4

39. DATA ANALYSIS Steven Frank and Laurence Hurst argued that a cytoplasmically inherited mutation in humans that has severe effects in males but no effect in females will not be eliminated from a population by natural selection because only females pass on mtDNA (S. A. Frank and L. D. Hurst. 1996. *Nature* 383:224). Using this argument, explain why males with Leber

hereditary optic neuropathy are more severely affected than females.

40. In a study of a muscle disorder, several affected families exhibited vision problems, muscle weakness, and deafness (M. Zeviani et al. 1990. *American Journal of Human Genetics* 47:904–914). Analysis of the mtDNA from affected members of these families revealed that large numbers of their mtDNA molecules possessed deletions of varying lengths. Different members of the same family and even different mitochondria from the same person possessed deletions of different sizes, so the underlying defect appeared to be a tendency for the mtDNA of affected persons to have deletions. A pedigree of one of the families studied is shown below (see Chapter 6 for a discussion of how to read and interpret pedigrees). The researchers concluded that this disorder is inherited as an autosomal dominant trait, and they mapped the disease-causing gene to a position on chromosome 10 in the nucleus.

    a. What characteristics of the pedigree rule out inheritance of a trait encoded by a gene in the mtDNA as the cause of this disorder?
    b. Explain how a mutation in a nuclear gene might lead to deletions in mtDNA.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

[Data from M. Zeviani et al. 1990. *American Journal of Human Genetics* 47:904–914.]

Description

In generation one, the male is affected and female is unaffected. They mate and have 2 affected sons and 2 unaffected sons in generation 2. One unaffected male from generation 2 mates with an unaffected female and has 2 unaffected daughters in generation 3. One affected male from generation 2 mates with an unaffected female and has 1 affected daughter and 1 unaffected son in generation 3. Another affected male from generation 2 mates with an unaffected female and has 1 affected son and 1 affected daughter in generation 3. The affected daughter of first affected male from generation2 mates with an unaffected male and has 1 affected son in generation 4. The unaffected son of second affected male from generation 2 mates with an unaffected female and has 2 unaffected sons in generation 4. The affected daughter of second affected male from generation 2 mates with an unaffected male and has 1 affected son and 1 unaffected son in generation 4. The unaffected daughter of unaffected male from generation 2 has 4 offspring of unidentified sex.

41. Mitochondrial DNA sequences have been detected in the nuclear genomes of many organisms, and cpDNA sequences are sometimes found in the mitochondrial genome. Propose a

mechanism for how such “promiscuous DNA” might move between nuclear, mitochondrial, and chloroplast genomes.

ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Section 11.1

1. The Y chromosome contains large amounts of constitutive heterochromatin. Why might there be more constitutive heterochromatin in the Y chromosome than in other chromosomes? (Hint: See Evolution of the Y Chromosome in Chapter 4.)

2. Polytene chromosomes are giant chromosomes found in cells of the salivary glands of larval fruit flies and some other organisms. Polytene chromosomes arise when repeated rounds of replication occur without cell division, producing thousands of copies of DNA that lie side by side. Why do polytene chromosomes occur in the cells of salivary glands of larval fruit flies but not in other tissues? Propose some possible reasons. (If you are unfamiliar with the life cycle of fruit flies, see pp. A2–A3 in the Reference Guide to Model Genetic Organisms at the end of this book.)

Section 11.4

3. The Out of Africa hypothesis (also called the African replacement hypothesis) proposes that *Homo sapiens* arose in Africa and evolved there for several hundred thousand years. Then, some 85,000 years ago, a small band of *Homo sapiens* migrated out of Africa and populated the remainder of the world. Based on this hypothesis, what predictions would you make about worldwide human variation in mtDNA?

4. What are some possible social and ethical issues associated with mitochondrial replacement therapy (MRT)? Present arguments for and against approving MRT for prevention of the births of children with mitochondrial disorders.

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Introduction

1. Create a concept map that summarizes the results of research on the relationship between telomere length and stress among children living in state-run orphanages in Romania. Include in your concept map how telomere length changes over cell divisions and the relationship between telomere length and stress.

Section 11.1

2. Outline the composition of eukaryotic chromatin by creating a concept map that includes the following terms: chromatin, protein, DNA, euchromatin, heterochromatin, histones, nonhistone proteins, facultative heterochromatin, constitutive heterochromatin, nucleosome, H1, H2A, H2B, H3, H4, linker DNA, protein octamer.

Section 11.3

3. Draw a concept map that explains the C-value paradox and the complexity of DNA sequences in eukaryotic genomes.

Section 11.4

4. Draw a concept map that summarizes the characteristics of organelle DNA by including the following terms: organelle DNA, mitochondrial DNA, chloroplast DNA, endosymbiotic theory, uniparental inheritance, replicative segregation, circular DNA, multiple copies of genome per cell, no histone proteins, small genome size .

SaplingPlus Self-study tools that will help you practice what you've learned and reinforce this chapter's concepts are available online. Go to www.saplinglearning.com.

CHAPTER 12

DNA Replication and Recombination

Courtesy of Lana Stewart

Children with Meier-Gorlin syndrome have mutations in components of the origin-replication complex. This impairment most likely slows down cell division and results in a reduction in growth.

The Importance of a Good Start

When Ryan was born, it was immediately clear that he was special. Not only was he small for his gestational age, he also possessed small ears and had no kneecaps. A genetic specialist quickly recognized that Ryan exhibited a rare and peculiar genetic condition known as Meier-Gorlin syndrome, which results from a flaw in DNA replication.

Each eukaryotic chromosome contains an immense amount of DNA. A typical human chromosome consists of a single DNA molecule that is over a hundred million base pairs (bp) long. One of the challenges that eukaryotic cells face is copying this immense amount of genetic information whenever a cell divides. The process of eukaryotic replication takes place at breakneck speed—up to 5000 bp of DNA is copied every minute—but because of the immense size of eukaryotic chromosomes, replicating a typical human chromosome from a single starting point would require a week or more. Cells copy their DNA much more rapidly, often within minutes or hours. How is this accomplished?

The rapid replication in eukaryotic cells is achieved because replication does not initiate at a single point (which is what happens in bacteria) but instead starts at thousands of replication origins simultaneously. The use of many origins allows the entire eukaryotic genome to be replicated in a timely manner but creates another problem: how to ensure that the genome is precisely replicated once and only once per cell cycle, so that no genes go unreplicated and none are replicated multiple times. How does a

cell ensure that replication at thousands of origins is initiated precisely only once per cell cycle?

This precise copying of eukaryotic DNA is accomplished by separating the initiation of replication into two distinct steps. In the first step, the origins are *licensed*—approved for replication. This step takes place during the G_1 stage of the cell cycle, when licensing factors attach to each origin. In the second step, the replication machinery initiates replication at each licensed origin during the S stage. The key to this process is that the replication machinery functions only at licensed origins and that licensing occurs early in the cell cycle.

The importance of proper replication licensing is illustrated by children who have Meier-Gorlin syndrome. These children experience a reduction in growth during prenatal development. Consequently, they are born small and continue to grow slowly as children, ending up with short stature. Other traits include missing or undeveloped kneecaps and small ears. Many experience difficulty feeding in infancy and childhood but have normal intellectual ability and life span.

Meier-Gorlin syndrome is inherited as an autosomal recessive condition; most children with the disorder are born to parents who are heterozygous carriers and do not have the condition. When scientists examined the genomes of children with this condition, they discovered that most have mutations in one of several genes

that code for a multiprotein complex called the origin-replication complex, which serves to initiate replication by binding to replication origins and licensing them for replication. In children with Meier-Gorlin syndrome, the origin-replication complex is defective. This impairment most likely slows down cell division and results in growth retardation.

DNA replication, essential to all life, is a highly complex process in which dozens of proteins, enzymes, and DNA structures ensure that DNA is copied accurately and quickly. As illustrated by the Meier-Gorlin syndrome, defects in a single component of this system can disrupt the entire process and have major consequences.

THINK-PAIR-SHARE

- Defects in initiation of replication presumably slow down DNA synthesis and cell division, resulting in the growth reduction seen in children with Meier-Gorlin syndrome. However, most children with Meier-Gorlin syndrome also have small ears and missing kneecaps. How might flaws in replication initiation cause some body parts to be affected and not others? Can you propose some possibilities?

This chapter focuses on DNA replication, the process by which a cell doubles its DNA before division. We begin with the basic mechanism of replication that emerged from the DNA structure discovered by Watson and Crick. We then examine several different modes of replication, the requirements of replication, and the universal direction of DNA synthesis. We also examine the enzymes and proteins that participate in the process. Finally, we consider

the molecular details of recombination, which is closely related to replication and is essential for the segregation of homologous chromosomes, the production of genetic variation, and DNA repair.

12.1 Genetic Information Must Be Accurately Copied Every Time a Cell Divides

In a schoolyard game, a verbal message, such as “John’s brown dog ran away from home,” is whispered to a child, who runs to a second child and repeats the message. The message is relayed from child to child around the schoolyard until it returns to the original sender. Inevitably, the last child returns with an amazingly transformed message, such as “Joe Brown has a pig living under his porch.” The larger the number of children playing the game, the more garbled the message becomes. This game illustrates an important principle: errors arise whenever information is copied, and the more times it is copied, the greater the potential number of errors.

A complex multicellular organism faces a problem analogous to that of the children in the schoolyard game: how to faithfully transmit genetic instructions each time its cells divide. The solution to this problem is central to replication. A single-celled human zygote contains 6.4 billion base pairs of DNA; even a low rate of error during copying, such as once per million base pairs, would result in 6400 mistakes made every time a cell divided—errors that would be compounded at each of the millions of cell divisions that take place in human development.

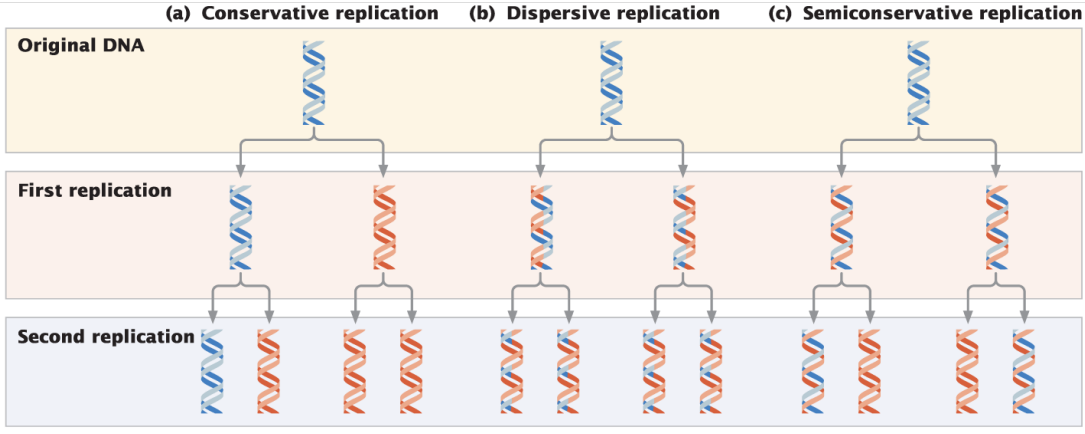
Not only must the copying of DNA be astoundingly accurate, it must also take place at rapid speed. The single circular chromosome of *Escherichia coli* contains about 4.6 million base pairs. At a rate of 1000 nucleotides per minute, replication of the entire chromosome would require over 3 days. Yet these bacteria are capable of dividing every 20 minutes. *E. coli* actually replicates its DNA at a rate of 1000 nucleotides per second, with less than one error in a billion nucleotides. How is this extraordinarily accurate and rapid process accomplished?

THINK-PAIR-SHARE Question 1

12.2 All DNA Replication Takes Place in a Semiconservative Manner

When Watson and Crick solved the three-dimensional structure of DNA in 1953 (see Figure 10.8), several important genetic implications were immediately apparent. The complementary nature of the two nucleotide strands in a DNA molecule suggested that during replication, each strand can serve as a template for the synthesis of a new strand. The specificity of base pairing (adenine with thymine, guanine with cytosine) implied that only one sequence of bases can be specified by each template strand, and so the two DNA molecules built on the pair of templates will be identical to the original. This process is called **semiconservative replication** because each of the original nucleotide strands remains intact (conserved), despite their no longer being combined in the same molecule; thus, the original DNA molecule is half (semi-) conserved during replication.

Initially, three models were proposed for DNA replication. In conservative replication (**Figure 12.1a**), the entire double-stranded DNA molecule serves as a template for a whole new molecule of DNA, and the original DNA molecule is *fully* conserved during replication. In dispersive replication (**Figure 12.1b**), both nucleotide strands break down (disperse) into fragments, which serve as templates for the synthesis of new DNA fragments, and then somehow reassemble into two complete DNA molecules. In this model, each resulting DNA molecule contains interspersed fragments of old and new DNA; none of the original molecule is conserved. Semiconservative replication (**Figure 12.1c**) is intermediate between these two models; the two nucleotide strands unwind, and each serves as a template for a new DNA molecule.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

12.1 Three proposed models of DNA replication: conservative replication, dispersive replication, and semiconservative replication. In this figure, the parental (original) DNA is colored blue, and newly synthesized DNA is colored red.

Description
Part a on the left shows conservative replication where original D N A helix is blue colored. First replication occurs and 1 red duplex and 1 blue duplex are formed below. Second replication occurs and blue duplex produces 1 red and 1 blue duplex while red duplex produces 2

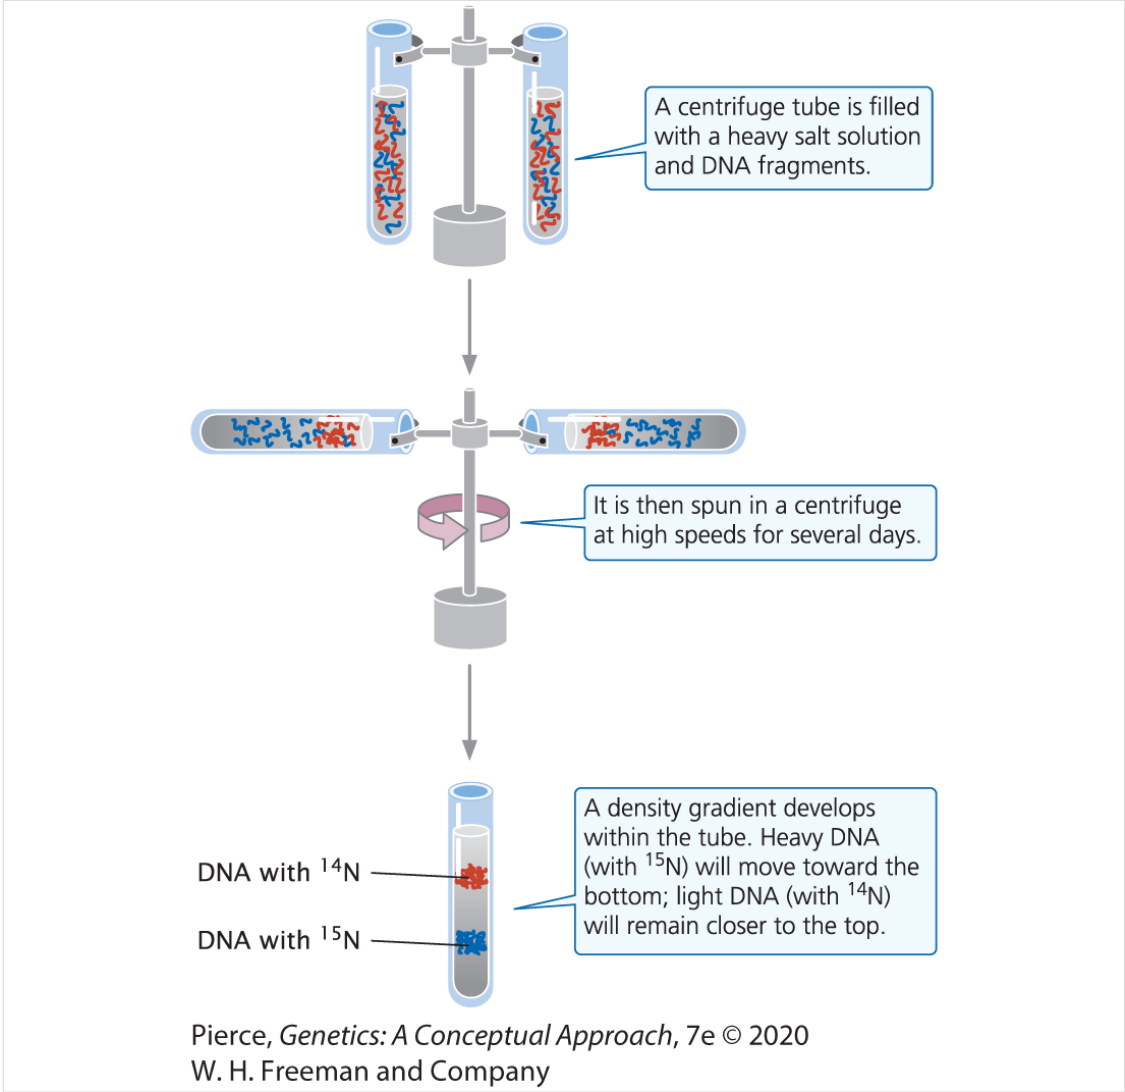
red duplexes below. Part b in the center shows dispersive replication where the original D N A strand is blue colored. First replication occurs and 2 D N A duplexes are produced below that are red-blue hybrid. Second replication occurs and each duplex produces 2 D N A duplexes below that are red-blue hybrid. Part c on the right shows semi conservative replication, where original D N A strand is blue colored. First replication occurs and 2 duplexes are produced below, each with a blue strand and a red strand. Second replication occurs and the following duplexes are produced below: 2 duplexes have a blue strand and a red strand each while 2 duplexes are completely red.

These three models allow different predictions to be made about the distribution of original DNA and newly synthesized DNA after replication. With conservative replication, after one round of replication, 50% of the molecules would consist entirely of the original DNA and 50% would consist entirely of new DNA. After a second round of replication, 25% of the molecules would consist entirely of the original DNA and 75% would consist entirely of new DNA. With each additional round of replication, the proportion of molecules with new DNA would increase, although the number of molecules with the original DNA would remain constant. Dispersive replication would always produce hybrid molecules, containing some original and some new DNA, but the proportion of new DNA within the molecules would increase with each replication event. In contrast, with semiconservative replication, one round of replication would produce two hybrid molecules, each consisting of half original DNA and half new DNA. After a second round of replication, half the molecules would be hybrid and the other half would consist of new DNA only. Additional rounds of replication would produce more and more molecules consisting entirely of new DNA, but a few hybrid molecules would persist.

Meselson and Stahl's Experiment

To determine which of the three models of replication applied to *E. coli* cells, Matthew Meselson and Franklin Stahl needed a way to distinguish old and new DNA. They accomplished this by using two isotopes of nitrogen, ^{14}N (the common form) and ^{15}N (a rare, heavy form). Meselson and Stahl grew a culture of *E. coli* in a medium that contained ^{15}N as the sole nitrogen source; after many generations, all the *E. coli* cells had ^{15}N incorporated into all the purine and pyrimidine bases of their DNA (see Figure 10.11). They took a sample of these bacteria, switched the rest of the bacteria to a medium that contained only ^{14}N, and then took additional samples of bacteria over the next few cellular generations. In each sample, the bacterial DNA that was synthesized before the change in medium contained ^{15}N and was relatively heavy, whereas any DNA synthesized after the switch contained ^{14}N and was relatively light.

Meselson and Stahl distinguished between the heavy ^{15}N-laden DNA and the light ^{14}N-containing DNA with the use of **equilibrium density gradient centrifugation** (**Figure 12.2**). In this technique, a centrifuge tube is filled with a heavy salt solution and a substance of unknown density—in this case, DNA fragments. The tube is then spun in a centrifuge at high speeds. After several days of spinning, a gradient of density develops within the tube, with high-density material at the bottom and low-density material at the top. The density of the DNA fragments matches that of the salt: light molecules rise and heavy molecules sink.



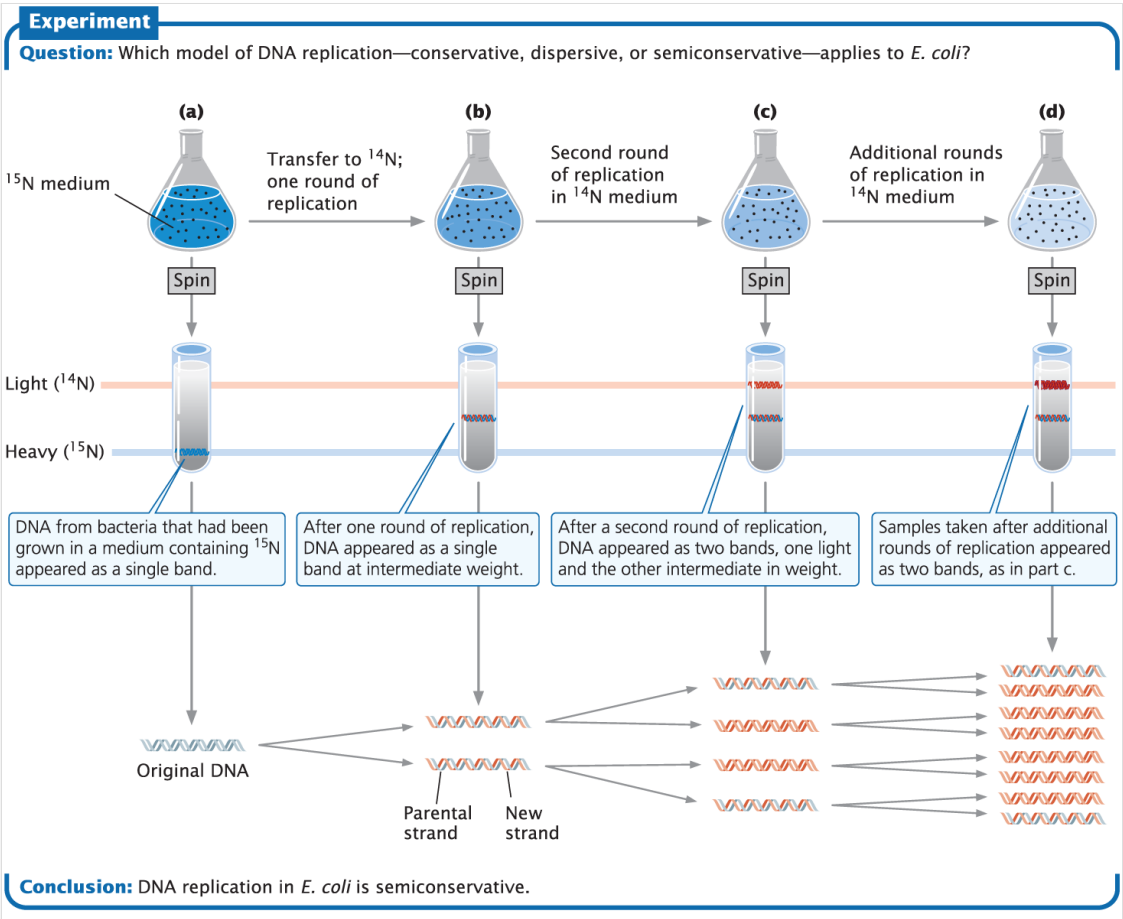
12.2 Meselson and Stahl used equilibrium density gradient centrifugation to distinguish between heavy ^{15}N-laden DNA and lighter ^{14}N-laden DNA.

Description
The illustration shows 2 tubes at the top containing red and blue colored D N A fragments. These tubes are positioned upright. A caption reads, a centrifuge tube is filled with a heavy salt solution and D N A fragments. These test tubes are now positioned horizontally in a centrifuge below and spun such that blue colored fragments move towards the test tube ends and red fragments move towards the test tube openings. A caption reads, It is then spun in a centrifuge at high speeds for several days. This leads to gradient density development. The illustration shows an upright test tube below with the red, lower-density, N labeled left superscript 14 D N A near the top and the blue, higher-density, N-labeled left superscript 15 D N A at the bottom. A caption reads, a density gradient develops within the tube. Heavy D N A (with N left superscript 15) will move toward the bottom; light D N A (with N left superscript 14) will remain closer to the top.

Meselson and Stahl found that DNA from bacteria grown only in a medium containing ^{15}N produced a single band at the position expected of DNA containing only ^{15}N (Figure 12.3a). DNA from bacteria transferred to the medium with ^{14}N and allowed one round of replication also produced a single band, but at a position intermediate between that expected of DNA containing only ^{15}N and that expected of

DNA containing only ^{14}N (Figure 12.3b). This result is inconsistent with the conservative replication model, which predicts one heavy band (the original DNA molecules) and one light band (the new DNA molecules). A single band of intermediate density is predicted by both the semiconservative and the dispersive models.

To distinguish between these two models, Meselson and Stahl grew the bacteria in a medium containing ^{14}N for a second generation. After a second round of replication in a medium with ^{14}N, two bands of equal intensity appeared, one in the intermediate position and the other at the position expected of DNA containing only ^{14}N (Figure 12.3c). All samples taken after additional rounds of replication produced the same two bands, and the band representing light DNA became progressively stronger (Figure 12.3d). Meselson and Stahl's results were exactly as expected for semiconservative replication and were incompatible with those predicted for both conservative and dispersive replication. **› TRY** PROBLEM 21



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

12.3 Meselson and Stahl demonstrated that DNA replication is semiconservative.

Description

The illustration begins with a question that reads, Which model of D N A replication—conservative, dispersive, or semiconservative—applies to E. coli? The Part a on the extreme left shows bacteria grown in the heavy N left superscript 15 medium. A part of it is spun below and a single band appears on the N left superscript 15 at the bottom of the test tube. A caption reads, D N A from bacteria that had been grown on medium containing N left superscript 15 appeared as a single band. This leads to an original blue-colored D N A duplex below. Part b on the top left shows a part of bacteria from N left superscript 15 medium to N left superscript 14 medium that has undergone one round of replication. This is spun below and a band appears in the middle of the test tube between N left superscript 15 and N left superscript 14 band positions. A caption reads, after one round of replication, the D N A appeared as a single band at intermediate weight. This further leads to two duplexes with 1 blue strand and 1 red strand each. One of the D N A helixes has one parental strand and one new strand. Part c on the top right shows a part of bacteria after one round of replication that undergoes second round of replication. A part of this is spun and two bands are obtained below as follows: one light band towards N left superscript 14 and one intermediate band in the middle of test tube. A caption reads, after a second round of replication, D N A appeared as two bands, one light and the other intermediate in weight. This further leads to 2 red duplexes and 2 duplexes with one red strand and 1 blue strand each. Part d on the extreme right shows a part of bacteria after two rounds of replication that undergoes additional rounds of replication in N left superscript 14 medium. This is spun and 2 bands are obtained below: one light band towards N left superscript 14 and one intermediate band in the middle of test tube. A caption reads, samples taken after additional rounds of replication appeared as two bands, as in part c. This further leads to 8 duplexes below as follows: 6 red duplexes and 2 duplexes with one red strand and 1 blue strand each.

THINK-PAIR-SHARE Question 2

CONCEPTS

Meselson and Stahl convincingly demonstrated that replication in *E. coli* is semiconservative: each DNA strand serves as a template for the synthesis of a new DNA molecule.

✔ CONCEPT CHECK 1

How many bands of DNA would be expected in Meselson and Stahl's experiment after two rounds of *conservative* replication?

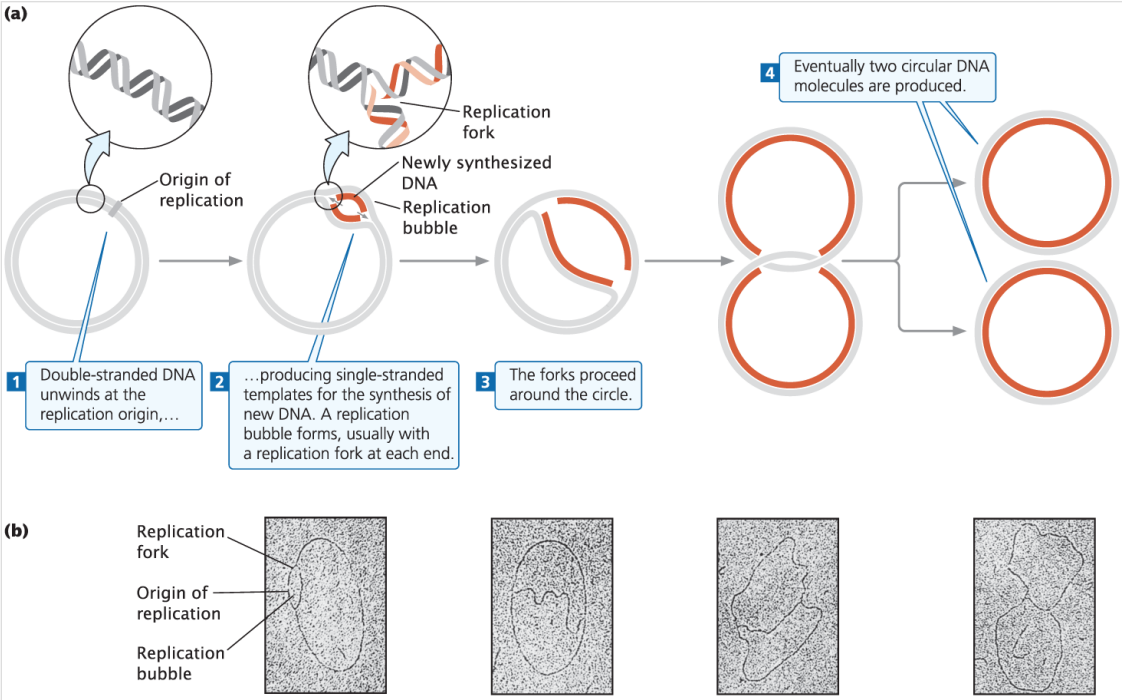
Modes of Replication

After Meselson and Stahl's work was published, investigators confirmed that other organisms also use semiconservative replication. No evidence was found for conservative or dispersive replication. There are, however, several different ways in which semiconservative replication can take place, differing principally in the nature of the template DNA—that is, whether it is linear or circular.

A segment of DNA that undergoes replication is called a **replicon**, and each replicon contains an **origin of replication**. Replication starts at the origin and continues until the entire replicon has been replicated. Bacterial chromosomes have a single origin of replication, whereas eukaryotic chromosomes contain many.

THETA REPLICATION

A common mode of replication that takes place in circular DNA, such as that found in *E. coli* and other bacteria, is called **theta replication** (**Figure 12.4a**) because it generates an intermediate structure that resembles the Greek letter theta (θ). In Figure 12.4a and all subsequent figures in this chapter, the original (template) strand of DNA is shown in gray and the newly synthesized strand of DNA is shown in red.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

12.4 Theta replication is a type of replication common in *E. coli* and other organisms possessing circular DNA. [Part b: Bernhard Hirt, L'Institut Suisse de Recherche Expérimentale sur le Cancer.]

Description

The illustration a at the top shows circular double-stranded D N A opening up at the origin of replication where a caption reads, double-stranded D N A unwinds at the replication origin. This leads to formation of a replication bubble to its right where new D N A strands are synthesized. The caption reads, producing single-stranded templates for the synthesis of the new D N A. A replication bubble forms, shown with a replication fork at each end. In the third stage, the forks extend throughout the circle. The caption reads, the forks proceed around the circle. In the fourth stage, two circular D N A strands are produced. The caption reads, eventually 2 circular D N A molecules are produced on the right. The electron microscopy images in part "b" below are as follows: The first photo on the extreme left shows a smaller circle formed along the line of a larger circle, the smaller circle being the replication bubble that appears at the start of replication at the origin of replication. The corner of the smaller bubble is labeled Replication fork and the outer line of the bubble is labeled origin of replication. The second and third photos on the right show the D N A strand with an organic theta symbol appearance, as the replication progresses. In the fourth photo, on the extreme right, there are 2 circular lines adjoined partially. A text below reads, Conclusion: the products of theta replication are 2 circular D N A molecules.

In theta replication, double-stranded DNA begins to unwind at the origin of replication, producing single nucleotide strands that then serve as templates on which new DNA can be synthesized. The

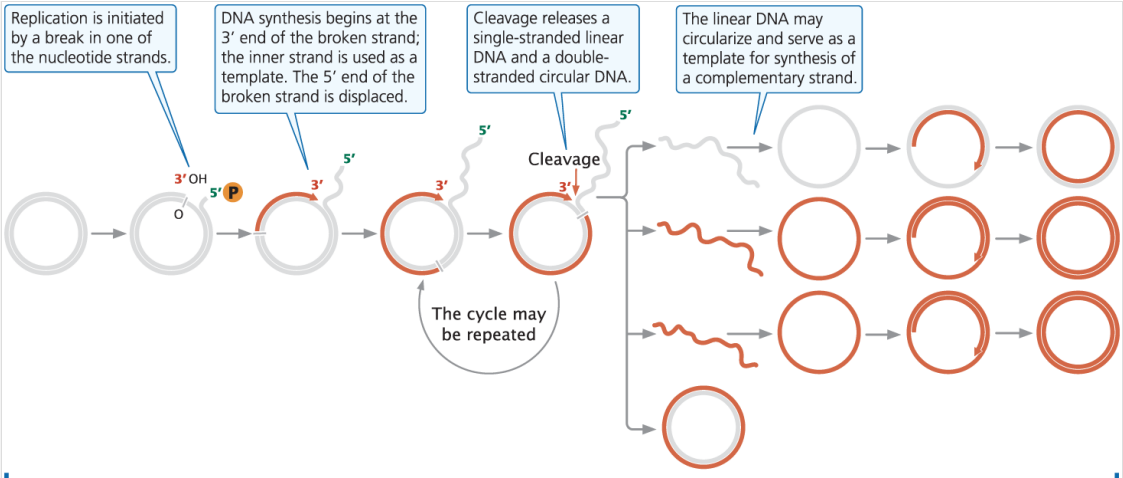
unwinding of the double helix generates a loop, termed a **replication bubble**. Unwinding may occur at one or both ends of the bubble, making it progressively larger. DNA replication on both of the template strands is simultaneous with unwinding. The point of unwinding, where the two strands separate from the double-stranded DNA helix, is called a **replication fork**.

If there are two replication forks, one at each end of the replication bubble, the forks proceed outward in both directions in a process called **bidirectional replication**, simultaneously unwinding and replicating the DNA until they eventually meet. If unidirectional replication with a single replication fork is present, it proceeds around the entire circle. Both bidirectional and unidirectional replication produce two complete circular DNA molecules, each consisting of one old and one new nucleotide strand.

John Cairns provided the first visible evidence of theta replication in 1963 by growing bacteria in the presence of radioactive nucleotides. After replication, each DNA molecule consisted of one "hot" (radioactive) strand and one "cold" (nonradioactive) strand. Cairns isolated DNA from the bacteria after replication, placed it on an electron-microscope grid, and then covered it with a photographic emulsion. Radioactivity present in the sample exposed the emulsion and produced a picture of the molecule (called an autoradiograph) in a manner similar to the light that exposes a photographic film. Because the newly synthesized DNA contained radioactive nucleotides, Cairns was able to produce electron micrographs of the replication process similar to those shown in **Figure 12.4b**.

ROLLING-CIRCLE REPLICATION

Another form of replication, called **rolling-circle replication** (**Figure 12.5**), takes place in some viruses and in the F factor of *E. coli* (a small circle of extrachromosomal DNA that controls mating, discussed in Section 9.3). This form of replication is initiated by a break in one of the nucleotide strands, which exposes a 3′-OH group and a 5′-phosphate group. New nucleotides are added to the 3′ end of the broken strand, using the inner (unbroken) strand as a template. As new nucleotides are added to the 3′ end, the 5′ end of the broken strand is displaced from the template, rolling out like thread being pulled off a spool. The 3′ end grows around the circle, giving rise to the name *rolling-circle replication*.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

12.5 Rolling-circle replication takes place in some viruses and in the F factor of *E. coli*.

Description

The illustration shows a gray colored circular D N A molecule on the left. This progresses to a break (labeled as O) in one of the nucleotide strand. The 3 prime end has an O H molecule and 5 prime has a P molecule. A caption reads, replication is initiated by a break in one of the nucleotide strands. D N A synthesis begins at 3 prime end. A caption reads, D N A synthesis begins at the 3 prime end of the broken strand; the inner strand is used as a template. The 5 prime end of the broken strand is displaced. The newly synthesized D N A strand on the right is red and increasing in length. A caption reads, cleavage releases a single-stranded linear D N A molecule from the double-stranded circular D N A. This stage can revert back to the previous stage and cycle may be repeated again. This leads to one original strand, two red strands, and one circular D N A with red strand on the outside, on the right side of the illustration. The original gray colored strand at the top right becomes circular and a complementary strand is formed around leading to a circular D N A strand. A caption reads, the linear D N A may circularize and serve as a template for the synthesis of a complementary strand. Both red colored strands eventually form one red circular D N A strand eventually. A caption reads, Conclusion: The products of rolling-circle replication are multiple circular D N A molecules.

The replication fork may continue around the circle a number of times, producing several linked copies of the same sequence. With each revolution around the circle, the growing 3′ end displaces the nucleotide strand synthesized in the preceding revolution. Eventually, the linear DNA molecule is cleaved from the circle, resulting in a double-stranded circular DNA molecule and a single-stranded linear DNA molecule. The linear molecule circularizes either before or after, serving as a template for the synthesis of a complementary strand.

LINEAR EUKARYOTIC REPLICATION

Circular DNA molecules that undergo theta or rolling-circle replication have a single origin of replication. Because of the limited size of these DNA molecules, replication starting from one origin can traverse the entire chromosome in a reasonable amount of time. The large linear chromosomes in eukaryotic cells, however, contain far too much DNA to be replicated speedily from a single origin. Eukaryotic replication proceeds at a rate ranging from 500 to 5000 nucleotides per minute at each

replication fork (considerably slower than bacterial replication). Even at 5000 nucleotides per minute at each fork, DNA synthesis starting from a single origin would require 7 days to replicate a typical human chromosome consisting of 100 million base pairs of DNA. The replication of eukaryotic chromosomes actually takes place in a matter of minutes or hours, not days. As discussed in the introduction to the chapter, this rapid rate is possible because replication is initiated at thousands of origins.

Typical eukaryotic replicons are from 20,000 to 300,000 base pairs in length (Table 12.1). At each origin of replication, the DNA unwinds and produces a replication bubble. Replication takes place on both strands at each end of the bubble, with the two replication forks spreading outward. Eventually, the replication forks of adjacent replicons run into each other, and the replicons fuse to form long stretches of newly synthesized DNA (Figure 12.6). Replication and fusion of all the replicons leads to two identical DNA molecules. Important features of theta replication, rolling-circle replication, and linear eukaryotic replication are summarized in Table 12.2. › **TRY** PROBLEM 22

TABLE 12.1 Number and length of replicons

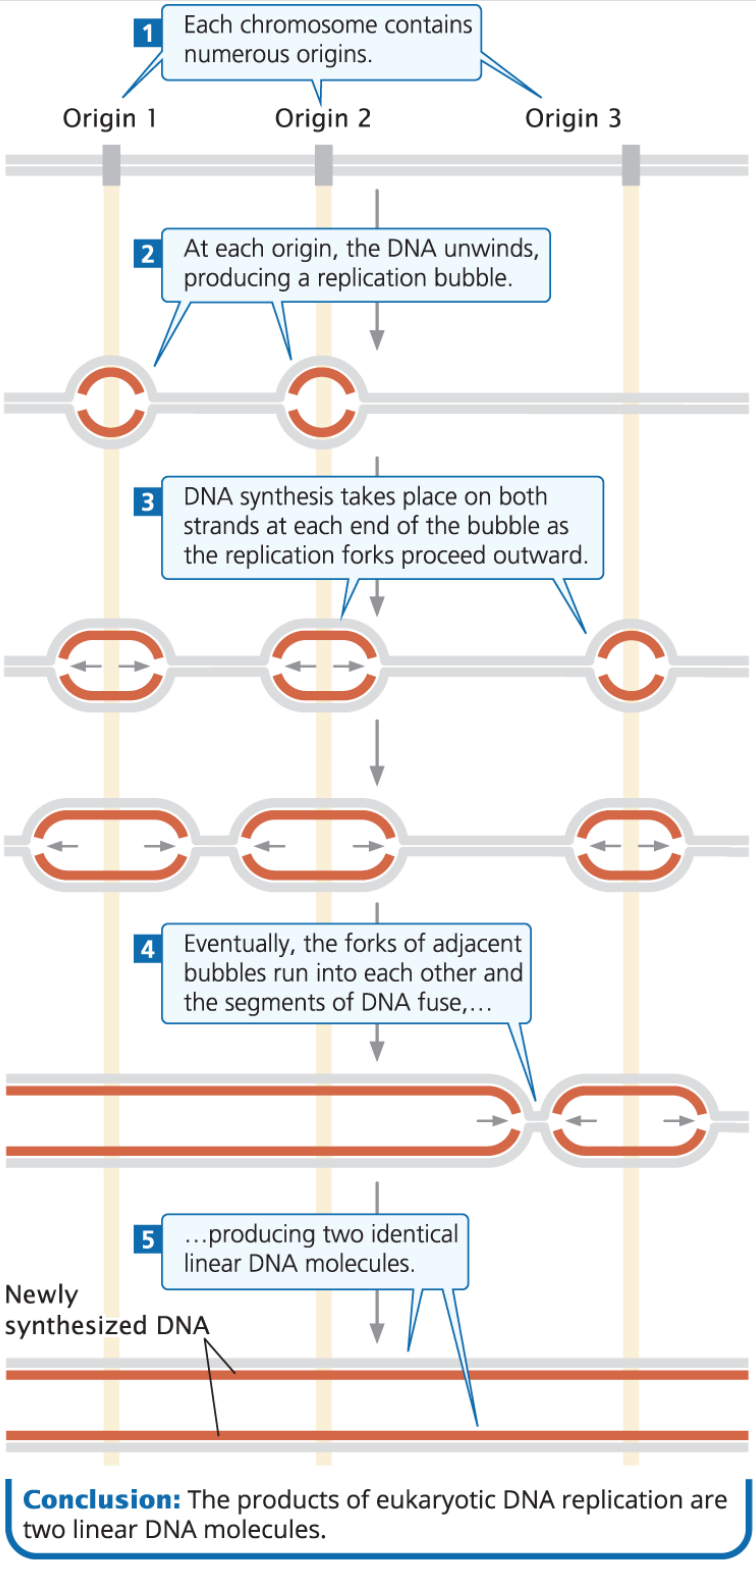
Organism	Number of Replication Origins	Average Length of Replicon (bp)
Escherichia coli (bacterium)	1	4,600,000
Saccharomyces cerevisiae (yeast)	500	40,000
Drosophila melanogaster (fruit fly)	3,500	40,000
Xenopus laevis (frog)	15,000	200,000
Mus musculus (mouse)	25,000	150,000

Data from B. L. Lewin, *Genes V* (Oxford: Oxford University Press, 1994), p. 536.

TABLE 12.2 Characteristics of theta, rolling-circle, and linear eukaryotic replication

Replication Model	DNA Template	Breakage of Nucleotide Strand	Number of Replicons	Unidirectional or Bidirectional	Products
Theta	Circular	No	1	Unidirectional or bidirectional	Two circular molecules

Rolling-circle	Circular	Yes	1	Unidirectional	One circular molecule and one linear molecule that may circularize
Linear eukaryotic	Linear	No	Many	Bidirectional	Two linear molecules



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020

12.6 Linear DNA replication takes place in eukaryotic chromosomes.

Description
The illustration shows different stages during the replication process, beginning with two linear D N A strands at the top. These linear D N As have 3 origins of replication: origin 1, origin 2, and origin 3. A caption reads, each chromosome contains numerous origins. In the next step below, the replication begins at origin 1 and origin 2 as the D N A unwinds and a semi circular replication bubble that is protruding outwards is formed. A caption reads, at each origin, the D N A unwinds, producing a replication bubble. In the next step below, the newly formed red D N A strands begin to increase in length as the replication bubble proceed outwards and a new replication bubble forms at origin 3. A caption reads, D N A synthesis takes place on both strands at each end of the bubble as the replication forks stretch outward. The newly formed D N A strands below keep increasing in size. A caption reads, eventually, the forks of adjacent bubbles run into each other and the segments of D N A fuse. The next step below shows the D N A strands newly synthesized at origin 1 and origin 2 fuse to become a linear D N A strand while the replication fork at origin C continues extending outwards. This leads to formation of 2 linear red colored, newly synthesized strands below for each of the older gray strands. A caption reads, producing two identical linear D N A molecules. A caption reads, Conclusion: The products of eukaryotic D N A replication are two linear D N A molecules.

CONCEPTS

Theta replication, rolling-circle replication, and linear eukaryotic replication differ with respect to the initiation and progression of replication, but all produce new DNA molecules by semiconservative replication.

✔ CONCEPT CHECK 2

Which type of replication requires a break in the nucleotide strand to get started?

a. Theta replication
b. Rolling-circle replication
c. Linear eukaryotic replication
d. All of the above

Requirements of Replication

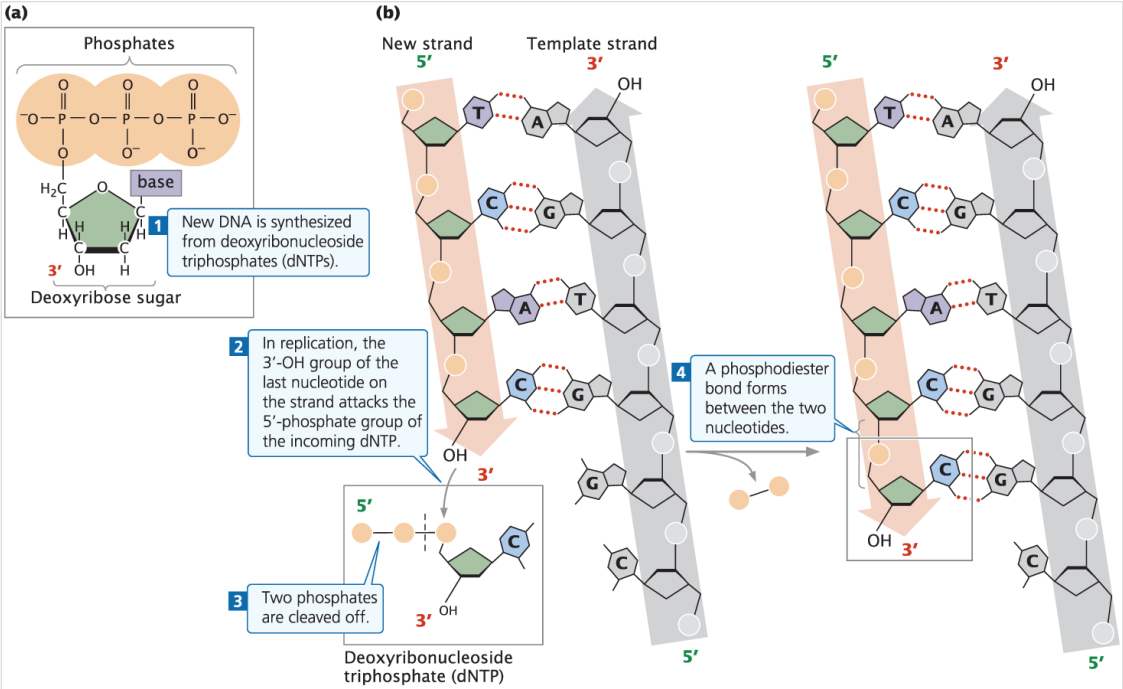
Although the process of replication includes many components, they can be combined into three major groups:

1. A template consisting of single-stranded DNA
2. Raw materials (substrates) to be assembled into a new nucleotide strand
3. Enzymes and other proteins that “read” the template and assemble the substrates into a DNA molecule

Because of the semiconservative nature of DNA replication, a double-stranded DNA molecule must unwind to expose the bases that act as a template for the assembly of new polynucleotide strands, which will be complementary and antiparallel to the template strands.

The raw materials from which new DNA molecules are synthesized are deoxyribonucleoside triphosphates (dNTPs), each consisting of a deoxyribose sugar and a base (a nucleoside) attached to

three phosphate groups (Figure 12.7a). In DNA synthesis, nucleotides are added to the 3′-OH group of the growing nucleotide strand (Figure 12.7b). The 3′-OH group of the last nucleotide on the strand attacks the 5′-phosphate group of the incoming dNTP. Two phosphate groups are cleaved from the incoming dNTP, and a phosphodiester bond is created between the two nucleotides.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

12.7 New DNA is synthesized from deoxyribonucleoside triphosphates (dNTPs). The newly synthesized strand is complementary and antiparallel to the template strand. The two strands are held together by hydrogen bonds (represented by red dotted lines) between the bases.

Description

Part a on the left shows a deoxyribonucleoside triphosphate. This molecule has a pentose sugar where C 1 and C 5 is bonded to a methylene group which is further bonded to 3 phosphate molecules. A caption reads, new D N A is synthesized from deoxyribonucleoside triphosphates or d N T Ps. Part b in the center shows a red colored newly synthesized strand forming from 5 prime to 3 prime to a grey colored template strand that runs from 5 prime to 3 prime. A d N T P containing the cytosine base being added to the ongoing strand and forming triple bond with a nucleotide containing guanine on the opposing strand. Similarly, T is double bonded to A. The nucleotides T, C, A, G are bonded to A, G, T, G respectively. A caption reads, In replication, the 3 prime O H group of the last nucleotide on the strand attacks the 5 prime phosphate group of the incoming d N T P. An illustration shows 2 magnified phosphate groups cleaving off from the d N T P. A caption reads, two phosphates are cleaved off. A new phosphodiester bond is formed between the two nucleotides. Part c on the right shows one more d N T P added to the newly synthesized strand. A caption reads, a phosphodiester bond forms between the 2 nucleotides.

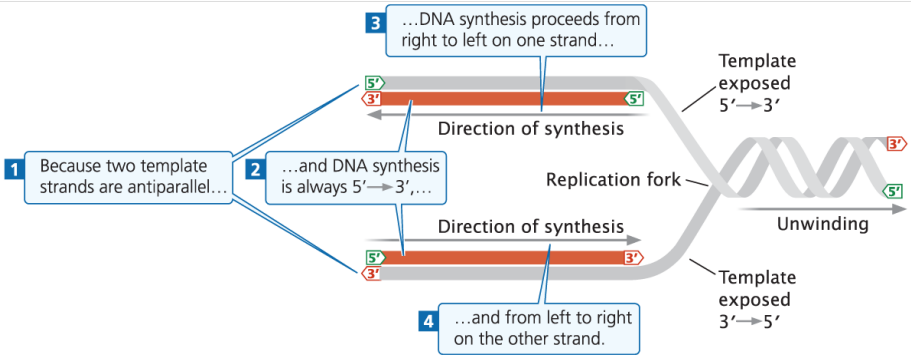
DNA synthesis does not happen spontaneously. Rather, it requires a host of enzymes and proteins that function in a coordinated manner. We examine this complex array of proteins and enzymes as we consider the replication process in more detail.

CONCEPTS

DNA synthesis requires a single-stranded DNA template, deoxyribonucleoside triphosphates, a growing nucleotide strand, and a group of enzymes and proteins.

Direction of Replication

In DNA synthesis, new nucleotides are joined one at a time to the 3′ end of the newly synthesized strand. **DNA polymerases**, the enzymes that synthesize DNA, can add nucleotides only to the 3′ end of the growing strand (not the 5′ end), so new DNA strands always elongate in the same 5′-to-3′ direction (5′ → 3′). Because the two single-stranded DNA templates are antiparallel and strand elongation is always 5′ → 3′, if synthesis on one template proceeds from, say, right to left, then synthesis on the other template must proceed in the opposite direction, from left to right (**Figure 12.8**). As DNA unwinds during replication, the antiparallel nature of the two DNA strands means that one template is exposed in the 5′ → 3′ direction and the other template is exposed in the 3′ → 5′ direction. So how can synthesis take place simultaneously on both strands at the replication fork?



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

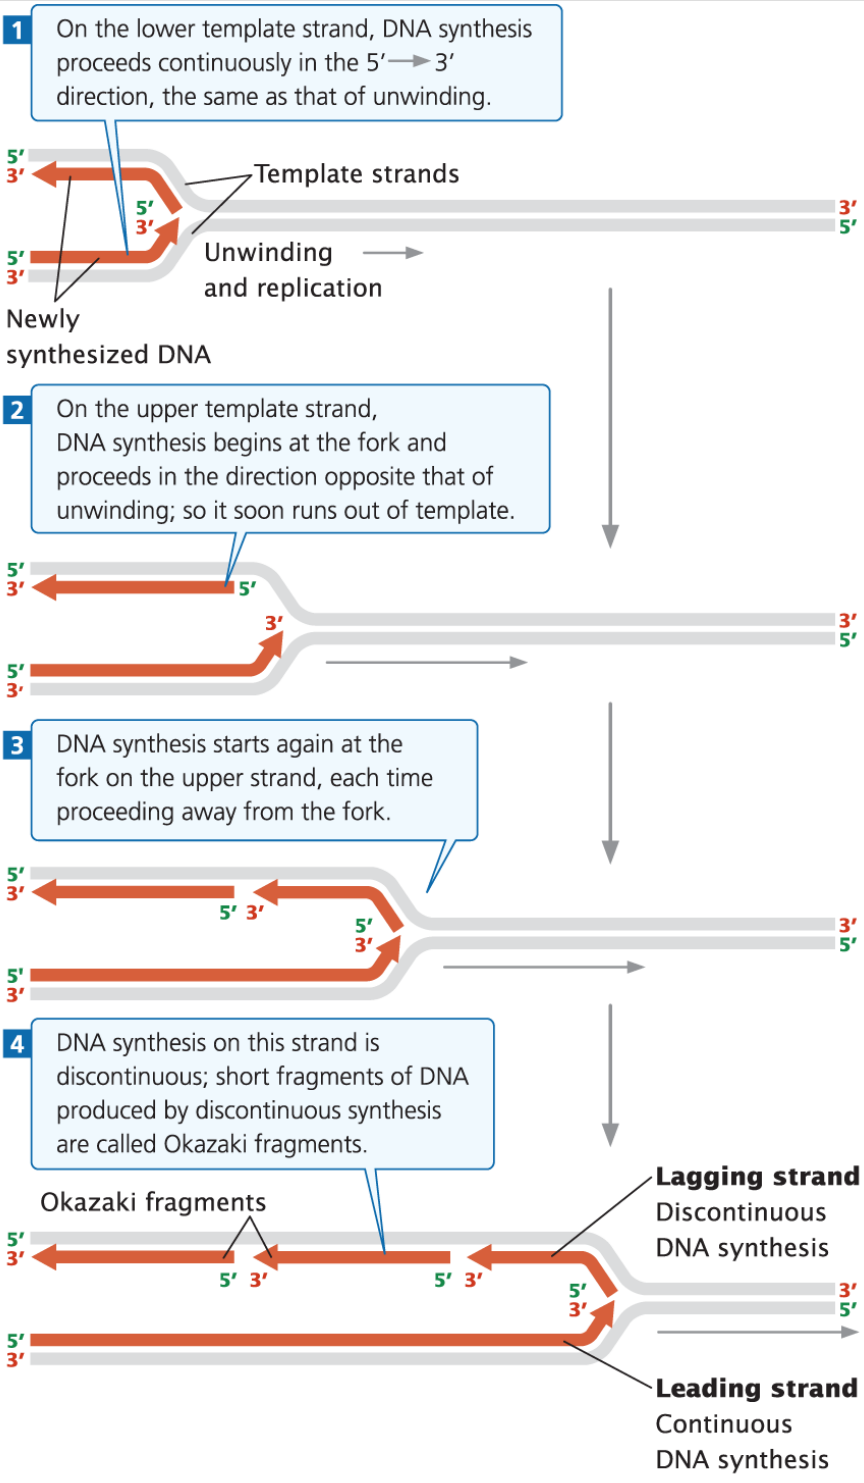
12.8 DNA synthesis takes place in opposite directions on the two DNA template strands. DNA replication at a single replication fork begins when a double-stranded DNA molecule unwinds to provide two single-stranded templates.

Description
The illustration shows a D N A molecule. The D N A strands are unwinding from left to right. A replication fork is present at the point where unwinding initiates. The template strands are antiparallel after unwinding. A caption reads, because two template strands are antiparallel and D N A synthesis is always 5 prime to 3 prime. For the top template strand that runs from 5 prime to 3 prime, the D N A synthesis occurs in opposite direction (right to left). A caption reads, D N A synthesis proceeds from right to left on one strand. For the bottom template strand that runs from 3 prime to 5 prime, the D N A synthesis occurs in opposite direction (left to right). A caption reads, and from left to right on the other strand.

CONTINUOUS AND DISCONTINUOUS REPLICATION

As the DNA unwinds, the template strand that is exposed in the 3′ → 5′ direction (the lower strand in Figures 12.8 and 12.9) allows the new strand to be synthesized continuously, in the 5′ → 3′ direction. This new strand, which undergoes **continuous replication**, is called the **leading strand**.

The other template strand is exposed in the 5′ → 3′ direction (the upper strand in Figures 12.8 and 12.9). After a short length of the DNA has been unwound, synthesis must proceed 5′ → 3′, that is, in the direction *opposite* that of unwinding (**Figure 12.9**). Because only a short length of DNA needs to be unwound before synthesis on this strand gets started, the replication machinery soon runs out of template. By that time, more DNA has unwound, providing a new template at the 5′ end of the new strand. DNA synthesis must start anew at the replication fork and proceed in the direction opposite that of the movement of the fork until it runs into the previously replicated segment of DNA. This process is repeated again and again, so synthesis of this strand is in short, discontinuous bursts. The newly made strand that undergoes **discontinuous replication** is called the **lagging strand**.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

12.9 DNA synthesis is continuous on one template strand of DNA and discontinuous on the other.

Description

The illustration shows a grey colored D N A double strand, at the top, that is unwinding from left to right. For the top D N A strand running from 5 prime to 3 prime, a red colored D N A strand is synthesized from light to left. For the bottom D N A strand running from 3 prime to 5 prime, a red colored D N A strand is synthesized from left to right. A caption reads, on the lower template strand, D N A synthesis proceeds continuously in the 5 prime to 3 prime direction, the same as that of unwinding. In the next step below, the newly synthesized D N A strand for the top D N A strand runs out of template. A caption reads, on the upper template strand, D N A synthesis begins at the fork and proceeds in the direction opposite that of unwinding; so it soon runs out of template. As the unwinding proceeds, another new strand begins from right to left at the top template strand. A caption reads, D N A synthesis starts again at the fork on the upper strand, each time proceeding away from the fork. The unwinding proceeds further to a third D N A strand below, known as the lagging strand, which starts from right to left on the top template strand. The newly synthesized discontinuous D N A strands on the top template strand are called Okazaki fragments and the single newly synthesized continuous strand at the bottom template strand is called the leading strand. A caption reads, D N A synthesis on this strand is discontinuous; short fragments of D N A produced by discontinuous synthesis are called Okazaki fragments.

OKAZAKI FRAGMENTS

The short lengths of DNA produced by discontinuous replication of the lagging strand are called **Okazaki fragments**, after Reiji Okazaki, who discovered them. In bacterial cells, each Okazaki fragment ranges from about 1000 to 2000 nucleotides in length; in eukaryotic cells, they are about 100 to 200 nucleotides long. Okazaki fragments on the lagging strand are linked together to create a continuous new DNA molecule. To see how replication occurs continuously on one strand and discontinuously on the other, view (A) **Animation 12.1**.

CONCEPTS

All DNA synthesis is 5′ → 3′, meaning that new nucleotides are always added to the 3′ end of the growing nucleotide strand. At each replication fork, synthesis of the leading strand proceeds continuously and that of the lagging strand proceeds discontinuously.

✔ CONCEPT CHECK 3

Discontinuous replication is a result of which property of DNA?

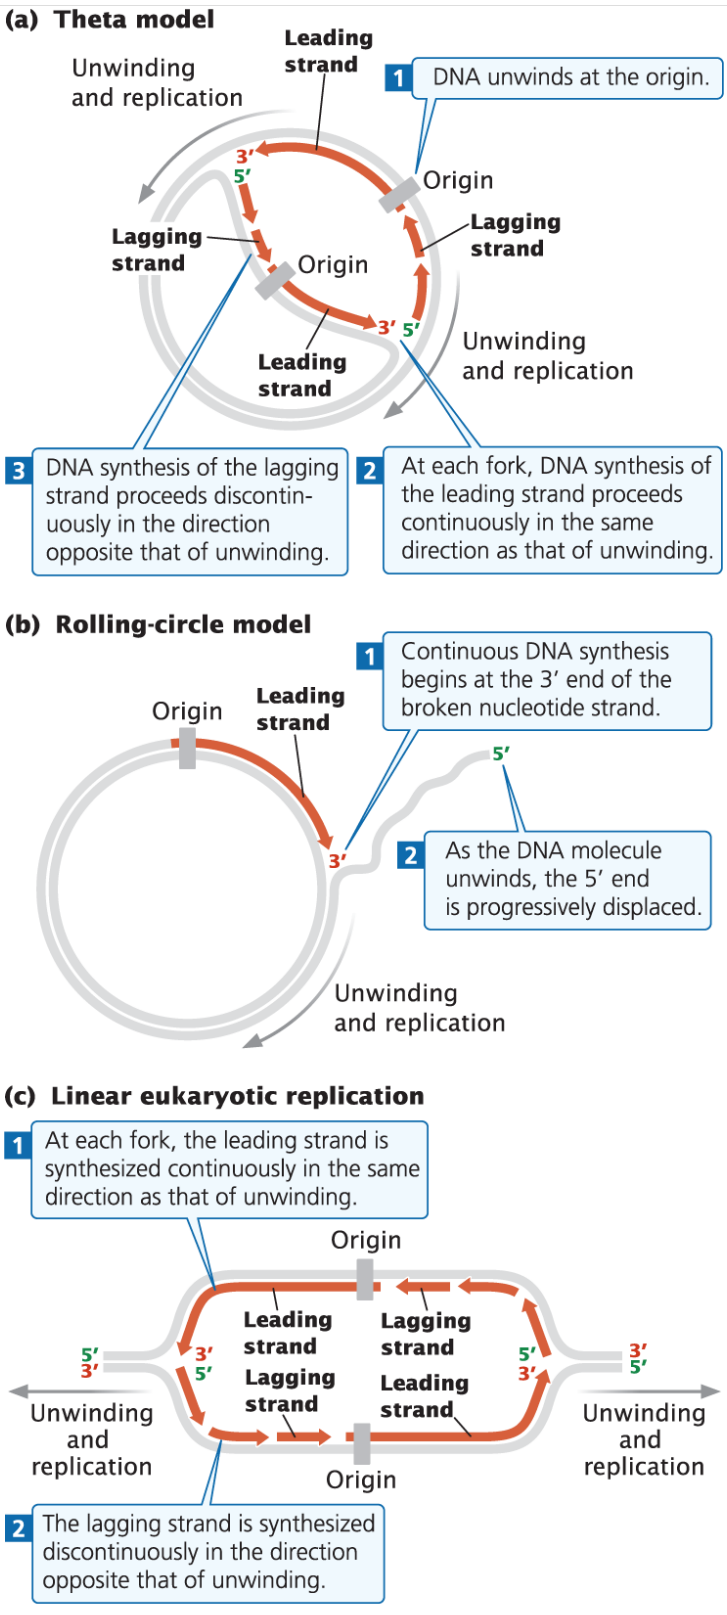
a. Complementary bases
b. Charged phosphate group
c. Antiparallel nucleotide strands
d. Five-carbon sugar

CONNECTING CONCEPTS CONNECT

The Direction of Synthesis in Different Modes of Replication

Let's relate the direction of DNA synthesis to the modes of replication examined earlier. In theta replication (**Figure 12.10a**), the DNA unwinds at one particular location, the origin, and a replication bubble is formed. If the bubble has two replication forks, one at each end, synthesis takes place simultaneously at both forks (bidirectional replication). At each fork, synthesis on one of the template strands proceeds in the same direction as that of unwinding; this newly replicated strand is the leading strand and is replicated continuously. On the other template strand, synthesis proceeds in the direction opposite that of unwinding; this newly synthesized strand is the lagging strand and is replicated discontinuously. Focus on just one of the template strands within the bubble. Notice that synthesis on this template strand is continuous at one

fork but discontinuous at the other. This difference arises because DNA synthesis is always in the same direction (5′ → 3′), but the two forks are moving in opposite directions.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

12.10 The process of replication differs in theta replication, rolling-circle replication, and linear eukaryotic replication.

Description
Part a at the top shows theta replication. Circular D N A double strands unwinds at the origin on both the strands. A caption reads, D N A unwinds at the origin. The unwinding and replication occur in both directions clockwise and anticlockwise from the origin. For the outer strand, the discontinuous lagging strand is synthesized anticlockwise and the continuous leading strand is also synthesized in the same direction (5 prime to 3 prime). A caption reads, at each fork, D N A synthesis of the leading strand proceeds continuously in the same direction as that of unwinding. For the inner strand, the continuous leading strand and discontinuous lagging strand are also anticlockwise. A caption reads, D N A synthesis of the lagging strand proceeds discontinuously in the direction opposite that of unwinding. Part b below shows rolling circle model. Circular D N A double strands unwinds at the origin in a clockwise direction. A continuous leading strand is synthesized in clockwise direction. A caption reads, continuous D N A synthesis begins at the 3 prime end of the broken nucleotide strand. As the leading strand is synthesized, the 5 prime end of the outer original D N A strand is displaced from its 5 prime end. A caption reads, as the D N A molecule unwinds, the 5 prime end is progressively displaced. Part c below shows linear eukaryotic replication. A double stranded D N A molecule unwinds in both left and right directions as a replication bubble is formed. The top strand, discontinuous lagging strand, and continuous leading strand are synthesized from right to left (from 5 prime to 3 prime). A caption reads, at each fork, the leading strand is synthesized continuously in the same direction as that of unwinding. The bottom strand, discontinuous lagging strand, and continuous leading strand are synthesized from left to right (from 5 prime to 3 prime). A caption reads, the lagging strand is synthesized discontinuously in the direction opposite that of unwinding.

Rolling-circle replication (**Figure 12.10b**) is somewhat different because there is no replication bubble. Replication begins at the 3′ end of the broken nucleotide strand. Continuous replication takes place on the circular template as new nucleotides are added to this 3′ end.

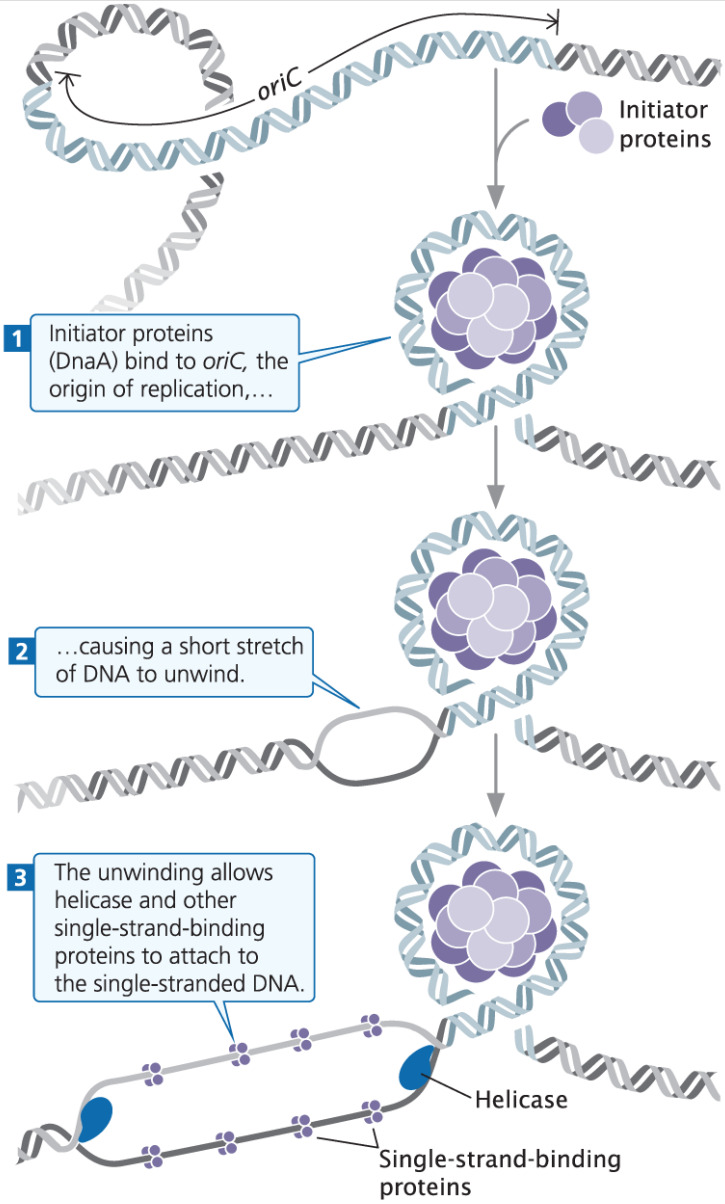
The replication of linear molecules of DNA, such as those found in eukaryotic cells, produces a series of replication bubbles (**Figure 12.10c**). DNA synthesis in these bubbles is the same as that in the single replication bubble of theta replication; it begins at the center of each replication bubble and proceeds at two forks, one at each end of the bubble. At both forks, synthesis of the leading strand proceeds in the same direction as that of unwinding, whereas synthesis of the lagging strand proceeds in the direction opposite that of unwinding. ❯ **TRY PROBLEM 24a–c**

12.3 Bacterial Replication Requires a Large Number of Enzymes and Proteins

Replication takes place in four stages: initiation, unwinding, elongation, and termination. The following discussion of the process of replication will focus on bacterial systems, in which replication has been most thoroughly studied and is best understood. Although many aspects of replication in eukaryotic cells are similar to those in bacterial cells, there are some important differences. We compare bacterial replication with eukaryotic and archaeal replication in Section 12.4.

Initiation

The circular chromosome of *E. coli* has a single origin of replication (*oriC*). The minimal sequence required for *oriC* to function consists of 245 bp that contain several critical sites. **Initiator proteins** (known as DnaA in *E. coli*) bind to *oriC* and cause a short section of DNA to unwind. This unwinding allows helicase and other single-strand-binding proteins to attach to the polynucleotide strand (**Figure 12.11**).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

12.11 *E. coli* DNA replication begins when initiator proteins bind to *oriC*, the origin of replication.

Description

The illustration shows a stretch of D N A duplex, at the top, with a part in middle labeled o r i C. This stretch of D N A loops around initiator proteins. A caption reads, initiator proteins (D N A A) bind to O r i C, the origin of replication, causing a short stretch of D N A to unwind. In the next step below, two helicase proteins attach at a replication fork site each.

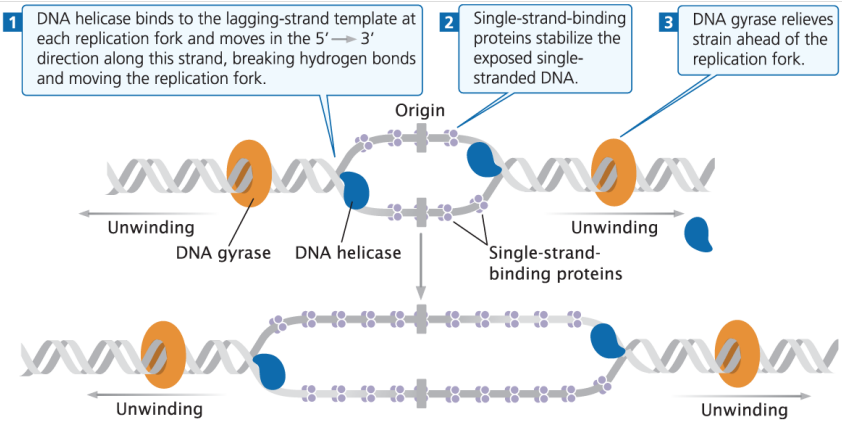
The template strands formed below have multiple clusters of single strand binding proteins attached to them. A caption reads, the unwinding allows helicase and other single-strand-binding proteins to attach to the single-stranded D N A.

Unwinding

DNA synthesis requires a single-stranded template, and therefore double-stranded DNA must be unwound before DNA synthesis can take place. The cell relies on several proteins and enzymes to accomplish the unwinding.

DNA HELICASE

DNA helicase breaks the hydrogen bonds that exist between the bases of the two nucleotide strands of a DNA molecule. In bacteria, helicase cannot *initiate* the unwinding of double-stranded DNA; the initiator protein first separates DNA strands at the origin, providing a short stretch of single-stranded DNA. Initiator protein, loader proteins, and other accessary proteins then recruit and load helicase onto the single-stranded DNA at each replication fork. Once bound to single-stranded DNA, helicase moves in the 5′→3′ direction along this strand, thus also moving the replication fork (**Figure 12.12**).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

12.12 DNA helicase unwinds DNA by binding to the lagging-strand template at each replication fork and moving in the 5′→3′ direction.

Description

The illustration shows a D N A double strand at the top where two helicase proteins are attached to one replication fork each. Three single strand binding proteins are attached to each of the template strands flanking the origin. The D N A is unwinding in both directions outwards from the replication forks formed. On both sides of the helicase proteins, one D N A gyrase molecule is encircling the original D N A double strand. A caption reads, D N A helicase binds to the lagging strand template at each replication fork and moves in the 5 prime to 3 prime direction along this strand, breaking hydrogen bonds and moving the replication fork. Single-strand-binding proteins stabilize the exposed single-stranded D N A. D N A gyrase relieves strain ahead of the replication fork. In the next step below, more single strand binding proteins are attached to each of the strands as the unwinding of the original D N A double strand continues.

SINGLE-STRAND-BINDING PROTEINS

After DNA has been unwound by helicase, **single-strand-binding proteins (SSBs)** attach tightly to the exposed single-stranded DNA (see Figure 12.12). These proteins protect the single-stranded

nucleotide chains and prevent the formation of secondary structures such as hairpins (see Figure 10.18) that would interfere with replication. Unlike many DNA-binding proteins, SSBs are indifferent to base sequence: they will bind to any single-stranded DNA. Single-strand-binding proteins form tetramers (groups of four); each tetramer covers from 35 to 65 nucleotides.

DNA GYRASE

Another protein essential for the unwinding process is the enzyme **DNA gyrase**, a topoisomerase. As discussed in Chapter 11 and the introduction to this chapter, topoisomerases control the supercoiling of DNA. They come in two major types: type I topoisomerases alter supercoiling by making single-strand breaks in DNA, while type II topoisomerases create double-strand breaks. DNA gyrase is a type II topoisomerase. In replication, it reduces the torsional strain (torque) that builds up ahead of the replication fork as a result of unwinding (see Figure 12.12). It reduces torque by making a double-strand break in one segment of the DNA helix, passing another segment of the helix through the break, and then resealing the broken ends of the DNA. This action, which requires ATP, removes a twist in the DNA and reduces the supercoiling.

A group of antibiotics called 4-quinolones kill bacteria by binding to DNA gyrase and inhibiting its action. The inhibition of DNA gyrase results in the cessation of DNA synthesis and bacterial growth. An example of a 4-quinolone is nalidixic acid, which was first

introduced in the 1960s and is commonly used to treat urinary infections. Many bacteria have acquired resistance to quinolones through mutations in the gene for DNA gyrase.

CONCEPTS

Replication is initiated at an origin of replication, where an initiator protein binds and causes a short stretch of DNA to unwind. DNA helicase breaks hydrogen bonds at a replication fork, and single-strand-binding proteins stabilize the separated strands. DNA gyrase reduces the torsional strain that develops as the two strands of double-helical DNA unwind.

✔ CONCEPT CHECK 4

Place the following components in the order in which they are first used in the course of replication: helicase, single-strand-binding protein, DNA gyrase, initiator protein.

Elongation

In the elongation stage of replication, single-stranded DNA is used as a template for the synthesis of DNA. This process requires a series of enzymes.

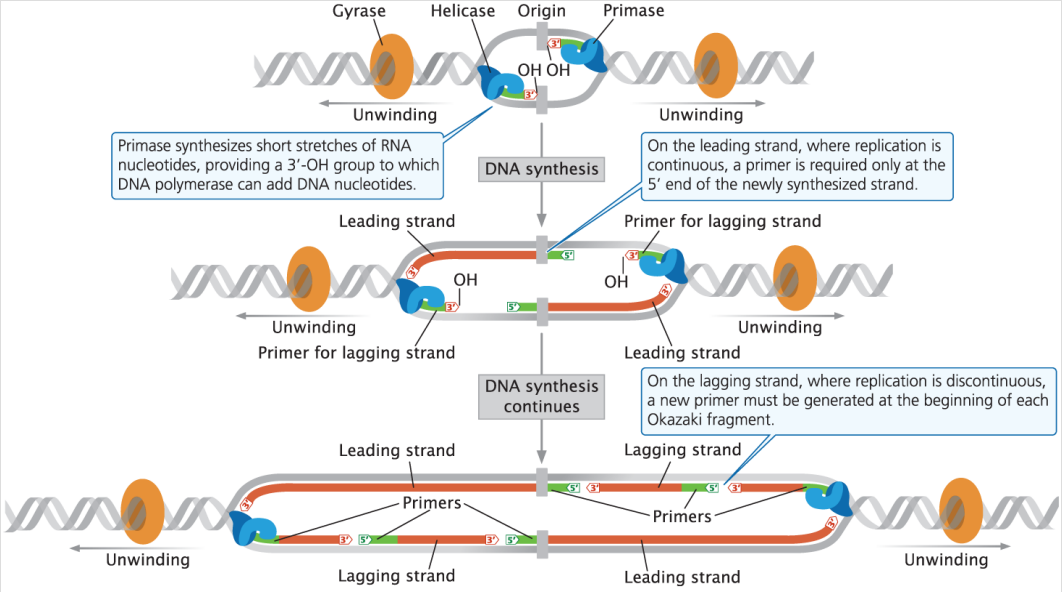
THE SYNTHESIS OF PRIMERS

All DNA polymerases require a nucleotide with a 3′-OH group to which a new nucleotide can be added. Because of this requirement,

DNA polymerases cannot initiate DNA synthesis on a bare template; rather, they require an existing 3′-OH group to get started. How, then, does DNA synthesis begin?

An enzyme called **primase** synthesizes short stretches (about 10–12 nucleotides long) of RNA nucleotides, or **primers**, which provide a 3′-OH group to which DNA polymerases can attach DNA nucleotides. (Because primase is an RNA polymerase, it does not require a preexisting 3′-OH group to start synthesis of a nucleotide strand.) All newly synthesized DNA molecules have short RNA primers embedded within them; these primers are later removed and replaced with DNA nucleotides.

On the leading strand at a replication fork, where DNA synthesis is continuous, a primer is required only at the 5′ end of the newly synthesized strand. On the lagging strand, where replication is discontinuous, a new primer must be generated at the beginning of each Okazaki fragment (**Figure 12.13**). Primase forms a complex with helicase at the replication fork and moves along the template of the lagging strand. The single primer on the leading strand is probably synthesized by the primase–helicase complex on the template of the lagging strand of the *other* replication fork, at the opposite end of the replication bubble. ❯ **TRY PROBLEM 29**



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

12.13 Primase synthesizes short stretches of RNA nucleotides, providing a 3′-OH group to which DNA polymerase can add DNA nucleotides.

Description

The illustration shows a D N A double strand, at the top, where two helicase proteins are attached to one replication fork each. The D N A is unwinding in both directions outwards from the replication forks formed. On both sides of the helicase proteins, one D N A gyrase molecule is encircling the original D N A double strand. A primase with a 3 prime O H group attaches to each of the helicase protein. A caption reads, primase synthesizes short stretches of R N A nucleotides, providing a 3 prime O H group to which D N A polymerase can add D N A nucleotides. D N A synthesis occurs below and a continuous leading strand is synthesized on the top strand and another continuous leading strand is synthesized on the bottom strand. A primer for lagging strand is bound to each of the helicase protein. A caption reads, on the leading strand, where replication is continuous, a primer is required only at the 5 prime end of the newly synthesized strand. The D N A synthesis continues below and the unwinding progresses. Two lagging strands are synthesized on each template strands while the leading strands continue to increase in length. A new primer is generated at the start of each Okazaki fragment. The unwinding continues and a caption reads, on the lagging strand, where replication is discontinuous, a new primer must be generated at the beginning of each Okazaki fragment.

CONCEPTS

Primase synthesizes a short stretch of RNA nucleotides (a primer), which provides a 3′-OH group for the attachment of DNA nucleotides to start DNA synthesis.

✔ CONCEPT CHECK 5

Primers are synthesized where on the lagging strand?

a. Only at the 5′ end of the newly synthesized strand
b. Only at the 3′ end of the newly synthesized strand
c. At the beginning of every Okazaki fragment
d. At multiple places within an Okazaki fragment

DNA SYNTHESIS BY DNA POLYMERASES

After DNA has unwound and a primer has been added, DNA polymerases elongate the new polynucleotide strand by catalyzing DNA polymerization. The best-studied polymerases are those of *E. coli*, which has at least five different DNA polymerases. Two of them, DNA polymerase I and DNA polymerase III, carry out DNA synthesis in replication; the other three have specialized functions in DNA repair (Table 12.3).

TABLE 12.3 Characteristics of DNA polymerases in *E. coli*

DNA Polymerase	5′→3′ Polymerase Activity	3′→5′ Exonuclease Activity	5′→3′ Exonuclease Activity	Function
I	Yes	Yes	Yes	Removes and replaces primers

II	Yes	Yes	No	DNA repair; restarts replication after damaged DNA halts synthesis
III	Yes	Yes	No	Elongates DNA
IV	Yes	No	No	DNA repair
V	Yes	No	No	DNA repair; translesion DNA synthesis

DNA polymerase III is a large multiprotein complex that acts as the main workhorse of replication. DNA polymerase III synthesizes DNA by adding new nucleotides to the 3′ end of a growing DNA strand. This enzyme has two enzymatic activities (see Table 12.3). Its 5′→3′ polymerase activity allows it to add new nucleotides in the 5′→3′ direction. Its 3′→5′ exonuclease activity allows it to remove nucleotides in the 3′→5′ direction, enabling it to correct errors. If a nucleotide with an incorrect base is inserted into the growing DNA strand, DNA polymerase III uses its 3′→5′ exonuclease activity to back up and remove the incorrect nucleotide. It then resumes its 5′→3′ polymerase activity. These two functions together allow DNA polymerase III to efficiently and accurately synthesize new DNA molecules. DNA polymerase III has high *processivity*, which means that it is capable of adding many nucleotides to the growing DNA strand without releasing the template: it normally holds on to the template and continues synthesizing DNA until the template has been completely replicated. The high processivity of DNA polymerase III is ensured by one of the polypeptides that constitutes the enzyme. This ring-shaped polypeptide, termed the ***β* sliding**

clamp, encircles the DNA and allows the polymerase to slide easily along the DNA template strand during replication. DNA polymerase III adds DNA nucleotides to the primer, synthesizing the DNA of both the leading and the lagging strands.

The first *E. coli* polymerase to be discovered, **DNA polymerase I**, also has 5′ → 3′ polymerase and 3′ → 5′ exonuclease activities (see Table 12.3), which allow the enzyme to synthesize DNA and to correct errors. Unlike DNA polymerase III, however, DNA polymerase I also possesses 5′ → 3′ exonuclease activity, which is used to remove the primers laid down by primase and replace them with DNA nucleotides by synthesizing in a 5′ → 3′ direction (see Figure 12.14). After DNA polymerase III has initiated synthesis at a primer and moved downstream, DNA polymerase I removes the RNA nucleotides of the primer, replacing them with DNA nucleotides. DNA polymerase I has lower processivity than does DNA polymerase III. The removal and replacement of primers appears to constitute the main function of DNA polymerase I. DNA polymerases II, IV, and V function in DNA repair.

Despite their differences, all of *E. coli*'s DNA polymerases

- synthesize any sequence specified by the template strand;
- synthesize in the 5′ → 3′ direction by adding nucleotides to a 3′-OH group;
- use dNTPs to synthesize new DNA;
- require a 3′-OH group to initiate synthesis;

- catalyze the formation of a phosphodiester bond by joining the 5′-phosphate group of the incoming nucleotide to the 3′-OH group of the preceding nucleotide on the growing strand, cleaving off two phosphates in the process;
- produce newly synthesized strands that are complementary and antiparallel to the template strands;
- are associated with a number of other proteins. **› TRY PROBLEM 26**

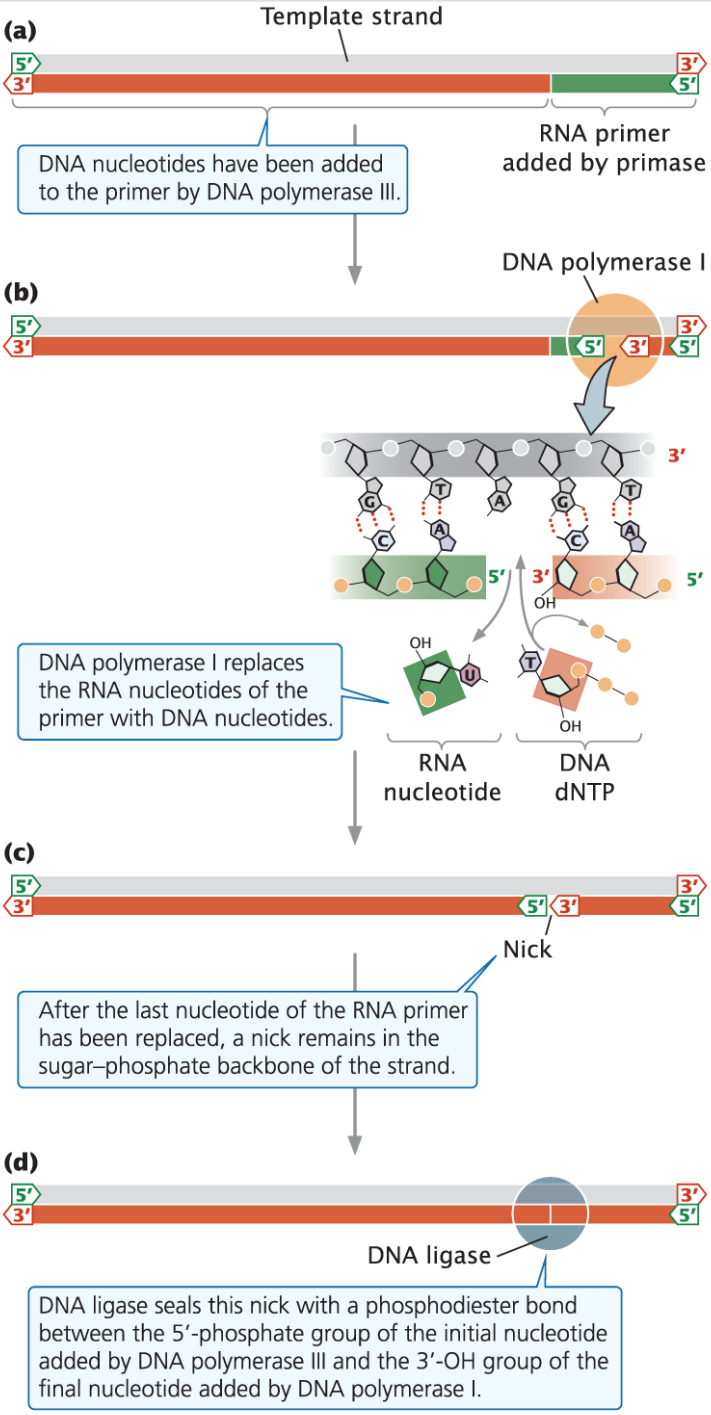
CONCEPTS

DNA polymerases synthesize DNA in the 5′ → 3′ direction by adding new nucleotides to the 3′ end of a growing nucleotide strand.

PRIMER REPLACEMENT AND DNA LIGASE

After DNA polymerase III attaches a DNA nucleotide to the 3′-OH group on the last nucleotide of the RNA primer, each new DNA nucleotide then provides the 3′-OH group needed for the next DNA nucleotide to be added. This process continues as long as a template is available (Figure 12.14a). DNA polymerase I follows DNA polymerase III and, using its 5′ → 3′ exonuclease activity, removes the RNA primer. It then uses its 5′ → 3′ polymerase activity to replace the RNA nucleotides with DNA nucleotides. DNA polymerase I attaches the first nucleotide to the OH group at the 3′ end of the preceding Okazaki fragment and then continues, in the 5′ → 3′ direction along

the nucleotide strand, removing and replacing, one at a time, the RNA nucleotides of the primer (Figure 12.14b).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

12.14 DNA ligase seals the nick left by DNA polymerase I in the sugar–phosphate backbone.

Description
Part a, at the top, shows a template D N A strand running from 5 prime to 3 prime. Below it is a newly synthesized D N A strand and towards the right side is a R N A primer added by primase. A caption reads, D N A nucleotides have been added to the primer by D N A polymerase 3. Part b below shows a round D N A polymerase 1 molecule attached to the D N A double strand at the site of R N A primer. An illustration shows the magnified view of polymerase replacing R N A nucleotides with the D N A nucleotides (d N T P). A caption reads, D N A polymerase 1 replaces the R N A nucleotide of the primer with D N A nucleotides. Part c below shows D N A template strand and below it; a larger newly synthesized strand and one shorter newly synthesized strand. The 3 prime end of shorter newly synthesized strand is adjacent to the 5 prime end of the larger strand with a small nick between them. A caption reads, After the last nucleotide of the R N A primer has been replaced, a nick remains in the sugar-phosphate backbone of the strand. Part d below shows a D N A ligase molecule encircling the strands at the site of the nick. A caption reads, D N A ligase seals this nick with a phosphodiester bond between the 5 prime P group of the initial nucleotide added by D N A polymerase 3 and the 3 prime O H group of the final nucleotide added by D N A polymerase 1.

After polymerase I has replaced the last nucleotide of the RNA primer with a DNA nucleotide, a break (or nick) remains in the sugar–phosphate backbone of the new DNA strand because the 3′-OH group of the last nucleotide to have been added by DNA polymerase I is not attached to the 5′-phosphate group of the first nucleotide added by DNA polymerase III (**Figure 12.14c**). This nick is sealed by the enzyme **DNA ligase**, which catalyzes the formation of a phosphodiester bond without adding another nucleotide to the

strand (Figure 12.14d). Some of the major enzymes and proteins required for bacterial DNA replication are summarized in Table 12.4.

TABLE 12.4 Components required for replication in bacterial cells

Component	Function
Initiator protein	Binds to origin and separates strands of DNA to initiate replication
DNA helicase	Unwinds DNA at replication fork
Single-strand-binding proteins	Attach to single-stranded DNA and prevent secondary structures from forming
DNA gyrase	Moves ahead of the replication fork, making and resealing breaks in the double-helical DNA to release the torque that builds up as a result of unwinding at the replication fork
DNA primase	Synthesizes a short RNA primer to provide a 3′-OH group for the attachment of DNA nucleotides
DNA polymerase	Elongates a new nucleotide strand from the 3′-OH group provided by the primer

III	
DNA polymerase I	Removes RNA primers and replaces them with DNA
DNA ligase	Joins Okazaki fragments by sealing breaks in the sugar–phosphate backbone of newly synthesized DNA

CONCEPTS

After primers have been removed and replaced, the nick in the sugar–phosphate backbone of the new DNA strand is sealed by DNA ligase.

✔ CONCEPT CHECK 6

Which bacterial enzyme removes the primers?

a. Primase
b. DNA polymerase I
c. DNA polymerase III
d. Ligase

ELONGATION AT THE REPLICATION FORK

Now that the major enzymatic components of elongation—DNA polymerases, helicase, primase, and ligase—have been introduced, let's consider how these components interact at the replication fork.

Because the synthesis of the leading and lagging strands takes place simultaneously, two units of DNA polymerase III must be present at the replication fork, one for each strand. These two units of DNA polymerase III are connected; the lagging-strand template loops around so that it is in position for 5′ → 3′ replication. In this way, the DNA polymerase III complex is able to carry out 5′ → 3′ replication simultaneously on both templates, even though they run in opposite directions. See how replication takes place on both strands simultaneously by viewing **Animation 12.2**.

In summary, each active replication fork requires five basic components:

1. Helicase to unwind the DNA
2. Single-strand-binding proteins to protect the single nucleotide strands and prevent secondary structures
3. DNA gyrase to remove strain ahead of the replication fork
4. Primase to synthesize primers with a 3′-OH group at the beginning of each DNA fragment
5. DNA polymerase to synthesize the leading and lagging nucleotide strands

You can see how the different components of the replication process work together by viewing **Animation 12.3** and **Animation 12.4**.

Termination

In some DNA molecules, replication is terminated whenever two replication forks meet. In others, specific termination sequences (called *Ter* sites) block further replication. A termination protein, called Tus in *E. coli*, binds to these sequences, creating a Tus-*Ter* complex that blocks the movement of helicase, thus stalling the replication fork and preventing further DNA replication. Each Tus-*Ter* complex blocks a replication fork moving in one direction but not the other.

The Fidelity of DNA Replication

Overall, the error rate in replication is less than one mistake per billion nucleotides. How is this incredible accuracy achieved?

DNA polymerases are very particular in pairing nucleotides with their complements on the template strand. Errors in nucleotide selection by DNA polymerase arise only about once per 100,000 nucleotides. Most of the errors that do arise in nucleotide selection are corrected in a second process called **proofreading**. When a DNA polymerase inserts an incorrect nucleotide into the growing strand, the 3′-OH group of the mispaired nucleotide is not correctly positioned in the active site of the DNA polymerase for accepting the next nucleotide. The incorrect positioning stalls the polymerization reaction, and the 3′ → 5′ exonuclease activity of DNA polymerase removes the incorrectly paired nucleotide. DNA polymerase then

inserts the correct nucleotide. Together, proofreading and nucleotide selection result in an error rate of only one in 10 million nucleotides.

A third process, called **mismatch repair** (discussed further in Chapter 18), corrects errors after replication is complete. Any incorrectly paired nucleotides remaining after replication produce a deformity in the secondary structure of the DNA; that deformity is recognized by enzymes, which excise the incorrectly paired nucleotide and use the original nucleotide strand as a template to replace the incorrect nucleotide. Mismatch repair thus requires the ability to distinguish between the old and the new strands of DNA because the enzymes need some way of determining which of the two incorrectly paired bases to remove. In *E. coli*, methyl groups (—CH_3) are added to particular nucleotide sequences but only *after* replication. Thus, immediately after DNA synthesis, only the old DNA strand is methylated. It can therefore be distinguished from the newly synthesized strand, and mismatch repair takes place preferentially on the unmethylated nucleotide strand. No single process could produce this level of accuracy; a series of processes are required, each process catching errors missed by the preceding ones.

THINK-PAIR-SHARE Question 3

CONCEPTS

DNA replication is extremely accurate, with less than one error per billion nucleotides. The high level of accuracy in DNA replication is produced by precise nucleotide selection, proofreading, and mismatch repair.

✔ CONCEPT CHECK 7

Which mechanism requires the ability to distinguish between newly synthesized and template strands of DNA?

a. Nucleotide selection
b. DNA proofreading
c. Mismatch repair
d. All of the above

CONNECTING CONCEPTS CONNECT

The Basic Rules of Replication

Bacterial DNA replication requires a number of enzymes (see Table 12.4), proteins, and DNA sequences that function together to synthesize a new DNA molecule. These components are important, but we must not become so immersed in the details of the process that we lose sight of the general principles of replication.

1. Replication is always semiconservative.
2. Replication begins at sequences called origins of replication.
3. DNA synthesis begins with the synthesis of short segments of RNA called primers.
4. The elongation of DNA strands is always in the 5′ → 3′ direction.
5. New DNA is synthesized from dNTPs; in the polymerization of DNA, two phosphate groups are cleaved from a dNTP, and the resulting nucleotide is added to the 3′-OH group of the growing nucleotide strand.
6. Replication is continuous on the leading strand and discontinuous on the lagging strand.
7. New nucleotide strands are complementary and antiparallel to their template strands.
8. Replication takes place at very high rates and is astonishingly accurate, thanks to precise nucleotide selection, proofreading, and mismatch repair.

12.4 Eukaryotic DNA Replication Is Similar to Bacterial Replication but Differs in Several Aspects

Although eukaryotic replication resembles bacterial replication in many respects, replication in eukaryotic cells presents several additional challenges. First, the much greater size of eukaryotic genomes requires that replication be initiated at multiple origins. Second, eukaryotic chromosomes are linear, whereas prokaryotic chromosomes are circular. Third, the DNA template is associated with histone proteins in the form of nucleosomes, and nucleosome assembly must immediately follow DNA replication.

Eukaryotic Origins of Replication

Researchers first isolated eukaryotic origins of replication from yeast cells by demonstrating that certain DNA sequences confer the ability to replicate when transferred from a yeast chromosome to small circular pieces of DNA (plasmids). These **autonomously replicating sequences (ARSs)** enabled any DNA they were attached to to replicate. They were subsequently shown to be the origins of replication in yeast chromosomes. The nature of origins of replication in many multicellular eukaryotes are still poorly understood. Origins in different eukaryotic organisms vary greatly in sequence, although they usually contain a number of A–T base pairs. Evidence suggests that eukaryotic origins are often defined more by modifications to chromatin structure (epigenetic modifications, see Chapter 21) than by specific sequences. A multiprotein complex, the **origin-recognition**

complex (ORC), serves as the initiator by binding to defined origins and initiating replication. In multicellular eukaryotes, there are often many more potential replication origins than are actually used during DNA synthesis. Whether the sites that are used are determined at random or are somehow specified is not known.

Another difference in replication of eukaryotes involves the role of the initiator. In bacteria, helicase is unable to bind to double-stranded DNA; initiator protein first melts DNA, creating a single-stranded template that helicase then binds to. In eukaryotes, however, the initiator ORC recruits and loads helicase onto double-stranded DNA at the origin. This takes place during G_1 of the cell cycle. Then during S phase, helicase becomes activated and begins separating double-stranded DNA into single-stranded templates that are used in DNA synthesis.

CONCEPTS

Eukaryotic DNA contains many origins of replication. At each origin, a multiprotein origin-recognition complex binds to double-stranded DNA and recruits helicase to the origin.

✔ CONCEPT CHECK 8

In comparison with prokaryotes, what are some differences in the genome structure of eukaryotic cells that affect how replication takes place?

DNA Synthesis and the Cell Cycle

In rapidly dividing bacteria, DNA replication is continuous. In eukaryotic cells, however, replication is coordinated with the cell cycle. Passage

through the cell cycle, including the onset of replication, is controlled by cell cycle checkpoints. The important G_1/S checkpoint (see Section 2.2) holds the cell in G_1 until the DNA is ready to be replicated. After the G_1/S checkpoint is passed, the cell enters S phase and the DNA is replicated. A replication licensing system ensures that the DNA is not replicated again until after the cell has passed through mitosis.

The Licensing of DNA Replication

The use of thousands of origins of replication in eukaryotes requires that the entire genome must be replicated once, and only once, in each cell cycle.

As discussed in the chapter introduction, initiation of DNA replication in eukaryotes is divided into two distinct steps. In the first step, the origins are *licensed*—approved for replication. This step takes place early in the cell cycle, when **replication licensing factors** attach to each origin. In the second step, the replication machinery initiates replication at each licensed origin. The key is that the replication machinery functions only at licensed origins and that licensing occurs early in the cell cycle.

Licensing occurs in G_1 of interphase when the origin-recognition complex binds to an origin. ORC, with the help of two additional licensing factors, allows a complex called MCM2-7 (for minichromosome maintenance) to bind to an origin. Then, in S phase, the MCM2-7 complex associates with several cofactors and forms an active helicase that unwinds double-stranded DNA for replication. After replication has begun, several

mechanisms prevent MCM2-7 from binding to DNA and reinitiating replication at the origins until after mitosis has been completed.

Unwinding

Helicases that separate double-stranded DNA have been isolated from eukaryotic cells, as have single-strand-binding proteins and topoisomerases (which have a function equivalent to the DNA gyrase in bacterial cells). These enzymes and proteins are assumed to function in unwinding eukaryotic DNA in much the same way as their bacterial counterparts do.

Topoisomerase enzymes are also required to remove supercoiling that builds up ahead of the replication fork in eukaryotes, just as DNA gyrase does in bacteria. Topoisomerase enzymes remove the supercoils by clamping tightly to the DNA and breaking one or both of its strands. The strands then revolve around each other, removing the supercoiling and the strain. After the DNA has relaxed, the topoisomerase reseals the broken ends of the DNA strands. Some anticancer drugs work by interfering with these topoisomerases. Camptothecin compounds, isolated from the happy tree *Camptotheca acuminate*, insert themselves into the DNA gap created by topoisomerase I and block the topoisomerase from resealing the broken ends of DNA. This poisons the topoisomerase so that it is unable to remove supercoils ahead of replication. Accumulating supercoils halts the replication machinery and prevents the proliferation of cancer cells. But like many other anticancer drugs, camptothecin also inhibits the replication of normal, noncancerous cells, which is why chemotherapy makes many patients sick.

THINK-PAIR-SHARE Question 4

Eukaryotic DNA Polymerases

Some significant differences between the processes of bacterial and eukaryotic replication are in the number and functions of DNA polymerases. Eukaryotic cells contain many more different DNA polymerases than bacteria do, which function in replication, recombination, and DNA repair.

Three DNA polymerases carry out most of nuclear DNA synthesis during replication: DNA polymerase α, DNA polymerase δ, and DNA polymerase ε (Table 12.5). **DNA polymerase α** has primase activity and initiates nuclear DNA synthesis by synthesizing an RNA primer, followed by a short string of DNA nucleotides. After DNA polymerase α has laid down from 30 to 40 nucleotides, **DNA polymerase δ** completes replication on the lagging strand. Similar in structure and function to DNA polymerase δ, **DNA polymerase ε** replicates the leading strand. Other DNA polymerases take part in repair and recombination or catalyze the replication of organelle DNA.

TABLE 12.5 DNA polymerases in eukaryotic cells

DNA Polymerase	5′→3′ Polymerase Activity	3′→5′ Exonuclease Activity	Cellular Function
α (alpha)	Yes	No	Initiation of

			nuclear DNA synthesis and DNA repair; has primase activity
δ (delta)	Yes	Yes	Lagging-strand synthesis of nuclear DNA, DNA repair, and translesion DNA synthesis
ε (epsilon)	Yes	Yes	Leading-strand synthesis
γ (gamma)	Yes	Yes	Replication and repair of mitochondrial DNA
ζ (zeta)	Yes	No	Translesion DNA synthesis
η (eta)	Yes	No	Translesion DNA synthesis
θ (theta)	Yes	No	DNA repair

ι (iota)	Yes	No	Translesion DNA synthesis
κ (kappa)	Yes	No	Translesion DNA synthesis
λ (lambda)	Yes	No	DNA repair
μ (mu)	Yes	No	DNA repair
σ (sigma)	Yes	No	Nuclear DNA replication (possibly), DNA repair, and sister-chromatid cohesion
ϕ (phi)	Yes	No	Translesion DNA synthesis
Rev1	Yes	No	DNA repair

Note: The three polymerases listed at the top of the table are those that carry out nuclear DNA replication.

Some DNA polymerases, such as DNA polymerase δ and DNA polymerase ε, are capable of replicating DNA at high speed and with high fidelity (few mistakes) because they have active sites that snugly and exclusively accommodate the four normal DNA nucleotides: adenosine, guanosine, cytidine, and thymidine monophosphates. As a result of this specificity, distorted DNA templates and abnormal bases are not readily

accommodated within the active site of the enzyme. When these errors are encountered in the DNA template, the high-fidelity DNA polymerases stall and are unable to bypass the lesion.

Other DNA polymerases have lower fidelity but are able to bypass distortions in the DNA template. These specialized **translesion DNA polymerases** generally have a more open active site and are able to accommodate and copy templates with abnormal bases, distorted structures, and bulky lesions. Thus, these specialized enzymes can bypass such errors, but because their active sites are more open and accommodating, they tend to make more errors. In replication, high-speed, high-fidelity enzymes are generally used until they encounter a replication block. At that point, one or more of the translesion DNA polymerases takes over, bypasses the lesion, and continues replicating a short section of DNA. Then the translesion polymerases detach from the replication fork, and high-fidelity polymerases resume replication with high speed and accuracy. DNA-repair enzymes often repair the errors produced by the translesion polymerases, although some of these errors may escape detection and lead to mutations.

THINK-PAIR-SHARE Question 5

CONCEPTS

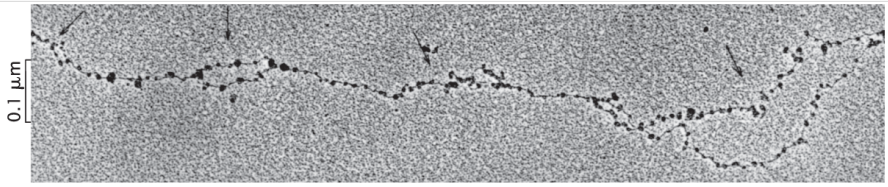
There are a large number of different DNA polymerases in eukaryotic cells. DNA polymerases α, δ, and ε carry out replication on the leading and lagging strands. Other DNA polymerases carry out DNA repair or synthesize organelle DNA. Specialized translesion polymerases are used to bypass distortions of the DNA template that normally stall the main DNA polymerases.

✔ CONCEPT CHECK 9

Some of the eukaryotic DNA polymerases have a tendency to make errors in replication. Why would a cell use an error-prone DNA polymerase instead of one that is more accurate?

Nucleosome Assembly

As we have seen, eukaryotic DNA is complexed with histone proteins to form nucleosomes, structures that contribute to the stability and packing of DNA (see Figure 11.4). In replication, chromatin structure is disrupted by the replication fork, but nucleosomes are quickly reassembled on the two new DNA molecules. Electron micrographs of eukaryotic DNA, such as that in **Figure 12.15**, show that recently replicated DNA is already covered with nucleosomes.



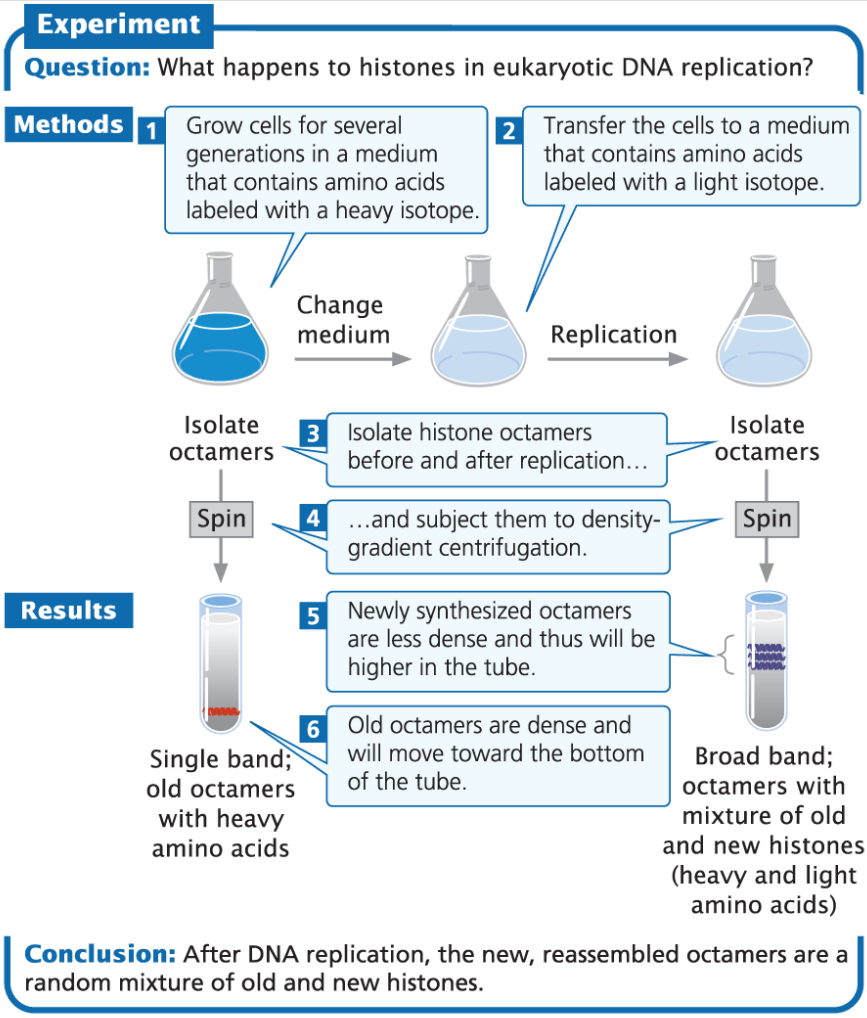
Victoria Foe.

12.15 Nucleosomes are quickly reassembled on newly synthesized DNA. This electron micrograph of eukaryotic DNA in the process of replication clearly shows that newly replicated DNA is already covered with nucleosomes (dark circles).

The creation of new nucleosomes requires three steps: (1) the disruption of the original nucleosomes on the parental DNA molecule ahead of the replication fork; (2) the redistribution of preexisting histones on the new DNA molecules; and (3) the addition of newly synthesized histones to complete the formation of new nucleosomes. Before replication, a single DNA molecule is associated with histone proteins. After replication and nucleosome assembly, two DNA molecules are associated with histone

proteins. Do the original histones of a nucleosome remain together, attached to one of the new DNA molecules, or do they disassemble and mix with new histones on both DNA molecules?

Techniques similar to those employed by Meselson and Stahl to determine the mode of DNA replication were used to address this question. Cells were cultivated for several generations in a medium containing amino acids labeled with a heavy isotope. The histone proteins incorporated these heavy amino acids and were dense (**Figure 12.16**). The cells were then transferred to a culture medium that contained amino acids labeled with a light isotope. Histones assembled after the transfer possessed the new, light amino acids and were less dense.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

12.16 Experimental procedure for studying how nucleosomes dissociate and reassociate in the course of replication.

Description

The illustration shows the question that reads, What happens to histones in eukaryotic DNA replication? The methods below show several flasks used for the following steps. 1, A caption to the first flask with a darker liquid reads, grow cells for several generations in medium that contains amino acids labeled with a heavy isotope. A part of this cell growth is saved and the remaining is transferred to a medium that contains amino acids labeled with a light isotope. 2, A caption referring to a flask of lighter liquid reads, transfer the cells to a medium that contains amino acids labeled with a light isotope. Replication occurs. Octomers from both the flasks are isolated. 3, isolate histone octamers before and after replication. The octomers obtained are spun below the respective flasks. 4, and subject them to density gradient centrifugation. The original cell growth gives a single red

colored band at the bottom of the test tube below, representing old octamers with heavy amino acids. 6, old octamers are dense and will move toward the bottom of the tube. The cell growth after changing medium gives 3 purple colored broad bands at the center of the test tube below, representing octamers with mixture of old and new histones (heavy and light amino acids). 6, newly synthesized octamers are less dense and thus will be higher in the tube. A caption below reads, After D N A replication, the new, reassembled octamers are a

random mixture of old and new histones.

After replication, when the histone octamers were isolated and centrifuged in a density gradient, they formed a continuous band between the positions expected of high-density (old) and low-density (new) octamers. This finding indicates that newly assembled octamers consist of a mixture of old and new histones. Further evidence indicates that reconstituted nucleosomes appear on the new DNA molecules quickly after the new DNA emerges from the replication machinery.

The reassembly of nucleosomes during replication is facilitated by proteins called histone chaperones, which are associated with the helicase enzyme that unwinds the DNA. The histone chaperones accept old histones from the original DNA molecule and deposit them, along with newly synthesized histones, on the two new DNA molecules. Current evidence suggests that the original histone octamer is broken down into two H2A–H2B dimers (each dimer consisting of one H2A and one H2B) and a single H3–H4 tetramer (each tetramer consisting of two H3 histones and two H4 histones). The old H3–H4 tetramer is then transferred randomly to one of the new DNA molecules and serves as a foundation onto which either new or old copies of H2A–H2B dimers are added. Newly synthesized H3–H4 tetramers and H2A–H2B dimers are also added to each new DNA molecule to complete the formation of new nucleosomes. The assembly of the new

nucleosomes is facilitated by a protein called chromatin-assembly factor 1 (CAF-1). ❯ **TRY** PROBLEM 31

CONCEPTS

After DNA replication, new nucleosomes quickly reassemble on the two new molecules of DNA. Nucleosomes break down in the course of replication and reassemble from a mixture of old and new histones. The reassembly of nucleosomes during replication is facilitated by histone chaperones and chromatin-assembly factors.

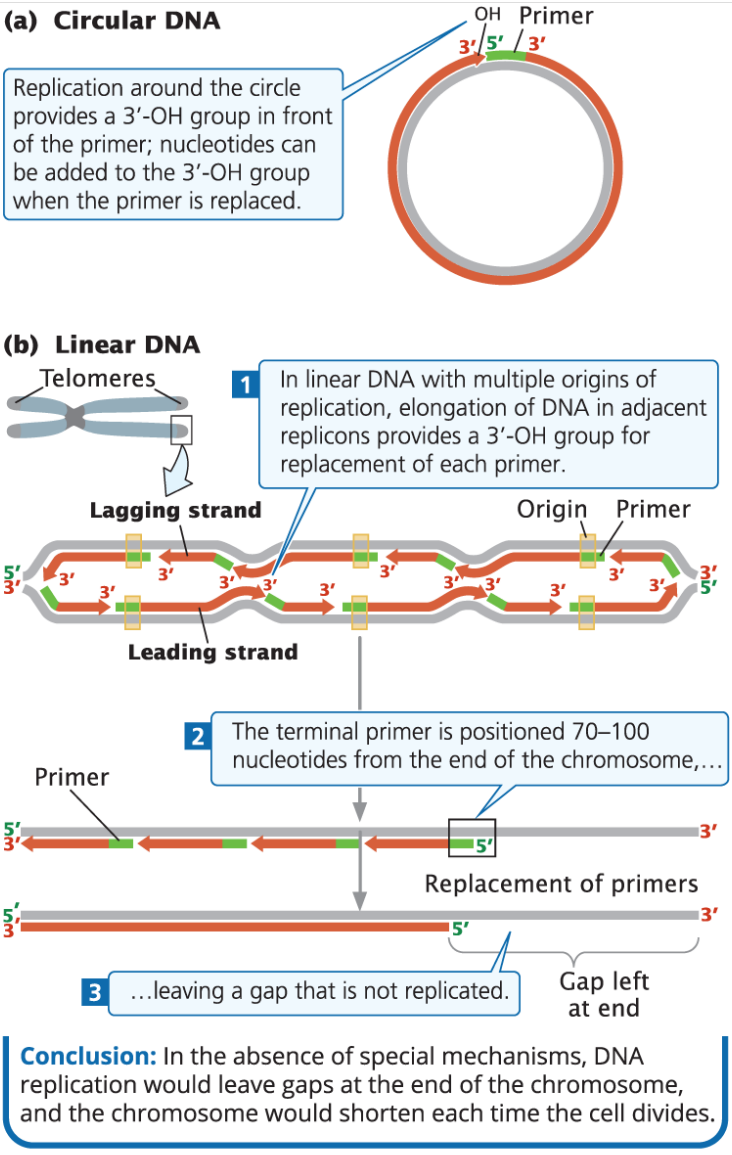
The Location of Replication Within the Nucleus

The DNA polymerases that carry out replication are frequently depicted as moving down the DNA template, much as a locomotive travels along a train track. Evidence suggests that this view is incorrect. A more accurate view is that the polymerase is fixed in location and the template DNA is threaded through it, with newly synthesized DNA molecules emerging from the other end.

Techniques of fluorescence microscopy, which are able to reveal active sites of DNA synthesis, show that most replication in the nucleus of a eukaryotic cell takes place at a limited number of fixed sites, often referred to as replication factories. Time-lapse micrographs reveal that newly duplicated DNA is extruded from these particular sites. Similar results have been obtained for bacterial cells.

Replication at the Ends of Chromosomes

A fundamental difference between eukaryotic and bacterial replication arises because eukaryotic chromosomes are linear and thus have ends. As already stated, the 3′-OH group needed by DNA polymerases is provided at the initiation of replication by RNA primers that are synthesized by primase. This solution is temporary, however, because eventually the primers must be removed and replaced by DNA nucleotides. In a circular DNA molecule, elongation around the circle eventually provides a 3′-OH group immediately in front of the primer (**Figure 12.17a**). After the primer has been removed, the replacement DNA nucleotides can be added to this 3′-OH group. But what happens when a DNA molecule is not circular but linear?



12.17 DNA synthesis at the ends of circular and linear chromosomes must differ.

Description

Illustration a, at the top, shows a circular D N A molecule and at its 3 prime end, an O H group is labeled. A primer is adjacent that runs from 5 prime to 3 prime. A caption reads, replication around the circle provides a 3 prime O H group in front of the primer; nucleotides can be added to the 3 prime O H group when the primer is replaced. Illustration b below shows an X-shaped chromosome with its tips labeled as telomeres. A zoomed out illustration shows three replication bubbles on a stretch of D N A. All the three replication bubbles have origins in the center (one on top strand and one on bottom strand). Continuous leading strands are elongating from left to right for bottom

template strand and right to left for the top template strand. The lagging strands are also elongating from right to left in top strand and left to right in bottom strand. A caption reads, in linear D N A with multiple origins of replication, elongation of D N A in adjacent replicons provides a 3 prime O H group for replacement of each primer. In the next step below, multiple discontinuous strands with markers at 5 prime end are marked from right to left. A caption reads, the terminal primer is positioned 70 to 100 nucleotides from the end of the chromosome. In the next step below, replacement of primers occur and a continuous strand is produced running from 3 prime to 5 prime. A gap is left at the end of this strand. A caption reads, leaving a gap that is not replicated. A caption below reads, Conclusion: In the absence of special mechanisms, D N A replication would leave gaps at the end of the chromosome, and the chromosome would shorten each time the cell divides.

THE END-REPLICATION PROBLEM

In linear chromosomes with multiple origins, the elongation of DNA in adjacent replicons provides a 3′-OH group preceding each primer (Figure 12.17b). At the very end of a linear chromosome, however, there is no adjacent stretch of replicated DNA to provide this crucial 3′-OH group. When the terminal primer at the end of the chromosome has been removed, it cannot be replaced by DNA nucleotides, so its removal produces a gap at the end of the chromosome, suggesting that the chromosome should become progressively shorter with each round of replication. This situation has been termed the end-replication problem.

The end-replication problem, as originally proposed, assumed that the terminal primer is located at the very end of the chromosome. Experimental evidence suggests that in some single-celled eukaryotes, such as yeast and some protozoans, the terminal primer is indeed placed at the very end of the chromosome, but this has not been demonstrated for more complex multicellular eukaryotes. Furthermore, chromosome ends in humans are known to shorten at a much faster rate than would be expected if only the terminal primer (which is only about 10 nucleotides long) was

not replaced. Research has now demonstrated that in replication of human chromosomes, the terminal primer is positioned not at the end of the chromosome but rather some 70 to 100 nucleotides from the end (see Figure 12.17b). This means that 70 to 100 nucleotides of DNA at the end of the chromosome are not replicated during the division of somatic cells, and the chromosome shortens by this amount each time the cell divides.

TELOMERES AND TELOMERASE

The end-replication problem suggests that chromosomes in eukaryotic cells should shorten with each cell division and eventually self-destruct. In single-celled eukaryotes, germ cells, and early embryonic cells, however, chromosomes do not shorten. So how are the ends of linear chromosomes in these cells replicated?

The ends of eukaryotic chromosomes—the telomeres—possess several unique features, one of which is the presence of many copies of a short repeated sequence. In humans, this telomeric repeat is TTAGGG (see Section 11.2). The strand containing this G-rich repeat typically protrudes beyond the complementary C-rich strand (**Figure 12.18a**; see also the section Telomere Structure in Chapter 11):

$$\text{toward centromere} \quad \leftarrow \quad \begin{matrix} 5'\text{-TTAGGGTTAGGGTTAGGG-}3' \\ 3'\text{-AATCCC-}5' \end{matrix} \quad \rightarrow \quad \text{end of ch}$$

The single-stranded protruding end of the telomere, known as the **G-rich 3′ overhang**, can be extended by **telomerase**, an enzyme that has both a protein and an RNA component (also known as a ribonucleoprotein). The RNA component of the enzyme contains from 15 to 22 nucleotides that are

complementary to the sequence on the G-rich strand. This RNA sequence pairs with the G-rich 3′ overhang (**Figure 12.18b**) and provides a template for the synthesis of additional DNA copies of the repeats. DNA nucleotides are added to the 3′ end of the G-rich strand one at a time (**Figure 12.18c**); after several nucleotides have been added, the RNA template moves down the DNA, and more nucleotides are added to the 3′ end of the G-rich strand (**Figure 12.18d**). In this way, the telomerase can extend the 3′ end of the chromosome without the use of a complementary DNA template (**Figure 12.18e**). How the complementary C-rich strand is synthesized (**Figure 12.18f**) is not clear. It may be synthesized by conventional replication, with DNA polymerase α synthesizing an RNA primer on the 5′ end of the extended (G-rich) template. The removal of this primer once again leaves a gap at the 5′ end of the chromosome, but this gap does not matter because the end of the chromosome is extended at each replication by telomerase, so the chromosome does not become shorter overall.

12.18 The enzyme telomerase is responsible for the replication of chromosome ends.

Description

The illustration shows telomere lengthening with 7 parts labeled “a” to “f”. Part “a” at the top shows the G-rich repeated sequence at the end of telomere. A caption reads, the telomere has a protruding end with a G-rich repeated sequence. Part “b” below shows telomerase with its complementary R N A template attaching to the telomere and providing an overhanging template strand for further D N A elongation. A caption reads, the R N A part of telomerase is complementary to the G-rich strand and pairs with it, providing a template for the synthesis of copies of the repeats. Part “c” below shows new D N A added, making the single-stranded section of the D N A longer. A caption reads, Nucleotides are added to the 3 prime end of the G-rich strand. Part “d” below shows the R N A template moving along the newly synthesized D N A nucleotides. A caption reads, after several nucleotides have been added, the R N A template moves along the D N A. Part “e” below shows more nucleotides added to the D N A strand thereby making the strand even longer. A caption reads, more nucleotides are added. This leads to the next part where the telomerase dissociates. A caption reads, the telomerase is removed. Part “f” below shows synthesis occurring on the complementary strand eventually filling in the gap. A caption reads, synthesis takes place on the complementary strand, filling in the gap due to the removal of the R N A primer at the end. Telomerase extends the length of the D N A and fills in the gap at the ends that would have been left by the R N A primer. A text below reads, Conclusion: Telomerase extends the D N A, filling in the gap due to the removal of the R N A primer.

Telomerase is present in single-celled eukaryotes, germ cells, early embryonic cells, and certain proliferative somatic cells (such as bone-marrow cells and cells lining the intestine), all of which must undergo continuous cell division. Most somatic cells have little or no telomerase activity, and chromosomes in these cells progressively shorten with each cell division. These cells are capable of only a limited number of divisions; when the telomeres have shortened beyond a critical point, the

chromosomes become unstable, have a tendency to undergo rearrangements, and are degraded. These events lead to cell death.

THINK-PAIR-SHARE Question 6

CONCEPTS

The ends of eukaryotic chromosomes are replicated by a ribonucleoprotein called telomerase. This enzyme adds extra nucleotides to the G-rich DNA strand of the telomere.

✔ CONCEPT CHECK 10

What would be the result if an organism's telomerase were mutated and nonfunctional?

a. No DNA replication would take place.
b. The DNA polymerase enzyme would stall at the telomere.
c. Chromosomes would shorten with each new generation.
d. RNA primers could not be removed.

TELOMERASE, AGING, AND DISEASE

The shortening of telomeres may contribute to the process of aging. The telomeres of genetically engineered mice that lack a functional telomerase gene (and therefore do not express telomerase in either somatic or germ cells) undergo progressive shortening in successive generations. After several generations, these mice show some signs of premature aging, such as graying, hair loss, and delayed wound healing. Through genetic engineering, it is also possible to create somatic cells that express telomerase. In these cells, telomeres do not shorten, cell aging is inhibited, and the cells divide indefinitely.

Some of the strongest evidence that telomere length is related to aging comes from studies of telomeres in birds. In 2012, scientists in the United Kingdom measured telomere length in red blood cells taken from 99 zebra finches at various times during their lives. The scientists found a strong correlation between telomere length and longevity: birds with longer telomeres lived longer than birds with short telomeres. The strongest predictor of life span was telomere length early in life, at 25 days, which is roughly equivalent to human adolescence. Although these observations suggest that telomere length is associated with aging in some animals, the precise role of telomeres in *human* aging remains uncertain.

Some diseases are associated with abnormalities of telomere replication. People who have Werner syndrome, an autosomal recessive disease, show signs of premature aging that begin in adolescence or early adulthood, including wrinkled skin, graying of the hair, baldness, cataracts, and muscle atrophy. They often develop cancer, osteoporosis, heart and artery disease, and other ailments typically associated with aging. The causative gene, *WRN*, has been mapped to human chromosome 8 and normally encodes a RecQ helicase enzyme, which is necessary for the efficient replication of telomeres. In people who have Werner syndrome, this enzyme is defective; consequently, the telomeres shorten prematurely.

Another disease associated with abnormal maintenance of telomeres is dyskeratosis congenita (DKC), which leads to progressive bone-marrow failure, in which the bone marrow does not produce enough new blood cells. People with an X-linked form of the disease have a mutation in a gene that encodes dyskerin, a protein that normally helps process the RNA component of telomerase. People who have the disease typically inherit short telomeres from a parent who carries the mutation and who is unable

to maintain telomere length in his or her germ cells owing to defective dyskerin. In families that carry this mutation, telomere length typically shortens with each successive generation, leading to anticipation: a progressive increase in the severity of the disease over generations (see Section 5.4).

Telomerase also appears to play a role in cancer. Cancer cells have the capacity to divide indefinitely, and telomerase is expressed in 90% of all cancers. Some recent evidence indicates that telomerase may stimulate cell proliferation independently of its effect on telomere length, so the mechanism by which telomerase contributes to cancer is not clear. As we will see in Chapter 23, cancer is a complex, multistep process that usually requires mutations in at least several genes. Telomerase activation alone does not lead to cancerous growth in most cells, but it does appear to be required, along with other mutations, for cancer to develop. Some experimental anticancer drugs work by inhibiting the action of telomerase.

One of the difficulties in studying the effect of telomere shortening on the aging process is that the expression of telomerase in somatic cells also promotes cancer, which may shorten a person's life span. To circumvent this problem, Antonia Tomás-Loba and her colleagues created genetically engineered mice that expressed telomerase and carried genes that made them resistant to cancer. These mice had longer telomeres, lived longer, and exhibited fewer age-related changes, such as skin alterations, decreases in neuromuscular coordination, and degenerative diseases, than did normal mice. These results support the idea that telomere shortening contributes to aging. › **TRY PROBLEM 33**

THINK-PAIR-SHARE Question 7

Replication in Archaea

The process of replication in archaea has a number of features in common with replication in eukaryotic cells. Many of the proteins taking part are more similar to those in eukaryotic cells than to those in bacteria. Like bacteria, some archaea have a single origin of replication, but many archaea have multiple origins, as eukaryotes do (although archaea have far fewer origins than are found in most eukaryotic chromosomes). The origins of archaea do not contain the typical sequences recognized by bacterial initiator proteins; instead, they have sequences that are similar to those found in some eukaryotic origins. The initiator proteins of archaea are also more similar to those of eukaryotes than to those of bacteria. These similarities in replication between archaeal and eukaryotic cells reinforce the conclusion that the archaea are more closely related to eukaryotic cells than to the prokaryotic bacteria.

12.5 Recombination Takes Place Through the Alignment, Breakage, and Repair of DNA Strands

Recombination is the exchange of genetic information between DNA molecules; when the exchange is between homologous DNA molecules, it is called **homologous recombination**. This process takes place in crossing over, in which homologous regions of chromosomes are exchanged and alleles are shuffled into new combinations (see Figure 7.5). Recombination is an extremely important genetic process because it increases genetic variation. Rates of recombination provide important information about linkage relations among genes, which is used to create genetic maps (see Figures 7.13 and 7.14). Recombination is also essential for some types of DNA repair (as we will see in Chapter 18).

Homologous recombination is a remarkable process: a nucleotide strand of one chromosome aligns precisely with a nucleotide strand of the homologous chromosome, breaks arise in corresponding regions of the two DNA molecules, parts of the molecules precisely change place, and then the pieces are correctly joined. In this complicated series of events, no genetic information is lost or gained. Although the precise molecular mechanism of homologous recombination is still not completely understood, the exchange is probably accomplished through the pairing of complementary

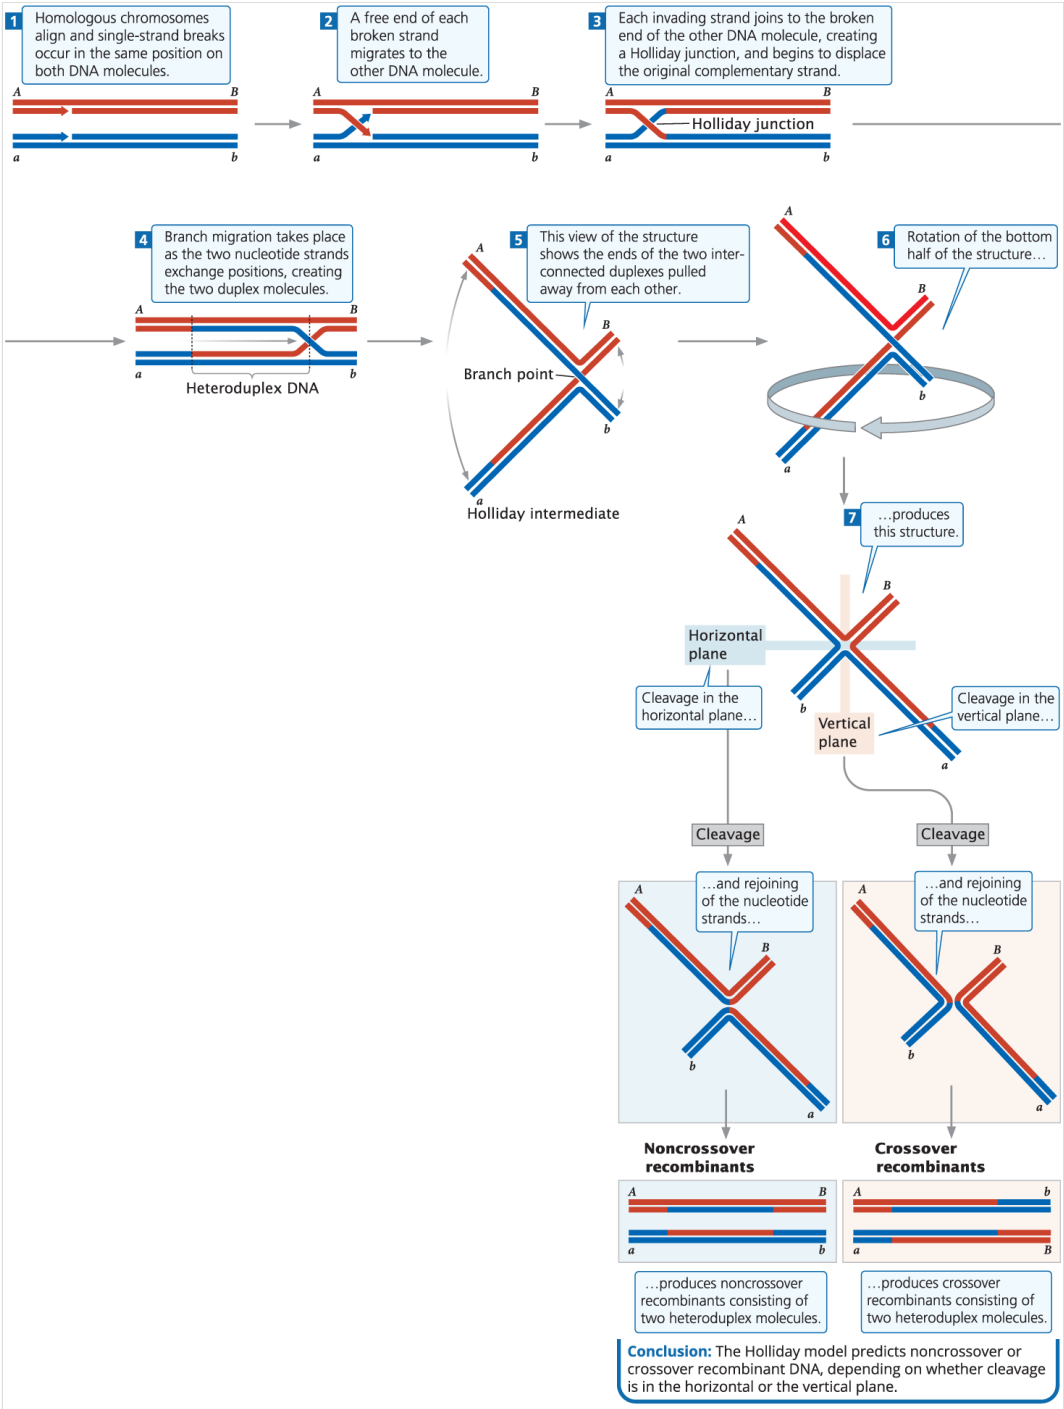
bases. A single nucleotide strand of one chromosome pairs with the complementary strand of another, forming **heteroduplex DNA**, which is DNA consisting of nucleotide strands from different sources (see the next section and Figure 12.19).

In meiosis, homologous recombination (crossing over) could theoretically take place before, during, or after DNA synthesis. Cytological, biochemical, and genetic evidence indicates that it takes place in prophase I of meiosis, whereas DNA replication takes place earlier, in interphase. Thus, crossing over must entail the breaking and rejoining of chromatids when homologous chromosomes are at the four-strand stage (see Figure 7.5). This section explores some theories about how the process of recombination takes place.

Models of Recombination

Homologous recombination takes place through several different pathways. One pathway is initiated by a single-strand break in each of two DNA molecules and includes the formation of a special structure called the **Holliday junction** (**Figure 12.19**). In this model, the double-stranded DNA molecules of two homologous chromosomes align precisely. A single-strand break in each of the DNA molecules provides a free end that invades and joins the free end of the other DNA molecule. Thus, strand invasion and joining take place on both DNA molecules, creating two heteroduplex DNAs, each consisting of one original strand plus one new strand from the

other DNA molecule. The point at which the nucleotide strands pass from one DNA molecule to the other is the Holliday junction. The junction moves along the molecules in a process called branch migration.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

12.19 The Holliday model of homologous recombination. In this model, recombination takes place through single-strand breaks, strand displacement, branch migration, and resolution of a single Holliday junction.

Description

The illustration shows 2 pairs of homologous chromosomes, represented by lines, on the right. There are red chromosomes with genes big A and big B and blue chromosomes with genes small A and small B. The bottom red chromosome and the upper blue strand have a nick. A caption reads, homologous chromosomes align and single-strand breaks occur in the same position on both D N A molecules. In the next step on the right, a free end from each of the broken strand migrates towards the other D N A molecule. Text reads, a free end of each broken strand migrates to the other D N A molecule. In the next step on the right, the broken strand joins the remaining part of the other D N A molecule and the junction is known as holiday junction. A caption reads, each invading strand joins to the broken end of the other D N A molecule, creating a Holliday junction, and begins to displace the original complementary strand.

The illustration shows different alignments of the heteroduplex, beginning with strands invading and the creation of a heteroduplex D N A, or the areas where the blue and red D N A strands, represented by lines, are complexed together. A caption reads, branch migration takes place as the two nucleotide strands exchange positions, creating the two duplex molecules. In the next step on the right, the ends of the interconnected duplexes are then pulled away from each other while they still are joined at the branch point. A caption reads, This view of the structure shows the ends of the 2 interconnected duplexes pulled away from one another. In the next step on the right, the bottom half rotates in a clockwise direction. A caption reads, rotation of the bottom half of the structure. In the next step, D N A strands align in the shape of a cross with each arm at an angle of 90 degrees from the other. The alignment is diagonal to the horizontal plane and vertical plane such that the long arms are at 45 degree angle from both horizontal and vertical plane. The long arms of the cross are heteroduplexed D N A, and the shorter arms are one red and one blue. A caption reads, produces this structure. Cleavage in horizontal plane leads to a chromosome below with genes big A and big B and other with small A and small B, even though the middle portion of the chromosome between the 2 genes are hybrid in color, red and blue. This further leads to formation of noncrossover recombinants below consisting of 2 heteroduplex molecules (one is red with genes big A big B with a portion of blue in middle of the lower chromosome; other is blue with genes small A small B and red portion in the middle of upper chromosome). A caption reads, cleavage in the horizontal plane and rejoining of the nucleotide strands produces noncrossover recombinants consisting of two heteroduplex molecules. Cleavage in the vertical plane leads to chromosome below with genes with big A small B on one side, and the other chromosome with genes small A big

B. This further leads to crossover recombinants below consisting of 2 heteroduplex molecules (one is hybrid with genes big A small B; other is hybrid with genes small A big B). A caption reads, cleavage in the vertical plane and rejoining of the nucleotide strands produces crossover recombinants consisting of two heteroduplex molecules.

The exchange of nucleotide strands and branch migration produce a structure termed the Holliday intermediate, which can be cleaved in one of two ways. Cleavage in the horizontal plane, followed by rejoining of the strands, produces noncrossover recombinants, in which the genes on the two ends of the molecules are identical with those originally present (gene *A* with gene *B*, and gene *a* with gene *b*). Cleavage in the vertical plane, followed by rejoining, produces crossover recombinants, in which the genes on the two ends of the molecules are different from those originally present (gene *A* with gene *b*, and gene *a* with gene *B*).

Another pathway for recombination is initiated by double-strand breaks in one of the two aligned DNA molecules (**Figure 12.20**). In this model, the removal of some nucleotides at the ends of the broken strands—followed by strand invasion, displacement, and replication—produces two heteroduplex DNA molecules joined by two Holliday junctions. The interconnected molecules produced in the double-strand-break model can be separated by further cleavage and reunion of the nucleotide strands in the same way that the Holliday intermediate is separated in the single-strand-break model. Whether crossover or noncrossover molecules are produced depends on whether cleavage is in the vertical or the horizontal

plane. View (A) **Animation 12.5** to see how the Holliday and double-strand-break models lead to recombination.

W. H. Freeman and Company

12.20 The double-strand-break model of recombination. In this model, recombination takes place through a double-strand break in one DNA duplex, strand displacement, DNA synthesis, and the resolution of two Holliday junctions.

Description

The illustration shows two double stranded D N A molecules that are represented by lines. The chromsomes are present at the top, where one is red and other is blue. A double strand break occurs in the blue D N A molecule present below. A caption reads, two double-stranded D N A molecules from homologous chromosomes align. A double-strand break occurs in one of the molecules. Few nucleotides around the break are enzymatically removed in the next step below. The top blue strand has 5 prime end and the remaining part begins with 3 prime end. The bottom blue strand has 3 prime end and the remaining part begins with 5 prime end. A caption reads, nucleotides are enzymatically removed, producing some single-stranded D N A on each side. In the next step below, the 3 prime end of the top blue strand invades and displaces the lower red D N A strand. A caption reads, a free 3 prime end of the broken blue strand invades and displaces a strand of the unbroken D N A molecule. In the next step below, the 3 prime end of the blue strand elongates and keeps on displacing the red strand. A caption reads, the 3 prime end then elongates, further displacing the original strand. In the next step below, the displaced D N A forms a loop and base pairs with the broken blue D N A strand. A caption reads, the displaced strand forms a loop that base pairs with the other strand of the broken D N A molecule. In the next step below, D N A synthesis begins at the 3 prime end of the bottom blue strand with the displaced red strand as a template. A caption reads, D N A synthesis is initiated at the 3 prime end of the bottom strand, the displaced loop being used as a template. Finally in the last step below, the 5 prime end of the top blue strand extends upwards and joins to the elongated 3 prime end of the same blue strand and 2 Holliday junctions are produced. A caption reads, Strand attachment produces 2 Holliday junctions, each of which can be separated by cleavage and reunion.

Evidence for the double-strand-break model originally came from results of genetic crosses in yeast that could not be explained by the Holliday model. Subsequent observations showed that double-strand breaks appear in yeast in prophase I, when crossing over takes

place, and that mutant strains that are unable to form double-strand breaks do not exhibit meiotic recombination. Although considerable evidence supports the double-strand-break model in yeast, the extent to which it applies to other organisms is not yet known.

CONCEPTS

Homologous recombination requires the formation of heteroduplex DNA consisting of one nucleotide strand from each of two homologous chromosomes. In the Holliday model, homologous recombination is accomplished through a single-strand break in each DNA molecule, strand displacement, and branch migration. In the double-strand-break model, recombination is accomplished through double-strand breaks, strand displacement, and branch migration.

✔ CONCEPT CHECK 11

Why is recombination important?

Enzymes Required for Recombination

Recombination between DNA molecules requires the unwinding of DNA helices, the cleavage of nucleotide strands, strand invasion, and branch migration, followed by further strand cleavage and union to remove Holliday junctions. The molecular mechanism of recombination has been extensively studied in *E. coli*. Although bacteria do not undergo meiosis, they do have a type of sexual reproduction (conjugation), in which one bacterium donates its

chromosome to another (discussed more fully in Section 9.3). Subsequent to conjugation, the recipient bacterium has two chromosomes, which may undergo homologous recombination. Geneticists have isolated mutant strains of *E. coli* that are deficient in recombination; the study of these strains has resulted in the identification of genes and proteins that take part in bacterial recombination, revealing several different pathways by which it can take place.

Three genes that play pivotal roles in *E. coli* recombination are *recB*, *recC*, and *recD*, which encode three polypeptides that together form the RecBCD protein. This protein unwinds double-stranded DNA and is capable of cleaving nucleotide strands. The *recA* gene encodes the RecA protein; this protein allows invasion of a DNA helix by a single strand and the subsequent displacement of one of the original strands. In eukaryotes, the formation and branch migration of Holliday structures is facilitated by the enzyme Rad51.

In *E. coli*, *ruvA* and *ruvB* genes encode proteins that catalyze branch migration, and the *ruvC* gene produces a protein, called resolvase, that cleaves Holliday structures. Cleavage and resolution of Holliday structures in eukaryotes is carried out by an analogous enzyme called GEN1. Single-strand-binding proteins, DNA ligase, DNA polymerases, and DNA gyrase also play roles in various types of recombination, in addition to their functions in DNA replication.

CONCEPTS

A number of proteins have roles in recombination, including RecA, RecBCD, RuvA, RuvB, resolvase, single-strand-binding proteins, DNA ligase, DNA polymerases, and DNA gyrase.

✔ CONCEPT CHECK 12

What is the function of resolvase in recombination?

a. It unwinds double-stranded DNA.
b. It allows a single DNA strand to invade a DNA helix.
c. It displaces one of the original DNA strands during branch migration.
d. It cleaves the Holliday structure.

Chapter 12 Review

CHAPTER SUMMARY

Section 12.2 Learning Objective: Be able to describe the process of semiconservative replication.

- DNA replication is semiconservative: The two nucleotide strands of DNA separate, and each serves as a template on which a new strand is synthesized.
- In theta replication, the two nucleotide strands of a circular DNA molecule unwind, creating a replication bubble. Within each replication bubble, DNA is normally synthesized on both strands and at the replication fork, producing two circular DNA molecules.
- Rolling-circle replication is initiated by a break in one strand of circular DNA, which produces a 3′-OH group to which new nucleotides are added while the 5′ end of the broken strand is displaced from the circle.
- Linear eukaryotic DNA contains many origins of replication. Unwinding and replication take place on both templates at both ends of the replication bubble until adjacent replicons meet, resulting in two linear DNA molecules.
- All DNA synthesis is in the 5′ → 3′ direction. Because the two nucleotide strands of DNA are antiparallel, replication takes

place continuously on one strand (the leading strand) and discontinuously on the other (the lagging strand).

Section 12.3 Learning Objective: Be able to outline the mechanism of bacterial replication.

- Replication in bacteria begins when an initiator protein binds to an origin of replication and unwinds a short stretch of DNA, to which DNA helicase attaches. DNA helicase unwinds the DNA at the replication fork, single-strand-binding proteins bind to the single nucleotide strands to prevent secondary structures, and DNA gyrase (a topoisomerase) removes the strain ahead of the replication fork that is generated by unwinding.
- During replication, primase synthesizes short primers consisting of RNA nucleotides, providing a 3′-OH group to which DNA polymerase can add DNA nucleotides.
- DNA polymerase adds new nucleotides to the 3′ end of a growing polynucleotide strand. Bacteria have two DNA polymerases that have primary roles in replication: DNA polymerase III, which synthesizes new DNA on the leading and lagging strands, and DNA polymerase I, which removes and replaces primers.
- DNA ligase seals the nicks that remain in the sugar–phosphate backbone when the RNA primers are replaced by DNA nucleotides.
- Several mechanisms ensure the high rate of accuracy in replication, including precise nucleotide selection, proofreading, and mismatch repair.

Section 12.4 Learning Objective: Be able to summarize the differences in eukaryotic and bacterial replication.

- Precise replication at multiple origins in eukaryotes is ensured by licensing factors that must attach to an origin before replication can begin.
- Eukaryotic nucleosomes are quickly assembled on new molecules of DNA; newly assembled nucleosomes consist of a random mixture of old and new histone proteins.
- The ends of linear eukaryotic DNA molecules are replicated by the enzyme telomerase. The shortening of telomeres in somatic cells may contribute to aging.
- The process of replication in archaea has some features in common with replication in eukaryotes.

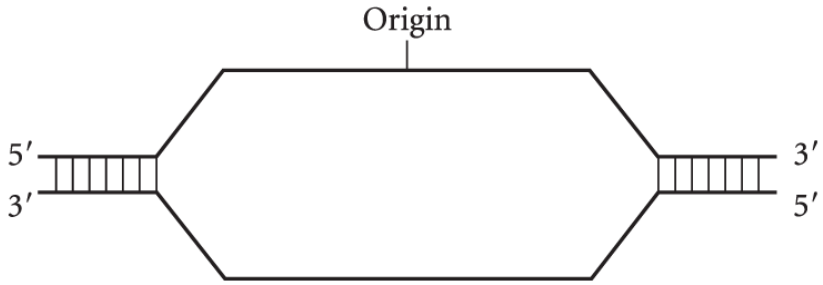
Section 12.5 Learning Objective: Be able to explain the molecular mechanism of homologous recombination.

- Homologous recombination takes place through alignment of homologous DNA segments, breaks in nucleotide strands, and rejoining of the strands. Homologous recombination requires a number of enzymes and proteins.

WORKED PROBLEMS

Problem 1

The following diagram represents the template strands of a replication bubble in a DNA molecule. Draw in the newly synthesized strands, and identify the leading and lagging strands.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The top strand has 5 prime end on the left side and the bottom strand has 5 prime end on the right side. In the middle a replication bubble is formed with origin labeled in the middle.

» Solution Strategy

What information is required in your answer to the problem?

The provided diagram with the newly synthesized strands drawn in and the leading and lagging strands labeled.

What information is provided to solve the problem?

A diagram of the template DNA with 5′ and 3′ ends labeled.

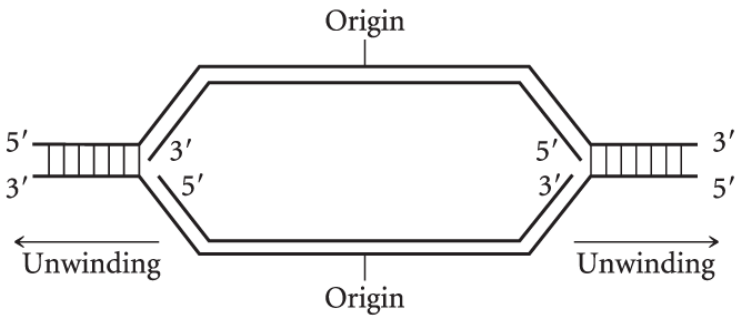
For help with this problem, review:

Direction of Replication in Section 12.2 and Figure 12.10c.

» Solution Steps

To determine the leading and lagging strands, first note which end of each template strand is 5′ and which end is 3′. With a pencil, draw in the strands being synthesized on these templates, and identify their 5′ and 3′ ends.

Recall: The two strands of DNA are antiparallel, so the newly synthesized strands should have a polarity opposite to the template strand.

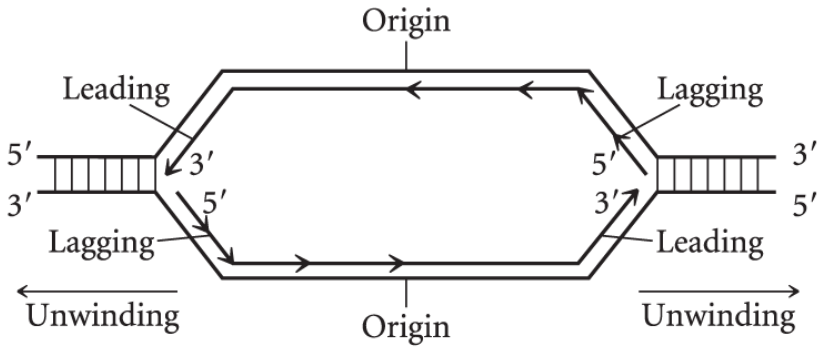


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The top strand has 5 prime end on the left side, and the bottom strand has 5 prime end on the right side. In the middle, a replication bubble is present with the origin labeled in the center. Within the bubble, below the top strand a new strand has 3 prime end on the left and 5 prime end on the right. Above the bottom strand a new strand has 5 prime end on the left and 3 prime on the right. Below both double-stranded D N A segments, arrows are extending outwards and labeled unwinding. A caption reads, recall the 2 strands of D N A are antiparallel, so the newly synthesized strand should have the opposite polarity form the template strand.

Next, determine the direction of replication for each new strand, which must be 5′ → 3′. You might draw arrows on the new strands to indicate the direction of replication. After you have established the direction of replication for each strand, look at each replication fork and determine whether the direction of replication for a strand is the same as the direction of unwinding. The strand on which replication is in the same direction as that of unwinding is the leading strand. The strand on which replication is in the direction opposite that of unwinding is the lagging strand.

Recall: DNA synthesis is always 5′ to 3′.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
The line drawing shows double stranded D N A with a replication bubble in between. The replication bubble has the newly synthesized strands within. Below the top strand, a newly synthesized strand is present with its top left end (3 prime) labeled leading strand and the top right end (5 prime) labeled lagging strand. Above the bottom strand, a newly synthesized strand has bottom left (5 prime) labeled lagging strand and the bottom right (3 prime) labeled as leading strand. Two arrows below the double stranded D N A point outward from the center and are labeled unwinding. A caption reads, hint: each replication fork should have one leading and one lagging strand.

Hint: Each replication fork should have one leading and one lagging strand.

Problem 2

Consider the experiment conducted by Meselson and Stahl in which they used ^{14}N and ^{15}N in cultures of *E. coli* and equilibrium density gradient centrifugation. Draw pictures to represent the bands produced by bacterial DNA in the centrifuge tube before the switch to a medium containing ^{14}N and after one, two, and three rounds of replication in that medium. Use separate sets of drawings to show the bands that would appear if replication were (a) semiconservative, (b) conservative, (c) dispersive.

» Solution Strategy

What information is required in your answer to the problem?

Drawings that represent the bands produced by bacterial DNA in the centrifuge tube before the switch to a medium containing ^{14}N and after one, two, and three rounds of replication in that medium; thus, you should have drawings of four tubes for each model of replication. You will need separate sets of drawings for semiconservative, conservative, and dispersive replication.

What information is provided to solve the problem?

- The bacterial DNA was originally labeled with ^{15}N, and then the bacteria were switched to a medium with ^{14}N (see discussion of experiment on pp. 347-348).
- Original DNA will contain ^{15}N. Newly synthesized DNA will contain ^{14}N.
- Equilibrium density gradient centrifugation was performed before the bacteria were switched to ^{14}N and after one, two, and three rounds of replication following the switch.

For help with this problem, review:

Meselson and Stahl's Experiment in Section 12.2.

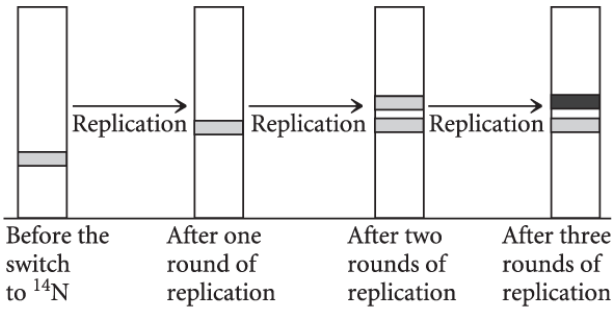
» Solution Steps

DNA labeled with ^{15}N will be denser than DNA labeled with ^{14}N; therefore, ^{15}N-labeled DNA will sink lower in the centrifuge tube. Before the switch to a medium containing ^{14}N, all DNA in the bacteria will contain ^{15}N and will produce a single band in the lower end of the tube.

a. With semiconservative replication, the two strands separate, and each serves as a template on which a new strand is synthesized. After one round of replication, the original template strand of each molecule will contain ^{15}N and the new strand of each molecule will contain ^{14}N, so a single band will appear in the centrifuge tube halfway between the positions expected of DNA containing only ^{15}N and of DNA containing

only ^{14}N. In the next round of replication, the two strands again separate and serve as templates for new strands. Each of the new strands contains only ^{14}N; thus, some DNA molecules will contain one strand with the original ^{15}N and one strand with new ^{14}N, whereas the other molecules will contain two strands with ^{14}N. This labeling will produce two bands, one at the intermediate position and one at a higher position in the tube. Additional rounds of replication should produce increasing amounts of DNA that contains only ^{14}N; so the higher band will get darker.

Hint: Review the distribution of new and old DNA in semiconservative, conservative, and dispersive replication in Figure 12.1.

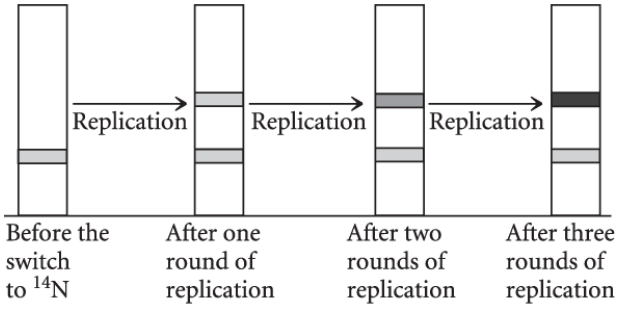


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

On the left side, a grey band appears near the bottom representing D N A before the switch to N left superscript 14. Replication occurs and a grey band appears just below the center after one round of replication, shown on the right. Replication occurs and two gray bands appear at the center after two rounds of replication, shown on the right. Replication occurs and the above band becomes black while the grey band remains as it is after three rounds of replication shown, on the right.

b. With conservative replication, the entire molecule serves as a template. After one round of replication, some molecules would consist entirely of ^{15}N, and others would consist entirely of ^{14}N; therefore, two bands would be present. Subsequent rounds of replication would increase the fraction of DNA consisting entirely of new ^{14}N; thus, the upper band would get darker. However, the original DNA with ^{15}N would remain, and so two bands would still be present.



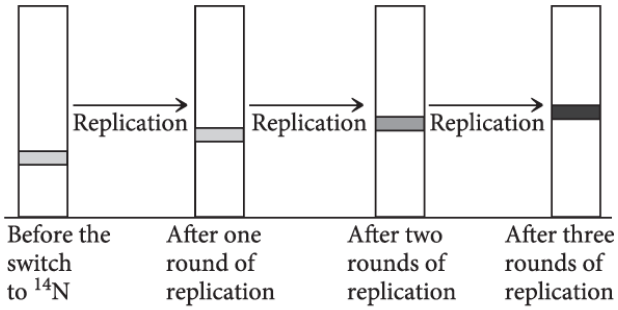
Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

On the left side, a grey band appears near the bottom representing D N A before the switch to N left superscript 14. Replication occurs and two grey bands appear (one at the center and one at the bottom) after one round of replication, shown on the right. Replication occurs and two gray bands appear (one darker grey and at the center and other at the bottom) after two rounds of replication, shown on the right. Replication occurs and the above band becomes black while the grey band remains as it is after three rounds of replication, shown on the right.

c. In dispersive replication, both nucleotide strands break down into fragments that serve as templates for the synthesis of new DNA. The fragments then reassemble into DNA molecules. After one round of replication, all DNA would contain approximately half ^{15}N and half ^{14}N, producing a single band halfway between

the positions expected of DNA labeled with ^{15}N and of DNA labeled with ^{14}N. With further rounds of replication, the proportion of ^{14}N in each molecule would increase; therefore, a single hybrid band would remain, but its position in the tube would move upward. The band would also get darker as the total amount of DNA increased.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

On the left side, a grey band appears near the bottom representing D N A before the switch to N left superscript 14. Replication occurs and one grey bands appears a little below the center after one round of replication, shown on the right. Replication occurs and a dark gray band appears just below the center after two rounds of replication, shown on the right. Replication occurs and a black band appears at the after three rounds of replication, shown on the right.

ANSWERS TO CONCEPT CHECKS

1. Two bands
2. b
3. c
4. Initiator protein, helicase, single-strand-binding protein, DNA gyrase.
5. c
6. b
7. c
8. Some differences are the size of eukaryotic genomes, the linear structure of eukaryotic chromosomes, and the association of DNA with histone proteins.
9. Error-prone DNA polymerases can bypass lesions in the DNA helix that stall accurate, high-speed DNA polymerases.
10. c
11. Recombination is important for genetic variation and for some types of DNA repair.
12. d

Chapter 12 Assessment

COMPREHENSION QUESTIONS

Section 12.2

1. What is semiconservative replication?

2. How did Meselson and Stahl demonstrate that replication in *E. coli* takes place in a semiconservative manner?

3. Draw a molecule of DNA undergoing theta replication. On your drawing, identify (a) origin of replication, (b) polarity (5′ and 3′ ends) of all template strands and newly synthesized strands, (c) leading and lagging strands, (d) Okazaki fragments, and (e) locations of primers.

4. Draw a molecule of DNA undergoing rolling-circle replication. On your drawing, identify the (a) origin, (b) template and newly synthesized strands, and (c) 5′ and 3′ ends of template and newly synthesized strands.

5. Draw a molecule of DNA undergoing linear eukaryotic replication. On your drawing, identify (a) origin of replication, (b) polarity (5′ and 3′ ends) of all template and newly

synthesized strands, (c) leading and lagging strands, (d) Okazaki fragments, and (e) locations of primers.

6. What are the three major requirements of replication?

7. What substrates are used in DNA synthesis?

Section 12.3

8. List the different proteins and enzymes taking part in bacterial replication. Give the function of each in the replication process.

9. Why is DNA gyrase necessary for replication?

10. What similarities and differences exist in the enzymatic activities of DNA polymerases I and III? What is the function of each DNA polymerase in bacterial cells?

11. Why is primase required for replication?

12. What three mechanisms ensure the accuracy of replication in bacteria?

Section 12.4

13. How does replication licensing ensure that DNA is replicated only once at each origin per eukaryotic cell cycle?

14. In what ways is eukaryotic replication similar to bacterial replication, and in what ways is it different?

15. What is the end-replication problem? Why, in the absence of telomerase, do the ends of linear chromosomes get progressively shorter each time the DNA is replicated?

16. Outline in words and pictures how telomeres at the ends of eukaryotic chromosomes are replicated.

Section 12.5

17. Explain how the type of cleavage of the Holliday intermediate leads to noncrossover recombinants and crossover recombinants.

18. What are some of the enzymes taking part in recombination in *E. coli*, and what roles do they play?

APPLICATION QUESTIONS AND PROBLEMS

Section 12.2

19. Suppose a future scientist explores a distant planet and discovers a novel form of double-stranded nucleic acid. When this nucleic acid is exposed to DNA polymerases from *E. coli*, replication takes place continuously on both strands. What conclusion can you draw about the structure of this novel nucleic acid?

20. Phosphorus is required to synthesize the deoxyribonucleoside triphosphates used in DNA replication. A geneticist grows some *E. coli* in a medium containing nonradioactive phosphorus for many generations. A sample of the bacteria is then transferred to a medium that contains a radioactive isotope of phosphorus (^{32}P). Samples of the bacteria are removed immediately after the transfer and after one and two rounds of replication. Assume that newly synthesized DNA contains ^{32}P and the original DNA contains nonradioactive phosphorus. What will be the distribution of radioactivity in the DNA of the bacteria in each sample? Will radioactivity be detected in neither, one, or both strands of the DNA?

21.

*A line of mouse cells is grown for many generations in a medium with ^{15}N. Cells in G_1 are then switched to a new medium that contains ^{14}N. Draw a pair of homologous chromosomes from these cells at the following stages, showing the two strands of DNA molecules found in the chromosomes (see Chapter 2 for a review of chromosomes in different stages of the cell cycle). Use different colors to represent strands with ^{14}N and ^{15}N.

    a. Cells in G_1, before switching to medium with ^{14}N
    b. Cells in G_2, after switching to medium with ^{14}N
    c. Cells in anaphase of mitosis, after switching to medium with ^{14}N
    d. Cells in metaphase I of meiosis, after switching to medium with ^{14}N

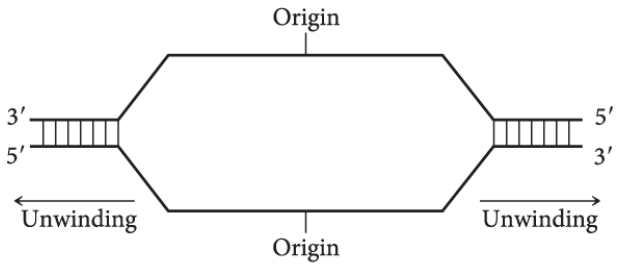
e. Cells in anaphase II of meiosis, after switching to medium with ^{14}N

22. *A circular molecule of DNA contains 1 million base pairs. If the rate of DNA synthesis at a replication fork is 100,000 nucleotides per minute, how much time will theta replication require to completely replicate the molecule, assuming that theta replication is bidirectional? How long will replication of this circular chromosome by rolling-circle replication take? Ignore replication of the displaced strand in rolling-circle replication.

23. A bacterium synthesizes DNA at each replication fork at a rate of 1000 nucleotides per second. If this bacterium completely replicates its circular chromosome by theta replication in 30 minutes, how many base pairs of DNA does its chromosome contain?

Section 12.3

24. *The following diagram represents a DNA molecule that is undergoing replication. Draw in the strands of newly synthesized DNA and identify (a) the polarity of the newly synthesized strands, (b) leading and lagging strands, (c) Okazaki fragments, and (d) RNA primers.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description
The top strand has 3 prime end on the left side and the bottom strand has 3 prime end on the right side. In the middle a replication bubble is formed with origin labeled in the center. The left end shows an arrow pointing towards left and is labeled unwinding. The right end shows an arrow pointing towards right and is labeled unwinding.

25. In **Figure 12.8**, which is the leading strand and which is the lagging strand?

26. *What would be the effect on DNA replication of mutations that destroyed each of the following activities of DNA polymerase I?
    a. 3′→5′ exonuclease activity
    b. 5′→3′ exonuclease activity
    c. 5′→3′ polymerase activity

27. Which of the DNA polymerases shown in **Table 12.3** have the ability to proofread?

28. How would DNA replication be affected in a bacterial cell that is lacking DNA gyrase?

29. *If the gene for primase were mutated so that no functional primase was produced, what would be the effect on theta

replication? On rolling-circle replication?

Section 12.4

30. Eukaryotic licensing factors prevent DNA replication from being initiated at origins more than once in the cell cycle. After replication has begun at an origin, a protein called Geminin inhibits licensing factors that are required for MCM2-7 to bind to an origin and initiate replication. Thus, when Geminin is present, MCM2-7 will not bind to an origin. At the end of mitosis, Geminin is degraded, allowing MCM2-7 to bind once again to DNA and relicense the origin. Marina Melixetian and her colleagues suppressed the expression of Geminin protein in human cells by treating the cells with small interfering RNAs (siRNAs) complementary to Geminin messenger RNA (M. Melixetian et al. 2004. *Journal of Cell Biology* 165:473–482). (Small interfering RNAs form a complex with proteins and pair with complementary sequences on mRNAs; the complex then cleaves the mRNA, so there is no translation of the mRNA; see Chapter 14.) Forty-eight hours after treatment with siRNA, the Geminin-depleted cells were enlarged and contained a single giant nucleus. Analysis of DNA content showed that many of these Geminin-depleted cells were 4n or greater. Explain these results.

31. *What results would be expected in the experiment outlined in **Figure 12.16** if, during replication, all the original histone proteins remained on one strand of the DNA and new histones attached to the other strand?

32. A number of scientists who study cancer treatment have become interested in telomerase. Why? How might anticancer therapies that target telomerase work? (See Chapter 23 on cancer genetics.)

33. *The enzyme telomerase is part protein and part RNA. What would be the most likely effect of a large deletion in the gene that encodes the RNA component of telomerase? How would the function of telomerase be affected?

34. Dyskeratosis congenita (DKC) is a rare genetic disorder characterized by abnormal fingernails and skin pigmentation, the formation of white patches on the tongue and cheek, and progressive failure of the bone marrow. An autosomal dominant form of DKC results from mutations in the gene that encodes the RNA component of telomerase. Tom Vulliamy and his colleagues examined a series of families with autosomal dominant DKC (T. Vulliamy et al. 2004. *Nature Genetics* 36:447–449). They observed that the median age of onset of DKC in parents was 37 years, whereas the median age of onset in the children of affected parents was 14.5 years. Thus, DKC in these families arose at progressively younger ages in successive generations, a phenomenon known as anticipation (see Chapter 5). The researchers measured the telomere lengths of members of these families; the measurements are given in the accompanying table. Telomeres normally shorten with age,

so telomere length was adjusted for age; the values given in the table are the differences between the actual length and the expected length based on age. Note that the values of all members of these families are negative, indicating that their telomeres are shorter than normal for their age; the more negative the number, the shorter the telomere.

Parent telomere length	Child telomere length
−4.7	−6.1
	−6.6
	−6.0
−3.9	−0.6
−1.4	−2.2
−5.2	−5.4
−2.2	−3.6
−4.4	−2.0
−4.3	−6.8
−5.0	−3.8
−5.3	−6.4

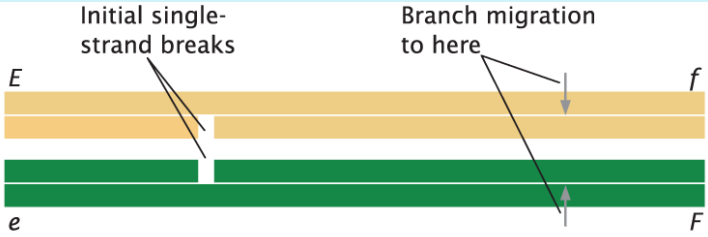
−0.6	−2.5
−1.3	−5.1
	−3.9
−4.2	−5.9

Note: The telomere lengths given in the table are the differences between the actual length and the expected length based on age. Negative values indicate shorter than expected telomeres.

a. How does the telomere length of the parents compare with the telomere length of the children? (Hint: Calculate the average telomere length of all parents and the average telomere length of all children.)
b. Explain why the telomeres of people with DKC are shorter than normal.
c. Explain why DKC arises at an earlier age in subsequent generations.

35. CONNECT An individual is heterozygous at two loci (*Ee Ff*), and the two genes are in repulsion (see pp. 187–188 in Chapter 7). Assume that single-strand breaks and branch migration occur at the positions shown at right. Using different colors to represent the two homologous chromosomes, draw the noncrossover recombinant and crossover recombinant DNA

molecules that will result from homologous recombination. (Hint: See Figure 12.19.)



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

Description

The top chromosome is yellow and has big E small F genes. The bottom chromosome is green and has small E big F genes. For the yellow D N A molecule, the big E locus is on the far left, one-third to the right is the single-stranded breaking point, one-third more to the right is an arrow pointing the branch migration point, and at the very end is the small F locus. For the green D N A molecule, small E focus is on far left, one-third to the right on the bottom D N A strand is the single-stranded breaking point, one-third more to the right is an arrow pointing the branch migration point, and at the very end is the big F locus.

CHALLENGE QUESTIONS

Section 12.3

36. A conditional mutation expresses its mutant phenotype only under certain conditions (the restrictive conditions) and expresses the normal phenotype under other conditions (the

permissive conditions). One type of conditional mutation is a temperature-sensitive mutation, which expresses the mutant phenotype only at certain temperatures.

Strains of *E. coli* have been isolated that contain temperature-sensitive mutations in genes encoding different components of the replication machinery. In each of these strains, the protein produced by the mutated gene is nonfunctional under the restrictive conditions. You grow these strains under the permissive conditions and then abruptly switch them to the restrictive conditions. After one round of replication under the restrictive conditions, you isolate DNA from each strain and analyze it. What characteristics would you expect to see in the DNA isolated from a strain with a temperature-sensitive mutation in the gene that encodes each of the following proteins?

a. DNA ligase
b. DNA polymerase I
c. DNA polymerase III
d. Primase
e. Initiator protein

Section 12.4

37.

DNA topoisomerases play important roles in DNA replication and in supercoiling (see Chapter 11). These enzymes are also the targets for certain anticancer drugs. Eric Nelson and his colleagues studied m-AMSA, one of the anticancer

compounds that acts on topoisomerase (E. M. Nelson, K. M. Tewey, and L. F. Liu. 1984. *Proceedings of the National Academy of Sciences of the United States of America* 81:1361–1365). They found that m-AMSA stabilizes an intermediate produced in the course of topoisomerase action. The intermediate consists of topoisomerase bound to the broken ends of the DNA. Breaks in DNA that are produced by anticancer compounds such as m-AMSA inhibit the replication of the cellular DNA and thus stop cancer cells from proliferating. Explain how m-AMSA and other anticancer agents that target topoisomerase enzymes taking part in replication might lead to DNA breaks and chromosome rearrangements.

38. * CONNECT The regulation of replication is essential to genomic stability. Normally, the DNA is replicated just once in every eukaryotic cell cycle (in the S phase). Normal cells produce protein A, which increases in concentration in the S phase. In cells that have a mutated copy of the gene encoding protein A, the protein is not functional, and replication takes place continuously throughout the cell cycle, with the result that cells may have 50 times the normal amount of DNA. Protein B is normally present in G_1 but disappears from the cell nucleus during the S phase. In cells with a mutated copy of the gene encoding protein A, the levels of protein B fail to drop in the S phase and, instead, remain high throughout the cell cycle. When the gene for protein B is mutated, no replication takes place. Propose a mechanism for how protein A and protein B might

normally regulate replication so that each cell gets the proper amount of DNA. Explain how mutation of these genes produces the effects just described.

🗣️ ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

Section 12.1

1. In the 1996 movie *Multiplicity*, Doug (played by Michael Keaton) is a construction worker who wants to spend more time with his family. He meets a friendly scientist who has developed a method for cloning humans. Doug decides to make a clone of himself who can take over his work while he spends quality time with his family. The clone, named Two, seems great at first, but problems surface in his functioning. Two decides to make a clone of himself, so he won't have to work, and creates Three. A fourth clone is eventually made. Each successive clone seems to have more problems. Ignore, for the present, the technical difficulties and ethical problems with making an instantaneous adult clone of a human. Is there any genetic validity to the premise that making a clone of a clone might create problems? If so, what might those problems be?

Section 12.2

2. In their experiment, could Meselson and Stahl have used two different isotopes of carbon instead of ^{14}N and ^{15}N? Why or why not? What about two different isotopes of sulfur?

Section 12.3

3. DNA polymerases cannot act as primers for replication, yet primase and other RNA polymerases can. Some geneticists have speculated that the inability of DNA polymerase to prime replication is a result of its proofreading function. This hypothesis argues that proofreading is essential for the faithful transmission of genetic information and that because DNA polymerases have evolved the ability to proofread, they cannot prime DNA synthesis. Explain why proofreading and priming functions in the same enzyme might be incompatible.

Section 12.4

4. Many anticancer drugs work by interfering with different components of the replication machinery. For example, camptothecin inhibits the action of topoisomerase during replication. These compounds often have unwanted side effects. What are some common negative side effects of chemotherapy, and why do they arise?

5. Okazaki fragments in bacterial cells are 1000 to 2000 nucleotides in length. Those in eukaryotic cells are much shorter, usually only 100 to 200 nucleotides in length. Propose some possible explanations for why Okazaki fragments in bacteria are longer

than those in eukaryotes. What difference between the two cell types could lead to the difference in Okazaki fragment length?

6. HeLa cells are a line of cells grown in laboratory culture that has been used extensively in research. This cell line was originally derived from malignant cervical cancer cells that were removed from a woman named Henrietta Lacks in 1951. They were subsequently grown in culture and shipped to research laboratories around the world, where they have been used in many important experiments. Like HeLa cells, many other cell lines were originally taken from cancerous tissue. Why are cancer cells often used for developing cell lines?

7. For centuries, people have searched for the fabled Fountain of Youth, said to confer the ability to forestall old age and remain young forever. To gain insight into how tackling aging by targeting telomerase might work, researchers looked at mice that lack a telomerase gene. These mice have shorter telomeres than normal mice and age prematurely. But when these mice are engineered to express telomerase in their somatic cells, their telomeres lengthen, and the effects of aging are reversed. This observation suggests that a drug that stimulates the expression of telomerase in somatic cells could prevent telomere shortening and stop the aging process. Do you think such a drug would work well in humans? What might be some potential side effects of such a drug?

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Introduction

1. Create a concept map that outlines the connection between origins of replication and Meier-Gorlin syndrome using the following main concepts: eukaryotic cells, large genome, numerous origins of replication, replication once per cell cycle, licensed replication, Meier-Gorlin syndrome, small stature, small ears, no kneecaps, origin-replication complex.

Sections 12.2 and 12.3

2. Outline the process of DNA replication in bacteria by drawing a concept map that includes the following terms: replication, origin of replication, initiator protein, replication bubble, continuous replication, discontinuous replication, leading strand, lagging strand, Okazaki fragments, DNA ligase, helicase, single-strand DNA, replication fork, single-strand binding proteins, DNA gyrase, primase, RNA primer, DNA polymerase I, DNA polymerase III.

Section 12.4

3. Draw a concept map that connects important concepts across Chapters 2 and 12: DNA replication, G_1/S checkpoint, interphase, S phase, sister chromatids, anaphase of mitosis,

semiconservative replication, $5' \rightarrow 3'$, continuous replication, discontinuous replication, lagging strand, leading strand.

4. Create a concept map that summarizes the differences in bacterial and eukaryotic replication.
5. Show the relationships among the following concepts by drawing a concept map: end of replication problem, telomeres, telomerase, G-rich strand, RNA primer, $3'$-OH, somatic cells, germ cells, end of chromosome, telomeric repeats, aging, cancer cells, limited cell divisions, telomere shortening.

CHAPTER 13

Transcription

Frank Krahmer/Getty Images.

DNA is a single-lane highway on which DNA and RNA polymerases race at high speeds, carrying out replication and transcription. Cells have evolved mechanisms to prevent and fix collisions that inevitably occur between these molecules.

Wrecks on the DNA Highway

DNA is a heavily used single-lane highway, in which DNA and RNA polymerases race at breakneck speeds, carrying out the vital processes of replication and transcription. And like cars traveling a

single-lane road, conflicts and collisions are inevitable. How do cells avoid these conflicts and deal with collisions?

As we discussed in Chapter 12, replication is the mechanism by which new DNA molecules are synthesized using single-stranded DNA templates through semiconservative replication. DNA synthesis is integral to cell division: before a cell can divide, it must copy its entire genome so that each cell resulting from division receives a complete set of genetic instructions. Transcription, discussed in this chapter, is equally important. It is the first step that uses the coding instructions in the DNA to create the traits of an organism, through the copying of DNA sequences into an RNA molecule.

Both replication and transcription require reading DNA polynucleotide strands. Although they begin at different places (replication begins at origins and transcription starts at promoters), both processes move in the same $5' \rightarrow 3'$ direction and can take place on either DNA strand, so encounters between DNA and RNA polymerases are sure to occur. These enzymes travel at remarkable speeds: replication in bacteria takes place at 1000 nucleotides per second; transcription is slower, but still incredibly fast, occurring at about 40 nucleotides per second. If these two processes meet head on, catastrophic collisions occur. Even when traveling in the same direction, differences in the speed of replication and transcription lead to rear-end crashes, like collisions between cars traveling at 10

mph and others traveling at 250 mph, all on the same single-lane road.

Head-on collisions between DNA and RNA polymerases usually bring a halt to replication and cause the premature termination of transcription. Replication must then be restarted for the entire genome to be copied. Similarly, transcription of individual genes must be reinitiated. Collisions also lead to DNA breaks and mutations, which cause genetic diseases, cancer, and other problems. Because of these negative consequences, cells have evolved a number of mechanisms to avoid, tolerate, and fix collisions between replication and transcription.

In bacteria, replication usually begins at a single origin, occurs continuously on both strands, and is not segregated in time from transcription, so conflicts between the two processes are common. Many bacteria have evolved in a simple way to avoid head-on collisions: highly transcribed and essential genes are transcribed in the same direction that replication occurs, so head-on clashes are avoided. For example, in the bacterium *Bacillus subtilis*, 94% of essential genes are transcribed in the same direction that replication occurs. Although codirectional replication and transcription avoid head-on collisions, this does not prevent rear-end wrecks, as the faster replication complexes overtake and ram into the slower-moving transcription enzymes. To deal with crashes, bacteria have evolved mechanisms to restart replication

forks stalled by collisions, remove transcription complexes blocked by collisions, and repair DNA breaks and mutations resulting from collisions.

For many years, researchers assumed that collisions would be less common in eukaryotic cells. Replication in eukaryotes is restricted to S phase (see Chapter 2), allowing transcription to occur without risk of colliding with replication complexes during other phases of the cell cycle. Also, the speeds of replication and transcription complexes in eukaryotes are more similar, reducing the risk of rear-end collisions. Nevertheless, research now shows that collisions between replication and transcription do occur in eukaryotes, and eukaryotes, like bacteria, have evolved mechanisms to avoid and correct damage caused by collisions. For example, gene expression that must take place in S phase is controlled so that transcription occurs in early S phase for genes that are replicated in late S phase, and vice versa. Key to the controlling conflicts between replication and transcription is the efficient and highly organized manner in which transcription occurs (discussed in this chapter) and the careful control of gene expression (discussed in Chapters 16 and 17).

THINK-PAIR-SHARE

- In bacteria, RNA polymerases carry out transcription more slowly than DNA polymerases carry out replication. Why is speed more important in replication than in transcription?

Collisions between replication and transcription complexes are just one of the many challenges created by the need to faithfully transcribe a DNA template into an RNA molecule. This chapter is about the process of transcription, the first step in the pathway of information transfer from DNA (genotype) to protein (phenotype). Transcription is a complex process that requires a DNA template, precursors to RNA nucleotides, and a number of protein components. As we examine the stages of transcription, try to keep all the details in perspective and focus on understanding how they relate to the overall purpose of transcription: the selective synthesis of an RNA molecule.

This chapter begins with a brief review of RNA structure and a discussion of the different classes of RNA. We then consider the major components required for transcription. Finally, we explore the process of transcription. At several points in the text, we pause to consider some general principles that emerge.

13.1 RNA, Consisting of a Single Strand of Ribonucleotides, Participates in a Variety of Cellular Functions

Before we begin our study of transcription, let's consider the past and present importance of RNA, review the structure of RNA, and examine some of the different types of RNA molecules.

An Early RNA World

Life requires two basic functions. First, living organisms must be able to store and faithfully transmit genetic information during reproduction. Second, they must have the ability to catalyze the chemical transformations that drive life processes. A long-held belief was that the functions of information storage and chemical transformation are handled by two entirely different types of molecules: genetic information is stored in nucleic acids, whereas chemical transformations are catalyzed by protein enzymes. This biochemical dichotomy created a dilemma: Which came first, proteins or nucleic acids? If nucleic acids carry the coding instructions for proteins, how could proteins be generated without them? Nucleic acids are unable to copy themselves, so how could they be generated without proteins? If DNA and proteins each require the other, how could life begin?

This apparent paradox was answered in 1981 when Thomas Cech and his colleagues discovered that RNA can serve as a biological catalyst. They found that some RNA molecules from the protozoan *Tetrahymena thermophila* can excise 400 nucleotides from its RNA in the absence of any protein. Other examples of catalytic RNAs have now been discovered in different types of cells. Called **ribozymes**, these catalytic RNA molecules can cut out parts of their own sequences, connect some RNA molecules together, replicate others, and catalyze the formation of peptide bonds between amino acids. The discovery of ribozymes complements other evidence suggesting that the original genetic material was RNA.

Self-replicating ribozymes probably first arose between 3.5 billion and 4 billion years ago and may have begun the evolution of life on Earth. Early life was probably an RNA world, where RNA molecules served both as carriers of genetic information and as catalysts that drove the chemical reactions needed to sustain and perpetuate life. These catalytic RNAs may have acquired the ability to synthesize protein-based enzymes, which are more efficient catalysts. With enzymes taking over more and more of the catalytic functions, RNA probably became relegated to the role of information storage and transfer. DNA, with its chemical stability and faithful replication, eventually replaced RNA as the primary carrier of genetic information. Nevertheless, RNA is either produced by or plays a vital role in many biological processes, including transcription, replication, RNA processing, and translation. Research in the past 20 years has also determined that newly discovered small RNA molecules play a fundamental role in many basic biological processes, demonstrating that life today is still very much an

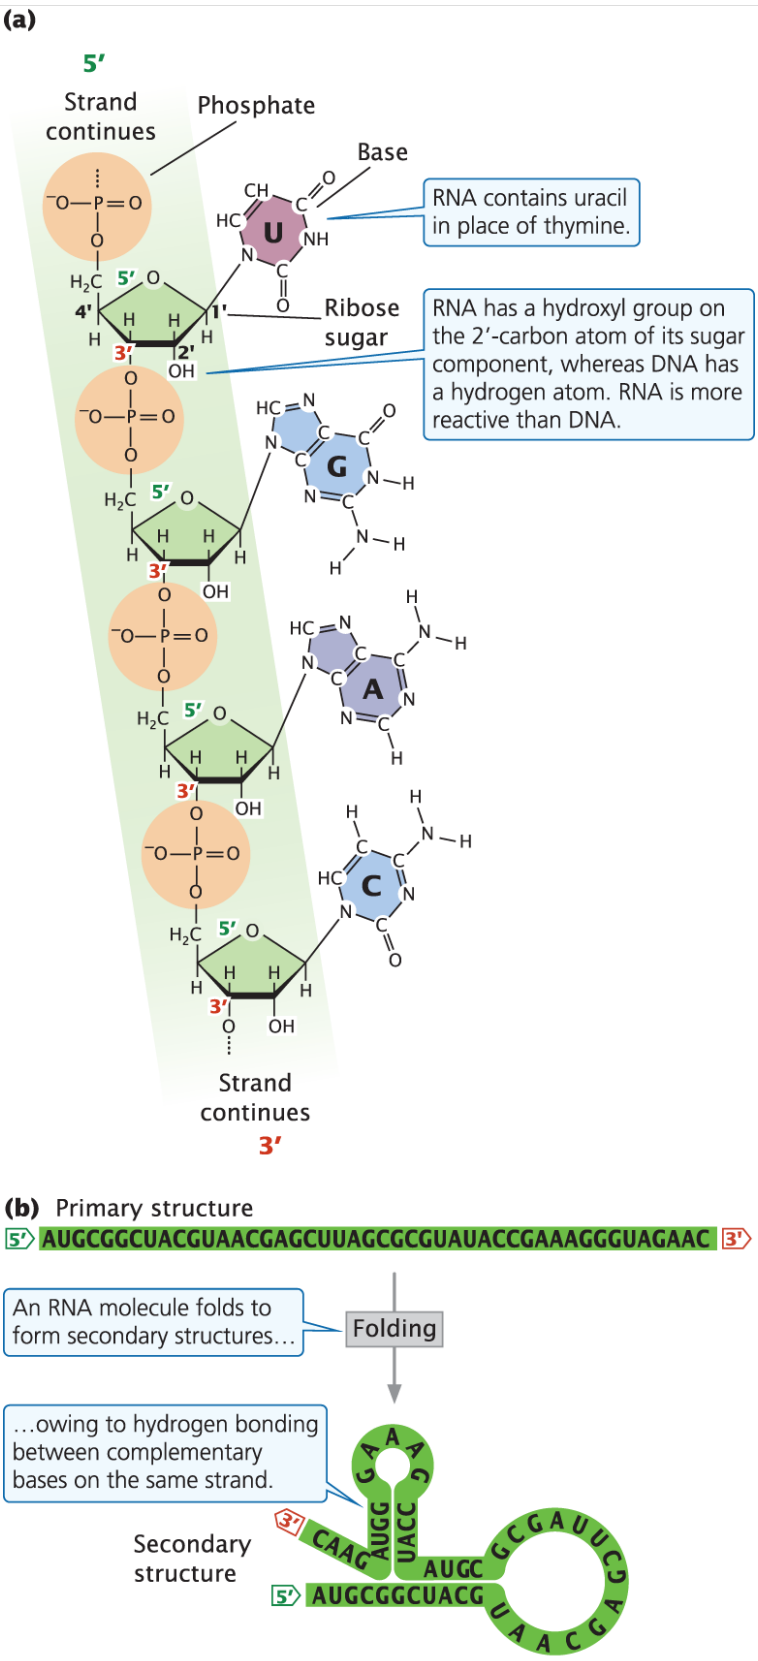
RNA world. These small RNA molecules will be discussed in more detail in Chapter 14.

CONCEPTS

Early in the history of life, RNA probably served both as the original genetic material and as biological catalysts.

The Structure of RNA

RNA, like DNA, is a polymer of nucleotides, each consisting of a sugar, a phosphate group, and a nitrogenous base, joined together by phosphodiester bonds (see Chapter 10). However, there are several important differences in the structures of DNA and RNA. Whereas DNA nucleotides contain deoxyribose sugars, RNA nucleotides have ribose sugars (**Figure 13.1a**). With a free hydroxyl group on the 2′-carbon atom of the ribose sugar, RNA is degraded rapidly under alkaline conditions. The deoxyribose sugar of DNA lacks this free hydroxyl group, so DNA is a more stable molecule. Another important difference is that the pyrimidine uracil is present in RNA instead of thymine, one of the two pyrimidines found in DNA.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

13.1 RNA has a primary and a secondary structure.

Description
Diagram a, at the top, shows an R N A strand from 5 prime to 3 prime. A phosphate group is bonded to C 5 prime of a sugar molecule while a uracil base is bonded to its C 1 prime. A phosphate group attached at C 3 prime bonds to the C 5 prime of next sugar molecule. A caption reads, R N A contains uracil in place of thymine. R N A has a hydroxyl group on the 2 prime carbon atom of its sugar component, whereas D N A has a hydrogen atom. R N A is more reactive than D N A. Diagram b, below labeled primary structure, shows a strand from 5 prime to 3 prime. The nucleotides are as follows: A, U, G, C, G, G, C, U, A, C, G, U, A, A, C, G, A, G, C, U, U, A, G, C, G, C, G, U, A, U, A, C, C, G, A, A, A, G, G, G, U, A, G, A, A, C. Folding occurs below. A caption reads, an R N A molecule folds to form secondary structures owing to hydrogen bonding between complementary bases on the same strand. The structure formed after folding has double-stranded stems and single-stranded loops. The first loop has the following sequence: G, A, A, A, G and the second loop has the following sequence: G, C, G, A, U, U, C, G, A, G, C, A, A, U.

A final difference in the structures of DNA and RNA is that RNA usually consists of a single polynucleotide strand, whereas DNA normally consists of two polynucleotide strands joined by hydrogen bonding between complementary bases (although some viruses contain double-stranded RNA genomes, as discussed in Chapter 9). Although RNA is usually single stranded, short complementary regions within a nucleotide strand can pair and form secondary structures (**Figure 13.1b**). These RNA secondary structures are often called hairpins (or hairpin-loop or stem-loop structures). When two regions within a single RNA molecule pair up, the strands in those regions must be antiparallel and with pairing between cytosine and guanine and between adenine and uracil (although occasionally guanine pairs with uracil).

The formation of secondary structures plays an important role in RNA function. Secondary structure is determined by the base sequence of the nucleotide strand, so different RNA molecules can assume different structures. Because their structure determines their function, RNA molecules have the potential for tremendous variation in function. With its two complementary strands forming a helix, DNA is much more restricted in the range of secondary structures that it can assume and so has fewer functional roles in the cell. Similarities and differences in DNA and RNA structures are summarized in Table 13.1.

› TRY PROBLEM 15

TABLE 13.1 Comparison of DNA and RNA structures

Characteristic	DNA	RNA
Composed of nucleotides	Yes	Yes
Type of sugar	Deoxyribose	Ribose
Presence of 2′-OH group	No	Yes
Bases	A, G, C, T	A, G, C, U
Nucleotides joined by phosphodiester bonds	Yes	Yes
Double or single stranded	Usually double	Usually single
Secondary structure	Double	Many

	helix	types
Stability	Stable	Easily degraded

Classes of RNA

RNA molecules perform a variety of functions in the cell. **Ribosomal RNA (rRNA)** and ribosomal protein subunits make up the ribosome, the site of protein assembly. We'll take a more detailed look at the ribosome in Chapter 14. **Messenger RNA (mRNA)** carries the coding instructions for a polypeptide chain from DNA to a ribosome. After attaching to the ribosome, an mRNA molecule specifies the sequence of the amino acids in a polypeptide chain and provides a template for the joining of those amino acids. Large precursor molecules, which are termed **pre-messenger RNAs (pre-mRNAs)**, are the immediate products of transcription in eukaryotic cells. Pre-mRNAs are modified extensively before becoming mRNA and exiting the nucleus for translation into protein. Bacterial cells do not possess pre-mRNA; in these cells, transcription takes place concurrently with translation.

Transfer RNA (tRNA) serves as the link between the coding sequence of nucleotides in an mRNA molecule and the amino acid sequence of a polypeptide chain. Each tRNA attaches to one particular type of amino acid and helps incorporate that amino acid into a polypeptide chain (as described in Chapter 15).

Additional classes of RNA molecules are found in the nuclei of eukaryotic cells. **Small nuclear RNAs (snRNAs)** combine with small protein subunits to form **small nuclear ribonucleoproteins** (snRNPs, affectionately known as "snurps"). Some snRNAs participate in the processing of RNA, converting pre-mRNA into mRNA. **Small nucleolar RNAs (snoRNAs)** take part in the processing of rRNA.

Two types of very small and abundant RNA molecules found in the cytoplasm of eukaryotic cells, termed **microRNAs (miRNAs)** and **small interfering RNAs (siRNAs)**, carry out RNA interference (RNAi), a process in which these small RNA molecules help trigger the degradation of mRNA or inhibit its translation into protein. More will be said about RNA interference in Chapter 14. Another class of small RNA molecules are **Piwi-interacting RNAs** (**piRNAs**; named after Piwi proteins, with which they interact). Found in mammalian testes, these RNA molecules are similar to miRNAs and siRNAs; they have a role in suppressing the expression of transposable elements (see Chapter 18) in reproductive cells. **Long noncoding RNAs (lncRNAs)** are relatively long RNA molecules found in eukaryotes that do not code for proteins. They provide a variety of functions, including regulation of gene expression. In prokaryotes, an RNA interference-like system has been discovered, in which small **CRISPR RNAs (crRNAs)** assist in the destruction of foreign DNA molecules. Some of the different classes of RNA molecules are summarized in **Table 13.2**.

TABLE 13.2 Locations and functions of different classes of RNA molecules

Class of RNA	Cell Type	Location of Function in Eukaryotic Cells*	Function
Ribosomal RNA (rRNA)	Prokaryotic and eukaryotic	Cytoplasm	Structural and functional components of the ribosome
Messenger RNA (mRNA)	Prokaryotic and eukaryotic	Nucleus and cytoplasm	Carries genetic code for proteins
Transfer RNA (tRNA)	Prokaryotic and eukaryotic	Cytoplasm	Helps incorporate amino acids into polypeptide chain
Pre-messenger RNA (pre-mRNA)	Eukaryotic	Nucleus	Precursor to mRNA

Small nuclear RNA (snRNA)	Eukaryotic	Nucleus	Processing of pre-mRNA
Small nucleolar RNA (snoRNA)	Eukaryotic	Nucleus	Processing and assembly of rRNA
MicroRNA (miRNA)	Eukaryotic	Nucleus and cytoplasm	Inhibits translation of mRNA
Small interfering RNA (siRNA)	Eukaryotic	Nucleus and cytoplasm	Triggers degradation of other RNA molecules
Piwi-interacting RNA (piRNA)	Eukaryotic	Nucleus and cytoplasm	Suppresses the transcription of transposable elements in reproductive cells
Long noncoding	Eukaryotic	Nucleus and	Variety of functions

RNA (lncRNA)		cytoplasm	
CRISPR RNA (crRNA)	Prokaryotic	—	Assists destruction of foreign DNA

*All eukaryotic RNAs are synthesized in the nucleus.

CONCEPTS

RNA differs from DNA in that RNA possesses a hydroxyl group on the 2′-carbon atom of its sugar, contains uracil instead of thymine, and is usually single stranded. Several classes of RNA exist within bacterial and eukaryotic cells.

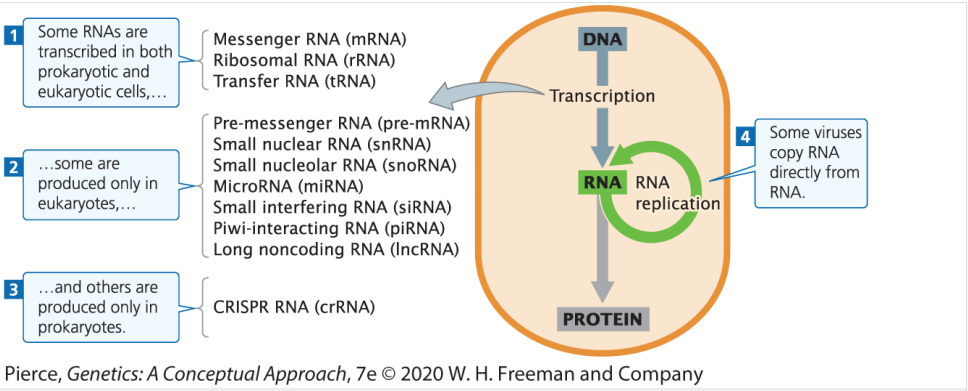
✔ CONCEPT CHECK 1

Which class of RNA is correctly paired with its function?

a. Small nuclear RNA (snRNA): processes rRNA
b. Transfer RNA (tRNA): attaches to an amino acid
c. MicroRNA (miRNA): carries information for the amino acid sequence of a protein
d. Ribosomal RNA (rRNA): carries out RNA interference

13.2 Transcription Is the Synthesis of an RNA Molecule from a DNA Template

All cellular RNAs are synthesized from DNA templates through the process of transcription (Figure 13.2). Transcription is in many ways similar to the process of replication, but a fundamental difference relates to the length of the template used. In replication, all the nucleotides in the DNA molecule are copied, but in transcription, only parts of the DNA molecule are transcribed into RNA. Because not all gene products are needed at the same time or in the same cell, the constant transcription of all of a cell's genes would be highly inefficient. Furthermore, much of the DNA does not encode any functional product, and transcription of such sequences would be pointless. Transcription is, in fact, a highly selective process: individual genes are transcribed only as their products are needed. However, this selectivity imposes a fundamental problem on the cell: how to recognize individual genes and transcribe them at the proper time and place.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

13.2 All cellular types of RNA are transcribed from DNA.

Description

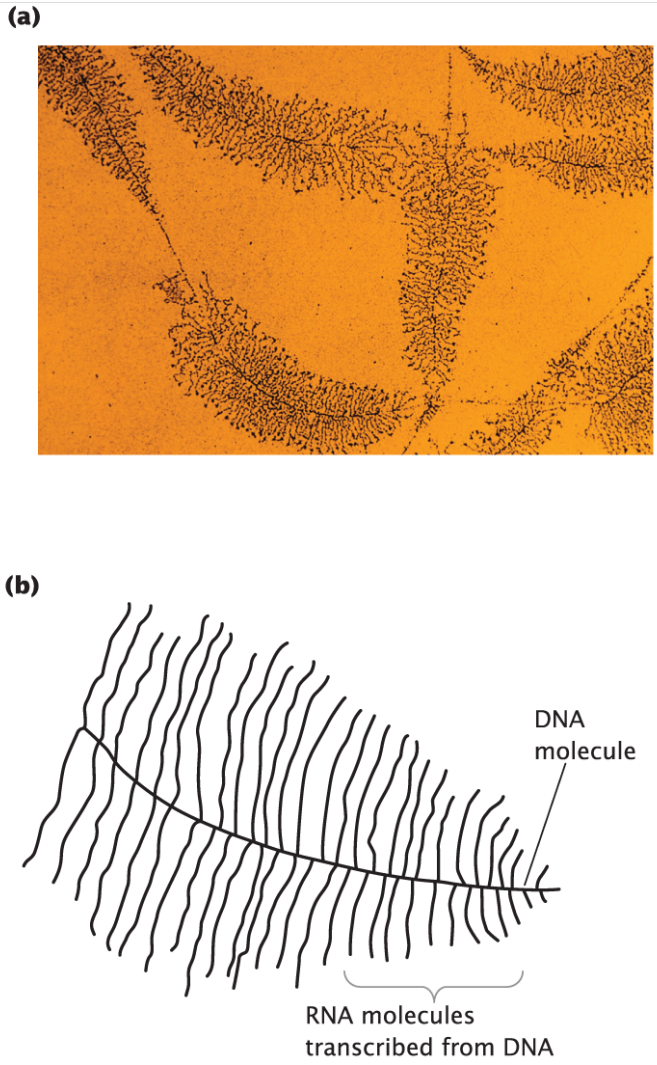
The illustration shows a cell where D N A undergoes transcription. A caption reads, some R N As are transcribed in both prokaryotic and eukaryotic cells. These R N As include messenger R N A (m R N A), ribosomal R N A (r R N A), and transfer R N A (t R N A). Another caption reads, Some are produced only in eukaryotes. These include pre-messenger R N A (pre-m R N A), small nuclear R N A (s n R N A), small nucleolar R N A (s n o R N A), micro R N A (m i R N A), small interfering R N A (s i R N A), piwi-interacting R N A (p i R N A), and long noncoding R N A (l n c R N A). A caption reads, and others are produced only in prokaryotes. These include C R I S P R R N A (c r R N A). After transcription, R N A is produced. R N A undergoes replication to produce R N A again. A caption reads, some viruses copy R N A directly from R N A. R N A eventually leads to protein formation.

Like replication, transcription requires three major components:

1. A DNA template
2. The raw materials (ribonucleotide triphosphates) needed to build a new RNA molecule
3. The transcription apparatus, consisting of the proteins necessary for catalyzing the synthesis of RNA

The Template

In 1970, Oscar Miller, Jr.; Barbara Hamkalo; and Charles Thomas used electron microscopy to demonstrate that RNA is transcribed from a DNA template. They broke open salamander oocytes, extracted chromatin, and spread the chromatin onto a fine-mesh grid. Under the electron microscope, they observed Christmas-tree-like structures, each consisting of a thin central fiber (the trunk of the tree) to which were attached strings (the branches) bearing granules (**Figure 13.3a**). The addition of deoxyribonuclease (an enzyme that degrades DNA) caused the central fibers to disappear, indicating that the "tree trunks" were DNA molecules. Ribonuclease (an enzyme that degrades RNA) removed the granular strings, indicating that the branches were RNA. Their conclusion was that each "Christmas tree" represents a gene undergoing transcription (**Figure 13.3b**). The transcription of each gene begins at the top of the tree; there, little of the DNA has been transcribed, and the RNA branches are short. As the transcription apparatus moves down the tree, transcribing more of the template, the RNA molecules lengthen, producing the long branches at the bottom.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company
Part a: Medical Images RM/Phototake, Inc.

13.3 Under the electron microscope, DNA molecules undergoing transcription exhibit Christmas-tree-like structures. (a) Electron micrograph of transcription units. (b) The trunk of each "Christmas tree" (a transcription unit) represents a portion of a DNA molecule; the tree branches are RNA molecules that have been transcribed from the DNA. As the transcription apparatus moves down the DNA, transcribing more of the template, the RNA molecules become longer and longer.

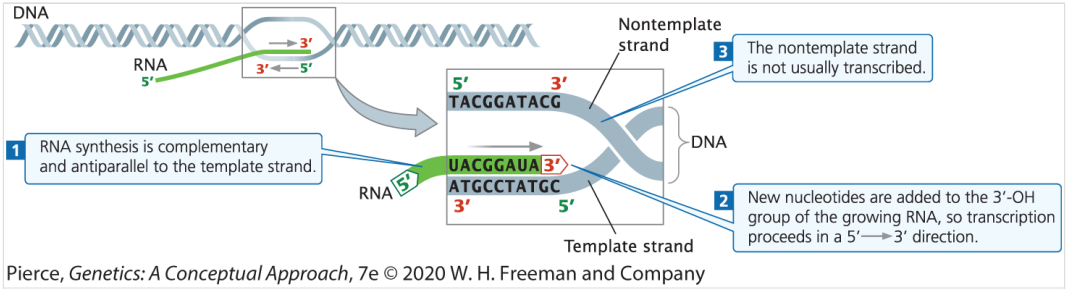
Description

The electron micrograph a shows various randomly arranged, black colored, transcription units that appear like miniature Christmas trees over an orange background. The drawing

b below shows a Christmas tree where the trunk represents a D N A molecule and the branches represent R N A molecules.

THE TRANSCRIBED STRAND

The template for RNA synthesis, as for DNA synthesis, is a single strand of the DNA double helix. Unlike replication, however, the transcription of a gene takes place on only one of the two nucleotide strands of DNA (Figure 13.4). The nucleotide strand used for transcription is termed the **template strand**. The other strand, called the **nontemplate strand**, is not ordinarily transcribed. Thus, within a gene, only one of the nucleotide strands is normally transcribed into RNA (although there are some exceptions to this rule).



13.4 Transcription produces RNA molecules that are complementary and antiparallel to one of the two nucleotide strands of DNA: the template strand.

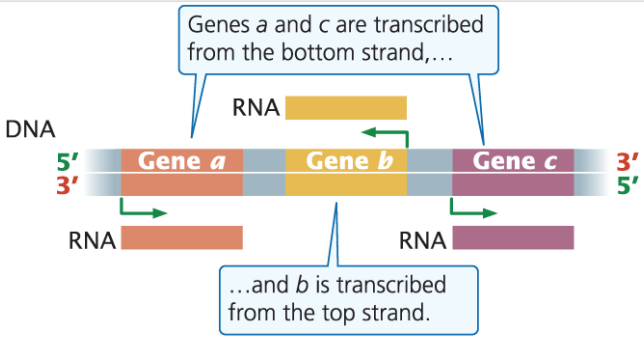
Description

The illustration shows a double helical D N A strand, at the top, with a replication bubble. A newly synthesized R N A is produced from 5 prime to 3 prime while the template strand is from 3 prime to 5 prime. The nucleotides of the newly synthesized R N A strand are: U, A, C, G, G, A, U, A which is complementary to the nucleotides on the template strand (A, T, G, C, C, T, A, T). A magnified view, on the right, shows the newly synthesized strand formed above the template D N A strand. A caption reads, R N A synthesis is complementary and

antiparallel to the template strand. New nucleotides are added to the 3 prime O H group of the growing R N A; so transcription proceeds in a 5 prime to 3 prime direction. A caption reads, The nontemplate strand is not usually transcribed.

During transcription, an RNA molecule that is complementary and antiparallel to the DNA template strand is synthesized (see Figure 13.4). The RNA transcript has the same polarity and base sequence as the nontemplate strand except that it contains U rather than T. In most organisms, each gene is transcribed from a single DNA strand, but different genes may be transcribed from different strands, as shown in **Figure 13.5**. ❯ **TRY PROBLEM 16**

THINK-PAIR-SHARE Question 1



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

13.5 RNA is transcribed from one DNA strand. In most organisms, each gene is transcribed from a single DNA strand, but different genes may be transcribed from either DNA strand.

Description
The illustration shows a double stranded D N A molecule with genes small A, small B, and small C. Genes small A and small C are transcribed from the bottom strand that runs from

3 prime to 5 prime. These genes are transcribed from left to right. Gene small B is transcribed from top strand that runs from 5 prime to 3 prime. This gene is transcribed from right to left. A caption reads, Genes small A and small C are transcribed from the bottom strand and small B is transcribed from the top strand.

CONCEPTS

Within a single gene, only one of the two DNA strands, the template strand, is usually transcribed into RNA.

✔ CONCEPT CHECK 2

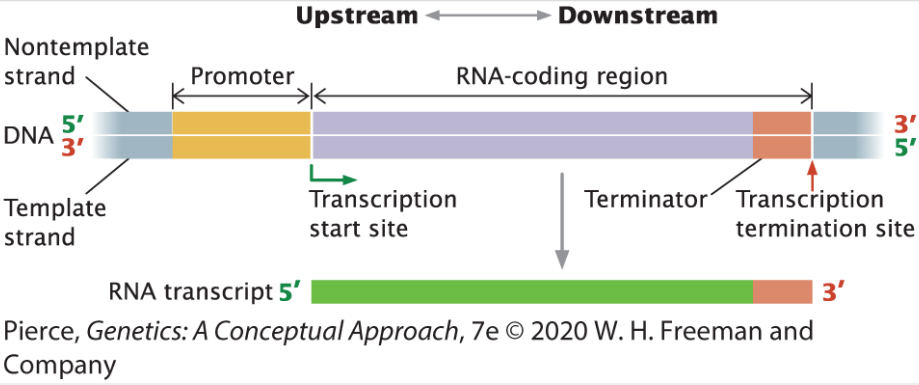
What is the difference between the template strand and the nontemplate strand?

THE TRANSCRIPTION UNIT

A **transcription unit** is a stretch of DNA that encodes an RNA molecule and the sequences necessary for its transcription. How does the complex of enzymes and proteins that performs transcription—the transcription apparatus—recognize a transcription unit? How does it know which DNA strand to read and where to start and stop? This information is encoded by the DNA sequence.

Included within a transcription unit are three critical regions: a promoter, an RNA-coding region, and a terminator (Figure 13.6). The **promoter** is a DNA sequence that the transcription apparatus

recognizes and binds. The promoter indicates which of the two DNA strands is to be read as the template and the direction of transcription. It also determines the transcription start site, the first nucleotide that will be transcribed into RNA. In many transcription units, the promoter is located next to the transcription start site but is not itself transcribed.



13.6 A transcription unit includes a promoter, an RNA-coding region, and a terminator.

Description

The top strand running from 5 prime end to 3 prime end is labeled as nontemplate strand, and the bottom strand running from 3 prime to 5 prime strand is labeled as template strand. From left to right, promoter is labeled on the left side of both strands. To its right, transcription start site begins, along with the R N A-coding region which ends at the Transcription termination site after a terminator sequence on the right side of the strands. A double headed arrow shows upstream on the left and downstream on the right. A transcription termination site is marked. A R N A transcript is formed below that from 5 prime to 3 prime.

The second critical region of the transcription unit is the **RNA-coding region**, a sequence of DNA nucleotides that is copied into an

RNA molecule. The third component of the transcription unit is the **terminator**, a sequence of nucleotides that signals where transcription is to end. Terminators are usually part of the RNA-coding sequence; transcription stops only after the terminator has been copied into RNA.

Molecular biologists often use the terms *upstream* and *downstream* to refer to the direction of transcription and the locations of nucleotide sequences surrounding the RNA-coding region. The transcription apparatus is said to move downstream during transcription: it binds to the promoter (which is usually upstream of the transcription start site) and moves toward the terminator (which is downstream of the start site).

When DNA sequences are written out, often the sequence of only one of the two strands is listed. Molecular biologists typically write the sequence of the nontemplate strand because it will be the same as the sequence of the RNA transcribed from the template strand (with the exception that U in RNA replaces T in DNA). By convention, the sequence of the nontemplate strand is written with the $5'$ end on the left and the $3'$ end on the right. The first nucleotide transcribed (the transcription start site) is numbered +1; nucleotides downstream of the start site are assigned positive numbers, and nucleotides upstream of the start site are assigned negative numbers. So, nucleotide +34 would be 34 nucleotides downstream of the start site, whereas nucleotide −75 would be 75 nucleotides upstream of the start site. There is no nucleotide numbered 0.

CONCEPTS

A transcription unit is a stretch of DNA that encodes an RNA molecule and the sequences necessary for its proper transcription. Each transcription unit includes a promoter, an RNA-coding region, and a terminator.

✔ CONCEPT CHECK 3

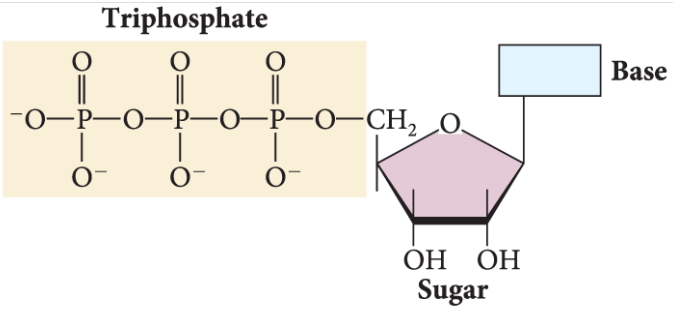
Which of the following phrases does *not* describe a function of the promoter?

a. Serves as the sequence to which the transcription apparatus binds
b. Determines the first nucleotide that is transcribed into RNA
c. Determines which DNA strand is the template
d. Signals where transcription ends

The Substrate for Transcription

RNA is synthesized from **ribonucleoside triphosphates (rNTPs)**, each consisting of a ribose sugar and a base (a nucleoside) attached to three phosphate groups (**Figure 13.7**). In RNA synthesis, nucleotides are added one at a time to the 3′-OH group of the growing RNA molecule. Two phosphate groups are cleaved from the incoming ribonucleoside triphosphate; the remaining phosphate group participates in a phosphodiester bond that connects the nucleotide to the growing RNA molecule. The overall chemical reaction for the addition of each nucleotide is

$$RNA_n + rNTP \rightarrow RNA_{n+1} + PP_i$$

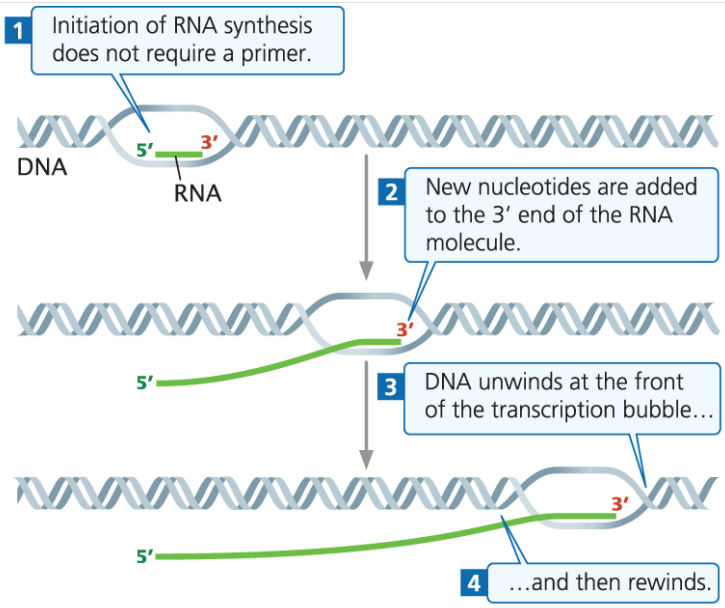


Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

13.7 Ribonucleoside triphosphates are substrates used in RNA synthesis.

Description
A triphosphate chain is bonded to the 5 prime carbon atom of the ribose sugar. A rectangular shaped base is bonded to the 1 prime carbon atom.

where PP_i represents pyrophosphate. Nucleotides are always added to the 3′ end of the RNA molecule, and the direction of transcription is therefore 5′→3′ (Figure 13.8), the same as the direction of DNA synthesis during replication. Thus, the newly synthesized RNA is complementary and antiparallel to the template strand. Unlike DNA synthesis, RNA synthesis does not require a primer.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

13.8 In transcription, nucleotides are always added to the 3′ end of the RNA molecule.

Description

The illustration shows a double helix D N A strand, at the top, with a replication bubble toward the left. A newly synthesized R N A strand runs from 5 prime to 3 prime and is present above the bottom D N A strand. A caption reads, initiation of R N A synthesis does not require a primer. The next step is shown below. As the replication bubble moves to the right, the newly synthesized R N A strand elongates and the 5 prime end extends outside the bubble. A caption reads, new nucleotides are added to the 3 prime end of the R N A molecule. The next step is shown below. As the replication bubble moves further to the right, the newly synthesized R N A strand elongates even more. A caption reads, D N A unwinds at the front of the transcription bubble and then rewinds.

CONCEPTS

RNA is synthesized from ribonucleoside triphosphates. Transcription is 5′→3′: each new nucleotide is joined to the 3′-OH group of the last nucleotide added to the growing RNA

molecule.

The Transcription Apparatus

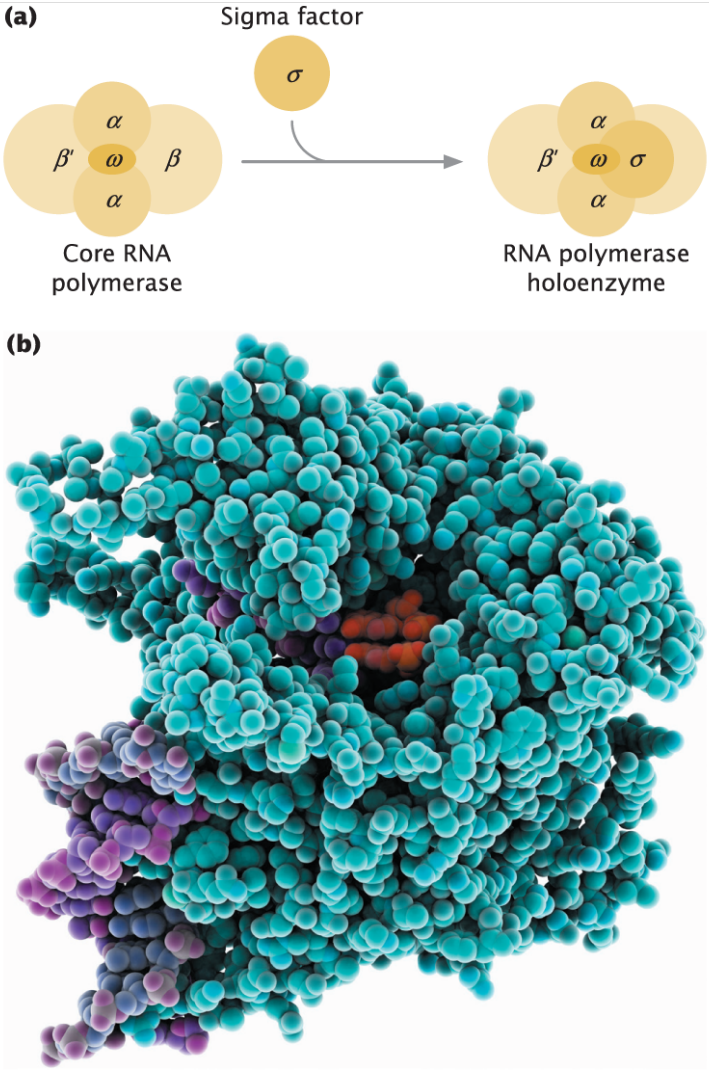
As we have seen, DNA replication requires a number of different enzymes and proteins. Although transcription might initially appear to be quite different because a single enzyme— **RNA polymerase**—carries out all the required steps, the two processes on closer inspection are actually similar. The action of RNA polymerase is enhanced by a number of accessory proteins that join and leave the polymerase at different stages of the process. Each accessory protein is responsible for providing or regulating a special function. Thus, transcription, like replication, requires an array of proteins.

BACTERIAL RNA POLYMERASE

Bacterial cells typically possess only one type of RNA polymerase, which catalyzes the synthesis of all classes of bacterial RNA: mRNA, tRNA, and rRNA. Bacterial RNA polymerase is a large multimeric enzyme (meaning that it consists of several polypeptide chains).

At the heart of most bacterial RNA polymerases are five subunits (individual polypeptide chains) that make up the **core enzyme**: two copies of a subunit called alpha (α) and single copies of subunits

beta (β), beta prime (β'), and omega (ω) (**Figure 13.9**). The ω subunit is not essential for transcription, but it helps stabilize the enzyme. The core enzyme catalyzes the elongation of the RNA molecule by the addition of RNA nucleotides. Other functional subunits join and leave the core enzyme at particular stages of the transcription process. The **sigma (σ) factor** controls the binding of RNA polymerase to the promoter. Without sigma, RNA polymerase initiates transcription at a random point along the DNA. After sigma has associated with the core enzyme (forming a **holoenzyme**), RNA polymerase binds stably only to the promoter and initiates transcription at the proper start site. Sigma is required only for promoter binding and initiation; after a few RNA nucleotides have been joined together, sigma usually detaches from the core enzyme. Many bacteria have multiple types of sigma factors; each type initiates the binding of RNA polymerase to a particular set of promoters.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company
Part b: Laguna Design/Science Source.

13.9 In bacterial RNA polymerase, the core enzyme consists of five subunits: two copies of alpha (*α*), a single copy of beta (*β*), a single copy of beta prime (*β′*), and a single copy of omega (*ω*). The core enzyme catalyzes the elongation of the RNA molecule by the addition of RNA nucleotides. (a) The sigma factor (σ) joins the core to form the holoenzyme, which is capable of binding to a promoter and initiating transcription. (b) The molecular model shows RNA polymerase (blue), binding DNA (purple), and synthesizing mRNA (red).

Description

The illustration a at the top shows core R N A polymerase has two copies of alpha, a single copy of beta, a single copy of beta prime , and a single copy of omega. A sigma factor enters the process and attaches to the core R N A polymerase. The core R N A polymerase with sigma factor is collectively labeled R N A polymerase holoenzyme. The molecular model b below shows a larger R N A polymerase represented by large number of blue tiny round structures, binds to the smaller D N A represented by purple tiny round structures, and synthesizes m R N A represented by tiny red round structures present at the center of the model.

Rifamycins are a group of antibiotics that kill bacterial cells by inhibiting RNA polymerase. These antibiotics are widely used to treat tuberculosis, a disease that kills almost 2 million people worldwide each year. The structures of bacterial and eukaryotic RNA polymerases are sufficiently different that rifamycins can inhibit bacterial RNA polymerases without interfering with eukaryotic RNA polymerases. Recent research has demonstrated that several rifamycins work by binding to the part of the bacterial RNA polymerase that clamps onto DNA and then jamming the RNA polymerase, thus preventing RNA polymerase from interacting with the promoter on the DNA.

EUKARYOTIC RNA POLYMERASES

Most eukaryotic cells possess three distinct types of RNA polymerase, each of which is responsible for transcribing a different class of RNA: **RNA polymerase I** transcribes rRNA; **RNA polymerase II** transcribes pre-mRNAs, snoRNAs, some miRNAs, and some snRNAs; and **RNA polymerase III** transcribes other small RNA

molecules—specifically tRNAs, small rRNAs, some miRNAs, and some snRNAs (Table 13.3). RNA polymerases I, II, and III are found in all eukaryotes. Two additional RNA polymerases, **RNA polymerase IV** transcribes siRNAs that silence transposons and **RNA polymerase V** transcribes siRNAs that play a role in DNA methylation and chromatin structure.

TABLE 13.3 Eukaryotic RNA polymerases

Type	Present in	Transcribes
RNA polymerase I	All eukaryotes	Large rRNAs
RNA polymerase II	All eukaryotes	Pre-mRNAs, snoRNAs, some miRNAs, some snRNAs
RNA polymerase III	All eukaryotes	tRNAs, small rRNAs, some miRNAs, some snRNAs
RNA polymerase IV	Plants	siRNAs that silence transposons
RNA polymerase	Plants	siRNAs that affect chromatin

The importance of RNA polymerase is illustrated by α-amanitin, a deadly compound produced by death cap mushrooms. α-Amanitin is a potent inhibitor of RNA polymerase II; it binds to RNA polymerase and jams the moving parts of the enzyme, interfering with its ability to move along the DNA template. In the presence of α-amanitin, RNA synthesis slows from its normal rate of several thousand nucleotides per minute to just a few nucleotides per minute. The results are catastrophic, leading to cell death. The liver, where the toxin accumulates, is irreparably damaged and stops functioning. In severe cases, it causes death.

All eukaryotic polymerases are large multimeric enzymes, typically consisting of more than a dozen subunits. Some subunits are common to all RNA polymerases, whereas others are limited to one of the polymerases. As in bacterial cells, a number of accessory proteins bind to the core enzyme and affect its function.

CONCEPTS

Bacterial cells possess a single type of RNA polymerase, consisting of a core enzyme and other subunits that participate in various stages of transcription. Eukaryotic cells possess several distinct types of RNA polymerase that transcribe different kinds of RNA molecules.

✔ CONCEPT CHECK 4

What is the function of the sigma factor?

13.3 Bacterial Transcription Consists of Initiation, Elongation, and Termination

Now that we've considered some of the major components of transcription, we're ready to take a detailed look at the process. Transcription can be conveniently divided into three stages:

1. Initiation, in which the transcription apparatus assembles on the promoter and begins the synthesis of RNA
2. Elongation, in which DNA is threaded through RNA polymerase and the polymerase unwinds the DNA and adds new nucleotides, one at a time, to the 3′ end of the growing RNA strand
3. Termination, the recognition of the end of the transcription unit and the separation of the RNA molecule from the DNA template

We first examine each of these steps in bacterial cells, in which the process is best understood; then we consider eukaryotic and archaeal transcription.

Initiation

Initiation comprises all the steps necessary to begin RNA synthesis, including (1) promoter recognition, (2) formation of a transcription

bubble, (3) creation of the first bonds between rNTPs, and (4) escape of the transcription apparatus from the promoter.

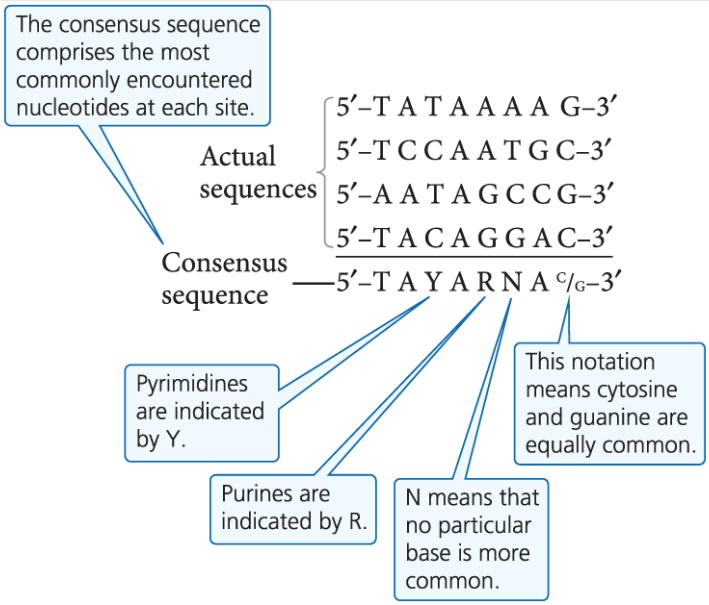
Transcription initiation requires that the transcription apparatus recognize and bind to the promoter. At this step, the selectivity of transcription is enforced: the binding of RNA polymerase to the promoter determines which parts of the DNA template are to be transcribed, and how often. Different genes are transcribed with different frequencies, and promoter binding is important in determining the frequency of transcription for a particular gene. Promoters also have different affinities for RNA polymerase. Even within a single promoter, affinity for RNA polymerase can vary with the passage of time, depending on the promoter's interaction with RNA polymerase and a number of other factors.

BACTERIAL PROMOTERS

Essential information for the transcription apparatus—where it will start transcribing, which strand is to be read, and in what direction the RNA polymerase will move—is embedded in the nucleotide sequence of the promoter. In bacterial cells, promoters are usually adjacent to the RNA-coding region.

An examination of many promoters in *E. coli* and other bacteria reveals a general feature: although most of the nucleotides at most sites vary among these promoters, short stretches of nucleotides are

common to many. Furthermore, the locations of these nucleotides relative to the transcription start site are similar in most promoters. These short stretches of common nucleotides are called consensus sequences. A **consensus sequence** is the set of the most commonly encountered nucleotides among sequences that possess considerable similarity, or *consensus* (Figure 13.10). The presence of consensus in a set of nucleotides usually implies that the sequence is associated with an important function. ❯ **TRY** PROBLEM 21



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

13.10 A consensus sequence consists of the most commonly encountered nucleotides at each site in a group of related sequences.

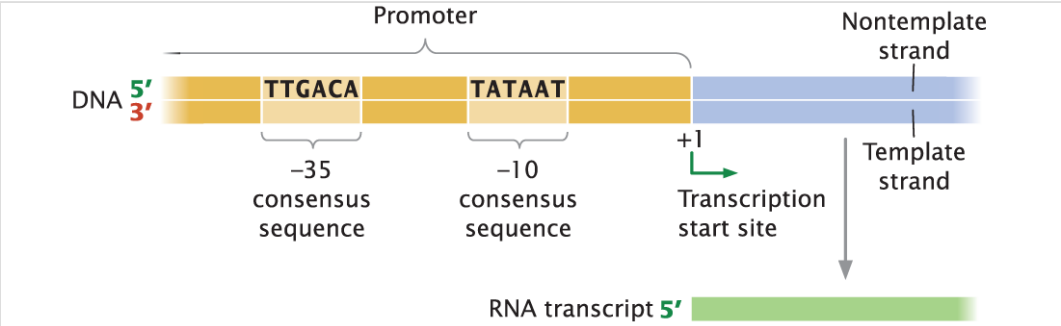
Description
The illustration shows 4 actual sequences and a consensus sequence. The first actual sequence, at the top, from 5 prime to 3 prime is as follows: T, A, T, A, A, A, A, G. The second actual sequence below from 5 prime to 3 prime is as follows: T, C, C, A, A, T, G, C. The third actual sequence below from 5 prime to 3 prime is as follows: A, A, T, A, G, C, C,

G. The fourth actual sequence below from 5 prime to 3 prime is as follows: T, A, C, A, G, G, A, C. The consensus sequence below is as follows: T, A, Y, A, R, N, A, C slash G. A caption reads, the consensus sequence comprises the most commonly encountered nucleotides at each site. Pyrimidines are indicated by the letter Y. Purines are indicated by R. N means that no particular base is more common. This notation C over G means cytosine and guanine are equally common.

The most commonly encountered consensus sequence, found in almost all bacterial promoters, is centered about 10 bp upstream of the start site. Called the **–10 consensus sequence**, or sometimes the Pribnow box, this consensus sequence,

$$5'-\text{TATAAT}-3'$$
$$3'-\text{ATATTA}-5'$$

is often written simply as TATAAT (**Figure 13.11**). Remember that TATAAT is just the *consensus* sequence—representing the most commonly encountered nucleotides at each of these sites (see Figure 13.10). In most prokaryotic promoters, the actual sequence is not TATAAT.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

13.11 In bacterial promoters, consensus sequences are found upstream of the start site, approximately at positions − 10 and − 35.

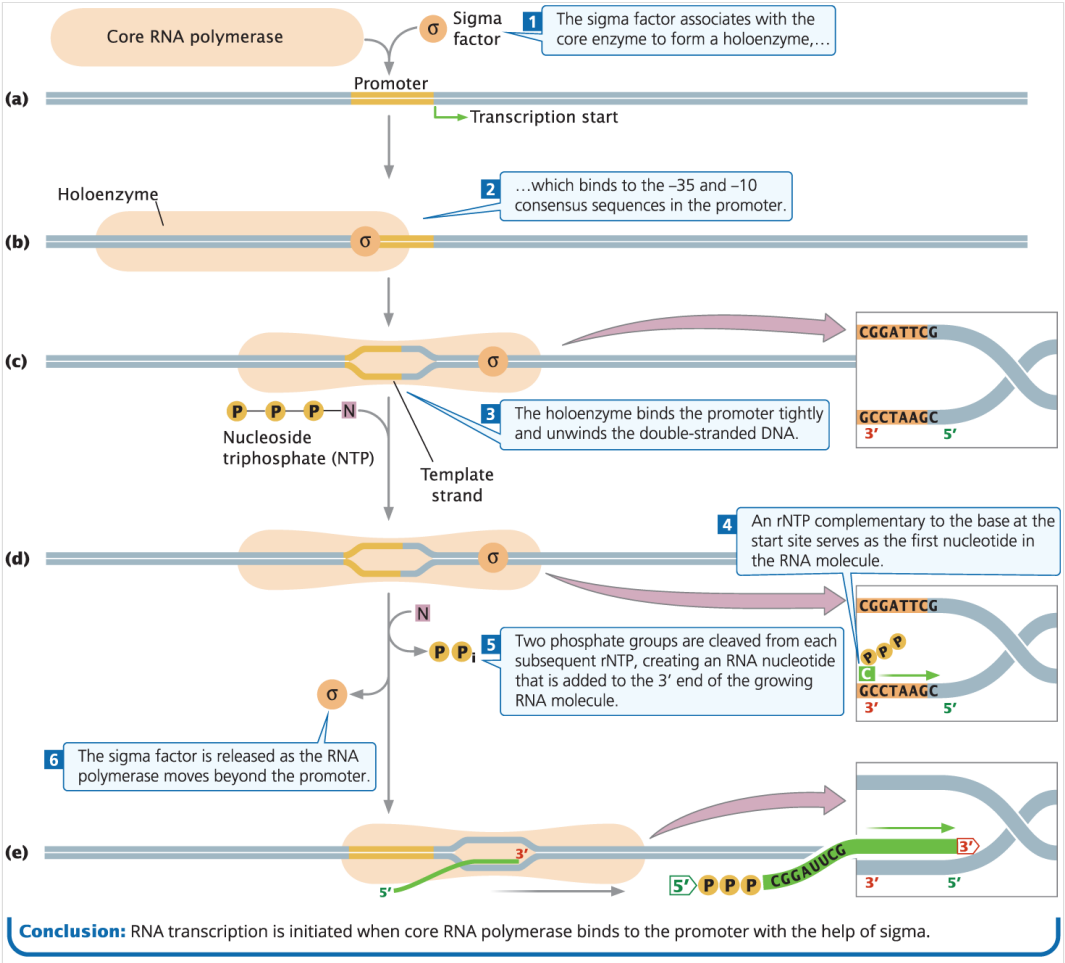
Description
The illustration shows a double stranded D N A molecule with a promoter on the left. The top D N A strand runs from 5 prime to 3 prime while the bottom strand runs from 3 prime to 5 prime. Two consensus sequences are marked at negative 35, on the left, and negative 10 sequences, in the center. Their sequences are as follows respectively: T, T, G, A, C, A and T, A, T, A, A, T. At the positive 1 position, on the right, of the bottom D N A strand, an arrow is drawn from left to the right, indicating the transcription start site. The R N A is being transcribed from the template strand which is the bottom D N A strand. The top D N A strand is labeled as non-template strand. The R N A transcript formed below starts from the 5 prime end.

Another consensus sequence common to most bacterial promoters is TTGACA, which lies approximately 35 nucleotides upstream of the start site and is termed the **− 35 consensus sequence** (see Figure 13.11). The nucleotides on either side of the − 10 and − 35 consensus sequences and those between them vary greatly from promoter to promoter, suggesting that these nucleotides are not very important in promoter recognition.

The function of these consensus sequences in bacterial promoters has been studied by inducing mutations at various positions within the consensus sequences and observing the effect of the changes on transcription. These studies reveal that most base substitutions within the − 10 and − 35 consensus sequences reduce the rate of transcription; these substitutions are termed *down mutations* because they slow down the rate of transcription. Occasionally, a

particular change in a consensus sequence increases the rate of transcription; such a change is called an *up mutation*.

The sigma factor, mentioned earlier, associates with the core RNA polymerase enzyme (**Figure 13.12a**) to form a holoenzyme, which binds to the − 35 and − 10 consensus sequences in the DNA promoter (**Figure 13.12b**). Although it binds only the nucleotides of the consensus sequences, the enzyme extends from −50 to +20 when bound to the promoter. The holoenzyme initially binds weakly to the promoter but then undergoes a change in structure that allows it to bind more tightly and unwind the double-stranded DNA (**Figure 13.12c**). Unwinding begins within the −10 consensus sequence and extends downstream for about 14 nucleotides, including the start site (from nucleotides to − 12 to + 2).



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

13.12 Transcription in bacteria is carried out by RNA polymerase, which must bind to the sigma factor to initiate transcription.

Description

Part a at the top shows a double stranded D N A that has a promoter in around the middle of the molecule. The end of the promoter is marked as transcription start. A sigma factor and a core R N A polymerase interact with the promoter. A caption reads, the sigma factor associates with the core to form a holoenzyme. Part b below shows a holoenzyme that binds to the consensus sequences. A caption reads, which binds to the negative 35 and negative 10 consensus sequences in the promoter. Part c below shows the formation of a replication bubble as the holoenzyme moves to the right. To the right of the replication bubble is the sigma factor. A magnified image shows the following sequence on the top strand: C, G, G, A, T, T, C, G and the following sequence on the bottom strand: G, C, C, T, A, A, G, C. A caption reads, the holoenzyme binds the promoter tightly and unwinds the

double-stranded D N A. A nucleoside triphosphate (N T P) molecule enters the process. Part d below shows two replication bubbles form and a newly synthesized R N A strand and extends out from the sigma factor at the end of the second replication bubble. A magnified image shows the first nucleotide C added just over the first nucleotide G of the bottom strand. The nucleotide has three phosphate molecules over it. Two phosphate groups (P and P subscript i) are cleaved from each subsequent r N T P. A caption reads, an r N T P complementary to the base at the start site serves as the first nucleotide in the R N A molecule. Two phosphate groups are cleaved from each subsequent r N T P, creating an R N A nucleotide that is added to the 3 prime end of the growing R N A molecule. The sigma factor is also released. A caption reads, the sigma factor is released as the R N A polymerase moves beyond the promoter. Part e below shows the R N A transcript elongates as the polymerase moves towards the right. A magnified image, on the bottom right, shows the newly synthesized R N A transcript. Three phosphates are attached at the 5 prime end, and the sequence is as follows: C, G, G, A, U, U, C, G.

Some bacterial promoters contain a third consensus sequence that also takes part in the initiation of transcription. Called the **upstream element**, this sequence contains a number of A–T pairs and is found at about − 40 to − 60. A number of proteins may bind to sequences in and near the promoter; some stimulate the rate of transcription and others repress it. We will consider these proteins, which regulate gene expression, in Chapter 16. ❯ **TRY PROBLEM 24**

THINK-PAIR-SHARE Question 2

CONCEPTS

A promoter is a DNA sequence that is adjacent to a gene and required for transcription. Promoters contain short consensus sequences that are important in the initiation of transcription.

✔ CONCEPT CHECK 5

What binds to the −10 consensus sequence found in most bacterial promoters?

a. The holoenzyme (core enzyme + sigma factor)
b. The sigma factor alone
c. The core enzyme alone
d. mRNA

INITIAL RNA SYNTHESIS

Once the holoenzyme has bound to the promoter, RNA polymerase is positioned over the transcription start site (at position +1) and has unwound the DNA to produce a single-stranded template. The orientation and spacing of the consensus sequences on a DNA strand determine which strand will be the template for transcription and thereby determine the direction of transcription.

The position of the start site is determined not by the sequences located there but by the locations of the consensus sequences, which position RNA polymerase so that the enzyme's active site is aligned for the initiation of transcription at +1. If the consensus sequences are artificially moved upstream or downstream, the location of the starting point of transcription correspondingly changes.

To begin the synthesis of an RNA molecule, RNA polymerase pairs the base at the start site on the DNA template strand with its

complementary base on an rNTP (Figure 13.12d). No primer is required to initiate the synthesis of the 5′ end of the RNA molecule. Two of the three phosphate groups are cleaved from each rNTP as the nucleotide is added to the 3′ end of a growing RNA molecule. However, because the 5′ end of the first rNTP does not take part in the formation of a phosphodiester bond, all three of its phosphate groups remain. An RNA molecule therefore possesses, at least initially, three phosphate groups at its 5′ end (Figure 13.12e).

Often in the course of initiation, RNA polymerase repeatedly generates and releases short transcripts, from 2 to 6 nucleotides in length, while still bound to the promoter. This process, termed **abortive initiation**, occurs in both prokaryotes and eukaryotes. After several abortive initiation attempts, the polymerase synthesizes an RNA molecule from 9 to 12 nucleotides in length, which allows the polymerase to transition to the elongation stage.

Elongation

At the end of initiation, RNA polymerase undergoes a change in its conformation (shape) and thereafter is no longer able to bind to the consensus sequences in the promoter. This change allows the polymerase to escape from the promoter and begin transcribing downstream. The sigma factor is usually released after initiation, although some RNA polymerases may retain sigma throughout elongation.

As it moves downstream along the template, RNA polymerase progressively unwinds the DNA at the leading (downstream) edge of the transcription bubble, joining nucleotides to the growing RNA molecule according to the sequence of the template, and rewinds the DNA at the trailing (upstream) edge of the bubble. In bacterial cells at 37°C, about 40 nucleotides are added per second. This rate of RNA synthesis is much lower than that of DNA synthesis, which is 1000 to 2000 nucleotides per second in bacterial cells.

THE TRANSCRIPTION BUBBLE

Transcription takes place within a short stretch of about 18 nucleotides of unwound DNA—the transcription bubble. Within this region, RNA is continuously synthesized. About 8 to 10 nucleotides of newly synthesized RNA are paired with nucleotides on the DNA template at any one time. As the transcription apparatus moves down the template, it generates positive supercoiling ahead of the transcription bubble and negative supercoiling behind it. Topoisomerase enzymes probably relieve the stress associated with the unwinding and rewinding of DNA in transcription, as they do in DNA replication.

TRANSCRIPTIONAL PAUSING

A number of features of RNA or DNA, such as secondary structures, specific sequences, or the presence of nucleosomes, cause RNA

polymerase to pause during the elongation stage of transcription. Such pauses are often caused by backtracking—when the RNA polymerase slides backward along the DNA template strand. Backtracking disengages the 3′-OH group of the RNA molecule from the active site of RNA polymerase and temporarily halts further RNA synthesis. Cells use several mechanisms to minimize backtracking, including proteins that cleave the backtracked RNA in the active site, generating a new 3′-OH group to which new nucleotides can then be added. In bacterial cells, translation of mRNA by ribosomes closely follows transcription (see Chapter 15), and the presence of ribosomes moving along the mRNA in a 5′→3′ direction prevents backtracking of the RNA polymerase at the 3′ end of the mRNA. Backtracking is important in transcriptional proofreading, as we will see shortly.

Transitory pauses in transcription are important in the coordination of transcription and translation in bacteria (see the discussion of attenuation in Chapter 16), as well as in the coordination of RNA processing in eukaryotes. Pausing also affects the rate of RNA synthesis. Sometimes a pause may be stabilized by sequences in the DNA that ultimately lead to the termination of transcription.

ACCURACY OF TRANSCRIPTION

Although RNA polymerase is quite accurate in incorporating nucleotides into the growing RNA chain, errors do occasionally arise. Research has demonstrated that RNA polymerase is capable of a

type of proofreading in the course of transcription. When RNA polymerase incorporates a nucleotide that does not match the DNA template, it backtracks and cleaves the last two nucleotides (including the misincorporated nucleotide) from the growing RNA chain. RNA polymerase then proceeds forward, transcribing the DNA template again.

CONCEPTS

Transcription is initiated at the transcription start site, which, in bacterial cells, is determined by the binding of RNA polymerase to consensus sequences of the promoter. No primer is required. Transcription takes place within a transcription bubble. DNA is unwound ahead of the bubble and rewound behind it. There are frequent pauses in the process of transcription.

Termination

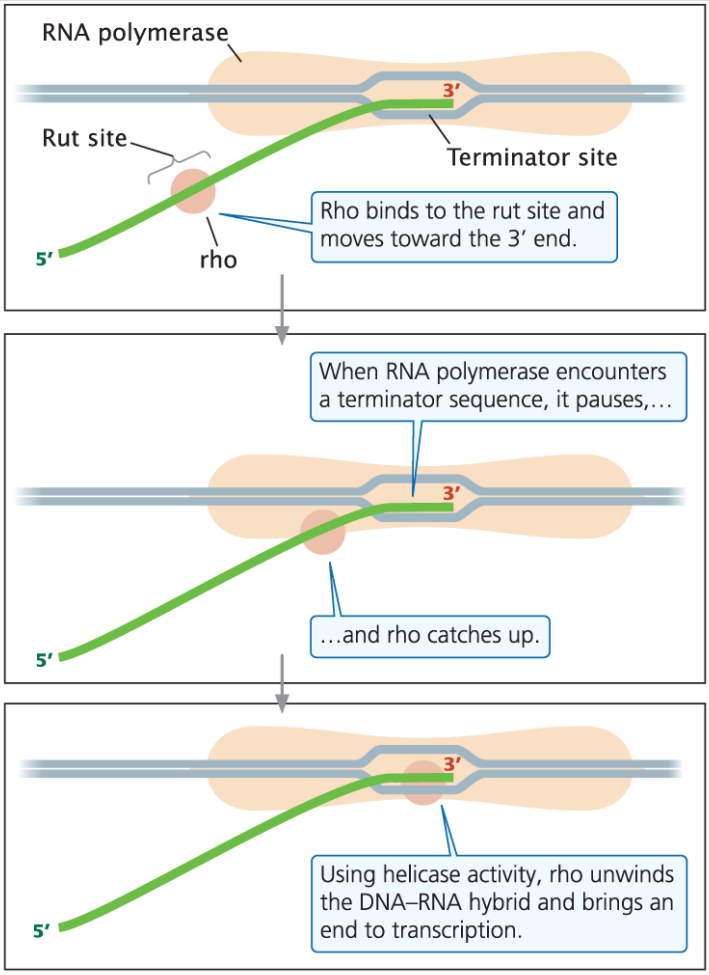
RNA polymerase adds nucleotides to the 3′ end of the growing RNA molecule until it transcribes a terminator. Most terminators are found upstream of the site at which termination actually takes place. Transcription therefore does not suddenly stop when polymerase reaches a terminator, like a car stopping at a stop sign. Rather, transcription stops after the terminator has been transcribed, like a car that stops only after running over a speed bump. At the terminator, several overlapping events are needed to bring an end to transcription: RNA polymerase must stop synthesizing RNA, the

newly made RNA molecule must be released from RNA polymerase, the RNA molecule must dissociate fully from the DNA, and RNA polymerase must detach from the DNA template.

Bacterial cells possess two major types of terminators. **Rho-dependent terminators** are able to cause the termination of transcription only in the presence of an ancillary protein called the **rho factor (ρ)**. **Rho-independent terminators** (also known as intrinsic terminators) are able to cause the end of transcription in the absence of the rho factor.

RHO-DEPENDENT TERMINATORS

Rho-dependent terminators have two features. The first is the DNA sequence of the terminator itself; this sequence causes the RNA polymerase to pause. The second feature is a DNA sequence upstream of the terminator that encodes a stretch of RNA that is usually rich in cytosine nucleotides and devoid of any secondary structures. This RNA sequence, called the rho utilization (rut) site, serves as a binding site for the rho factor. Once rho binds to the RNA, it moves toward its $3'$ end, following the RNA polymerase (**Figure 13.13**). When RNA polymerase encounters the terminator, it pauses, allowing rho to catch up. The rho factor has helicase activity, which it uses to unwind the DNA–RNA hybrid in the transcription bubble, bringing transcription to an end.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

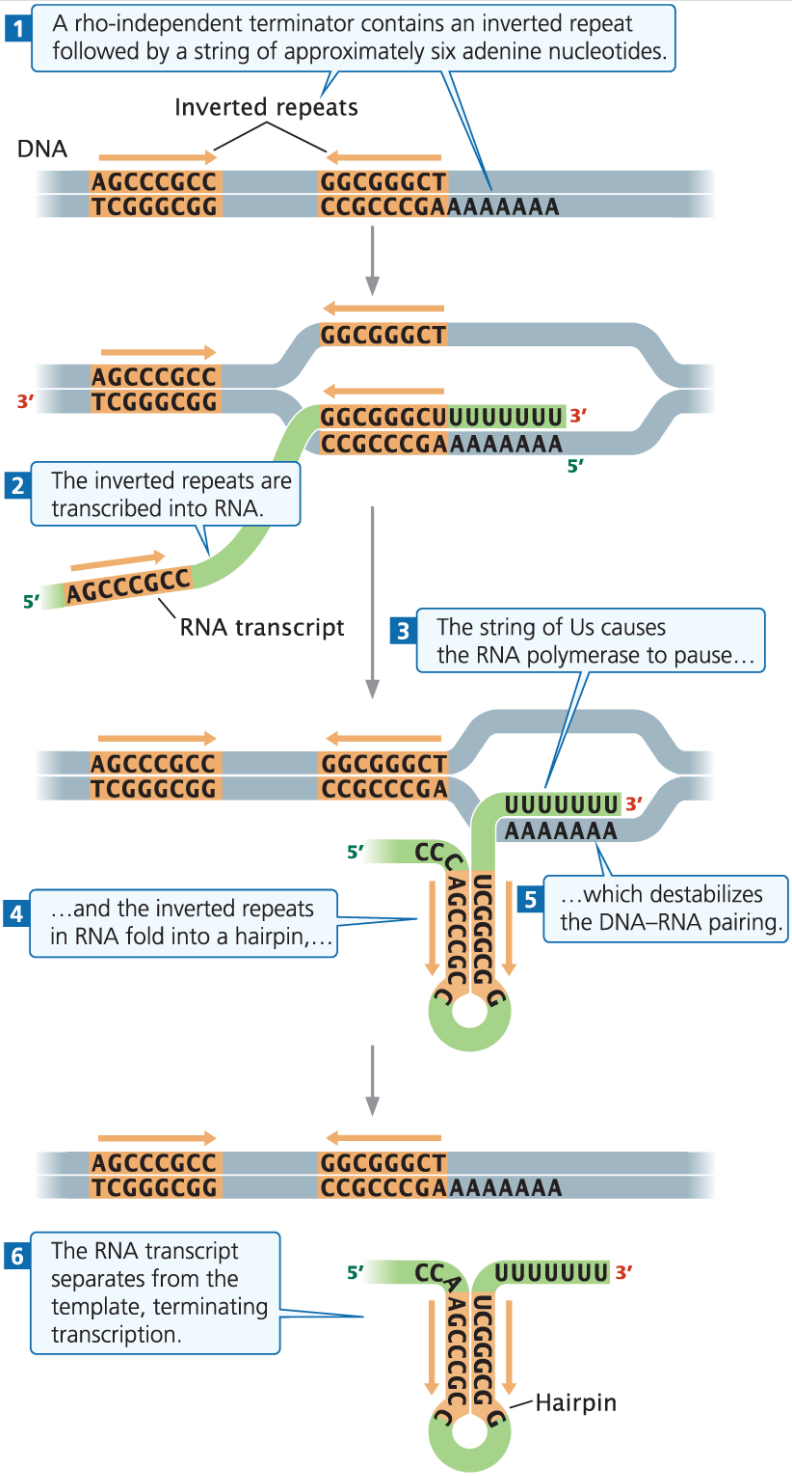
13.13 The termination of transcription in some bacterial genes requires the presence of the rho factor.

Description

The illustration shows R N A polymerase bound to the double stranded D N A around the termination site. The R N A sequence has the round shaped protein r h o attached to it on a site labeled as rut site. A terminator site is marked on the bottom strand. A caption reads, R h o binds to the rut site and moves toward the 3 prime end. In the next step below, the R N A polymerase encounters the terminator sequence. A caption reads, when R N A polymerase encounters a terminator sequence, it pauses and r h o catches up. In the next step below, the r h o protein moves along the R N A sequence toward the end where the termination site is located. A caption reads, using helicase activity, r h o unwinds the D N A-R N A hybrid and brings an end to transcription.

RHO-INDEPENDENT TERMINATORS

Rho-independent terminators, which make up about 50% of all terminators in prokaryotes, have two common features. First, they contain inverted repeats, which are sequences of nucleotides on the same strand that are inverted and complementary. When these inverted repeats are transcribed into RNA and bind to each other, a hairpin forms (Figure 13.14). Second, in rho-independent terminators, a string of seven to nine adenine nucleotides follows the inverted repeat in the template DNA. The transcription of these adenines produces a string of uracil nucleotides after the hairpin in the transcribed RNA.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

13.14 Rho-independent termination in bacteria is a multistep process.

Description
The illustration shows two D N A strands containing 2 closely spaced inverted repeat sequences, and a R N A strand transcribed from this section of the D N A. The first inverted repeat has an arrow over it pointing right and the second inverted repeat has an arrow pointing left. On the template D N A sequence, right after the second inverted repeat is a string of A's. A caption reads, a r h o-independent terminator contains an inverted repeat follow by a string of approximately six adenine nucleotides. A newly synthesized R N A is formed below with the inverted repeats transcribed into it. A caption reads, the inverted repeats are transcribed into R N A. The U's at the end of the R N A transcript cause the polymerase to pause. A caption reads, the string of U's causes the R N A polymerase to pause and the inverted repeats in R N A fold into a hairpin, which stabilizes the D N A-R N A pairing. In the next step below, the hair pin loop separates from the template. A caption reads, the R N A transcript separates from the template, terminating transcription. A caption reads, Conclusion: Transcription terminates when inverted repeats form a hairpin followed by a string of uracils.

The string of uracils in the RNA molecule causes the RNA polymerase to pause, allowing time for the hairpin structure to form. Evidence suggests that the formation of the hairpin destabilizes the DNA–RNA pairing, causing the RNA molecule to separate from its DNA template. Separation may be facilitated by the adenine–uracil base pairings, which are relatively weak compared with other types of base pairings. When the RNA transcript has separated from the template, RNA synthesis can no longer continue (see Figure 13.14). › **TRY PROBLEM 29**

POLYCISTRONIC mRNA

In bacteria, a group of genes is often transcribed into a single RNA molecule; such a molecule is termed **polycistronic mRNA**. Thus, polycistronic mRNA is produced when a single terminator is present at the end of a group of several genes that are transcribed together, instead of each gene having its own terminator. Polycistronic mRNA does occur in some eukaryotes, such as *Caenorhabditis elegans*, but it is uncommon in eukaryotes.

You can view the process of transcription, including initiation, elongation, and termination, in (A) **Animation 13.1**. The animation shows how the different parts of the transcription unit interact to bring about the complete synthesis of an RNA molecule.

THINK-PAIR-SHARE Question 3

CONCEPTS

Transcription ends after RNA polymerase transcribes a terminator. Bacterial cells possess two types of terminators: a rho-independent terminator, which can end transcription by itself; and a rho-dependent terminator, which can end transcription only in the presence of the rho factor.

✔ CONCEPT CHECK 6

What characteristics are most commonly found in rho-independent terminators?

CONNECTING CONCEPTS CONNECT

The Basic Rules of Transcription

Before we examine the process of eukaryotic transcription, let's summarize some of the general principles that we've observed in our exploration of bacterial transcription.

1. Transcription is a selective process; only certain parts of the DNA are transcribed at any one time.
2. RNA is transcribed from a single strand of DNA. Within a gene, only one of the two DNA strands—the template strand—is usually copied into RNA.
3. Ribonucleoside triphosphates are used as the substrates in RNA synthesis. Two phosphate groups are cleaved from a ribonucleoside triphosphate, and the resulting nucleotide is joined to the $3'$-OH group of the growing RNA strand.
4. The transcribed RNA molecule is antiparallel and complementary to the DNA template strand. Transcription is always in the $5' \rightarrow 3'$ direction, meaning that the RNA molecule grows at the $3'$ end.
5. Transcription depends on RNA polymerase, a large multimeric enzyme. RNA polymerase consists of a core enzyme, which is capable of synthesizing RNA, and other subunits that may join transiently to perform additional functions.
6. A sigma factor enables the core enzyme of RNA polymerase to bind to a promoter and initiate transcription.
7. Promoters contain short sequences crucial to the binding of RNA polymerase to DNA; these consensus sequences are interspersed with nucleotides that play no known role in transcription.
8. RNA polymerase binds to DNA at a promoter, begins transcribing at the start site of the gene, and ends transcription after a terminator has been transcribed.
9. Topoisomerase enzymes remove supercoiling that develops ahead of and behind the transcription bubble as the DNA is unwound and rewound during transcription.

13.4 Eukaryotic Transcription Is Similar to Bacterial Transcription but Has Some Important Differences

Transcription in eukaryotes is similar to bacterial transcription in that it includes initiation, elongation, and termination, and the basic principles of transcription already outlined apply to eukaryotic transcription. However, there are some important differences between bacterial and eukaryotic transcription. Eukaryotic cells possess three different RNA polymerases, each of which transcribes a different class of RNA and recognizes a different type of promoter. Thus, a generic promoter cannot be described for eukaryotic cells; rather, a promoter's description depends on whether the promoter is recognized by RNA polymerase I, II, or III. Another difference is in the nature of promoter recognition and initiation. Many accessory proteins take part in the binding of eukaryotic RNA polymerases to DNA templates, and the different types of promoters require different proteins.

Transcription and Nucleosome Structure

Transcription requires that sequences on DNA be accessible to RNA polymerase and other proteins. In eukaryotic cells, however, DNA is complexed with histone proteins in highly compressed chromatin (see Figure 11.4). How can the proteins necessary for transcription gain access to eukaryotic DNA when it is complexed with histones?

The answer to this question is that chromatin structure is modified before transcription so that the DNA is in a more open configuration and is more accessible to the transcription machinery. Several types of proteins have roles in chromatin modification, as noted in Chapter 11. Acetyltransferases, for example, add acetyl groups to amino acids at the ends of the histone proteins, which destabilize nucleosome structure and make the DNA more accessible. Other types of histone modification, such as the addition of methyl groups, can also affect chromatin packing. In addition, chromatin-remodeling proteins may bind to the chromatin and displace nucleosomes from promoters and other regions important for transcription. We will take a closer look at the changes in chromatin structure associated with gene expression in Chapter 17.

CONCEPTS

The initiation of transcription in eukaryotes requires modification of chromatin structure so that DNA is accessible to the transcription machinery.

Promoters

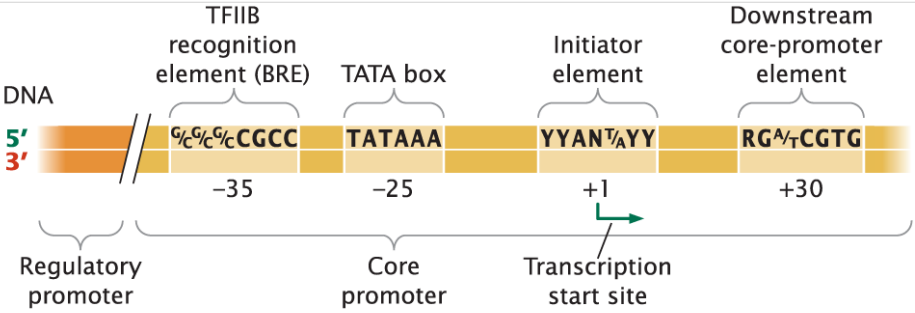
A significant difference between bacterial and eukaryotic transcription is the existence of three different eukaryotic RNA polymerases, which recognize different types of promoters. In bacterial cells, the holoenzyme (the RNA polymerase core enzyme plus the sigma factor) recognizes and binds directly to sequences in the promoter. In eukaryotic cells, promoter recognition is carried out by accessory proteins that bind to the promoter and then recruit a specific RNA polymerase (I, II, or III).

One class of accessory proteins comprises **transcription factors**, which bind to DNA sequences and affect levels of transcription. One group of these, called **general transcription factors**, combine with RNA polymerase to form the **basal transcription apparatus**—a group of proteins that assembles near the transcription start site and is sufficient to initiate minimal levels of transcription. Other transcription factors bind to other DNA sequences and bring about higher levels of transcription by stimulating the assembly of the basal transcription apparatus at the start site.

Here we focus our attention on promoters recognized by RNA polymerase II, which transcribes the genes that encode proteins. A promoter for a gene transcribed by RNA polymerase II typically consists of two primary parts: the core promoter and the regulatory promoter.

CORE PROMOTER

The **core promoter** is located immediately upstream of the gene (Figure 13.15) and is the site to which the basal transcription apparatus binds. The core promoter typically includes one or more consensus sequences. One of the most common of these sequences is the **TATA box**, which has the consensus sequence TATAAA and is located − 25 to − 30 bp upstream of the start site. Additional consensus sequences that may be found in the core promoters of genes transcribed by RNA polymerase II are shown in Figure 13.15. These consensus sequences are recognized by certain transcription factors, which bind to them and serve as a platform for the assembly of the basal transcription apparatus.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

13.15 The promoters of genes transcribed by RNA polymerase II consist of two primary parts: a core promoter and a regulatory promoter. Both parts typically contain consensus sequences, but not all the consensus sequences shown here are found in all promoters.

Description

The regulatory promoter, on the extremne left, is upstream the start site and the core promoter region starts after regulatory promoter. The transcription start site is marked

below initiator element at positive 1 position. The 4 core promoters from left to right are as follows:

T F 2 B recognition element (B R E) has sequence G over C, G slash C, G slash C, C, G, C, C. The T F 2 B recognition element is at the negative 35 position.

T A T A box has sequence T, A, T, A, A, A. The T A T A box is at negative 25 position.

Initiator element has sequence Y, Y, A, N, T slash A, Y, Y. The initiator element is at positive 1 position.

Downstream core-promoter element has sequence R, G, A slash T, C, G, T, G. The downstream core-promoter element is at positive 30 position.

REGULATORY PROMOTER

The **regulatory promoter** is located immediately upstream of the core promoter (see Figure 13.15). A variety of different consensus sequences can be found in regulatory promoters, and they can be mixed and matched in different combinations. Transcription factors bind to these sequences and, either directly or indirectly, make contact with the basal transcription apparatus and affect the rate at which transcription is initiated. Transcription factors may also regulate transcription by binding to more distant sequences called **enhancers**. The DNA between an enhancer and the promoter loops out so that transcription factors bound to the enhancer can interact with the basal transcription apparatus at the core promoter. Enhancers will be discussed in more detail in Chapter 17.

POLYMERASE I AND III PROMOTERS

RNA polymerase I and RNA polymerase III each recognize promoters that are distinct from those recognized by RNA polymerase II. For example, promoters for small rRNA and tRNA genes, transcribed by RNA polymerase III, contain **internal promoters** that are downstream of the start site and are transcribed into the RNA.

CONCEPTS

In eukaryotes, general transcription factors and RNA polymerase assemble on promoters to form the basal transcription apparatus, which binds to DNA near the transcription start site and is necessary for transcription to take place at minimal levels. Other transcription factors bind to other consensus sequences in promoters and enhancers and affect the rate of transcription.

✔ CONCEPT CHECK 7

What is the difference between the core promoter and the regulatory promoter?

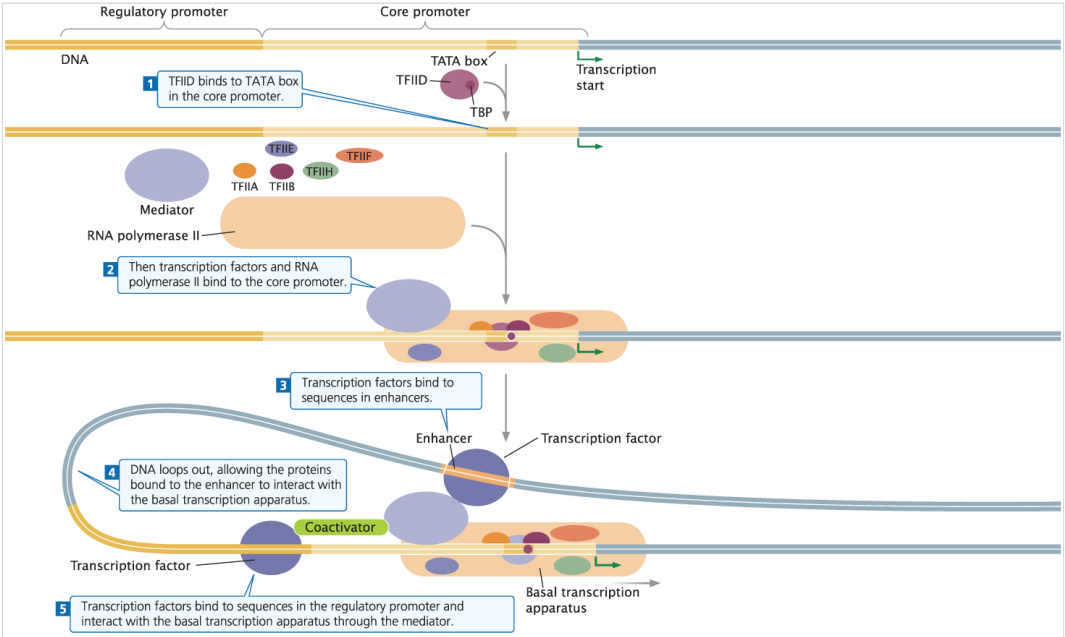
a. Only the core promoter has consensus sequences.
b. The regulatory promoter is farther upstream of the gene.
c. Transcription factors bind only to the core promoter and not to the regulatory promoter.
d. Both b and c.

Initiation

Transcription in eukaryotes is initiated through the assembly of the transcription machinery on the promoter. This machinery consists of RNA polymerase II and a series of transcription factors that form

a giant complex consisting of 50 or more polypeptides. Assembly of the transcription machinery begins when regulatory proteins bind DNA near the promoter and modify the chromatin structure so that transcription can take place. These and other regulatory proteins then recruit the basal transcription apparatus to the core promoter.

The basal transcription apparatus consists of RNA polymerase II, a series of general transcription factors, and a complex of proteins known as the mediator (Figure 13.16). The general transcription factors include TFIIA, TFIIB, TFIID, TFIIE, TFIIF, and TFIIH, in which *TFII* stands for "*t*ranscription *f*actor for RNA polymerase *II*" and the final letter designates the individual factor.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

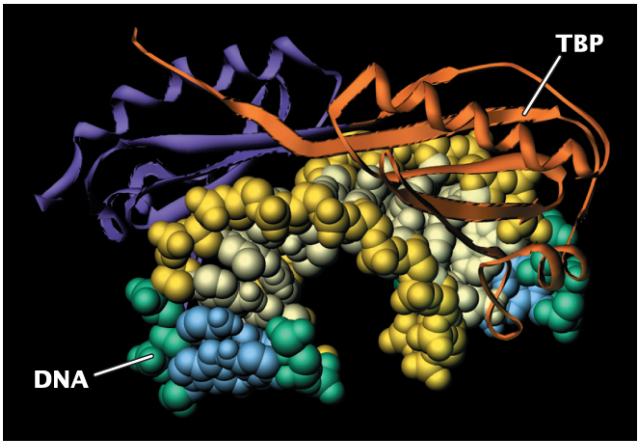
13.16 Transcription is initiated at RNA polymerase II promoters. Transcription is initiated by the binding of the TFIID transcription factor to the TATA box, followed by the binding of a preassembled holoenzyme containing general transcription

factors, RNA polymerase II, and the mediator. TBP stands for “TATA-binding protein.”

Description
The illustration shows a double D N A strand at the top. The D N A has the following from left to right: the regulatory promoter, core promoter with a T A T A box, and a transcription start site. A T F 2 D molecule with T B P binds at the T A T A box. A caption reads, T F 2 D binds to the T A T A box in the core promoter. A mediator, transcription factors T F 2 A, T F 2 B, T F 2 E, T F 2 H, T F 2 F, and R N A polymerase 2 enter the process. A caption reads, then transcription factors and R N A polymerase 2 bind to the core promoter. In the next step below, the D N A loops out. A transcription factor attaches at the end of regulatory promoter (co-activator) and a transcription factor attaches at the enhancer on the looped out D N A strand. A co-activator extends between mediator and transcription factor. The basal transcription apparatus moves towards the right. A caption reads, transcription factors bind to sequences in enhancers. D N A loops out, allowing the proteins bound to the enhancer to interact with the basal transcription apparatus. Transcription factors bind to sequences in the regulatory promoter and interact with the basal transcription apparatus through the mediator.

RNA polymerase II and the general transcription factors assemble at the core promoter, forming a pre-initiation complex. Recall that in bacteria, the sigma factor recognizes and binds to the promoter sequence. In eukaryotes, the function of sigma is replaced by that of the general transcription factors. A first step in initiation is the binding of TFIID to the TATA box on the core promoter. TFIID consists of at least nine polypeptides. One of those polypeptides is the **TATA-binding protein (TBP)**, which recognizes and binds to the TATA box. The TATA-binding protein binds to the minor groove of the DNA double helix and straddles the DNA like a molecular saddle (Figure 13.17), bending the DNA and partly unwinding it. Other

general transcription factors bind to additional consensus sequences in the core promoter and to RNA polymerase II, and position the polymerase over the transcription start site.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

13.17 The TATA-binding protein (TBP) binds to the minor groove of DNA, straddling the double helix of DNA like a saddle.

Description
The molecular model shows ribbon structure of T B P which is straddling the D N A molecule. The D N A molecule is represented in an almost semi-circular shape through a space-filling model.

After the RNA polymerase and general transcription factors have assembled on the core promoter, conformational changes take place in both the DNA and the polymerase. These changes cause 11 to 15 bp of DNA surrounding the transcription start site to unwind, producing the single-stranded DNA that will serve as a template for transcription.

The DNA template strand is positioned within the active site of the RNA polymerase, creating a structure called the open complex. After the open complex has formed, the synthesis of RNA begins as phosphate groups are cleaved off rNTPs and nucleotides are joined together to form an RNA molecule. As in bacterial transcription, the RNA polymerase may generate and release several short RNA molecules in abortive initiation attempts before it initiates the synthesis of a full-length RNA molecule. › **TRY** PROBLEM 35

CONCEPTS

Transcription in eukaryotes is initiated when the basal transcription apparatus—consisting of RNA polymerase, general transcription factors, and a mediator—assembles on the core promoter and becomes an open complex.

✔ CONCEPT CHECK 8

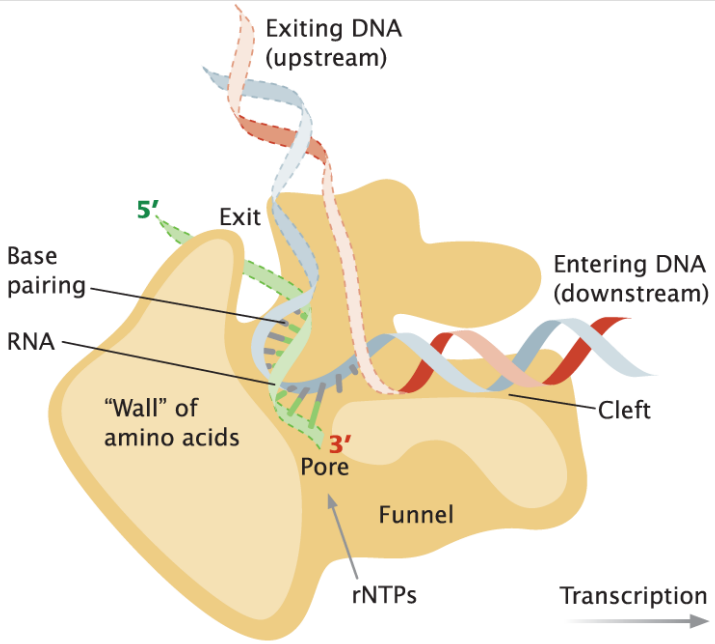
What is the role of TFIID in transcription initiation?

Elongation

After about 30 bp of RNA have been synthesized, the RNA polymerase moves downstream of the promoter and begins the elongation stage of transcription. Many of the general transcription factors are left behind at the promoter, where they can serve to

quickly reinitiate transcription with another RNA polymerase enzyme.

The molecular structure of eukaryotic RNA polymerase II and how it functions during elongation were revealed through the work of Roger Kornberg and his colleagues, for which Kornberg was awarded a Nobel Prize in chemistry in 2006. The RNA polymerase maintains a transcription bubble during elongation, in which about eight nucleotides of the growing RNA molecule remain paired with the DNA template strand. The DNA double helix enters a cleft in the polymerase and is gripped by jawlike extensions of the enzyme (**Figure 13.18**). The two strands of the DNA are unwound, and nucleotides that are complementary to the template strand are added to the growing 3′ end of the RNA molecule. As it funnels through the polymerase, the DNA–RNA hybrid hits a wall of amino acids and bends at almost a right angle; this bend positions the end of the DNA–RNA hybrid at the active site of the polymerase, where new nucleotides are added to the 3′ end of the growing RNA molecule. The newly synthesized RNA is separated from the DNA and runs through another cleft in the enzyme before exiting from the polymerase.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

13.18 The structure of RNA polymerase II is a source of insight into its function.
The DNA double helix enters RNA polymerase II through a cleft in the enzyme and unwinds. The DNA–RNA duplex is bent at a right angle, which positions the 3′ end of the RNA at the active site of the enzyme. At the active site, new nucleotides are added to the 3′ end of the growing RNA molecule.

Description

The illustration shows different regions of the R N A polymerase 2 molecule. The left half is labeled “wall” of amino acids. The bottom is labeled as funnel and in the middle of the polymerase is a pore. At the pore, the 3 prime end of the R N A is marked and r N T P’s enter the funnel. At the top of the R N A polymerase is an opening is present from where the 5 prime end of the R N A strand exits. On the right side of the polymerase is a region labeled as cleft, where downstream double stranded D N A enters the polymerase. At the top, upstream D N A is exiting after it gets unwounded in the middle of the molecule. The D N A strand serves as a template for R N A synthesis. A newly synthesized R N A strand leaves from the top, parallel to the exiting D N A. Transcription direction is marked towards the right.

Termination

The three eukaryotic RNA polymerases use different mechanisms for termination. RNA polymerase I requires a termination factor similar to the rho factor used in terminating the transcription of some bacterial genes. Unlike rho, which binds to the newly transcribed RNA molecule, the termination factor for RNA polymerase I binds to a DNA sequence downstream of the terminator.

RNA polymerase III ends transcription after transcribing a terminator sequence that produces a string of uracil nucleotides in the RNA molecule. Recent research demonstrates that secondary structures, such as hairpins and stems, often occur upstream of the string of uracils and are necessary for termination. Thus, RNA polymerase III uses a termination mechanism similar to rho-independent termination in bacteria.

The termination of transcription by RNA polymerase II does not occur at specific sequences. Instead, RNA polymerase II often continues to synthesize RNA hundreds or even thousands of nucleotides past the coding sequence necessary to produce the mRNA. As we will see in Chapter 14, the pre-mRNA is cleaved at a specific site, designated by a consensus sequence, while transcription is still taking place at the $3'$ end of the molecule. Cleavage cuts the pre-mRNA into two pieces: the mRNA that will eventually encode the protein and another piece of RNA that has its $5'$ end trailing out of the RNA polymerase (**Figure 13.19**). An enzyme

(called Rat1 in yeast) attaches to the 5′ end of this RNA and moves toward the 3′ end, where the RNA polymerase continues the transcription of RNA. Rat1 is a 5′→3′ exonuclease—an enzyme capable of degrading RNA in the 5′→3′ direction. Like a guided torpedo, Rat1 homes in on the polymerase, chewing up the RNA as it moves. When Rat1 reaches the transcription machinery, transcription terminates. Note that this mechanism is similar to that of rho-dependent termination in bacteria (see Figure 13.13), except that rho does not degrade the RNA molecule.

THINK-PAIR-SHARE Question 4

DNA
5
…and moves toward the RNA polymerase, degrading the RNA as it goes.
5′
3′
DNA
6
When Rat1 reaches the polymerase, transcription is terminated.
5′
3′

13.19 Termination of transcription by RNA polymerase II requires the Rat1 exonuclease. Cleavage of the pre-mRNA produces a $5'$ end to which Rat1 attaches. Rat1 degrades the RNA molecule in the $5' \rightarrow 3'$ direction. When Rat1 reaches the polymerase, transcription is halted.

Description

The illustration shows two D N A strands at the top. A R N A polymerase molecule slides along the lower D N A strand and a replication bubble is formed to initiate R N A synthesis. The pre-m R N A strand formed elongates and its 5 prime end extends out while the 3 prime end remains in the replication bubble. In the middle of this pre-m R N A strand is a cleavage site. A caption reads, R N A polymerase 2 transcribes well past the coding sequences of most genes. In the next step below, cleavage at the cleavage point occurs while the pre-m R N A was still elongating. A caption reads, cleavage is near the 3 prime end of the R N A while R N A polymerase continues transcribing. In the next step below, the attached 5 prime end of the pre-m R N A transcript has a round structure R a t 1 exonuclease attached to it. The cleaved pre-m R N A transcript remains intact. A caption reads, the R a t 1 exonuclease attaches to the 5 prime end of the trailing R N A. In the next step below, the exonuclease moves towards the R N A polymerase as it degrades the R N A simultaneously. The cleaved pre-m R N A transcript remains intact. A caption reads, and moves toward the R N A polymerase, degrading the R N A as it goes. In the next step below, R a t 1 reaches the polymerase, transcription stops. R a t 1 and D N A polymerase 2 are released from the reaction. The cleaved pre-m R N A transcript remains intact throughout. In the end, the D N A strands resume the original shape.

CONCEPTS

The three RNA polymerases found in all eukaryotes use different mechanisms of termination. Transcription by RNA polymerase II is terminated when an exonuclease enzyme attaches to the cleaved $5'$ end of the RNA, moves down the RNA, and reaches the polymerase enzyme.

✔ CONCEPT CHECK 9

How are the processes of RNA polymerase II termination in eukaryotes and rho-dependent termination in bacteria similar, and how are they different?

13.5 Transcription in Archaea Is More Similar to Transcription in Eukaryotes Than to Transcription in Bacteria

Some 2 billion to 3 billion years ago, life diverged into three lines of evolutionary descent: the bacteria (also called eubacteria), the archaea, and the eukaryotes (see Chapter 2). Although bacteria and archaea are superficially similar—both are unicellular and lack a nucleus—the results of studies of their DNA sequences and other biochemical properties indicate that they are as distantly related to each other as they are to eukaryotes. The evolutionary distinctions between archaea, bacteria, and eukaryotes are clear. But did eukaryotes first diverge from an ancestral prokaryote, with a later separation of prokaryotes into bacteria and archaea, or did the archaea and the bacteria split first, with the eukaryotes later evolving from one of these groups?

Studies of transcription in bacteria, archaea, and eukaryotes have yielded important clues to the evolutionary relationships between these organisms. Archaea, like bacteria, have a single RNA polymerase, but this enzyme is most similar to the RNA polymerases of eukaryotes. As discussed earlier, bacterial RNA polymerase consists of 5 subunits, whereas eukaryotic RNA polymerases are much more complex; RNA polymerase II, for

example, is composed of 12 subunits. Archaeal RNA polymerase is similarly complex, with 11 or more subunits. Furthermore, the amino acid sequence of archaeal RNA polymerase is similar to that of eukaryotic RNA polymerase II.

Archaeal promoters contain a consensus sequence similar to the TATA box found in eukaryotic promoters. The archaeal TATA box is found approximately 27 bp upstream of the transcription start site and helps to determine the location of the transcription start site, as it does in eukaryotes. Archaea possess a TATA-binding protein (TBP), which is a critical transcription factor for all three of the eukaryotic polymerases but not for bacterial RNA polymerase. TBP binds the TATA box in archaea with the help of another transcription factor, TFIIB, which is also found in eukaryotes but not in bacteria. However, some other regulators of transcription found in archaea are more similar to those found in bacteria, so transcription in archaea is not entirely eukaryotic in nature. As prokaryotes, archaea lack a nuclear membrane, but many species do produce histone proteins, which help compact the DNA and form nucleosome-like structures.

Thus, transcription, one of the most basic of life processes, has strong similarities in eukaryotes and archaea, suggesting that these two groups are more closely related to each other than either is to bacteria. This conclusion is supported by other data, including those obtained from a comparison of gene sequences.

CONCEPTS

The process of transcription in archaea has many similarities to transcription in eukaryotes.

Chapter 13 Review

CHAPTER SUMMARY

Section 13.1 Learning Objective: Be able to explain how the structure of RNA allows it to participate in a variety of cellular functions.

- Early life used RNA both as the carrier of genetic information and as a biological catalyst.
- RNA is a polymer consisting of nucleotides joined together by phosphodiester bonds. Each RNA nucleotide consists of a ribose sugar, a phosphate group, and a nitrogenous base. In contrast to DNA, RNA contains the base uracil and is usually single stranded, which allows it to form secondary structures.
- Cells possess a number of different classes of RNA. Ribosomal RNA is a component of the ribosome, messenger RNA carries coding instructions for proteins, and transfer RNA helps incorporate amino acids into a polypeptide chain.

Section 13.2 Learning Objective: Be able to describe the major components required for transcription.

- The template for RNA synthesis is single-stranded DNA. In transcription, RNA synthesis is complementary and antiparallel

to the DNA template strand. A transcription unit consists of a promoter, an RNA-coding region, and a terminator.
- The substrates for RNA synthesis are ribonucleoside triphosphates.
- RNA polymerase in bacterial cells consists of a core enzyme, which catalyzes the addition of nucleotides to an RNA molecule and other subunits. The sigma factor controls the binding of the core enzyme to the promoter.
- Eukaryotic cells contain multiple types of RNA polymerases.

Section 13.3 Learning Objective: Be able to outline the process of bacterial transcription.

- The process of transcription consists of three stages: initiation, elongation, and termination.
- Transcription begins at the start site, which is determined by consensus sequences in a promoter. A short stretch of DNA is unwound near the start site, RNA is synthesized from a single template strand of DNA, and the DNA is rewound at the lagging end of the transcription bubble. RNA polymerases are capable of proofreading. There are frequent pauses in the process of transcription.
- RNA synthesis ceases after a terminator sequence has been transcribed. Bacterial cells have two types of terminators: rho-independent terminators and rho-dependent terminators.

Section 13.4 Learning Objective: Be able to compare and contrast transcription in bacteria and eukaryotes.

- The initiation of transcription in eukaryotes requires the modification of chromatin structure. Different types of RNA polymerases in eukaryotes recognize different types of promoters.
- For genes transcribed by RNA polymerase II, general transcription factors, which bind to the core promoter, are part of the basal transcription apparatus. Other transcription factors bind to sequences in regulatory promoters and enhancers and interact with the basal transcription apparatus.
- The three RNA polymerases found in all eukaryotes use different mechanisms of termination.

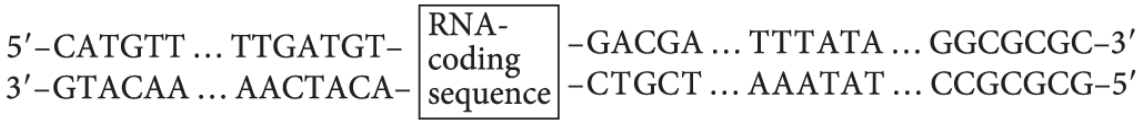
Section 13.5 Learning Objective: Be able to compare transcription in archaea to that in bacteria and eukaryotes.

- Transcription in archaea has many similarities to transcription in eukaryotes.

WORKED PROBLEMS

Problem 1

The accompanying diagram represents a sequence of nucleotides surrounding an RNA-coding sequence.



Description
The top strand reads, 5 prime C A T G T T ellipsis T T G A T G T, R N A coding sequence, G A C G A ellipsis T T T A T A ellipsis g G G C G C G C 3 prime.

The bottom strand reads, 3 prime G T A C A A ellipsis A A C T A C A, R N A coding sequence, C T G C T ellipsis A A A T A T ellipsis C C G C G C G 5 prime.

a. Is the RNA-coding sequence likely to be from a bacterial cell or from a eukaryotic cell? How can you tell?
b. Which DNA strand will serve as the template strand during the transcription of the RNA-coding sequence?

» Solution Strategy

What information is required in your answer to the problem?

a. Whether the sequence is likely to be from a bacterial or a eukaryotic cell, and why.
b. Which strand is the template strand.

What information is provided to solve the problem?

- The nucleotide sequences of both strands of DNA.
- The $5'$ and $3'$ ends of the strands.

For help with this problem, review:

The Template in Section 13.2, Bacterial Promoters in Section 13.3, and Promoters in Section 13.4.

» Solution Steps

a. Bacterial and eukaryotic cells use the same DNA bases (A, T, G, and C), so the bases themselves provide no clue to the origin of the sequence. The RNA-coding sequence must be accompanied by a promoter, and bacterial and eukaryotic cells do differ in the consensus sequences found in their promoters, so we should examine the sequence for the presence of familiar consensus sequences. On the bottom strand to the right of the RNA-coding sequence, we find AAATAT, which, written in the conventional manner (5′ on the left), is 5′–TATAAA–3′. This sequence is the TATA box, which is found in most eukaryotic promoters. However, the sequence is also quite similar to the − 10 consensus sequence (5′–TATAAT–3′) found in bacterial promoters.

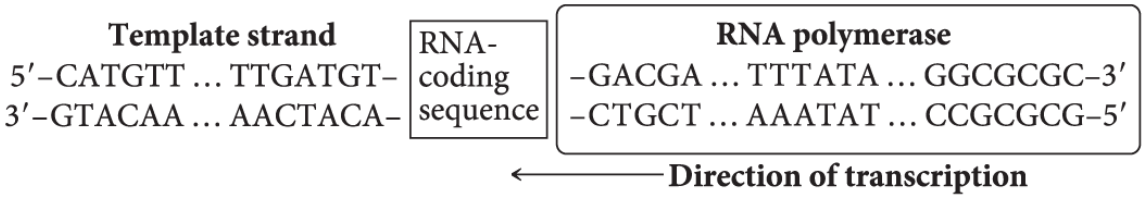
> **Hint:** Review the consensus sequences found in bacterial and eukaryotic promoters in Figures 13.11 and 13.15.

Farther to the right on the bottom strand, we also see 5′–GCGCGCC–3′, which is the TFIIB recognition element (BRE, see **Figure 13.15**) in eukaryotic RNA polymerase II promoters. No similar consensus sequence is found in bacterial promoters, so we can be fairly certain that this sequence is a eukaryotic promoter and an RNA-coding sequence.

b. The TATA box and BRE of RNA polymerase II promoters are upstream of the RNA-coding sequence, so RNA polymerase must bind to these sequences and then proceed downstream,

transcribing the RNA-coding sequence. Thus, RNA polymerase must proceed from right (upstream) to left (downstream). The RNA molecule is always synthesized in the 3′→5′ direction and is antiparallel to the DNA template strand, so the template strand must be read 3′→5′. If the enzyme proceeds from right to left and reads the template in the 3′→5′ direction, the upper strand must be the template, as shown in the accompanying diagram.

Recall: During transcription, the template strand is read 3′→5′.



Description
The illustration shows the following D N A template strand: The upper D N A strand is as follows: 5 prime C, A, T, G, T, T, ellipsis T, T, G, A, T, G, T, then the R N A coding sequence and the beginning of R N A polymerase G, A, C, G, A ellipsis T, T, T, A, T, A ellipsis G, G, C, G, C, G, C 3 prime; end of R N A polymerase. The lower D N A strand is as follows: 3 prime G, T, A, C, A, A ellipsis A, A, C, T, A, C, A, then the R N A coding sequence and the beginning of R N A polymerase C, T, G, C, T ellipsis A, A, A, T, A, T ellipsis C, C, G, C, G, C, G 5 prime; end of R N A polymerase. The direction of transcription is from 5 prime to 3 prime of the lower D N A strand.

Problem 2

Suppose that a consensus sequence in the regulatory promoter of a eukaryotic gene that encodes enzyme A was deleted. Which of the

following effects would result from this deletion? Explain your reasoning.

a. Enzyme A would have a different amino acid sequence.
b. The mRNA for enzyme A would be abnormally short.
c. Enzyme A would be missing some amino acids.
d. The mRNA for enzyme A would be transcribed but not translated.
e. The amount of mRNA transcribed would be affected.

» Solution Strategy

What information is required in your answer to the problem?

The result (*a*, *b*, *c*, *d*, or *e*) that would occur if a consensus sequence in the regulatory promoter were deleted.

What information is provided to solve the problem?

The deleted consensus sequence is in the regulatory promoter.

For help with this problem, review:

Section 13.4.

» Solution Steps

The correct answer is part *e*. The regulatory promoter contains binding sites for transcription factors. These sequences are not part of the RNA-coding sequence for enzyme A, so the mutation would have no effect on the length or the amino acid sequence of the enzyme, eliminating answers *a, b,* and *c*. The regulatory promoter affects transcription, but not translation, so answer d is not correct. The binding of transcription factors to the regulatory promoter affects the amount of transcription that takes place through interactions with the basal transcription apparatus at the core promoter.

ANSWERS TO CONCEPT CHECKS

1. b
2. The template strand is the DNA strand that is copied into an RNA molecule, whereas the nontemplate strand is not copied.
3. d
4. The sigma factor controls the binding of RNA polymerase to the promoter.
5. a
6. Inverted repeats followed by a string of adenine nucleotides.
7. b
8. TFIID binds to the TATA box and helps to center the RNA polymerase over the transcription start site.
9. Both processes use a protein that binds to the RNA molecule and moves down the RNA toward the RNA polymerase. They differ in that rho does not degrade the RNA, whereas Rat1 does.

Chapter 13 Assessment

COMPREHENSION QUESTIONS

Section 13.1

1. CONNECT Draw an RNA nucleotide and a DNA nucleotide, highlighting the differences. How is the structure of RNA similar to that of DNA? How is it different? (See Chapter 10 for a review of DNA structure.)

2. What are the major classes of cellular RNA?

3. Why is DNA more stable than RNA?

Section 13.2

4. What parts of DNA make up a transcription unit? Draw a typical bacterial transcription unit, and identify its parts.

5. What is the substrate for RNA synthesis? How is this substrate modified and joined together to produce an RNA molecule?

6. Describe the structure of the bacterial RNA polymerase holoenzyme.

7. Give the names of the RNA polymerases found in eukaryotic cells and the types of RNA that they transcribe.

Section 13.3

8. What are the three basic stages of transcription? Describe what happens at each stage.

9. Draw a typical bacterial promoter, and identify any common consensus sequences.

10. What are the two basic types of terminators found in bacterial cells? Describe the structure of each type.

Section 13.4

11. Compare the roles of general transcription factors that bind to the core promoter and other transcription factors that bind to the regulatory promoter and enhancers.

12. How are transcription and replication similar, and how are they different?

13. How is transcription different in bacteria and eukaryotes? How is it similar?

APPLICATION QUESTIONS AND PROBLEMS

Introduction

14. CONNECT Rear-end collisions between replication and transcription (discussed in the introduction to this chapter) are less likely in eukaryotes because the two processes occur at comparable speeds. Bacteria, in contrast, replicate their DNA almost 10 times faster than they carry out transcription. Can you suggest some reasons why bacteria replication is faster than eukaryotic replication?

Section 13.1

15. *An RNA molecule has the following percentages of bases: A = 23%, U = 42%, C = 21%, and G = 14%

    a. Is this RNA single stranded or double stranded? How can you tell?

    b. What would be the percentages of bases in the template strand of the DNA that contains the gene for this RNA?

Section 13.2

16. *The following diagram represents DNA that is part of the RNA-coding sequence of a transcription unit. The bottom strand is the template strand. Give the sequence found on the RNA molecule transcribed from this DNA, and identify the $5'$ and $3'$ ends of the RNA.

5′–ATAGGCGATGCCA–3′

3′–TATCCGCTACGGT–5′ ← Template strand

17. For the RNA molecule shown in **Figure 13.1a**, write out the sequence of bases on the template and nontemplate strands of DNA from which this RNA is transcribed. Label the 5′ and 3′ ends of each strand.

18. The following sequence of nucleotides is found in a single-stranded DNA template:

    ATTGCCAGATCATCCCAATAGAT

    Assume that RNA polymerase proceeds along this template from left to right.

    a. Which end of the DNA template is 5′, and which end is 3′?

    b. Give the sequence and identify the 5′ and 3′ ends of the RNA transcribed from this template.

19. Assume that a mutation occurs in the gene that encodes each of the following RNA polymerases. Match the mutation with its possible effects by placing the correct letter or letters in the blanks below. There may be more than one effect for each mutated polymerase.

A mutation in the gene that codes for	Effects
RNA polymerase I	_____

RNA polymerase II	_____
RNA polymerase III	_____

Possible effects

a. tRNA is not synthesized.

b. Some ribosomal RNA is not synthesized.

c. Ribosomal RNA is not processed.

d. pre-mRNA is not processed.

e. Some mRNA molecules are not degraded.

f. pre-mRNA is not synthesized.

Section 13.3

20. Provide the consensus sequence for the *first three* of the actual sequences shown in **Figure 13.10**.

21. *Write the consensus sequence for the following set of nucleotide sequences.

AGGAGTT
AGCTATT
TGCAATA
ACGAAAA
TCCTAAT
TGCAATT

22. CONNECT List at least five properties that DNA polymerases and RNA polymerases have in common. List at least three differences. See Chapter 12 for information on DNA polymerases.

23. Most RNA molecules have *three* phosphate groups at the 5′ end, but DNA molecules never do. Explain this difference.

24. *Write a hypothetical sequence of bases that might be found in the first 20 nucleotides of a promoter of a bacterial gene. Include both strands of DNA, and identify the 5′ and 3′ ends of both strands. Be sure to include the transcription start site and any consensus sequences found in the promoter.

25. *What would be the most likely effect of a mutation at the following locations in an *E. coli* gene?

    a. −8

    b. −35

    c. −20

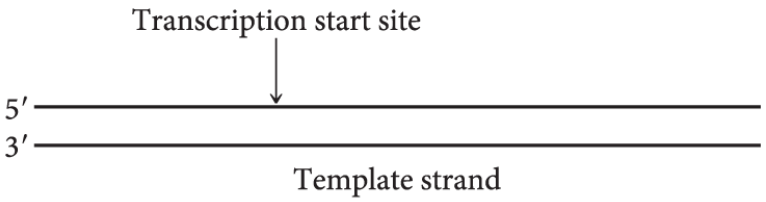
    d. Start site

26. A strain of bacteria possesses a temperature-sensitive mutation in the gene that encodes the sigma factor. The mutant bacteria produce a sigma factor that is unable to bind to RNA polymerase at elevated temperatures. What effect will this

mutation have on the process of transcription when the bacteria are raised at elevated temperatures?

27. On **Figure 13.5**, indicate the locations of the promoters and terminators for genes *a*, *b*, and *c*.

28. The following diagram represents a transcription unit on a DNA molecule.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

Description
D N A double strand is represented by two parallel horizontal lines. The top strand runs from 5 prime and the bottom strand runs from 3 prime. Transcription start site is marked a little before the center of the top strand, using a downward arrow.

a. Assume that this DNA molecule is from a bacterial cell. Draw the approximate locations of the promoter and terminator for this transcription unit.

b. Assume that this DNA molecule is from a eukaryotic cell. Draw the approximate location of an RNA polymerase II promoter.

29. *The following DNA nucleotides are found near the end of a bacterial transcription unit.

3′ – AGCATACAGCAGACCGTTGGTCTGAAAAAAGCATACA – 5′

a. Mark the point at which transcription will terminate.

b. Is this terminator rho-independent or rho-dependent?

c. Draw a diagram of the RNA that will be transcribed from this DNA, including its nucleotide sequence and any secondary structures that form.

30. A strain of bacteria possesses a temperature-sensitive mutation in the gene that encodes the rho subunit. At high temperatures, rho is not functional. When these bacteria are raised at elevated temperatures, which of the following effects would you expect to see? Explain your reasoning for accepting or rejecting each of these five options.

    a. Transcription does not take place.

    b. All RNA molecules are shorter than normal.

    c. All RNA molecules are longer than normal.

    d. Some RNA molecules are longer than normal.

    e. RNA is copied from both DNA strands.

31. Suppose that the string of A nucleotides following the inverted repeat in a rho-independent terminator was deleted but the inverted repeat was left intact. How would this deletion affect termination? What would happen when RNA polymerase reached this region?

32. CONNECT Compare and contrast replication (see chapter 12) and transcription by making a table listing similarities and differences between transcription and replication. List as many as you can think of.

Section 13.4

33. The following diagram represents a transcription unit in a hypothetical DNA molecule.

$$5' \ldots \text{TTGACA} \ldots \text{TATAAT} \ldots 3'$$
$$3' \ldots \text{AACTGT} \ldots \text{ATATTA} \ldots 5'$$

a. On the basis of the information given, is this DNA from a bacterium or from a eukaryotic organism?

b. If this DNA molecule is transcribed, which strand will be the template strand and which will be the nontemplate strand?

c. Where, approximately, will the transcription start site be?

34. Computer programmers, working with molecular geneticists, have developed programs that can identify genes within long stretches of DNA sequence. Imagine that you are working with a programmer on such a project. On the basis of what you know about the process of transcription, what sequences should the program use to identify the beginning and end of a gene?

35. *Through genetic engineering, a geneticist mutates the gene that encodes TBP in cultured human cells. This mutation

destroys the ability of TBP to bind to the TATA box. Predict the effect of this mutation on cells that possess it.

36. CONNECT Elaborate repair mechanisms that prevent permanent mutations in DNA are associated with replication (see Chapter 18), yet no similar repair process is associated with transcription. Can you think of a reason for this difference between replication and transcription? (Hint: Think about the relative effects of a permanent mutation in a DNA molecule and one in an RNA molecule.)

CHALLENGE QUESTIONS

Section 13.3

37. Many genes in both bacteria and eukaryotes contain numerous sequences that can cause pauses in or premature termination of transcription. Nevertheless, the transcription of these genes within a cell normally produces multiple RNA molecules thousands of nucleotides long without pausing or premature termination. However, when a single round of transcription of these genes takes place in a test tube, RNA synthesis is frequently interrupted by pauses and premature terminations, which reduce the rate at which transcription takes place and frequently shorten the lengths of the mRNA molecules produced. Most pauses and premature terminations occur when

RNA polymerase temporarily backtracks (i.e., backs up) for one or two nucleotides along the DNA. Experimental findings have demonstrated that most pauses and premature terminations disappear if several RNA polymerases are simultaneously transcribing the DNA molecule. Propose an explanation for this observation of faster transcription and longer mRNAs when the template DNA is being transcribed by multiple RNA polymerases.

Section 13.4

38. Enhancers are sequences that affect the initiation of the transcription of genes that are hundreds or thousands of nucleotides away. Transcription factors that bind to enhancers usually interact directly with transcription factors at promoters by causing the intervening DNA to loop out. An enhancer of bacteriophage T4 does not function by looping of the DNA (D. R. Herendeen et al. 1992. *Science* 256:1298–1303). Propose some mechanisms other than DNA looping by which this enhancer might affect transcription at a gene thousands of nucleotides away.

39. *The locations of the TATA box in two species of yeast, *Saccharomyces pombe* and *Saccharomyces cerevisiae*, differ dramatically. The TATA box of *S. pombe* is about 30 nucleotides upstream of the transcription start site, similar to the location in most other eukaryotic cells. However, the TATA box of *S. cerevisiae* is 40 to 120 nucleotides upstream of the start site.

To better understand what sets the start site in these organisms, researchers at Stanford University conducted a series of experiments to determine which components of the transcription apparatus of these two species could be interchanged (Y. Li et al. 1994. *Science* 263:805–807). In these experiments, different general transcription factors and RNA polymerases were switched in *S. pombe* and *S. cerevisiae*, and the effects of each switch on the level of RNA synthesis and on the starting point of transcription were observed. The results from one set of experiments are shown in the table below. Components cTFIIB, cTFIIE, cTFIIF, and cTFIIH are general transcription factors from *S. cerevisiae*. Components pTFIIB, pTFIIE, pTFIIF, and pTFIIH are general transcription factors from *S. pombe*. Components cPol II and pPol II are RNA polymerase II from *S. cerevisiae* and *S. pombe*, respectively. The table indicates whether the component was present (+) or missing (–) in each experiment. In the accompanying gel, the presence of a band indicates that RNA was produced, and the position of the band indicates whether it was the length predicted when transcription begins 30 bp downstream of the TATA box or when it begins 40 to 120 bp downstream of the TATA box.

Components	Experiment 1	2	3	4	5	6	7
cTFIIE	+	−	+	+	+	+	−
cTFIIH + cTFIIF	+	−	+	+	+	−	+
cTFIIB + cPol II	+	−	−	−	−	−	−
pPol II	−	+	+	+	−	+	+
pTFIIB	−	+	+	−	+	+	+
pTFIIE + pTFIIH + pTFIIF	−	+	−	−	−	−	−

Description

The table has 6 rows and 8 columns. The column headers are as follows: Components and Experiment numbers 1 through 7. The row entries are as follows:

Row 1: c T F 2 E; positive, negative, positive, positive, positive, positive, negative.

Row 2: c T F 2 H plus c T F 2 F; positive, negative, positive, positive, positive, negative, positive.

Row 3: c T F 2 B plus c P o l 2; positive, negative, negative, negative, negative, negative, negative.

Row 4: p P o l 2; negative, positive, positive, positive, negative, positive, positive.

Row 5: p T F 2 B; negative, positive, positive, negative, positive, positive, positive.

Row 6: p T F 2 E plus p T F 2 H plus p T F 2 F; negative, positive, negative, negative, negative, negative, negative.

The gel below shows the following information:

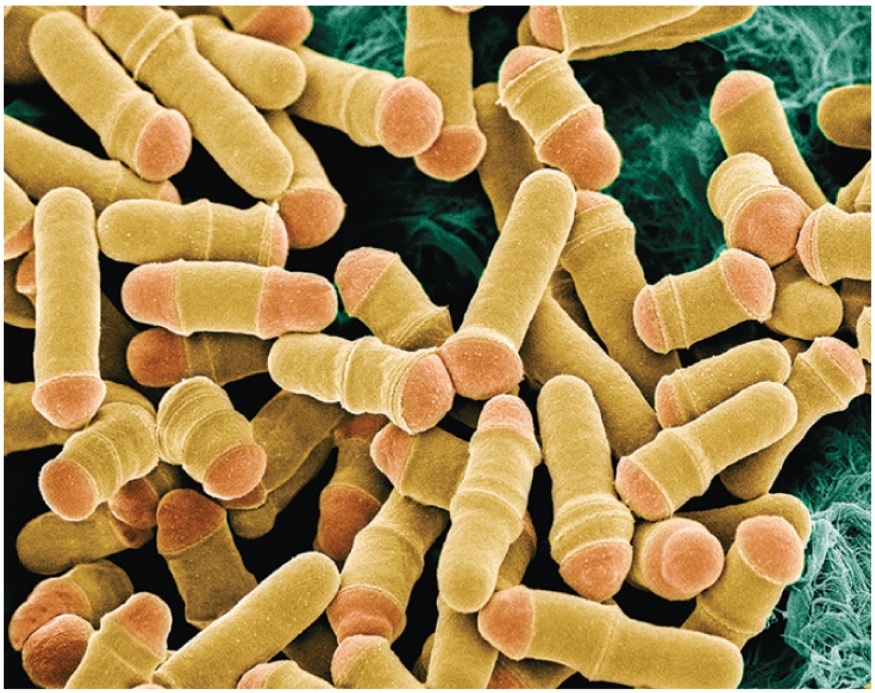
Transcription at S pombe start site (30 b p downstream from T A T A box): blank space, band, band.

Transcription at S cerevisiae start site (40 to 120 b p downstream from T A T A box): band.

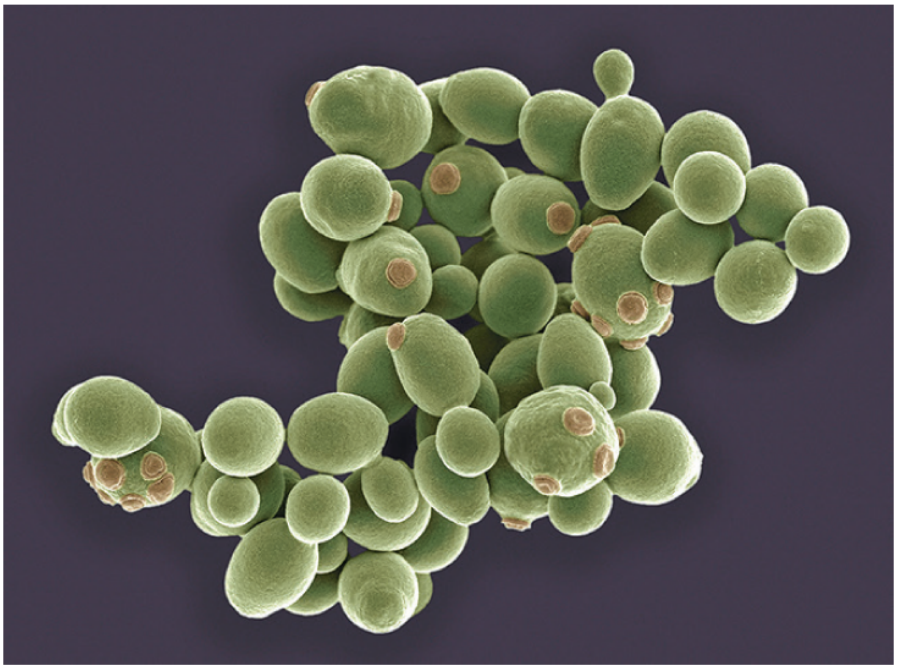
a. What conclusion can you draw from these data about what components determine the start site for transcription?

b. What conclusions can you draw about the interactions of the different components of the transcription apparatus?

c. Propose a mechanism that might have caused the transcription start site in *S. pombe* to be about 30 bp downstream of the TATA box, while the start site for transcription in *S. cerevisiae* is 40 to 120 bp downstream of the TATA box.



Steve Gschmeissner/Science Source.



Steve Gschmeissner/Science Source.

40. DATA ANALYSIS Glenn Croston and his colleagues studied the relation between chromatin structure and transcription activity. In one set of experiments, they measured the level of in vitro transcription of a *Drosophila* gene by RNA polymerase II in the presence of DNA and various combinations of histone proteins (G. E. Croston et al. 1991. *Science* 251:643–649).

    First, they measured the level of transcription of naked DNA, with no associated histone proteins. Then they measured the level of transcription after nucleosome octamers (without H1) were added to the DNA. The addition of the octamers caused the level of transcription to drop by 50%. When both nucleosome octamers and H1 proteins were added to the DNA, transcription was greatly repressed, dropping to less than 1% of that obtained with naked DNA, as shown in the following table.

GAL4-VP16 is a protein that binds to the DNA of certain eukaryotic genes. When GAL4-VP16 is added to DNA, the level of transcription by RNA polymerase II is greatly elevated.

Treatment	Relative amount of transcription
Naked DNA	100
DNA + octamers	50
DNA + octamers + H	+1
DNA + GAL4-VP16	1000
DNA + octamers + GAL4-VP16	1000
DNA + octamers+H1 + GAL4-VP16	1000

Even in the presence of the H1 protein, GAL4-VP16 stimulates high levels of transcription.

Propose a mechanism by which the H1 protein represses transcription and by which GAL4-VP16 overcomes this repression. Explain how your proposed mechanism would produce the results obtained in these experiments.

ACTIVE LEARNING: THINK-PAIR-SHARE QUESTIONS

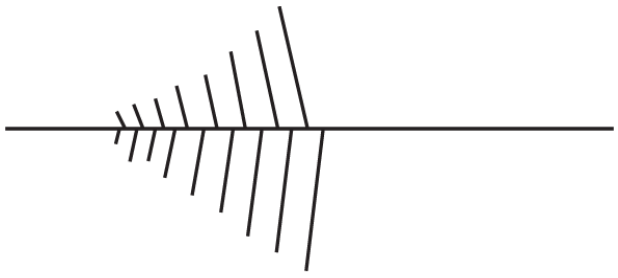
Section 13.2

1. Usually, within a gene, only one of the DNA strands is transcribed into RNA (see Figure 13.5). Why haven't both strands in a DNA molecule evolved to carry genetic information? In other words, why might we not expect both strands to carry genetic information and be transcribed into RNA?

Section 13.3

2. Why do consensus sequences have consensus? In other words, why do copies of consensus sequences in different species tend to have similar nucleotides? Hint: Consensus sequences are usually found in stretches of DNA that have important functions, such as promoters.

3. The following diagram represents one of the Christmas-tree-like structures shown in **Figure 13.3**.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

f. Approximate location of the promoter
g. Possible location of a terminator
h. Upstream and downstream directions
i. Molecules of RNA polymerase (use dots to represent these molecules)

Section 13.4

4. List some of the ways in which eukaryotic transcription is more complex than transcription in bacteria. Propose some possible reasons for the greater complexity of transcription in eukaryotic cells.

ACTIVE LEARNING: CONCEPT MAPPING EXERCISES

Introduction

1. Draw a concept map that illustrates the causes and consequences of collisions between replication and transcription. Include at least the following terms: replication, transcription, collisions, head-on collisions, rear-end collisions, $5'\rightarrow3'$ direction, template DNA, replication stalling, premature termination of transcription, DNA breaks, mutations, co-directional replication and transcription, DNA repair, restarting replication, removing transcription complexes.

Section 13.1

2. Create a concept map that compares and contrasts the structures of DNA and RNA. Include similarities and differences in their structures.

Section 13.2

3. Draw a concept map that summarizes DNA sequences involved in transcription by including the following terms: transcription, DNA template strand, DNA nontemplate strand, promoter, RNA-coding sequence, terminator, transcription start site, RNA molecule, transcription unit.

Section 13.3

4. Outline the process of transcription in bacteria by creating a concept map that includes the following terms: transcription,

ribonucleoside triphosphates, $5' \rightarrow 3'$, RNA polymerase, sigma factor, promoter, holoenzyme, promoter, −10 consensus sequence, −35 consensus sequence, transcription bubble, transcription pausing, transcription initiation, termination, terminator, rho factor, rho-independent terminator, rho-dependent terminator.

Section 13.4

5. Create a concept map that illustrates transcription in eukaryotes by including the following terms: eukaryotic transcription, RNA polymerase I, RNA polymerase II, RNA polymerase III, transcription factors, basal transcription apparatus, regulatory promoter, core promoter, enhancer, TATA box.

CHAPTER 14

RNA Molecules and RNA Processing

Mondadori Portfolio/Getty Images.

Family of Tsar Nicholas Romanov II of Russia. The boy in front is the tsar's son, Alexei, who suffered from hemophilia.

A Royal Disease

On August 12, 1904, Tsar Nicholas Romanov II of Russia wrote in his diary: "A great never-to-be forgotten day when the mercy of God has

visited us so clearly." That day, Alexei, Nicholas's first son and heir to the Russian throne, had been born.

At birth, Alexei was a large and vigorous baby, with yellow curls and blue eyes, but at 6 weeks of age he began spontaneously hemorrhaging from the navel. The bleeding persisted for several days and caused great alarm. As he grew and began to walk, Alexei often stumbled and fell, as all children do. Even his small scrapes bled profusely, and minor bruises led to significant internal bleeding. It soon became clear that Alexei had hemophilia.

Marked by slow clotting and excessive bleeding, hemophilia is caused by a mutation in one of several genes that encode proteins involved in the process of blood clotting. In people with hemophilia, minor injuries can result in life-threatening blood loss, and spontaneous bleeding into joints erodes the bone, with crippling consequences.

Alexei suffered from classic hemophilia, which is an X-linked genetic disorder. He inherited the hemophilia mutation from his mother, Alexandra, who was a carrier. The mutation appears to have originated with Queen Victoria of England (see Figure 6.8). In all, ten of Queen Victoria's male descendants suffered from hemophilia. Six female descendants, including her granddaughter Alexandra (Alexei's mother), were carriers.

During his childhood, Alexei experienced a number of severe bleeding episodes. The royal physicians were often helpless during these crises—they had no treatment that would stop the bleeding. At this time, the Russian Revolution broke out. Bolsheviks captured the tsar and his family and held them captive in the city of Yekaterinburg. On the night of July 16, 1918, a firing squad executed the royal family and their attendants, including Alexei and his four sisters. For many years, the bodies of the tsar's family were lost, but their skeletons were eventually recovered from two graves outside Yekaterinburg. Comparisons of mitochondrial DNA and nuclear DNA from the bones and from descendants of relatives of the family verified that the bones were indeed those of the royal family. Although this analysis determined the identity of the remains, the molecular nature of the royal hemophilia long remained unknown.

In 2009, geneticists analyzed DNA from the bones of the tsar's family to determine the genetic nature of the royal hemophilia. In people with X-linked hemophilia, a mutation commonly occurs in one of two genes on the X chromosome: the gene for blood coagulation factor VIII or the gene for blood coagulation factor IX.

In eukaryotic cells, genes are often interrupted by noncoding sequences. Those parts of a gene that encode the amino acids of a protein are called exons, while the noncoding sequences are called introns. Initially, both exons and introns are transcribed into pre-mRNA, but in a process called RNA splicing, the introns are later cut out and the exons pasted together. Examination of the

sequences of the two clotting factor genes in Alexandra's DNA revealed no mutations in the nucleotides that encode amino acids, but a mutation was present in one of the introns of her gene for factor IX. This mutation altered the splicing of the exons, creating a new stop signal in the coding sequence of the mRNA and producing a truncated, defective clotting factor IX. Both normal and mutant alleles were detected in Alexandra's DNA, as is expected of a heterozygous carrier. DNA from Alexei carried only the mutant allele, which caused his hemophilia.

THINK-PAIR-SHARE

- Classic hemophilia is inherited as an X-linked recessive condition. When a female is heterozygous for an X-linked recessive mutation such as hemophilia, what proportion of her male offspring are expected to have hemophilia? Examine the pedigree of the royal family in Figure 6.8. Calculate the proportion of affected male offspring born to females heterozygous for hemophilia. Carry out a chi-square goodness-of-fit test comparing the numbers of observed and expected male progeny of these females affected by hemophilia. What conclusion can you draw from the chi-square test?
- Hemophilia in the royal family was caused by the presence of a mutation in the gene for factor IX that altered the splicing of the exons and created a new stop signal in the mRNA for factor IX. Explain how a splicing mutation could produce a premature stop signal.

As illustrated by Alexei's hemophilia, RNA processing is critically important for the proper synthesis of proteins. In eukaryotic cells, RNA molecules are often extensively modified after transcription: for genes that encode proteins, a modified nucleotide called the 5′ cap is added to the 5′ end, a tail of adenine nucleotides is added to

the 3′ end, and introns are cut out of the middle. In both prokaryotes and eukaryotes, rRNAs and tRNAs are also modified after transcription.

In Chapter 13, we focused on transcription—the process by which RNA molecules are synthesized. In this chapter, we examine the function and processing of RNA. We begin by taking a careful look at the nature of the gene. We then examine messenger RNA (mRNA), its structure, and how it is modified in eukaryotes after transcription. Then we turn to transfer RNA (tRNA), the adapter molecule that forms the interface between amino acids and mRNA in protein synthesis. We examine ribosomal RNA (rRNA), the structure and organization of rRNA genes, and how rRNAs are processed. Finally, we consider a newly discovered group of very small RNAs that play important roles in numerous biological functions.

As we explore the world of RNA and its role in gene function, we will see evidence of two important characteristics of this nucleic acid. First, RNA is extremely versatile, both structurally and biochemically. It can assume a number of different secondary structures, which provide the basis for its functional diversity. Second, RNA processing and function frequently include interactions between two or more RNA molecules.

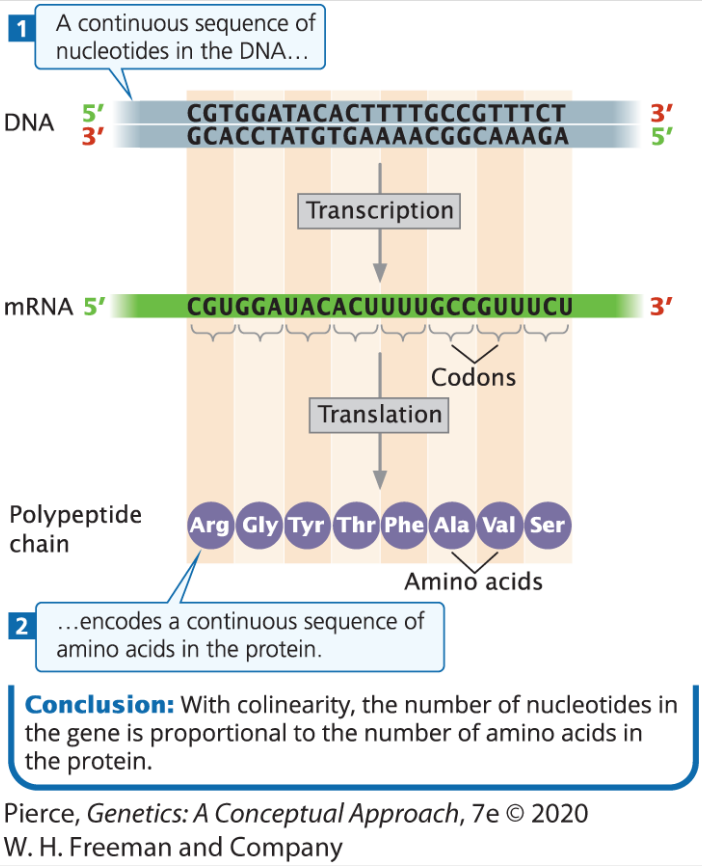
14.1 Many Genes Have Complex Structures

What is a gene? As noted in Chapter 3, the definition of a gene often changes as we explore different aspects of heredity. A gene was defined in Chapter 3 as an inherited factor that determines a characteristic. This definition may have seemed vague because it says only what a gene does, not what a gene is. Nevertheless, this definition was appropriate at the time because our focus was on how genes influence the inheritance of traits. We did not have to consider the physical nature of the gene in learning the rules of inheritance.

Knowing something about the chemical structure of DNA and the process of transcription now enables us to be more precise about what a gene is. Chapter 10 described how genetic information is encoded in the base sequence of DNA: a gene consists of a set of DNA nucleotides. But how many nucleotides constitute a gene, and how is the information in those nucleotides organized? In 1902, Archibald Garrod correctly suggested that genes encode proteins. Proteins are made of amino acids, so a gene contains nucleotides that specify amino acids. Therefore, for many years, the working definition of a gene was a set of nucleotides that specifies the amino acid sequence of a protein. As geneticists learned more about the structure of genes, however, it became clear that this concept of a gene was an oversimplification.

Gene Organization

Early work on gene structure was carried out largely through the examination of mutations in bacteria and viruses. This research led Francis Crick to propose in 1958 that genes and proteins are **colinear**—that there is a direct correspondence between the nucleotide sequence of DNA and the amino acid sequence of a protein (**Figure 14.1**). The concept of colinearity suggests that the number of nucleotides in a gene should be proportional to the number of amino acids in the protein encoded by that gene. In a general sense, this concept is true for genes found in bacterial cells and in many viruses, although these genes are slightly longer than would be expected if colinearity were strictly applied because the mRNAs encoded by the genes contain sequences at their ends that do not specify amino acids. At first, eukaryotic genes and proteins were also assumed to be colinear, but there were hints that eukaryotic gene structure is fundamentally different. Eukaryotic cells were found to contain far more DNA than is required to encode proteins (see Chapter 11). Furthermore, many large RNA molecules observed in the nucleus were absent from the cytoplasm, suggesting that nuclear RNAs undergo some type of change before they are exported to the cytoplasm.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

14.1 The concept of colinearity suggests that a continuous sequence of nucleotides in DNA encodes a continuous sequence of amino acids in a protein.

Bacterial genes are colinear with proteins, but eukaryotic genes often are not.

Description

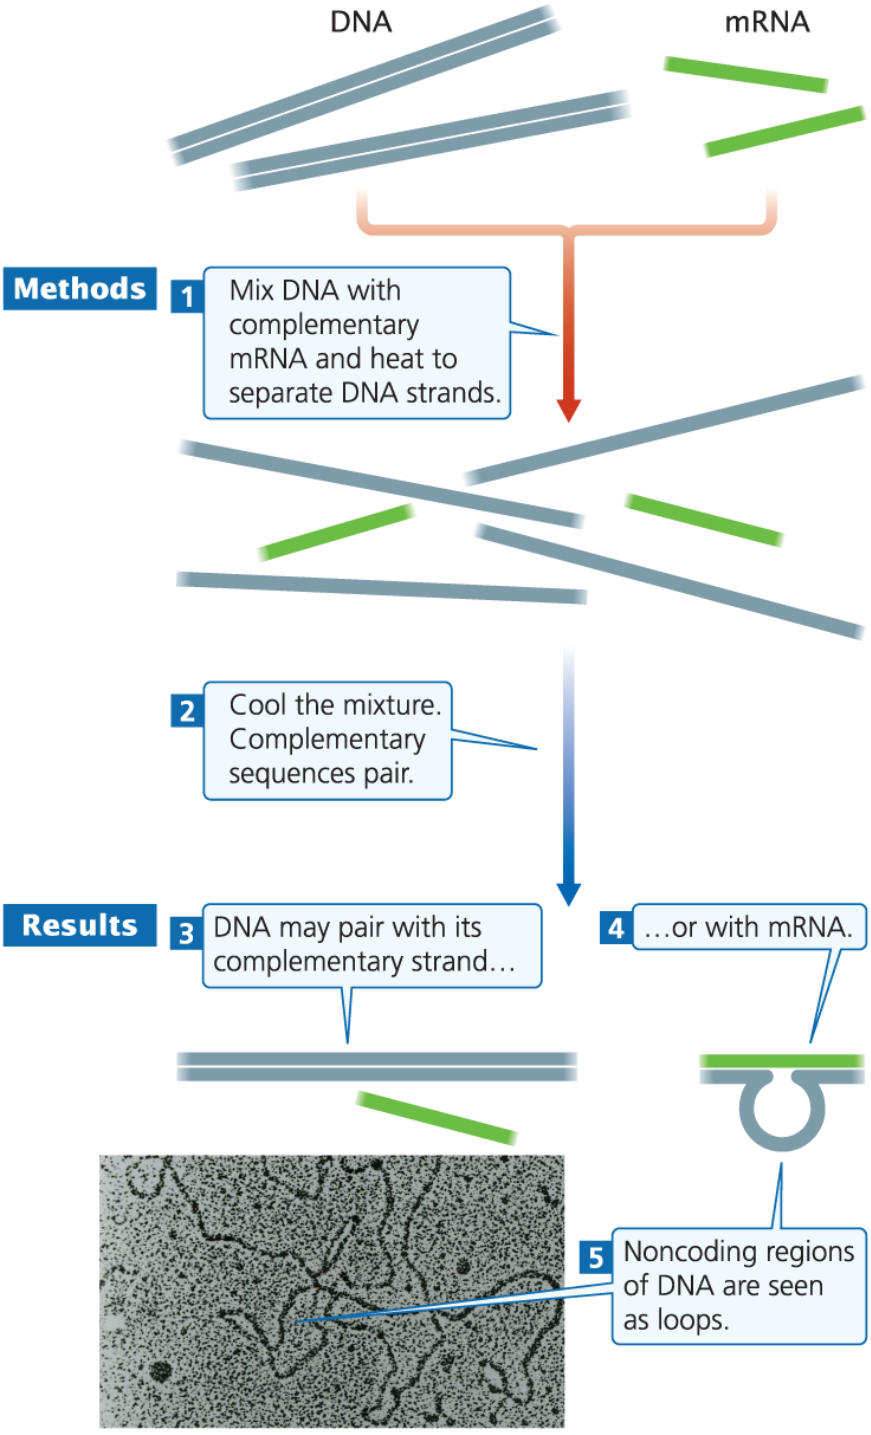
The illustration shows a D N A double strand, at the top. The upper strand runs from 5 prime to 3 prime and the nucleotides are as follows: C, G, T, G, G, A, T, A, C, A, C, T, T, T, T, G, C, C, G, T, T, T, C, T. The lower strand below runs from 3 prime to 5 prime and the nucleotides are as follows: G, C, A, C, C, T, A, T, G, T, G, A, A, A, A, C, G, G, C, A, A, A, G, A. A caption reads, a continuous sequence of nucleotides in the D N A. Transcription occurs and an m R N A transcript running from 5 prime to 3 prime is obtained below. The codons formed after transcription along with the corresponding amino acids formed after translation are as follows: C G U (A r g); G G A (G l y); U A C (T y r); A C U (T h r); U U U (P h e); G C C (A l a); G U U (V a l); U C U (S e r). A caption reads, encodes a continuous sequence of amino acids in the protein. All these amino acids formed are arranged to form

a large polypeptide chain. A caption below reads, With colinearity, the number of nucleotides in the gene is proportional to the number of amino acids in the protein.

Most geneticists were nevertheless surprised by the announcement in the 1970s that not all genes are continuous. Researchers observed four coding sequences in a gene from a eukaryote-infecting virus that were interrupted by nucleotides that did not specify amino acids. This discovery was made when the viral DNA was hybridized with the mRNA transcribed from it and the hybridized structure was examined using an electron microscope (**Figure 14.2**). The DNA was clearly much longer than the mRNA because regions of DNA looped out from the hybridized molecules. These regions of DNA contained nucleotide sequences that were absent from the coding nucleotides in the mRNA. Many other examples of interrupted genes were subsequently discovered; it quickly became apparent that most eukaryotic genes consist of stretches of coding and noncoding nucleotides.

Experiment

Question: Is the coding sequence in a gene always continuous?



Conclusion: Coding sequences in a gene may be interrupted by noncoding sequences.

Proc. Nati. Acad. Sci. USA Vol. 74, No. 8, pp. 3171–3175,
Fig. 4g August 1977 Biochemistry.

14.2 The noncolinearity of eukaryotic genes was discovered by hybridizing DNA with the mRNA transcribed from it.

Description

The illustration begins with a question that reads, Is the coding sequence in a gene always continuous? The illustration shows 2 double-stranded, larger, D N A molecules and 2 single-stranded, relatively small, m R N A molecules. The illustration shows methods below where D N A is mixed with complementary R N A and heated. A caption reads, mix D N A with complementary m R N A and heat to separate D N A strands. In the next step below, the D N A double strands separate and emerge as separate entities. A caption reads, cool the mixture complementary sequences pair. The results below show, the D N A may pair up with complementary D N A strand or may pair up with a complementary m R N A strand such that the non coding area loops out. A caption reads, D N A may pair with its complementary strand or with m R N A. An electron micrograph shows loops of non coding regions. A caption reads, noncoding regions of D N A are seen as loops. A caption below reads, Conclusion: Coding sequences in a gene may be interrupted by non coding sequences.

CONCEPTS

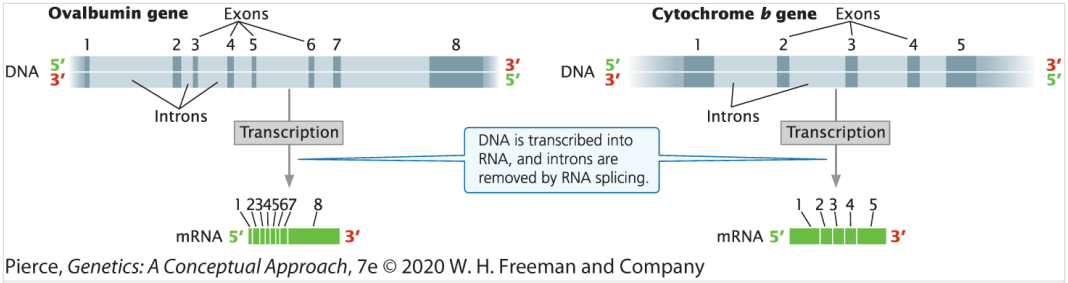
When a continuous sequence of nucleotides in DNA encodes a continuous sequence of amino acids in a protein, the two are said to be colinear. In eukaryotes, not all genes are colinear with the proteins that they encode.

✔ CONCEPT CHECK 1

What evidence indicated that eukaryotic genes are not colinear with the proteins that they encode?

Introns

Many eukaryotic genes contain RNA coding regions called **exons** and noncoding regions called intervening sequences, or **introns**. For example, the gene encoding the protein ovalbumin has eight exons and seven introns; the gene for cytochrome *b* has five exons and four introns (Figure 14.3). The average human gene contains from eight to nine introns. All the introns and exons are initially transcribed into RNA, but during or after transcription, the introns are removed and the exons are joined to yield the mature RNA.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020 W. H. Freeman and Company

14.3 The coding sequences of many eukaryotic genes are disrupted by noncoding introns.

Description

The illustration shows a D N A double strand of ovalbumin gene, at the top left, containing 8 exons numbered 1 to 8. Between each of these exons are introns of varying lengths. Transcription occurs and the exons fuse together into one continuous m R N A strand below. The m R N A runs from 5 prime to 3 prime and 1 to 8 exons arranged from left to right. The illustration also shows a D N A double strand for cytochrome small B gene, at the top right, which has 5 exons numbered 1 to 5. Between each of these exons are introns of varying lengths. Transcription occurs and the exons fuse together into one continuous m R N A strand below. The m R N A runs from 5 prime to 3 prime and 1 to 5 exons arranged from left to right. A caption referring to the transcription phase of both genes reads, D N A is transcribed into R N A and introns are removed by R N A splicing.

Introns are common in eukaryotic genes but are rare in bacterial genes. For a number of years after their discovery, introns were thought to be entirely absent from prokaryotic genomes, but they have now been observed in archaea, bacteriophages, and even some bacteria. Introns are present in mitochondrial and chloroplast genes as well as in the nuclear genes of eukaryotes. Among eukaryotic genomes, the sizes and numbers of introns appear to be directly related to organismal complexity: yeast genes contain only a few short introns, *Drosophila* introns are longer and more numerous, and most vertebrate genes are interrupted by long introns. Different classes of eukaryotic genes—those that encode rRNA, tRNA, and proteins—may contain introns. The numbers and sizes of introns vary widely: some eukaryotic genes have no introns, whereas others may have more than 60; intron length varies from fewer than 200 nucleotides to more than 50,000. Introns tend to be longer than exons, and most eukaryotic genes contain more noncoding nucleotides than coding nucleotides.

Geneticists have long debated the evolutionary origin of introns. One idea, called the *intron late hypothesis*, proposes that introns were absent from ancient organisms but were later acquired by eukaryotes. Another idea, termed the *intron early hypothesis*, suggests that early ancestors of bacteria, archaea, and eukaryotes possessed introns that were later lost by prokaryotes and simple eukaryotes. Evidence suggests that introns have been lost *and* gained over

evolutionary time. Many researchers now assume that the earliest eukaryotes possessed introns because divergent eukaryotes have introns in the same positions in their genes, suggesting that these introns were present in the ancestors of all eukaryotes.

There are four major types of introns, differentiated by how the intron is removed from RNA (**Table 14.1**). **Group I introns**, found in some genes of bacteria, bacteriophages, and eukaryotes, are self-splicing: they can catalyze their own removal. **Group II introns** are present in some genes of mitochondria, chloroplasts, archaea, and a few bacteria; they are also self-splicing, but their mechanism of splicing differs from that of the group I introns. **Nuclear pre-mRNA introns** are the best studied; they include introns located in the protein-encoding genes of the eukaryotic nucleus. The splicing mechanism by which these introns are removed is similar to that of the group II introns, but nuclear introns are not self-splicing; their removal requires a spliceosome that includes small nuclear RNAs (snRNAs, discussed in Section 14.2) and a number of proteins. **Transfer RNA introns**, found in tRNA genes of bacteria, archaea, and eukaryotes, use yet another splicing mechanism that relies on enzymes to cut and reseal the RNA. In addition to these major types, there are several other types of introns.

TABLE 14.1 Major types of introns

Type of Intron	Location	Splicing Mechanism

Group I	Genes of bacteria, bacteriophages, and eukaryotes	Self-splicing
Group II	Genes of bacteria, archaea, and eukaryotic organelles	Self-splicing
Nuclear pre-mRNA	Protein-encoding genes in the nucleus of eukaryotes	Spliceosomal
Transfer RNA	tRNA genes of bacteria, archaea, and eukaryotes	Enzymatic

Note: There are also several types of minor introns, including group III introns, twintrons, and archaeal introns.

We'll take a detailed look at the chemistry and mechanics of RNA splicing in Section 14.2. For now, we should keep in mind two general characteristics of the splicing process: (1) the splicing of all pre-mRNA introns takes place in the nucleus; and (2) the order of exons in DNA is usually maintained in the spliced RNA; that is, the coding sequences of a gene may be split up, but they are not usually jumbled up. **› TRY PROBLEM 22**

THINK-PAIR-SHARE Question 1

CONCEPTS

Many eukaryotic genes contain exons and introns. Both are transcribed into RNA, but introns are later removed by RNA processing. The numbers and sizes of introns vary from gene to gene. Introns are common in eukaryotic genes but uncommon in bacterial genes.

✔ CONCEPT CHECK 2

What are the four major types of introns?

The Concept of the Gene Revisited

How does the presence of introns affect our concept of a gene? To define a gene as a sequence of nucleotides that encodes amino acids in a protein no longer seems appropriate because this definition excludes introns, which do not specify amino acids. This definition also excludes the nucleotides that encode the 5′ and 3′ ends of an mRNA molecule, which, as we will see, are required for translation but do not encode amino acids. And defining a gene in these terms also excludes sequences that specify rRNA, tRNA, and other RNAs that do not encode proteins. Given our current understanding of DNA structure and function, we need a more precise definition of a gene.

Many geneticists have broadened the concept of a gene to include all sequences in DNA that are transcribed into a single RNA molecule.

Defined this way, a gene includes all exons, all introns, and those sequences at the beginning and end of the RNA that are not translated into protein. This definition also includes DNA sequences that encode rRNAs, tRNAs, and other types of non-messenger RNA. Some geneticists have expanded the definition of a gene even further to include the entire transcription unit—the promoter, the RNA-coding region, and the terminator. However, new evidence now calls into question even this definition. Research suggests that much of the genome is transcribed into RNA, although it is unclear what, if anything, much of this RNA does. What *is* certain is that the process of transcription is more complex than formerly thought, and defining a gene as a sequence that is transcribed into an RNA molecule is not as straightforward as formerly thought. The more we learn about the nature of genetic information, the more elusive the definition of a gene seems to become.

THINK-PAIR-SHARE Question 2

CONCEPTS

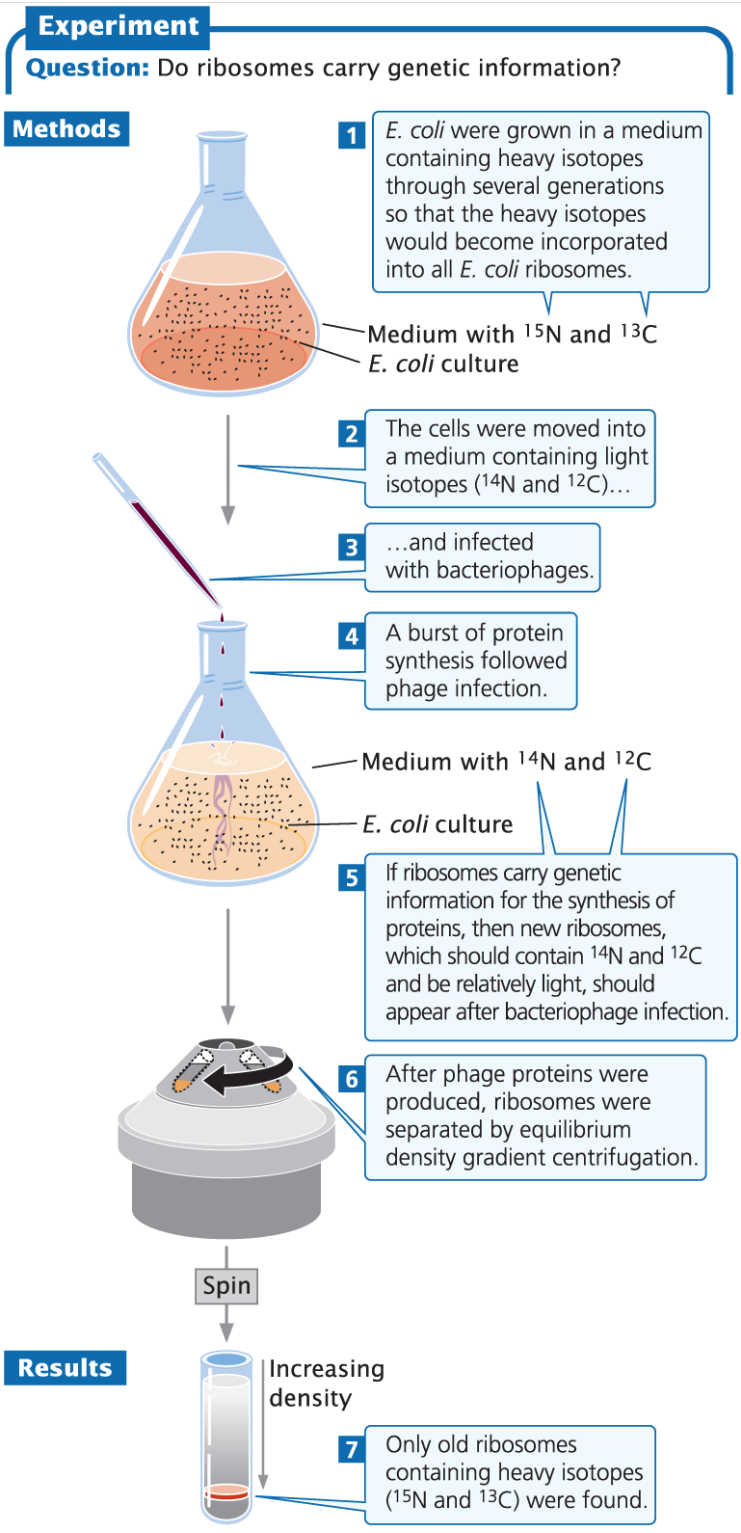
The discovery of introns forced a reevaluation of the definition of a gene. Today, a gene is often defined as a DNA sequence that encodes an RNA molecule or the entire DNA sequence required to transcribe and encode an RNA molecule.

14.2 Messenger RNAs, Which Encode Proteins, Are Modified after Transcription in Eukaryotes

As soon as DNA was identified as the source of genetic information, it became clear that DNA cannot directly encode proteins. In eukaryotic cells, DNA resides in the nucleus, yet protein synthesis takes place in the cytoplasm. Geneticists recognized that an additional molecule must take part in transferring genetic information.

The results of studies of bacteriophage infection conducted in the late 1950s and early 1960s pointed to RNA as a likely candidate for this transport function. Bacteriophages inject their DNA into bacterial cells, where that DNA is replicated (see Chapter 9), and large amounts of phage protein are produced on the bacterial ribosomes. As early as 1953, Alfred Hershey discovered a type of RNA that was synthesized rapidly after bacteriophage infection. Findings from later studies showed that this short-lived RNA had a nucleotide composition similar to that of the phage DNA but quite different from that of the bacterial RNA. These observations were consistent with the idea that RNA was copied from DNA and that this RNA then directed the synthesis of proteins.

At the time, ribosomes were known to be *somehow* involved in protein synthesis, and much of the RNA in a cell was known to be in the form of ribosomes. Were ribosomes the agents by which genetic information was moved to the cytoplasm for the production of protein? Using isotopes of nitrogen and carbon and equilibrium density gradient centrifugation (see Figure 12.2), Sydney Brenner, François Jacob, and Matthew Meselson demonstrated in 1961 that they were not. They showed that new ribosomes are *not* produced during the burst of protein synthesis that accompanies bacteriophage infection (**Figure 14.4**). Thus, ribosomes could not be the carriers of the genetic information needed to produce new phage proteins.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020

14.4 Brenner, Jacob, and Meselson demonstrated that ribosomes do not carry genetic information.

Description

The figure begins with a question that reads, Do ribosomes carry genetic information? The illustration shows a flask with a medium containing heavy isotopes (N left superscript 15 and C left superscript 13), at the top. A caption reads, E coli were grown in medium containing heavy isotopes through several generations so that the heavy isotopes would become incorporated into all E coli ribosomes. The cells were then transferred to a flask, placed below, with light isotopes N left superscript 14 and C left superscript 12. The cells are infected with bacteriophages. A caption reads, the cells were moved into medium containing light isotopes N left superscript 14 and C left superscript 12 and infected with bacteriophages. A burst of protein synthesis followed phage infection. If ribosomes carry genetic information for the synthesis of proteins, then new ribosomes, which should contain N left superscript 14 and C left superscript 12 and be relatively light, should appear after bacteriophage infection. The culture is then subjected to centrifugation below. A caption reads, after phage proteins were produced, ribosomes were separated by equilibrium density gradient centrifugation. The culture is spun. The results show the components with increased density settling below in a test tube. A caption reads, only old ribosomes containing heavy isotopes (N left superscript 15 and C left superscript 13) were found. A caption below reads, Conclusion: Ribosomes are not produced in phage reproduction and therefore do not carry genetic information.

In a related experiment, François Gros and his colleagues infected *E. coli* cells with bacteriophages while adding radioactively labeled uracil, which would become incorporated into newly produced phage RNA, to the medium in which they grew. Gros and his colleagues found that the newly produced phage RNA was short-lived, lasting only a few minutes, and was associated with ribosomes but was distinct from them. They concluded that this short-lived RNA carries the genetic information for proteins to the ribosome,

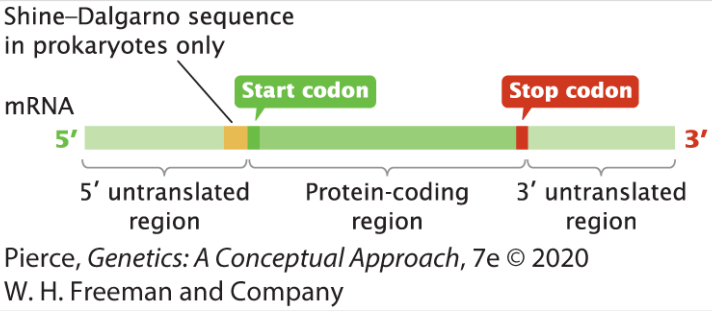
where translation occurs. The term *messenger RNA* was coined for this carrier.

The Structure of Messenger RNA

Messenger RNA functions as the template for protein synthesis. It carries genetic information from DNA to a ribosome, where it helps assemble amino acids in their correct order. In bacteria, mRNA is transcribed directly from DNA, but in eukaryotes, a pre-mRNA (also called the *primary transcript*) is first transcribed from DNA and then processed to yield the mature mRNA. We will reserve the term *mRNA* for RNA molecules that have been processed and are ready to undergo translation.

In an mRNA molecule, each amino acid of a protein is specified by a set of three nucleotides, called a **codon**. Both prokaryotic and eukaryotic mRNAs contain three primary regions (**Figure 14.5**). The first, the **5′ untranslated region (5′ UTR**; sometimes called the *leader*), is a sequence of nucleotides at the 5′ end of the mRNA that does not encode any of the amino acids of a protein. In bacterial mRNA, this region contains a consensus sequence (AGGAGG) called the **Shine–Dalgarno sequence**, which serves as the ribosome-binding site during translation (see Chapter 15); it is found approximately seven nucleotides upstream of the first codon translated into an amino acid (called the start codon). The Shine–Dalgarno sequence is complementary to a sequence found in one of

the RNA molecules that make up the ribosome, and it pairs with that sequence during translation. Eukaryotic mRNA has no equivalent RNA-binding consensus sequence in its 5′ untranslated region. In eukaryotic cells, ribosomes bind to a modified 5′ end of mRNA, as discussed later in this section.



14.5 Three primary regions of mature mRNA are the 5′ untranslated region, the protein-coding region, and the 3′ untranslated region.

Description
The illustration shows an m R N A that runs from 5 prime to 3 prime. The left part represents 5 prime untranslated region. A Shine-Dalgarno sequence is present only in case of prokaryotes. A start codon marks the beginning of protein coding region and a stop codon marks its end. To the right of the stop codon is 3 prime untransalated region.

The second primary region of mRNA is the **protein-coding region**, which comprises the codons that specify the amino acid sequence of the protein. The protein-coding region begins with a start codon and ends with a stop codon.

The third region of mRNA is the **3′ untranslated region** (**3′ UTR**; sometimes called the *trailer*), a sequence of nucleotides at the 3′ end

of the mRNA that is not translated into amino acids. The 3′ UTR affects the stability of mRNA and helps regulate the translation of the mRNA protein-coding sequence. View **Animation 14.1** to see how mutations in different regions of a gene affect the flow of information from genotype to phenotype.

CONCEPTS

Messenger RNA molecules contain three primary regions: a 5′ untranslated region, a protein-coding region, and a 3′ untranslated region. The 5′ and 3′ untranslated regions do not encode any amino acids of a protein but contain information that is important for RNA stability and the regulation of translation.

Pre-mRNA Processing

In bacterial cells, transcription and translation take place simultaneously: while the 3′ end of an mRNA is undergoing transcription, ribosomes attach to the Shine–Dalgarno sequence near the 5′ end and begin translation. Because transcription and translation are coupled, bacterial mRNA has little opportunity to be modified before protein synthesis. In contrast, transcription and translation are separated in both time and space in eukaryotic cells. Transcription takes place in the nucleus, whereas translation takes place in the cytoplasm; this separation provides an opportunity for eukaryotic RNA to be modified before it is translated. Indeed,

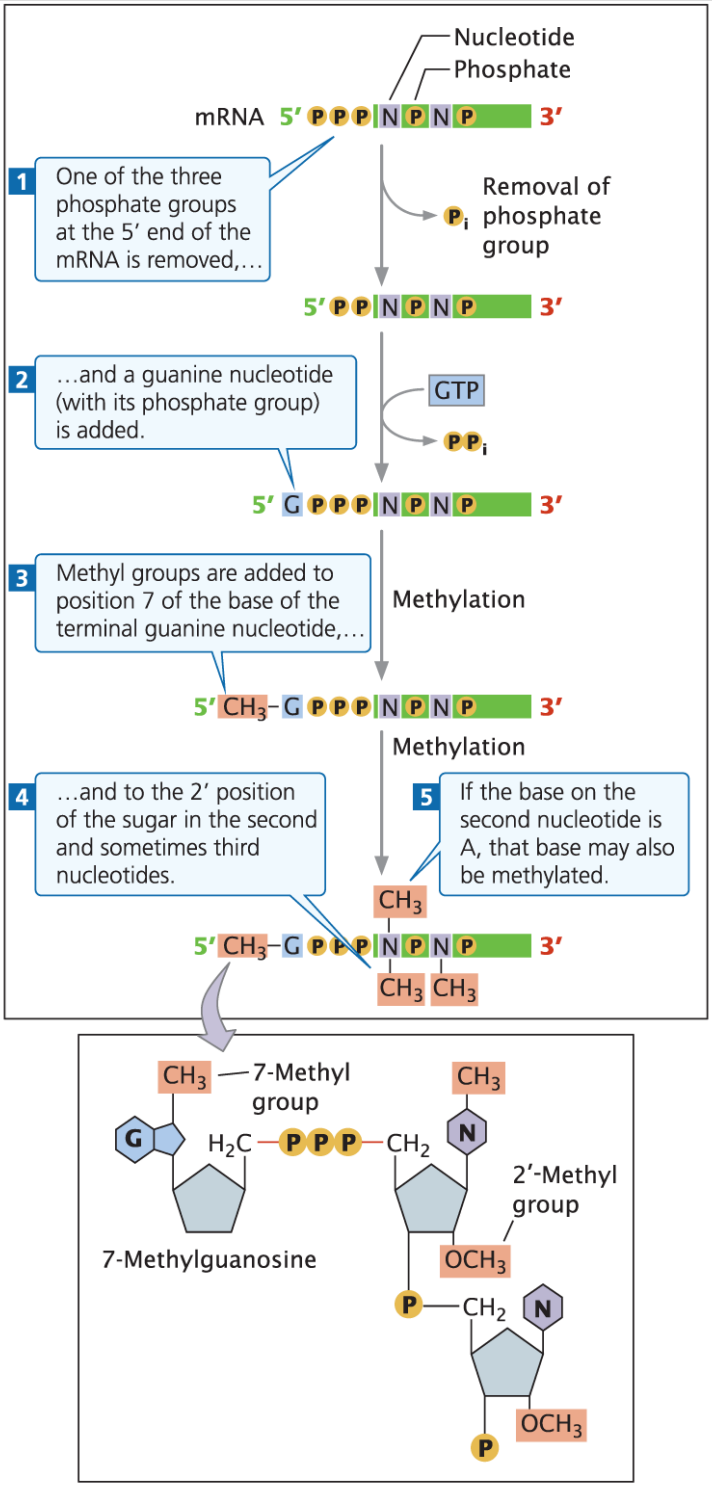
eukaryotic mRNA is extensively altered after transcription. Changes are made to the 5′ end, the 3′ end, and the protein-coding region of the RNA molecule (Table 14.2).

TABLE 14.2 Posttranscriptional modifications to eukaryotic pre-mRNA

Modification	Function
Addition of 5′ cap	Facilitates binding of ribosome to 5′ end of mRNA, increases mRNA stability, enhances RNA splicing
3′ cleavage and addition of poly(A) tail	Increases stability of mRNA, aids in export of mRNA from the nucleus, and facilitates binding of ribosome to mRNA
RNA splicing	Removes noncoding introns from pre-mRNA, facilitates export of mRNA to cytoplasm, allows for multiple proteins to be produced through alternative splicing
RNA editing	Alters nucleotide sequence of mRNA
Internal RNA modifications	Influence splicing, mRNA degradation, and translation

ADDITION OF THE 5′ CAP

One type of modification of eukaryotic pre-mRNA is the addition of a structure called a **5′ cap**. The cap is formed by the addition of an extra guanine nucleotide to the 5′ end of the mRNA and the addition of methyl groups (CH_3) to the base in that guanine, forming 7-methylguanosine. Methyl groups are also added to the 2′-OH group of the sugar of the first and sometimes second nucleotides adjacent to 7-methylguanosine (**Figure 14.6**). If the first adjacent nucleotide has adenine, the adenine base itself may also be methylated. The 7-methylguanosine nucleotide and these additional methyl groups constitute the 5′ cap.



Pierce, *Genetics: A Conceptual Approach*, 7e © 2020
W. H. Freeman and Company

14.6 Most eukaryotic mRNAs have a 5′ cap. The cap consists of 7-methylguanosine attached to the pre-mRNA by a unique 5′–5′ bond (shown in

detail in the bottom box) and additional methyl groups added to the first few nucleotides.

Description
The illustration shows an m R N A strand running from 5 prime to 3 prime, at the top. The 5 prime end has 3 phosphate molecules and the m R N A has a series of alternate nucleotide and phosphate. Caption 1 reads, one of the three phosphate groups at the 5 prime end of the m R N A is removed. A phosphate group is removed. G T P enters and P P subscript 1 leaves below. The 5 prime end of m R N A has a guanine attached. Caption 2 reads, and a guanine nucleotide (with its phosphate group) is added. Methylation occurs and a methyl group (C H subscript 3) is added to guanine at 5 prime end. Caption 3 reads, methyl groups are added to position 7 of the base of the terminal guanine nucleotide. In the next step below, nucleotides in the m R N A are also methylated. Caption 4 reads, and to the 2 prime position of the sugar in the second and sometimes third nucleotides. If the base on the second nucleotide is A, that base may also be methylated. A magnified image below shows 7-methyl guanosine group bonded to three phosphate groups and other methylated nucleotides in the m R N A.

The addition of the cap takes place rapidly after the initiation of transcription. The cap functions in the initiation of translation, as we'll see in Chapter 15. Cap-binding proteins recognize the cap and attach to it; a ribosome then binds to these proteins and moves downstream along the mRNA until the start codon is reached and translation begins. The presence of a 5′ cap also increases the stability of mRNA and influences the removal of introns.

As noted in the discussion of transcription in Chapter 13, three phosphate groups are present at the 5′ end of all RNA molecules because phosphate groups are not cleaved from the first ribonucleoside triphosphate in the transcription reaction. The 5′ end

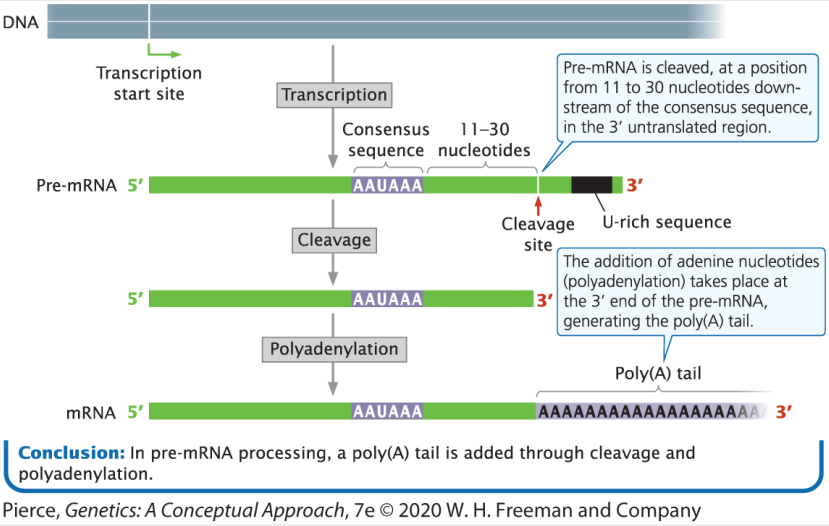
of pre-mRNA can be represented as 5′–PPPNPNP … , in which the letter *N* represents a ribonucleotide and *P* represents a phosphate. Shortly after the initiation of transcription, one of the three 5′ phosphate groups is removed and a guanine nucleotide is added (see Figure 14.6). This guanine nucleotide is attached to the pre-mRNA by a unique 5′ – 5′ bond, which is quite different from the usual 5′ – 3′ phosphodiester bond that joins all the other nucleotides in RNA. One or more methyl groups are then added to the 5′ end of the mRNA; the first of these methyl groups is added to position 7 of the base of the terminal guanine nucleotide, making the base 7-methylguanine. Next, a methyl group may be added to the 2′ position of the sugar in the second and third nucleotides (see Figure 14.6). Rarely, additional methyl groups may be attached to the bases of the second and third nucleotides of the pre-mRNA.

Several different enzymes take part in the addition of the 5′ cap. The initial step is carried out by an enzyme that associates with RNA polymerase II. Because neither RNA polymerase I nor RNA polymerase III have this associated enzyme, RNA molecules transcribed by these polymerases (rRNAs, tRNAs, and some snRNAs) are not capped.

ADDITION OF THE POLY(A) TAIL

A second type of modification to eukaryotic mRNA is the addition of 50 to 250 or more adenine nucleotides at the 3′ end, forming a

poly(A) tail. These nucleotides are not encoded in the DNA but are added after transcription in a process termed *polyadenylation* (Figure 14.7). Many eukaryotic genes transcribed by RNA polymerase II are transcribed well beyond the end of the coding sequence (see Chapter 13); most of the extra material at the 3′ end is then cleaved, and the poly(A) tail is added. More than 1000 nucleotides may be removed from the 3′ ends of some pre-mRNA molecules before polyadenylation.



14.7 Most eukaryotic mRNAs have a 3′ poly(A) tail.

Description

The illustration shows a double stranded D N A molecule at the top with a transcription start site towards its left end. Transcription occurs a pre- m R N A transcript is formed below. From left to right, the regions of the strand are labeled as follows: consensus sequence (A, A, U, A, A, A), 11 to 30 nucleotide region, cleavage site, an unlabeled region, and U-rich sequence. A caption reads, pre-messenger R N A is cleaved at a position from 11 to 30 nucleotides downstream of the consensus sequence, in the 3 prime untranslated region. Cleavage occurs below and the region after the cleavage site is lost. Polyadenylation occurs below and a poly A tail is added at the 3 prime end. The strand is

now labeled as m R N A. A caption reads, the addition of adenine nucleotides or polyadenylation takes place at the 3 prime end of the pre-m R N A, generating the poly A tail. A caption below reads, in pre- m R N A processing, a poly (A) tail is added through cleavage and polyadenylation.

Processing of the 3′ end of pre-mRNA requires sequences (collectively termed the *polyadenylation signal*) located both upstream and downstream of the site where cleavage occurs. The consensus sequence AAUAAA (called the poly(A) consensus sequence) is usually 11 to 30 nucleotides upstream of the cleavage site (see Figure 14.7) and determines the point at which cleavage will take place. A sequence rich in uracil nucleotides (or in guanine and uracil nucleotides) is typically downstream of the cleavage site. A large number of proteins take part in finding the cleavage site and removing the 3′ end. After cleavage has been completed, adenine nucleotides are added without a template to the new 3′ end, creating the poly(A) tail.

The amount of protein produced by a cell depends not only on the amount of mRNA transcribed but also on the stability of the mRNA that is transcribed. Thus, one way in which eukaryotic cells regulate the expression of genes is by controlling degradation of mRNA. The poly(A) tail and the 5′ cap are important in this process, conferring stability on those mRNAs that have these modifications. The 5′ cap and poly(A) tail protect mRNA from degradation by 5′ and 3′ exonucleases, thus increasing the time during which the mRNA remains intact and available for translation. The stability conferred

by the poly(A) tail depends on proteins that attach to the tail and on its length. The poly(A) tail also facilitates attachment of the ribosome to the mRNA and plays a role in export of the mRNA to the cytoplasm.

Poly(U) tails are added to the 3′ ends of some mRNAs, microRNAs, and snRNAs. Poly(U) tails on some mRNAs may facilitate their degradation. › **TRY** PROBLEM 33
