Chapter 65

Disorders of the Spleen

Matthew R. Porembka

Majella Doyle

William C. Chapman

The spleen is a small, purplish, sponge-like organ found in the left upper abdominal quadrant.¹ Although there is no mention of the spleen in the Bible, it receives considerable attention in the Talmud and post-Talmudic literature. Classically identified as the seat of laughter, there has been much debate over whether the spleen is truly necessary.² It is said that Galen called it an “organ full of mystery” as early as the second century A.D. Although we have come to understand much about the structure and function of the spleen since those times, much of what intrigued Galen still remains a mystery today. The spleen has been classified into different organ systems including the circulatory system, the hematopoietic system, the mononuclear phagocyte system, or the lymphatic system. However, it is probably more accurate to describe the spleen as a clearinghouse for circulating cellular elements—a place where multiple organ systems converge in both structure and function.

DEVELOPMENT AND ANATOMY

The spleen is derived from embryonic mesoderm. The developing organ first becomes apparent during the fifth week of gestation as mesodermal cells coalesce between the leaflets of the dorsal mesogastrium, posterior to the developing stomach. As development continues, independent lobules enveloped by mesogastrium become evident. In time, they fuse to form a multilobulated mass that eventually differentiates into a well-formed organ by late fetal life.³ Occasionally, a stray lobule may fail to fuse with the others, develop independently, and give rise to an accessory spleen, a functioning mass of splenic tissue set apart from the body of the organ proper. The mesogastrium enveloping the lobules eventually gives rise to the organ's capsule and trabecular skeleton, and the posterior and anterior attachments give rise to the primary supporting structures: the splenorenal and gastrosplenic ligaments, respectively.⁴ The colonization of the cellular elements of the spleen occurs first with the erythroid and myeloid progenitors, followed by the first hematopoietic stem cells. Finally, lymphoid-tissue-inducer cells are observed and provide the necessary local cellular signals to trigger the unique architecture of the splenic cellular elements. This development is highly similar to that of lymph nodes.⁵

Gross Anatomy

Grossly, the spleen may appear in a variety of shapes. It may be wedge-shaped (44%), tetrahedral (42%), or triangular (14%), depending on its relationships with the stomach, left kidney, pancreas, and colon. The average adult spleen measures 13 to 15 cm in length, 8 to 10 cm in width, and 4 cm in thickness, with a weight of 150 g and a corresponding blood volume of ~300 mL.⁴ However, the size of the spleen varies with age, immunologic status, and nutritional status.¹

The nonperfused organ appears purplish in color with a solid, sponge-like texture throughout. It is covered by a fibrous connective tissue capsule that is 1.5 mm thick and composed of collagen and elastin fibers.¹ This capsule surrounds all but the hilum of the spleen.⁴ Continuous with the capsule, involutions penetrate the body of the organ to form trabeculae, the fibrous supporting skeleton of the spleen.³ Finally, a serosal membrane, derived from peritoneum, covers the organ externally and adheres to the capsule. This mesothelial membrane covers the entire organ except at its hilum and the reflections of its primary supporting ligaments.¹

In the majority of people, the spleen is divided into the superior lobe and inferior lobe, but further division into subsegmental lobes can be seen.⁶ Avascular planes separate each lobe and they are defined by discrete, nonanastomosing circulatory pathways.^{1, 3, 6}

Location and Relationships

The spleen is located in the left upper quadrant of the abdominal cavity, posteriorly, at the level of the ninth to eleventh thoracic vertebrae. The superior, or diaphragmatic, surface of the organ is convex in shape, smooth, and related to the left hemidiaphragm; whereas the inferior, or visceral, surface is somewhat triangular and rests on the splenic flexure of the colon.^{1, 4}

The medial portion of the spleen is concave and divided by a longitudinal ridge into a gastric surface anteriorly and a renal surface posteriorly. The gastric surface contains the hilum of the organ and relates to the fundus of the stomach and the tail of the pancreas. The tail of the pancreas touches the spleen in 30% of cases and is within 1 cm of it in 73% of the population, contributing to the risk of pancreatic injury in patients undergoing splenectomy.⁷ The renal surface borders the superolateral surface of the left kidney and left adrenal gland. Figure 65.1 shows the gross appearance of the spleen as well as its relationship to the adjacent pancreatic tail and branch vessels of the splenic artery.

The spleen is supported by a number of suspensory ligaments: the splenorenal posteriorly, the gastrosplenic anteromedially, the splenophrenic superiorly, and the splenocolic inferiorly.¹ The splenorenal and gastrosplenic ligaments provide the majority of support to the organ and are considered primary. The splenorenal ligament supports the organ posteriorly and serves as a conduit for the organ's neurovascular bundle, whereas the gastrosplenic ligament stabilizes the spleen anteromedially to the greater curvature of the stomach and contains the short gastric and gastroepiploic vessels. The other ligaments of the spleen play a secondary role in the support of the organ and are generally

P.1370

avascular.^{1, 4} However, in certain pathologic states, such as portal hypertension, significant collateral circulation through these planes may occur.

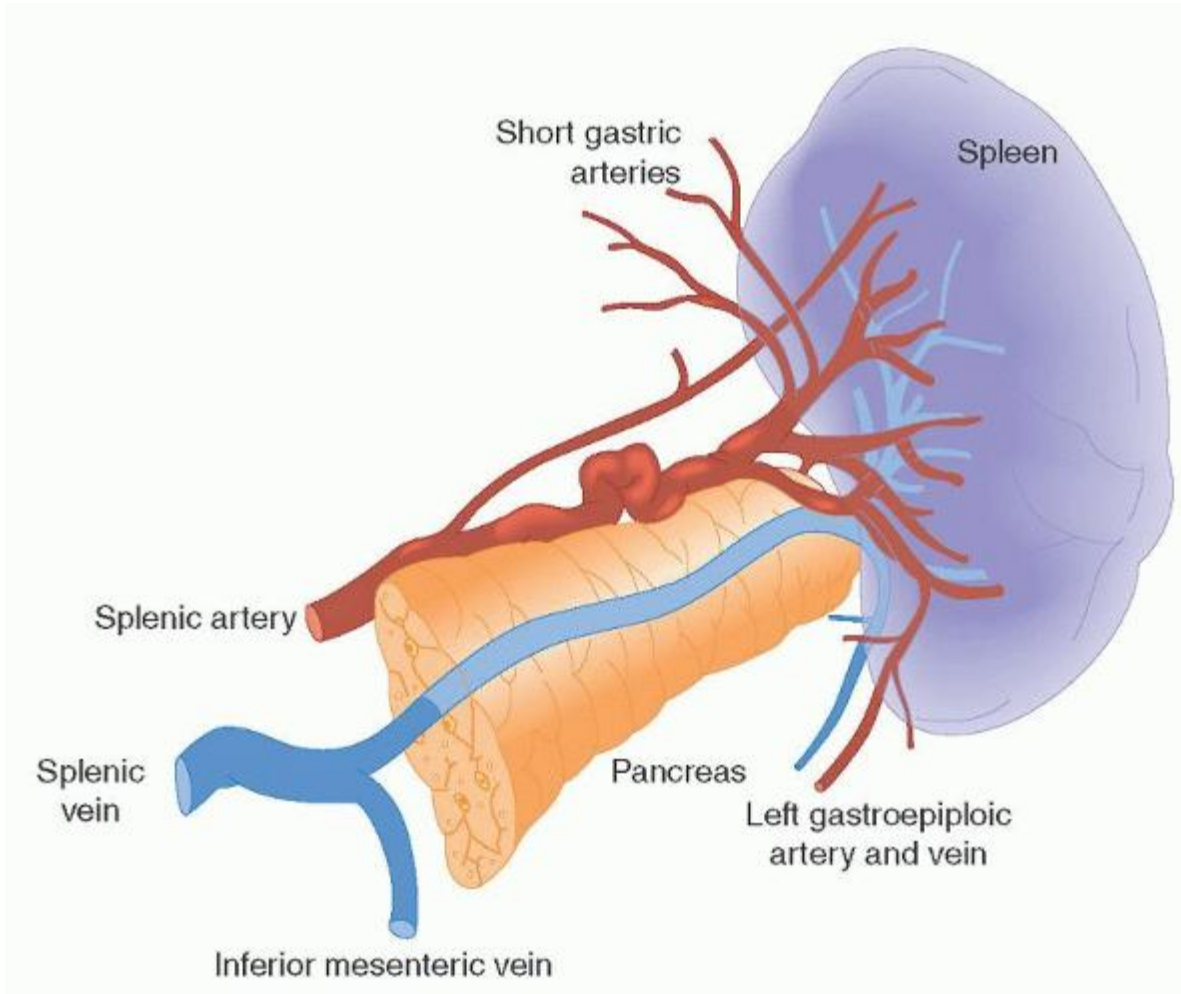

FIGURE 65.1. Illustration of the spleen and relationship to the adjacent pancreatic tail and branch vessels of the splenic artery and vein. (Redrawn and modified from Cameron JL, ed. Atlas of surgery. Philadelphia, PA: BC Decker, 1990.)

Vascular Supply

The spleen is a highly perfused organ. Although it represents only ~0.2% of the total body weight, it receives > 5% of the total cardiac output.⁸ The main blood supply to the spleen is the highly variable splenic artery, which delivers 250 to 300 ml of arterial blood per minute. It arises as a branch of the aorta's celiac trunk in the midline and follows a tortuous course to the left, enveloped within the splenorenal ligament, to supply the organ.¹

The splenic artery is a highly unpredictable vessel that displays variations in course and dimension. In 95% of the population, it travels along the upper border of the pancreas, but it may also travel in front of, within, or behind the pancreatic tissue. Along its tortuous course, the splenic artery gives rise to the left gastroepiploic artery and the short gastric arteries, both of which run within the gastrosplenic ligament. At its terminal end, the splenic artery branches into a number of smaller arteries, or segmental branches, before penetrating the hilum of the organ. These smaller arteries are

also highly variable but are most often four in number and include the superior polar, superior middle, inferior middle, and inferior polar splenic arteries. The segmental branches penetrate the organ by traveling within the trabeculae (sheaths of fibrous connective tissue derived from the involution of the spleen's fibrous capsule) and ramify within the body of the organ. Additional sources of arterial blood to the spleen include direct tributaries and collateral circulation provided by branches of the pancreatic and short gastric arteries.^{1, 4}

Venous drainage is facilitated primarily by the splenic vein. It is formed by the coalescence of the segmental splenic veins, as they leave the hilum of the organ, and the left gastroepiploic vein. Occasionally, short gastric veins may also participate. The splenic vein courses toward the midline along the superior border of the pancreas, where it joins the superior mesenteric vein to form the portal vein. Along the way, the splenic vein receives venous tributaries from the pancreas and, in 60% of cases, also receives the inferior mesenteric vein.^{1, 4}

Lymphatics

The spleen, which is considered by many to be a lymphatic organ, has no afferent lymphatics, yet a significant amount of lymph fluid is expressed by the organ and drains via efferent vessels that form around the arterioles. The lymphatics travel with the neurovascular bundle through the trabeculae, exiting at the hilum.^{3, 9} In turn, the lymphatic fluid is directed toward the nodes of the splenic hilum, the splenic artery, and the pancreas (the pancreaticosplenic nodes), and eventually drains to the nodes of the celiac axis.⁴

Innervation

The spleen is innervated by fibers of the sympathetic nervous system which originate at the level of T-6 to T-8 and pass with the greater thoracic splanchnic nerve to the celiac ganglion.¹⁵ From there, they pass to the organ via the arterial tree, with resulting vasomotor function.¹ It is believed that, similar to other mammals, the autonomic nervous system regulates changes in spleen volume, resulting in the expulsion of stored red blood cells during times of physiologic need.^{18, 25}

Of interest are studies that relate the sympathetic innervation of the spleen to the immune system.^{10, 11, 12} These studies suggest that spleen innervation also supplies branches to the lymphocytic tissue of the white pulp, and that the innervation is plastic and able to be remodeled depending on the host's current immune state.¹³ In this respect, these investigators argue, the central nervous system is hard-wired to the immune system and may mediate the observed immunosuppressive effects of stress.

Accessory Spleens

An accessory spleen is a functioning lobule of splenic tissue set apart from the body of the spleen proper. It is an anatomic variant present in 10% to 30% of the general population and appears to be found with greater frequency in patients with hematologic disorders. Figure 65.2 shows a typical example of an accessory spleen.

These supernumerary organs arise during embryologic development when an encapsulated lobule of precursor cells fails to fuse with others forming the spleen proper; they are solitary in ~88% but can be multiple in 10% of cases.¹⁴ In the majority of cases, accessory spleens receive their blood supply from a tributary of the splenic artery and are found most often near the hilum of the organ or within one of the primary supporting ligaments. However, they may be found within secondary supporting ligaments or within the greater omentum or even in as remote a location as the pelvis of the female or the scrotum of the male. They may be mistaken for malignancy on imaging studies, such as computed tomography (CT) or endoscopic ultrasound.

Because accessory spleens perform the same functions as the spleen proper, they are subject to the same pathologic conditions that affect the parent organ. Therefore, they may enlarge after splenectomy, causing a relapse of the disease process for which the spleen was removed. The presence of an unrecognized accessory spleen can account for failure of certain surgical procedures such as splenectomy for immune thrombocytopenic purpura (ITP).^{15, 16, 17, 18} In patients who continue to have thrombocytopenia after splenectomy, a search for a missed accessory spleen should be considered. Diagnosis may be made using abdominal sonography, CT, magnetic resonance imaging, nuclear scintigraphy, or Doppler sonography.¹⁹

Splenosis

In addition to accessory spleens, extrasplenic tissue may occur via traumatic autotransplantation in the form of splenosis. This is the migration and subsequent proliferation of dislodged splenic

P.1371

tissue, and it is reported to occur in up to 75% of patients who undergo splenectomy for traumatic injury. Rarely, splenosis

may be found in the gynecologic patient or in the thorax after rupture of the spleen and left hemidiaphragm.^{20, 21, 22} Histologic examination of splenic tissue reveals the same elements of the parent organ: white pulp, red pulp, and marginal zones.²⁰ It follows, therefore, that splenic tissue should preserve at least some splenic function. Indeed, it has been observed that postsplenectomy patients with splenic tissue do retain the ability to clear erythrocytes of undesirable inclusion bodies. However, it has not been demonstrated that this provides sufficient protection from postsplenectomy infectious complications, and the practice of splenic tissue reimplantation after splenectomy has been abandoned.²³

FIGURE 65.2. Autopsy photograph demonstrating accessory spleen (large arrow) and its relationship to the splenic hilum, pancreas (small arrow), and adjacent liver. L, liver; S, spleen. (Photograph provided by Hedi Wingard, M.D., Department of Pathology, Vanderbilt University Medical Center.)

Wandering Spleen

Wandering spleen refers to migration of the spleen from its normal location in the left upper quadrant. With an incidence of <0.5% in splenectomy series, the major complication of an ectopic spleen is torsion, either acutely or chronically. Signs and symptoms include vague or chronic abdominal discomfort and a tender abdominal mass; and CT assessment of viability leads to the decision of splenectomy versus splenopexy.

Microscopic Anatomy

Splenic tissue is supported by a scaffold of trabeculae, a dense, fibrous connective tissue skeleton that gives rise to an intrasplenic meshwork of collagen fibers. Vascular elements enter the spleen at the hilum, branch through the trabeculae,

and penetrate the body of the organ to supply the microcirculation.¹ As the arterial elements enter the parenchyma, they become surrounded by an aggregate of lymphoid tissue, which follows vessels in a sheathlike distribution. Aggregates of lymphoid tissue are collectively called the white pulp. White pulp may be arranged in this coaxial fashion, or it may appear as isolated follicles within the parenchyma of the organ. The balance of splenic tissue beneath the capsule is known as the red pulp. It is composed of vascular, circulatory, and mononuclear phagocytic elements. Additionally, an intermediate region can be observed at the junction between the white and red pulp; it is known as the marginal zone. Nerves and lymphatics follow the distribution of the larger vessels throughout the body of the organ.

White Pulp

The white pulp structure resembles that of a lymph node, with organized T and B cell compartments surrounding branching arterial vessels. The organization of the cellular elements within the white pulp is created and maintained by local chemokine gradients specific to T and B cells.^{3, 9} White pulp may be observed in one of two arrangements: a periarteriolar lymphatic sheath (PALS) or a lymphoid follicle. The PALS is a collection of T lymphocytes that surrounds intraparenchymal arterioles and follows these vessels in a coaxial fashion for several millimeters throughout their terminal distribution. Within the PALS, T cells interact with dendritic cells and passing B cells. The lymphoid follicles are spherical collections of B lymphocytes. These follicles are usually distributed along the length of the PALS in an eccentric fashion and house activated B cells undergoing clonal expansion.⁹

Red Pulp

The red pulp represents approximately three-fourths of the splenic volume and is composed primarily of vascular elements surrounded by a fibrocellular reticulum that contains mononuclear phagocytic cell lines and circulating elements of blood in transit.¹ The chief vascular component of the red pulp is the splenic sinus, a preliminary venous element whose structure is unique to this organ. The sinus is composed of an incomplete lining of elongated endothelial cells surrounded by a highly fenestrated basement membrane. The structure is supported externally by reticulin fibers wrapped in a transverse fashion. These stress fibers also have actin- and myosin-like filaments which regulate the porosity of the sinus. The unique architecture of the splenic sinus has been compared to the structure of a wooden barrel, with the elongated endothelial cells resembling the planks or staves and the external reticulin fibers representing the hoops.³

The splenic sinuses permeate the surrounding fibrocellular reticulum that supports them. Two-dimensional histologic observation reveals an intervening reticulum arranged in cords called splenic cords or cords of Billroth.¹ These cords actually are a three-dimensional meshwork of densely packed elements (fibroblasts, collagen fibers, and cells of the mononuclear phagocytic lines). Terminal arterioles and capillaries deliver circulating blood to this meshwork that percolates through the cord toward the sinuses. Thus, circulating elements of blood in transit are also packed within the cords: erythrocytes, platelets, macrophages, lymphocytes, plasma cells, and granulocytes.^{1, 3, 9}

Marginal Zone

The marginal zone is a transitional region between the white and red pulp and contains both lymphocytic and mononuclear phagocytic elements. Within this transitional zone, three distinct regions can be identified. Moving from white to red pulp are the marginal sinus, the marginal zone proper, and the perimarginal cavernous sinus plexus.³

The marginal sinus is a vascular sinus that surrounds the white pulp and is a region where arterioles terminate into an anastomosing complex of vascular spaces. External to the marginal sinus is the marginal zone. This transitional region contains elements of both white and red pulp and is where much of the circulating blood is presented to lymphocytic and mononuclear phagocytic cells.^{3, 24} Figure 65.3 illustrates a schematic view of the microcirculation within the spleen.

Many different cell types reside in the marginal zone. Its foundation is a framework of reticular fibroblasts which is continuous with the reticular fibroblasts of the red pulp and the cells lining the marginal sinus. The marginal zone macrophage, metallophilic macrophage, and B cell are the key cell types in this transitional zone. The marginal zone B cell is a specialized subset of B cells that differ phenotypically and functionally from follicular B cells and are considered a bridge between the innate and adaptive immune systems.²⁵ Interactions between these cells are key in the marginal zone's organization and integrity. Many transient cells

P.1372

pass through this area as they circulate into the red pulp and back into the blood stream. Diapedesis of lymphocytes and dendritic cells occurs through a barrier cell layer from the marginal sinus into the white pulp; however, the exact mechanism of this localization remains unknown.^{25, 26}

FIGURE 65.3. Schematic illustration of the microcirculation of the spleen. S, splenic sinus. (Redrawn and modified from Greep RO, ed. *The spleen*. New York: McGraw-Hill, 1966.)

Microvasculature

As the splenic artery approaches the body of the organ, it divides into a series of branches, the proper splenic arteries. On average, four proper splenic arteries then enter the organ at the hilum and branch into trabecular arteries, so named because they run within the framework of the fibrous connective tissue skeleton, the trabeculae. Trabecular arteries leave the fibrous trabeculae and penetrate the parenchyma by branching into central arteries that immediately become surrounded by a cuff of white pulp, the PALS.^{3, 9}

As the central arteries pass through the white pulp sheath, they give off lateral branches at right angles, most of which terminate in and supply the marginal sinuses, and others that terminate within the marginal zone or red pulp.^{9, 27} The right angle by which these lateral tributaries branch off from the central artery is thought to mediate a plasma-skimming effect which functions to hemoconcentrate the blood with a greater number of cellular elements.^{27, 28, 29} This skimming effect may also help regulate plasma volume. Central arteries continue from the white pulp sheath through the marginal zone and eventually terminate in the red pulp, giving off additional lateral branches along the way that are known as penicillar arterioles.¹ The penicillar arterioles, which are named for their resemblance to *Penicillium* molds, terminate in one of three fashions: They may circle back and supply the marginal sinus; they may terminate in the red pulp, supplying the splenic cords; and a minority may terminate directly into the venous sinuses for direct venous return. Eventually, the central artery itself terminates within the red pulp.^{24, 27, 29}

Circulating elements of splenic blood flow begin their return by first entering the splenic sinuses, the preliminary venous vessels. Flow may enter the sinuses directly from arterial connections in a closed circulatory fashion. Alternatively, plasma and blood cells may reach the sinuses only after percolating through the reticulum of the parenchyma in an open circulatory fashion. Eventually, the venous sinuses coalesce and drain into trabecular veins that give rise to the segmental veins and, finally, the splenic vein.^{24, 27, 29}

The exact details of splenic microcirculation remain elusive despite much research since its first description in 1901. The currently accepted models that describe the flow of blood through the vessels of the spleen discuss this in terms of the pathway taken, or route, and the kinetics, or speed of flow. Closed circulation implies that blood passes directly from artery to capillary to vein. In terms of the spleen, blood traveling along a closed circulatory path follows the terminal arterioles to capillaries and, eventually, into the venous sinuses. Indeed, such direct connections have been observed.^{24, 27, 29}

The term open circulation implies that cells and plasma circulate outside of endothelium-lined vascular channels. As it pertains to the spleen, circulating blood may follow one of two open pathways: It may leave the endothelium-lined marginal sinus, traverse the white pulp, and drain into the open-ended sinuses of the perimarginal cavernous sinus plexus²⁷; or it may leave penicillar arterioles that terminate in stroma of the red pulp, traverse the splenic cords, and reenter the venous sinuses through their fenestrations. Indeed, the unique vascular channels and microarchitecture of the spleen can support these open circulatory pathways, which also have been observed.^{9, 24, 29}

Another model for discussing splenic microcirculation describes it in terms of kinetics or speed of flow.^{1, 27} Accordingly, intrasplenic circulation may be fast, intermediate, or slow, traversing the organ in seconds, minutes, or hours.¹ Fast flow occurs along paths of low resistance, traverses the organ in seconds, and accounts for ~90% of splenic flow.²⁴ Pathways that support fast flow include the open circulation of the marginal zone and, to a lesser extent, the closed circulation of direct arterial, capillary, and sinus connections.²⁷

Elements that flow at an intermediate speed cross the circulation within minutes rather than seconds and represent ~9% of flow across the organ. These elements are thought to follow the open circulation through the cords where red cell processing— pitting and culling—occurs.

Finally, slow-flowing elements may take more than a day to traverse the organ and represent 1% of splenic flow. This is thought to represent a pool of maturing reticulocytes, which travel to the spleen from the bone marrow and undergo maturation before being released into the circulation.²⁷ The role of the spleen in this function is well documented and supported by the fact that asplenic patients have a high concentration of immature reticulocytes in their peripheral circulation.³⁰

SPLENIC FUNCTION

The functions of the spleen are probably best understood in terms of its unique structure. Composed of several different tissue types, it lies at the crossroads between the arterial supply and venous return. In this respect, the spleen functions as a unique lymphoid organ where elements of the circulatory, reticuloendothelial, and immune systems interact. Thus, it is ideally suited to play a critical role in the surveillance of circulating blood.

The spleen functions as a filter of the circulating blood, a coordinator of the immune response, and a reservoir for circulating cells and platelets. Additionally, the spleen may have a number of other responsibilities, including hematopoiesis, hemoglobin degradation and iron recovery, and plasma volume regulation.

Filter Function

One of the primary functions of the spleen is to filter blood. Elements removed from circulation by the spleen include aging or abnormal red cells, intraerythrocyte inclusions, and foreign particulate matter.³

Culling

The removal of aging or abnormal red blood cells by the spleen occurs within the cords of Billroth and is known as culling. Cells bound for destruction become trapped within the reticulum meshwork and, as their splenic transit time increases, they succumb to phagocytosis by resident macrophages.

Another theory contends that as erythrocytes age, they lose significant amounts of cytoplasmic membrane. Senescent cells therefore lack the deformability necessary to negotiate the meshwork and ultimately become trapped. This theory applies to red cells that are morphologically abnormal secondary to congenital disorders such as sickle cell anemia and hereditary spherocytosis. Finally, it has been proposed that as erythrocytes age, they expose surface antigens that are recognized by self-directed antibodies. Once opsonized with antibody, senescent cells are easily trapped by cordal macrophages.^{3, 9, 30, 31}

Pitting

In addition to culling, the spleen also functions to remove intraerythrocyte inclusions from circulating red cells. The ability of the spleen to clear these inclusions while maintaining the integrity of the red cell itself is known as pitting and is an exclusive function of splenic tissue.

P.1373

Undesirable intracellular elements removed by the spleen include circulating particulate matter, Heinz bodies (denatured hemoglobin), Howell-Jolly bodies (nuclear remnants), and Pappenheimer bodies (iron granules). Pitting occurs as cells

within the cords attempt to reenter the circulation through the splenic sinuses. To do this, they must pass through slit-like fenestrations of the sinus endothelium. As this occurs, the deformable portion of the cell bends to negotiate the opening, whereas the inclusion, which is nondeformable, is unable to pass through the narrow passage; thus, it is left behind to be phagocytized by resident macrophages. The passage of red cells through the slits is mediated by active changes within the sinus endothelial cell stress fibers. These cells have been shown to have cytoskeletons that include the contractile protein components actin and myosin.^{3, 22, 31} Figure 65.4 is a schematic representation of the process of pitting.

Evidence that supports the role of the spleen in culling and pitting is found in the fact that, after splenectomy, asplenic and hyposplenic patients lose their ability to clear damaged red cells and intraerythrocyte inclusion bodies from the circulation. These patients display peripheral blood smears with an abnormal variety of erythrocytes, many with intracellular inclusions. In fact, determination of the percentage of pitted erythrocytes is a well-established method of assessing splenic function.^{30, 31}

Clearance of Particulate Matter

Another important filtering function of the spleen is its ability to remove particulate matter from the circulation. As blood travels through the meshwork of the cords, foreign particles are exposed to splenic macrophages that clear them by phagocytosis. Experiments with injected carbon particles have confirmed this process and have identified the cells chiefly responsible for this function: The macrophages surrounding the splenic sinuses.

FIGURE 65.4. Schematic representation of process of pitting by the spleen. This process is believed to be responsible for removal of undesirable elements from circulation, including particulate matter, Heinz bodies (denatured hemoglobin), Howell-Jolly bodies (nuclear remnants), and Pappenheimer bodies (iron granules). A: Red blood cell (RBC) flows from open circulation and approaches fenestration of sinus. B: RBC begins to enter sinus through fenestration; note inclusion body within RBC. C: RBC transverses sinus; membrane-bound inclusion body lags behind. Sinus macrophage begins to approach inclusion body. D: RBC within sinus returns to venous circulation. Inclusion body succumbs to sinus macrophage. (Modified from Weintraub LR. Splenectomy: who, when, and why? *Hosp Pract (Off Ed)* 1994;29.)

Immune Function

Because the spleen is composed of lymphocytic tissue, circulatory elements, and mononuclear phagocytic cell lines, it is ideally suited to play a coordinating role in the immune response. The organ's function in this respect includes its role in the nonspecific as well as the specific arm of the immune response, making it an important organ for immune homeostasis. The nonspecific immune functions of the spleen include the clearance of pathogens, the clearance of opsonized erythrocytes and platelets, and the production of complement. The ability of the spleen to clear blood-borne microorganisms and debris combined with its highly organized lymphoid compartment makes the spleen the most important organ for antibacterial and antifungal immune reactivity.

The spleen plays a significant role in the removal of bloodborne pathogens from the circulation. Once coated with complement, bacteria and viruses become circulating immune complexes. Although the liver clears some of these complexes, many others are delivered to the spleen and eliminated by marginal zone cells expressing specific receptors including pattern-recognition receptors, C-type lectin SIGNR1, and type 1 scavenger receptor MARCO.³² Marginal zone metallophilic macrophages also function to concentrate pathogens in the spleen, leading to their opsonization, and produce high levels of interferon- α and interferon- β

P.1374

after viral exposure.²⁶ Marginal zone B cells are specialized to detect circulating pathogens, after which they rapidly differentiate into immunoglobulin (Ig) M producing plasma cells or antigen presenting cells capable of CD4⁺ T cell activation.²⁶ The contribution of the spleen to this process is supported by the fact that asplenic patients display a higher level of circulating immune complexes than do spleen-competent subjects.

The ability of the spleen to clear encapsulated bacteria is especially significant. Because these organisms have the ability to evade antibody and complement binding, their clearance depends on prolonged contact between pathogen and macrophage. It is well recognized that asplenic or hyposplenic patients are prone to a syndrome of fulminant septicemia, most often involving encapsulated bacteria: Overwhelming postsplenectomy sepsis.³¹

The spleen also plays a major role in the removal of opsonized erythrocytes and platelets from the circulation. In certain pathologic states, such as autoimmune hemolytic anemia or ITP, circulating elements become opsonized with IgG antibody. The resulting cell-antibody complexes enter the spleen and encounter Fc receptor-laden macrophages in the marginal zone, where they are destroyed.³

Several proteins and glycoproteins of the complement system are synthesized by mononuclear phagocytic cells in the spleen, namely properdin and tuftsin. Properdin is an opsonin that plays a critical role in the alternative pathway and has been detected in the monocytes of the spleen. Tuftsin stimulates interleukin-1 production and binds to granulocytes to initiate phagocytosis.³ Although these elements are also produced at other locations including tissue macrophages and the liver, the spleen's contribution is significant, and they are found in lower concentrations in the circulation of asplenic or hyposplenic patients. Patients who have lost their spleens also display a decreased concentration of C3 and factor B.³³

Specific Immune Response

The spleen is also uniquely suited to play a coordinating role in the specific arm of the immune response. Because white pulp and vascular elements lie adjacent to each other, this may serve as an interface between the lymphocytic populations of T and B cells and the elements of circulating blood.

As circulating blood enters the spleen, 90% of it passes through the marginal sinuses and surrounding zones.²⁷ Here, foreign antigens are exposed to the lymphocytic tissue of the PALS and the follicles, stimulating them to respond. After antigen-specific differentiation in the white pulp follicles, plasmablasts migrate to the bridging channels of the marginal zone within the red pulp.³⁴ The anatomic localization of the plasmablasts in the spleen resembles that found in lymph nodes. Antibodies produced at this location rapidly enter the circulation. The spleen also plays an important role in the induction of cell-mediated immunity. Once activated, antigen presenting cells enter the white pulp, resulting in the activation of T cells. Activated T cells then localize to the periphery of the B cell follicles where costimulatory signals are exchanged, resulting in B cell isotype switching in the follicle. These activated B cells then either migrate to the marginal zone, or remain in the germinal center. It should be noted that although these functions also occur within lymph nodes, asplenic patients demonstrate a specific response to blood-borne antigens. For example, the production of IgM in asplenic patients is both delayed and diminished. On the other hand, specific immune factors that rise in the circulation after a splenectomy include IgE and self-directed autoantibodies. This is likely due to structural differences between the lymph nodes and spleen which carry antigen to each. Antigens transported to the white pulp are from the circulating blood, whereas those delivered to lymph nodes are carried by the lymph.^{35, 36}

Cellular Reservoir Function

The ability of the spleen to function as a reservoir for circulating elements has been the subject of much study. Platelet sequestration by the spleen is well documented. Newer evidence supports the spleen as a primary site of production and a reservoir for white blood cells.³

The spleen is considered a reservoir for platelets because it can sequester large quantities of thrombocytes and, in turn, release them on demand. In nonpathologic states, the spleen sequesters ~30% of the body's platelets and can release them into the circulation in response to certain stimuli. For example, in response to an increase in circulating catecholamines, the spleen releases significant numbers of sequestered thrombocytes into the circulation.³⁷

The role of the spleen as a platelet reservoir is most dramatically demonstrated by the fact that pathologically enlarged spleens sequester greater quantities of platelets. In splenomegaly secondary to portal hypertension, the organ can sequester up to 90% of the body's reserves and result in severe thrombocytopenia. On the other hand, in the postoperative period after splenectomy, there is a significant rise in circulating platelet counts. Sometimes this effect is transient, possibly because the liver compensates by increasing its ability to sequester thrombocytes.³⁸

The spleen has been also demonstrated to sequester a significant portion of red cell volume during times of inactivity, reducing blood viscosity and heart workload.³⁹ Increases in the hematocrit after exercise reproducibly occur secondary to release of erythrocytes from the spleen. Splenic volume and the retention of erythrocytes in the splenic sinuses is thought to be mediated through the contractility of the stress fibers supporting the splenic sinuses.³ The mechanism of splenic volume change likely involves both direct innervation by autonomic fibers as well as the hormonal effects of catecholamines. α -Adrenergic blockade abolished the responses of the spleen to norepinephrine and direct neural stimulation.^{10, 11, 12}

The ability to produce and sequester various groups of leukocytes allows the spleen to act as a mediator between the different arms of the immune response. One study has shown that as blood enters the spleen, lymphocytes selectively migrate to their respective zones: T cells to the lymphatic tissue of the PALS, and B cells to the follicles and red pulp. Mitogen-stimulated B lymphocyte proliferation can be upregulated in the setting of inflammation by the serotonin-rich platelets located in the spleen.³ The spleen is also a reservoir for granulocytes, readily mobilized under stress, and memory B cells.⁴⁰ The spleen also plays an important role in the coordination of the cellular innate immune response. It has been shown that a subset of innate immune cells including undifferentiated myeloid cells reside in the spleen and greatly outnumber those cells found in the circulation. These myeloid cells cluster in the cords of the subcapsular red pulp and can be released in response to injury, inflammation, and sepsis to regulate the host's immune response.⁴¹ In addition, this population of undifferentiated myeloid cells has been implicated as an important mediator of tumor-induced immune suppression. In cancer patients, these cells have been termed myeloid-derived suppressor cells and are upregulated in the spleen and peripheral circulation. The degree of this upregulation correlates to the disease stage.⁴²

Erythropoietic Function

The spleen produces red blood cells during fetal development and during certain pathologic states. During the fifth month of fetal development, it is a major source of red blood cell production, after which it loses this ability. Pathologic states associated with splenic hematopoiesis include myeloid metaplasia. However, the production of cells by the spleen under these abnormal conditions results not from the reactivation of fetal stem cells but from displaced bone marrow cells that take up residence in the confines of the organ.¹⁴

P.1375

Iron Metabolism

As red blood cells are destroyed within the splenic cords, their contents are degraded in the phagolysosome of sinusoid macrophages. The hemoglobin is recycled into heme and sent to the bone marrow for use in the manufacture of new erythrocytes or stored as ferritin. Large complexes of ferritin form into hemosiderin, both of which can be mobilized into the circulation during times of iron deficiency.^{43, 44} The spleen's storage ability of iron is clearly demonstrated by the fact that asplenic patients display lower serum iron levels for a considerable amount of time after splenectomy.³¹

The spleen also scavenges hemoglobin that is released from intravascular destruction of erythrocytes. Intravascular hemoglobin is rapidly bound by haptoglobin, which is removed in the spleen through a receptor-mediated endocytosis directed by CD163, a hemoglobin-specific receptor on the surface of macrophages.⁴⁵

The ability to scavenge for iron also plays an important antibacterial role. Iron is a necessary nutrient for many bacterial pathogens which secrete siderophores to compete for iron in the host's serum and tissues. Specialized macrophages in the red pulp of the spleen can be stimulated by these bacteria through toll-like receptors resulting in the secretion lipocalin-2, a molecule that complexes with siderophores limiting bacterial growth.⁴⁶

SPLENIC DISORDERS AND INDICATIONS FOR SPLENECTOMY

The causes of splenomegaly and indications for splenectomy can often be confusing. There are many potential causes of splenomegaly that must be considered in any patient undergoing evaluation with an unknown diagnosis. It cannot be overstated that patients without a known cause of splenomegaly should rarely undergo splenectomy and then only after a thorough workup has been completed to assess the likely etiology of this finding.

Splenomegaly is often the result of some other condition, not the result of a primary pathologic state. The spleen rarely harbors a primary malignancy such as lymphoma that is not apparent at other sites after a careful survey by history, by physical examination, with limited imaging studies, and with peripheral blood studies. The temptation to perform a splenectomy for diagnostic purposes early in the workup of the stable patient should be strongly resisted. It is unlikely to yield a diagnosis, and, in some situations, may entail significant risk to the patient with no benefit (as in splenomegaly resulting from portal hypertension).

It is important to remember that splenic size is not always a reliable guide to splenic function, because palpable spleens are not always pathologic and abnormal spleens are not always palpable. In a survey of healthy first-year college students, 3% were found to have splenomegaly, and 5% of all hospitalized patients have been noted to have splenomegaly.⁴⁷ Patients with cirrhosis and portal hypertension almost always have splenomegaly, but even with significant thrombocytopenia, which is often present, no specific therapy is indicated because this condition rarely results in specific complications. The important clinical issue involves determining when abnormal splenic function is occurring, ascertaining the responsible etiology, if possible, and only then assessing therapeutic options.⁴⁸

Chauffard introduced the concept of hypersplenism in 1907, although the exact clinical definition remains confusing in practice even today. The criteria for this diagnosis generally include four features: cytopenia with anemia, thrombocytopenia, leukopenia, or some combination; compensatory bone marrow hyperplasia; splenomegaly; and improvement or resolution in these findings after splenectomy. Hypersplenism has been further classified into primary hypersplenism, when no etiologic factor for splenomegaly has been found; and secondary hypersplenism, when splenomegaly is the result of another recognized condition (such as portal hypertension or an infiltrative process). With continued progress in diagnosis of the causes of splenomegaly, there has been a continued drop in the frequency of cases of primary hypersplenism. Given the nonspecific nature of this diagnosis and uncertainties regarding its therapeutic implications, it is used less often today.

Perhaps a more useful guide in the assessment of splenomegaly is to consider the mechanisms responsible for the splenic enlargement. Eichner et al. divided the causes of splenomegaly into six major categories, listed in Table 65.1.⁴⁷ The likely mechanisms for resulting cytopenias in specific disease states are shown in Table 65.2. It is interesting that the degree of splenomegaly on physical examination, radiographic assessment, or at the time of splenectomy does not appear to correlate with the magnitude of cytopenia.

Although most attention regarding splenic dysfunction relates to splenomegaly and related cytopenias, occasionally patients develop hyposplenic conditions, usually from splenic infarction (such as sickle cell disease). In this group, consideration should be given to vaccination against encapsulated organisms, and potential infectious complications should be considered if unexplained fever or signs of sepsis develop, similar to postsplenectomy patients.

Indications for Splenectomy

A recent review of indications for splenectomy demonstrates the evolution of surgical management for splenic disorders. Over a 10-year period, the most common indications for splenectomy (trauma, incidental, hematologic malignancy, iatrogenic, and cytopenia) saw a drop of between 30% and 50%. In addition, the

P.1376

absolute number of splenectomies decreased over the period of review.⁷⁰ Nevertheless, splenectomy is an accepted and often definitive treatment modality for a number of diseases, as discussed below.

TABLE 65.1 CLASSIFICATION OF SPLENOMEGALY BY MECHANISM

Mechanism	Causative Diseases
Immune response work hypertrophy	Subacute bacterial endocarditis Infectious mononucleosis Felty syndrome
Red blood cell destruction work hypertrophy	Spherocytosis Thalassemia major Pyruvate kinase deficiency
Congestive (venous outflow obstruction)	Cirrhosis and portal hypertension Splenic vein thrombosis
Infiltrative	Sarcoidosis Amyloidosis Gaucher disease
Neoplastic	Lymphoproliferative Myeloproliferative Sarcoma Metastatic carcinoma
Miscellaneous	Trauma Splenic cysts Hemangioma

Data from Eichner ER, Whitfield CL. Splenomegaly. An algorithmic approach to diagnosis. JAMA 1981;246:2858-2861; Eichner ER. Splenic function: normal, too much and too little. Am J Med 1979;66:311-320; Sheldon GF, Croom RD, Meyer AA. The spleen. In: Sabiston DC, ed. Textbook of surgery, 14th ed. Philadelphia, PA: WB Saunders, 1991:1108-1133.

Immune Thrombocytopenic Purpura

ITP is an acquired isolated thrombocytopenia in which circulating antiplatelet antibodies bind to platelets and are cleared by phagocytic cells from circulation (see Chapter 47). The humoral cause of the disease was established in 1951, when a hematologist in training infused himself with the plasma from a patient with ITP and developed thrombocytopenia and

platelet destruction. Today, between 40% and 80% of patients with ITP have identified autoantibodies to platelet-specific glycoproteins, including GPIIb/IIIa and GPIb/IX. In addition, dendritic cells with upregulated costimulatory molecules appear to play a major role in the pathophysiology of the disease through the enhancement of B and T cell responses to platelets.⁴⁹ Macrophage-mediated platelet destruction is believed to play an important role in refractory disease through the presentation of new antigens.⁵⁰ The spleen likely has a dual role in this disease by both producing IgG and providing the location for removal of platelets from the circulatory system.

ITP most commonly presents in women in their 20s and 30s, and they often present with bleeding after minor trauma, with nosebleeds or petechiae. There are often no physical findings, and importantly, the spleen is almost always normal in size. The primary laboratory abnormality is thrombocytopenia with platelet counts typically $<50 \times 10^9/L$ and sometimes as low as $10 \times 10^9/L$. There is evidence of immature platelets on peripheral smears, and bone marrow smears show increased numbers of megakaryocytes. ITP can occur in childhood and often follows a viral illness. Most cases are acute and resolve spontaneously within 6 months to 1 year. However, a small number is at risk for major bleeding, and ~5% of children develop chronic severe thrombocytopenia that requires treatment, including splenectomy in some cases.⁵⁰

First-line treatment of patients with ITP and symptomatic bleeding or platelet counts $<30 \times 10^9/L$ is with corticosteroids, with the goal of achieving and maintaining a hemostatic platelet count. Typical regimens include daily oral prednisone or pulses of high-dose dexamethasone. Both regimens are effective and currently are being compared in a randomized clinical trial (NCT00991939). For thrombocytopenic crises and overt bleeding, a rapid increase in platelet count may be achieved with IVIg (1 g/kg) or anti-D (for Rh-positive patients) followed by platelet transfusion and steroid administration.

Almost all patients with ITP will progress to second-line treatment as remission with corticosteroids is often not durable and the long-term side effects are unacceptable. Options for patients who fail steroid treatment include splenectomy, rituximab, and the TPO-receptor agonists. The timing of second-line treatments is not well studied, is inconsistent among recent consensus statements, and should be a shared decision between patient and physician that is tailored to fit the patient's condition and goals.^{16, 51, 52}

Splenectomy remains the most effective treatment of ITP. Initial response to splenectomy ranges from 40% to 86%. In a systematic review evaluating the efficacy of splenectomy in patients with ITP over 58 years of age, complete remission was achieved in 66% of patients, partial response in 22%, and recurrence was uncommon.¹⁷ Splenectomy can usually be performed electively unless patients have active, ongoing bleeding. Despite the thrombocytopenia, the circulating platelets function normally, and preoperative platelet transfusions are usually unnecessary and may be ineffective in raising the platelet count because of the rapid sequestration by the spleen.

Rituximab is a chimeric monoclonal antibody against B cells expressing CD20. Although normal platelet counts ($>150 \times 10^9/L$) were achieved in 44% of patients and a partial response was seen in 63% ($>30 \times 10^9/L$), median duration of response was only 10.5 months. Rituximab carries significant risks: 3.7% of patients experienced a severe or life-threatening toxicity and 2.9% died.^{53, 54, 55}

TPO-receptor agonists effectively achieve durable increases in platelet counts, but require continuous treatment. Platelet counts respond in approximately 80% of patients, including those who have failed splenectomy and rituximab. Although the risk profile appears to be favorable, long-term risks have not yet been fully studied.^{53, 54, 55}

When patients fail splenectomy or rituximab, third-line treatments with TPO-receptor agonists or immunosuppressive agents may be indicated. Failure after splenectomy should prompt a search for accessory spleens, as their removal may induce remission. Accessory spleens have been reported in 10% to 30% of patients with ITP.^{15, 18, 99} Technetium sulfacolloid scanning or ¹¹¹indium-labeled scanning is useful to demonstrate accessory splenic tissue.¹⁹

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) generally occurs between the ages of 10 and 40 years and is more common in women than in men (see Chapter 48). TTP is associated with genetic mutations in ADAMTS13 gene, the von Willebrand factor-cleaving protease, or acquired autoantibody inhibitors usually formed after therapy with ticlopidine or clopidogrel. The disorder occasionally occurs during pregnancy or in the postpartum period, and a familial form of the disease exists.⁵⁶ TTP is characterized by thrombocytopenia, microangiopathic hemolytic anemia, neurologic abnormalities, renal failure, and fever. TTP is likely to be the result of the abnormal presence of a platelet-aggregating agent in the circulation. Studies suggest that this agent is von Willebrand factor, which is found in excess in patients with TTP. Platelet aggregation leads to microvascular thrombi, typically in the brain, heart, spleen, kidneys, pancreas, and adrenals. Nearly 90% of adults with ADAMTS13 deficiency will respond to daily plasma exchange with plasmapheresis and transfusion of fresh-frozen plasma. Patients with acquired autoantibodies can be treated with high-dose glucocorticoids, rituximab, or splenectomy. Surgical

treatment is considered in patients who have frequent relapses of TTP and may prolong the disease-free interval.^{56, 57, 58, 59}

Hereditary Anemias

Hereditary spherocytosis is inherited as an autosomal dominant disease in which the red cell membrane includes a defective protein, spectrin (see Chapter 27). The spleen destroys the resulting

P.1377

defective, spherical red cells. These patients have an anemia and significant reticulocytosis. Peripheral smears demonstrate spherocytes, and these patients have a negative Coombs test. Elective splenectomy will correct the anemia. Ideally, splenectomy is performed after the age of 5 or 6 years to minimize the potential risks of postsplenectomy infections. Because of the rapid red cell turnover, these patients often develop calcium bilirubinate gallstones, and consideration should be given to concomitant cholecystectomy at the time of splenectomy if they are present.¹⁸

Sickle cell anemia is an autosomal recessive condition that also results in defective red blood cells (see Chapter 33). Because of the frequency of sludging and thrombosis in small vessels, these patients more often develop infarcts in the spleen, which over time results in autosplenectomy. In rare patients, however, splenectomy may be indicated for acute splenic sequestration crisis, hypersplenism, massive splenic infarction, and splenic abscess.⁶⁰ Unlike hereditary spherocytosis, splenectomy has little effect on anemia related to the sickle cell condition.

Thalassemia major is an autosomal dominant condition in which abnormal hemoglobin forms protein precipitates in the red cell, recognized as Heinz bodies on a peripheral smear. These patients can develop significant splenomegaly with resulting cytopenia. In this condition, splenectomy can lessen the need for transfusion.

Malignant Tumors of the Spleen

Malignant diseases affecting the spleen can be divided into lymphoproliferative disorders, myeloproliferative disorders, metastatic lesions, and primary splenic neoplasms. Metastatic disease is not uncommon. Melanoma, breast, lung, renal, and ovarian lesions are the main source. Metastatic lesions usually reflect vastly disseminated disease secondary to hematogenous spread. Autopsy series have demonstrated splenic metastasis in 2.3% to 7.1% of cancer patients.⁶¹

Primary tumors of the spleen are exceedingly rare. They include hemangiosarcoma, hemangiopericytoma, plasmacytomas, and malignant fibrous histiocytomas. All of these conditions may present with splenomegaly and are uniformly treated with splenectomy.

Lymphoma

Lymphoma is a common tumor leading to splenomegaly or a splenic mass (see Chapters 88 and 89), although the spleen is rarely the primary site. Non-Hodgkin lymphoma, including splenic marginal zone lymphoma, can present with massive splenomegaly. Although splenectomy has been shown to be a therapeutic treatment of hypersplenism by increasing blood counts, it has not improved long-term survival.⁶²

Hodgkin Lymphoma

Hodgkin lymphoma, described by Thomas Hodgkin in 1832, is a highly curable malignant lymphoma characterized by typical multinucleated giant cells (Reed-Sternberg) (see Chapters 93 and 94) and predictable stepwise progression from one lymph node basin to another. Histologic subtypes fall into five categories: lymphocyte-rich classical, lymphocyte-predominant, nodular sclerosing, mixed cellularity, and lymphocyte-depleted. Most patients initially present with asymptomatic peripheral lymphadenopathy, most often in the cervical region (60% to 80%). Other nodal regions, including the mediastinal, axillary, inguinal, and retroperitoneal regions, are less often involved at initial presentation. The presence of B symptoms, including fever, weight loss > 10%, and night sweats, is noted. Extralymphatic and splenic involvement is also used to stage patients. Below the diaphragm, the first nodal tissue involved is the spleen, with 35% of stage I or II patients having occult splenic disease.⁶³

Historically, staging laparotomy was used in patients with Hodgkin lymphoma suspected of harboring subdiaphragmatic disease. In this procedure, lymph nodes were sampled from the para-aortic, paracaval, and iliac regions, and liver biopsies were performed along with splenectomy. With the enhanced accuracy of CT and other imaging studies for staging purposes, the increased effectiveness of medical treatments, and the associated surgical risk, the need for surgical staging has essentially been eliminated.⁶³

Leukemia

In chronic lymphocytic leukemia and less often in chronic myelocytic leukemia, massive splenomegaly can result in significant symptoms from the mass effect of the enlarged spleen, necessitating splenectomy (see Chapters 90 and 81). Likewise, patients may develop significant cytopenia that is refractory to conventional medical measures (i.e., corticosteroids, immunosuppression) and may be candidates for splenectomy. The decision to undertake splenectomy must be made with caution, because these patients often are immunosuppressed and malnourished and have a higher operative mortality risk as well as a higher rate of perioperative complications.⁶⁴

Hairy cell leukemia can lead to infiltrative splenomegaly and pancytopenia, which may limit cytotoxic chemotherapy (see Chapter 91). With the introduction of effective medical therapies, the indications for splenectomy are now limited to spontaneous splenic rupture and severe thrombocytopenia with bleeding. Resistant disease should prompt investigations to confirm an accurate diagnosis.⁶⁵

Myelofibrosis

Myelofibrosis describes a group of disorders characterized by acquired mutations that target the hematopoietic stem cells, and induce dysregulation of cellular signaling, clonal proliferation, and abnormal cytokine signaling. Prominent bone marrow fibrosis and disruption of normal hematopoiesis results, and can be associated with enlargement of the liver and spleen as a result of extramedullary hematopoiesis⁶⁶ (see Chapter 83). Massive splenomegaly may lead to pancytopenia, portal hypertension, early satiety, and pain. Splenectomy remains a viable treatment for refractory, symptomatic massive splenomegaly in myelofibrosis. Approximately 50% of patients will be rendered transfusion-independent. In addition, most experience resolution of mechanical symptoms and subjective improvement in constitutional symptoms. The median response is 12 months.⁶⁷ Caution must be taken with splenectomy in patients with myelofibrosis, as the procedure carries a perioperative mortality rate of 5% to 10% and a morbidity rate of approximately 25%.⁶⁷

Splenic Cysts

Cystic lesions of the spleen are rare and represent a challenge for physicians to diagnose and treat. The number of asymptomatic cysts incidentally diagnosed continues to rise because of increased utilization of abdominal imaging, including computer tomography, ultrasound, and magnetic resonance.

Splenic cysts are categorized based on the presence or absence of an epithelial lining. Cysts with an epithelial lining are considered primary and can be further subdivided into parasitic or nonparasitic. Secondary cysts, or pseudocysts, lack an epithelial lining and are believed to result from trauma in the majority of cases^{68, 69} (Fig. 65.5).

Primary cysts possess an epithelial lined lumen and can be divided into parasitic and nonparasitic. Parasitic cysts are most often multilocular, associated with hepatic cysts, and occur after infection with *Echinococcus granulosus*. They make up

P.1378

the majority of splenic cysts worldwide and are endemic in South America and the Mediterranean. Parasitic cysts, however, are rare in the Western world. Surgery must be undertaken carefully, as rupture can result in anaphylactic shock or disseminated scoliceal infection. In the presence of large numbers of cysts, surgical treatment is contraindicated and medical therapy with mebendazole, an effective antiparasitic therapy, is an alternative. Treatment of a single or few cysts can be managed sequentially with medical treatment, chemical sterilization (cetrimide 0.1%), and cyst evacuation.⁷⁰

FIGURE 65.5. Large symptomatic splenic pseudocyst developing after blunt trauma to the spleen.

Nonparasitic cysts are usually congenital and can be further divided into endodermoid, dermoid, or epidermoid cysts. Epidermoid cysts are the most common congenital cysts (~90%) and present most often in children and young adults. They are derived from inclusions of splenic surface epithelial lining into the splenic parenchyma during development or from an accelerated secretion of lining cells from an unknown cause.⁷¹ Dermoid cysts are exceedingly rare; they contain all three embryonic germ layers and make up the remainder of nonparasitic congenital cysts. Endodermoid cysts are not true cysts, but rather cystic vascular lesions composed of several ectatic vessels that are best described as lymphangioma or hemangioma (Fig. 65.6). These benign tumors are most often incidental findings when imaging studies or laparotomy are performed, or they may be found at autopsy. Occasionally, the patient may develop significant splenomegaly and cytopenia, leading to the need for splenectomy. Usually, however, the diagnosis can be made on the basis of imaging studies alone and splenectomy avoided. In cases of doubt, follow-up imaging studies demonstrating the absence of change over time should avoid unnecessary splenectomy.⁶⁸

The spleen is the intraperitoneal organ that is most often injured after abdominal trauma. Although 75% of nonparasitic splenic cysts are posttraumatic, 30% of patients cannot recall the inciting event.⁶⁹ Pseudocysts may contain a mixture of blood and necrotic debris, as they commonly form after intraparenchymal or subcapsular hematomas organize and subsequently degenerate (Fig. 65.7). Pancreatic pseudocysts have been reported to burrow into the substance of the spleen, and this should be kept in mind in the patient with a history of pancreatic trauma or pancreatitis. Assessment of cyst fluid amylase levels may provide a clue to the pancreatic origin in such a case.⁷² Management of cysts in these cases is usually directed toward treatment of underlying pancreatitis.

FIGURE 65.6. Computed tomographic scan (A) and gross photograph (B) of spleen in 35-year-old woman with marked splenomegaly from splenic hemangioma. The arrow demonstrates central hemangioma with surrounding uninvolved splenic parenchyma. This benign tumor had caused significant thrombocytopenia, resulting in spontaneous bleeding before splenectomy.

Splenic cysts are often asymptomatic (70%) but can also present with vague abdominal pain. The pain can be constant or intermittent, left-sided or epigastric, and occasionally radiates to the left shoulder. Physical exam can reveal a painless abdominal mass in 50% of patients. Radiologic examination with ultrasound, CT, or magnetic resonance imaging can characterize the cyst as unilocular or multilocular and provide insight into anatomic relationships. Prior to any invasive procedure, determination of parasitic antibody titers are of great importance to rule out parasitic infection. Ultrasound-guided percutaneous cyst aspiration may be useful for obtaining definitive diagnosis, decreasing the size of the cyst, and excluding communicating pancreatic origin.

The majority of patients with splenic cysts are asymptomatic and do not require specific treatment. Nonoperative treatment is recommended for small cysts up to 5 cm in diameter. In patients with symptomatic cysts, surgical intervention is recommended. Although percutaneous drainage and alcohol ablation is often successful in initially reducing the size of the cyst, the procedure is often plagued with a high incidence of recurrence, necessitating

P.1379

definitive surgical correction.^{73, 74} For single, unilocular superficial cysts, laparoscopic marsupialization or fenestration with splenic preservation should be undertaken. Deep cysts, or those located at either splenic pole, can be resected with partial splenectomy, which provides immunologic protection and improved outcomes when compared to splenic autotransplantation. Complete splenectomy is indicated in cases of giant cysts surrounded by splenic parenchyma or multilocular cysts.^{18, 69, 71}

FIGURE 65.7. A: CT of a 43-year-old woman who was scanned after developing left upper quadrant pain. She had no history of trauma. CT showed a splenic pseudocyst. B: After aspiration, some blood is seen in the cyst lumen. The cyst rapidly reaccumulated, and the patient subsequently had a successful laparoscopic cyst derroofing.

Splenic Abscess

Splenic abscesses may also occur when a simple cyst is secondarily infected, for example, after aspiration, or as a primary abscess, usually from a hematogenous source. Splenic abscesses usually develop from hematogenous seeding, from a distant site of infection, in the setting of intravenous drug abuse, or after splenic infarction, as in patients with sickle cell disease. Immunocompromised patients are at higher risk. There are rarely specific symptoms present, suggesting the spleen as the specific site of infection, although left upper quadrant tenderness may be present in patients with significant abscess cavities. Abdominal CT scanning is the most helpful imaging technique, demonstrating low-density lesions in the spleen, which may contain gas and present peripheral enhancement.⁷⁴ CT can also be used to direct placement of percutaneous drainage catheters, which can provide successful treatment in the majority of cases. Multilocular abscesses with thick septations or necrotic debris generally require surgery, although percutaneous catheter drainage may lead to improvement of the patient's general condition without adverse effect on subsequent operation.^{73, 74} Antimicrobial therapy is based on aspirate culture data, with *Staphylococcus* and *Streptococcus* species being common pathogens.

Felty Syndrome

Felty syndrome composes a triad of rheumatoid arthritis, neutropenia, and splenomegaly in <1% of patients with rheumatoid arthritis. Clinically, patients present with severe joint destruction and other systemic manifestations such as leg ulcers, rheumatoid nodules, vasculitis, lymphadenopathy, and hepatomegaly. Antibody-coated neutrophils are cleared from the circulation in the spleen, and neutropenia can develop. Recurrent bacterial infections, a major source of morbidity, are due to the decreased granulopoiesis, increased peripheral destruction of neutrophils, and defects in

neutrophil function. Methotrexate, or other disease-modifying antirheumatic drugs (DMARDs), is the first-line treatment for Felty syndrome with granulocytopenia and increased infection rate. If DMARD treatment is unsuccessful, low-dose granulocyte colony-stimulating factor is recommended. Splenectomy is indicated only in treatment-resistant cases in which splenomegaly is present; splenectomy is contraindicated in patients with large granular lymphocyte (LGL) expansion, as the procedure has no effect and may actually cause deterioration.^{18, 75, 76}

Abdominal Trauma and Splenic Injury

Splenic preservation is the main goal of the modern management of blunt traumatic splenic injuries. Nonoperative management is often successful in about 90% of patients. The degree of splenic injury is measured using contrast-enhanced CT scans and graded according to the American Association for the Surgery of Trauma (AAST) criteria (Table 65.3). The finding of active arterial contrast extravasation from the spleen, referred to a “blush,” is an indicator of failure of conservative management in adults. Most injuries of grade 3 or less are successfully managed nonoperatively, whereas the presence of a high grade injury (Grade 4 or 5) or a contrast blush predicts the need for intervention (Fig. 65.8).⁷⁷ The primary requirement for nonoperative management is hemodynamic stability, and therefore close monitoring is required in all cases. A continued transfusion requirement and/or hypotension in the face of adequate resuscitation are indications for urgent intervention. A recent meta-analysis of 24,615 patients demonstrated that 12% of patients failed conservative management, ultimately requiring intervention. It also suggested that failure

P.1380

of conservative management in older patients may be associated with increased mortality.^{78, 79}

TABLE 65.3 AAST GRADES OF SPLENIC INJURY

Grade 1	Minor subcapsular tear 1 cm or subcapsular hematoma <10% SA
Grade 2	Capsular tear not involving trabecular vessels, <3 cm or subcapsular hematoma between 10% and 50% SA
Grade 3	Laceration >3 cm parenchymal depth involving trabecular vessels or subcapsular hematoma >50% S, or expanding or ruptured hematoma
Grade 4	Laceration involving the hilum with >25% devascularization of the spleen or intraparenchymal hemorrhage with active bleeding
Grade 5	Completely shattered spleen

SA, surface area.

FIGURE 65.8. A: Contrast-enhanced CT showing a grade 1 splenic laceration in the inferior pole, with associated

hemoperitoneum; the patient was successfully managed conservatively. B: Contrast-enhanced CT showing a grade 5 splenic laceration with evidence of active extravasation and perisplenic hematoma. This patient required urgent splenectomy.

Options for operative intervention consist primarily of open splenectomy, with splenic repair and partial splenectomy utilized rarely. In addition to splenectomy, splenic artery embolization has become an integral adjunct in the management of high-grade splenic injuries and in patients with active contrast extravasation. With adequate patient selection, angioembolization has decreased the failure rate of nonoperative management to 4% in some recent series.⁷⁷

Delayed Splenic Rupture

Delayed splenic rupture has been reported in patients experiencing blunt abdominal trauma, a setting in which patients develop splenic hemorrhage >7 days after their original injury.⁸⁰ This problem most likely represents an injury in evolution, when the initial imaging study (most commonly CT or ultrasound) at the time of the trauma fails to demonstrate a significant injury. These patients usually have an initial splenic contusion that continues to slowly enlarge and, at some later date, results in disruption of the splenic capsule. This is an uncommon occurrence, but should be considered in any patient who develops significant left upper quadrant pain, distention, and signs of bleeding or shock after an episode of trauma.^{81, 82} The treatment is urgent intervention with angiography or splenectomy, depending on the patient's clinical picture.

Spontaneous Splenic Rupture

Spontaneous rupture of the spleen is extremely rare and for unknown reasons occurs predominantly in males. Predisposing conditions include splenic infarctions, coagulation disorders, thrombocytopenia, portal hypertension, vasculitis, venous thrombosis in the spleen and focal splenic lesions, lymphoma, and leukemia. Spontaneous rupture is most often secondary to a neoplastic etiology. Overall mortality with rupture is about 12% with splenomegaly, advanced age (>40 years), and a neoplastic etiology predicting an increased risk of death.⁸³

These patients usually develop acute left upper quadrant pain that may be associated with referred pain in the left shoulder. Initially, this may be contained beneath the splenic capsule as a subcapsular hematoma, but if intraperitoneal rupture occurs, patients may present with acute severe pain and hypovolemic shock. Ultrasonography or CT scanning is a confirmatory study, demonstrating intraperitoneal fluid (blood) and subcapsular hematoma. Urgent or emergent splenectomy is definitive treatment for these patients. Splenic conservation may be an option in some, because the grade of injury tends to be less severe compared to traumatic splenic injury.

SPLENECTOMY: SURGICAL TECHNIQUE

Open Splenectomy

Historically, splenectomy has been performed via a midline or left subcostal incision, depending on the surgeon's preference and the presence or absence of significant splenomegaly. In patients with massive splenomegaly (>2,000 g), a midline incision may be preferred to allow adequate mobilization and delivery of the spleen into the operative field.

Once the abdomen is entered, a careful search is made for accessory spleens, which may be found anywhere in the abdomen but are most often found in the splenic hilum or in the mesentery of the intestine.

In patients with significant splenomegaly, initial ligation of the splenic artery causes the spleen to decrease in size, lessen its distention, decrease the risk of capsular avulsions, and decrease splenic bleeding should a capsular tear occur. This portion of the procedure is performed by dividing the avascular gastrohepatic ligament above the pancreas and isolating the artery near its point of origin from the hepatic artery. Care must be taken to avoid injury to the adjacent pancreas. This step is optional and can be omitted if the artery is not readily accessible, because aggressive attempts at splenic artery ligation can result in pancreatic injury.

There are ligamentous attachments to the spleen that must then be divided before the inflow vessels in the hilum can be ligated. The phrenosplenic attachment is avascular and can be divided with sharp dissection. The gastrosplenic ligament (and short gastric vessels) and the splenocolic ligament are divided. Finally, the inflow vessels to the splenic hilum are individually ligated, taking care during this portion of the procedure to avoid injury to the tail of the pancreas. Closed suction drainage of the splenic bed is not routinely used, but a drain can be placed if there

P.1381

is suspicion of a possible pancreatic injury. If this occurs, evacuation of pancreatic fluid minimizes the risk of abscess formation and allows for a controlled pancreatic fistula that will usually seal with observation alone. Conversely, if a

symptomatic fluid collection develops in the bed of an undrained spleen in the postoperative period, then a percutaneous drain can be placed under CT or ultrasound guidance.

Partial splenectomy is unlikely to be a realistic option for patients with marked splenomegaly, but may be an option for patients with splenic pseudocysts in whom unroofing of the cyst is the primary objective. This may also be an option in patients with splenic trauma in whom splenorrhaphy may allow splenic preservation. Uranus et al. report successful partial splenectomy using a surgical stapler, and this may occasionally be helpful. Partial splenectomy has also been reported in patients undergoing splenectomy for Gaucher disease.

Laparoscopic Splenectomy

Since laparoscopic splenectomy was first described in 1991 by Delaitre et al.⁸⁴ it has become the standard operative approach for the elective treatment of many benign and malignant diseases of the spleen.^{15, 18} Numerous studies have demonstrated the advantages of the laparoscopic approach compared to open splenectomy, including decreased blood loss, shorter hospital stays, accelerated recovery, and decreased convalescence. As outcomes have continued to improve, the procedure has been applied to an increasing array of splenic pathologies, and is now one of the most common laparoscopic solid-organ procedures. The indications for laparoscopic splenectomy have been expanded and now include ITP, hereditary spherocytosis, hemolytic anemia, TTP, leukemias, splenic myelofibrosis, sickle cell disease, lymphomas, myelodysplastic syndrome, multiple myeloma, and accessory splenectomy.

Massive splenectomy is no longer an absolute contraindication for laparoscopic splenectomy. Superior outcomes over open splenectomy in patients with massive spleens have been demonstrated, including decreased blood loss, reduced transfusion requirement, fewer reoperations for bleeding, and an average reduction in hospital stay by 8 days. Decreased blood loss continues to be the greatest advantage of laparoscopic splenectomy in patients who are coagulopathic and at risk for massive hemorrhage.^{62, 85, 86} The decision to perform laparoscopic splenectomy in a patient with splenomegaly is a multifactorial decision that depends on the underlying disease process, comorbidities, and surgeon experience. The effect of the surgeon's learning curve has been clearly demonstrated in laparoscopic splenectomy, with the average conversion rate depending on experience and ranging from 1.2% to 15%.⁸⁵

The operative approach for laparoscopic splenectomy continues to evolve with the introduction of new surgical technology. After induction of general anesthesia, a nasogastric tube and Foley catheter are placed to decompress the stomach and bladder, respectively. The patient is placed into the right lateral decubitus position, and three or four working ports are placed for the introduction of the laparoscopic instruments, including an angled laparoscope. The lateral port is most often placed at the level of the eleventh rib tip, the medial port in midline, and the middle port halfway between the two, ~4 cm below the inferior tip of the spleen. In patients with a supramassive spleen (>22 cm in craniocaudal length or 19 cm in width), the addition of a hand port has been shown to greatly reduce operative time without increasing length of stay or convalescence. This approach allows the insertion of the surgeon's nondominant hand into the abdominal cavity while maintaining pneumoperitoneum. Positioning is slightly altered by placing the patient's side at a 45-degree angle. After positioning and setup is complete, a careful inspection of the abdomen is carried out to identify other disease or the presence of accessory spleens, focused on the hilum, omentum, and lesser sac.⁸⁶

The dissection then proceeds in five stages: division of the short gastric vessels, division of the splenocolic ligament, ligation of the inferior polar vessels, hilar control, and division of the phrenic attachments of the spleen. Much of the dissection may be carried out with harmonic shears, and the hilar structures are ligated and divided with an endoscopic stapling device. The spleen is then placed in an extraction bag, morcellated in situ, and the fragments removed.

COMPLICATIONS OF SPLENECTOMY

The overall complication rate for laparoscopic splenectomy is ~9%. The most common complications of splenectomy include bleeding, injury to the adjacent pancreas with resulting pancreatitis, and pancreatic pseudocyst, abscess, or fistula formation. These patients can also develop injury to the adjacent stomach or splenic flexure of the colon if care is not taken in dividing the ligamentous attachments to these structures.

Postoperative thrombocytosis can occur, and aspirin (one low-dose aspirin per day) should be considered if the platelet count is $>1,500 \times 10^9/L$, to minimize the risks of thrombosis or embolism. The thrombocytosis is usually transient, with return of platelet counts to normal ranges by 2 years after splenectomy.

Thrombosis of the portal venous system is a unique, and potentially life-threatening, complication after splenectomy. Although this complication was once believed to be rare, improvements in radiologic techniques have demonstrated portal venous thrombosis much more frequently than previously thought, with a number of cases occurring asymptotically. The reported incidence of portal venous thrombosis varies greatly within the literature. Initial

retrospective reviews demonstrated incidences between 5% and 15%. When prospectively analyzed, however, the incidence was found to be greatly unappreciated, with 19% to 55% of patients developing portal venous thrombosis. Asymptomatic thrombosis was observed in 33% to 66% of postsplenectomy patients. Patients with larger diameter splenic veins and those operated on for hematological malignancy were found to be at increased risk for thrombosis.^{87, 88, 89}

When symptomatic, portal venous thrombosis most often presents between 2 and 22 days postoperatively with vague, nonspecific complaints including decreased appetite, vague abdominal pain, nausea, and malaise. Abdominal pain is a rare sign that is present only in cases of severe ischemia. Fever and leukocytosis are common. Risk factors highly associated with portal venous thrombosis include splenomegaly, hematologic malignancy, and thrombocytosis. Normal D-dimer levels have a 98% negative predictive value. Contrast-enhanced CT scanning is the preferred method of evaluation as it can assess the portal circulation as well as other common etiologies of abdominal pain.^{89, 90}

Once the diagnosis of portal venous thrombosis is made, systemic anticoagulation should be started immediately. With prompt anticoagulation, recanalization can occur rapidly in over 90% of patients. However, patients who received treatment 10 days after the procedure uniformly failed.⁹¹ Although treatment with thrombolytics and antiplatelet agents has been reported, indications for routine use are still yet to be determined.^{89, 92}

Infection Risk Postsplenectomy

Infectious complications are increased after splenectomy, and this can occur both in the early postoperative period and after a significant time has passed. The rate of early postoperative infections is particularly high when multiple other procedures are performed (e.g., after complex injuries in the setting of multiple trauma).^{93, 94} The complication of overwhelming postsplenectomy infection (OPSI) has received significant attention. In addition to

P.1382

OPSI, postsplenectomy patients are at risk for multiple and recurrent episodes of severe infection requiring hospitalization.⁹⁵

Overwhelming Postsplenectomy Infection

One of the most important developments affecting the splenectomy procedure has been the recognition of the life-long increased risk of severe infection and sepsis after splenectomy. In 1969, Diamond described a case of postsplenectomy fulminant bacteremia leading to rapid death and popularized the term OPSI.⁹⁶

Pathophysiology

In the early postoperative period, infection is usually caused by Staphylococci and enteric Gram-negative bacilli. Outside this interval, the most common organisms responsible for OPSI are encapsulated bacteria, with *Pneumococcus* being most common (incidence, 50% to 90%).⁹⁷ Other responsible organisms include *Neisseria meningitidis*, *Escherichia coli*, *Haemophilus influenzae*, *Staphylococcus*, and *Streptococcus*; and infections occur at rates that range from 7% to 12%.⁹⁸

The special susceptibility of the asplenic patient to encapsulated organisms is likely due to compromised humoral immunity. After splenectomy, a subset of IgM memory B cells that responds to bacterial polysaccharides is severely depleted. These memory B cells have undergone mutation, selection, and class switch in response to a specific antigen and produce antibodies rapidly on second challenge from the same antigen. The IgM memory B cells are responsible for the T cell-independent response and require a functional spleen for their generation and survival.^{99, 100} Studies confirm that bacteria-specific IgM production in asplenic patients is both delayed and diminished.¹⁰¹

Also, it has been demonstrated that asplenic patients have lower circulating levels of certain complement factors, including properdin, tuftsin, C3, and factor B.¹⁰² Tuftsin is a tetrapeptide that stimulates phagocytosis by binding to specific receptors on granulocytes, monocytes, macrophages, and natural killer cell-modulating biologic activity. The spleen also produces properdin, a crucial factor in the alternative pathway of complement activation. The alternate pathway is activated in the absence of antibody and forms C3 convertase. Properdin binds to C3 convertase, preventing its rapid decay, and allows for conversion of C3 to C3b.

There is also evidence that splenectomy results in defects of cellular immunity. After splenectomy for trauma, a cohort of patients was found to have a significant reduction in the percentage of CD4⁺ T cells, specifically in the CD45RA⁺ subset. This was accompanied by impairment in primary immune responsiveness in a number of cellular and humoral assays.⁹⁹

Incidence

OPSI is most common in the very young, in patients with underlying malignancies or other medical conditions, and within the first 2 years after splenectomy, although it has been reported 20 to 40 years after surgery. The precise incidence of OPSI is controversial, but is estimated between 0.18 and 0.89 person-years^{95, 96, 97, 98, 102, 103}; published estimates vary widely secondary to different disease definition, duration of follow-up, age stratification, indication for splenectomy, and age. OPSI is greatest in the very young and diminishes with age: 15.7% in infants, 10.4% in children <5 years old, 4.4% in children <16 years old, and 0.9% in adults.⁸ Although the incidence in adults is similar to that of the general population, mortality from sepsis is increased 58-fold in the asplenic population, with a fatality rate between 50% and 90%.^{95, 96, 97, 98, 102, 103} Underlying pathology, like youth, also imparts an increased risk of OPSI with the highest risk associated with underlying immune disorders and Hodgkin lymphoma.⁹⁷

Clinical Course

OPSI usually presents with fever and brief upper respiratory tract infection, and pursues a rapid course with evolution to sepsis, shock, disseminated intravascular coagulation, and multiple organ failure within hours. Any asplenic patient with fever should be evaluated for possible OPSI. Key to successful treatment is prompt administration of broad-spectrum intravenous antibiotics. A complete septic workup, including routine laboratory tests, appropriate imaging, and microbiology cultures, should be performed, but should never delay the initiation of antibiotics. In fully developed OPSI, mortality rates of 50% to 90% have been reported; 80% of deaths occur within 48 hours.^{95, 97} More recent information suggests that when informed patients seek medical attention promptly, mortality rates may be reduced to 10%.

Prevention of Overwhelming Postsplenectomy Infection

The guidelines for the prevention of OPSI center around vaccination, antibiotic prophylaxis, patient education, and strategies aimed at preserving splenic function. Recommended vaccines include the meningococcal vaccine, 23-valent polysaccharide pneumococcal vaccine for patients between 2 and 64 years old, and the H. influenzae conjugate vaccine. For patients undergoing elective splenectomy, vaccination should be performed at least 2 weeks before surgery to maximize the antibody against T cell-dependent immunogens. In emergent cases, patients should be vaccinated 14 days after their surgery.^{98, 104}

Repeat vaccination is safe in those who mount an antibody response based on measurement of antibody levels.^{104, 105} Currently, a single revaccination with the 23-valent polysaccharide pneumococcal vaccine is recommended at least 5 years after the first dose, with no further dosing recommended routinely. Reimmunization against meningococcal and H. influenzae are not recommended.¹⁰⁶ Regardless, many patients do not receive any revaccination because of a general lack of understanding about their condition and the unclear role of revaccination.⁹⁴

Children <5 years old also require aggressive immunization and antibiotic prophylaxis after splenectomy. Initial vaccination is provided with the H. influenzae vaccine, meningococcal vaccine, and 7-valent pneumococcal conjugate vaccine. If not previously immunized against pneumococcus, an additional dose of the 7-valent vaccine is recommended no less than 6 to 8 weeks after the last dose, with a final 23-valent vaccine booster 3 to 5 years after the last dose. Daily antibiotic prophylaxis with penicillin V potassium (125 mg twice a day until 3 years of age and 250 mg twice a day thereafter) is recommended for all children under the age of 5 years. If no invasive pneumococcal infections are experienced, prophylaxis may be discontinued after the age of 5 after appropriate immunizations have been obtained.¹⁰⁶

One of the most important, and most overlooked, aspects of prevention is patient education. Up to 50% of asplenic patients are unaware of their increased risk of serious infection, and 30% to 40% do not recall being vaccinated.⁹⁷ Few are provided with antibiotics to take empirically at the onset of fever, and one-half would not spontaneously tell an uninformed emergency department doctor about their splenectomies.⁹⁸ Asplenic patients should be extensively counseled about their health risks, the need for reimmunization, and the importance of informing future caregivers of their condition.

Autotransplantation of Splenic Tissue

Extrasplenic tissue may emerge secondary to traumatic autotransplantation, known as splenosis. Although this tissue appears as normal spleen, with white pulp, red pulp, and marginal zones, extrasplenic tissue is insufficient to recapitulate the host immune response and is not a recommended practice for patients undergoing splenectomy.^{21, 23}

Chapter 66

Tumors of the Spleen

Daniel A. Arber

A variety of tumors and tumorous proliferations may involve the spleen, and there are several that are unique to this organ. This chapter focuses on the unique proliferations as well as other neoplastic causes of splenomegaly. Splenomegaly, however, is not restricted to neoplastic causes and may occur with secondary hypersplenism, which may be secondary to autoimmune or para-neoplastic causes, infectious processes, and passive congestion due to other nonneoplastic medical disorders.

PATTERNS OF TUMOROUS SPLEEN PROLIFERATIONS

Although splenomegaly is often present with splenic neoplasia, some tumors and tumorous proliferations may be found incidentally in normal-sized spleens during radiologic staging or in spleens removed due to traumatic rupture or incidentally removed during other surgical procedures. The pattern of splenic infiltration may be helpful in the differential diagnosis of splenic tumors and the gross disease patterns tend to mimic histologic patterns (Fig. 66.1 and Table 66.1).¹ The most common disease patterns are diffuse, miliary, and nodular disease. Diffuse disease generally results in splenomegaly with complete infiltration of the splenic parenchyma. This often imparts a glassy and homogeneous red appearance to the cut surface of the spleen. This usually is due to obliteration of the normal splenic white pulp by a cellular proliferation of the red pulp. This disease pattern has traditionally been attributed to leukemic infiltration, T-cell lymphomas, and histiocytic tumors. Many of the red pulp proliferations previously considered to be histiocytic, however, have now been shown to represent T-cell neoplasms. The miliary pattern shows small, punctate tan or white areas throughout the cut surface of the spleen. These usually represent expansion of the splenic white pulp, the normal B-cell compartment of the spleen. However, a similar gross appearance may occur with granulomatous infections. The white pulp expansion pattern most commonly occurs in florid reactive hyperplasia and with low-grade B-cell lymphomas. The nodular disease pattern is characterized by one or more distinct tumor nodules in the spleen which may be identified

incidentally on imaging studies. These nodules are usually firm and tan or white in cases of large cell lymphoma, Hodgkin disease, or metastatic tumors, and are bloody with a beefy-red appearance in vascular proliferations. Cystic lesions of the spleen may also show a nodular pattern of involvement.

CYSTS AND ABSCESSSES

Cysts of the spleen are found in <1% of splenectomy specimens.² They occur most commonly in men in the third decade of life. They are usually asymptomatic; however, they may cause a splenic mass and be associated with abdominal pain. Splenic cysts may be essentially any size but are on average 10 cm in diameter.³ Splenic cysts may be designated as primary or secondary, also considered true and false cysts, respectively. Both types are usually unilocular, but some small primary cysts are multilocular. Primary cysts are reported to represent approximately 20% of all splenic cysts, but small primary cysts of the spleen are probably underrepresented in older studies and more extensive evaluation of nonparasitic cysts shows that the vast majority are true cysts.^{4, 5} Primary cysts have a firm, rough, and trabecular cyst wall that shows fibrosis and an epithelial lining on histologic examination (Fig. 66.2). The lining may be of mesothelial or squamous epithelium with the latter probably representing a metaplastic change.⁶ The epithelial lining of primary cysts may be patchy, with denuded areas present that may simulate a secondary cyst. Primary cysts can be further subdivided into parasitic and nonparasitic types. Primary parasitic cysts related to echinococcal infection (hydatid cysts) are common worldwide, but are uncommon in Western countries. Parasitic cysts are readily identified by the presence of parasite scolices in the cyst contents. Nonparasitic primary cysts appear to arise from congenital inclusions of capsular mesothelium.⁷ Small multilocular primary cysts of the spleen occurring at the splenic capsule have in the past been mistaken for lymphangiomas.⁸ Patients with primary cysts may have elevations of CA19-9 and carcinoembryonic antigen.^{9, 10} Primary cysts are usually treated with splenectomy, and partial resection by laparoscopic methods often leads to recurrence.^{11, 12}

Secondary cysts are reportedly more common, representing approximately 80% of splenic cysts in most studies, but more detailed evaluation can confirm many of these as having a focal epithelial lining and thus they are really primary.⁴ The true secondary cysts are often associated with a history of abdominal trauma and are probably acquired after hematoma or infection. The cysts are unilocular and usually have a smooth lining. They differ histologically from primary cysts by the complete absence of an epithelial lining, and are thus unlikely to recur even if only partially resected. The cyst wall may contain hemosiderin or calcification.

Some secondary cysts of the spleen may represent resolved abscesses. Multiple small splenic abscesses usually do not develop associated fibrosis with resolution, but larger abscesses are often single and develop a wall of surrounding fibrosis virtually identical to that seen in secondary cysts. Although relatively uncommon, splenic abscesses are most often associated with sepsis or

P.1385

endocarditis. They may also occur following abdominal trauma, including splenic rupture, by contiguous spread of infection from other organs, or in association with functional asplenia in sickle cell anemia.^{13, 14, 15} Most splenic abscesses are due to polymicrobial infection, but common organisms include *Streptococcus*, *Staphylococcus*, *Escherichia coli*, and *Salmonella*.¹⁶

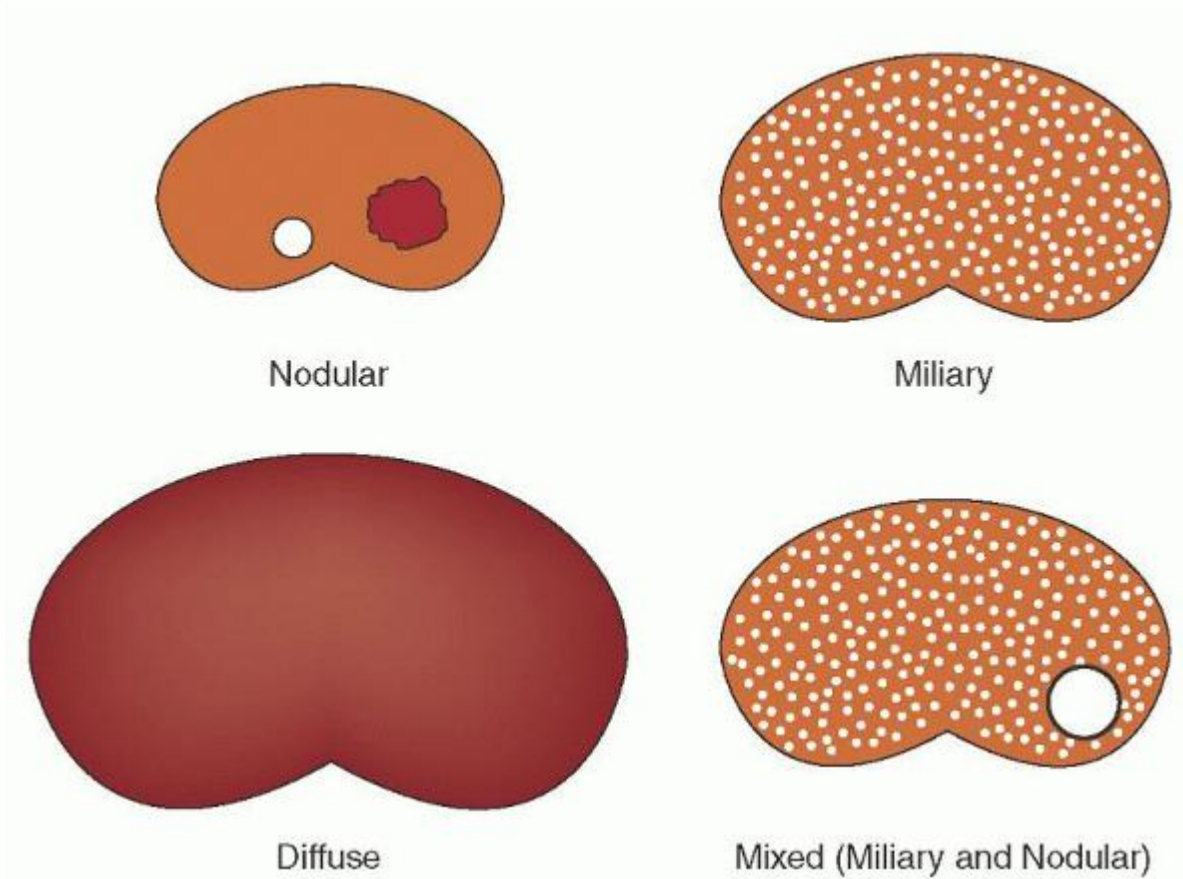

FIGURE 66.1. Gross patterns of splenic tumor involvement. Nodular tumor infiltrates may form solid firm masses or may be hemorrhagic masses. The miliary pattern shows small punctate white foci that usually correspond to expansions of the white pulp. The diffuse pattern shown is usually associated with massive splenomegaly and corresponds to a red pulp expansion. Mixed patterns may be seen when the spleen is involved by more than one process or when a low-grade lymphoma transforms to high-grade disease.

TABLE 66.1 PATTERNS OF SPLENIC TUMOR INVOLVEMENT

Diffuse (Predominantly Red Pulp) Disease	Miliary (Predominantly White Pulp) Disease	Predominantly Nodular Disease
Peliosis	Marked white pulp hyperplasia	Cysts
Hemangiomas	Chronic lymphocytic leukemia/small lymphocytic lymphoma	Abscess
Lymphangiomas	lymphoma	Inflammatory pseudotumor
Acute leukemias	Prolymphocytic leukemia	Hamartoma
Hairy cell leukemia	Most follicular lymphomas	Hemangioma
Hairy cell leukemia variant	Mantle cell lymphoma	Sclerosing angiomatoid nodular transformation
Diffuse red pulp small B-cell lymphoma	Splenic marginal zone lymphoma	Littoral cell angioma
Chronic myeloproliferative neoplasms	Lymphoplasmacytic lymphoma ^a	Epithelioid hemangioendothelioma
Lymphoblastic lymphoma	Early involvement by large B-cell lymphoma	Angiosarcoma

lymphoma

Hepatosplenic T-cell lymphoma

Large granular lymphocytosis

Lymphoplasmacytic lymphoma^a

^a More than one pattern may occur with some diseases.

Partial splenectomy has been used successfully in the treatment of nonparasitic splenic cysts.¹⁷

VASCULAR PROLIFERATIONS

Vascular tumors are the most common tumors of the spleen. Vascular proliferations may be diffuse or may form a tumor mass. Peliosis is a rare, diffuse vascular proliferation that is usually an incidental finding occurring in adults.^{18, 19, 20} It may be associated with hepatic peliosis and may occur with anabolic steroid use, in association with malignancies, and following solid organ transplantation, as well as in patients with hepatic cirrhosis, tuberculosis, and aplastic anemia. Peliosis results in dilated vascular spaces, usually 1 mm or less in diameter, that involve the entire splenic parenchyma (Fig. 66.3). Splenic peliosis appears to be associated with an increased risk of splenic rupture.^{19, 21, 22}

Hemangiomas are benign tumors that are also usually asymptomatic, but may cause splenomegaly, abdominal pain, and hypersplenism.^{2, 23, 24, 25} Most hemangiomas are localized and form single or multiple tumor nodules that contain cystic blood-filled spaces grossly. These spaces are lined by endothelial cells, and papillary projections may occur in areas with thrombi. The tumor nodules are usually surrounded by fibrosis and may show calcification. Plain abdominal radiographs, computed tomographic scans, and sonograms are nonspecific, but all show discrete solid and cystic masses, often with evidence of calcification.^{26, 27} Diffuse hemangiomatosis of the spleen is less common, is often associated with systemic hemangiomatosis, results in massive splenomegaly, and may be associated with coagulopathies.^{28, 29} Diffuse hemangiomatosis differs from peliosis by the presence of intervening fibrosis in hemangiomatosis, which is not a feature of peliosis.

FIGURE 66.2. Primary cysts. A: Primary cyst of the spleen showing a trabeculated inner surface on gross examination. B: The cyst shows an epithelial lining on histologic sections, a feature that is definitional of a primary cyst.

Localized lymphangiomas of the spleen may be difficult to distinguish from hemangiomas or primary cysts, but usually contain proteinaceous fluid rather than the blood of an hemangioma.^{2, 23, 30} Diffuse lymphangiomatosis may be localized to the spleen, but is usually a systemic process and most commonly occurs in children and young adults with massive splenomegaly.^{30, 31, 32, 33, 34} The splenic parenchyma is replaced by multiple cysts, up to 3 cm in diameter, imparting a spongy appearance (Fig. 66.4). The cysts are filled with thick pink to brown fluid. Large localized lymphangiomas and lymphangiomatosis of the spleen may be treated with splenectomy.³⁰

P.1386

FIGURE 66.3. Splenic peliosis. Peliosis of the spleen shows expanded small vessels that diffusely involve the spleen without forming a nodular mass and without intervening fibrosis.

Although hemangiomas and lymphangiomas of the spleen are similar to those of other sites, there are two unique vascular proliferations of the spleen. Littoral cell angioma is a tumor presumably derived from the normal splenic lining cell, also known as the littoral cell.^{24, 35} These tumors may occur at any age and usually cause mild to moderate splenomegaly. Many tumors, however, are found incidentally. The tumor forms multiple spongy dark red nodules that can measure up to 9 cm in diameter (Fig. 66.5). Histologically these tumors differ from hemangiomas in that the vascular spaces are lined by plump cells with nuclear enlargement and often show papillary areas and lining cells sloughing into the vascular spaces. The lining cells of littoral cell angioma have a unique immunophenotype, expressing vascular, histiocytic, and dendritic-associated markers CD31, CD68, CD163, and CD21. In contrast to hemangiomas and normal sinus lining cells, the lining cells of littoral cell angioma do not express CD34 or CD8. Most cases of littoral cell angioma are treated with splenectomy without recurrence, but there are two reports of late abdominal and liver metastasis after 4 and 8 years.^{36, 37} Both cases showed solid foci of clear cells and probably represent littoral cell hemangioendotheliomas.

Sclerosing angiomatoid nodular transformation (SANT) is the other vascular proliferation unique to the spleen.^{38, 39, 40} To date, SANT has only been reported in adults, usually presenting as an incidental mass, and less commonly with splenomegaly or abdominal pain. It usually forms a single fibrotic nodule that contains vascular spaces, including slitlike spaces, fibrosis with spindled cells, and splenic sinus lining cells without nuclear atypia, mitotic figures, or necrosis. Cases of this type have been interpreted in the past as epithelioid and spindled hemangioendotheliomas or as inflammatory pseudotumors (see below), but they have not recurred or metastasized after splenectomy. SANT is now felt to be a reactive fibrous entrapment of altered red pulp, presumably following some form of splenic injury, rather than a true neoplasm. More recent reports have described an increase in IgG4-positive plasma cells in SANT and some studies suggest an association with Epstein-Barr virus (EBV) in this proliferation.^{39, 41, 42} However, the EBV-positive cases appear to be overlap proliferations with splenic inflammatory pseudotumor and SANT is typically EBV-negative.⁴³

FIGURE 66.5. Littoral cell angioma. A: Multinodular hemorrhagic lesions of the spleen in littoral cell angioma. B: Microscopically, there are papillary vascular spaces with plump lining cells and histiocytes.

FIGURE 66.4. Lymphangiomatosis. Cut surface of a spleen. Multiple, variably sized cysts are present.

Angiosarcoma of the spleen occurs most commonly in adults and is usually associated with splenomegaly, abdominal pain, and cytopenias.^{24, 44, 45, 46} Splenic rupture is common in these patients. Because most angiosarcomas involving the spleen are high-grade sarcomas with dissemination, it is often difficult to determine whether the splenic tumor is primary or secondary. The tumor forms an infiltrating mass that may have areas of cystic hemorrhage. The histologic appearance may be varied; however, angiosarcomas characteristically show cytologic atypia, high mitotic activity, and necrosis. Many cases may be difficult to differentiate from other high-grade sarcomas, and immunohistochemical detection of vascular antigen expression, such as CD31, CD34,

P.1387

and von Willebrand factor, is necessary to diagnose such cases. High-grade angiosarcomas involving the spleen have a

generally poor prognosis, with most patients dying of disease within 1 year of diagnosis; however, rare cases with long-term survival following splenectomy have been reported.⁴⁶

Low-grade angiosarcomas, also known as epithelioid hemangioendotheliomas, are much less common than high-grade tumors.^{47, 48, 49} These are reported to occur in both children and adults, but some of the adult cases have features similar to those more recently described for SANT (see above). Patients usually present with anemia and may have hyper- or hyposplenism. These tumors are better circumscribed than high-grade angiosarcomas with more bland epithelioid cells, vascular spaces, and prominent fibrosis. They also usually lack necrosis. The cells may show intracellular lumina and will express vascular-associated antigens. These tumors may be incidental findings, are usually localized to the spleen, and do not tend to recur after splenectomy.

LYMPHOID PROLIFERATIONS

Essentially any lymphoproliferative disorder may involve the spleen and splenic involvement may be the first evidence of disease. Despite this, most lymphoid proliferations involving the spleen are disseminated at the time of splenic involvement and are accompanied by lymphadenopathy.^{50, 51, 52, 53} Two types of splenic lymphoma, however, are unique to the spleen and present with splenomegaly without lymphadenopathy.

Splenic marginal zone lymphoma was originally described as a splenic lymphoma with features that mimicked hairy cell leukemia.⁵⁴ Although sharing some morphologic and immunophenotypic features, splenic marginal zone lymphoma appears to be distinct from both nodal and extranodal (nonsplenic) marginal zone lymphomas.⁵⁵ It is the most common lymphoma type in patients with so-called splenic lymphoma with circulating villous lymphocytes.^{56, 57, 60} Splenic marginal zone lymphoma most commonly occurs in elderly patients with massive splenomegaly (Fig. 66.6).^{53, 61, 62, 63, 64, 65} Although splenic hilar lymph nodes are often involved by disease, other adenopathy is not usually present. Patients frequently have a lymphocytosis. The abnormal lymphoid cells may vary in appearance, but some cases have circulating lymphocytes with villous cytoplasmic projections that differ from hairy cell leukemia lymphocytes by having only unipolar or bipolar projections as opposed to the more uniform villous projections of hairy cell leukemia. The spleen is uniformly enlarged without a distinct mass. The white pulp is massively expanded by a biphasic population of small lymphocytes that may cause a gross miliary pattern of the spleen parenchyma. The central white pulp lymphocytes are small with scant cytoplasm and are surrounded by a bandlike proliferation of more irregular small lymphocytes with abundant clear to pink cytoplasm on histologic sections. These cells are CD20⁺ B cells that express BCL2, but do not express CD10, or CD43. A subset of cases may express CD5. The pattern of infiltration is distinct from hairy cell leukemia, which causes a diffuse red pulp infiltrate, and splenic marginal zone lymphoma does not usually demonstrate tartrate-resistant acid phosphatase (TRAP) positivity or expression of Annexin A1, CD25, or CD103 of hairy cell leukemia.

FIGURE 66.6. Splenic marginal zone lymphoma and metastatic carcinoma. A: Gross appearance of the miliary pattern of splenic involvement by splenic marginal zone lymphoma. Note the white, larger mucoid lesion at the left, which represents metastatic papillary serous ovarian carcinoma resulting in a mixed disease pattern of infiltration. B: The splenic marginal zone lymphoma shows biphasic white pulp with small round cells in the center and larger lymphocytes with more cytoplasm in the outer marginal zones. Similar cells with clear cytoplasm are also present in the adjacent red pulp.

Although peripheral blood and bone marrow involvement by splenic marginal zone lymphoma are common,⁶⁶ most cases are indolent and do well with splenectomy with or without chemotherapy.^{61, 67} In a series of 60 patients, all treated with splenectomy and almost half receiving chemotherapy, the overall survival was 103 months with a range of 2 to 164 months. The subset of more aggressive cases tended to show involvement of bone marrow and nonhematopoietic sites.⁶⁷ Other features reported to be associated with more aggressive disease include increased numbers of large lymphoma cells, p53 overexpression, and loss of chromosomal regions 7q and 17p.^{67, 68, 69, 70} A large series of 309 patients found a

76% 5-year cause-specific survival, with factors associated with worse survival on multivariate analysis being hemoglobin <12 g/dl, lactate dehydrogenase levels greater than normal, and albumin levels <3.5 g/dl.⁷¹ More recently, patients have shown excellent responses to rituximab alone or with chemotherapy without splenectomy.^{72, 73} Rare cases have recurred in lymph nodes with transformation to diffuse large B-cell lymphoma,^{74, 75} and one report described cases with transformation to micronodular T-cell-rich large B-cell lymphoma.⁷⁶ Cases of splenic marginal zone lymphoma with hepatitis C virus infection and mixed cryoglobulinemia are reported to have regressed with hepatitis C antiviral therapy.^{77, 78} Most cases, however, occur in the absence of hepatitis C infection, and rituximab with or without chemotherapy appears to have major activity in these patients.⁷⁹ Splenic red pulp small B-cell lymphoma and hairy cell leukemia variant share some similarities with splenic marginal zone lymphoma and are both considered as provisional entities in the 2008 World Health Organization classification.^{80, 81} They differ from splenic marginal zone lymphoma by being primarily red pulp small B-cell proliferations. All are CD5 and CD10 negative B-cell proliferations. Hairy cell leukemia variant is typically composed of cells similar to prolymphocytes with prominent nucleoli, but these cells also show cytoplasmic projections suggestive of hairy cells. Despite the morphologic similarity to hairy cell leukemia, hairy cell leukemia variant does not usually express CD25 or Annexin A1, markers typically expressed in hairy cell leukemia. It is important to distinguish hairy cell leukemia variant from splenic

P.1388

marginal zone lymphoma, because hairy cell leukemia variant is a more aggressive disease.⁸²

Hepatosplenic T-cell lymphoma is the other lymphoma type unique to the spleen. It also presents with massive splenomegaly as well as hepatomegaly and usually with bone marrow disease.^{83, 84, 85, 86, 87, 88, 89} This lymphoma most commonly occurs in young adults with a male predominance. Patients present with fever, weight loss, and jaundice in addition to hepatosplenomegaly and may have pancytopenia and circulating lymphoma cells in the peripheral blood. Rare cases have occurred after solid organ transplantation,^{90, 91} and recently cases associated with inflammatory bowel disease and rheumatoid arthritis have been reported. These latter cases may occur in older patients and are felt to be associated with immunomodulator and tumor necrosis factor- α inhibitor therapies.⁹² This tumor was originally described as erythrophagocytic T γ lymphoma⁹³ and has also been referred to as hepatosplenic $\gamma\delta$ T-cell lymphoma. The lymphoma diffusely expands the spleen without a discrete mass and medium-sized cells with irregular nuclear contours and abundant cytoplasm infiltrate the splenic red pulp (Fig. 66.7), often with loss of the splenic white pulp. The liver involvement is sinusoidal rather than forming a tumor mass. Hemophagocytosis may also be present and some cases in the past may have been interpreted as malignant histiocytosis. The cells express T-cell-associated markers, such as CD2, CD3, CD5, CD7, and CD43, but may show aberrant loss of one or more of these markers. The cells also usually express CD16, CD56, and TIA-1, but do not show other features of natural killer cells. The cells are negative for EBV, granzyme B, and perforin. Most cases are neoplasms of $\gamma\delta$ T-cells, which do not express CD4, CD8, or T-cell receptor β -chains. However, some cases are $\alpha\beta$ T-cell neoplasms and there appears to be no significance to subdividing this lymphoma by T-cell type⁸⁹; cases with both immunophenotypes show the characteristic combined cytogenetic abnormalities of isochromosome 7q and trisomy 8.^{94, 95, 96} Hepatosplenic T-cell lymphoma is an aggressive disease that may show initial improvement following splenectomy and/or chemotherapy, but usually behaves aggressively with a median survival of 8 months (range 0 to 42 months) reported in one study. Patients with longer survival have received a variety of combination chemotherapy and hematopoietic stem cell transplantation approaches.^{89, 97}

Secondary involvement of the spleen by lymphoproliferative disorders is also common.⁵³ Hairy cell leukemia is one that frequently presents with splenomegaly without lymphadenopathy. The patients are usually elderly, with pancytopenia that includes monocytopenia. Peripheral blood and bone marrow are virtually always involved to some degree, although blood involvement may be minimal. The spleen is enlarged by a diffuse or red pulp infiltrate of small lymphocytes. The white pulp is decreased or absent and dilated blood-filled spaces, often termed red blood cell "lakes," are common in the red pulp. The blood, bone marrow, and splenic lymphocytes are monotypic B cells that lack CD5 and express CD11c, CD25, Annexin A1, and CD103, as well as being positive by cytochemistry or immunohistochemistry for TRAP. A subset of cases shows expression of CD10 or lacks expression of CD11c, CD25, or CD103.⁹⁸ In the past TRAP cytochemistry was considered the gold standard for diagnosis of hairy cell leukemia, but it has been largely replaced by immunophenotypic evaluation. The blood changes of circulating lymphocytes with villous cytoplasmic projections may be difficult to distinguish from splenic lymphoma with villous lymphocytes, usually secondary to splenic marginal zone lymphoma. However, the pattern of the splenic infiltration between the two diseases differs, with a red pulp or diffuse pattern in hairy cell leukemia and a predominantly white pulp expansion in splenic marginal zone lymphoma.

FIGURE 66.7. Hepatosplenic T-cell lymphoma. Medium-sized lymphoma cells are infiltrating the splenic red cords and sinuses of the red pulp.

Other lymphomas of small B lymphocytes may secondarily involve the spleen resulting in splenomegaly, and include chronic lymphocytic leukemia/small lymphocytic lymphoma, lymphoplasmacytic lymphoma, mantle cell lymphoma, and follicular lymphoma. With the exception of a subset of cases of lymphoplasmacytic lymphoma, these disorders all infiltrate and expand the splenic white pulp. The majority of large B-cell lymphomas and virtually all cases of Hodgkin lymphoma involving the spleen form distinct tumor nodules with adjacent uninvolved splenic tissue. A subset of large B-cell lymphomas and lymphoplasmacytic lymphomas will primarily involve the splenic red pulp and before immunophenotyping may mimic other disorders, including leukemic infiltrates in the case of red pulp large B-cell lymphoma and possibly hairy cell leukemia in the case of red pulp lymphoplasmacytic lymphoma. T-cell lymphomas and the rare histiocytic tumors typically enlarge the spleen by expanding the splenic red pulp in a diffuse manner.

ACUTE LEUKEMIA AND MYELOPROLIFERATIVE NEOPLASMS

In acute leukemia, splenomegaly may be due to an increase in either lymphoblasts or myeloblasts in the red pulp. This is rarely an isolated finding, and does not usually create diagnostic difficulty. Myeloproliferative neoplasms characteristically cause splenomegaly, and in some cases this enlargement is massive. Primary myelofibrosis most commonly causes massive splenomegaly, usually over 1,000 g.^{99, 100} The splenomegaly may be associated with a wasting syndrome that is improved with splenectomy. Splenectomy in this disorder, however, is associated with an increased risk for blast transformation.¹⁰¹ The cause of splenomegaly in most myeloproliferative neoplasms is expansion of the splenic red pulp by abnormal hematopoiesis. The red pulp cords and sinuses are filled with varying numbers of nucleated red blood cells, maturing granulocytes, and atypical megakaryocytes (Fig. 66.8). There may be other causes of noticeable splenomegaly in patients with myeloproliferative neoplasms. A rapidly enlarging spleen may signal accelerated phase or blast transformation. Detection of increased numbers of CD34⁺ immature cells in the red pulp may be a useful clue to such transformation. In essential thrombocythemia, the spleen may be enlarged due to increased numbers of platelet-filled macrophages in the red pulp. In the early phase of polycythemia vera, massive congestion by red blood cells may be the cause of splenomegaly.¹⁰²

OTHER TUMOROUS PROLIFERATIONS

Splenic hamartomas are also known as splenomas or spleen-in-spleen syndrome, and are benign splenic proliferations.^{103, 104, 105, 106, 107} They may occur at any age and are usually incidental findings,

P.1389

although up to 30% of patients have cytopenias due to hypersplenism. They form single or multiple, sometimes scarring masses of the splenic parenchyma. They are grossly bulging masses when the spleen is cut (Fig. 66.9), but are more indistinct on histologic sections because these proliferations represent a reduplication of splenic red pulp tissue with normal splenic sinus lining cells and a lack of normal white pulp. They are also associated with fibrosis, which may include bizarre stromal cells, but these proliferations have no malignant potential. It is not clear whether splenic hamartomas are actually neoplasms or represent an unusual reparative process.

FIGURE 66.8. Chronic myelogenous leukemia involving the spleen. The red pulp is expanded by aggregates of erythroid and myeloid precursors admixed with scattered megakaryocytes.

Inflammatory pseudotumor of the spleen and liver are distinct from inflammatory pseudotumors or inflammatory myofibroblastic tumors of other sites.¹⁰⁸ In the spleen, these tumors occur more commonly in adult women who may present with symptoms that may include fever, weight loss, malaise, anemia, leukocytosis, thrombocytosis, polyclonal hypergammaglobulinemia, and an elevation of the erythrocyte sedimentation rate.^{109, 110, 111, 112, 113} Infectious disease evaluations are usually negative. The splenic mass is usually solitary and may be up to 12 cm in diameter. The tumor is a dense nodule containing a mixed inflammatory infiltrate and fibrosis. The spindled fibrotic cells of this unique tumor contain evidence of clonal EBV and the infected spindled cells in most cases express the follicular dendritic cell marker CD21. Some hepatic cases have recurred, but splenic cases treated with splenectomy have not. Some authors have suggested that these proliferations represent an unusual type of follicular dendritic cell tumor¹¹⁴ termed inflammatory pseudotumor-like follicular dendritic cell sarcoma, although other follicular dendritic cell tumors are not associated with the EBV.

FIGURE 66.9. Splenic hamartoma and splenic involvement by classical Hodgkin lymphoma. The hamartoma represents a bulging red mass to the left, whereas the Hodgkin lymphoma forms multiple firm white nodules throughout the spleen. Hamartomas are often incidental findings in spleens removed for other reasons.

Primary sarcomas, other than angiosarcoma, and carcinomas of the spleen are extremely uncommon. Reported cases of sarcoma include malignant fibrous histiocytoma, fibrosarcoma, leiomyosarcoma, rhabdosarcoma, histiocytic sarcoma, interdigitating dendritic cell sarcoma, and fibroblastic reticular cell tumor.^{3, 115, 116, 117, 118, 119, 120, 121} Primary carcinomas reported include squamous cell carcinoma arising in a cyst, mucinous cystadenocarcinoma and carcinosarcoma both possibly arising from peritoneal surface epithelium, and primary transitional cell carcinoma.^{122, 123, 124, 125} Although still rare, carcinoma of the spleen from metastasis or direct tumor extension is more common than primary disease. One third of metastatic tumors are only identified on microscopic examination,¹²⁶ so the frequency of splenic involvement may be underestimated by imaging studies. Lung, gastric, ovarian, and breast carcinoma primaries are the most common to involve the spleen, and splenectomy may be performed for solitary splenic metastases.^{127, 128, 129}

Chapter 67

Hematopoietic Neoplasms: Principles of Pathologic Diagnosis

Daniel A. Arber

The hematopoietic neoplasms consist of acute and chronic leukemias, Hodgkin and non-Hodgkin lymphomas, plasma cell tumors, and the rare histiocytic and dendritic neoplasms. Each of these disease categories is now recognized to represent various heterogeneous disease groups that include a large number of distinct biologic entities.^{1, 2} With the great advances in targeted therapies and molecular genetic discoveries in the area of hematopoietic tumors, the number of distinct entities will continue to grow. Although the diagnosis and classification of these tumors were originally based primarily on morphologic features, sometimes supplemented by cytochemical studies,^{3, 4, 5, 6, 7} the diagnosis of hematopoietic tumors now requires a complex battery of specialized tools that almost always include immunophenotyping and frequently require cytogenetic and molecular genetic studies. Despite these advances, morphologic evaluation remains the cornerstone for the pathologic diagnosis for most diseases. Morphologic evaluation allows for cost-effective tissue processing and triaging for appropriate ancillary tests, which becomes increasingly important as the number of molecular genetic tests grows in this area.

PREOPERATIVE CONSIDERATIONS

Special considerations are often needed prior to sampling of tissue that is suspected to contain a hematopoietic neoplasm.^{8, 9, 10, 11, 12} The testing that will be needed depends on the clinical differential diagnosis as well as the initial pathologic impression of the sample. However, if the correct specimen types for ancillary tests are not saved prior to the initial pathologic review, the tissue may not be sufficient for these additional tests. Therefore, the hematologist, pathologist, or surgeon performing the procedure should have a clear understanding of the specimen requirements for the various tests that might be needed to rule in or out all suspected diseases. This often requires direct communication with the surgical pathologist or hematopathologist who will ultimately receive the sample prior to obtaining tissue. The submission of fresh tissue on saline-soaked gauze is ideal for tissue samples; however, this may not be feasible if the sample is taken at night or in a clinic that is physically separate from where the sample will be processed. Even in the latter setting, however, the sample may be sent by courier to a remote location quickly so that the tissue can be correctly triaged. In the absence of central processing of the sample, the physician performing the procedure must be aware of how to collect samples that are adequate for immunophenotyping studies, molecular and cytogenetic studies, and possible cultures. This problem is even more complicated when reference laboratories are used for different types of testing, an increasingly common practice, resulting in the need to split what may be very small samples prior to sending them out for these studies.

Ideally, the entire fresh sample is submitted to the pathology department within minutes of removal. There it may be received by a resident, technician, pathology assistant, or pathologist. No matter who receives the specimen, the clinical indication for the biopsy as well as any special clinical concerns or testing requirements needs to be clearly communicated. For tissues removed to rule out lymphoma, the specimens should be sampled in the fresh state. One protocol for lymph node sampling is provided in Figure 67.1⁸ and is discussed in more detail below. Hematologists and pathologists should work together to establish a suitable protocol for their institution. Special needs should be communicated to the pathologist in advance of obtaining the sample, to ensure that the supporting testing areas, such as cytogenetics or microbiology, are prepared to receive the sample or to make arrangements to send samples quickly to the

appropriate reference laboratory. It is worth noting that surgical pathologists receive lymph node specimens for a variety of indications, most of which do not require special processing and are simply formalin fixed. Without adequate clinical information and communication to alert them to a possibility of lymphoma or another hematopoietic tumor, tissue may not be sent for flow cytometry or cytogenetic studies, or saved for possible molecular genetic studies. Because the differential diagnosis of malignant lymphoma often includes infectious etiologies, the need for cultures or other infectious disease testing requiring fresh tissue or other special tissue preparation must also be communicated.

SPECIMEN PROCESSING

Triaging Protocols

How a sample for a suspected hematologic disorder is triaged often depends on the specimen type. Peripheral blood, bone marrow aspirate, and fine needle aspirate samples are often

P.1392

triaged at the bedside by the physician collecting the sample. In this setting, the treating physician often orders flow cytometry immunophenotyping, cytogenetics, molecular genetics, and even cultures on samples collected in different tubes. Because the diagnosis of most disorders is still based in large part on morphologic features, it is advisable to use the initial bone marrow aspirate material for fresh smears, prepared at the bedside, or to make touch preparations for morphology in all cases with inadequate aspirate material (see Chapter 1). Subsequent aspirations may be more hemodiluted, but are usually still suitable for ancillary studies. In contrast, the triaging of tissue biopsy specimens is usually performed after the sample is submitted to the laboratory, as mentioned above and illustrated in Figure 67.1.^{8, 9} If lymphoma is suspected, sections of fresh material should be fixed for morphologic evaluation. If enough tissue is obtained, a portion of fresh tissue may also be sent for flow cytometry, and possibly for cytogenetics or cultures. Additional material may be frozen for future molecular genetic studies. In the rare instance where electron microscopy may be needed, a small portion of fresh tissue should be saved in glutaraldehyde. The exact tests performed, however, will depend on the clinical indication for the biopsy and communication between the pathologist and the treating hematologist.

FIGURE 67.1. Schematic of protocol for processing lymph node biopsies from patients suspected of having lymphoid malignancies.

Tissue Fixation and Processing

Proper specimen fixation and processing are essential for morphologic evaluation as well as for the optimal performance of ancillary studies.^{10, 11, 12} If lymphoma is suspected, thin sections of fresh material should be fixed for morphologic evaluation. In the past, special fixatives containing heavy metals such as mercuric chloride were used to improve cell morphology, but these fixatives are less commonly employed today due to difficulties in disposing of the mercury. Such fixatives also disrupt nucleic acids, making molecular studies often impossible. More routine formalin fixation will usually provide appropriate sections, as long as the tissue is fixed adequately, usually meaning overnight fixation of thin sections

in fresh neutral buffered formalin. Formalin-fixed tissue is satisfactory for many DNA-based molecular assays, but some tests cannot be performed on fixed tissue. Tissue that is frozen should be stored at the lowest possible temperature (preferably -70°C to -80°C) and should not be stored in defrostable freezers.

Bone marrow aspirate specimens should be sent fresh after collection with minimal anticoagulant. Bone marrow biopsies should also be submitted fresh, or in fixative if delivery to the laboratory may be delayed. Again, heavy metal fixatives are less commonly available today and formalin or Bouin fixation is more frequently used. Bone marrow biopsies also must undergo decalcification, which may degrade some antigens and may reduce the ability to perform some assays. Decalcification in ethylenediaminetetraacetic acid is considered the most gentle for antigen preservation,¹³ but some methods take several days to obtain adequate decalcification and this method is not routinely performed in most laboratories.

SAMPLING METHODS AND THEIR LIMITATIONS

Open Biopsy

The ideal specimen for pathologic evaluation is a large portion of tissue, received fresh and taken from an open biopsy. Such samples allow the maximum amount of tissue for morphologic analysis and ancillary studies. However, the increasing use of less-invasive procedures requires different approaches for different specimen types.

Peripheral Blood

Peripheral blood is often the easiest sample to obtain for an initial evaluation for a hematologic malignancy. Analysis of blood may allow for a diagnosis of leukemia or even peripheral blood involvement by lymphoma, although the absence of neoplastic cells in the blood cannot exclude disease elsewhere. Limitations to blood analysis include the inability to classify blast proliferations with <20% circulating blasts, and the lack of architecture needed for classification of some lymphomas involving blood. Despite these limitations, when the blood is involved by a hematopoietic tumor, morphologic, immunophenotypic, and molecular genetic studies of the blood may be of value in some patients. However, if a bone marrow is to be performed, duplication of testing on both the blood and marrow is usually unnecessary.

Bone Marrow Aspirate and Biopsy

Evaluation of marrow material will often provide much more information than peripheral blood alone in terms of classifying leukemic processes and determining the marrow blast percentage. In addition, some acute leukemias with monocytic features will have an increase in marrow blasts, but show maturation of neoplastic cells in the blood that may mimic chronic myelomonocytic leukemia; therefore, bone marrow assessment is essential in that setting. Both aspirate and biopsy materials provide critical information. Some diseases, such as lymphomas and metastatic tumors, may focally involve the marrow and are often associated with fibrosis, both factors that may make them undetectable on aspirate smears alone. When such focal disease processes are suspected, biopsies from more than one site will produce a higher yield for disease detection.¹⁴

Fine-Needle Aspirate and Core Biopsy

Fine-needle aspiration has become common as an evaluation tool for solid tumors and even lymphoma due to it being a relatively noninvasive procedure. The technique is ideal for the evaluation of relapse of disease but is now often used for initial patient evaluation. Although fine-needle aspiration coupled with flow cytometry immunophenotyping is ideal for the diagnosis of many low-grade lymphomas,^{15, 16} it has significant limitations due to the inability to determine architectural features of the lymphoma, to grade some lymphomas properly, and to identify focal disease or transformation. The addition of needle biopsies with or without aspiration and immunophenotyping overcomes some of these limitations, but a significant number of cases will need to go on to open biopsy for diagnosis and/or classification. Because of these limitations, excisional biopsy of easily accessible lymph nodes, when available, is preferred over lymph node aspiration or needle biopsy as an initial diagnostic procedure.

Laparoscopic Biopsy

Laparoscopic biopsies and other more invasive biopsy techniques often obtain more tissue than core biopsies, but often fragment

P.1393

the specimen, especially with laparoscopic splenectomy specimens.¹⁷ Despite this, the fragments are usually large enough to determine the architectural pattern of the lymphoid infiltrate.

IMMUNOPHENOTYPING

Immunophenotyping is now essential in the diagnosis and classification of most hematopoietic tumors.² It is necessary to distinguish precursor B- from precursor T-lymphoblastic leukemia/lymphoma, to detect aberrant immunophenotypes in both lymphoid and myeloid leukemias, and to determine B-cell clonality and aberrancies in malignant lymphomas. Flow cytometry and immunohistochemistry are the primary methods currently used, and they have different advantages in the evaluation of these diseases.

Flow Cytometry

Flow cytometry is ideal for tumors involving blood and bone marrow because the cells are already in a cell suspension, a necessary factor for this analytic technique. This method, however, is also ideal for nonsclerotic lymph node specimens, in which a cell suspension can often be made easily. The method requires the processing of unfixed tissue, either fresh or in transport media. As described in Chapter 2, flow cytometry is ideal for evaluating surface antigen expression on cell suspensions and allows for the evaluation of multiple antigens on a given cell. This method is most helpful for acute leukemias and low-grade lymphomas in which aberrant antigen expression in combinations is common on the neoplastic cells.^{18, 19} Detection of nuclear and cytoplasmic antigens, such as cyclin D1 and BCL2, is more difficult with this methodology.¹⁶

Immunohistochemistry

Immunohistochemistry can be performed on fixed, paraffin-embedded tissue and allows for morphologic correlation with antigen expression. This is most useful in tumors with only scattered tumor cells, such as Hodgkin lymphoma, which is usually not detectable by current flow cytometry methods. Paraffin section immunohistochemistry also allows for detection of cytoplasmic and nuclear antigens that do not routinely work well by flow cytometry and allows fairly complete immunophenotyping of disorders that do not have fresh tissue available,²⁰ although the number of markers detectable by this method is still less than can be assessed by flow cytometry immunophenotyping. Table 67.1 lists the most commonly used antibodies in paraffin section immunohistochemistry for hematopoietic tumors.

GENETIC TESTING

Genetic analysis has become increasingly important in the diagnosis, classification, and prognosis assessment of hematopoietic tumors.^{21, 22} These techniques are described in more detail in other chapters; however, it is important to understand the general utility of the various assays that are currently available. Gene array analysis has contributed greatly to our understanding of a variety of hematopoietic tumors in recent years, but it is not used as a diagnostic tool in most laboratories and is being largely supplanted by sequencing methods in the research setting. Karyotype analysis is still the best overall screening method for most tumors and will detect most gross chromosomal abnormalities, including translocations, deletions, and aneuploidy. This method has the advantage of an overall screen of all chromosomes, compared to the more targeted detection of abnormalities with the other molecular genetic methods, and should be performed on all suspected acute leukemias or myeloproliferative neoplasms. The submission of samples for karyotype analysis in cases of suspected malignant lymphoma shows more institutional variability.

Many important genetic abnormalities, however, are cryptic at the karyotype level of detection and these include some translocations, such as the t(12;21)(p13;q22) of pediatric acute lymphoblastic leukemia; B- and T-cell antigen-receptor rearrangements of malignant lymphomas; and gene mutations, such as those seen in many acute myeloid leukemias. Karyotype analysis is also difficult on slower-growing tumors, such as low-grade lymphomas, and will not work on fixed tissues. Therefore, a variety of other techniques is also commonly used to evaluate the molecular genetic changes of these tumors. Although Southern blot analysis has traditionally been considered the gold standard for the detection of many abnormalities, gene rearrangement studies, the need for large amounts of fresh or frozen tumor tissue, the complexity of the assay, and the relatively long turnaround time of this assay have resulted in most diagnostic laboratories abandoning this method. Fluorescence in situ hybridization (FISH) is a commonly used technique that can be performed on metaphases or intact cell nuclei, and this method is ideal for the detection of translocations, deletions, and trisomies. FISH panels to detect common, disease-specific abnormalities with prognostic significance are now routine assays performed at diagnosis for cases of suspected chronic lymphocytic lymphoma and plasma cell myeloma and are becoming more common for other neoplasms. The various polymerase chain reaction (PCR) methods are rapid means of detecting translocations and gene rearrangements, and can detect lower tumor volumes than FISH methods. Quantitative PCR assays are used to determine levels of minimal residual disease, such as to monitor patients being treated for chronic myelogenous leukemia. Other in situ hybridization methods are useful to localize infectious agents, in particular the Epstein-Barr virus, in specific cell types and this method is often used in the diagnosis of classical Hodgkin lymphoma and nasal natural killer (NK)/T-cell lymphoma. The introduction of next-generation sequencing platforms into clinical

laboratories will increase the number of genetic targets for a given case in the near future. Therefore, a variety of molecular diagnostic tools is now available to supplement karyotype analysis in the evaluation of hematopoietic tumors.

OTHER ANCILLARY METHODS

New molecular genetic technology will certainly become available for diagnostic use in the future, yet other more traditional ancillary techniques are actually becoming less common in the routine diagnosis of hematopoietic tumors. Specifically, electron microscopy is rarely used and has been largely supplanted by immunophenotypic methods. Similarly, the diagnostic utility of many histochemical and cytochemical assays has also diminished. Although the proper classification of some of the acute myeloid leukemias in the “not otherwise specified” group of the World Health Organization (WHO) classification still have cytochemical criteria, it is now generally recognized that subgroups of acute myeloid leukemia defined solely by these methods have little clinical relevance.^{23, 24}

THE DIAGNOSTIC REPORT

The diagnostic report for hematopoietic tumors should ideally summarize all diagnostic material and testing from a sample.²⁵ This would include a combination of peripheral blood, marrow aspirate, and marrow biopsy for bone marrow samples. The morphologic review should be performed and interpreted in combination with immunophenotyping and cytogenetic and molecular genetic studies. The report should state the relevant

P.1394

P.1395

clinical information and indication for biopsy/aspiration. In addition, the report should clearly define the methodology used for any special studies (such as flow cytometry vs. immunohistochemistry; PCR vs. FISH, etc.), the antibodies studied and their results, a summary of the interpretation of each special study, and a final interpretation of the significance of all of the assays performed. The final diagnosis should clearly identify the site from which the specimen was obtained, and should, when possible, provide a diagnosis using the most current version of the WHO classification of hematopoietic tumors which is summarized in Table 67.2. Such comprehensive reports are more complicated to produce, but are necessary to classify most hematopoietic neoplasms properly. This approach may require amending initial interpretations, based on morphology and immunophenotyping, to provide the complete assessment that includes cytogenetic and molecular genetic results.

TABLE 67.1 COMMONLY USED MARKERS FOR THE CHARACTERIZATION OF HEMATOPOIETIC AND LYMPHOID NEOPLASMS IN PARAFFIN-EMBEDDED TISSUE SECTIONS

Category	CD Antigen or Antibody	Reactivity in Normal Cells^a	Reactivity in Neoplasms^a
Pan-leukocyte	CD45	B cells, most T cells, macrophages, and granulocytes	Most NHLs and leukemias
T cell	CD1a	Cortical thymocytes and Langerhans cells	Precursor T-cell lymphoblastic leukemia/lymphoma, Langerhans cell histiocytosis
	CD3	T cells	Most T-cell neoplasms
	CD5	T cells and subset of small B cells	Many T-cell lymphomas and leukemias and subset of diffuse small B-cell neoplasms, such as small lymphocytic lymphoma/chronic lymphocytic leukemia and mantle cell lymphoma
	CD7	Most T cells and NK cells	Many T-cell lymphomas and leukemias

	CD43	T and NK cells, some macrophages, granulocytes, and plasma cells	Most T-cell lymphomas, some B-cell lymphomas, acute myeloid leukemias, and plasma cell neoplasms
	CD45RO	Most T and NK cells, some macrophages, some myeloid cells	Most T-cell lymphomas, some B-cell lymphomas
	CD57	Some NK cells, subset of T cells	Some NK- and T-cell lymphomas/leukemias and some lymphoblastic lymphomas
	TCR β	α/β T cells	Many T-cell lymphomas
	TCR γ	γ/δ T cells	γ/δ T-cell lymphomas
B cell	CD10	Precursor B cells and germinal center B cells, some germinal center T cells	Many precursor B-lymphoblastic leukemias/lymphomas, some precursor T-lymphoblastic leukemias/lymphomas, angioimmunoblastic T-cell lymphoma, many follicular lymphomas, Burkitt lymphoma
	CD20	B cells	Most B-cell NHLs, L&H cell in LPHD; RS cells in some cases of classic Hodgkin disease
	CD21	Mantle and marginal zone B cells, FDC	Some mantle and marginal lymphomas, FDC tumors
	CD23	Mantle zone B cells, some FDC	Chronic lymphocytic leukemia/small lymphocytic lymphoma, some follicular lymphomas
	CD45RA	B cells and subset of T cells	B-cell NHL, L&H cells in LPHD, some T-cell lymphoid and myeloid leukemias
	CD79a	B cells	Most B-cell NHLs and many B-cell leukemias
	PAX5	B cells	Most B-NHL, L and H cell in LPHD; RS cells in classic Hodgkin disease, some acute myeloid leukemias
	Anti-immunoglobulin	B cells, plasma cells	B-cell NHL and plasma cell neoplasms
Hodgkin related	CD15	Granulocytes and some macrophages	RS cells in classical Hodgkin lymphoma; some T- and B- large cell lymphomas; some carcinomas
	CD30	Activated B and T cells	RS cells in classical Hodgkin lymphoma; most cases of ALCL; other T- and B-cell NHLs
Miscellaneous	CD34	Progenitor cells	Some acute myeloid leukemias and some precursor lymphoblastic

		leukemias/lymphomas
CD56	NK cells, few T cells	Many NK-cell neoplasms
CD123	Plasmacytoid dendritic cells	Blastic plasmacytoid dendritic cell tumors; some acute leukemias; hairy cell leukemia
CD138	Plasma cells	Multiple myeloma and plasmacytoid lymphomas
CD163	Macrophages and granulocytes	True malignant histiocytosis; some myeloid leukemias
S100	Langerhans cells, interdigitating dendritic reticular cells, sometimes FDC	Langerhans cell histiocytes, sinus histiocytosis with massive lymphadenopathy, rare T-cell lymphomas, myeloid leukemias
Terminal deoxyribonucleotidyl transferase	Precursor marrow cells, cortical thymocytes	Most precursor B- or T-lymphoblastic leukemias/lymphomas, some acute myeloid leukemias
Ki-67	Proliferating cells (not in G ₀ phase of cell cycle)	Proliferating cells
Myeloperoxidase	Myeloid cells	Myeloid leukemias
BCL2	Nonfollicular center B cells, T cells	Most follicular lymphomas, many other diffuse NHLs and leukemias
BCL6	Germinal center B cells	Most follicular lymphomas and some diffuse large B-cell lymphomas
ALK1	No expression in normal lymphoid cells	Subset of ALCL, DLBCL and inflammatory myofibroblastic tumor cases
Cyclin D1	Minimal to no expression in normal lymphoid cells	Mantle cell lymphoma, hairy cell leukemia, and some cases of plasma cell myeloma

ALCL, anaplastic large cell lymphoma; FDC, follicular dendritic cell; L&H, lymphocyte and histiocytic; LPHD, lymphocyte-predominant Hodgkin disease; NHL, non-Hodgkin lymphoma; NK, natural killer; RS, Reed-Sternberg.

^aIn most cases the immunoreactivity of each antibody is not exclusive to the cell type or neoplasm listed and positive results must be interpreted in the context of the entire immunophenotype.

TABLE 67.2 2008 WORLD HEALTH ORGANIZATION CLASSIFICATION OF HEMATOPOIETIC AND LYMPHOID NEOPLASMS

Myeloproliferative Neoplasms

Chronic myelogenous leukemia, *BCR-ABL1*

Chronic neutrophilic leukemia

Polycythemia vera

Primary myelofibrosis

Essential thrombocythemia

Chronic eosinophilic leukemia, not otherwise specified

Mastocytosis

Myeloproliferative neoplasms, unclassifiable

Myeloid and lymphoid neoplasms associated with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*

Myelodysplastic/Myeloproliferative Neoplasms

Chronic myelomonocytic leukemia

Atypical chronic myeloid leukemia, *BCR-ABL1* negative

Juvenile myelomonocytic leukemia

Myelodysplastic/myeloproliferative neoplasm, unclassifiable

Myelodysplastic Syndromes

Refractory cytopenia with unilineage dysplasia

Refractory anemia with ring sideroblasts

Refractory cytopenia with multilineage dysplasia

Refractory anemia with excess blasts

Myelodysplastic syndrome with isolated del(5q)

Myelodysplastic syndrome, unclassifiable

Childhood myelodysplastic syndrome

Acute Myeloid Leukemia (AML) and Related Precursor Neoplasms

AML with recurrent genetic abnormalities

AML with t(8;21) (q22;q22) (*RUNX1-RUNX1T1*)

AML with inv(16)(p13.1q22) or t(16,16) (p13.1;q22) (*CBFB-MYH11*)

Acute promyelocytic leukemia with t(15;17)(q24.1;q21.1) (*PML-RARA*)

AML with t(9;11)(p22;q23) (*MLLT3-MLL*)

AML with t(6;9)(p23;q34) (*DEK-NUP214*)

AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2) (*RPNI-EVII*)

AML (megakaryoblastic) with t(1;22)(p13;q13) (*RBM15-MKLI*)

Provisional entity: AML with mutated *NPM1*

Provisional entity: AML with mutated *CEBPA*

AML with myelodysplasia-related changes

Therapy-related myeloid neoplasms

AML not otherwise specified

AML minimally differentiated

AML without maturation

AML with maturation

Acute myelomonocytic leukemia
 Acute monoblastic and monocytic leukemia
 Acute erythroid leukemia
 Acute megakaryocytic leukemia
 Acute basophilic leukemia
 Acute panmyelosis with myelofibrosis

Myeloid sarcoma

Myeloid proliferations related to Down syndrome

Blastic plasmacytoid dendritic cell neoplasm

Acute Leukemias of Ambiguous Lineage

Precursor Lymphoid Neoplasms

B-lymphoblastic leukemia/lymphoma, not otherwise specified

B-lymphoblastic leukemia/lymphoma with t(v;11q23)(*MLL*)

B-lymphoblastic leukemia/lymphoma with t(12;21)(p13;q22) (*ETV6-RUNX1*)

B-lymphoblastic leukemia/lymphoma with t(5;14)(q31;q32) (*IL3-IGH@*)

B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3) (*TCF3-PBX1*)

B-lymphoblastic leukemia/lymphoma with hyperdiploidy

B-lymphoblastic leukemia/lymphoma with hypodiploidy

T-lymphoblastic leukemia/lymphoma

Mature B-Cell Neoplasms

Chronic lymphocytic leukemia/small lymphocytic lymphoma

B-cell prolymphocytic leukemia

Splenic B-cell marginal zone lymphoma

Hairy cell leukemia

Splenic B-cell lymphoma/leukemia, unclassifiable

Lymphoplasmacytic lymphoma

Heavy-chain diseases

Plasma cell neoplasms

Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)

Nodal marginal zone lymphoma

Follicular lymphoma

Primary cutaneous follicle center lymphoma

Mantle cell lymphoma

Diffuse large B-cell lymphoma (DLBCL), not otherwise specified

T-cell/histiocyte-rich large B-cell lymphoma

Primary DLBCL of the central nervous system

Primary cutaneous DLBCL, leg type
EBV-positive DLBCL of the elderly
DLBCL associated with chronic inflammation
Lymphomatoid granulomatosis
Primary mediastinal (thymic) large B-cell lymphoma
Intravascular large B-cell lymphoma
ALK-positive large B-cell lymphoma
Plasmablastic lymphoma
Large B-cell lymphoma associated with HHV8-associated multicentric Castleman disease
Primary effusion lymphoma
Burkitt lymphoma
B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma
B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma

Mature T- and NK-Cell Neoplasms

T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
Chronic lymphoproliferative disorder of NK cells
Aggressive NK-cell leukemia
EBV-positive T-cell lymphoproliferative diseases of childhood
Adult T-cell leukemia/lymphoma
Extranodal NK/T-cell lymphoma, nasal type
Enteropathy-type T-cell lymphoma
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Mycosis fungoides
Sézary syndrome
Primary cutaneous CD30-positive T-cell lymphoproliferative disorders
Primary cutaneous $\gamma\delta$ T-cell lymphoma
Primary cutaneous CD8⁺ aggressive epidermotropic cytotoxic T-cell lymphoma
Primary cutaneous CD4-positive small/medium T-cell lymphoma
Peripheral T-cell lymphoma, not otherwise specified
Angioimmunoblastic T-cell lymphoma
Anaplastic large cell lymphoma, *ALK*-positive
Anaplastic large cell lymphoma, *ALK*-negative

Hodgkin Lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma

Nodular sclerosis classical Hodgkin lymphoma

Mixed cellularity classical Hodgkin lymphoma

Lymphocyte-rich classical Hodgkin lymphoma

Lymphocyte-depleted classical Hodgkin lymphoma

Immunodeficiency-Associated Lymphoproliferative Disorders

Lymphoproliferative diseases associated with primary immune disorders

Lymphomas associated with HIV infection

Posttransplant lymphoproliferative disorders

Other iatrogenic immunodeficiency-associated B-cell lymphoproliferative disorders

Histiocytic and Dendritic Cell Neoplasms

Histiocytic sarcoma

Langerhans cell histiocytosis/sarcoma

Interdigitating dendritic cell sarcoma

Follicular dendritic cell sarcoma

Other rare dendritic cell tumors

Disseminated juvenile xanthogranuloma

AML, acute myeloid leukemia; DLBCL, diffuse large B-cell lymphoma; EBV, Epstein-Barr virus; HHV8, human herpes virus-8; HIV, human immunodeficiency virus; NK, natural killer.

The pathologic diagnosis of hematopoietic tumors now requires a broad approach that involves very close interactions between hematologists and pathologists as well as interactions with a variety of laboratories. Excellent communication between the physician performing the diagnostic procedure and the laboratories is needed to ensure that the specimen is handled in the most efficient manner and to obtain the most accurate and rapid diagnosis for the patient.

Chapter 68

Principles and Pharmacology of Chemotherapy

Kenneth R. Hande

PRINCIPLES OF CHEMOTHERAPY

To optimally treat cancer patients, clinicians should understand the principles of cancer chemotherapy as well as the pharmacology of the drugs they are administering. The first section of this chapter reviews our understanding of (a) cancer biology, (b) mechanisms of antineoplastic drug action, (c) mechanisms of drug resistance, (d) drug toxicities, (e) pharmacologic principles (common and unique), and (f) potentials and limitations of therapy for individual patients. Specific drugs used to treat hematologic malignancies, their mechanism of action, and their toxicities are summarized in the second section of this chapter.

Cancer Biology

Most cancers are detected when there are 10^4 to 10^{11} neoplastic cells present.¹ The large number of cells present at diagnosis usually requires multiple courses of treatment or a long duration of therapy to result in a cure. Even if a drug, or a combination of drugs, is quite effective in killing cancer cells, such that it kills 999 of every 1,000 cells present (99.9% cell kill), one treatment will reduce a tumor population from 10^{11} to 10^8 cells. At least four treatments are therefore necessary to eliminate the final cancer cell, assuming there is no tumor cell growth during the treatment period. In fact, because of toxicity to normal tissues and the time needed for normal tissue recovery, cancer chemotherapy must be spaced out in treatment cycles. During the period between cycles, tumor regrowth occurs. Thus, most curative treatment regimens require prolonged therapy, often using multiple courses of chemotherapy, with the number of courses depending on the tumor mass at the time of diagnosis and the sensitivity of the tumor to the drugs. The fraction cell kill (e.g., 90%, 99%, 99.99% cell kill) depends on the sensitivity of cells to the antineoplastic drug and the dose of drug administered. Rapidly dividing cells are generally more sensitive to antineoplastic agents while nondividing cells are generally resistant.

Most cancers do not grow at a fixed rate throughout their course. Initial growth rates may be exponential. Gompertzian growth is sigmoid. In the Gompertzian model, the growth fraction of the tumor reduces as the tumor enlarges.² Because a significant proportion of cells in a large tumor mass are often in a resting or dormant phase, presumably as a result of lack of adequate nutrients or oxygen, they may not be affected by chemotherapy. The best opportunity for cell kill by chemotherapy is in the early portion of the growth curve, when all cells are dividing.

Recurrence of cancer after "complete remission" (disappearance of all detectable disease) can be explained by the inability of current staging methods to detect fewer than 10^3 to 10^4 tumor cells in the body even by the most sensitive means. Chemotherapy that kills several logs of tumor cells (e.g., from 10^{11} to 10^4) eliminates all visible evidence of cancer and prolongs survival, but the malignancy will recur at a later time. Examples of possible clinical courses associated with cancer chemotherapy are illustrated in Figure 68.1.

The growth fraction of a cancer represents the percentage of cells progressing actively through the cell cycle. A cell cycle is marked by two observable events. In S-phase (synthesis), DNA replication occurs; during M-phase (mitosis), cellular division into two daughter cells is noted.¹ G_1 (gap) is the time between the end of mitosis and the start of the next S-phase. G_2 is the time between the completion of S-phase and the start of M-phase. Cells that have ceased to proliferate for prolonged periods have entered a G_0 phase (or resting phase) of the cell cycle (Fig. 68.2). Some drugs are cytotoxic when exposed to cancer cells in any phase of the cell cycle. Other drugs are phase-specific; that is, they are cytotoxic to cells only in a particular phase of the cell cycle. Cytarabine, for example, is an S-phase-specific agent, whereas vincristine is M-phase-specific. For cells to be killed by cytarabine, the drug must be present when the cell is synthesizing DNA.

Mechanisms of Antineoplastic Drug Action

Antineoplastic agents have been discovered by many methods. Exposing cancer cells in culture to natural or synthetic compounds to screen for materials with antineoplastic activity has identified a number of active antineoplastic agents (drugs such as paclitaxel). Since DNA is important in cell division, compounds blocking DNA synthesis have been

developed. Over the past 20 years, genes and their protein products that regulate cell division have been identified. The molecular pathways by which these oncogenes cause cellular proliferation have been determined.³ Knowledge of molecular pathways critical to the growth of cancer cells has led to the targeted development of molecules altering specific pathways (e.g., tyrosine kinase inhibitors, angiogenesis inhibitors). During the past two decades, the development of cancer drugs has shifted from a screening process where active agents are identified and their mechanism of action later defined, to first identifying a targetable pathway, finding a compound to block that pathway, and then testing for antineoplastic activity.

No matter how an antineoplastic has been developed, these drugs interfere with an essential step required for cell growth or division. The initial target of antineoplastic drugs varies widely, from direct attack on the DNA molecule to inhibition of signal transduction molecules. However, all antineoplastic agents cause a disruption in a cellular process so significant to the cancer cell that it requires the cell to either quickly repair the damage or to initiate the process of apoptosis (programmed cell death). Essentially, all antineoplastic agents result in cancer cell death through initiation of apoptosis.⁴ Apoptosis is the normal physiologic process of cellular suicide, which occurs in all living organisms to eliminate unwanted, functionally abnormal, or harmful cells. In apoptosis, in contrast to cellular necrosis, the cell shrinks and condenses, fragmenting into multiple membrane-bound bodies (apoptotic bodies) that are engulfed by surrounding cells without inflammation or damage to the surrounding tissues. Biochemically, apoptosis is characterized by fragmentation of nuclear DNA, demonstrated by a typical ladder pattern on agarose gel electrophoresis.

To understand how cytotoxic agents initiate apoptosis, an understanding of the events that occur during the normal cell cycle is important. As previously mentioned, DNA synthesis is not continuous from one mitosis to the next but takes place in only a specific period of the cell cycle, the S-phase. Similarly, mitosis or the M-phase takes up only a small part of the cell cycle.¹ In most, if not all cells, the cell cycle is temporarily halted during the G₁-S-phase checkpoint and at the G₂-M-phase checkpoint. At these times, cells determine whether to continue into the S-phase, initiate the process of apoptosis, or undergo DNA repair. Passage into a new phase of the cell cycle requires activation of a series of enzymes called cyclin-dependent kinases, which activate another group of enzymes (the cyclins).⁵ If cells are damaged by

P.1400

chemotherapeutic agents and are unable to repair the damage, apoptosis is initiated at the G₁-S or G₂-M checkpoint, provided the mechanisms for apoptosis are in place. Several critical factors are needed for apoptosis to occur such as p53, p63, and p21. P53 is a nuclear phosphoprotein capable of binding to specific DNA sequences and activating selected target genes triggering apoptosis. Cells with a mutated P53 gene have a relative resistance to cancer chemotherapeutic agents and are unable to initiate apoptosis properly.⁶ P21 is a protein induced by p53 that binds to and inactivates the cyclins required for progression of cells into the S-phase. Other factors are known to affect the apoptotic pathway. A protein originally found in B cell lymphomas, bcl-2, blocks apoptosis. Caspases are the key machinery causing the breakdown of DNA and proteins. Caspases are specialized proteases existing as proenzymes, which can be rapidly activated by a number of factors. The Fas ligand and tumor necrosis factor stimulate the protease cascade. It is clear that antineoplastic agents provide the initial trigger for beginning the pathway to programmed cell death (Fig. 68.3). However, the presence, or absence, of apoptotic proteins is as important as the initial interaction between a cytotoxic drug and its effector in determining whether tumor cell kill occurs.⁴

FIGURE 68.1. Schematic representation of clinical course of two patients with Hodgkin disease. Both patients A and B are diagnosed with a clinically detected tumor mass (10^{11} cells). Both patients are treated with ABVD (doxorubicin, bleomycin, vincristine, and DTIC) every 2 weeks. One course of therapy for patient A results in a 2-log tumor cell kill. Patient B's therapy results in only a 1-log tumor cell kill. Some tumor growth occurs while waiting for normal tissue recovery before initiation of the next treatment. Three months into therapy, neither patient A nor B has clinically detectable disease. Treatment is stopped after 6 months of therapy. Patient A is cured, whereas disease recurs in patient B 3 months after stopping therapy.

FIGURE 68.2. The cell cycle. The cell cycle is marked by two observable events. During S-phase (synthesis), DNA replication occurs; and during M-phase (mitosis), cells divide. G₁ and G₂ (gap) are times between completion of M-phase and start of S-phase and between completion of S-phase and start of M-phase, respectively. During G₁ and G₂, the cell prepares for the S- and M-phases of the cell cycle. Cells may temporarily cease to divide and enter a resting or G₀ phase of the cell cycle. The G₁-S checkpoint is a critical phase in the cell cycle, when directions for entering S-phase or committing to apoptosis (programmed cell death) are given.

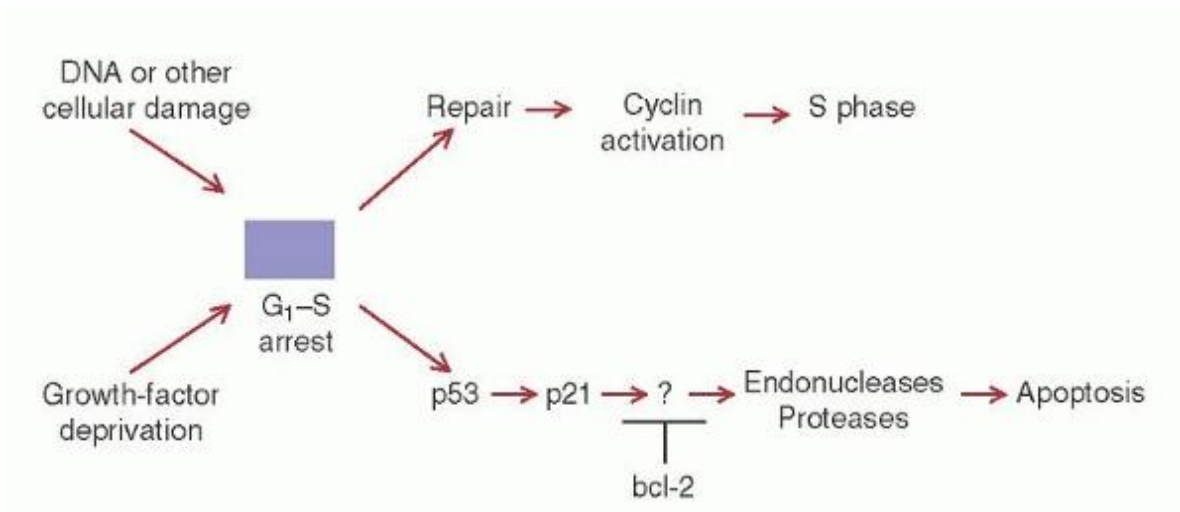

FIGURE 68.3. Potential pathways involved in cytotoxicity induced by chemotherapy. Chemotherapeutic drugs or growth factor deprivation damages cells. Cells are arrested at the G₁-S checkpoint. If the damage is sublethal, it may be repaired

and the cell proceeds to S-phase. If significant DNA damage is present, the process of programmed cell death is initiated. Critical factors, such as p53 and p21 gene products, are required for the cell to undergo apoptosis.

P.1401

Resistance to Anticancer Drugs

The presence of cancer cells that are resistant to chemotherapeutic agents is a common clinical occurrence. It has been postulated that by the time the number of cancer cells reaches 10^3 to 10^6 , a resistant clone has developed.⁷ Unfortunately, there are many ways in which cells can become resistant to an antineoplastic agent. Steps in antineoplastic drug disposition within the cell are represented schematically in Figure 68.4. For an anticancer drug to be active, it must (a) be taken up into a cancer cell and (b) be converted into an active agent. It must then make its way within the cell to its target without being (c) metabolically inactivated, (d) chemically inactivated, or (e) excreted from the cell. Once it interacts with its cellular target, the cell must not be able to (f) alter the target or (g) repair the damage to the target. Finally, (h) mechanisms for apoptosis must be in place, as discussed in the preceding section. Examples of drug resistance at all of these steps have been described.⁸ Not only are there multiple potential mechanisms for drug resistance, but an individual tumor cell can become resistant to a particular drug in many ways. For example, resistance to methotrexate (MTX) has been described in some cell lines with altered folate transport that limits MTX uptake into cells.⁹ In other cell lines, MTX resistance results from the overexpression of the target enzyme, dihydrofolate reductase (DHFR).

Cancer cells may become simultaneously resistant to several types of chemotherapeutic drugs. Cells that express the multidrug resistance gene (MDR) produce a glycoprotein of 170-kDa weight known as p-glycoprotein or p170.⁸ Originally described in 1976, this protein is a drug transporter that sits in the cell wall of resistant tumor cells. P-glycoprotein transports a number of antineoplastic agents, most of which are hydrophobic, including vinca alkaloids, epipodophyllotoxins, anthracyclines, actinomycin, and taxanes. Cells in which the MDR gene is activated develop simultaneous resistance to these antineoplastic agents. The presence of p-glycoprotein on tumor cells has been correlated with poor prognosis in hematologic tumors.¹⁰ Efforts have been directed at inhibiting p-glycoprotein. However, MDR inhibitors often block either the hepatic or renal excretion of anticancer drugs, thereby increasing drug toxicity.¹¹ Clinical effectiveness of these MDR inhibitors has not been demonstrated. Cancer cell lines have been characterized that do not overexpress p-glycoprotein but do display a similar cross-resistance pattern. These lines have different types of transport proteins, such as MDR-related protein (MRP) or breast cancer resistance protein (BCRP). MRP and BCRP, like p-glycoprotein, are members of the adenosine triphosphate (ATP) binding cassette gene superfamily, but are structurally dissimilar to p-glycoprotein and with different inhibitors.^{12, 13} In summary, tumor cells can develop resistance to antineoplastic drugs by numerous mechanisms. Resistance occurs as a result of random mutational changes in a population of cancer cells. Mutations to a drug-resistant cell line are estimated to occur at a population size of 10^4 to 10^6 tumor cells, a size smaller than is clinically detectable. Therefore, drug-resistant cancer cell populations will be present in the majority of tumors at diagnosis. The early presence of resistant tumor cells leads to the rationale for (a) early treatment of cancers to avoid multiple resistant populations and (b) use of multiple agents with differing mechanisms of action.

FIGURE 68.4. Potential pathways for antineoplastic drug disposition in tumor cells. For a drug to be effective, the drug, or its active metabolite, must reach its target site within the cell. Possible steps required for a drug to reach its receptor or to be inactivated include: (1) uptake into a cell through a particular transport protein; (2) enzymatic conversion of the drug to an inactive metabolite; (3) enzymatic conversion of the drug to its active metabolite; (4) binding of an active metabolite by a cellular protein or thiol, thereby inactivating drug; (5) excretion of the drug from the cell via an efflux transport pump; (6) alteration in the genetic makeup of the cell, changing the drug receptor site or number; and (7) changes in the ability of a cell to repair damage of a drug at its receptor.

Drug Toxicity

As opposed to many other classes of drugs, the therapeutic window for chemotherapeutic agents is narrow (Fig. 68.5). The dose of drug needed to achieve adequate tumor cell kill often causes toxicity to normal tissues. For many antineoplastic agents, a sigmoidal curve defining the relationship between toxicity and the dose of drug administered (or the area under the plasma drug concentration [AUC] versus time curve) has been demonstrated. At low drug concentrations, no cytotoxicity is observed. With increasing concentration, cell kill is proportional to dose. At higher concentrations, the effect plateaus. Similar relationships correlating the dose of drug and the antitumor response have also been demonstrated.¹⁴ A positive relationship between the drug dose administered and the tumor response rate has been found for many tumors, including the lymphomas. Higher response rates and an increased chance for cure are achieved with higher doses of selected agents.^{15, 16} For this reason, clinicians generally try to push doses of agents to toxicity to maximize the chance for cure. The optimal dose or AUC for an individual patient with a particular cancer is unknown.

Chemotherapeutic agents cause a wide variety of toxicities (Table 68.1). Myelosuppression and nausea are seen, to some degree, with many anticancer drugs. Nausea and vomiting, although generally self-limited and not life-threatening, are very distressing to patients. The emetogenic potential of antineoplastic

P.1402

agents varies from drug to drug and is dose-dependent¹⁷ (Table 68.2). Serotonin receptors, located within the vagal and splanchnic nerves of the gastrointestinal system and in the brain, are critical in the initiation of nausea by chemotherapeutic agents. The development of specific type 3 serotonin (5-hydroxytryptamine or 5HT₃) receptor blockers,

such as ondansetron, dolasetron, and granisetron, and NK-1 inhibitors, such as aprepitant, has resulted in major improvement in control of chemotherapy-induced emesis.^{17, 18}

FIGURE 68.5. Schematic representation curves relating drug concentrations to response. Antibacterial agents (A) have a wide therapeutic window, with a significant difference in the dose that produces bacterial cell kill and the dose that causes toxicity to normal tissues. For antineoplastic drugs (B), the therapeutic window is narrow (e.g., doses adequate to produce tumor cell kill usually produce toxicity to normal tissues). For a few cancers, such as ovarian (C), the shape of the dose-response curve has been defined.¹⁴ For most tumors, however, a specific dose-response (or AUC-response curve) has not been defined.

Myelosuppression is the most common dose-limiting antineoplastic agent toxicity. The suppression of hematopoietic cell lines is determined by the kinetics of the specific cell line in the peripheral compartment. Anemia occurs as a late effect because of the long half-life of red blood cells (120 days). Thrombocytopenia occurs in an intermediate time frame (platelet half-life 5 to 7 days), whereas granulocyte suppression occurs earliest. Granulocytopenia is a more frequent occurrence than thrombocytopenia or anemia. The white blood cell count usually drops 5 to 14 days after drug administration, with recovery by 7 to 21 days. Several exceptions are recognized, such as a predominant thrombocytopenia seen with carboplatin and delayed myelosuppression with busulfan and the nitrosoureas (occurring 4 to 5 weeks posttherapy). The degree and duration of bone marrow suppression are related directly to the dose of drug administered. High-dose chemotherapy regimens, used with stem cell transplantation, generally result in 10 to 25 days with neutrophils $<500/\text{mm}^3$ and thrombocytopenia lasting for a more extended period. The length of cytopenias depend upon the stem cell source with peripheral blood shorter (10 to 14 days) than bone marrow (20 to 25 days). An increased risk of infectious complications occurs that is related directly to the degree and duration of granulocytopenia.¹⁹ The development of recombinant hematopoietic colony-stimulating factors (CSFs), such as erythropoietin, thrombopoietin, granulocyte-macrophage CSF, and granulocyte-CSF, has shortened the duration of bone marrow suppression but not eliminated it. CSFs are now commonly used prophylactically with regimens expected to produce an incidence of febrile neutropenia $>20\%$. Guidelines for the use of these important, yet expensive, factors are available and should be followed.²⁰

The range of toxicities associated with antineoplastic agents is too great to review in detail in this chapter. Readers are referred to reviews on endocrine,²¹ oral,²² renal,²³ neurologic,²⁴ hepatic,²⁵ pulmonary,²⁶ cardiac,²⁷ and cutaneous²⁸ toxicities of antineoplastic agents. Physicians must also remember that most antineoplastic agents have teratogenic and mutagenic potential. Alkylating agents are the most damaging to testicular and ovarian function. Damage is dependent on

drug dose, the age of the patient (older patients are more likely to experience toxicity), and sex (males more than females).²⁹ Second malignancies (primarily acute leukemia) have been associated with alkylating agents, epipodophyllotoxins, nitrosoureas, and anthracyclines.³⁰ Concomitant radiation therapy increases the risk of second malignancies (such as sarcomas or breast cancer) 5 to 20 years following therapy.

General Pharmacologic Principles

Antitumor activity of an antineoplastic agent is best correlated with the concentration of drug that reaches the site of drug action within the cancer cell (Fig. 68.5A). Several factors may affect what

P.1403

P.1404

happens to a drug following administration until it reaches its site of action (Fig. 68.6). Pharmacokinetics describes what happens to a drug following administration (what the body does to the drug). Pharmacokinetics represents an attempt to predict quantitatively how a patient will handle a given dose of drug.³¹ Important pharmacokinetic parameters include (a) bioavailability or absorption, (b) volume of distribution, (c) clearance or drug elimination, and (d) drug half-life (Fig. 68.7). Pharmacodynamics describes what effect the drug has on a particular tissue (what the drug does to the body).

TABLE 68.1 ANTINEOPLASTIC DRUG TOXICITY

TABLE 68.2 EMETIC POTENTIAL OF SELECTED ANTINEOPLASTIC AGENTS

High (>90% risk)

Carmustine	Dactinomycin
Cisplatin	Mechlorethamine
Cyclophosphamide (>1.5 mg/m ²)	Streptozocin
Dacarbazine	

Moderate (30-90% risk)

Alemtuzumab	Doxorubicin
Azacytidine	Epirubicin
Bendamustine	Idarubicin
Carbazitaxel	Ifosfamide
Carboplatin	Irinotecan
Clofaribine	Methotrexate (>250 mg/m ²)
Cyclophosphamide (>1.5 g/m ²)	Oxaliplatin
Cytarabine (>1 g/m ²)	Pralatrexate
Daunorubicin	Temozolomide

Low (10-30% risk)

Bortezomib	Mitomycin
Cytarabine (<1 g/m ²)	Mitoxantrone
Docetaxel	Paclitaxel
Eribulin	Panitumumab
Etoposide	Pegylated liposomal doxorubicin
5-Fluorouracil	Pemetrexed
Chlorambucil	Romidesin
Gemcitabine	Temsirolimus
Ixabepilone	Topotecan
Hydroxyurea	Trastuzumab
Melphalan	Vorinostat
Methotrexate (<250 mg/m ²)	

Minimal (<10% risk)

Bevacizumab	2-Chlorodeoxyadenosine
-------------	------------------------

Bleomycin	Fludarabine
Busulfan	Rituximab
Cetuximab	Vinca alkaloids

Bioavailability, the percentage of a dose of drug that reaches the plasma compartment, defines drug absorption (Fig. 68.7). Drugs given intravenously have, by definition, 100% bioavailability. Factors that decrease the bioavailability of orally administered drugs include poor solubility in aqueous solutions or metabolism of the drug by the intestine or liver before entry into the systemic circulation (first-pass effect). Bioavailability of poorly soluble drugs, such as etoposide, decreases at high oral drug doses.³² Bioavailability of orally administered 6-mercaptopurine (6-MP) and 5-fluorouracil is low because of extensive first-pass hepatic drug metabolism.^{33, 34} With poor or widely variable bioavailability of a particular agent, an intravenous route of administration is preferred. The most important factor regarding bioavailability is the variation from patient to patient in the amount of oral drug absorbed (coefficient of variation). If bioavailability of an oral anticancer drug were 50% in all patients, simply doubling the drug dose would produce an equivalent response to intravenously administered drug. However, the variation from patient to patient in the AUC achieved is usually greater with oral than with intravenously administered drug.³⁵ Therefore, variation in toxicity is also greater.

After a drug reaches the bloodstream, it is distributed into tissues. Figure 68.8 illustrates a plasma concentration-versustime curve for a drug with a typical two-phase (distribution and elimination) decline in plasma concentration. Distribution may be affected by drug binding to plasma proteins (usually albumin or α_1 -acid glycoprotein). Only free drug is biologically active. Decreasing the amount of bound drug by having a low serum albumin concentration or displacing drug from its binding site may increase toxicity (as seen with etoposide).³⁶ Distribution of drug into a "third space," such as ascites or a pleural effusion, may slow clearance and increase toxicity, as is noted with MTX.³⁷

Clearance is expressed as the volume of biologic fluid (usually plasma) from which a drug can be removed per unit of time. Clearance of most drugs is constant over a range of plasma concentrations, which means that the mechanism for elimination is not saturated. However, some drugs, such as paclitaxel, demonstrate saturable elimination at high plasma concentrations.³⁸ This means that a greater proportional drug effect is noted when high drug doses are employed. Clearance measurements allow physicians to maintain a particular plasma concentration because the dosage rate = clearance \times desired plasma concentration.

Removal of drugs from the circulation occurs primarily by metabolism, renal elimination, or hepatic excretion. If urinary excretion is an important route of elimination, renal failure results in slower removal of the drug from the body. Administration of the usual dosage of a drug cleared by the kidney to a patient with renal insufficiency leads to greater drug accumulation and an increased likelihood of toxicity. In such cases, drug dosage needs to be modified to prevent excess toxicity. Using available data on drug clearance, the appropriate dose in renal insufficiency may be calculated as follows: Dose in renal insufficiency = normal dose \times (clearance in renal insufficiency \div normal clearance)

In contrast to a predictable decline in renal drug clearance when glomerular filtration is reduced, it is not possible to make a general prediction of the effect of liver disease on hepatic biotransformation of drugs. Even in advanced hepatocellular disease, the magnitude of impairment in drug clearance usually is only two- to fivefold. The extent of such changes cannot be predicted by common tests of liver function. Consequently, even when it is suspected that drug elimination is altered in liver disease, there is no quantitative base on which to adjust the dosage regimen other than assessment of clinical response. Antineoplastic drugs for which dose modifications are indicated for renal or hepatic insufficiency are listed in Table 68.3.

The hepatic metabolism of drugs may be altered by genetic deficiency of a metabolizing enzyme or by inhibition of metabolism by another drug. Pharmacogenomics is the study of how a particular patient's genetic makeup affects drug metabolism. It is now recognized that some patients inherit a mutated gene which produces an inactive or much less active enzyme important in clearing a drug from the body.³⁹ Such patients have a markedly lower drug clearance and a higher incidence of toxicity. Examples include the inherited deficiencies of dihydropyrimidine dehydrogenase, the enzyme that degrades 5-fluorouracil⁴⁰; UGT1A1, the enzyme that inactivates irinotecan⁴¹; and thiopurine methyltransferase, the enzyme that degrades azathioprine and 6-MP.⁴²

FIGURE 68.6. Schematic representation of drug disposition in the body. For a drug to function, it must be taken into the body (1) and the drug must avoid being cleared from the body by metabolism (2) or excretion (5). It must reach its site of action in active form (3), without being inactivated by protein binding (4).

Certain antineoplastic drugs are metabolized by the hepatic P-450 microsomal enzyme system (vincas, epipodophyllotoxins, cyclophosphamide, tyrosine kinase inhibitors, and the taxanes). The activity of the microsomal enzyme systems may be increased with concomitant use of phenobarbital, phenytoin, or other drugs. Use of anticonvulsants has been shown to increase the catabolism of teniposide, a drug eliminated from the body through hepatic microsomal metabolism.⁴³ Clearance of drugs metabolized by the hepatic P-450 enzyme system, such as paclitaxel or Taxotere, can be decreased with concomitant use of P-450 inhibitors, such as ketoconazole or selected antiretroviral agents.

It is important to recognize the unpredictable variation in the way chemotherapeutic drugs are handled by the body. Mean values for bioavailability, clearance, and volume of distribution of anticancer agents have standard deviations of 20%, 50%, and 30%, respectively. This means that target drug concentrations may vary widely from patient to patient, even those whose renal and hepatic function appears similar. This is particularly important for drugs with a low therapeutic index and necessitates that all patients receiving chemotherapy must be carefully monitored.

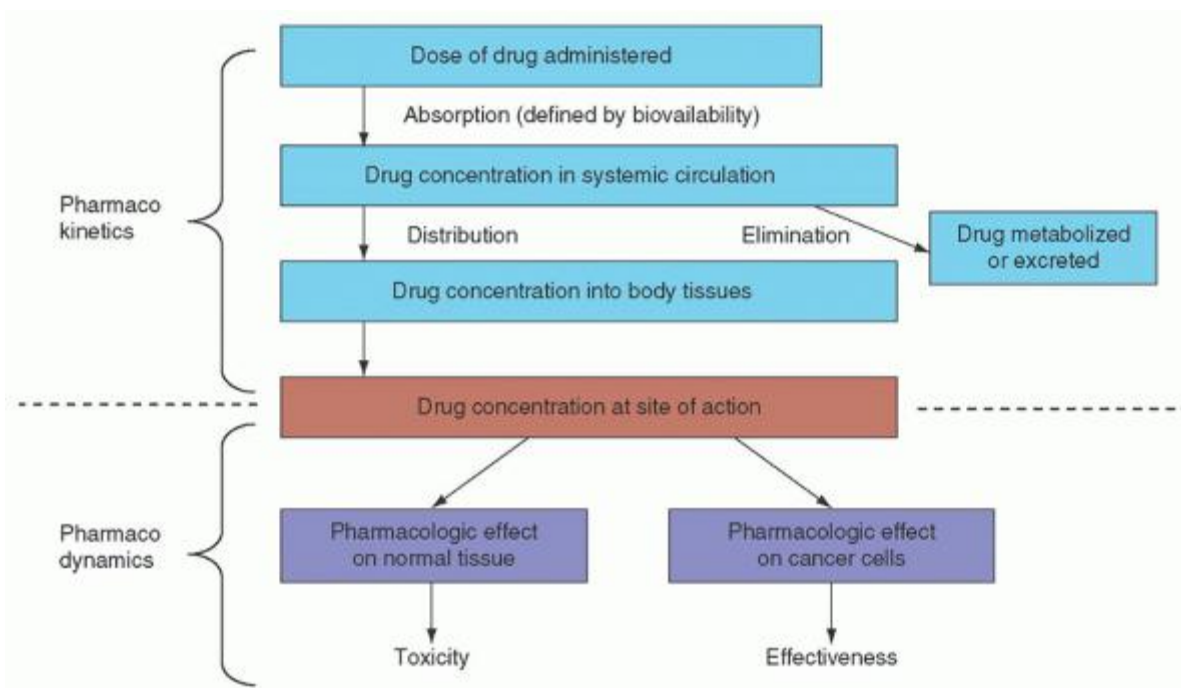

FIGURE 68.7. Pathway of a drug administered to a patient. Pharmacokinetics describes what the patient's body does to a drug. Pharmacodynamics describes what the drug does to the patient's tissues or cancer cells.

Approach to the Patient with Cancer

Before initiating cancer chemotherapy, a physician should (a) verify the accuracy of the diagnosis, (b) understand the natural history of the illness, and (c) identify, with the patient, the goals of therapy. Verification of the diagnosis, in nearly every case, requires histologic documentation of cancer. Once the diagnosis is established, the physician and patient must decide whether cure is possible or palliation is the optimal goal. If cure is the goal, the patient and physician may be willing to tolerate more severe toxicity. The patient must be a partner in such decisions. In many cases, several options may be reasonable and an informed patient can direct the physician as to whether intensive, potentially toxic therapy should be tried for a relatively small chance of cure.^{44, 45}

P.1406

Fortunately, curative therapy, even for disseminated disease, is available for many hematologic malignancies, including Hodgkin and non-Hodgkin lymphomas, and acute and chronic leukemia. In some illnesses, such as chronic lymphocytic leukemia and low-grade lymphomas, curative therapy may not be available, but the disease is often indolent. A discussion of these illnesses and their natural histories can reassure patients and help them understand why chemotherapy is not being immediately initiated. If high-dose, aggressive curative chemotherapy is planned, patients and their families need to be aware of anticipated and potential toxicities.

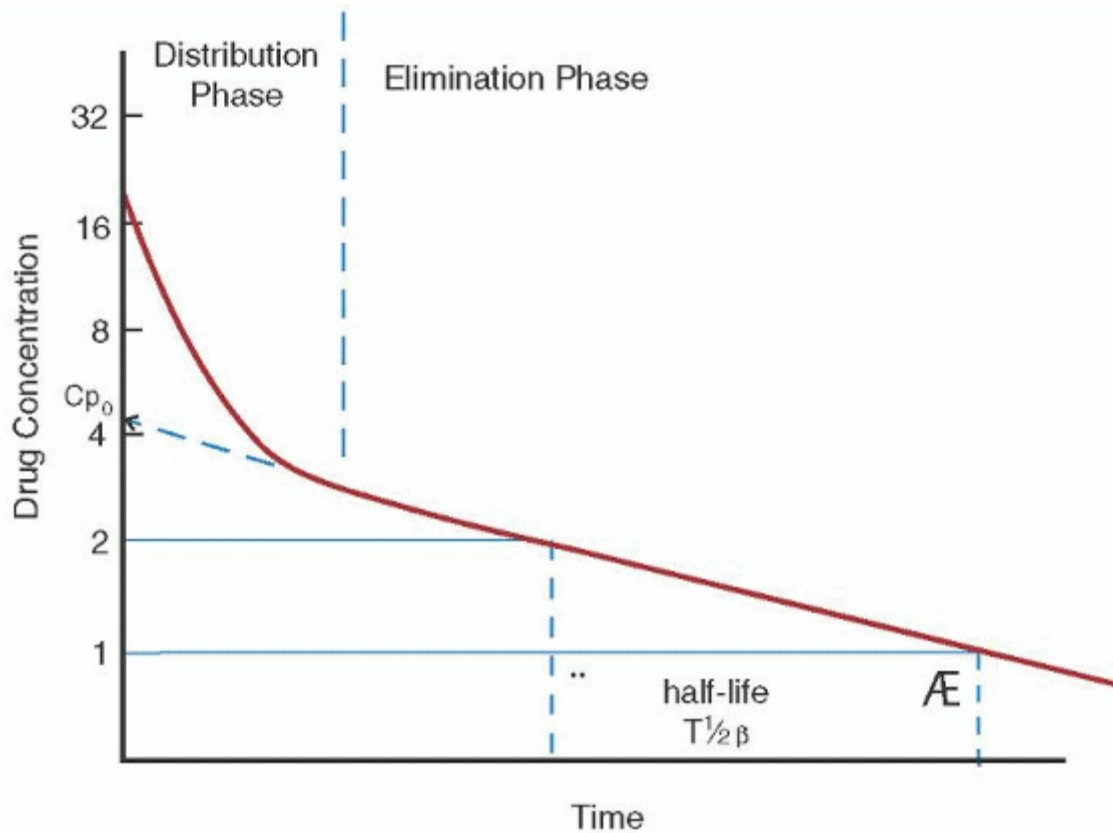

FIGURE 68.8. Plasma concentrations of a typical drug at various times following intravenous administration. Following an early distribution phase, drug concentrations decrease in a log-linear manner. C_{p0} is the hypothetical drug plasma concentration at time zero if equilibrium were achieved instantaneously. The drug's half-life is the time required for its concentration to decrease by half.

TABLE 68.3 DRUGS REQUIRING DOSE ALTERATIONS FOR ORGAN TOXICITY

Nephrotoxicity	Hepatic Toxicity
Arsenic trioxide	Bortezomib
Bleomycin	Cytarabine
Capecitabine	Daunorubicin ^a
Carboplatin ^a	Doxorubicin ^a
Cisplatin ^a	Docetaxel ^a
Cladribine	Epirubicin ^a
Cyclophosphamide (if CrCl < 20 ml/min)	Etoposide
Daunorubicin ^a	Everolimus
Deoxycoformycin	5 Fluorouracil
Etoposide	Idarubicin
Fludarabine	Imatinib
Hydroxyurea	Irinotecan ^a
Ifosfamide	Ixabepilone
Irinotecan	Nilotinib

Lenalidomide	Paclitaxel ^a
Methotrexate ^a	Procarbazine
Mithramycin	Temsirolimus
Mitomycin ^a	Vinblastine ^a
Nitrosoureas ^a	Vincristine ^a
Oxaliplatin (if CrCl < 20 ml/min)	Vinorelbine ^a
Pemetrexede	
Pentostatin	
Sorafenib	
Streptozocin	
Topotecan ^a	
Vandetanib	

^a Major dose adjustment.

The use of chemotherapy for treatment of an individual requires a detailed knowledge of the patient, including his or her medical and psychological status, specific knowledge of the drugs to be used, and the availability of appropriate laboratory and hospital support services. Combination chemotherapy (use of several drugs simultaneously) is usually employed and multiple cycles of drugs administered to achieve adequate tumor cell kill without life-threatening toxicity or the development of tumor cell resistance. Certain patient selection factors are important in planning treatment. Age alone is seldom a reason to exclude patients from chemotherapy.⁴⁶ However, age-related changes in organ function, including reduced marrow reserve, abnormal liver function tests, and decreased renal function, are commonly seen and may increase the risk of toxicity. The performance status of a patient (either Karnofsky or American Joint Committee on Cancer scale) usually correlates with response and tolerance to chemotherapy (Table 68.4).

The nutritional state of a patient is important. Malnourished patients with hypoalbuminemia may have increased toxicity when highly protein-bound drugs are used.³⁶

Guidelines for dosing of chemotherapy drugs in obese patients have been developed.⁴⁷ Doses based on actual body weight are generally recommended, as myelosuppression is the same or less pronounced in the obese than the non-obese cancer patient given full-weight-based doses. Fixed dosing of carboplatin, vincristine, and bleomycin is appropriate. Altered organ function may eliminate the opportunity to use certain drugs (e.g., doxorubicin in patients with heart failure or bleomycin in patients with severe pulmonary toxicity). Drug doses may require modification for decreases in blood counts (Table 68.5) and also for changes in renal and hepatic function (see General Pharmacologic Principles).

It is common to re-evaluate patients after two to four cycles of chemotherapy to determine treatment effectiveness. If a response is seen, therapy is usually continued for a set number of courses or two cycles past a complete response. If tumor progression is noted, therapy should generally be discontinued. For patients with stable disease, an assessment of drug toxicity is important. If therapy is tolerable, a decision to continue treatment is reasonable, with the understanding that disease progression will eventually occur. Physicians administering potentially toxic chemotherapy must make certain that they have appropriate monitoring and support facilities available for their patients in the event of untoward toxicity.

DRUGS USED TO TREAT CANCER

A comprehensive review of the pharmacology of all chemotherapeutic agents is beyond the scope of this chapter. This section focuses on those agents most commonly used in the therapy of hematologic malignancies. Important information necessary for the optimal use of these drugs requires knowledge of their (a) mechanism of action; (b) pharmacology, including bioavailability, routes of elimination, and important drug interactions; and (c) toxicities. Table 68.6 summarizes this information for the majority of antineoplastic agents. A more detailed review of the agents commonly used to treat hematologic malignancies follows.

TABLE 68.4 KARNOFSKY AND AMERICAN JOINT COMMITTEE ON CANCER (AJCC) PERFORMANCE STATUS SCALES

Karnofsky Description	Karnofsky Scale (%)	AJCC Scale	AJCC or ECOG Description
Normal; no complaints; no evidence of disease		1000	Normal activity
Able to carry on normal activity; minor signs or symptoms of disease	90		
Normal activity with effort; some signs or symptoms of disease	80	801	Symptomatic and ambulatory; cares for self
Cares for self; unable to carry on normal activity or to do active work	70		
Requires occasional assistance but is able to care for most of own needs	60	602	Ambulatory >50% of time; occasionally needs assistance
Requires considerable assistance and frequent medical care	50	503	Ambulatory 50% or less of time; nursing care needed less of time
Disabled; requires special care and assistance	40		
Severely disabled; hospitalization indicated although death not imminent	30		
Very sick; hospitalization necessary; active supportive treatment necessary	20	204	Bedridden; may need hospitalization
Moribund, fatal processes progressing rapidly	10		
Dead	0		

Alkylating Agents (Actinomycin-D, Bendamustine, Busulfan, Chlorambucil, Cyclophosphamide, Dacarbazine, Hexamethylmelamine, Ifosfamide, Melphalan, Mechlorethamine, Mitomycin C, Nitrosoureas (BCNU, CCNU), Procarbazine, Streptozocin, Temozolomide, Thiotepea)

Mechanism of Action

Alkylating agents covalently bind alkyl groups (one or more saturated carbon atoms) to cellular molecules, including DNA, RNA, and proteins. Alkylating agents form reactive carbonyl groups in plasma and within tissues. Attack at electron-rich sites on adenine or guanine (S_N1 agents) in DNA is the primary mechanism for cytotoxicity.⁴⁸ The pattern of DNA lesions generated by an alkylating agent depends on the number of reactive sites within the alkylating agent, its particular reactivity, the type of alkyl group addition (methyl or chloroethyl) and the DNA substrate (double- or single-strand). Many alkylating agents (bendamustine, chlorambucil, cyclophosphamide, ifosfamide, mustard, melphalan) contain two reactive nitrochloroethyl groups, which allow them to react with both strands of DNA, forming cross-linkage (Fig. 68.9). Other agents (procarbazine, dacarbazine, temozolomide) produce single-strand alkylation. Most alkylators preferentially attack the N^7 position of guanine. Nitrosoureas, procarbazine, and dacarbazine (DTIC) attack the O^6 position. Depending on the site of DNA binding, the base adducts produced by alkylating agents block DNA replication and transcription, leading to cell death. However, alkylating agents may also compromise genome integrity, inducing mutagenesis. Alkylating agents are cell cycle-nonspecific.

TABLE 68.5 GENERALIZED DOSE ADJUSTMENT GUIDELINES FOR HEMATOLOGIC TOXICITY^a

100% Dose	75% Dose	50% Dose	Omit
------------------	-----------------	-----------------	-------------

Granulocyte	>2,000	1,500-1,999	1,000-1,499	<1,000
White blood cell	>3,500	3,000-3,500	2,500-2,999	<2,500
Platelet	>100,000	75,000-100,000	50,000-75,000	<50,000

“In selected circumstances, such as the treatment of leukemia, these guidelines do not apply. Specific guidelines accompanying individual protocols should be sought.

There are multiple enzymes that have been identified that can repair the genomic damage caused by alkylating agents.⁴⁸ An example is the repair of alkylation sites on DNA by O⁶ methyl transferase; the overexpression of this enzyme in a cancer cell produces resistance to nitrosoureas but not to nitrogen mustard or cyclophosphamide.⁴⁹ An imbalance of any one repair enzyme can increase or decrease the alkylation sensitivity of a cell. Inhibitors of DNA-repair enzymes (such as Poly ADP ribose polymerase or PARP) may increase cell sensitivity to alkylating agents.

The most widely used alkylating agents in hematology are the nitrogen mustards: mechlorethamine, cyclophosphamide, ifosfamide, melphalan, and chlorambucil. Thiotepea is an aziridine that is closely related to the mustards. Busulfan is an alkyl sulfonate that has a poorly understood selective toxicity for myeloid precursors. Procarbazine and DTIC are metabolized to reactive intermediates that decompose to produce methyl diazonium, which covalently binds DNA. The basis of cytotoxicity of these nonfunctional alkylating agents is probably the formation of DNA strand breaks and inhibition of DNA polymerase.⁵⁰ Bendamustine, a recently FDA-approved alkylating agent for treatment of chronic lymphocytic leukemia and lymphomas, regulates different genes compared to other alkylating agents.⁵¹ It is not cross resistant with other alkylators and is effective against both quiescent and dividing cells. It produces more durable and extensive DNA double-strand breaks than do cyclophosphamide or melphalan.

Cellular thiols can provide nucleophilic targets, which bind alkylating agents before they reach their DNA target. Increasing or decreasing the concentration of thiols can decrease or increase antineoplastic drug activity and/or toxicity. Buthione sulfonamide (BSO) decreases glutathione synthesis (a naturally occurring thiol) and increases alkylating agent cytotoxicity.⁵² Amifostine (WR2721) provides an exogenous nucleophilic thiol that can decrease alkylating agent toxicity.⁵³

P.1408

TABLE 68.6 CHEMOTHERAPEUTIC AGENTS (EXCLUDING HORMONAL AGENTS)

Name (Synonym)	Drug Class	Action	Clearance Route^a	Major Toxicity
Alemtuzumab (Campath [®])	Radioactive monoclonal antibody	Binds to CD ₅₂ to target radioactivity	Radioactive extinction	Myelosuppression Hypersensitivity reaction Infection
Altretamine (Hexalen [®] , hexamethylmelamine)	Nonclassical alkylating agent	Unknown, may alkylate DNA	Hepatic metabolism	Hypersensitivity reaction, deficient synthesis of key proteins (clotting factors, insulin), CNS depression, pancreatitis
Anagrelide (Agrylin [®])	Phospholipase inhibitor	Prevents megakaryocytes from maturing	Metabolism via CYP/A2	Palpitations, headache, nausea, abdominal pain, dizziness
Arsenic trioxide (Trisenox [®] , ATO)	Targeted drug	Degrades PML-RAR fusion protein	Hepatic metabolism	APL differentiation syndrome, Q-T prolongation, nausea,

Asparaginase (Elspar [®] , Oncaspar [®] , pegasparaginase)	Enzyme	Breaks down the amino acid asparagine; sensitive lymphocytes lack ability to synthesize asparagine	Hepatic metabolism	fatigue N&V, neurotoxicity, myelosuppression, diarrhea, diabetes, anticoagulation
Azacitidine (Vidaza [®])	Hypomethylating agent	Inhibitor of DNA methylation	Hepatic metabolism	Myelosuppression
Bexarotene (Targretin [®])	Retinoid	Binds to the retinoid X receptor to induce cellular differentiation	Oxidative hepatic metabolism	Hepatotoxicity, hyperlipidemia, hypothyroidism, photosensitivity, teratogenicity
Bendamustine (Trenda [®])	Alkylating agent	Forms DNA cross-links	Hydrolysis in plasma to inactive metabolites	Nausea, fatigue, myelosuppression, fever
Bevacizumab (Avastin [®])	Monoclonal antibody to VEGF	Decreases angiogenesis	Protein degradation	Hypertension, headache, bleeding, thrombosis, proteinuria
Bleomycin (Blenoxane [®])	Antibiotic	Single-strand DNA breaks	Renal	Hypersensitivity reaction, pulmonary fibrosis, skin and mucocutaneous reactions, fevers
Bortezomib (Velcade [®])	Proteasome inhibitor (targeted agent)	Inhibits protein destruction blocking NFK- β	Oxidative hepatic metabolism	Nausea, fatigue, diarrhea, peripheral neuropathy, thrombocytopenia
Brentuximab vedotin	Monoclonal antibody	Binds with CD30 antigen with toxin then internalized	Hepatic	Hypersensitivity reaction, neuropathy, fatigue, fever, diarrhea, neutropenia
Busulfan (Myleran [®] , Busulfex [®])	Alkylating agent	Forms DNA cross-links.	Metabolism	Myelosuppression, hepatotoxicity (venoocclusive disease), pulmonary fibrosis
Capecitabine (Xeloda [®])	Antimetabolite	A 5-FU prodrug	Hepatic metabolism	Diarrhea, myelosuppression, palmar-plantar erythrodysesthesia

Carboplatin (CBDCA, Platinum complex Paraplatin [®])		Produces DNA cross-links	Renal	Thrombocytopenia, leukopenia, nephrotoxicity, ototoxicity, neuropathy, N&V
Carmustine (BCNU)	Nitrosourea	Alkylates DNA at O ⁶ position of guanine	Hepatic metabolism	Delayed (4-6 wk) myelosuppression, pulmonary toxicity, hepatotoxicity
Cetuximab (Erbix [®])	Monoclonal antibody	Binds to the epidermal growth factor receptor	Binding of antibody to receptor	Anaphylactic reaction, skin rash, fevers
Chlorambucil (Leukeran)	Alkylating agent	Cross-links DNA	Metabolism	Myelosuppression, pulmonary toxicity, hepatotoxicity
Cisplatin (CDDP) (Platinol [®])	Platinum complex	Produces DNA cross-links	Protein binding	Nephrotoxicity, N&V, ototoxicity, alopecia, neuropathy
Cladribine (Leustatin TM) (2-chlorodeoxy adenosine)	Antimetabolite (purine analog)	Incorporation into DNA; NAD consumption	Renal	Myelosuppression, fever, renal toxicity (high-dose)
Clofarabine (Clolar [®])	Antimetabolite	Incorporates into DNA; inhibits DNA polymerase	Renal	Nausea, hepatotoxicity, palmar-plantar erythrodysesthesia
Cyclophosphamide (Cytosan [®] , Neosar [®])	Alkylating agent	Cross-links DNA strands	Hepatic metabolism (renal)	Myelosuppression, N&V, cystitis, cardiac (high-dose)
Cytarabine (Cytosar [®] , ara-C, cytosine arabinoside, DepoCyt TM)	Antimetabolite (pyrimidine analog)	Incorporates into DNA; inhibits DNA polymerase	Hepatic metabolism	Myelosuppression, N&V, mucositis, ocular, hepatic
Dacarbazine (DTIC)	Nonclassical alkylating agent	DNA methylation	Renal (hepatic metabolism)	Vesicant, myelosuppression, N&V, hepatic
Dactinomycin (Cosmegen [®]) (actinomycin-D)	Antibiotic	DNA intercalation	Biliary	Myelosuppression, N&V, vesicant, mucositis
Dasatinib (Sprycel TM)	Targeted agent, signal transduction inhibitor	Inhibits the tyrosine kinase of several growth factor receptors including bcr-abl	Hepatic metabolism (CYP 3A4) and biliary excretion	Fluid retention, N&V, diarrhea, myelosuppression, hypothyroidism

Daunorubicin (Cerubidine [®] , DaunoXome [®])	Antibiotic (anthracycline)	Topoisomerase inhibition, DNA intercalation, free-radical formation	Biliary excretion, hepatic metabolism	Myelosuppression, N&V, cardiomyopathy, vesicant, red urine, mucositis
Decitabine (Dacogen [®])	Hypomethylating agent	Allows activation of tumor suppressor genes	Hepatic deamination	Myelosuppression, fatigue, nausea, teratogen
Denileukin diftitox (Ontak [®])	Toxin-fusion protein	Binds to the IL-2 receptor, where the diphtheria toxin is internalized	Proteolytic degradation	Infusion reactions (fever, hypotension, myalgias), skin rash, transaminitis, vascular leak syndrome, hypothyroidism
Docetaxel (Taxotere [®])	Tubulin binder	Mitotic spindle inhibitor	Hepatic metabolism, biliary excretion	Myelosuppression, hypersensitivity (steroids needed), fluid retention, neuropathy
Doxorubicin (Adriamycin [®] , Rubex [®] , Myocet [™] , Doxil [®])	Topoisomerase inhibitor (Anthracycline)	Topoisomerase inhibition, free-radical formation	Biliary excretion, hepatic metabolism	Myelosuppression, N&V, cardiomyopathy, vesicant, red urine, mucositis
Epirubicin (Ellence [™])	Topoisomerase inhibitor (Anthracycline)	Inhibits topoisomerase II	Hepatic metabolism and excretion	Nausea, vomiting, myelosuppression, cardiac toxicity
Erlotinib (Tarceva [®])	Targeted agent	Inhibits the tyrosine kinase of the epidermal growth factor receptor	Hepatic oxidative metabolism	Skin rash, diarrhea
Etoposide (VePesid [®] , VP-16, Etopophos [®] , Toposar [®] , etoposide phosphate)	Topoisomerase inhibitor	Inhibits topoisomerase II	Renal (hepatic metabolism)	Myelosuppression, mucositis, hypersensitivity reaction
Everolimus (Affinitor [®])	Targeted therapy	Blocks oncogenic pathway through m-TOR inhibition	Hepatic metabolism through CYP3A4	Edema, rash, stomatitis, diarrhea, myelosuppression, infection
Fludarabine (fludarabine phosphate, Fludara [®])	Antimetabolite (purine analog)	Inhibits DNA polymerase, incorporation into DNA and RNA, NAD depletion	Renal	Myelosuppression, mucositis, hypersensitivity reaction, neurologic

Fluorouracil (5-FU, Adrucil [®] , FUDR [®])	Antimetabolite (pyrimidine analog)	Inhibits thymidylate synthetase, incorporated into DNA and RNA	Hepatic metabolism	Myelosuppression (more with bolus), diarrhea & mucositis (more with continuous infusion), stomatitis, cardiac ischemia, CNS (cerebellar ataxia)
Gefitinib (Iressa [®])	Targeted therapy	Block the tyrosine kinase of EGFR	Hepatic metabolism via CYP3A4	Rash, diarrhea
Gemcitabine (Gemzar [®])	Antimetabolite	Inhibits ribonucleotide reductase, incorporated into DNA as false nucleotide	Metabolism	Myelosuppression, nausea, diarrhea, hepatic, fever
Hydroxyurea (Hydrea [®] , Droxia [™] , Mylocel [™])	Antimetabolite	Inhibits ribonucleotide reductase	Hepatic metabolism, renal	Myelosuppression, mucositis
Idarubicin (Idamycin [®])	Topoisomerase inhibitor (anthracycline)	Similar to doxorubicin	Hepatic	Similar to doxorubicin
Ifosfamide (Ifex [®])	Alkylating agent	Cross-links DNA strands through alkyl groups	Hepatic metabolism, renal excretion.	Myelosuppression, N&V, neurologic, alopecia, cystitis (must be given with MESNA)
Imatinib mesylate (Gleevec [™] , STI-575)	Targeted agent	Inhibits the tyrosine kinase of the bcr-abl and c-kit oncogenes	Hepatic metabolism	Nausea, diarrhea, fluid retention, abnormal LFTs, hypothyroidism
Interferon- α (INF- α , Intron A [®] , Roferon [®])	Biologic	Degradation of messenger RNAs, modulation of oncogene expression, increase in NK cells and other immunoregulatory elements	Renal metabolism	Fever, chills, myalgias, headache, fatigue, anorexia, myelosuppression, hepatic, CNS, depression
Ibritumomab (Zevalin [™])	Monoclonal antibody	Antibody to CD20 coupled to Y ⁹⁰	Radioactive decay	Myelosuppression, allergic reactions, hypothyroidism
Irinotecan (Camptosar [®] , CPT-11)	Topoisomerase I inhibitor	Inhibits topoisomerase I	Metabolism, biliary excretion	Myelosuppression, diarrhea, pneumonitis,

				stomatitis
Lenalidomide (Revlimid [®])	Immunomodulator	Uncertain—possible TNF- α inhibitor; inhibits angiogenesis	Renal	Teratogenicity, myelosuppression, DVTs, diarrhea, fatigue
Lomustine (CeeNU [®] , CCNU)	Alkylating nitrosourea	Same as carmustine	Same as carmustine	Same as carmustine
Mechlorethamine (nitrogen mustard, Mustargen [®])	Alkylating agent	Cross-links DNA via alkylation	Tissue binding	Vesicant, ototoxicity, myelosuppression, N&V
Melphelan (Alkeran [®] , L-PAM, phenylalanine mustard)	Alkylating agent	Cross-links DNA strands via alkylation	Spontaneous degradation, protein binding	Myelosuppression, pulmonary fibrosis (rare), N&V (high-dose)
Mercaptopurine (6-MP, Purinethol [®])	Antimetabolite (purine analog)	Incorporation into DNA	Hepatic metabolism	Myelosuppression, hepatotoxicity
Methotrexate (MTX)	Antimetabolite (folic acid analog)	Inhibits dihydrofolate reductase with decreased thymidylate and protein synthesis	Renal excretion	Myelosuppression, mucositis, hepatotoxicity (chronic low-dose), renal (high-dose), pulmonary
Mitomycin (Mutamycin [®])	Antibiotic	Cross-links DNA strands	Hepatic metabolism	Myelosuppression, N&V, vesicant, pulmonary, hepatic, renal
Mitoxantrone (Novantrone [®] , DHAD)	Anthraquinone	Similar to doxorubicin	Hepatic metabolism	Similar to doxorubicin, blue-green urine
Nelarabine (Arranon [®])	Antimetabolite (purine analog)	Incorporated into DNA and blocks DNA replication	Hepatic demethylation	Neurotoxicity including somnolence, fatigue, dizziness, headache, myelosuppression
Nilotinib (Tasigna [®])	Targeted therapy	Inhibits the tyrosine kinase of BCR/ABL	Hepatic metabolism via CYP3A4	Myelosuppression, QT prolongation, N & V, hepatic toxicity, edema
Ofatumumab (Arzerra [®])	Monoclonal antibody	Binds to CD20	Proteolytic degradation	Infusion reaction, infection, myelosuppression, HBV reactivation
Oxaliplatin (Eloxatin [®])	Platinum complex	Produces DNA cross-links	Renal and tissue binding	Hypersensitivity reaction, neuropathy,

				hepatitis, pulmonary fibrosis
Paclitaxel (Taxol [®] , Abraxane [®])	Plant alkaloid	Mitotic spindle inhibitor, stabilizes microtubulin.	Hepatic metabolism, biliary excretion	Myelosuppression, hypersensitivity syndrome (use with steroids and antihistamines), mucositis, neuropathy, myalgia
Panitumumab (Vectibix [™])	Monoclonal antibody	Binds to EGFR	Proteolytic degradation	Rash, infusion reaction, diarrhea
Pazopanib (Votrient [®])	Targeted agent	Inhibits the TKI of VEGF receptors	Hepatic metabolism via CYP3A4	Hypertension, hair color change, diarrhea, myelosuppression, QT prolongation, hepatotoxicity
Pemetrexed (Alimta [®])	Antimetabolite	An antifolate that inhibits dihydrofolate reductase, and thymidylate synthetase	Renal	Myelosuppression, fatigue, N&V
Pentostatin (Nipent [®] , 2-deoxycoformycin)	Antimetabolite (purine analog)	Adenosine deaminase inhibitor.	Renal	Myelosuppression, fever, rash, hepatotoxicity, pulmonary, CNS
Prelatexate (Folotyn [®])	Antimetabolite	Inhibits DHFR (see methotrexate)	Renal	Myelosuppression, mucositis
Procarbazine (Matulane)	Nonclassical alkylating agent	Alkylates DNA; DNA strand breaks	Hepatic metabolism	Myelosuppression, N&V, CNS (confusion, depression), MAO inhibition, hepatic, pulmonary
Rituximab (Rituxan [®])	Monoclonal antibody	Binds to CD20 on lymphocytes and initiates complement-mediated cytotoxicity	Proteolytic degradation	Fevers, hypersensitivity reaction, Hepatitis B reactivation, infection
Sorafenib (Nexavar [®])	Targeted therapy	Inhibits the tyrosine kinase of VEGFR, PDGFR, c-kit, and FLT-3	Hepatic metabolism: Oxidation and glucuronidation	Fatigue, palmar-plantar erythrodysesthesia, hypertension, hyperphosphatemia, rash proteinuria

Streptozocin (Zanosar [®])	Alkylating nitrosourea	Methylation of O ⁶ -guanine of DNA	Renal	Myelosuppression, N&V, renal, diabetes, vesicant
Sunitinib (Sutent [®])	Targeted therapy	Inhibits the tyrosine kinases of VEGFR, PDGFR, c-kit; inhibits angiogenesis	Hepatic oxidative metabolism	Hypertension, bleeding, diarrhea, mucositis, fatigue
Temozolomide (Temodar [®])	Atypical alkylating agent	Methylates DNA guanine resulting in strand breaks	Metabolism by hydrolysis	Myelosuppression, N & V, fatigue
Teniposide (VM-26, Vumon [®])	Microtubulin inhibitor	Binds to topoisomerase II, causing DNA strand breaks	Hepatic metabolism	Myelosuppression, hypersensitivity reactions
Temsirolimus (Torisel [®])	Targeted agent	Inhibits m-TOR	Hepatic metabolism and biliary excretion	Edema, hyperlipidemia, myelosuppression, hepatic toxicity, hyperglycemia
Thalidomide (Thalomid [®])	Immunomodulatory agent	Suppresses TNF, blocks angiogenesis, increases IL2 and interferon	Nonenzymatic hydrolysis	Birth defects, thrombosis, fatigue, somnolence, neuropathy
Thioguanine (6-thioguanine, 6-TG, Tabloid [®])	Antimetabolite (purine analog)	Incorporates into DNA as fraudulent nucleotide	Hepatic metabolism	Myelosuppression, hepatic venoocclusive disease
Thiotepa (Thioplex [®])	Alkylating agent	Trifunctional alkylating agent, cross-links DNA	Metabolism	Myelosuppression, stomatitis
Topotecan (Hycamtin [®])	Topoisomerase I inhibitor	Inhibits the enzyme topoisomerase I, causing DNA stand breaks	Renal	Myelosuppression, N&V
Tositumomab (Bexxar [®])	Monoclonal antibody	Radioactive drug that binds to CD20	Proteolytic degradation	Myelosuppression, fever, nausea, hypersensitivity reaction
Trastuzumab (Herceptin [®])	Monoclonal antibody	Binds to the Her2 ^{neu} oncogene, resulting in apoptosis	Protein binding and proteolytic degradation	Hypersensitivity reaction, cardiomyopathy, fever, diarrhea
Tretinoin (ATRA, Vesanoind [®])	Targeted retinoid therapy	Induces maturation of promyelocytes	Hepatic oxidative metabolism and	Fever, dyspnea, pulmonary infiltrates (retinoic acid)

				glucuronidation syndrome), headache, fever, neurologic, hepatic
Venmurafanib (Zelboraf [®])	Targeted agent	Inhibits the tyrosine kinase of the BRAF oncogene	Hepatic metabolism	Rash, erythema, squamous cell skin cancers, photosensitivity, abnormal LFTs, fatigue
Vinblastine (Velban [®] , VLB)	Microtubulin inhibitor	Binds to tubulin, prevents formation of mitotic spindle	Hepatic	Myelosuppression, vesicant, neurotoxin
Vincristine (Oncovin [®] , Vincasar [®] , VCR)	Microtubulin inhibitor	Binds to tubulin, prevents formation of mitotic spindle	Hepatic	Neurotoxin, vesicant, CNS
Vinorelbine (Navelbine [®])	Microtubulin inhibitor	Binds to tubulin, prevents formation of mitotic spindle	Hepatic	Myelosuppression, vesicant, neuropathy
Vismodegib (Erivedge [®])	Targeted agent	Inhibits the Hedgehog signaling pathway	Hepatic metabolism and excretion	Teratogenic, fatigue, muscle spasms, diarrhea, alopecia
Vorinostat (Zolinza [®])	Histone deacetylase inhibitor	Inhibits histone deacetylase to unmask DNA methylation	Hepatic	Fatigue, diarrhea, N&V pulmonary emboli

P.1409

P.1410

P.1411

Clinical Pharmacology

Binding of alkylating agents or their reactive intermediates to sulfhydryl groups on glutathione or proteins is the primary route of drug clearance. Dosage alterations for hepatic or renal function impairment are usually not needed.

Mechlorethamine rapidly degrades in solution and must be reconstituted just before administration. Cyclophosphamide and ifosfamide require activation via the cytochrome P-450 system to produce 4-hydroxy derivatives, which are taken up in tumor tissue⁵⁴ and decompose to form the active metabolite, phosphoramidate mustard (Fig. 68.10). Drugs that alter the microsomal enzyme system, such as phenobarbital, can alter the plasma kinetics of cyclophosphamide and its metabolites. However, these kinetics changes do not appear to affect the toxicity of this drug. Ifosfamide, a structural analog of cyclophosphamide, is activated less readily than cyclophosphamide, so higher drug doses are required.⁵⁵ Although only a small amount of a dichlorethyl metabolite is formed with cyclophosphamide,

P.1412

this metabolite is generated to a significant extent with ifosfamide and may account for the central nervous system (CNS)

toxicity seen with this drug. The release of acrolein and dichlorethyl metabolites into the bladder results in cystitis with both cyclophosphamide and ifosfamide. Mercaptoethane sulfonate (MESNA) is administered to all patients receiving ifosfamide and to patients receiving high-dose cyclophosphamide. MESNA binds to reactive urinary metabolites of these alkylating agents and prevents cystitis.⁵⁶ In plasma, MESNA circulates in an inactive dimesna form so that antineoplastic activity is not altered. Oral bioavailability of cyclophosphamide is excellent, whereas the bioavailability of melphalan (30%) and chlorambucil (50%) are reduced and variable. The AUC of melphalan is reduced by concomitant use of cimetidine.⁵⁷

FIGURE 68.9. Mechanism of attachment of alkylating agents to DNA. Alkylating agents (in this case, those with two nitrochloroethyl groups) form reactive intermediates that bind to the N7 position of guanine. Bifunctional alkylating agents can bind to two guanine molecules, resulting in cross-linkage of DNA strands.

FIGURE 68.10. Metabolism of cyclophosphamide and ifosfamide. These drugs can be metabolized to the active agents (vertical metabolism) or to inactive metabolites (horizontal metabolism).

Toxicity

Although alkylating agents share a common mechanism of action, toxicity of alkylating agents varies significantly because of differences in pharmacokinetics, lipid solubility, membrane transport properties, and the presence of specific DNA-repair mechanisms. Marrow suppression occurs in all hematopoietic cell types. However, the pattern of suppression varies from drug to drug. A relative platelet- and stem cell-sparing effect occurs with cyclophosphamide. In contrast, busulfan is especially damaging to stem cells. The hematopoietic depression produced by the nitrosoureas is delayed (3 to 6 weeks). Nausea and vomiting are frequent with high doses of alkylators, but decrease with low-dose oral regimens. Alopecia is seen primarily with cyclophosphamide. Pulmonary fibrosis can be seen with all alkylating agents, but particularly with busulfan and the nitrosoureas.⁵⁸ Bladder toxicity is seen with ifosfamide and cyclophosphamide. Hepatic toxicity is noted with high-dose thiotepa, cyclophosphamide, busulfan, or BCNU therapy used in stem cell transplant regimens.⁵⁹ Ifosfamide, busulfan, and the nitrosoureas cause CNS toxicity, more frequently at high doses.⁶⁰ Renal toxicity is seen with the nitrosoureas and ifosfamide.⁶¹ High-dose cyclophosphamide produces water retention. All of the alkylating agents result in gonadal atrophy, and permanent loss of reproductive function can occur.⁶² All alkylating agents are teratogenic and carcinogenic. An increased risk of second cancers (usually acute myelogenous leukemia) has been reported with melphalan, procarbazine, and cyclophosphamide.

Antimetabolites (Azathioprine, Cladribine, Clofarabine, Cytarabine, Fludarabine, Gemcitabine, Hydroxyurea, Mercaptopurine, Methotrexate, Pentostatin, Thioguanine)

Antimetabolites prevent the synthesis of molecules required for DNA synthesis. Antimetabolites are cell cycle-specific agents that must be present during the S-phase of the cancer cell cycle for cytotoxicity. The schedule of drug administration is very important with these agents. Many antimetabolites are prodrugs that require metabolism to an active molecule. The pharmacology of selected antimetabolites most frequently used in the treatment of hematologic malignancies is reviewed in the following.

Methotrexate and Pralatrexate (Folotyn®)

Mechanism of Action

MTX, an analog of folic acid (Fig. 68.11), and pralatrexate are tight-binding inhibitors of DHFR, the enzyme required for converting folate to its active (tetrahydrofolate) form.⁶³ In the presence of MTX, tetrahydrofolates, needed as cofactors for purine and thymidine formation, are depleted, leading to inhibition of DNA synthesis and subsequent cell death. Cytotoxicity is related to the time MTX or MTX polyglutamate is present within the cell at

P.1413

concentrations great enough to inhibit DHFR.⁶⁴ 5-Formal tetrahydrofolate (calcium leucovorin or citrovorum factor), administered 24 hours after the administration of MTX, can rescue normal cells from the effects of MTX by providing a reduced form of folic acid to the cells. Resistance to MTX has been related to the presence of increased levels of the target enzyme, DHFR, as the result of increased expression or amplification of the DHFR gene.

FIGURE 68.11. Structures of selected antimetabolites used for treatment of hematologic malignancies.

Clinical Pharmacology

MTX can be given orally, intravenously, or by intrathecal injection. With standard oral doses (7.5 to 20 mg/m²), absorption is variable, with bioavailability decreasing at higher doses.⁶⁵ MTX is primarily eliminated by glomerular filtration and renal tubular secretion. In patients with renal dysfunction, MTX clearance is delayed, resulting in prolonged exposure and increased toxicity.⁶⁶ Patients with renal insufficiency should not be given MTX or must have plasma drug concentrations closely monitored, with leucovorin rescue employed if clearance is delayed. Retention of drug in ascites or pleural effusions can prolong MTX half-life and increase toxicity.³⁷

Toxicity

The primary toxicities associated with MTX are myelosuppression and mucositis.⁶³ High-dose MTX can result in renal failure as a consequence of drug precipitation in renal tubules in the presence of acidic urine. The routine use of adequate prehydration, alkalinization of the urine, and measurement of MTX concentrations is required with high-dose MTX

therapy.⁶⁷ Chronic MTX administration can be associated with liver disease, manifested by portal fibrosis and occasional cases of cirrhosis.⁶⁸ MTX is also associated with the development of pulmonary toxicity.⁶⁹ CNS toxicity has been reported with MTX, particularly with high doses of MTX and concomitant cranial irradiation. Intrathecal MTX administration may cause arachnoiditis.⁷⁰

Pyrimidine Analogs (Cytosine Arabinoside [ara-C and Liposomal ara-C], Gemcitabine, 5-Azacytidine, Decitabine)

The drugs listed above are all analogs of the naturally occurring pyrimidine, cytosine. Gemcitabine is occasionally used as third-line therapy for lymphomas but will not be further discussed. 5-Azacytidine and decitabine, although cytidine analogs, are believed to function through inhibition of histone deacetylase (HDAC) and will be discussed in a later section.

Mechanism of Action

Cytosine arabinoside (ara-C, cytarabine, liposomal ara-C, or DepoCyt™) is an analog of deoxycytidine with substitution of an arabinose sugar for the normally occurring deoxyribose sugar (Fig. 68.11). Once it enters a cell, ara-C must undergo metabolic activation to cytosine arabinoside triphosphate by a series of enzyme-mediated phosphorylation steps (Fig. 68.12). Cytosine arabinoside triphosphate competitively inhibits DNA polymerase- α . Cytosine arabinoside triphosphate is also incorporated into DNA, a feature that correlates closely with cytotoxicity. Incorporated ara-C inhibits both DNA template function and chain elongation.⁷¹ Ara-C-mediated DNA damage then induces apoptosis. Several mechanisms of resistance to ara-C have been described, including: (a) deletion of deoxycytidine kinase, the initial enzyme involved in ara-C activation; (b) increased levels of cytidine deaminase in tumor cells, resulting in rapid conversion of ara-C to inactive uracil arabinoside; and (c) decreased presence of nucleoside transport sites on tumor cells.

Clinical Pharmacology

Ara-C is rapidly converted to the inactive metabolite, ara-U, by the degradative enzyme, cytidine deaminase, present in the liver. The large capacity of the liver for metabolizing ara-C results in (a) a short plasma half-life of ara-C (2 to 3 hours), (b) adequate capacity for clearance of ara-C even in the presence of hepatic damage,

P.1414

and (c) urinary excretion of high concentrations of ara-U.⁷² Because of the short drug half-life and the S-phase specificity of ara-C, prolonged infusion or multiple-day administration schedules are required for cytotoxicity. Cytarabine encapsulated into multivesicular lipid-based capsules (DepoCyt™) has been developed as a means of sustaining cytotoxic ara-C concentrations at the tumor site. Liposomal ara-C acts as a depot form of ara-C and has been found useful in the therapy of neoplastic meningitis.⁷³

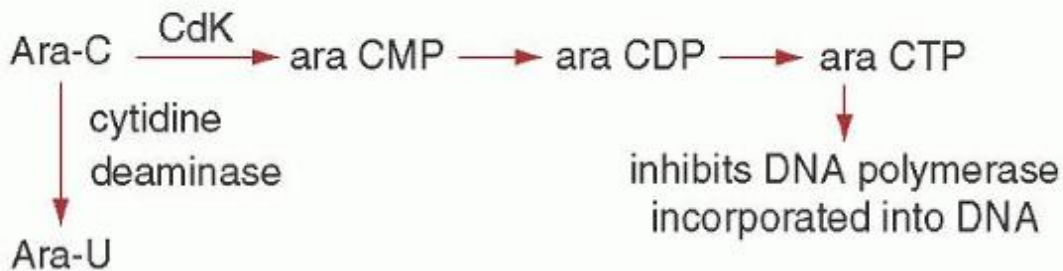

FIGURE 68.12. Metabolism of cytosine arabinoside (ara-C) by tumor cells. Ara-C is phosphorylated to its active metabolite, cytosine arabinoside triphosphate (ara-CTP), by a series of enzymatic steps, beginning with deoxycytidine kinase (CdK). Metabolism via the enzyme cytidine deaminase converts ara-C to the inactive metabolite, uracil arabinoside (ara-U).

Toxicity

Single high-dose boluses of ara-C are well tolerated but clinically ineffective because of the rapid inactivation of the agent. Continuous infusion or repeated administration of ara-C for 24 to 48 hours results in significant myelosuppression.⁷⁴ Nausea, vomiting, and diarrhea may occur after ara-C administration, especially with high-dose regimens. These symptoms typically subside quickly after the treatment. High-dose ara-C regimens (doses of 3 g/m² every 6 to 12 hours for 8 to 12 doses) have been associated with the development of cholestatic jaundice and elevations of hepatic transaminases. In addition, cerebral and cerebellar dysfunction has been reported in ~20% of patients receiving high-dose ara-C.⁷⁵ This toxicity is more common in patients >50 years of age and in patients with renal insufficiency. A steroid-

responsive conjunctivitis noted after high-dose ara-C has led to the routine prophylactic use of saline or steroid eye drops in patients receiving the high-dose regimens. Intrathecal injection of liposomal ara-C is associated with chemical arachnoiditis (headache, fever, nausea, vomiting) which can be treated with steroids.

Hydroxyurea

Mechanism of Action

Hydroxyurea inhibits ribonucleotide reductase, the enzyme responsible for the conversion of ribonucleotide diphosphates to the deoxyribonucleotides required for DNA synthesis and repair.⁷⁶ Hydroxyurea kills cells selectively in the S-phase of the cell cycle. Doses of 0.5 to 2.0 g/day result in a rapid (2 to 5 days) decrease in peripheral white blood counts. The rapid onset of effect on circulating leukemia cell populations and the brief duration of action have led to the routine use of this agent in patients with significantly elevated leukemic blast counts or in those with elevated platelet counts.⁷⁷

Clinical Pharmacology

Hydroxyurea is well absorbed orally (90% to 100% bioavailability), with minimal patient-to-patient variability.⁷⁸ It is excreted primarily in the urine with a plasma half-life of 4 hours.⁷⁹ Although precise guidelines are not available, patients with renal failure should have drug doses reduced.

Toxicity

Hydroxyurea's primary toxicity is myelosuppression.⁸⁰ Myelosuppression occurs 2 to 5 days following drug administration and is generally not severe. Reversal of myelosuppression is rapid following discontinuation of drug. Nausea, vomiting, anorexia, and diarrhea can be seen, but are typically mild. Uncommon toxicities include pulmonary fibrosis, hepatotoxicity, fever, and leg ulceration.

Purine Antimetabolites (6-Mercaptopurine, 6-Thioguanine, Azathioprine, Nelarabine, Cladribine, Clofarabine, Fludarabine)

6-Mercaptopurine, 6-thioguanine, azathioprine, nelarabine, cladribine, clofarabine, and fludarabine are all purine nucleoside analogs used in therapy of hematologic malignancies. The first four are guanine analogs, while the last three are analogs of adenine. All share many similarities. Nucleoside analogs are transported across cell membranes and phosphorylated to a triphosphate metabolite which is then incorporated into DNA. Once incorporated, nucleoside analogs interfere with DNA synthesis, lead to termination of DNA chain elongation, and inhibit DNA-repair mechanisms.⁸¹ Similarities and differences among these drugs are reviewed below.

Mechanism of Action of Guanine Nucleotides

6-Mercaptopurine is used in maintenance therapy for children with acute lymphoblastic leukemia. 6-Thioguanine is a second-line agent for therapy of acute myelogenous leukemia. Azathioprine, a prodrug of 6-MP, is used as an immunosuppressant. Nelarabine (Arranon[®]) is approved for the treatment of relapsed T cell acute lymphoblastic leukemias (ALL) and lymphoblastic lymphomas. The mechanism of action of these three agents is similar. These nucleoside analogs enter cells, are converted to triphosphates, and incorporated into DNA where they terminate DNA synthesis. 6-MP is an analog of hypoxanthine (Fig. 68.11). It is converted to 6-MP ribose triphosphate, which is incorporated into DNA (Fig. 68.13). 6-Thioguanine is activated in a manner similar to that outlined for 6-MP. Azathioprine is rapidly cleaved by nonenzymatic mechanisms to 6-MP and methyl-4-nitro-5-imidazole derivatives. The imidazole derivatives react with thiol and cysteine residues. Alkylation of lymphocyte thiol groups may be important in inducing immunosuppression.⁸² Ara-GTP, the active metabolite of nelarabine, is incorporated into T cell lines 20- to 40-fold more efficiently than into B cell lymphoblasts.⁸³

Clinical Pharmacology of Guanine Nucleotides

Azathioprine is rapidly cleaved to 6-MP after absorption. Clearance of 6-MP occurs primarily through two routes of catabolism. 6-MP is oxidized to the inactive metabolite, 6-thiouric acid, by xanthine oxidase (Fig. 68.13). 6-MP also undergoes S-methylation by the enzyme thiopurine methyl transferase (TPMT) to yield less active 6-methyl mercaptopurine.⁸⁴ Oral absorption of 6-MP is incomplete and highly variable. The low bioavailability (5% to 37%) is a result of a large first-pass effect as drug is absorbed into the portal circulation and metabolized by xanthine oxidase in the liver. The use of concomitant allopurinol (an inhibitor of xanthine oxidase) increases 6-MP bioavailability fivefold, increasing toxicity.⁸⁵ This important drug interaction must be remembered for 6-MP and azathioprine. Patient-to-patient variation in TPMT activity can result in significant changes in 6-MP metabolism and in drug toxicity. One in 300 subjects has absent TPMT activity. Patients with low TPMT activity are susceptible to severe 6-MP- and azathioprine-induced myelosuppression.⁸⁶ Patients with high TPMT concentrations may be a higher risk for relapse as a result of rapid drug inactivation. Genetic testing for the TPMT gene is available. Nelarabine is a water-soluble prodrug of ara-G. Following

intravenous administration, nelarabine is rapidly metabolized (<1 hour) by O-demethylation to ara-G, which is primarily transported into

P.1415

lymphoblasts, phosphorylated, and incorporated into DNA.⁸³ A small amount of ara-G is cleared via the kidneys so that increased toxicity may be expected in patients with creatinine clearance less than 50 ml/min. As an adenosine deaminase inhibitor, pentostatin can reduce conversion of nelarabine to ara-G, thereby reducing efficacy. Pentostatin and nelarabine should not be used in combination.

FIGURE 68.13. Mechanism of activation and catabolism of azathioprine and 6-mercaptopurine. Active metabolites are indicated by surrounding boxes. Inactive (or less active) metabolites are indicated by italic print. HGPRT, hypoxanthine-guanine phosphoribosyltransferase; TPMT, thiopurine methyltransferase; xo, xanthine oxidase.

Toxicity of Guanine Nucleotides

The dose-limiting toxicity of 6-MP, 6-thioguanine, azathioprine, and nelarabine is myelosuppression, occurring 1 to 4 weeks following onset of therapy and reversible when the drugs are discontinued.^{83, 84} Immunity to infectious agents or vaccines is subnormal. Gastrointestinal mucositis and stomatitis are modest but appear to be more common in adults than in children. Hepatotoxicity, seen in a small number of patients receiving 6-MP, is usually mild and reversible, with a clinical picture of cholestatic jaundice, although elevations of transaminases may be seen.⁸⁷ Frank hepatic necrosis and venoocclusive disease can occur. 6-MP and azathioprine are potentially teratogenic. Neurologic events (seizures, peripheral neuropathy) have been associated with nelarabine use.

Mechanism of Action of Adenine Nucleosides (Fludarabine, Cladribine, Clofarabine)

Fludarabine (Fludara[®]) (Fig. 68.11) is a fluoridated analog of 9-β-D-arabinofuranosyladenine (ara-A) used to treat CLL and refractory indolent lymphomas. When administered, fludarabine is dephosphorylated in plasma, enters cells, and then is again phosphorylated to 2-fluoro-ara-ATP (Fig. 68.14).⁸⁸ F-ara-ATP inhibits DNA polymerase, ribonucleotide reductase, DNA primase, and DNA ligase I, resulting in DNA deletions and mutations.⁸⁹ Fludarabine is also incorporated into DNA, where it is an effective DNA chain terminator. Cladribine (Leustatin[®] or 2-chlorodeoxyadenosine, 2CdA), an adenosine analog found to be more cytotoxic to lymphocytes than fludarabine, is used to treat hairy cell leukemia. The 5'-triphosphate metabolite (2-chloro-2'-deoxyadenosine 5'-triphosphate, 2-CdATP) accumulates in cells that are rich in deoxycytidine kinase, primarily lymphoid cells. 2-CdATP is incorporated into DNA, producing DNA strand breaks and inhibition of DNA synthesis in dividing cells.⁹⁰ Clofarabine, 2-chloro-9(2-deoxy-2-fluoro β-D arabinosyl) 9H purine-6 amine, is similar in structure to cladribine with the addition of a fluorine at the 2-carbon position of the sugar moiety.⁹¹ The addition of the fluorine molecule increases resistance to the cleavage of the glycosidic bond compared to cladribine. As with cladribine and fludarabine, clofarabine is phosphorylated intracellularly to the active triphosphate form. Clofarabine triphosphate inhibits DNA synthesis through its inhibitory action on ribonucleotide reductase and DNA polymerase. Clofarabine is approved for treatment of refractory ALL and AML.

Although the effects of F-ara-A and 2CdA on DNA synthesis account for their activity in dividing cells, these nucleosides are also cytotoxic to cancers with very low growth fractions, such as indolent lymphomas. Although the specific mechanism by which they induce cell death among quiescent cells is still under investigation, several proposed mechanisms of action include the ability to inhibit RNA polymerase and to deplete nicotinamide adenine dinucleotide (NAD), with resultant decrease in cellular energy stores and interference with normal DNA-repair processes.⁹²

FIGURE 68.14. Activation pathway and mechanism of action of fludarabine.

Clinical Pharmacology of Adenine Nucleosides

Fludarabine undergoes rapid (2 to 4 minutes) conversion to 2F-ara-A. 2-F-ara-A is excreted primarily in the urine, with few metabolites noted. In patients with renal function impairment, clearance of 2-F-ara-A decreases significantly.⁸⁹ Dose reduction is recommended for patients with renal dysfunction. Oral bioavailability is ~75%. Bioavailability of subcutaneously administered cladribine is excellent. Oral bioavailability averages 50%.⁹³ Cladribine is cleared primarily by the kidneys (50% of total dose) via a cation organic carrier system. Although dose adjustment guidelines for patients with renal insufficiency are not available, caution should be used in giving cladribine to patients with renal failure. Significant patient-to-patient variability (+/-28%) exists in the AUC achieved following administration of drug by any method.⁹⁴ Roughly 50% of an administered clofarabine dose is excreted unchanged in the urine within 24 hours. This suggests that dose alteration will be needed for renal insufficiency, but studies in patients with renal failure have not been completed. The drug half-life is 5.2 hours.

Administration of clofarabine prior to cytarabine increases intracellular accumulation of ara-CTP in AML blasts.⁹⁵

Toxicity of Adenine Nucleosides

The dose-limiting toxicity of fludarabine is myelosuppression occurring a median of 12 to 16 days after beginning therapy. Cytopenias may be prolonged.⁹⁶ Other toxicities include mild nausea and vomiting (36% of patients), fever (60%), infection (33%), peripheral sensorimotor neuropathy (rare), autoimmune hemolytic anemia (rare), and hepatocellular toxicity with elevations in serum transaminases (rare).^{81, 89} An irreversible neurotoxicity syndrome has occurred in patients receiving high doses (>40 mg/m²/day for 5 days). Mild, reversible neurotoxicity has been seen at lower doses, with increased frequency and severity in older patients.⁹⁷ Pulmonary toxicity, characterized by fever, cough, hypoxia, and diffuse interstitial pneumonitis, has also been reported. Fludarabine is immunosuppressive and is associated with an increased risk of opportunistic infections.⁹⁸ CD4 and CD8 T-lymphocyte subpopulations drop to 150 to 200/mm³ after therapy.

The dose-limiting toxicity of cladribine is myelosuppression. Grade 3 or 4 neutropenia occurs in half of treated patients at standard doses. Fever (>100°F) has been seen in two-thirds of patients, often beginning 5 to 7 days into therapy or during the period of neutropenia.⁹⁹ Cladribine suppresses CD4⁺ lymphocytes. The CD4:CD8 ratio may remain depressed for up to 16 months after therapy, with associated opportunistic infections including *Candida* or *Aspergillus*.⁹⁸ After high-dose cladribine therapy (5 to 10 times the recommended therapeutic dose), renal failure and progressive irreversible motor weakness with paraparesis have been reported. Betticher et al.¹⁰⁰ have shown that

P.1416

reducing the dose of cladribine from 0.7 to 0.5 mg/kg per cycle decreases both the rate of grade 3 myelosuppression (33% to 8%) and the risk of infection (30% to 7%). No change in lymphoma response rate was noted with this dose reduction. The primary toxicity of clofarabine is myelosuppression leading to an increased risk of infection. Nausea and vomiting are

seen but are generally mild. Severe reversible hepatic toxicity is noted in 15% to 40% of patients receiving clofarabine.^{96, 101}

Pentostatin

Mechanism of Action

Pentostatin (deoxycoformycin, DCF) is a potent inhibitor of adenosine deaminase. It is active in the treatment of chronic lymphoid malignancies, particularly hairy cell leukemia.¹⁰² Inhibition of adenosine deaminase results in inability of the cell to catabolize adenosine and deoxyadenosine. Intracellular concentrations of deoxy-ATP increase and exert a negative feedback on ribonucleotide reductase, resulting in an imbalance in deoxynucleotide pools. This imbalance inhibits DNA synthesis and impairs replication, with arrest of cells in the G₁ and S phases of the cell cycle. The malignant cells of hairy cell leukemia and CLL have low levels of adenosine deaminase, making them particularly sensitive to the effects of pentostatin.¹⁰³

Clinical Pharmacology

Plasma pentostatin concentrations greatly exceed those needed to inhibit adenosine deaminase. Pentostatin's terminal half-life is 3 to 15 hours in humans. Forty to 80% of the drug is excreted unchanged in urine within 24 hours.¹⁰⁴ Plasma clearance correlates with creatinine clearance. Dosage reduction should be considered for patients with impairment in renal function. Pentostatin is not bioavailable by the oral route, because of its acid lability.

Toxicity

At doses used in hairy cell leukemia (4 mg/m² biweekly), therapy is usually well tolerated.¹⁰⁵ Toxicities include worsening of neutropenia, mild to moderate lethargy, anorexia, rash, and reactivation of herpes zoster late in therapy. Nausea, although usually mild, can occasionally be severe. Delayed emesis is seen.

Histone Deacetylase Inhibitors (Vorinostat, Romidepsin) and Hypomethylating Agents (5-Azacytidine, Decitabine)

Eukaryotic DNA is organized in a macromolecular complex wrapped around histone proteins. Amino acid residues on the histone tail can be modified by acetylation and by methylation. These modifications change the structure of the histone-DNA complex. Histone acetyltransferases (HATs) are enzymes that acetylate histone molecules, resulting in opening of the chromatin, thereby allowing transcription factors access to DNA promoter regions. In contrast, HDACs remove acetyl groups from histone proteins, leading to condensation of DNA and inactivation of gene transcription.¹⁰⁶ Increased HDAC activity has been associated with a decrease in tumor suppressor gene expression, alterations in intrinsic and extrinsic apoptotic pathways, and decreased apoptosis. Romidepsin (Istodax[®]) and vorinostat (Zolinz[®]) are HDAC inhibitors approved for treatment of cutaneous T cell lymphomas.

Similarly, a large number of genes are silenced by methylation in some cancers. This methylation may block the gene promoter region of tumor suppressor genes.¹⁰⁷ 5-Azacytidine (Vidaza[®]) and decitabine (Dacogen[®]) are methyltransferase inhibitors which block the methylation of DNA with the hope of activating tumor suppressor genes. 5-Azacytidine and decitabine have been approved for treatment of MDS and are being used in AML.

Mechanism of Action

Vorinostat is a potent inhibitor of several HDACs (1, 2, 3, and 6), while romidepsin inhibits class 1 HDAC enzymes.^{106, 108, 109} It is uncertain whether specificity of any HDAC inhibition impacts antineoplastic activity. Inhibition of HDAC induces genes that cause apoptosis or differentiation. Clinical studies have demonstrated hyperacetylation in tumor cells following vorinostat administration. However, no correlation between tumor acetylation status and response has been seen, suggesting that other mechanisms of action may impact on antineoplastic activity.¹⁰⁸ HDAC inhibitors also induce oxidative damage, have antiangiogenic effects, and disrupt cell cycle checkpoints. The specific mechanism of antineoplastic activity remains uncertain.

5-Azacytidine and decitabine (5-aza-deoxycytidine) are both nucleoside analogs. Like cytarabine, they undergo phosphorylation within the cell to a triphosphate form and then are incorporated into DNA. Once incorporated into DNA, these agents bind the enzyme DNA methyltransferase, inhibit methyltransferase activity, and result in DNA hypomethylation.¹¹⁰ Hypomethylation reverses silenced tumor suppressor gene loci. The silenced genes may play an important role in terminal differentiation, apoptosis, or senescence of leukemic cells.¹¹¹

Clinical Pharmacology

Vorinostat is available as an orally administered, 100-mg capsule that is generally given with food. Both vorinostat and romidepsin are primarily inactivated by metabolism (glucuronidation and hydrolysis) with metabolites excreted in the

urine. Vorinostat has a short half-life (2 hours); despite the short plasma half-life, accumulation of acetylated histones continues for over 10 hours after administration.¹⁰⁶ Use of vorinostat or romidepsin in patients with renal or hepatic insufficiency has not been studied. However, since drug clearance is primarily via metabolism, dose adjustment for renal insufficiency is not thought to be needed.

Following IV or subcutaneous administration, decitabine and 5-azacytidine are rapidly inactivated by hepatic metabolism (primarily via the enzyme cytidine deaminase). There is little protein binding. The half-lives of 5-azacytidine and decitabine are 4 hours and 30 minutes, respectively. The drugs do not have oral bioavailability because of rapid decomposition in acidic solutions. Because of an association between the length of drug exposure with DNA methylation and the short half-life of these drugs, continuous treatment of azanucleosides over several days is recommended.¹¹¹ Dose adjustments for hepatic or renal insufficiency have not been studied but are unlikely to be needed.

Toxicity

The most common toxicities of HDAC inhibitors include nausea, vomiting, diarrhea, thrombocytopenia, anemia, and taste disorders. Dose-limiting side effects are generally thrombocytopenia and dehydration.¹¹² Pulmonary emboli have been reported in 4% to 5% of cancer patients receiving vorinostat. QT prolongation is noted with both vorinostat and romidespin.¹⁰⁶ The primary toxicity of decitabine and azacytidine is myelosuppression. Gastrointestinal toxicities, including nausea, vomiting, and constipation, are seen, usually transient in nature (1 to 4 days), and improve over time.¹¹³

Hormonal Therapies

A comprehensive review of all hormonal therapies is beyond the space limitation of this chapter. Of the several types of hormonal agents used in cancer therapy, corticosteroids are the class of drugs used to treat hematologic malignancies. Corticosteroids are also useful in managing complications of cancer, including chemotherapy-induced emesis, hypercalcemia, and increased

P.1417

intracranial pressure. Prednisone and dexamethasone are synthetic glucocorticoids most commonly used in oncology. They are respectively 4- and 30-fold more potent than the naturally occurring glucocorticoid, cortisol. Prednisone and cortisol have roughly equivalent mineralocorticoid effects while dexamethasone lacks significant mineralocorticoid activity.

Mechanism of Action

Several cancers depend on specific hormones for growth and cellular integrity. Altering the hormonal balance can cause tumor regression in patients. The mechanism of corticosteroid cytotoxicity to lymphocytes is mediated via binding to the glucocorticoid receptors, which induces apoptosis in these hormone-sensitive cells.¹¹⁴

Clinical Pharmacology

Prednisone is an inactive prodrug that requires hepatic activation to produce prednisolone, the active moiety. Oral bioavailability of corticosteroids is excellent (>80%). The plasma half-life of prednisone is 1 hour for prednisolone and 4 hours for dexamethasone. In contrast to cortisol, synthetic glucocorticoids have little protein binding. Drugs activating the microsomal enzyme system (such as phenytoin) increase degradation, while cytochrome P450 inhibitors (such as aprepitant) increase glucocorticoid concentrations.¹¹⁵

Toxicity

Prednisone and dexamethasone have little mineralocorticoid activity; therefore most side effects are related to suppression of the hypothalamic-pituitary-adrenal (H-P-A) axis and the development of iatrogenic Cushing's syndrome. In general, suppression of the H-P-A axis is not seen in patients who have received glucocorticoids for less than 3 weeks. A gradual tapering of glucocorticoids is recommended for those on these agents for longer periods. Side effects are dose- and schedule-related.¹¹⁶ Commonly affected systems include: skin (purpura, thinning, acne), eye (cataracts), heart (hypertension, hyperlipidemia), endocrine (diabetes, adrenal insufficiency), GI (PUD, steatohepatitis), bone (osteoporosis), muscle (myopathy), psychiatric (euphoria, psychosis), and an increased risk of infections. Many of these toxicities are seen only with long-term therapy.

Microtubulin Agents

Two general classes of microtubulin inhibitors are used in cancer therapy: the vincas and the taxanes. The vinca alkaloids block microtubulin formation, while the taxanes (docetaxel, ixabepilone, and paclitaxel) stabilize microtubulin bundles,

leading to their dysfunction. Since taxanes are not generally used in therapy of leukemias and lymphomas, only the vinca alkaloids will be reviewed here.

Vinca Alkaloids (Vinblastine, Vincristine, and Vinorelbine)

Mechanism of Action

The vinca alkaloids vinblastine, vincristine, and vinorelbine bind to tubulin and prevent the formation of microtubulin, a protein that is essential for maintenance of cellular shape and for formation of the mitotic spindle.¹¹⁷ Vinca alkaloids bind to a site on microtubulin distinct from the taxanes. Cells treated with vinca alkaloids are arrested in metaphase.¹¹⁸ Disruption in microtubular formation leads to initiation of apoptosis. Differences in activity and toxicity of the vinca alkaloids result from variation in their pharmacokinetics, their differential effects on various tubulin isoforms, and variations in tissue penetration and cellular retention. Resistance is a result of the presence of p-glycoprotein or reduced tubulin binding resulting from mutations in tubulin.

Clinical Pharmacology

All vincas are rapidly taken up into cells. However, vincas differ in cellular retention (vinblastine greater than vincristine). All vincas are extensively bound to tissues and to proteins with long terminal half-lives (20 to 60 hours).¹¹⁹ CNS penetration is poor. All of the vinca alkaloids are metabolized by the liver via hepatic cytochrome P450 3A4 (CYP 3A4) and excreted into the bile. Drugs that block CYP 3A4 may inhibit vinca clearance, causing increased toxicity.¹²⁰ Doses of the vinca alkaloids should be reduced in patients with hepatic dysfunction, but not in patients with renal insufficiency. Specific dose reduction guidelines with impairment of hepatic function are not available.

Toxicity

Vincristine causes little myelosuppression. Its dose-limiting and most frequent toxicity is neurotoxicity,^{118, 121} manifested by a symmetric, distal, sensory-motor neuropathy. Loss of deep tendon reflexes in the lower extremities and paresthesias of the fingers and toes are common early findings. Continued use of the drug can result in further motor neuropathy, which may be only partially reversible when the drug is stopped. Neuropathies of the motor cranial nerves have also been reported, as have constipation, cramps, and paralytic ileus. Hair loss is commonly seen following vincristine administration. The dose-limiting toxicity of vinblastine is hematopoietic, with thrombocytopenia and leukopenia commonly occurring after administration of the drug.¹²² The onset of myelosuppression tends to occur earlier with this agent than with other antineoplastic agents, with the leukocyte nadir typically seen by day 4 to 7 and recovery by day 10 to 14. Severe neurotoxic symptoms are unusual with vinblastine, but use of the drug is associated with myalgias and an autonomic neuropathy manifested by orthostatic hypotension or paralytic ileus. The dose-limiting toxicity of vinorelbine is myelosuppression.¹²³ Vinorelbine is less neurotoxic than vincristine. Injection-site reactions of erythema, pain, and vein discoloration occur in one-third of patients, with severe vein toxicity seen in 2% of patients treated with vinorelbine. Respiratory reactions have been reported. All vincas are potent vesicants, with severe local tissue damage associated with extravasation of these drugs into soft tissues.

Monoclonal Antibodies

Monoclonal antibodies have been used in cancer therapy over 30 years. Initial monoclonal antibodies were produced in mice. The development of techniques to convert portions of the murine antibody to a human subclass (chimerization), to convert all of the antibody, except the hypervariable region, to human amino acid sequences (humanization), or to make a totally human monoclonal antibody have advanced the field.¹²⁴ The humanized proteins have a longer half-life and can better activate human complement stimulating complement-mediated cytotoxicity or activate antibody-dependent cell-mediated cytotoxicity (ADCC). Seven monoclonal antibodies (alemtuzumab, brentuximab vedotin, gemtuzumab, ibritumomab, atumumab, rituximab, and tositumomab) have been approved for treatment of hematologic malignancies and are briefly reviewed.

Rituximab (Rituxan®) and Ofatumumab (Arzerra™)

Mechanism of Action

Both rituximab and ofatumumab bind to the protein CD20. CD20 is a nonglycosylated protein of 33 to 35 daltons that is expressed on the surface of human B lymphocytes. CD20 is expressed on all B cell malignancies except most ALL and myeloma. Rituximab is a genetically engineered mouse/human chimeric IgG monoclonal

P.1418

antibody with human constant regions and mouse variable regions. Several mechanisms of cytotoxicity have been

demonstrated.^{124, 125} Antibody-mediated cellular toxicity (ADCC), resulting from the ligation of the Fc portion of the monoclonal antibody to Fc receptors expressed by accessory cells, occurs. Rituximab is also capable of binding complement and triggering complement-dependent cell lysis (CDC) of human B cells. Cross-linking of CD20 molecules can trigger apoptosis. Ofatumumab is a fully human monoclonal antibody which binds to a site on CD20 different from rituximab. Compared to rituximab, ofatumumab enhances in vitro CDC and ADCC due to greater reactivity with human complement and effector cells.^{126, 127} Head-to-head clinical trials comparing of rituximab to ofatumumab have not been performed.

Clinical Pharmacology

Rituximab and ofatumumab antibody concentrations in plasma following drug administration are proportional to the dose of drug administered, although there is marked inter-individual variation in maximal drug concentration (5- to 50-fold). Antibody half-life ranges from 30 to 400 hours for rituximab and 7 days for ofatumumab.^{128, 129} With weekly administration schedules, there is progressive accumulation of rituximab from week 1 to week 4. Drug clearance is not affected by chemotherapy. Drug elimination probably occurs by protein binding and proteolytic degradation. Clearance may be related to variable amounts of tumor cells present in the body and the concentration of CD20 antigens to which the drug binds.¹²⁹

Toxicity

Mild toxicity is seen in the majority of patients receiving rituximab or ofatumumab, but severe toxicity (NCI grade 3 or 4) is rare. Infusion reactions, resulting from release of cytokines occurring when antibody binds to CD20 cell, result in mild nausea, chills, rigors, tachycardia, fever, and skin rash within 1 to 3 hours following treatment in some patients. Slow drug administration is recommended for patients receiving their first cycle of drug to minimize such reactions. Serious infusion-related reactions (bronchospasm, hypotension, acute respiratory distress syndrome, and shock) have been reported during drug infusions in less than 1% of infusions. The incidence of infusion-related reactions decreases with subsequent infusions. Grade 3 to grade 4 neutropenia (2% to 6%), anemia (1% to 3%), and thrombocytopenia (1% to 2%) are uncommon. B cell lymphocyte counts are reduced for ~6 months.^{128, 129} Late onset neutropenia, occurring 40-350 days following therapy, has been noted in 3-7% of patients. Multifocal leukoencephalopathy has been reported with rituximab.¹³⁰ Interstitial lung disease and reactivation of hepatitis B have been noted with rituximab therapy. A late occurring neutropenia has been noted following rituximab therapy.

⁹⁰Y-Ibritumomab Tiuxetan (Zevalin®) and ¹³¹I-Tositumomab (Bexxar®)

Mechanism of Action

⁹⁰Y-ibritumomab and ¹³¹I-tositumomab are also monoclonal antibodies directed at the CD20 antigen but have an attached radioactive moiety designed to result in radiation-induced cytotoxicity to cells expressing the CD20 antigen.^{131, 132} Ibritumomab is a monoclonal antibody combined with tiuxetan, which acts as a chelation site for Indium-111 and Yttrium-90 (Y-90). Indium-111 is a gamma-emitter used to assess biodistribution of ibritumomab while Y-90 emits beta particles. Beta-emission induces cellular damage through the formation of free radicals (in both target cells and surrounding cells). Roughly 85% of non-Hodgkin lymphomas express the CD20 antigen on their surface.¹³³ A pretreatment therapy of unlabeled antibody to CD20 is given prior to administration of radioactive-tagged antibody to minimize targeting of radio labeled antibody to normal B cells in the circulatory system. ¹³¹I-Tositumomab is a radio-iodinated derivative of a murine IgA lambda monoclonal antibody covalently linked to iodine 131.

Clinical Pharmacology

⁹⁰Y-Ibitumomab is a pure β -emitter with a half-life of 64 hours. ¹³¹I-Tositumomab has both β and α radiation. Clearance of ¹³¹I-tositumomab-labeled antibodies varies significantly among patients, and dosing for an individual patient is derived from quantitative whole-body imaging of a test dose. The half-life of elimination averages 67 hours. More rapid clearance is noted in patients with a more extensive tumor burden.

Toxicity

The primary toxicity of both ¹³¹I-tositumomab and ⁹⁰Y-ibitumomab is myelosuppression occurring about 1 month after dosing. The median platelet and neutrophil nadirs are 43,000 and 690, respectively, with tositumomab. Using ⁹⁰Y-ibitumomab, grade 4 neutropenia, thrombocytopenia, and anemia occur in 35%, 14%, and 8% of patients, respectively.^{131, 133} Nadirs occur 7 to 9 weeks posttherapy. Nonhematologic toxicity includes asthenia, hypothyroidism, infusion reactions, and fevers. Infusion reactions including anaphylaxis are seen in 25% to 30% of patients (anaphylaxis less common). Myelodysplasia and mucocutaneous reactions (erythema multiforme) have been noted days to months following therapy.¹³⁴

Alemtuzumab (Campath®)

Alemtuzumab is a humanized monoclonal antibody directed against the CD52 antigen expressed not only by most lymphomas and lymphoid leukemias but also by normal B and T lymphocytes, NK cells, monocytes, macrophages, dendritic cells, and neutrophils. The CD52 antigen is not internalized after antibody binding; antitumor effects are mediated by antibody-dependent cell-mediated cytotoxicity.¹³⁵ Alemtuzumab also alters signal transduction, which may contribute to cytotoxicity. Because it binds to normal B and T cells and normal neutrophils (triggering complement lysis), transfusion reactions are frequent. The drug is therefore administered by slow infusion or by subcutaneous injection. Patients receiving subcutaneous alemtuzumab have local skin reactions which may be severe. Treatment results in myelosuppression and long-term immunosuppression. There is a high risk of opportunistic infections.¹³⁶

Brentuximab Vedotin—(Adcetris™)**Mechanism of Action**

Brentuximab vedotin is a conjugate of a chimeric IgG1 monoclonal antibody against CD 30 linked to a cytotoxic drug, monomethyl auristatin E. CD 30 is a member of the TNF family expressed on the tumor cells of Hodgkin's lymphoma and anaplastic large cell lymphoma. Monomethyl auristatin E (MMEA) is a synthetic inhibitor of tubulin polymerization. After binding to cells expressing CD30, the antibody-drug conjugate is internalized in lysosomes. The peptide linking the antibody to the drug is then cleaved, releasing MMEA into cells where it binds to tubulin and causes cell cycle arrest and apoptosis.¹⁴⁰ A small fraction of MMEA diffuses out of tumor cells where it results in cytotoxicity to cells in the microenvironment.¹⁴¹

Clinical Pharmacology

Brentuximab is administered intravenously every 3 weeks. The half-life of the antibody- drug conjugate is 4 to 6 days, while the half-life of MMEA is 3 to 4 days.¹³⁷ Steady state plasma levels are achieved in 21 days. Most MMEA is cleared via the liver into the stool (72%) as intact drug. There is modest metabolism via CYP 3A4. Information regarding dose adjustments or renal or hepatic insufficiency is not yet available, but it is unlikely that renal impairment would affect drug clearance.

P.1419

Toxicity

As with many monoclonal antibodies, infusion reactions can be seen during drug infusion (10%) with occasional anaphylaxis.^{138, 139} Peripheral neuropathy, which often improves with drug discontinuation, is noted in 20% to 50% of patients. Other toxicities seen with brentuximab vedotin include fatigue, fever, nausea and diarrhea, and neutropenia. Progressive multifocal leukoencephalopathy (PML) due to reactivation of JC virus has been seen. A high incidence of pulmonary toxicity was noted when brentuximab has been combined with bleomycin.

Gemtuzumab Ozogamicin (Mylotarg®)

Gemtuzumab is a monoclonal antibody to the CD33 antigen, found on myeloid cells, linked to the antibiotic calicheamicin. The postulated mechanism of action is through binding of the antibody to myeloblast with internalization of calicheamicin. Calicheamicin binds to DNA, resulting in DNA strand breaks. Because of lack of clinical studies clearly demonstrating antineoplastic activity, gemtuzumab was withdrawn from clinical use in the United States in 2010.

Molecularly Targeted Therapies

In the early years of cancer drug development, antineoplastic agents were often discovered by testing biologics or chemicals for ability to kill cancer cells in culture. If activity was identified, then the mechanism of action of that material was later determined. With advances in cancer biology and sequencing of the human genome, our understanding of how cancers develop and what processes are critical in cancer proliferation has grown. For the past two decades, most cancer drugs have been developed by identifying a critical pathway needed by a particular cancer and then identifying a drug which blocks that critical pathway. Molecular targeted therapies are drugs which selectively target specific molecular features of cancer cells such as aberrations in genes or proteins which regulate tumor cell growth. The best of these drugs target genes or proteins which are critically responsible for tumor growth or survival, such as the BCR-ABL protein in CML. Of the many target agents developed in the past 15 years, those used in treatment of hematologic malignancies will be reviewed here. The targets include: the IL-2 receptor (denileukin diftitox), the BCR-ABL oncoprotein (imatinib, dasatinib, nilotinib), the retinoic acid pathway (ATRA, arsenic trioxide), and the proteasome (bortezomib).

Denileukin Diftitox

Mechanism of Action

Denileukin diftitox (Ontak[®]) is a fusion protein containing peptide sequences for human interleukin (IL-2) and diphtheria toxin.¹⁴⁰ The IL-2 portion of this fusion protein binds to cells that express IL-2 receptors. Once bound to the IL-2 receptor, the diphtheria toxin protein is internalized, inhibits cellular protein synthesis, and results in cell death. Three types of IL-2 receptors exist: high-, intermediate-, and low-affinity. The fusion protein is internalized only with intermediate- or high-affinity IL-2 receptors. Expression of high-affinity IL-2 receptors is normally restricted to activated T lymphocytes and lymphomatous cells of T or B cell origin. Denileukin diftitox has been approved for use in cutaneous T cell lymphomas.¹⁴¹

Clinical Pharmacology

There is wide variation in serum concentrations of denileukin diftitox after intravenous administration (coefficient of variation >50%).¹⁴¹ A terminal half-life of ~75 minutes is seen with initial therapy, but this decreases to 43 minutes with continued therapy, as antibodies to denileukin diftitox appear. Animal studies have shown that the drug is cleared via hepatic protein degradation.

Toxicity

Hypersensitivity reactions, such as dyspnea, back pain, rash, hypertension, and chest tightness, occur during or within 24 hours of drug infusion in 60% of patients.^{141, 142} These symptoms resolve within 48 hours and can usually be controlled with use of steroids, antihistamines, or slowing of drug infusion. Constitutional and gastrointestinal symptoms (nausea/vomiting, asthenia, myalgias, headache, diarrhea) are seen in 92% of patients (grade 3 or 4 in one-third). A vascular leak syndrome (hypotension, edema hypoalbuminemia) occurs up to 2 weeks postinfusion in 25% of treated patients. The drug should not be given if the serum albumin is less than 3.0 g/dL. Myelosuppression is uncommon.

Retinoids

All-Trans Retinoic Acid or Tretinoin

Mechanism of Action. In acute promyelocytic leukemia, the retinoic acid receptor (RAR) is translocated next to a nuclear protein gene (PML). Fusion of RAR protein with the nuclear protein, PML, prevents normal differentiation of myeloid cell.¹⁴³ Retinoids are vitamin A derivatives that are essential for normal controlled cellular growth and development. ATRA binds to one or more nuclear receptors to decrease proliferation and induces differentiation of APL cells.¹⁴⁴ Pharmacologic concentrations of ATRA (1 μ M) reverse the inhibition of differentiation of the promyelocytes and induce remission of APL by providing retinoic acid to activate repressed genes.

Clinical Pharmacology. Tretinoin is well absorbed. Peak plasma ATRA concentrations of 350 ng/mL are achieved 1 to 2 hours following ATRA dosing and drop rapidly ($t_{1/2}$ = 50 minutes). ATRA is metabolized by the hepatic P450 microsomal enzyme system. Use of ATRA stimulates this degradative pathway. ATRA plasma concentrations, therefore, decrease with prolonged drug use.¹⁴⁵ Variation in hepatic microsomal metabolism accounts for significant patient-to-patient and day-to-day variation in ATRA clearance.¹⁴⁶

Toxicity. Many patients tolerate tretinoin with minimal morbidity. However, 20% to 25% of patients may develop a syndrome characterized by unexplained fever, leukocytosis, dyspnea with interstitial pulmonary infiltrates, peripheral edema, pleuropericardial effusions, hypotension, and acute renal failure.¹⁴⁷ Patients with 4 of these symptoms are classified as having a severe differentiation syndrome (also call retinoic acid syndrome), while those with 3 symptoms have intermediate syndrome. The differentiation syndrome occurs more frequently in patients with elevated WBC or renal insufficiency. Steroids are used to treat and prevent this syndrome. Pseudo-tumor cerebri, hyperlipidemia, and abnormal liver function tests have been observed with therapy. ATRA, like other retinoids, has significant teratogenic properties, particularly during the first trimester of pregnancy.¹⁴⁸

Bexarotene

Mechanism of Action. Bexarotene (Targretin[®]) is a retinoid approved for therapy of cutaneous T cell lymphoma. Retinoid modulation of tumor growth is mediated through binding to nuclear receptors that function as transcription factors to regulate gene expression in T cells. Two receptor families, retinoic acid nuclear receptors (RARs) and retinoid X nuclear receptors (RXRs) have been identified.¹⁴⁹ Bexarotene selectively binds and activates RXR receptors, inducing apoptosis in selected cell types through triggering of a variety of downstream events.¹⁵⁰

Clinical Pharmacology. Bexarotene is available as a topical gel for application to skin lesions or as an oral capsule for systemic therapy. Peak plasma concentrations are seen 2 to 3 hours after oral administration. Drug half-life is 4 to 7 hours. Bexarotene, like

P.1420

other retinoids, undergoes metabolism by the hepatic cytochrome P450 enzyme system (CYP3A4). Drug interactions with other CYP 3A4-metabolized drugs may occur. Gemfibrozil increases bexarotene concentrations and toxicity.

Toxicity. The most common bexarotene-associated toxicities are hyperlipidemia (82%), hypercholesterolemia (30%), central hypothyroidism (29%), headache (20%), asthenia (16%), pruritus (13%), and leukopenia (11%).^{151, 152} Side effects are more common at higher drug doses. Pancreatitis may result from hyperlipidemia. Use of lipid-lowering agents and thyroid replacement are often required. Thyroid function tests must be monitored.

Signal Transduction Inhibitors

Several antineoplastic agents have been FDA approved that inhibit a tyrosine kinase associated with signal transduction molecules activated in cancer cells. Inhibitors of the BCR-ABL (imatinib, dasatinib, nilotinib), PDGFR (sunitinib and sorafenib), EGFR (erlotinib, gefitinib), BRAF (vemurafenib), hedgehog (vismodegib), and VEGFR (sunitinib, pazopanib, and sorafenib) tyrosine kinases are clinically available. Imatinib mesylate, nilotinib, and dasatinib are currently approved for treatment of chronic myelogenous leukemia (CML). Other approved tyrosine kinase inhibitors are used primarily for treatment of solid tumors and will not be discussed in this chapter.

Imatinib Mesylate

Mechanism of Action

CML is characterized by a reciprocal exchange of genetic material between chromosomes 9 and 22 (t9; 22). A new gene is formed, the BCR-ABL proto-oncogene, which encodes a signal transduction protein that is autonomous. Increased activity of the BCR-ABL proto-oncogene leads to cellular proliferation, decreased apoptosis, or both.¹⁵³ The intracellular component of the BCR-ABL signal transduction protein contains a tyrosine kinase that activates subsequent signaling molecules by taking a phosphate from ATP and transferring it to a second signaling molecule. Imatinib mesylate (Gleevec[®]) binds to the ATP-binding site of the BCR-ABL oncoprotein and prevents transfer of phosphate from ATP to the second messenger (Fig. 68.15). Imatinib inhibits the tyrosine kinase of the BCR-ABL, c-kit, and PDGF oncogenes.¹⁵⁴

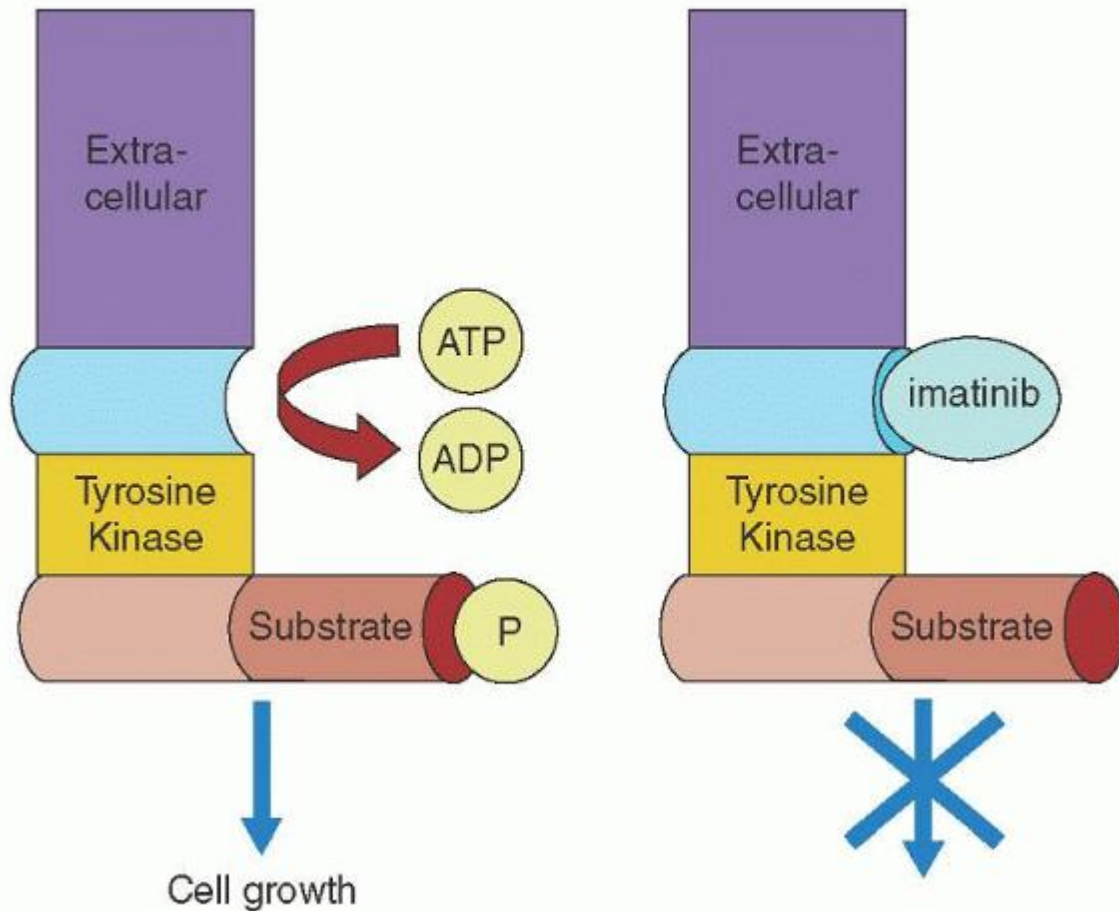

FIGURE 68.15. The BCR-ABL oncoprotein is shown schematically. This is a transmembrane protein with a tyrosine kinase on the intracellular part of the molecule. Imatinib mesylate binds to the tyrosine kinase, preventing activation of second-messenger proteins.

Clinical Pharmacology

Imatinib mesylate is given orally at doses of 400 to 800 mg/day. Bioavailability is 98%, with a drug half-life of 18 hours. Imatinib is cleared by hepatic microsomal cytochrome P450 metabolism (CYP 3A4) to a metabolite that has similar potency.¹⁵⁵ Biliary excretion of parent drug and metabolite account for 70% of drug clearance. However, no evidence of decreased clearance or increased drug toxicity has been seen in patients with hepatic or renal dysfunction.^{156, 157} Drugs that alter the hepatic CYP 3A4 metabolism have the potential to alter clearance of all BCR-ABL TKIs.¹⁵⁸

Toxicity

Mild nausea (70%), diarrhea (56%), and fluid retention are the most common toxicities associated with imatinib.^{154, 159} Edema can usually be managed with diuretics or dose reductions. Hematologic toxicity is mild and associated with a more advanced stage (e.g., CML blast crisis). Severe toxicity (grade 3 or 4) is rare (15% of patients). Abnormal liver function tests have been reported but require discontinuation of therapy in <0.5% of patients.

Dasatinib (Sprycel®)

Mechanism of Action

Roughly 25% to 45% of CML patients given imatinib discontinue this drug within 5 years either due to development of tumor resistance or to drug intolerance. To address this problem, several additional BCR-ABL TKIs have been developed. Dasatinib inhibits the ABL kinase present in patients with CML but differs from imatinib in that it can bind to both active and inactive conformations of the ABL kinase domain.¹⁶⁰ This less exacting requirement for binding allows dasatinib to

inhibit BCR-ABL mutations resistant to imatinib. Dasatinib also inhibits the SRC kinase.¹⁶¹ Dasatinib is a 100- to 300-fold more potent ABL kinase inhibitor than imatinib.

Clinical Pharmacology

Dasatinib is metabolized primarily by the hepatic cytochrome enzyme system (CYP 3A4). Concurrent use of drugs that induce or inhibit CYP 3A4 should be avoided if possible.¹⁶¹ Dasatinib's solubility is pH-dependent, so H₂ blockers and proton pump inhibitors should not be used with dasatinib. Antacids can be used, but 2 hours before or after administration of dasatinib.

Toxicity

Fluid retention, nausea, vomiting, and diarrhea are the most common toxicities seen with dasatinib use. Pleural effusions are noted in 8% of treated patients. Myelosuppression is common (50% grade 3 or 4).¹⁶² Grade 3 to 4 thrombocytopenia is seen in 35% to 80% of patients. Dasatinib may prolong the Q-T interval, increasing the risk of arrhythmias. Correcting hypokalemia and hypomagnesemia to minimize this effect is recommended.

Nilotinib (Tasigna®)

Mechanism of Action

Nilotinib is a second generation BCR-ABL TKI. It is similar in structure to imatinib but allows a better topologic fit with the ABL kinase and a 30-fold increase in potency.¹⁶³ Nilotinib also inhibits the KIT and platelet-derived growth factor tyrosine kinases, again more potent than imatinib.¹⁶⁴ Although both nilotinib and dasatinib are effective in most BCR-ABL mutants associated with resistance to imatinib (75% response rates), neither are effective against the T315I mutant.^{163, 164}

Clinical Pharmacology

Nilotinib is given orally at a dose of 400 mg twice daily. The plasma half-life is 15 to 17 hours and 98% of the drug is proteinbound. The metabolism of nilotinib is mainly hepatic. Drugs that inhibit CYP3A4 or prolong the QT interval should be avoided.

P.1421

Toxicity

Mild skin rash (28%), nausea (24%), pruritus (24%), and headache (19%) are common side effects, but rarely are severe.¹⁶³ Peripheral edema and pleural effusions seldom occur with nilotinib. Grade 3/4 neutropenia and thrombocytopenia were each reported in 29% of patients.¹⁶⁴ Typical biochemical abnormalities include increased serum lipase, hyperbilirubinemia (usually indirect), hyperglycemia and elevated transaminases. Prolongation of the Q-T interval is noted.

Proteasome Inhibitors—Bortezomib (Velcade®)

Mechanism of Action

Bortezomib targets and blocks the action of the proteasome. The proteasome is a large enzyme complex which breaks down proteins that have been selected for degradation.¹⁶⁵ The degradation process requires the proteins to transverse the regulatory gate of the proteasome. Bortezomib is a modified boronic peptide. It inhibits the chymotryptic site of the 26S proteasome, an enzyme that regulates protein degradation.¹⁶⁶ Bortezomib inhibits the degradation of proteins involved in regulation of cell proliferation and survival. It deregulates signaling molecules that are critical to the interaction of myeloma cells with the bone marrow microenvironment, leading to growth inhibition and apoptosis. Several intracellular molecules important in apoptosis, including NF-κB, JNK, Bcl-2, p53, and gp130 are modulated by proteasome degradation.

Clinical Pharmacology

The primary mechanism of bortezomib clearance is oxidative metabolism via the cytochrome P450 enzyme system (CYP 3A4, 2D6, 2C19, 2C9, and 1A2). Bortezomib penetrates poorly into the CNS. Dose adjustments are not needed with renal insufficiency.¹⁶⁷ Information regarding dose adjustments for hepatic insufficiency is lacking. Drug interactions could be expected with agents that inhibit cytochrome P450 metabolism.¹⁶⁸

Toxicity

The most frequent toxicities (>30%) associated with bortezomib treatment include fatigue/weakness, GI disturbances (nausea/anorexia/diarrhea/constipation), myelosuppression (neutropenia/thrombocytopenia), and peripheral neuropathy.¹⁶⁸ Peripheral neuropathy may be seen in up to 35% of patients; however, many myeloma patients have an underlying neuropathy prior to starting bortezomib. The neuropathy is related to the duration of treatment. Dose reductions based on the presence of neuropathy are needed and can result in improvement of neuropathy in 65% to 70% of patients.¹⁶⁹

Topoisomerase II Inhibitors (Doxorubicin, Daunorubicin, Epirubicin, Idarubicin, Mitoxantrone, Etoposide, and Teniposide)

Mechanism of Action

Topoisomerases are nuclear enzymes that make the transient strand breaks in DNA to allow the cell to manipulate DNA topology by passing an intact helix through a transient break in the DNA backbone.¹⁷⁰ This is a mechanism to relieve super coiling and tension on the DNA molecule. DNA topoisomerase I makes single-strand breaks in the DNA, whereas topoisomerase II makes double-strand breaks and passes double-stranded DNA through the break. Topoisomerase enzymes are needed for DNA replication, chromosome condensation, and chromosome segregation. Topoisomerase II inhibitors (doxorubicin, daunorubicin, epirubicin, idarubicin, mitoxantrone, etoposide, and teniposide) act by poisoning this enzyme to prevent it from relegating cleaved DNA (Fig. 68.16).¹⁷¹ This converts topoisomerase II into a toxin, by introducing high levels of transient protein-associated breaks in the genome of treated cells. Failures to repair the DNA break by the cell results in apoptosis. Currently available topoisomerase I inhibitors are irinotecan (CPT-11) and topotecan. As these agents are not frequently used in treatment of hematologic neoplasms, they will not be further discussed in this section. Topoisomerase II inhibitors include the anthracyclines, epipodophyllotoxins and mitoxantrone.

FIGURE 68.16. The catalytic cycle of topoisomerase II. Topoisomerase II binds to DNA. In the presence of magnesium and ATP, an intact DNA helix can pass through a temporary break in DNA with subsequent relegation. Topoisomerase II inhibitors block this cycle at the stage of DNA cleavage. (From Osheroff N, Zechiedrich EL, Gale KC. Catalytic functions of DNA topoisomerase II. *Bioassays* 1991;12:269-275.)

Anthracyclines (Doxorubicin, Daunorubicin, Epirubicin, and Idarubicin)

Clinical Pharmacology

Clearance of all anthracyclines occurs through hepatic metabolism and biliary excretion. Urinary excretion accounts for only ~10% of anthracycline clearance.^{172, 173, 174} Dose reduction is required for patients with jaundice, although specific dose reduction guidelines are not available. Use of doxorubicin in patients with hepatic dysfunction does not appear to increase cardiac toxicity, but an increase in mucositis and myelosuppression occurs. Liposomal-encapsulated anthracyclines (liposomal doxorubicin [Doxil[®], Myocet[™]] or liposomal daunomycin [DaunoXome[®]]) act as depot forms of

drug.^{175, 176} The delayed release of the anthracyclines from the liposome produces lower peak plasma concentrations and less cardiotoxicity.

Toxicity

The acute dose-limiting toxicity of the anthracyclines is myelosuppression, with a nadir in leukocytes expected around day 10 to 14, with recovery usually by day 21 to 28.¹⁷¹ Other acute systemic toxicities include nausea, vomiting, alopecia, and P.1422

mucositis. Anthracyclines cause severe local tissue reactions if extravasation occurs during infusion. The most serious toxicity associated with anthracyclines is cardiotoxicity. Anthracyclines cause a dose-dependent congestive cardiomyopathy that often leads to congestive heart failure. Late-onset cardiomyopathy can appear months to years after treatment is completed.¹⁷⁷ The mechanism underlying the cardiotoxic effects of anthracyclines remains uncertain but is thought to be via formation of free radicals, generated by iron-doxorubicin complexes that damage cardiac cellular membranes¹⁷⁸; cardiotoxicity may also be related to anthracycline damage to cardiac stem cells. The cardiac damage caused by anthracyclines is cumulative. With total doses of doxorubicin $<350 \text{ mg/m}^2$, heart failure is seen in $<5\%$ of cases. The risk of toxicity is related to the peak plasma concentration, so continuous infusions reduce the risk of heart failure compared to administration by large bolus injections. At equally myelosuppressive doses, epirubicin may be less cardiotoxic than doxorubicin.¹⁷⁸ Liposomal formulations of doxorubicin and daunorubicin have been investigated in the hopes of increasing tumor selectivity, which would allow an increase in the tolerated dose. The liposomal formulation of doxorubicin has reduced cardiotoxicity. Liposomal formulations of doxorubicin and daunorubicin are, however, associated with palmar-plantar erythrodysesthesia syndrome.^{175, 176}

Mitoxantrone

Clinical Pharmacology

Efforts to synthesize compounds with better antineoplastic activity and less toxicity than doxorubicin led to the discovery of mitoxantrone. Hepatic metabolism is the primary mechanism for mitoxantrone clearance, with only 6% to 11% being cleared by the kidney.¹⁷⁹

Toxicity

The primary dose-limiting toxicity of mitoxantrone is myelosuppression. Other potential toxicities include nausea, vomiting, alopecia, and cardiotoxicity. At doses that produce equivalent drops in white blood cell and platelet counts (75 mg/m^2 of doxorubicin vs. 15 mg/m^2 of mitoxantrone), nausea, vomiting, and alopecia are less frequent with mitoxantrone than with doxorubicin.^{179, 180} With commonly used dosages, approximately twice as much mitoxantrone can be given before heart failure develops as compared to doxorubicin. Acute leukemia is also a potential serious side effect of therapy using mitoxantrone.

Epipodophyllotoxins (Etoposide and Teniposide)

Clinical Pharmacology

Etoposide is poorly soluble in water. It is dissolved in a solubilizer composed of polysorbate 80, polyethylene glycol, and alcohol (Tween 80) and diluted to a concentration $<0.4 \text{ mg/mL}$ to avoid precipitation. These additives are believed to induce the hypersensitivity reactions occasionally seen with etoposide infusion. Approximately one-third of administered intravenous etoposide is excreted in the urine, and hepatic glucuronidation may account for another 25% of etoposide's metabolism.¹⁸¹ Etoposide is also hepatically metabolized to O-demethyl metabolites.¹⁸² Etoposide clearance is modestly decreased in patients with renal dysfunction, but not with hepatic obstruction. Biliary drug excretion is minimal so that only modest dose adjustment is required in the presence of obstructive jaundice. Etoposide is highly bound to plasma proteins, with only 6% to 8% of drug nonbound. Because free drug is biologically active, conditions that decrease protein binding or decrease albumin increase the pharmacologic effect of a given drug dose. Teniposide has less water solubility, decreased renal clearance (10%), and is even more tightly bound to plasma proteins than etoposide. Teniposide has a longer drug half-life and increased biliary clearance compared to etoposide. Anticonvulsants, such as phenobarbital and phenytoin, increase teniposide clearance, presumably by increasing hepatic metabolism.¹⁸³ This increased clearance results in a lower efficacy of chemotherapy in children with ALL receiving teniposide chemotherapy plus anticonvulsants. Etoposide is available as an oral capsule. Bioavailability of oral etoposide ranges from 40% to 80% and varies with the drug dose.³² Oral etoposide absorption is linear up to doses of 250 mg, but decreases with doses of $>300 \text{ mg}$. Oral etoposide

administration results in significantly greater variability in drug exposure than does intravenous administration.¹⁸⁴ Etoposide phosphate is a water-soluble prodrug that is rapidly changed to etoposide by endogenous phosphatases.¹⁸⁵

Toxicity

Common toxicities of etoposide and teniposide include bone marrow suppression, dose-dependent nausea or vomiting, and alopecia.¹⁸¹ Myelosuppression is the dose-limiting toxicity at usual therapeutic doses. At very high doses, such as those used with bone marrow transplantation regimens, mucositis becomes dose-limiting. Liver toxicity, fever, and chills are also seen with high-dose therapy. Hypersensitivity reactions, including vasomotor changes related to the pulmonary and gastrointestinal systems, although infrequent, can be life-threatening. These reactions may be due to hypersensitivity to the Tween 80 needed to solubilize the intravenous etoposide preparation. Hypersensitivity reactions can usually be ameliorated with histamine blockade and/or by using a slower infusion rate. Etoposide phosphate may reduce the risk of a hypersensitivity reaction, because no solubilizer is required. The most serious adverse event associated with etoposide and teniposide is the development of AML.¹⁸⁶ Therapy-related AML also occurs with other topoisomerase II inhibitors, but at a lower frequency. Leukemia develops relatively early after topoisomerase II inhibitor therapy (2 to 5 years) and can be distinguished from other therapy-related malignancies by a unique molecular marker: A balanced translocation involving the MLL (mixed-lineage leukemia) gene on chromosome 11 band q23.

Platinum Analogs (Cisplatin, Carboplatin, Oxaliplatin)

Mechanism of Action

The platinum analogs, cisplatin, carboplatin, and oxaliplatin, are heavy-metal complexes that induce tumor cell kill by cross-linking DNA strands in a manner analogous to the alkylating agents. Reactive aquated platinum intermediates are formed within cells, which directly and covalently bind to DNA, leading to DNA

P.1423

cross-links¹⁸⁷ (Fig. 68.17). Cisplatin is more reactive in water than carboplatin or oxaliplatin. The difference in aqueous stability, differences in the reactive groups, and spatial differences between platinum compounds appear to account for the variations in pharmacokinetics and toxicity among platinum agents. The amount of platinum bound to DNA after cisplatin, carboplatin, and oxaliplatin administration is similar, although the time frame for forming DNA adducts varies, with oxaliplatin and carboplatin taking more time than cisplatin.¹⁸⁸ Platinum compounds are effective in the treatment of solid tumors and are used as second-line agents in the treatment of lymphomas.¹⁸⁹

FIGURE 68.17. Sites of covalent binding of cisplatin to DNA. After forming an aquated reactive intermediate, cisplatin binds to guanine (and occasionally adenine) bases within the DNA molecule. Some adducts result in intrastrand DNA cross-links.

Clinical Pharmacology

The reactive intermediates of the platinum analogs rapidly bind to proteins and other nucleophilic compounds. Only the free (unbound) species are cytotoxic.¹⁹⁰ Over 90% of cisplatin is protein-bound and inactivated within 2 to 4 hours.¹⁹¹ Thus, protein binding represents the major route of cisplatin elimination. In contrast, only 20% to 40% of platinum is protein-bound at 2 hours following carboplatin administration. Renal excretion is the primary route of carboplatin elimination (70% to 90% of total clearance). Carboplatin clearance is highly correlated with creatinine clearance. Carboplatin doses should be calculated based on an individual patient's creatinine clearance.¹⁹² Oxaliplatin is also extensively cleared by the kidney (50%), but to a lesser degree than carboplatin. Increased toxicity following oxaliplatin therapy is not seen in patients with renal function impairment unless a patient's creatinine clearance falls to <20 mL/minute.¹⁹³

Toxicity

The toxicity profiles of cisplatin, oxaliplatin, and carboplatin differ. Myelosuppression is rare with cisplatin, although moderate anemia is common. Nausea and vomiting are common cisplatin toxicities, but the incidence can be reduced with decadron and serotonin antagonists.⁷⁷ Nephrotoxicity, manifest by azotemia and electrolyte disturbances (primarily hypomagnesemia and hypokalemia), is dose-related.¹⁹⁴ Although pre- and posttreatment hydration (with chloride-containing solutions) and diuresis reduce the incidence and severity of cisplatin nephrotoxicity, moderate and permanent reductions in glomerular filtration rate (GFR) may still occur.¹⁹⁵ Neurotoxicity from cisplatin is cumulative, dose-related, and usually begins as a "stocking-glove" type of peripheral neuropathy. The toxicity profile of carboplatin differs from cisplatin, with dose-limiting myelosuppression being the major toxicity following carboplatin administration.¹⁹⁶ Renal and ototoxicities noted with cisplatin are infrequent after carboplatin administration, although peripheral neuropathy is still seen. Nausea and vomiting after carboplatin usually are mild to moderate. Oxaliplatin results in neurotoxicity that is both acute and chronic. Reversible, cumulative peripheral sensory neuropathy is the primary dose-limiting factor of oxaliplatin

therapy. Hematologic and gastrointestinal toxicities occur but are mild to moderate. Ototoxicity and nephrotoxicity are uncommon.¹⁹⁷

Other Chemotherapeutic Agents Used in Hematology

Anagrelide (Agrylin®)

Mechanism of Action

Anagrelide is an oral imidazoquinazoline found to result in thrombocytopenia in the 1980s.¹⁹⁸ The precise mechanism of action is not known but anagrelide and its metabolite, 3-hydroxy anagrelide, block the maturation of platelets and reduce platelet counts. In contrast to hydroxyurea, anagrelide does not affect DNA or induce angiogenesis.¹⁹⁹

Clinical Pharmacology

Anagrelide is rapidly (2 hours) absorbed and then metabolized via the CYP1A2 to an active (3-hydroxy anagrelide) and inactive metabolite. Its half-life is 2 hours and that of the active metabolite is 4 hours.²⁰⁰

Toxicity

Because anagrelide and 3-hydroxy anagrelide inhibit phosphodiesterase, the main side effects (vasodilatation, tachycardia, headache, palpitations) are related to the positive inotropic effects of this drug.

Asparaginase

Mechanism of Action

Certain cells, particularly those of lymphocytic origin, lack the capacity to synthesize the amino acid asparagine. L-Asparaginase is an enzyme derived from bacteria that reduces blood asparagine to undetectable levels, thereby depriving cells of this amino acid. The cytotoxic effects of L-asparaginase on lymphoblasts result from the inhibition of protein synthesis when cells are depleted of asparagine.²⁰¹

Clinical Pharmacology

After intravenous enzyme administration, plasma asparagine levels fall rapidly and remain low for up to 10 days.²⁰⁰ Asparaginase can be detectable in the blood for 1 to 3 weeks, but as antibodies are formed, clearance of the drug is greatly accelerated. Asparaginase is degraded by protein metabolism. Trough asparaginase concentrations of 0.3 IU/ml are recommended for all leukemic patients.²⁰²

Toxicity

Toxic effects of asparaginase related to inhibition of protein synthesis include a decrease in circulating levels of albumin, clotting factors, insulin, and lipoproteins.²⁰³ Synthesis of anticoagulant proteins, such as antithrombin III, protein C, and protein S, is also reduced. Hypersensitivity reactions (urticaria, anaphylaxis, serum sickness) are common, with frequencies ranging from 20% to 40%. Conjugation of polyethylene glycol to asparaginase (pegasparaginase, Oncaspar®) prevents uptake of the drug by the reticuloendothelial system, making it less immunogenic and prolonging its circulating half-life. The incidence of hypersensitivity reactions to pegasparaginase in patients who have had reactions to Escherichia coli asparaginase is ~30%. The relative effectiveness and toxicity of asparaginase and pegasparaginase remain to be established.²⁰¹ Toxic reactions to both asparaginase and pegasparaginase include cerebral dysfunction (25% of patients), vomiting, chills (often an immediate reaction), pancreatitis (15% of patients), and liver function abnormalities.²⁰³

Arsenic Trioxide

Mechanism of Action

Arsenic trioxide (ATO, Trisenox®) is used for treatment of promyelocytic leukemia.²⁰⁴ Trivalent arsenic interacts with thiol groups in cells, primarily proteins that contain cysteine residues.²⁰⁵ The outcome of this interaction depends on the cell type and the dose and duration of arsenic exposure. The specific mechanism for ATO effects in APL has not clearly been defined, but As₂O₃ stimulates differentiation of APL cells, induces apoptosis, and inhibits NF-κB.

Clinical Pharmacology

Arsenic trioxide is methylated presumably in the liver and then excreted in the urine as metabolites.²⁰⁵ The antineoplastic effect of these metabolites is unknown. ATO has a half-life of 17 hours and distributes throughout the body. Drug penetration into the CNS is seen (14% of plasma concentrations).²⁰⁶ No dosage guidelines for patients with hepatic or renal insufficiency are currently available.

Toxicity

The most common ATO side effects include nausea, rash, fatigue, fever, headaches, diarrhea, and mild hepatotoxicity.^{204, 205, 206} The most common life-threatening toxicities include hypokalemia (13%), hyperglycemia (10%), the APL differentiation syndrome, and cardiac toxicity. Cardiac toxicity is primarily manifest by Q-T prolongation on the EKG, but Torsades de Pointe and sudden death have been reported. The "retinoid acid syndrome," similar to that noted following ATRA treatment, is frequently seen (25% of patients). The incidence of myelosuppression is low. Although arsenic is a known carcinogen, neurotoxin, and renal toxin, secondary malignancies, renal toxicity, and neuropathy have rarely been complications of arsenic trioxide therapy to date.

Bleomycin

Mechanism of Action

Bleomycin is a mixture of low-molecular-weight glycopeptides of which bleomycin A₂ is the major species. Bleomycin can be administered subcutaneously, intramuscularly, or intravenously and has been instilled into pleural and pericardial spaces to act as a sclerosing agent in patients with malignant effusions. Bleomycin produces single- and double-strand DNA breaks, which result in chromosomal deletions and fragmentation.²⁰⁷ The DNA strand breaks are generated by production of free radicals by a Fe (II)-bleomycin complex, which intercalates into DNA and allows one bleomycin molecule to cleave both strands of DNA.²⁰⁸

Clinical Pharmacology

Absorption after intramuscular or subcutaneous injection of bleomycin is nearly complete. Renal clearance accounts for 65% of total drug clearance. Patients with renal failure have a prolonged drug half-life and an increased risk of developing pulmonary toxicity.^{209, 210} A 75% dose reduction has been recommended for patients with a creatinine clearance <25 mL/minute. Approximately 45% of an intracavitary dose of bleomycin is absorbed into the systemic circulation, and 30% is excreted in urine.²¹¹

Toxicity

Bleomycin is not myelosuppressive. Fever occurs within 48 hours of drug administration in ~25% of patients. Rare acute allergic reactions have been noted with this drug.²¹² The most prominent toxic effect of bleomycin is a chronic interstitial pneumonitis, which may continue on to fibrosis, hypoxia, and death.²¹³ Pulmonary toxicity, manifested by cough, dyspnea, and pulmonary infiltrates, occurs more often at higher cumulative drug doses but can occur following any dose. Approximately 10% of patients who receive a total drug dose of >400 mg develop pulmonary toxicity. Risk factors for pulmonary toxicity include individual doses >25 U/m², advancing age, underlying lung disease, and previous radiation therapy to the chest.²¹⁴ Patients who receive high oxygen concentrations during anesthesia following bleomycin therapy have been associated with increased frequency of bleomycin lung toxicity in some studies but not others. No specific therapy is effective, other than stopping the drug. Bleomycin can also result in cutaneous toxicities of hyperpigmentation, erythema, desquamation, nail changes, and alopecia. Reynaud's phenomena have been reported.

Interferon Mechanism of Action

Interferons (IFNs) are a family of glycoproteins of which some are inhibitors of viral replication and tumor growth. Type I interferons include α , β , and ω subtypes while type II interferon has only INF γ . Type I interferon α is used for treatment of hematologic malignancies. IFN- α 2b (Intron A[®]) and IFN- α 2a (Roferon[®]) are recombinant products that differ by one amino acid of 166. A pegylated interferon is also available. IFNs have multiple effects on cytokine production and regulation of tumor oncogenes and antioncogenes. The specific mechanism of antitumor activity of the IFNs is unclear, but the IFNs produce direct antiproliferative effects on tumor cells, increase host-mediated immune defenses, and inhibit angiogenesis.^{215, 216, 217} They stimulate activity of T cells, natural killer cells, dendritic cells, monocytes, and macrophages.

Clinical Pharmacology

The IFNs can be administered subcutaneously, intramuscularly, or intravenously. Following exposure to IFN, expression of >20 genes is altered. The optimal dose and administration route of IFN are not clear. IFN- α 2a is metabolized by the liver and filtered through the glomeruli, while INF- α 2b is metabolized and cleared by the kidney. The half-life of interferon α is 2 to 3 hours,²¹⁸ although its biologic effect is much longer. The half-life of pegylated interferon is 177 hours.

Toxicity

IFN- α use is associated with many toxicities, including a flulike syndrome manifested by myalgias and fatigue in patients who are not premedicated with antipyretics.^{219, 220} The severity of myalgias decreases with continued drug use. Nausea and vomiting are noted less often. Somnolence and lethargy occur when higher doses of IFN are used. Other, less common side effects include myelosuppression, diarrhea, mild alopecia, skin rashes, and elevated hepatic enzymes. Depression, anxiety, and suicidal ideation may occur with IFN therapy.²²¹ These toxic effects are readily reversed when administration of the IFN is stopped. Some of the immediate systemic toxicity associated with the use of this agent can be prevented by administration of acetaminophen or megestrol.

Thalidomide (Thalomid®) and Lenalidomide (Revlimid®)

Mechanism of Action

Thalidomide and lenalidomide are immunomodulatory drugs with a wide range of potential antineoplastic actions. Both drugs have similar immunomodulatory effects. Lenalidomide was developed after thalidomide and is more potent with fewer side effects. Thalidomide and lenalidomide activate T cells and stimulate endogenous cytokine release including IL-2, and IFN- α production.²²² They inhibit TNF- α synthesis and block the activation of NF- κ B kinase. They increase NK cell number and function. Thalidomide and lenalidomide also inhibit the action of vascular endothelial growth factor (VEGF) and block angiogenesis. The specific mechanism of antineoplastic immunomodulation of these two agents remains uncertain.

Clinical Pharmacology

The structure of thalidomide and its analog, lenalidomide, are shown in Figure 68.18. Thalidomide is a mixture of R and S enantiomers. It undergoes rapid spontaneous hydrolysis in plasma to multiple hydroxylated metabolites. Very little thalidomide undergoes hepatic metabolism via the cytochrome P450 system, so CYP-directed drug interactions are unlikely. Absorption of oral thalidomide is slow (3 to 4 hours) but extensive

P.1425

(80% bioavailability). Drug half-life is 6 hours. Ninety percent of the drug is excreted in the stool or urine within 48 hours, mostly as metabolites. The effect of food on thalidomide absorption is minimal. Repeat dosing does not affect kinetics. Because thalidomide is mainly hydrolyzed and passively excreted, its clearance is not expected to be altered in patients with impaired liver or renal function.²²³ Lenalidomide is rapidly absorbed when given by mouth ($t_{\max} = 1.0$ hour). Food does not alter drug absorption but does slow oral absorption. In normal volunteers, two-thirds of an administered dose is excreted unchanged in the urine.²²⁴ Drug half-life is 3 hours. Lenalidomide is effective in myeloma patients with renal insufficiency but increased toxicity (myelosuppression and neuropathy) is noted in this population. Dose reductions may be needed for individuals with renal insufficiency.²²⁵

FIGURE 68.18. The chemical structures of thalidomide and lenalidomide.

Toxicity

Thalidomide is a potent teratogen. Use of thalidomide as a sedative in the late 1950s resulted in birth defects in >10,000 infants.²²⁶ Birth defects include absent or hypoplastic limbs, ear or eye deformities, and heart defects. Thalidomide administration to pregnant women is absolutely contraindicated. Women of child-bearing age must have a negative pregnancy test before starting thalidomide, use two effective forms of birth control, and have a pregnancy test every 4

weeks. Breastfeeding is prohibited. Men must use a condom or refrain from intercourse. Common thalidomide toxicities include neuropathy, somnolence, and constipation. The incidence of neuropathy is 38% at 6 months and 73% at 12 months.²²⁷ Clinical features are tingling or painful distal paresthesias affecting primarily the feet but sometimes the hands. The duration of thalidomide therapy correlates directly with the development of neurotoxicity. Some degree of sedation is universal, dose-dependent, and usually appears 2 weeks after initiation of therapy. Some patients suffer from depression. Tremors and/or headaches occur in 5% to 20% of patients. Venous thrombosis is seen in 2% to 23% of patients, with higher risk in patients >60 years of age. Sinus bradycardia is noted in 5% of patients. Constipation develops a few days after starting treatment in >50% of patients. Hypothyroidism occurs in 20% of patients occurring 1 to 6 months after starting therapy. A maculopapular skin rash or pruritus is seen in 20% to 50% of patients. Stevens-Johnson syndrome is occasionally seen (<1%).

Although lenalidomide does not cause birth defects in animal models, because of its similarity to thalidomide, this drug should not be given to pregnant women. The most common lenalidomide toxicity is a reversible myelosuppression (neutropenia and thrombocytopenia). Sedation is not seen with lenalidomide. Neuropathy has been noted but is felt to occur less frequently than with thalidomide.²²⁷ Skin rash and itching are seen in 25% of patients. Deep-vein thrombosis has been noted when lenalidomide has been used with dexamethasone.²²⁸ Hypothyroidism occurs in 5% to 10% of patients receiving lenalidomide. An increased risk of development of second malignancies has been reported with both thalidomide and lenalidomide.²²⁹

The Future

Additional genes, signaling pathway molecules, and posttranslational events important in the development and growth of hematologic cancers will continue to be discovered. Accruing knowledge of cancer biology identifies potential new pathways for therapy. In 2012, over 900 potential antineoplastic agents were in development. Readers are referred to websites: <http://www.clinicaltrials.gov> and www.phrma.org/research/new-medicines for details of potential antineoplastic agents in clinical development. While it is hard to predict the future, it is likely that drugs targeting additional signal transduction pathways^{230, 231, 232, 233, 234} and additional monoclonal antibodies or antibody-drug conjugates²³⁵ are likely to be developed. Drugs targeting new pathways such as the Flt-3 tyrosine kinase, present in one-third of AML patients,²³⁶ phosphatidylinositol kinase (PI3K), upregulated in B cell malignancies,²³⁷ and Bruton's tyrosine kinase (Btk)²³⁸ appear promising. New, less toxic and more specific IMiDs (pomalidamide) and proteasome inhibitors (carfilzomib)²³⁸ appear close to FDA review. Innovative immunomodulatory therapies are under development.^{239, 240} Readers will need to continue to monitor the medical literature to keep pace with these rapidly changing developments in treatments for hematologic cancers.

Chapter 69

Supportive Care in Hematologic Malignancies

Andrew J. Moore

Mary A. Vu

Stephen A. Strickland

Patients with hematologic neoplasms are at significant risk for complications both from the malignancy as well as the required therapy. The morbidity and mortality associated with the expected cytopenias, the therapeutic modalities, as well as the potential organ impairment present significant challenges to patients and health care providers alike. The frequency and severity of these complications vary among patients and according to the underlying disease process. Continued investigation and advances in antibiotics, antiemetics, and palliative therapies are allowing us to better meet the ever changing needs of our patients and ensure the provision of quality care. This chapter provides an overview of

current recommendations and recent advances in the management of challenges encountered in the care of patients with hematopoietic malignancies.

INFECTIOUS DISEASE ISSUES RELATED TO HEMATOLOGIC MALIGNANCY

Deficits in Host Defense

Patients with hematologic malignancies are at increased risk for infection due to impaired host defense from the underlying malignancy along with concomitant illnesses or extrinsic factors including marrow-suppressive therapy. Hematologic malignancies are often associated with specific or global immune abnormalities that result in increased frequency of infections or opportunistic infections even in the absence of treatment. Understanding the different risk factors in the individual patient allows appropriate preventive strategies and treatments to be implemented more effectively. Defects in host defense mechanisms associated with specific malignancy are outlined in Table 69.1, whereas Table 69.2 identifies opportunistic infections by the host defects, such as those caused by impairment of phagocytosis (mainly neutropenia), defective production of circulating antibody (humoral immunity), and impaired cellular immunity. Concomitant illnesses, such as diabetes, nephrotic syndrome, cardiac disease, and liver disease contribute to infection risk and influence management decisions.¹

Neutrophil Defects

Neutrophils play a critical role in the innate immune response, mediating both antimicrobial and inflammatory responses. They are produced in the bone marrow under the influence of an array of cytokines. Mature neutrophils circulate in the peripheral blood for only 3 to 6 hours, placing a demand on the marrow for an impressive capacity for constitutive neutrophil production that can be rapidly upregulated in response to acute bacterial, fungal, or inflammatory stresses.² Deficits in neutrophil number and functional defects of mature neutrophils predispose to life-threatening infections, while disruption of the maturation sequence underlies the pathophysiology of myelodysplasia and leukemia.

Neutropenia, defined as a decrease of the peripheral blood neutrophil count below $0.1 \times 10^9/L$, predisposes to bacterial and fungal infections. The severity ($0.1 \times 10^9/L$) and length of neutropenia (>2 weeks) contribute to the risk of serious infections.³ Neutropenia is usually caused by decreased production. Localizing signs and symptoms are often absent in the setting of severe neutropenia because of a lack of inflammatory response from absent granulocytes. Fever remains the most common sign of infection associated with neutropenia.

Neutropenia is a common complication of acute leukemia (AL) and is often prolonged during induction therapy.⁴ In chronic myeloid leukemia (CML), neutropenia typically occurs with the development of blast crisis, with the evolution of myelofibrosis (MF), or with therapy. Mild neutropenia is observed in patients with MF and multiple myeloma (MM), but it is uncommon during untreated phases. Neutropenia occurring in patients with Hodgkin lymphoma (HL) or non-Hodgkin lymphoma (NHL) is typically a result of marrow invasion with tumor or marrow fibrosis and occurs in conjunction with other cytopenias. Hairy cell leukemia patients may become neutropenic secondary to tumor cell invasion, splenomegaly, or both, but may also result from defects in cell-mediated immunity, monocytopenia, and decreased T cells after nucleoside analog therapy.⁵ In patients with T cell large granular lymphocytic leukemia, neutropenia may be the primary problem.

Functional defects in morphologically normal neutrophils have been described in hematologic malignancies, particularly myeloproliferative neoplasms (MPNs) and myelodysplastic syndrome (MDS).⁶ Such defects increase the susceptibility to infection.⁷ Neutrophils from untreated patients with CML may be mildly defective with respect to phagocytosis, oxygen consumption, and bactericidal capacity, and tend to have decreased concentrations of lactoferrin, elastase, collagenase, and peroxidase.⁸ Myeloblasts and lymphoblasts found in AL patients are of no benefit to the host against infection.

Deficient Immunoglobulin Production

The humoral immune response is one of the two main arms of the immune system. In this response, the immune system triggers specific B cells to proliferate and secrete their specific antibodies. Impaired humoral immunity is a major cause of frequent and severe infection in patients with hematologic malignancies. A decrease in Th2 CD4 T-lymphocyte-B-lymphocyte interaction results in decreased antibody production, complement-mediated damage, and phagocytosis. Diminished immunoglobulin synthesis is a major contributor to infection in patients with CLL, MM, and some B cell types of NHL.^{9,10,11} Myeloma and other plasma cell dyscrasias are often functionally hypogammaglobulinemic despite elevated total immunoglobulin. Splenectomized patients have impaired antibody response, reduced levels of tuftsin (natural activator of phagocyte cells), and are at increased risk for infections similar to those of patients with hypogammaglobulinemia, particularly encapsulated organisms (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*).¹²

Defects in Cellular Immunity

Cellular immunity comprised of T lymphocytes, macrophages, and natural killer cells recognizes and combats pathogens that proliferate intracellularly. Cellular immune mechanisms are important in immunity to all classes of infectious agents, including most viruses and many bacteria (e.g., *Mycoplasma*, *Chlamydia*, *Listeria*, *Salmonella*, and *Mycobacterium*), parasites (e.g., *Trypanosoma*, *Toxoplasma*, and *Leishmania*), and fungi (e.g., *Histoplasma*, *Cryptococcus*, and *Coccidioides*).¹³ T lymphocytes are activated by dendritic cells, macrophages, and B lymphocytes, which present foreign antigens in the context of the host's own major histocompatibility complex antigen to the T cell receptor. Activated T cells then act in several ways to fight infection. Cytotoxic CD8⁺ T cells directly attack and lyse host cells that express foreign antigens. Helper CD4⁺ T cells stimulate the proliferation of B cells and the

P.1427

production of immunoglobulins. Defects in cell-mediated immunity characterized by impaired Th1 CD4⁺ T lymphocytes and/or macrophage function results in increased risk of infections with intracellular bacteria, fungi, parasites, and viruses (Table 69.2).

TABLE 69.1 HOST DEFECTS PREDISPOSING TO COMPLICATIONS IN HEMATOLOGIC MALIGNANCIES

Disease	Host Defect	Complications
Acute myeloid leukemia	Neutropenia	Bacterial infections, including perirectal abscess, typhlitis, sinusitis; superinfections when hospitalized; increasing problem of methicillin-resistant <i>Staphylococcus aureus</i> and coagulase-negative staphylococci; <i>Clostridium difficile</i> colitis; aspergillosis with prolonged neutropenia; viral infections (herpes simplex)
	Thrombocytopenia, disseminated intravascular coagulation	Hemorrhage
	Hyperleukocytosis	Leukostasis, tumor lysis
Acute lymphoblastic leukemia	Neutropenia	Bacterial infections (see Acute myeloid leukemia)
	Cellular immunity while on maintenance therapy	<i>Pneumocystis jirovecii</i> , disseminated varicella
	Thrombocytopenia	Hemorrhage
Chronic myeloid leukemia	Hyperleukocytosis	Tumor lysis, leukostasis
	Mild defects in neutrophil function	No increased risk of infections except in blast crisis
	Thrombocytosis, platelet dysfunction	Increased risk of thrombosis and hemorrhage, similar to other myeloproliferative disorders
Chronic lymphocytic leukemia	Decreased immunoglobulins	Infections with encapsulated organisms (pneumococcus, <i>Haemophilus influenzae</i> , meningococcus)
	Cellular immunity	Mycobacteria, fungal, viral (herpetic), <i>Salmonella</i>
Hodgkin lymphoma	Immune dysfunction	AIHA, ITP, red cell aplasia
	Cellular immunity	Viral (herpes zoster, other), <i>P. jiroveci</i> , fungal, mycobacteria, listeriosis, <i>Salmonella</i>

	Cytokine production	B symptoms, pruritus, eosinophilia
	Splenectomized	Encapsulated organisms (above), increased risk of leukemia
	Immune dysfunction	ITP, AIHA
	Mediastinal disease	SVC syndrome
Non-Hodgkin lymphoma		
Small B cell lymphoma	Decreased Igs	Similar infections to CLL
PTCL, particularly angioimmunoblastic and subcutaneous panniculitis like PTCL	Immune dysfunction	AIHA
	Cytokine production	B symptoms, hemophagocytic syndrome, eosinophilia
Large B cell lymphoma	Mediastinal disease	SVC syndrome, pericardial disease
T-lymphoblastic lymphoma	Mediastinal disease	SVC syndrome, tumor lysis, CNS disease
Mantle cell lymphoma	Colonic polyposis	Gastrointestinal bleed
Burkitt lymphoma	Gastrointestinal primary	Obstruction, perforation, tumor lysis, CNS disease with advanced-stage disease
Multiple myeloma	Paraprotein	Hyperviscosity, hemorrhage
	Decreased Igs	Similar infections to CLL
	Osteoclast overactivity	Hypercalcemia
Waldenström macroglobulinemia	IgM paraprotein	Hyperviscosity, hemorrhage
Hairy cell leukemia	Neutropenia	Bacterial and fungal infections
	Cellular immunity	<i>P. jirovecii</i> , atypical mycobacteria
	Immune dysfunction	Periarteritis nodosa, lymphocytic vasculitis
	Monocytopenia	—
T cell large granular lymphocyte leukemia	Neutropenia	Bacterial infections
	Immune dysregulation, positive rheumatoid factor, antinuclear antibody	ITP, AIHA, red cell aplasia
Adult T cell leukemia/lymphoma	Cellular immunity	Opportunistic infections (<i>Strongyloides stercoralis</i> , <i>P. jirovecii</i>)
	Parathyroid hormone-related protein	Hypercalcemia

AIHA, autoimmune hemolytic anemia; CLL, chronic lymphocytic leukemia; CNS, central nervous system; Ig, immunoglobulin; ITP, immune thrombocytopenic purpura; PTCL, peripheral T cell lymphoma; SVC, superior vena cava.

Multiple factors determine the severity and frequency of impaired cellular immunity. There may be differences in the stages of disease studied, the therapy used, and the sensitivity of the tests used to measure cellular immunity. Patients

with HL often do not respond to new antigens and lose prior sensitivity as well.^{13,14} Patients with CLL usually show reduced or absent lymphocyte transformation with phytohemagglutinin but do not lose skin hypersensitivity to antigens such as old tuberculin.¹⁵ Patients with HL do not mount

P.1428

either a primary or a secondary immune response, whereas those with CLL maintain secondary responses but cannot mount a primary response. Depressed cellular immunity is uncommon in AL¹⁶ except during maintenance therapy in ALL.¹⁷

Approach to Infection in the Immunocompromised Host

The initial assessment of a febrile immunocompromised host is dependent on the underlying hematologic condition and other associated risk factors. It should focus on determining the potential sites and causative organisms and assessing the patient's severity of illness. Although fever remains the most important clue to an infectious process, the characteristic signs and symptoms of infection may be absent in more than one-half of infected neutropenic patients, and routine cultures are often negative.³ It is estimated that 60% or more of neutropenic patients who become febrile have an established or occult infection.¹⁸ No known factors accurately predict which patients with fever and neutropenia are most likely to have bacteremia. As a result, a careful history and screening physical examination must be performed with special attention to the most common sites of infection: skin, oropharynx, nares, sinuses, lungs, GI tract (including perianal area), soft tissues, and indwelling catheter devices.

Risk assessment should be performed as part of the initial evaluation as it helps stratify the severity and facilitate goal-directed therapies. Assessing risk may determine the type of empiric antibiotic therapy (oral vs. intravenous), venue of treatment (inpatient vs. outpatient) and duration of antibiotic therapy. The most commonly used index for the stratification of risk for complications in febrile neutropenic patients is the Multinational Association for Supportive Care in Cancer (MASCC) index (Table 69.3).¹⁹ The following independent factors were found to be predictive of lower risk for complications: (1) burden of illness characterized by low or moderate symptoms, (2) absence of hypotension, (3) absence of chronic obstructive pulmonary disease, (4) presence of solid tumor or absence of previous fungal infection in patients with hematologic malignancies, (5) outpatient status, (6) absence of dehydration, and (7) an age less than 60 years. These variables predicting low risk were assigned an integer weight, and a risk index score consisting of the sum of these integers was derived. A score of 21 or greater identified low-risk patients with a positive predictive value of 91%, specificity of 68%, and sensitivity of 71%; whereas those with scores less than 21 are at higher risk for complications.¹⁹

In general, most experts consider high-risk patients to be those with anticipated prolonged (>7 days duration) and profound neutropenia (ANC < 0.1 × 10⁹/L) or significant medical comorbid conditions, including hypotension, pneumonia, new abdominal pain, or neurologic changes. High-risk patients warrant inpatient therapy with intravenous antibiotics. Lower-risk patients, including those with anticipated brief (<7 days duration), neutropenic periods, and few comorbidities, are candidates for empiric oral therapy.

Initial evaluation of neutropenic fever (Table 69.4) should include blood cultures, a urinalysis and urinary Gram stain, complete blood count with a differential, and blood chemistry tests to assess liver and renal function. Chest radiographs should be obtained for all patients with respiratory signs or symptoms, as well as viral swabs, and cultures of aspirated or biopsy material from accessible body sites that appear infected. At least two sets of blood cultures are recommended, with a set collected simultaneously from each lumen of an existing central venous catheter (CVC), if present, and from a peripheral vein site according to the updated guidelines from the Infectious Diseases Society of America (IDSA).³ An aggressive diagnostic workup is warranted if any localizing signs or symptoms are elicited. Patients who are unable to undergo invasive diagnostic procedures to determine an infectious etiology should be treated with empiric antibiotics until the appropriate diagnostic workup can be safely performed, or until the neutropenia resolves. Additional radiographic tests, such as computed tomography (CT) scans of the sinuses, chest, and abdomen, as well

P.1429

as examination of cerebrospinal fluid, may be necessary in selected patients. Noninfectious causes such as drug reactions, mucositis, graft-versus-host disease (GVHD) should be considered in patients with persistent fever. Superinfection with fungi or *Clostridium difficile* needs to be considered as well. Frequent reassessment of the patient's clinical status will help determine whether there is a need for additional coverage or changes to the ongoing antimicrobial regimen.

TABLE 69.3 THE MASCC RISK INDEX SCORE: DETERMINING THE RISK OF SERIOUS COMPLICATIONS IN FEBRILE NEUTROPENIA

Category	Weight
Burden of illness: no or mild symptoms	5
No hypotension	5
No chronic obstructive pulmonary disease	4
Solid tumor or no previous invasive fungal infection	4
Outpatient status	3

Burden of disease: moderate symptoms	3
No dehydration	3
Age < 60 y	2

MASCC, Multinational Association of Supportive Care in Cancer. The maximum theoretical score is 26 because the maximum favorable weight for burden of disease is 5.

Empiric Antibiotic Therapy: Current Guidelines and Regimens

The goal of initial empiric antibiotic therapy is to prevent serious morbidity and mortality due to bacterial pathogens until further culture results are available. In the early 1970s combination regimens incorporating two or three additive or synergistic drugs were used, such as antipseudomonal penicillin and an aminoglycoside. Subsequent regimens included beta-lactam and beta-lactamase inhibitor such as ticarcillin-clavulanic acid and piperacillin-tazobactam. Decades of well-studied clinical trials have not yet identified a superior empiric therapeutic regimen for the initial treatment of febrile neutropenic patients.²⁰ Effective regimens (combination or monotherapy) share certain essential features, including bactericidal activity, antipseudomonal activity, and minimal toxicity. Initial choice of antimicrobials should be based on the risk status of the patient (low vs. high), on localizing signs or symptoms of infection, and on the epidemiology of pathogens and antibiotic susceptibility patterns in individual centers. Evidence-based guidelines are available for additional guidance on antibiotic therapy for neutropenic patients with fever.^{3,21,22} An algorithm for managing patients with febrile neutropenia is provided in Figure 69.1.

Initial Antibiotics for High-risk Patients

Monotherapy with selected broad-spectrum beta-lactams with activity against *Pseudomonas* species is as effective as combination antibiotic regimens (beta-lactam plus aminoglycoside) for empiric therapy of uncomplicated fever and neutropenia, and has fewer toxicities.^{23,24} Antibiotics recommended by the IDSA as appropriate monotherapy include the following: cefepime, imipenem-cilastatin, meropenem, and piperacillin-tazobactam.³ Many centers have found that ceftazidime is no longer reliable as empiric monotherapy for neutropenic fever because of decreasing potency against gram-negative organisms and poor activity against many gram-positive pathogens, such as streptococci.^{25, 26} and ²⁷ Other antimicrobials (aminoglycosides, fluoroquinolones, and/or vancomycin) may be added to the initial regimen for management of complications such as hypotension and pneumonia, or there are specific clinical indications including suspected catheter-related infections, skin or soft-tissue infections, or if antimicrobial resistance is suspected or proven.

A meta-analysis of randomized trials involving cefepime reported that cefepime was associated with increased 30-day mortality when used for empiric therapy for neutropenic fever; however, no increase in infection-related mortality was noted.²⁸ Subsequent analysis by the FDA failed to demonstrate a statistically significant increase in 30-day mortality for cefepime-treated

P.1430

patients compared with controls, and thus concluded that cefepime remains a reasonable option for treating febrile neutropenia.^{28,29}

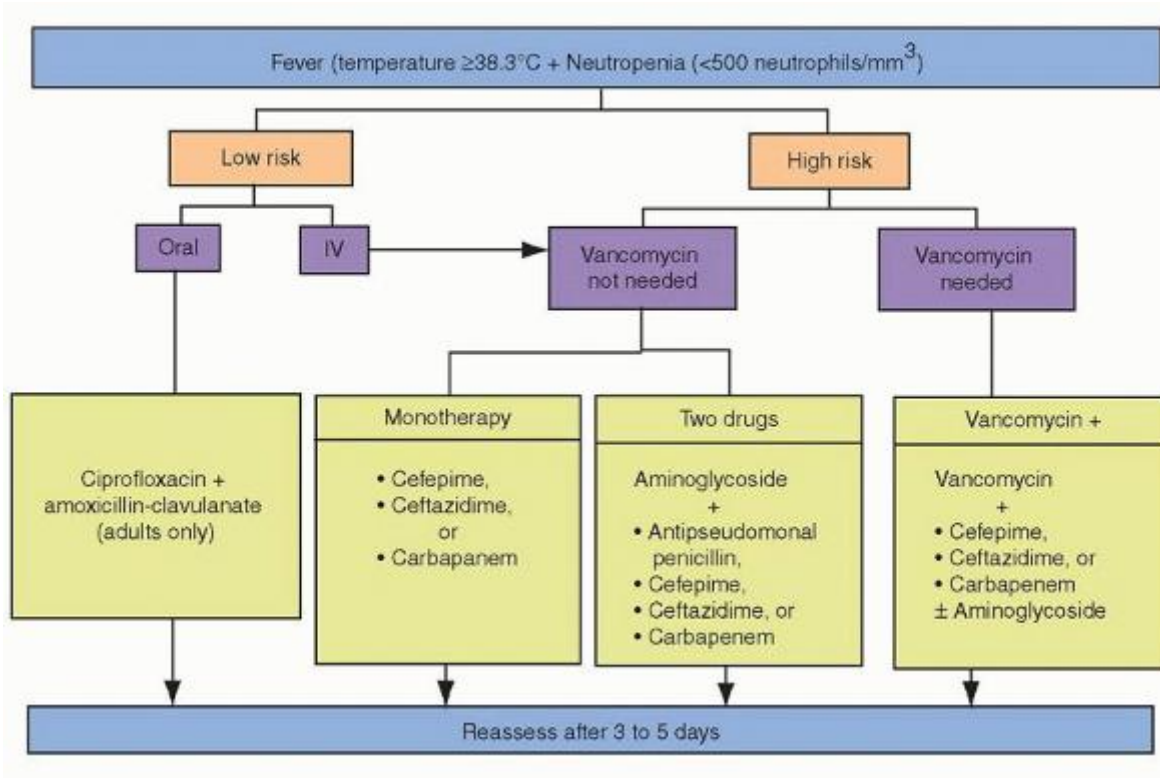

FIGURE 69.1. Empiric antibiotic regimens in febrile neutropenia.

Empiric combination therapy should be used in cases of severe sepsis or septic shock, or high prevalence of multidrug-resistant gram-negative bacilli. Effective antibiotic combinations include one of the aforementioned beta-lactams plus an aminoglycoside (choice based on local resistance, typically amikacin). Fluoroquinolones may be an acceptable alternative to aminoglycosides at institutions where prevalence of quinolone-resistant bacteria is low, or in patients with renal insufficiency. Febrile neutropenic patients with candiduria or oral thrush should also be covered by empiric antifungal therapy.

Role of Vancomycin and Other Agents in Gram-positive Coverage

Empiric vancomycin use in febrile neutropenia has led to considerable debate and concern, as the uncontrolled use of vancomycin facilitates vancomycin-resistant organisms. Randomized trial data provided by the European Organization for Research and Treatment of Cancer (EORTC) failed to demonstrate a true clinical advantage for empiric vancomycin in adults.³⁰ It decreased the number of days the patient had fever, but did not improve survival and was associated with increased incidence of nephrotoxicity and hepatotoxicity. Empiric vancomycin should therefore be reserved for specific settings during neutropenia, including (1) hypotension or septic shock without an identified pathogen, (2) clinically apparent catheter-related infection, (3) positive blood cultures with a gram-positive organism prior to identification and susceptibility testing (linezolid or daptomycin are reasonable alternatives in environments with high prevalence of vancomycin-resistant enterococcus [VRE]), or (4) known colonization with methicillin-resistant *Staphylococcus aureus* (MRSA) or penicillin-resistant *S. pneumoniae*. Consideration should also be given to discontinuation of the empiric vancomycin after 2 to 3 days if the initial cultures are negative. Vancomycin plus aztreonam is an acceptable regimen in febrile neutropenic patients with allergies to beta-lactams.³¹

Lower-risk Patients with Fever and Neutropenia

Patients with fever and neutropenia can be stratified according to their risk of developing life-threatening infectious complications.^{21,22} Outpatient management with close monitoring and follow-up may be feasible for patients with MASCC scores of 21 or greater given the lower risk of complications. The IDSA, the American Society of Clinical Oncology (ASCO), and the National Comprehensive Cancer Network (NCCN) support the use of outpatient oral antibiotic therapy in carefully selected lower-risk patients with neutropenic fever. Ciprofloxacin plus amoxicillin/clavulanate is recommended for adult patients. Clindamycin can be substituted for amoxicillin/clavulanate in patients allergic to penicillins.³ Fluoroquinolones have an importance in the outpatient management of febrile neutropenic adults since they are the only class of oral antibiotics with activity against *P. aeruginosa*.

Evaluation of Response and Duration of Therapy

Modifications of the initial antimicrobial regimen are made based on new physical findings, microbiologic data, or persistent fever that indicates a resistant organism. It often takes 3 to 5 days to determine the efficacy of the initial antibiotic regimen (Fig. 69.2). Low-risk patients may become afebrile as early as 2 days, and high-risk patients may take as long as 7 days to have a response to the antibiotics. Antibiotics should be continued for a minimum of 7 days or until the documented infection has been eradicated. It is preferable to have neutrophil recovery ($ANC > 0.5 \times 10^9/L$) before discontinuing therapy. If the patient continues to be febrile 3 to 5 days after the initiation of empiric antibiotics, one of three choices can be made: continue the same antibiotics if the patient is stable and no source of infection has been found; change or add antibiotics if the patient develops a new complication, there are new findings on evaluation, or the patient appears to worsen clinically; or add an antifungal drug.^{3,32}

Empiric amphotericin B has been replaced with the use of less toxic antifungals, such as caspofungin, micafungin, voriconazole, posaconazole, and the lipid formulations of amphotericin B. Risk of fungal infection (*Aspergillus* and *Candida*) rises precipitously in patients with profound neutropenia and persistent fevers after 7 to 10 days. Empiric antifungal therapy has been shown to reduce infectious mortality in patients with new or persistent fever occurring after 1 week of antibiotic therapy.^{33,34} Fluconazole is highly effective in the treatment of oropharyngeal and esophageal candidiasis and may be as effective as amphotericin B for systemic candidiasis in patients who are hemodynamically stable and have not been on antifungal prophylaxis. Broader spectrum antifungal agents are indicated in the setting of suspected *Aspergillus*,

P.1431

atypical fungi, and several clinically relevant *Candida* species (*C. krusei*, *C. tropicalis*, *C. lusitanae*, and *Torulopsis glabrata*) due to the absent or poor activity of fluconazole against these organisms.

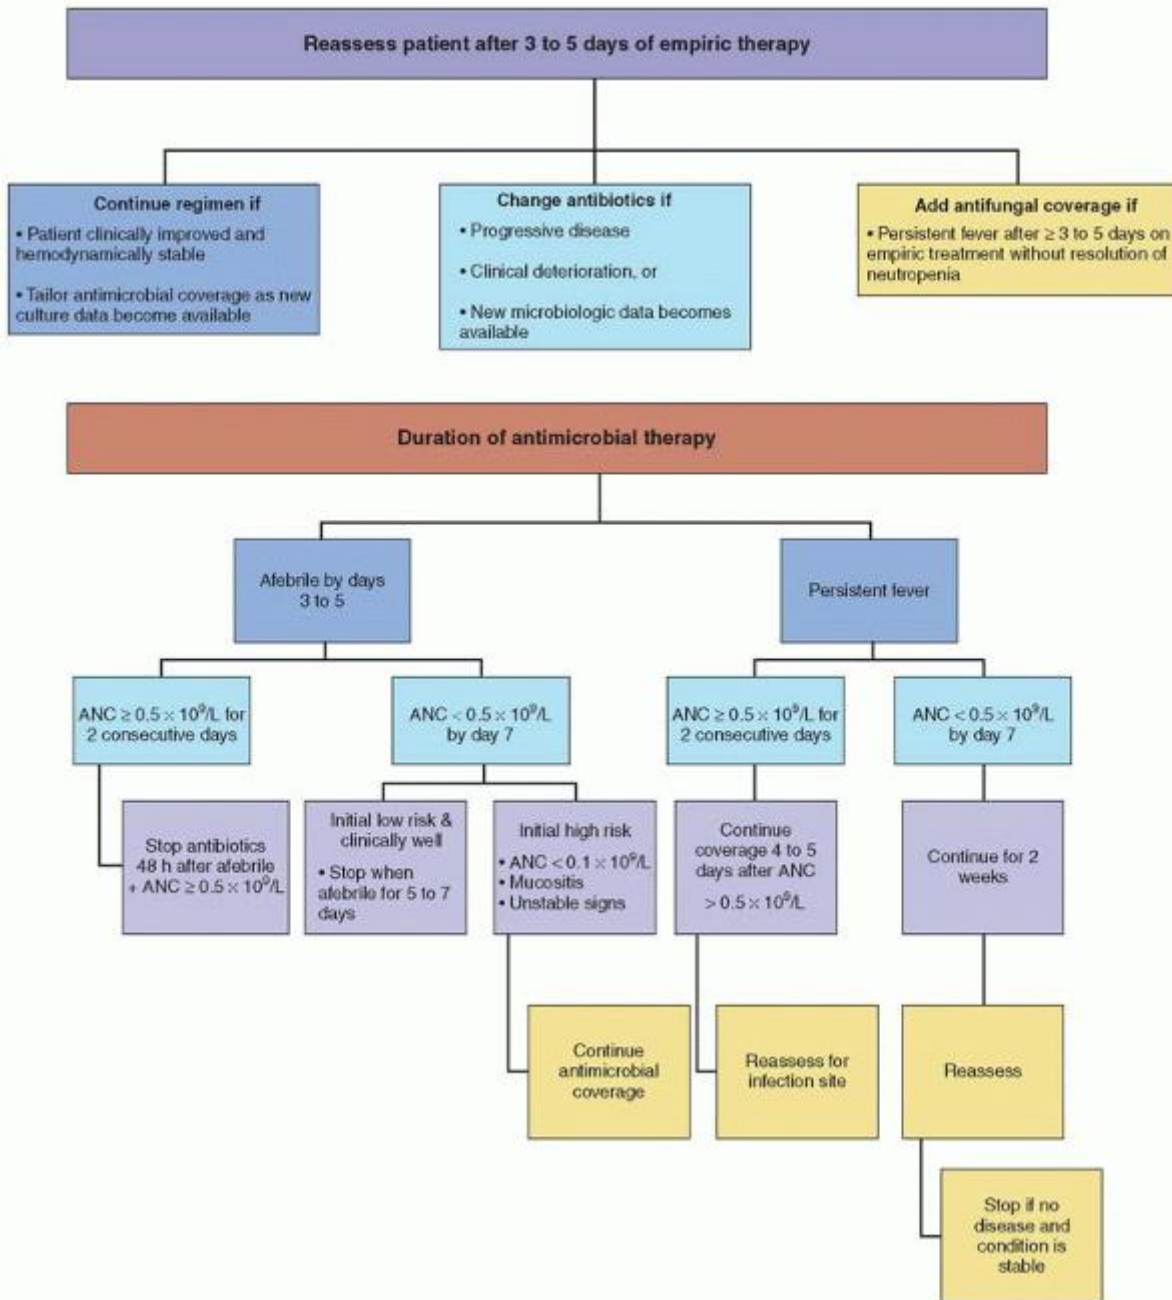

FIGURE 69.2. Common modifications of empiric antimicrobial therapy in the febrile neutropenic patient.

Echocardiography is recommended for *S. aureus* bloodstream infections to determine the presence or absence of endocarditis, and thus clarify the need for prolonged antibiotic therapy. Transesophageal echocardiography is more sensitive and preferred when compared with a transthoracic approach.³⁵

Myeloid Colony-stimulating Factors

Prophylactic use of myeloid colony-stimulating factors (CSFs) is common in the setting of intensive chemotherapy regimens such as stem cell transplantation. Multiple randomized clinical trials of prophylactic recombinant granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) have shown benefits in reducing the time to neutrophil recovery and the duration of fever and hospitalization in patients with hematologic neoplasms.^{36,37} Prophylactic G-CSF and GM-CSF in autologous and allogeneic hematopoietic stem cell transplantation (HSCT) recipients have been associated with a small reduction in the risk of documented infections but do not appear to affect infection-related or treatment-related mortality.³⁸ Empiric use of CSFs in the management of neutropenic fever is not standard practice, as no consistent benefit has been demonstrated in terms of morbidity or mortality among

randomized controlled trials of their use in patients with febrile neutropenia.^{39,40} Neither ASCO nor EORTC recommend the routine use of growth

P.1432

factors to treat episodes of febrile neutropenia unless patients are at high risk for infection-related complications, such as those older than 65 years, or those with prolonged (>10 days) and profound ($<0.1 \times 10^9/L$) neutropenia, active infection, hypotension, and/or multiorgan dysfunction^{39,40} (Fig. 69.3).

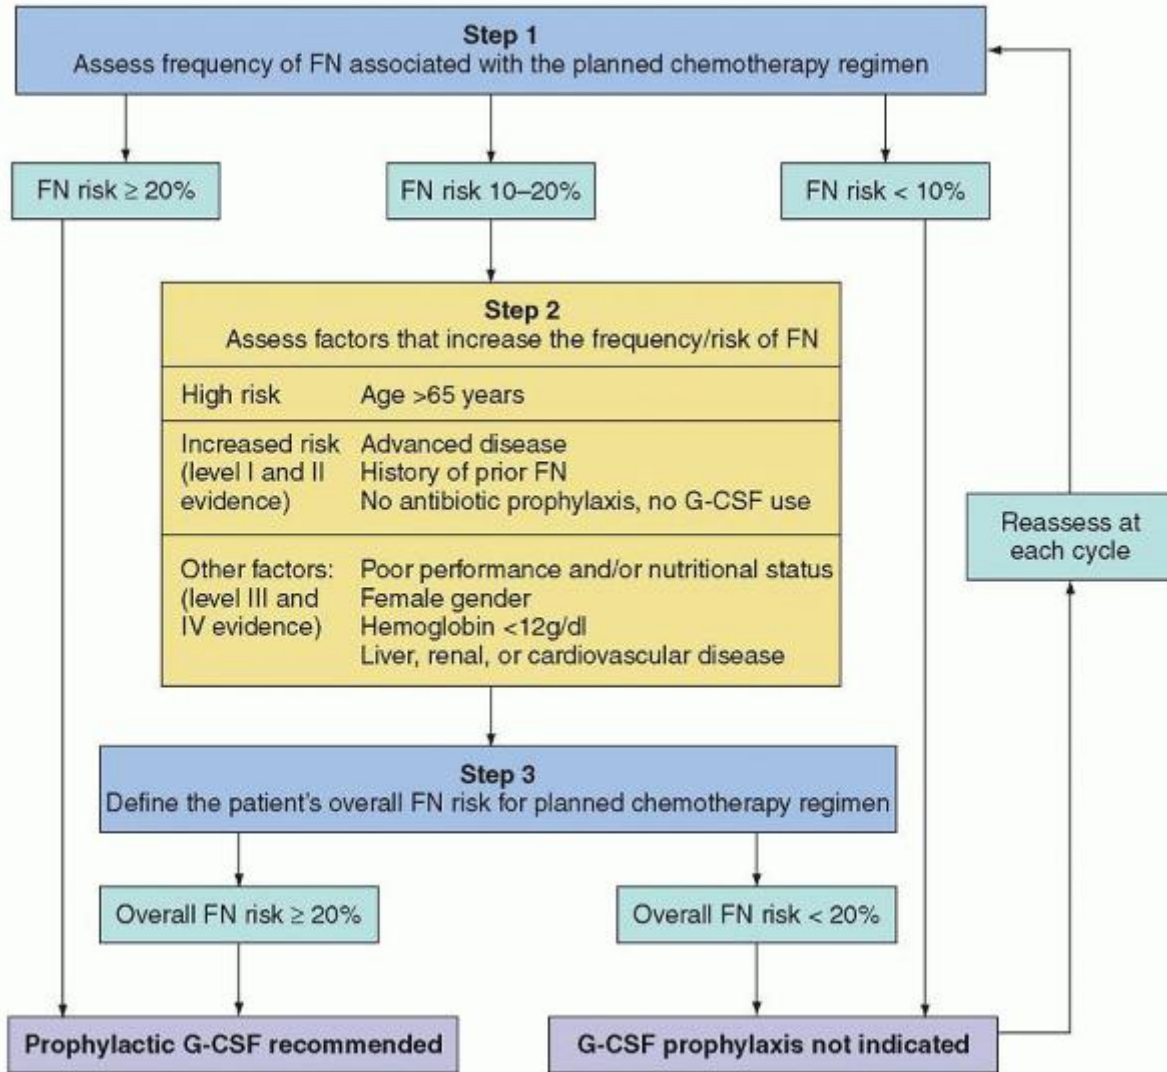

FIGURE 69.3. Algorithm to decide prophylactic G-CSF usage. FN, febrile neutropenia; G-CSF, granulocyte colony-stimulating factor. (With permission from Aapro MS, Bohlius J, Cameron DA, et al. 2010 update of EORTC guidelines for the use of granulocyte colony-stimulating factor to reduce the incidence of chemotherapy-induced febrile neutropenia in adult patients with lymphoproliferative disorders and solid tumours. *Eur J Cancer* 2011;47:8-32.)

G-CSF has a mild toxicity profile, with bone pain occurring 1 to 2 days prior to neutrophil recovery being the most common side effect. Recombinant yeast-derived GM-CSF reportedly has a better side effect profile than *E. coli*-derived GM-CSF (less fever, rash, and myalgias), although a randomized trial failed to reveal statistically significant differences.⁴¹ High-dose GM-CSF has been associated with hepatic transaminase elevation, serositis, fluid retention, venous thrombosis, and reactivation of autoimmune disease. A syndrome of hypoxemia, flushing, cardiovascular instability, musculoskeletal pain, nausea, and vomiting has also been described with intravenous GM-CSF.⁴²

Pegfilgrastim offers once-per-cycle administration compared to the required daily doses of the nonpegylated CSFs, and a single dose of pegfilgrastim has been shown to exert a prolonged effect lasting for approximately 14 days or until

neutrophil recovery.⁴³ Two small phase II trials involving lymphoma patients demonstrated similar efficacy of pegfilgrastim versus filgrastim in regards to reduction of febrile neutropenia after chemotherapy administration.^{44,45}

Granulocyte Transfusions

The role of granulocyte transfusions in the management of neutropenic fever is poorly defined. Although some small series and case report studies have attributed benefit to granulocyte transfusions in profoundly neutropenic patients with documented severe bacterial and fungal infections, others have failed to demonstrate significance.^{46,47} A Cochrane Review of 8 randomized controlled trials found the data inconclusive.^{46,48} The rationale for granulocyte transfusions is to provide support for the neutropenic patient with a life-threatening infection by augmenting the number of circulating neutrophils until autologous myeloid regeneration occurs. Rare adverse events associated with granulocyte transfusions include transmission of infections (commonly CMV), HLA alloimmunization, fever, potential transfusion associated graft-versus-host disease if granulocytes are not irradiated, and progressive platelet refractoriness. Appropriate patient selection is necessary prior to administration of granulocyte transfusions, given the risks and the marginal benefits reported.

SPECIFIC FEBRILE SYNDROMES, SELECTED PATHOGENS, AND TREATMENTS

Sepsis and Septic Shock

Severe sepsis and septic shock are associated with a high mortality rate. Published mortality rates vary between 20% and 60%.^{49,50} Common sequelae include acute respiratory distress syndrome (ARDS) and multisystem organ failure, which accounts for the high mortality of this syndrome. The source of septicemia is not apparent in 30% of cases, despite positive identification of an organism.^{50,51}

P.1433

Sepsis is defined as the presence of systemic inflammatory response syndrome (SIRS) associated with a confirmed infectious process.⁵² SIRS can be self-limited or can progress to severe sepsis and septic shock. Along this continuum, circulatory abnormalities (intravascular volume depletion, peripheral vasodilatation, myocardial depression, and increased metabolism) lead to an imbalance between systemic oxygen delivery and oxygen demand, resulting in global tissue hypoxia or shock. SIRS criteria include two or more of the following: (1) temperature greater than 38°C or less than 36°C, (2) heart rate greater than 90 beats per minute, (3) respiratory rate greater than 20 breaths per minute or a PCO₂ less than 32 mm Hg, or (4) white blood cell count greater than $12 \times 10^9/L$ or less than $4 \times 10^9/L$, or the presence of more than $0.1 \times 10^9/L$ immature band neutrophils.⁵²

Bloodstream Infections

Bloodstream infection is a common complication of patients undergoing cytotoxic chemotherapy. Common sources include skin breakdown, intravenous catheters, as well as the digestive and respiratory tracts. Following documented bacteremia, repeat blood cultures should be obtained to confirm the effectiveness of therapy. Evaluation to identify the source of the infection should also be performed.

Gram-positive Bacteria

Staphylococcus species are the most common cause of bacteremia. Staphylococcus aureus is a coagulase positive bacteria, which commonly colonizes the nares and the skin of many individuals, and can cause both local disease (wound infection, cellulitis) and systemic disease (bacteremia, endocarditis, septic arthritis, and osteomyelitis). Removal of intravascular catheters should be considered in patients with S. aureus bacteremia. The risk of endocarditis following S. aureus bacteremia warrants a transesophageal echocardiogram to determine the absence or presence of heart valve vegetations and thus define the necessary duration of therapy.^{35,53,54,55,56} A 2-week course of intravenous antibiotics may be sufficient for S. aureus bacteremia with a negative transesophageal echocardiogram.³⁵ Nafcillin is the drug of choice for treating methicillin-susceptible S. aureus, whereas vancomycin should be reserved for MRSA or the treatment of penicillin-allergic patients.⁵⁷

Methicillin-resistant S. aureus (MRSA) is recognized as a major cause of infection in the health care setting and is now emerging in the community.⁵⁸ MRSA isolates are resistant to all beta-lactam antibiotics as well as cross-resistant to multiple classes of antibiotics. Community-acquired MRSA strains are generally susceptible to clindamycin and TMP/SMX. The standard treatment for MRSA is vancomycin. Clinical infections caused by vancomycin-intermediate and vancomycin-resistant S. aureus have been reported sporadically and generally occur only in patients receiving prolonged courses of vancomycin.⁵⁸ Failure of vancomycin in MRSA bacteremia has been associated with increasing vancomycin minimum

inhibitory concentrations well within what is currently considered the susceptible range.⁵⁹ New guidelines on vancomycin dosing and therapeutic monitoring have been published based on these observations. Serum vancomycin trough concentrations should be maintained above 10 mg/L to avoid development of resistance.⁶⁰

Linezolid and daptomycin are active against the majority of gram-positive organisms, including MRSA^{61, 62, 63, 64} and⁶⁵; however, the use of these drugs should be limited to specific situations. Daptomycin, a bactericidal lipopeptide (6 mg/kg daily) is an acceptable option for *S. aureus* bacteremia.⁶⁶ Daptomycin is inactivated by lung surfactant and therefore should not be used to treat pneumonia. Linezolid should be used cautiously in patients with compromised bone marrow function, as myelosuppression has been associated with prolonged exposure. Thrombocytopenia occurs in 0.3% to 10% of those on linezolid and increases with the duration of use. Myeloid recovery of neutropenic cancer patients is not delayed with short courses; however, data for prolonged exposure (greater than 14 days) is limited.^{41,61} Linezolid is not approved for treatment of catheter-related infections or gram-negative infections, as these patients have a higher chance of death compared with those receiving vancomycin or oxacillin for intravascular catheter-related infection with gram-positive and gram-negative organisms.⁶⁷ Linezolid seems at least as effective as vancomycin against nosocomial MRSA pneumonia in most published studies, although a controversial post hoc subgroup analysis suggests linezolid has a slight advantage over vancomycin on survival and cure rates.^{68,69} The American Thoracic Society and IDSA guidelines on nosocomial MRSA pneumonia consider linezolid and vancomycin to each be acceptable options for suspected or proven MRSA pneumonia.⁷⁰

Neutropenic patients with severe mucositis are at increased risk for bacteremia with viridans group streptococci (VGS), a commensal normal oral flora. Other risk factors for VGS include prophylaxis with TMP/SMX or fluoroquinolones and the use of histamine-2 blockers.⁷¹ Neutropenic patients with VGS bacteremia may have a low-grade fever and facial flushing prodrome followed by high fever and chills. Complications include toxic-shock-like syndrome characterized by hypotension, respiratory distress, renal failure, and a centrifugal maculopapular rash usually starting on the trunk with subsequent desquamation of the palms and soles. Septic shock may be more common in children than in adults.⁷² Resistance of VGS to beta-lactams has been recognized and empiric use of vancomycin as initial therapy is recommended pending susceptibility testing.

Vancomycin-resistant enterococcus (VRE) bloodstream infection is an important cause of morbidity. The portal of entry for enterococcal bacteremia may be an indwelling central catheter or mucositis from chemotherapy or radiation toxicity. Risk factors for VRE include prolonged hospitalization, neutropenia, chemotherapy-induced mucositis, and use of vancomycin, cephalosporins, and metronidazole.⁷³ VRE bloodstream infections in cancer patients are associated with significant reduction in survival and frequent microbiologic failure, despite treatment with linezolid and/or daptomycin.⁷⁴ Optimal therapy for VRE infection in cancer patients is not well defined. Catheter removal from patients with indwelling lines and VRE bacteremia should always be considered. Linezolid, quinupristin-dalfopristin, and daptomycin have been used with variable success rates^{41,75,76}; and tigecycline has demonstrated activity in vitro.

Quinupristin/dalfopristin (a 30:70 mixture of two semisynthetic streptogramin antibiotics) has been shown to be safe and effective in serious vancomycin-resistant *E. faecium* infections, but is not active against *E. faecalis*. Common adverse effects including arthralgias, myalgias, and conjugated hyperbilirubinemia may limit its use in certain patients.⁷⁵

Gram-negative Bacteria

Infections caused by gram-negative bacilli typically occur in the lungs, in the urinary tract, and in the bloodstream and are a significant cause of morbidity and mortality.⁷⁷ Gram-negative bacilli most commonly responsible for infection in humans are *Enterobacter* species, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Escherichia coli*, *Acinetobacter* species, and *Serratia marcescens*. Mortality related to infections caused by gram-negative bacilli ranges from 20% to 60% depending on the site of infection and a patient's comorbid conditions. Inappropriate initial antimicrobial therapy and a delay in drug administration are associated with poorer patient outcomes.^{78,79} Prompt treatment with adequate coverage, especially for *P. aeruginosa*, should be initiated until susceptibility results are available, to minimize mortality and morbidity.

P.1434

Double coverage for gram-negative bloodstream infections in combination with an aminoglycoside has been shown to result in increased toxicity and no improvement in overall survival.^{24,80,81} Empiric use of an aminoglycoside should therefore be limited to patients with hemodynamic instability and those in whom there is a high suspicion for antibiotic-resistant gram-negative bacterial infections. Fluoroquinolones with adequate antipseudomonal activity may be an acceptable alternative to an aminoglycoside as part of a combination regimen, depending on local susceptibility patterns.

Infections caused by *P. aeruginosa* remain the most lethal gram-negative pathogens in neutropenic patients. Empiric combination of an antipseudomonal beta-lactam antibiotic plus an aminoglycoside or antipseudomonal fluoroquinolone is recommended until susceptibility data is available, since no single antimicrobial is effective against 100% of *Pseudomonas* isolates.^{75,82} Infections due to strains of *P. aeruginosa* resistant to all common antipseudomonal agents are an increasing problem.⁸³ Ecthyma gangrenosum is the most characteristic skin lesion associated with systemic *P. aeruginosa* infection.

Escherichia coli and *Klebsiella* species are common gram-negative pathogens in neutropenic patients. The use of prophylactic antibiotics such as ciprofloxacin or TMP/SMX may increase the prevalence of resistant enteric organisms such as *Enterobacter*, *Citrobacter*, and *Serratia* species which may carry an inducible beta-lactamase that may contribute to treatment failure with third-generation cephalosporins like ceftazidime. Carbapenems, fluoroquinolones, and piperacillin-tazobactam may be used in this setting. *Stenotrophomonas maltophilia* is an increasingly common cause of infection in patients who have been on broad-spectrum antibiotics or who have intravascular catheters.⁷⁵ TMP/SMX is the treatment of choice for patients with this infection but ticarcillin-clavulanate or moxifloxacin may be effective in patients intolerant to TMP/SMX. *Acinetobacter baumannii* bacteremia is frequently associated with infected intravascular catheters and is often resistant to multiple antibiotics, including imipenem-cilastatin.⁸⁴ Ampicillin-sulbactam, tigecycline, or colistin may be effective, but consultation with an infectious diseases specialist is encouraged when dealing with *Acinetobacter* infections.

Fungemia

Pathogenic fungi include yeasts and molds. *Candida* species are yeasts that form part of the normal flora and typically gain access to the bloodstream through disruption of anatomic barriers (mucositis or indwelling catheters). Molds are ubiquitous soil inhabitants whose conidia or spores are inhaled. Aspergillosis is the most common mold infection in cancer patients, but other pathogenic fungi (e.g., zygomycetes, *Fusarium* and *Scedosporium* species) have also been reported.

Candidemia and Invasive Candidiasis

Candida species are the fourth most common cause of nosocomial bloodstream infections in the United States.^{85,86} Mortality rates of candidemia range between 20% and 40%.⁸⁶ *C. albicans* is the most common, although the frequency of non-*albicans* candidemia is increasing, presumably as a consequence of widespread fluconazole prophylaxis. Clinical findings vary from asymptomatic to full-blown septic shock. *C. tropicalis* is highly virulent in neutropenic hosts. *C. krusei* is generally resistant to fluconazole, and *C. glabrata* has variable susceptibility. *C. parapsilosis* is associated with the vascular catheters and lipid formulations used for total parenteral nutrition.

Comparison of IV fluconazole with amphotericin B as therapy for candidemia in neutropenic and nonneutropenic patients has found similar overall response rates, but less toxicity with fluconazole.^{87,88} Anidulafungin appears to be similar to fluconazole in treating invasive candidiasis.⁸⁹ Voriconazole provides equivalent benefit and has less nephrotoxicity compared to the sequential combination of amphotericin B followed by fluconazole in nonneutropenic patients.⁹⁰ Caspofungin has a slightly higher response rate and is less toxic than amphotericin B as initial therapy for invasive candidiasis, and micafungin has been shown to be as effective as amphotericin B.^{91,92,93}

IDSA guidelines for management of candidiasis recommend an echinocandin (caspofungin, micafungin, or anidulafungin) for treatment of candidemia in neutropenic patients.⁹⁴ Lipid formulations of amphotericin B are recommended in complicated infections such as endocarditis and meningitis or in hemodynamically unstable patients where invasive mold infection is suspected.⁹⁴ Echinocandins are also advised in patients who develop breakthrough candidemia while receiving an azole. Voriconazole should be considered for treatment of *C. krusei*, which is generally resistant to fluconazole, and when a mold-active agent is warranted. Patients with candidemia should undergo ophthalmologic evaluation with fundoscopic exam, and it is recommended that intravascular catheters be removed from patients with candidemia.⁹⁴

Aspergillosis is addressed in the pneumonia section; zygomycosis (mucormycosis) is covered under sinus infection; and cryptococcosis is under central nervous system (CNS) infections.

CENTRAL NERVOUS SYSTEM INFECTIONS

Infection of the CNS can present with subtle nonspecific findings such as fever, headache, photophobia, changes in mental status, or more dramatic findings such as loss of consciousness and seizure. Prompt diagnosis and initiation of therapy are crucial to minimize negative clinical outcomes. CNS infections can be divided into surgical- and nonsurgical-related complications and infections. The IDSA has published guidelines on the management of CNS infections.^{95,96}

Central Nervous System Infections Unrelated to Neurosurgery

Meningitis and encephalitis are part of a clinical spectrum of CNS disorders causing fever and meningismus. Encephalitis may manifest with signs and symptoms of meningeal inflammation, but is distinguished by the predominance of

alterations of consciousness and neurologic deficits. Initial evaluation generally involves head CT to rule out intracranial bleeding in addition to brain MRI and lumbar puncture (assuming no contraindication). Cerebrospinal fluid (CSF) studies should be tailored to specific host factors, epidemiologic exposures, and clinical presentation, but should generally include a cell count with differential, glucose, protein, Gram stain, cryptococcal antigen, fungal culture, and bacterial culture. Noninfectious causes of meningitis include carcinomatous meningitis, nonsteroidal antiinflammatory medications, TMP/SMX, and serum sickness (e.g., associated with antilymphocyte gammaglobulin or intravenous immunoglobulin [IVIG]).

Empiric treatment for suspected bacterial meningitis should include antimicrobial agents that penetrate the blood-brain barrier and enter the CSF, such as ceftriaxone, ampicillin, and vancomycin.⁹⁵ This regimen provides coverage against the most common causes of bacterial meningitis, including penicillin-resistant pneumococci and listeriosis. The combination of vancomycin and TMP/SMX may be used in patients allergic to penicillins.⁹⁵ Cefepime or meropenem should be used instead of ceftriaxone in patients at risk for *P. aeruginosa* meningitis (e.g., neutropenia, neurosurgery within the past 2 months, allogeneic HSCT, prior history of *P. aeruginosa* infection). Meropenem should also provide appropriate coverage against *Listeria*. Conflicting results have been reported regarding the use of dexamethasone as an adjuvant therapy in the management of bacterial meningitis. Data

P.1435

from a large meta-analysis found dexamethasone to not provide significant reductions in death or neurologic sequelae, although a statistically significant reduction in hearing loss was observed among surviving patients.⁹⁷ ISDA guidelines for the management of bacterial meningitis support the incorporation of adjuvant dexamethasone in pediatric patients with *H. influenzae* type B meningitis and in adult patients with pneumococcal meningitis.⁹⁵

Encephalitis in patients with cancer is most commonly caused by HSV. Intravenous acyclovir should be considered as empiric therapy for HSV in patients with suspected encephalitis (fever, mental status changes, CSF pleocytosis, and focal changes on EEG or MRI, especially in the temporal lobes). CSF studies should include PCR for HSV and CSF cytology. PCR for arboviruses should be considered in patients with exposure to endemic areas. The CSF should also be sent for nucleic acid amplification, adenosine deaminase level, and culture for tuberculosis in patients with known or suspected encephalitis. Patients with severe impairment of cellular immunity (e.g., allogeneic HSCT recipient, advanced AIDS) should be evaluated with PCR for CMV, VZV, HHV-6, and toxoplasmosis as well as culture for *Nocardia*. Most cases of encephalitis occur in HSCT patients and are due to reactivation of latent viral, bacterial, or parasitic infections: herpesviruses (HSV, VZV, CMV, EBV, human herpes virus [HHV]-6), adenovirus, mycobacteria, and *Toxoplasma gondii*.

Herpes viruses

HSV meningoencephalitis has been associated with older age, steroid therapy, and brain irradiation. The diagnosis is usually made by viral PCR from the CSF and enhancement of the temporal lobe on MRI. Intravenous acyclovir should be considered as empiric therapy for HSV.⁹⁶ Other, less common herpesvirus infections can also be diagnosed by PCR of viral DNA in the CSF. Detection of high levels of EBV DNA should raise suspicion of EBV-related lymphoproliferative disorder, but primary EBV encephalitis and myelitis have been described.^{98,99} HHV-6 has been associated with a characteristic syndrome in HSCT patients consisting of confusion, lethargy, fever, rash, and hippocampal enhancement on T2-weighted MRI FLAIR images.¹⁰⁰ The diagnosis is made by detection of HHV-6 DNA in the CSF by PCR. Ganciclovir or foscarnet may be used in treating HHV-6 infections.¹⁰¹ Adenoviral encephalitis in HSCT patients has been reported as part of disseminated adenoviral infection and treatment with cidofovir may be attempted.⁹⁶

Other uncommon but important causes of meningoencephalitis are due to new primary infections rather than reactivation. Advanced age and cancer are risk factors for encephalitis from West Nile virus (WNV) transmitted by mosquitoes and for which there is no proven therapy.¹⁰²

Brain Abscess

Brain abscesses that develop during neutropenia are typically caused by fungi (commonly *Aspergillus* and *Candida*).¹⁰³ Bacterial abscesses may occur as a local extension of infection of the sinuses or dental caries and are often caused by a mixed aerobic and anaerobic flora (*Streptococci*, *Staphylococcus*, *Bacteroides*). Other causes of CNS abscesses in patients with impaired cellular immunity include toxoplasmosis, nocardiosis, cryptococcosis, and mycobacterial infections.¹⁰³

Noninfectious etiologies include CNS malignancies, including secondary lymphomas and EBV-associated posttransplant lymphoproliferative disease (PTLD) in patients with impaired cellular immunity. Given the broad differential diagnosis of new focal CNS lesions in the highly immunocompromised patient, a brain biopsy is recommended if feasible. Cultures and

stains should include bacteria, fungi, mycobacteria, and *Nocardia* species. Serum galactomannan, CSF galactomannan, and beta-d-glucan testing are useful to facilitate a diagnosis of CNS aspergillosis.

Brain abscesses usually manifest with headache, focal neurologic findings, or seizures.^{104,105} MRI typically shows single or multiple lesions with edema and ring enhancement. Manifestations of CNS aspergillosis include focal seizures, hemiparesis, cranial nerve palsies, and hemorrhagic infarcts due to vascular invasion.¹⁰⁶ *Aspergillus* brain abscesses are typically multiple, hypodense, and nonenhancing with little mass effect. CT scans with contrast enhancement may initially fail to reveal focal lesions, but subsequently evolve focal ring-enhancing or hemorrhagic lesions.¹⁰⁷

Initial therapy with ceftriaxone plus metronidazole is advised in immunocompetent patients with a bacterial brain abscess.^{3,104,105,108} Patients with prolonged neutropenia should be treated with the combination of meropenem or cefepime plus metronidazole and voriconazole.^{3,104} Adjustments may be needed for patients requiring certain antiepileptic agents (e.g., phenytoin) due to the potential for significant drug-drug interactions with voriconazole (as well as itraconazole and posaconazole).¹⁰⁹ Empiric high-dose TMP/SMX (trimethoprim component: 5 mg/kg every 8 hours) should be considered to cover toxoplasmosis and nocardiosis in allogeneic HSCT recipients and patients with severe T cell impairment. Retrospective analysis of CNS aspergillosis treated with voriconazole as either primary or salvage therapy indicated that 34% had a complete or partial response¹¹⁰ and compares favorably to previous reports in which frequency of successful responses to amphotericin B in CNS aspergillosis was close to zero.¹¹¹

Cryptococcosis

Lymphoid malignancy and corticosteroid therapy are major risk factors for cryptococcal infection.¹¹² Host defense against cryptococcal infection is dependent on T cell immunity. Isolated neutropenia is rarely associated with cryptococcal infection. The principal portal of entry of this organism is by inhalation. Spread to the blood and then to the central nervous system is a prerequisite for subsequent development of cryptococcal meningitis. Although meningitis is the most common presentation of cryptococcal infection, other manifestations include pneumonia, fungemia, cutaneous infections, and visceral dissemination. Visual loss may be a consequence of endophthalmitis (a space-occupying lesion in the visual pathway), direct invasion of the optic nerve, and elevated intracranial pressure.¹¹³

The IDSA recommends a regimen of amphotericin B (0.7 to 1 mg/kg daily) plus 5-fluorocytosine (100 mg/kg daily) for the first 2 weeks, followed by life-long maintenance fluconazole therapy in AIDS-associated cryptococcal meningitis.¹¹⁴ In the absence of modern randomized studies, the same induction regimen is recommended in non-AIDS-associated cryptococcal meningitis, followed by fluconazole for at least 10 weeks or until immunosuppressive agents have been discontinued.¹¹⁴ Reduction of the dosage of 5-fluorocytosine may be considered to minimize delay of myeloid recovery in neutropenic patients.

Toxoplasmosis

Reactivation of previously acquired infections is responsible for the majority of opportunistic CNS infections caused by *T. gondii*. The organism can be acquired by ingestion of undercooked meat or through contact with feline feces. CNS toxoplasmosis is typically associated with disseminated infection, and risk factors include therapy with corticosteroids, alemtuzumab, cytotoxic agents, and/or radiation therapy, and poorly controlled malignancy. Although toxoplasmosis is an uncommon complication of HSCT, nearly all occurrences are associated with seropositivity prior to transplantation.¹¹⁵ It tends to occur in the presence of moderate to severe GVHD with a median day of onset of disease at 64 days post-HSCT.¹¹⁶

P.1436

FIGURE 69.4. Central nervous system toxoplasmosis: magnetic resonance imaging study of the brain before therapy (A) and after therapy (B) with pyrimethamine and sulfadiazine.

Common clinical findings for CNS toxoplasmosis include altered mental status, coma, seizures, cranial nerve abnormalities, and motor weakness.¹¹⁷ MRI typically shows two or more lesions that may be ring-enhancing (Fig. 69.4). The differential diagnosis includes bacterial infection, invasive aspergillosis, nocardiosis, and malignancy. Differentiating toxoplasmosis from lymphoma is particularly difficult; [18F] fluorodeoxyglucose positron emission tomography typically shows increased metabolism in lymphoma.¹¹⁸ CSF in toxoplasmosis is usually normal but mononuclear pleocytosis and elevated protein levels may occur. In addition to CNS involvement, toxoplasma may also present with myocarditis, interstitial pneumonitis, culture-negative sepsis, and hemophagocytic syndrome. Definitive diagnosis of toxoplasmosis relies on demonstration of tachyzoites and cysts in histopathologic sections, but PCR testing of serum and CSF may facilitate earlier diagnosis.^{117,119} Oral sulfadiazine 1 to 1.5 g every 6 hours plus pyrimethamine (loading dose of 200 mg, followed by 75 mg daily) is the initial treatment of choice for toxoplasmosis. Folinic acid (10 to 20 mg daily) should be administered to reduce myeloid toxicity. At 4 to 6 weeks after resolution of symptoms and signs of infection and radiologic improvement, switching to a maintenance regimen (sulfadiazine 0.5 to 1 g four times daily plus pyrimethamine 50 mg/day) is reasonable. Maintenance therapy should be continued for the duration of immunosuppression and until radiologic resolution. Clindamycin and primaquine may be used instead, after verifying normal glucose-6-phosphate dehydrogenase activity in patients intolerant of sulfonamides. Atovaquone may also be used after exhausting other options.⁹⁶

Dementias

Progressive multifocal leukoencephalopathy (PML) is a demyelinating disease associated with lytic infection of oligodendrocytes by the human polyomavirus JC virus.⁴⁰ Patients may develop rapidly progressive dementia as well as focal motor neuropathy or cerebellar degeneration. This disease is most commonly seen in patients with advanced AIDS. However, PML is also seen in severely immunocompromised persons with hematologic malignancies and in HSCT recipients. Several reports have linked the use of rituximab with the development of PML and prompted an FDA advisory regarding a possible association.¹²⁰ PML has also been reported with other immunosuppressants and biologics including belatacept,¹²¹ brentuximab,¹²² efalizumab,¹²³ fludarabine,¹²⁴ infliximab,¹²⁵ and mycophenolate.¹²⁶ Brain MRI typically reveals unilateral or bilateral white matter disease without mass effect or enhancement. Diagnosis is generally confirmed by detection of the JC virus in spinal fluid by PCR (90% sensitivity) or by brain biopsy. There is no established therapy for PML and the prognosis is poor.

Infections Related to Neurosurgical Procedures and/or Devices

Neurosurgical procedures such as resection of tumor, insertion of a shunt for hydrocephalus, or insertion of an Ommaya reservoir each carry a risk for infectious complications. Infection risk is further increased with use of steroids and brain

irradiation. Early postoperative infections after placement of intraventricular devices are usually caused by skin flora: coagulase-negative staphylococci, *S. aureus*, streptococci, and *Propionibacterium acnes*. Enterobacteriaceae and *P. aeruginosa* account for approximately 10% of infections. Coagulase-negative staphylococci and *P. acnes* usually cause indolent late postoperative infections.

Infection of a shunt or an Ommaya reservoir may manifest with malfunction of the device, fever, or altered mental status. Overt signs of meningitis, such as meningismus and photophobia are often absent. CT imaging may suggest meningitis, ventriculitis, or a brain abscess if the device is infected at the proximal end. Evaluation of the CSF is required for diagnosis confirmation. Infections occurring in the distal region of the device may manifest as a soft tissue infection. In cases of ventriculoatrial shunts, distal infections may cause persistently positive blood cultures, thrombophlebitis, endocarditis, or septic pulmonary emboli. Distal ventriculoperitoneal shunt infections are associated with peritonitis and intraabdominal collections. Removal of the entire device plus systemic antibiotics is the most effective approach to eradicate infection. Use of parenteral and intraventricular instillation of antibiotics without hardware removal has demonstrated variable success, and recurrence of infection is common, particularly those caused by *S. aureus*.¹²⁷ Antibiotic therapy should be tailored to the specific pathogen isolated. In acutely ill patients with meningitis suspected to be related to prior neurosurgery, empiric therapy with parenteral vancomycin should be administered to cover *Staphylococcus*, *Streptococcus*, and *Propionibacterium* species in combination with an agent with activity against Enterobacteriaceae and *P. aeruginosa* such as ceftazidime or meropenem.⁹⁵

OROPHARYNGEAL AND SINUS INFECTIONS

The mucosal linings of the gastrointestinal and respiratory tracts constitute the first line of host defense against a variety of pathogens. During the course of treatment for hematologic malignancy these barriers often are compromised and expose patients to infections and invasions by local flora, resulting in bacteremia and candidemia. Chronic GVHD may further compromise mucosal immunity, including defective salivary immunoglobulin secretion.

Mucositis may extend into the esophagus, causing retrosternal chest discomfort. Mucosal lesions are usually caused by HSV and/or *Candida* species, but are occasionally caused by CMV, fungal (i.e., *Histoplasma*), or bacterial pathogens such as viridans group streptococcal infections and oral anaerobes (i.e., *Pseudomonas* species).

Oral mucosal candidiasis or thrush is common with T cell immunodeficiency. Cytotoxic chemotherapy, corticosteroids, and antibiotics predispose to oral candidiasis. The most common presentation is white adherent plaques on the palate, buccal mucosa, tongue, or gingiva. Pseudohyphae on a wet mount or Gram stain establish the diagnosis. Therapy includes local treatments such as clotrimazole troches or oral fluconazole.

Esophageal candidiasis may present as odynophagia and initial therapy with fluconazole is advised. Therapeutic options for fluconazole-resistant mucosal candidiasis include an echinocandin, voriconazole, posaconazole, or amphotericin B. Most fluconazole-resistant *Candida* isolates are susceptible to voriconazole and posaconazole, but cross-resistance may occur.

P.1437

Congestion, sinus tenderness, and fever are common nonspecific signs of sinusitis. Respiratory bacterial pathogens, including *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis* predominate the etiology of sinusitis in immunocompetent patients. Common pathogens in those that are immunocompromised include *P. aeruginosa*, *S. aureus*, Enterobacteriaceae, and molds, and warrant investigation with sinus and facial imaging. Treatment of sinusitis in immunocompetent patients involves standard antibiotic regimens, such as amoxicillin-clavulanate, azithromycin, clarithromycin, or a cephalosporin with activity against respiratory pathogens. In addition to standard antibiotic therapy, neutropenic patients with symptoms or signs of sinusitis should have a CT scan of the sinuses and an otolaryngologist consultation and consideration of endoscopy to assess the possibility of invasive mold. Endoscopy with or without mucosal biopsy is often helpful in distinguishing these entities when there is no response to empiric antifungal or antiviral therapy or if clinical deterioration follows initial response to therapy. Systemic azole or amphotericin B therapy is preferred in patients with AIDS, neutropenic cancer patients, patients with recurrent perineal candidiasis, or those with refractory proven oropharyngeal candidiasis.⁸⁷

The presence of a heterogeneous mass or bony erosion on CT is highly suggestive of invasive fungal sinusitis. Periorbital swelling and diplopia may be observed late in the course of infection. *Aspergillus* species are the most common isolate, but zygomycetes (e.g., *Mucor*, *Rhizopus*) as well as less common molds such as *Fusarium* are also being recognized.

Aggressive surgical debridement in addition to antifungal therapy with two broad-spectrum antifungals is usually required to optimize the chances of recovery. Empiric therapy should include a lipid formulation of amphotericin B (5 mg/kg/d) to ensure treatment against *Aspergillus* species and zygomycetes.¹²⁸ Antifungal therapy should be continued for weeks to months even if all of the visualized necrotic tissue is fully resected. Voriconazole may be substituted for many cases of fungal sinusitis, but should be avoided in zygomycetes (*Mucor*, *Rhizopus*) infections which are not susceptible to voriconazole. Posaconazole is an oral azole with activity against zygomycetes and may provide a useful alternative to an amphotericin B formulation for long-term therapy.¹²⁹ Posaconazole therapy does require adequate food intake for optimal absorption to reach therapeutic levels.¹³⁰

LUNG INFECTIONS

Pneumonia is the most common infectious cause of death in immunocompromised patients. Numerous noninfectious processes should also be considered in patients with pulmonary infiltrates: malignancy, its treatment (drug toxicity, radiation pneumonitis), congestive heart failure, pulmonary hemorrhage, pulmonary embolism with infarction, cryptogenic organizing pneumonia (also known as bronchiolitis obliterans organizing pneumonia), and acute respiratory distress syndrome. It is imperative that prompt empiric therapy should be initiated when an infectious cause is suspected. The differential diagnosis of pulmonary infiltrates in patients with hematologic malignancies is shown in Table 69.5. Noninfectious causes of interstitial pneumonitis (IP) in the febrile patient are diagnosed only after exclusion of infectious etiologies.

Pulmonary Infiltrates in Neutropenic Patients

Diagnosing the etiology of pulmonary infiltrates in neutropenic patients can be challenging for many clinicians. Physical findings of consolidation and sputum production may be absent as a result of the neutropenia. General work-up for suspected pneumonia should include routine blood cultures, a chest radiograph, and if possible, sputum culture and Gram stain. Respiratory viral pathogens should be considered during peak season and local pattern of infections. Rapid testing for influenza A and B may be performed using a throat or nasopharyngeal swab but viral culture is more definitive. Nasopharyngeal wash may also be used to diagnose respiratory viral infections. Legionellosis can be diagnosed based on urine antigen testing or sputum culture. While the urine antigen testing is more easily obtained, it only detects *Legionella pneumophila* type I.¹³¹ Broad-spectrum antibiotics should be initiated immediately and therapy tailored once culture data become available.

Initial Antimicrobial Therapy

In patients with less than 7 days of neutropenia, pulmonary infections are likely to be caused by Enterobacteriaceae, *P. aeruginosa*, and *S. aureus*. Community respiratory viruses should also be considered during winter months. If community-acquired pneumonia is suspected, a macrolide or fluoroquinolone should be given to cover for atypical pneumonia organisms. The addition of TMP/SMX should be considered if PJP is suspected. Vancomycin or linezolid should be added for pneumonia in patients colonized with MRSA and for nosocomial pneumonia. If clinical improvement occurs within 48 to 72 hours of therapy, the antibiotic regimen should be tailored based on available culture data and continued for at least 10 to 21 days and until neutropenia resolves. In the absence of clinical improvement, resistant bacterial and nonbacterial pathogens including filamentous fungi should be considered.

Pulmonary Infiltrates in Patients with Defects in Cell-mediated Immunity

In addition to the common bacterial causes of pneumonia, patients with defects in cell-mediated immunity are at risk for infections with *P. jirovecii*, *Nocardia* species, and viruses, as well as *Legionella*, mycobacteria, mold, and fungi. Invasive procedures, including bronchoscopy for bronchoalveolar lavage (BAL) and/or biopsy, should be considered to aid in diagnosis.

Fungal Pneumonia

Patients with allogeneic HSCT, prolonged high-dose systemic corticosteroids, immunosuppression with T cell suppressants and neutropenia for more than 10 days are at increased risk of fungal pneumonia. Chest CT imaging is recommended in patients failing to respond to initial empiric treatment or those in whom there is a high suspicion for fungal or mold infection.¹³² CT may disclose lesions missed by the chest radiograph as well as findings characteristic of invasive fungal disease: well-circumscribed, dense infiltrates, the "halo sign," and/or cavitation.¹³³ Other angioinvasive infections including *P. aeruginosa* may cavitate. The galactomannan assay is specific for invasive aspergillosis,¹³⁴ whereas the beta-D-glucan assay detects aspergillosis and other invasive fungal infections including invasive candidiasis, PJP, and fusariosis.¹³⁵ Galactomannan assay testing is associated with a sensitivity of 70% and specificity of 89% for invasive aspergillosis.¹³⁶ False-positive results may be more common in children and allogeneic HSCT recipients with concomitant use of

piperacillin/tazobactam.^{137,138} Rising serum galactomannan levels correlate with failure of antifungal therapy, whereas decreasing levels are associated with positive outcomes in patients with invasive aspergillosis.^{139,140}

Aspergillus species are by far the most common invasive mold infections (Fig. 69.5). Voriconazole is currently the treatment of choice for invasive aspergillosis.^{34,137} Amphotericin B is active against *Aspergillus* species (with the exception of *Aspergillus terreus*), but may be inferior to voriconazole in aspergillosis.¹³⁷ Initial antifungal therapy should be either with voriconazole or a lipid formulation of amphotericin B in patients at high risk for invasive mold diseases or with suspected pneumonia of unknown etiology. Echinocandins have not been evaluated as initial monotherapy for invasive aspergillosis, but have favorable response

P.1438

rates in patients refractory or intolerant to triazoles or amphotericin B.¹⁴¹ Posaconazole has been used successfully as salvage therapy for a variety of invasive fungal infections refractory to standard therapy.¹⁴² Posaconazole is currently approved by the FDA for prophylaxis of invasive *Aspergillus* and *Candida* infections, and in the European Union is indicated for treatment of invasive aspergillosis and other invasive fungal infections refractory to standard antifungal agents.¹⁴³

TABLE 69.5 DIFFERENTIAL DIAGNOSIS OF PULMONARY INFILTRATE IN THE IMMUNOCOMPROMISED PATIENT

Cause	Diagnosis
Infectious Causes	
Bacterial pneumonia	Lung infiltrate: positive culture from blood, BAL, or pleural fluid; resolution with antibiotics.
CMV pneumonia	Intranuclear or intracytoplasmic CMV inclusions in pulmonary epithelial cells in TBB specimen or BAL fluid, or positive BAL culture for CMV. Quantitative PCR can be monitored for response.
Other viral pneumonias	May be preceded by rhinorrhea, sore throat, and cough; diffuse interstitial pattern. Most common are RSV, influenza, parainfluenza, and adenovirus. Diagnosis can be made by detection of virus or viral antigen on throat swabs, nasal washes, or BAL fluid; immunologic and molecular techniques (PCR) are available.
<i>Legionella</i> pneumonia	Positive culture of <i>Legionella</i> species from sputum, BAL fluid, or pleural fluid, or positive test for <i>Legionella</i> antigen by DFA test in BAL fluid, or a positive urinary <i>Legionella pneumophila</i> antigen or <i>Legionella</i> titer $\geq 1:256$ with compatible clinical features.
Invasive pulmonary aspergillosis	Halo or crescent sign on high-resolution chest CT; positive galactomannan assay; pathologic evidence of invasion of lung tissue by acutely branching septate hyphae consistent with <i>Aspergillus</i> species, or isolation of <i>Aspergillus</i> species from BAL fluid or bronchial washing with consistent clinical and radiologic features.
<i>Pneumocystis jirovecii</i> Pneumonia	Fever and dyspnea may precede interstitial pneumonia. Detection of cysts or trophic forms of the organism in cytocentrifuge preparation in BAL fluid.
<i>Candida</i> and other fungal pneumonia	Histologic evidence of tissue invasion by <i>Candida</i> or other fungal species.
<i>Mycobacterium tuberculosis</i>	Positive culture of <i>M. tuberculosis</i> from sputum, bronchial washing, BAL fluid, or lung biopsy showing caseating granuloma with acid-fast organisms.
Nontuberculous mycobacteria (NTM) infection	Consistent clinical and radiologic findings with either: (a) isolation of NTM from sputum, bronchial washing, or BAL fluid and lung biopsy showing mycobacterial histopathology features; or (b) isolation of NTM from lung tissue,

blood, or bone marrow culture.

Nocardia pneumonia Presumptive diagnosis can be made if acid-fast filamentous rods are visualized on TBB or BAL fluid; also, *Nocardia* species are gram-positive rods. Requires 5-21 d for culture. Disseminated disease occurs in one-third of patients, with brain abscess as the most common site.

Noninfectious Causes

- Diffuse alveolar hemorrhage $\geq 20\%$ hemosiderin-laden macrophages in BAL fluid or hemosiderin-laden macrophages in lung tissue.
- Chemotherapy-induced pneumonitis History of receiving chemotherapeutic agent, with BAL or lung biopsy showing atypical type II pneumocytes with consistent clinical features and no evidence of lung infection.
- Radiation pneumonitis History of receiving radiation, with BAL lymphocytosis with consistent clinical and radiologic features and no evidence of lung infection.
- Congestive heart failure (CHF) Clinical diagnosis of CHF (bibasilar rales, left ventricular third sound, and radiologic evidence of pulmonary edema with resolution of symptoms with diuretics), or pulmonary artery occlusion pressure >18 mm Hg. Older age and prior chemotherapy, particularly with anthracyclines, are contributing factors.
- Pulmonary emboli Diagnostic confirmation strategy varies among institutions; suspected with clinical features, elevated D-dimer, and V/Q scan and confirmed by spiral CT pulmonary angiography.
- Leukoagglutinin reaction Sudden onset of respiratory distress after transfusion. The incidence of transfusion-related lung injury (TRALI) is 0.04%-0.1%; mortality is estimated at 5%-8%.
- ARDS/diffuse alveolar damage Acute-onset, bilateral lung infiltrates on chest radiography, pulmonary artery wedge pressure ≤ 18 mm Hg, or the absence of clinical evidence of left atrial hypertension, and $PaO_2/FiO_2 \leq 300$ (acute lung injury) or ≤ 200 (ARDS).
- Nonspecific pneumonitis Lung biopsy showing nonspecific inflammation and variable fibrosis with no evidence of lung infection, and without alternative clinical diagnosis.
- Pulmonary infiltrates of unclear etiology Data from imaging, cultures, serology, and FB inconclusive for a firm diagnosis.

ARDS, acute respiratory distress syndrome; BAL, bronchoalveolar lavage; CMV, cytomegalovirus; CT, computed tomography; DFA, direct immunofluorescent antibody; FB, fiberoptic bronchoscopy; PCR, polymerase chain reaction; RSV, respiratory syncytial virus; TBB, transbronchial biopsy.

Endemic Fungi

Commonly known endemic fungi include *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces dermatitidis*. These dimorphic fungi exist in nature in the fruiting mycelial stage and then convert to the yeast stage at body temperature. Endemic mycoses in the central United States include histoplasmosis and blastomycosis. Immunocompetent hosts are typically asymptomatic following inhalation of *Histoplasma* microconidia but may manifest acute fever, pulmonary infiltrates, and hypoxia. Immunocompromised patients have a higher risk of disseminated histoplasmosis involving the liver, spleen, lymph nodes, bone marrow, adrenal glands, mucocutaneous tissues, gastrointestinal tract, and CNS. Chest radiographs may show a miliary reticulonodular appearance similar to that seen with tuberculosis. Blood cultures may be positive in disseminated histoplasmosis. Antigen detection in blood, urine, and BAL is both

sensitive and specific.¹⁴⁴ Antibody detection may also be useful, but false-negative results may occur in immunocompromised patients.¹⁴⁵ Biopsy specimens showing small intracellular or narrow budding yeast are suggestive of the diagnosis and should be confirmed by culture. IDSA guidelines recommend amphotericin B for severe pulmonary or disseminated histoplasmosis.¹⁴⁵ Prolonged therapy with itraconazole may be initiated after stabilization of disease, and should be continued for the duration of immunosuppression.¹⁴⁵

FIGURE 69.5. A: Chest CT of a hematopoietic cell transplant recipient who developed pulmonary *Aspergillus* infection after prolonged immunosuppression. B: Photomicrograph of the characteristic 45° angle branching of septate hyphal forms of *Aspergillus*. Gomori methenamine silver stain, × 400. (Courtesy of Margie Scott.)

Coccidioides immitis is endemic in the southwestern United States. *C. immitis* is more likely to be pathogenic in patients with compromised cell-mediated immunity. High rates of treatment failure and death have been reported in patients with hematologic malignancies.¹⁴⁶ The diagnosis is most often established by finding the fungus in BAL, sputum, or biopsies. Serology is positive in only 55% of patients. *Coccidioidomycosis* can involve virtually any organ in disseminated disease but has tropism for bone and the CNS. Therapy for disseminated disease generally requires amphotericin B followed by maintenance fluconazole.¹⁴⁷

Pneumocystis Jirovecii Pneumonia (PJP)

Pneumocystis jirovecii (formerly *P. carinii*) is classified as a fungus rather than a protozoan based on gene sequence data, although it lacks ergosterol, the main fungal cell-wall component. Defective T cell immunity and steroid use are risk factors for PJP. *Pneumocystis jirovecii* can have a fulminant course with rapid progression to respiratory failure in immunocompromised patients.¹⁴⁸ Patients with pneumonia from *P. jirovecii* usually present with rapid onset of dyspnea, nonproductive cough, hypoxemia, and fever. Radiologic studies generally show diffuse bilateral interstitial infiltrates but can show focal infiltrates. Pleural effusion is uncommon. Diagnosis of PJP relies on visualization of the organism microscopically, as it does not grow in culture. BAL is the standard diagnostic modality for PJP, but induced sputum has acceptable yield in some institutions.¹⁴⁹ Immunofluorescent staining with monoclonal antibodies is more sensitive than silver staining or Wright-Giemsa staining.¹⁵⁰ PJP frequently results in positive serum beta-d-glucan testing.¹⁵¹ Treatment should be started based on clinical suspicion, and TMP-SMX (5 mg/kg IV every 8 hours) remains the treatment of choice.³ Prednisone should be added to the empiric treatment regimen if the pO₂ is <70 mmHg.¹⁵² Alternatives for TMP/SMX-allergic/intolerant patients include dapsone, atovaquone, or clindamycin-primaquine for infections of moderate severity and IV pentamidine for infections of high severity.

Viral Pneumonia

Pneumonia due to respiratory viruses (respiratory syncytial virus [RSV], influenza, parainfluenza, adenovirus) is more common in patients with defects in cell-mediated immunity. Treatment with ribavirin (RSV, parainfluenza)^{153,154} with or without immunoglobulins or cidofovir (adenovirus)¹⁵⁵ has not been shown to change outcome. Prompt treatment of RSV upper respiratory illnesses in HSCT recipients with a combination of aerosolized ribavirin and IVIG prevents progression to

pneumonia in a pilot study.¹⁵⁶ Oseltamivir and zanamivir are effective in HSCT and immunocompromised patients with influenza and are recommended in documented or suspected influenza infections.^{3,157}

CMV pneumonia is a significant complication of allogeneic HSCT. It typically develops between 40 and 100 days posttransplant and presents with fever, dyspnea, hypoxemia, and diffuse interstitial infiltrates (Fig. 69.6). CMV pneumonia after day 100 is becoming more common and should be considered in patients with a history of previous CMV reactivation. In transplant patients the diagnosis is established by a compatible clinical syndrome with detection of CMV in BAL (by culture or cytopathology showing characteristic intracytoplasmic and intranuclear inclusions) or tissue (by culture or histologic diagnosis). CMV pneumonia is rare in nontransplant patients and the culture alone is not considered sufficient to make the diagnosis, as CMV can be shed from pulmonary secretions without causing invasive disease.^{158,159} Frontline treatment of CMV pneumonia typically consists of ganciclovir 5 mg/kg IV every 12 hours with IVIG 500 mg/kg every 48 hours for 3 weeks, although foscarnet (90 mg/kg every 12 hours) is an acceptable alternative to the ganciclovir.¹⁶⁰

Hospital-Acquired Pneumonia

Hospital-acquired pneumonia (HAP) is considered “early” when it happens within 4 days of admission or “late” when it occurs 5 days or more after admission.⁷⁰ Late HAP is more likely to be caused by multidrug-resistant pathogens. Risk factors for

P.1440

multidrug-resistant pathogens include previous antimicrobials in the preceding 90 days, hospitalization for 2 days or more in the preceding 90 days, residing within a nursing home, chronic dialysis, home wound care, and exposure to others with multidrug-resistant pathogens.⁷⁰ Initial therapy for HAP depends on severity of illness of the patient, previous antimicrobial exposures and hospitalizations, and institutional antibiogram data. Empiric therapy should include an antipseudomonal beta-lactam plus an antipseudomonal fluoroquinolone, or an aminoglycoside plus either linezolid or vancomycin to cover MRSA with subsequent tailoring of regimen once culture data becomes available.⁷⁰

FIGURE 69.6. The spectrum of cytomegalovirus (CMV) disease in the abnormal human host. A: Chest radiograph demonstrating diffuse interstitial infiltrates in patient 60 days after cord blood transplant. B: Chest CT showing bilateral fine nodular infiltrates. C: CMV inclusion disease of the colon. Typical infected cells show cellular ballooning with dense primary nuclear inclusions surrounded by a thin, cleared rim; secondary inclusions appear as cytoplasmic granules after the nucleus has filled with virions. D: CMV hepatitis demonstrated on liver biopsy. Viral cytopathic effect may be difficult to establish, but rare viral inclusions with surrounding parenchymal changes are diagnostic of CMV. Hematoxylin and eosin stain $\times 400$. (Photomicrographs courtesy of Margie Scott.)

GASTROINTESTINAL INFECTIONS

Neutropenic Enterocolitis (Typhlitis)

Typhlitis refers to inflammation of the cecum and results from a combination of neutropenia and defects in the bowel mucosa related to cytotoxic chemotherapy. When it extends beyond the cecum, the broader term neutropenic enterocolitis is used.¹¹⁰ Differential diagnosis for etiology of typhlitis includes *C. difficile* colitis, CMV enteritis, bowel ischemia, and GI tract GVHD.¹⁶¹ Typhlitis is pathologically characterized by ulceration and necrosis of the bowel wall, hemorrhage, and masses of organisms. Clinical signs include fever, abdominal pain and tenderness, and radiologic evidence of right colonic inflammation. Nausea, vomiting, and diarrhea (bloody or nonbloody) are the most common associated symptoms. Abdominal distention, tenderness, and a right lower quadrant fullness or mass reflect a thickened bowel. Bacteremia with bowel flora, *P. aeruginosa*, and polymicrobial sepsis may occur. Clostridium species are the most common anaerobic pathogens. Typhlitis should be suspected if right lower quadrant pain and bloody diarrhea are present. Surgical intervention may be required in the event of an intraabdominal catastrophe.

An abdominal and pelvic CT scan should be performed in patients with suspected typhlitis or undiagnosed abdominal pain in the setting of neutropenia. Positive CT scan findings are present in about 80% of cases¹⁶² and include a right lower quadrant inflammatory mass, pericecal fluid, soft tissue inflammatory changes, localized bowel wall thickening and mucosal edema,

P.1441

and a paralytic ileus. All patients should be assessed for *C. difficile* infection. Treatment requires broad-spectrum antibiotics with activity against aerobic gram-negative bacilli and anaerobes (e.g., ceftazidime plus metronidazole, imipenem, meropenem, or piperacillin/tazobactam) and supportive care, including intravenous fluids or parental nutrition and bowel rest. The majority of patients will respond to antibiotic therapy and supportive care without the need for surgery. Indications for surgery often include (1) persistent gastrointestinal bleeding after resolution of neutropenia, thrombocytopenia, and clotting abnormalities; (2) intraperitoneal perforation; (3) uncontrolled sepsis despite fluid and vasopressor support; and (4) an intraabdominal process (such as appendicitis) that would require surgery in the absence of neutropenia.¹⁶³

Clostridium Difficile Colitis

Pseudomembranous enterocolitis that is caused by *Clostridium difficile* may occur as a complication of antibiotic therapy, and stool should be assayed for the *C. difficile* toxin.¹⁶⁴ The clinical presentation includes asymptomatic carriage, colitis without pseudomembrane formation, pseudomembranous colitis, and fulminant colitis with toxic megacolon. In severe *C. difficile* disease, paralytic ileus, toxic dilatation of the colon, and bowel perforation may occur. Abdominal radiographs may show nonspecific dilation of the colon with mucosal edema ("thumbprinting"). The mainstay of diagnosis is detection of *C. difficile* toxin A, toxin B, or both, in the stool with a cytotoxin test, enzyme immunoassay, or PCR for the toxin gene. Enzyme immunoassays have variable sensitivity, while DNA amplification testing for *C. difficile* has a reported sensitivity greater than 95%.¹⁶⁵ Empiric therapy for *C. difficile* enterocolitis should be instituted despite a negative stool evaluation if suspicion remains high and other causes of diarrhea have been excluded. Traditional options for the treatment of *C. difficile* include oral or intravenous metronidazole and oral vancomycin.

Metronidazole is recommended as frontline therapy for uncomplicated cases, as its efficacy is similar to oral vancomycin, and the selection pressure on other flora is less dangerous.¹⁶⁶ Oral vancomycin may be more efficacious in severe and refractory *C. difficile* colitis and should be considered for treatment in these cases.^{167,168} Fidaxomicin has also been found to be equivalent to oral vancomycin and is FDA approved for the treatment of *C. difficile*-associated diarrhea.¹⁶⁹ Nitazoxanide and rifaximin are under investigation. Patients in whom oral agents cannot be administered should receive intravenous metronidazole. In cases involving toxic dilatation of the colon or perforation, subtotal colectomy, diverting ileostomy, or colostomy may be required.

GENITOURINARY INFECTIONS

Neutropenic patients with a urinary tract infection often do not show pyuria and are far more likely to become bacteremic compared with nonneutropenic patients. While treatment is typically reserved for symptomatic episodes in nonneutropenic patients, intervention should be considered in neutropenic patients with asymptomatic bacteruria. Candiduria may represent colonization in a patient with an indwelling urinary catheter, particularly in the setting of broad-spectrum antibiotics. Removal of the urinary catheter is frequently sufficient therapy. Patients with neutropenic fever and candiduria should receive systemic antifungal therapy over concerns of potential occult invasive candidiasis. Fluconazole 400 mg/day for 1 to 2 weeks is the treatment of choice. In the case of non-*Albicans* candiduria, another azole or amphotericin should be used. Echinocandins are minimally present in the urine, and they are not effective in the treatment of candiduria.¹⁷⁰

Hemorrhagic cystitis is a common consequence of some cytotoxic regimens, particularly cyclophosphamide. A viral etiology should be considered in HSCT recipients and other immunocompromised patients with unexplained hematuria. Adenovirus, the polyomavirus BK, and CMV have been associated with hemorrhagic cystitis. Adenovirus hemorrhagic cystitis is usually self-limiting, but low-dose cidofovir (1 to 3 mg/kg/week, without probenecid) is occasionally used with the aim of preventing disseminated adenoviral disease.¹⁷¹ BK virus commonly reactivates after allogeneic HSCT, but only a minority of patients (typically those with high viral loads) develop hemorrhagic cystitis. Treatment consists of supportive care and reduction of immunosuppressants if possible.

SKIN AND SOFT TISSUE INFECTIONS

Skin eruption caused by infections must be distinguished from noninfectious ones such as drug reactions (including chemotherapy-induced hand-foot syndrome), Sweet syndrome, erythema multiforme, vasculitis, leukemia cutis, pyoderma gangrenosum, tumor, and GVHD. When evaluating the potential for a skin/soft tissue infection, careful examination of all line sites and perineal areas are essential. Early biopsy of skin lesions for histology and culture is recommended. Antimicrobial therapy should be tailored to the probable organisms: staphylococci and streptococci for catheter-associated processes and gram-negative and anaerobic organisms for perineal processes, respectively.

Vancomycin may be considered for cellulitis, disseminated papules/lesions, and wound infections. Acyclovir, famciclovir, or valacyclovir should be considered for vesicular lesions after appropriate diagnosis is made for HSV or VZV.

VZV and herpes simplex virus (HSV) generally present as vesicular lesions and may be indistinguishable. Scrapings from the base of vesicles should be sent for direct fluorescent antibody (DFA) testing to diagnose VZV and for shell-vial culture to diagnose HSV. Intravenous acyclovir is the treatment of choice for VZV and HSV in the immunocompromised host.¹⁷² In immunocompetent patients, oral acyclovir, valacyclovir, and famciclovir have been used successfully.

Gram-positive bacteria that cause skin and soft tissue infections include *Streptococcus* (group A and B) and *S. aureus*. Gram-negative bacilli with propensity to cause dermatologic infections include *P. aeruginosa*, *Stenotrophomonas maltophilia*, *Aeromonas hydrophila*, and *Vibrio vulnificus*. The latter classically presents with septicemia and secondary cellulitis with hemorrhagic bullae following ingestion of contaminated seafood by patients with underlying liver disease. *V. vulnificus* may also present as a primary cellulitis with bacteremia when an open wound is exposed to seawater.

Ecthyma gangrenosum is typically a manifestation of *P. aeruginosa* or other gram-negative bacilli. It can be variable in its appearance but often presents as a dark, necrotic lesion in neutropenic patients. Antibiotic therapy with an antipseudomonal agent should be initiated and early surgical consultation for possible debridement is imperative.¹⁷³

A rapidly progressive deep soft tissue infection with gas formation suggests clostridial myonecrosis (or polymicrobial necrotizing fasciitis) caused by *Clostridium* species. The lesions may become necrotic, bullous, and hemorrhagic. Systemic toxicity including fever, malaise, and mental status changes occur early. Extensive surgical debridement may be life-saving if initiated early, but the mortality rate remains high. Polymicrobial sepsis with enteric flora is commonly observed in association with clostridial bloodstream infection. In neutropenic patients, metronidazole plus an antipseudomonal cephalosporin or single-agent therapy with imipenem, meropenem, or piperacillin/tazobactam are recommended.¹⁷⁴

Skin lesions of disseminated candidiasis are small, raised discrete erythematous papules.¹⁷⁵ The lesions resemble those of heat rash early in their presentation. They are usually not tender.

P.1442

Concurrent myalgias raise the possibility of *Candida* myositis. Biopsy and fungal staining of cutaneous lesions can provide an immediate clue to the diagnosis, prompting the early addition of antifungal therapy. Blood cultures are typically positive.

VIRAL INFECTIONS

Respiratory viruses include influenza, parainfluenza, respiratory syncytial virus, human metapneumovirus, adenoviruses, rhinoviruses, and coronaviruses. Most respiratory viruses typically cause self-limited infection in healthy persons, but cause significant morbidity and mortality in immunocompromised patients with hematologic malignancies and HSCT recipients.¹⁷⁶ The role of empiric antiviral therapy in the treatment of neutropenic fevers is not well defined. Antiviral drugs are indicated in the management of neutropenic fevers only if there is clinical and laboratory evidence of active viral infection.³ Respiratory virus testing (including testing for influenza, parainfluenza, adenovirus, respiratory syncytial virus [RSV], and human metapneumovirus) and chest radiography are indicated for patients with upper respiratory symptoms such as cough and coryza. Although aerosolized and oral administration of ribavirin has been used, no antiviral agent has been proven to be effective against parainfluenza virus. Similarly, there is no clear indication for aerosolized or oral ribavirin or other antiviral against RSV pneumonia though modest effect has been observed in retrospective analysis.¹⁵⁴

Influenza Virus

Influenza results in annual epidemics of respiratory viral illness during the winter. Unlike the mild and typically self-limited disease seen in immunocompetent patients, immunocompromised patients frequently have a more severe course. Several existing antiinfluenza agents are commercially available. Amantadine and rimantadine are active against influenza A, but not influenza B. Resistance to these agents may rapidly develop during therapy. The neuraminidase inhibitors, zanamivir and oseltamivir, are active against both influenza A and B. They are effective in reducing the duration of influenza illness if started early after onset of symptoms, and they have a prophylactic benefit during community outbreaks.^{177,178} Oseltamivir appears to be both safe and effective against influenza infections among HSCT recipients. If influenza is suspected, empiric therapy with an antiinfluenza agent (e.g., oseltamivir and zanamivir) should be initiated while awaiting test results.^{3,178} Choice of drug should be based on the susceptibility patterns of the predominant influenza strain(s).

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) infection can cause high mortality in patients with acute leukemia and in HSCT recipients.¹⁷⁹ Upper respiratory symptoms (sinusitis, coryza, rhinorrhea) usually precede lower respiratory tract involvement (dyspnea, wheezing) and pneumonia, but may be absent. Uncontrolled studies suggest that aerosolized ribavirin and IVIG containing high RSV neutralizing titers for at least 24 hours prior to respiratory failure prevent respiratory failure and result in much better outcomes.¹⁸⁰ Inhaled ribavirin and immunoglobulin should be considered in patients with RSV infection at highest risk for severe complications, such as allogeneic HSCT recipients, patients with acute leukemia, and those with persistent neutropenia.³

Adenovirus

The spectrum of adenoviral infections in immunocompromised patients extends from asymptomatic shedding to fatal multisystem disease and includes upper respiratory tract infection, pneumonia, renal parenchymal disease, hemorrhagic cystitis, hepatitis, small and large bowel disease, and encephalitis. Viral shedding from throat secretions, urine, and stool is common, occurring in approximately 5% to 20% of HSCT recipients, and should not be equated with disease. Gastroenteritis and hemorrhagic cystitis are usually self-limited, whereas pneumonia and disseminated disease are associated with a high mortality rate. Adenoviral infection is more common in young transplant patients, those who receive T cell-depleted transplants, and those who receive stem cells from unrelated donors.¹⁵⁵ Supportive care is important, though cidofovir may be beneficial.¹⁷¹

Parvovirus B19

Parvovirus B19 is a DNA virus that is transmitted via respiratory secretions and blood products. Infection in immunocompromised persons unable to mount a protective antibody response may cause prolonged fever, chronic pure red cell aplasia, thrombocytopenia, or pancytopenia. Predisposing conditions include acute and chronic leukemias, myelodysplastic syndrome, lymphoma, HSCT, potent antineoplastic chemotherapy, and systemic steroids. Diagnosis of parvovirus B19 infection in the immunocompromised patient relies on PCR detection of viral DNA from serum; these patients may be incapable of antibody responses. Treatment often consists of IVIG.¹⁸¹

INFECTIONS IN HEMATOPOIETIC STEM CELL TRANSPLANTATION PATIENTS

Autologous and allogeneic HSCT recipients have a unique set of infectious disease problems. Infection is reported as the primary cause of death in 8% of autologous HSCT patients and 17% to 20% of allogeneic HSCT recipients.¹⁸² High-dose chemotherapy or chemoradiotherapy preparative regimen causes short-term cytopenias and often mucositis, followed by profound immunosuppression with weeks to months of defective T cell-mediated immunity. All HSCT recipients experience profound immunosuppression at some point and the degree of immunosuppression experienced by individual patients varies greatly and is influenced by several factors. GVHD severity correlates with the degree of immunosuppression and infectious complications. This correlation is due to a variety of factors, including damage to lymphoid microenvironments, adverse effects of GVHD on homeostatic peripheral expansion, as well as the impact that chronic immunosuppression has on a reconstituting immune system. Recipient factors such as age, comorbidities, and infectious exposure prior to transplant contribute substantially to the risk for posttransplant infectious complications. Graft-associated factors also play an important role. Peripheral blood stem cell graft recipients show more rapid immune reconstitution,¹⁸³ whereas umbilical cord blood transplantation in adults,^{184,185} and transplantation of profoundly T cell-depleted haploidentical grafts result in poor immune reconstitution and higher rates of infectious complications.

Most infections in autologous HSCT recipients occur during neutropenia or within the first few months after transplantation before reconstitution of cellular immunity. Recipients of CD34⁺ cell-enriched autografts appear to have a similar risk to allogeneic HSCT recipients for CMV and other opportunistic infections.¹⁸⁶ Recipients of allogeneic peripheral blood stem cell grafts undergo more rapid immune reconstitution than those who receive marrow.¹⁸⁷ Reconstitution of cellular and humoral immunity in allogeneic transplant patients occurs gradually over a period of 1 to 2 years. Duration of T cell immunity defects varies, depending on factors such as cancer type, manipulation of the stem cells preinfusion, and the age of the recipients.¹⁸⁸ Infectious disease risk profiles vary depending on the type of transplant as well as the many variants associated with an HSCT (conditioning regimen,

P.1443

degree of HLA matching, stem cell source, and GVHD prophylaxis). The spectrum of pathogens to which HSCT recipients are most susceptible follows a time line corresponding to the predominant immune defects as outlined in Figure 69.7.

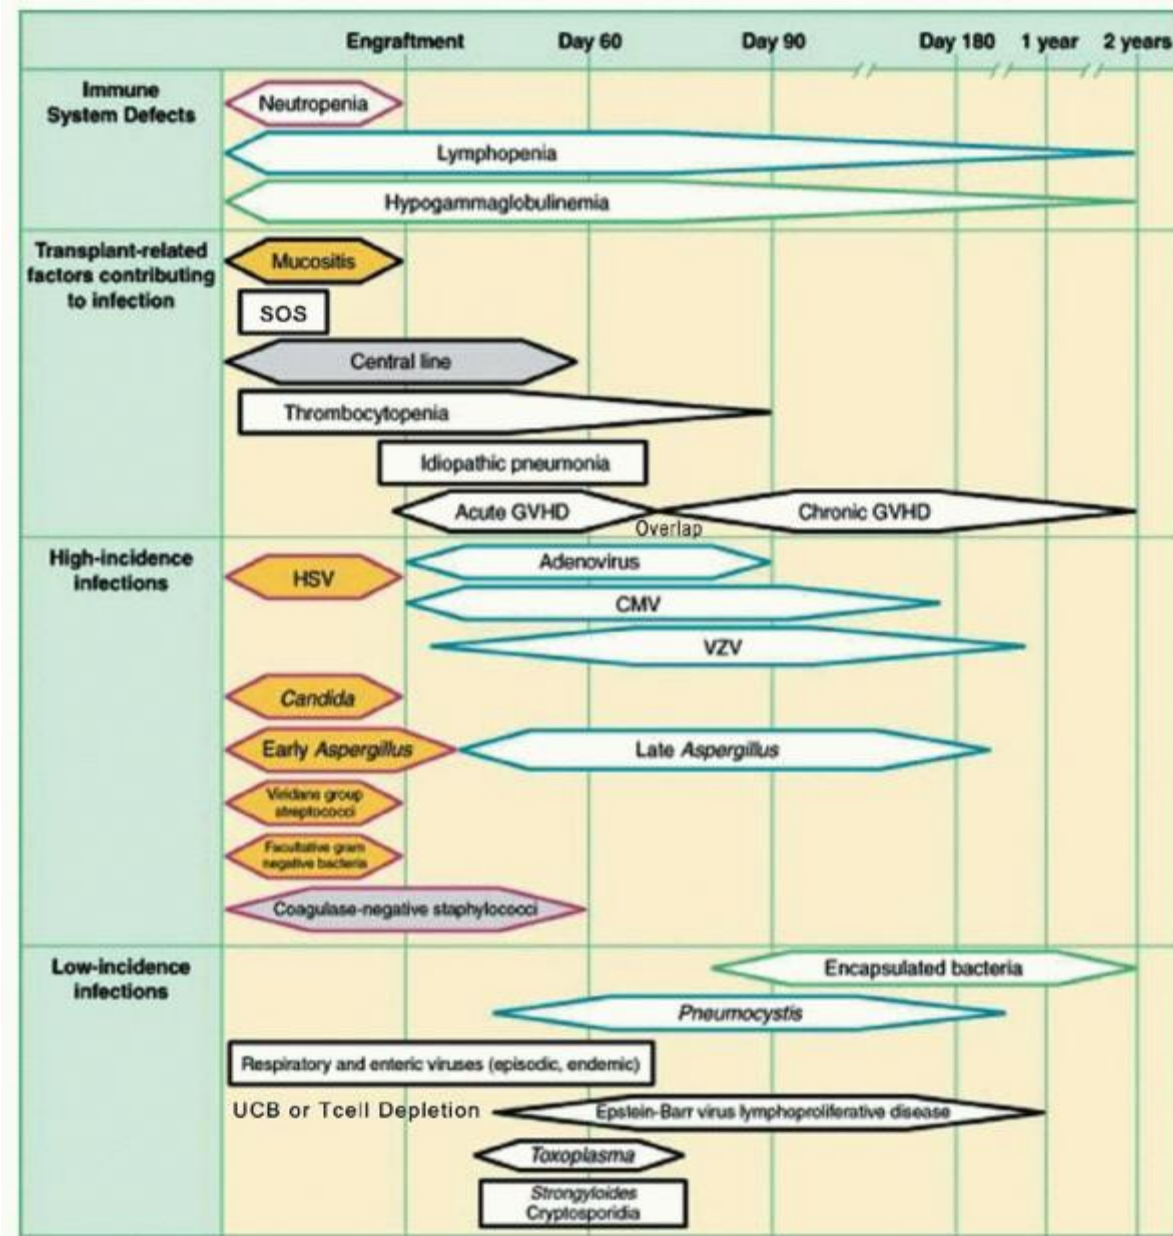

FIGURE 69.7. Phases of predictable opportunistic infections and complications among patients undergoing hematopoietic stem cell transplantation. CMV, cytomegalovirus; GVHD, graft-versus-host disease; HSV, herpes simplex virus; SOS, sinusoidal obstruction syndrome; UCB, umbilical cord blood; VZV, varicella zoster virus. Adapted from Van Burik J-AH, Freifeld AG. Infection in the severely immunocompromised host. In: Abeloff MD, Armitage JO, Niederhuber JE, et al., eds. Clinical oncology, 3rd ed. Philadelphia, PA: Churchill Livingstone; 2004:942.

Neutropenia is the principal host defect in the first few months after HSCT and predisposes patients to bacterial, fungal, and viral infections. The risk of bacterial infection, central venous catheter (CVC) infection, and reactivation of herpes simplex are highest in the preengraftment period. Prolonged neutropenia and antibiotic therapy leads to a steady rise in the risk of invasive fungal infection, which then decreases after engraftment. After myeloid engraftment, qualitative dysfunction of phagocytes persists because of immunosuppressive agents and corticosteroid. Cellular immune dysfunction peaks at approximately day 40 after engraftment and the typical onset of GVHD. The risk of opportunistic viruses and molds during this period is associated with the severity of GVHD and immunosuppressive regimens. Long-term venous access catheters continue to give rise to infection as long as the access is maintained. Continuation of prophylactic antimicrobials beyond 1 year depends on the individual patient's infection history and the ability to wean immunosuppressive therapy.¹⁸²

Preventing Early Infectious Disease (0 to 100 days after HSCT): Early after HSCT, neutropenia is the principal host defense defect, predisposing mainly to bacterial and fungal infections. Presence of a CVC remains as a risk factor for bacterial infection even after myeloid engraftment. Management of bacterial infections in the early neutropenic phase of the transplant is similar to the management of febrile neutropenia seen with any other myelosuppressive therapy. Bacterial infections account for over 25% of fevers in the preengraftment phase of allogeneic HSCT.¹⁸⁹ The source of infection is usually the gut and oral flora due to mucositis, even though the increased use of CVCs has increased the risk of gram-positive bacteremias from skin flora. Streptococcal infections may be seen in patients with severe mucositis. The risk of late bacterial infections (those that occur after engraftment) depends on the immune status of the patient. Allogeneic HSCT recipients are at risk for bacterial infections with encapsulated organisms (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*) if they develop chronic GVHD or profound hypogammaglobulinemia.¹⁹⁰ Prophylactic fluoroquinolones are often maintained until marrow engraftment. This practice has been shown to reduce the incidence of infections, particularly

P.1444

those due to gram-negative organisms, but has not been shown to definitively decrease infection-related mortality.^{81,176} Antibiotic prophylaxis has been found to significantly decrease the risk for all-cause mortality when compared with placebo or no treatment in neutropenic patients,^{81,191} IDSA and ASBMT guidelines do recommend prophylactic fluoroquinolone in high-risk patients with expected duration of neutropenia >7 days.¹⁸²

Viral Infections

Cytomegalovirus

CMV infection has been a major source of morbidity and mortality in transplant recipients prior to the era of proper prophylaxis and monitoring for reactivation. Transplant recipients are at risk for reactivation (if CMV seropositive pre-HSCT) and also primary infection (from stem cells or blood products from CMV seropositive donors). Incidence of primary infection has decreased with the increasing use of leukofiltered blood products.

CMV infection is defined as the reactivation of the virus and the detection of the virus in the blood or other body fluids in the absence of organ-specific abnormalities (pneumonitis, hepatitis, colitis, and retinitis). CMV disease is defined as the isolation of the virus from body fluids or tissues in a symptomatic patient or the histopathologic evidence of CMV on tissue biopsy (see Fig. 69.6). Risk factors for the development of CMV disease include older recipient age, pretransplant seropositivity of the recipient or donor, or both, and severe acute GVHD.^{192,193} T cell depletion of the stem cell graft or treatment of the recipient with antithymocyte globulin for GVHD increases the likelihood of CMV reactivation.¹⁹⁴

The incidence of CMV reactivation in allogeneic transplant recipients who are seropositive before transplant is 60% to 70%, as compared to a 10% to 30% incidence of primary infection in seronegative recipients.^{195, 196} and ¹⁹⁷ Prior to the use of ganciclovir, CMV interstitial pneumonitis occurred in 15% to 30% of HSCT allograft recipients and the ensuing mortality was as high as 85%; however, mortality remained high at 30% to 50% even with the combined use of ganciclovir and CMV-specific immune globulin (Ig).¹⁹⁴

Administration of CMV-safe or leukofiltered blood products is recommended to all seronegative autologous or allogeneic HSCT recipients to prevent primary CMV infection.^{195,198} CMV surveillance starting at the time of engraftment is recommended in instances of recipient and/or donor CMV seropositivity. Tests used for CMV surveillance include CMV pp65 antigenemia assay, DNA PCR detection methods, or CMV blood cultures.¹⁹⁹ Detection of CMV in the blood is the strongest predictor of CMV disease, but 12% to 20% of patients with negative surveillance cultures still develop CMV disease. While high-dose intravenous acyclovir significantly reduces the incidence of all forms of CMV disease or delays the onset of CMV infection, it does not prevent CMV viremia.^{200,201}

There are two recommended strategies for prevention of CMV disease. One strategy is prophylaxis with ganciclovir, valganciclovir, or valacyclovir, starting from engraftment until day 100, or longer if the patient remains at risk for CMV reactivation (active GVHD, high-dose steroids, low CD4 count).^{199,202} The other strategy is close surveillance and preemptive therapy with ganciclovir or foscarnet when CMV reactivation is detected. Both strategies reduce the incidence of CMV disease in the first 100 days; however, the median onset of CMV disease has shifted from 50-60 days to 160-176 days post-HSCT in the preemptive era.¹⁹⁷

Preemptive therapy with ganciclovir for patients with positive CMV surveillance cultures (blood, urine, throat, or bronchoalveolar lavage fluid) has demonstrated improved survival at 100 and 180 days post-HSCT, but has failed to provide an overall survival advantage.²⁰³ Protracted ganciclovir prophylaxis can lead to emergence of resistant strains and

the failure of natural immunity against CMV to develop, thus resulting in late recrudescence.^{196,204,205} Optimal preemptive therapy appears to be 1 to 2 weeks of twice-a-day induction followed by maintenance until PCR or antigen negativity.¹⁸²

Ganciclovir is the drug of choice for CMV infection and disease, but its myelosuppressive effects may preclude its use in patients with significant cytopenias. Foscarnet is an equally effective alternative and can be used to treat ganciclovir-refractory CMV infections or in patients with significant cytopenias. Although it is not myelosuppressive, foscarnet is associated with renal toxicity and electrolyte imbalances.¹⁶⁰ Cidofovir is another nephrotoxic antiviral with efficacy against CMV, but there are few data on its use in the stem cell transplant patient population.²⁰⁶ Maribavir is the latest antiviral in the armamentarium of drugs available for management of CMV and has been found to decrease rates of CMV infection when used as prophylaxis in the stem cell transplant setting,²⁰⁷ but has failed to prevent CMV disease in a randomized phase III study.²⁰⁸

Herpes Simplex Virus

HSV reactivation occurs in as many as 80% of seropositive allogeneic transplant recipients, causing mucocutaneous oral or genital lesions, esophagitis, and, occasionally, pneumonia or encephalitis. Testing all transplant recipients for herpes simplex virus exposure (HSV IgG) is recommended. Antiviral prophylaxis with acyclovir, valacyclovir, or famciclovir is recommended for all seropositive patients until the time of engraftment. Although its use is not recommended past 1 month after transplant, some patients with recurrent lesions might benefit from longer use of the prophylaxis.^{209,210}

Varicella Zoster Virus

Impaired cellular immunity is the principal risk factor for VZV disease. Current recommendations are to test every transplant patient for varicella zoster virus serostatus (IgG). VZV reactivation may occur at any time after engraftment in autologous and allogeneic transplant recipients. Disseminated VZV is seen in as many as 30% of cases and is associated with a high mortality. Many centers administer oral acyclovir or valacyclovir for ~12 months after transplant to VZV-seropositive patients.²¹⁰ Seronegative patients should be given varicella zoster immune globulin within 96 hours of exposure to a VZV vaccine or upon contact with active infection.

Fungal Infections

Most fungal infections in the SCT population are due to *Candida* or *Aspergillus*. The etiology in the remaining <10% are uncommon fungi, such as *Fusarium*, *Scedosporium*, *Blastomyces*, and *Histoplasma*. Prevention of fungal infections in these patients is key. Fluconazole prophylaxis at a dose of 400 mg/day, beginning at the time of transplant and until the time of engraftment, provides adequate protection against invasive yeast infections.^{189,211,212} Failure of fluconazole prophylaxis against *Candida* is usually a result of the emergence of resistant yeast forms (*C. krusei*, *C. glabrata*). Empiric therapy for fungal infections in febrile neutropenic patients is considered the standard of care, and several studies are examining the preemptive approach.^{33,141} The toxicity of intravenous amphotericin B is substantial and it is no longer recommended for prophylaxis. Lipid formulations of amphotericin (Abelcet, Amphotec, and AmBisome) have fewer renal and infusional toxicities. Newer antifungal agents have changed the approach to prevention and treatment of fungal infections in SCT patients. Caspofungin, micafungin, and anidulafungin are echinocandins with a broad spectrum of activity against several species of *Candida* and *Aspergillus*. Triazoles such as voriconazole, posaconazole, and ravuconazole also have activity against *Aspergillus* and a wide variety of yeasts and molds.¹³⁷

P.1445

Pneumocystis jirovecii pneumonia (PJP) is not a protozoan, but resembles a fungus based on molecular studies. Prophylaxis against PJP is recommended in all allogeneic HSCT recipients from the time of engraftment until 6 months after transplant, or even longer if the patient is on high doses of immunosuppressive drugs for chronic GVHD. Oral TMP-SMX is the drug of choice, but aerosolized pentamidine, dapsone, dapsone in combination with trimethoprim or pyrimethamine, pyrimethamine and sulfadoxine, and atovaquone can be used as alternatives.^{213,214,215,216} Patients should be tested for glucose 6-phosphate dehydrogenase deficiency before initiation of dapsone. Guidelines for PJP prophylaxis in autologous SCT patients are less clear and should be considered in patients who are deemed high-risk, such as those who receive fludarabine or cladribine and those who have had prolonged steroid use before transplant.

Toxoplasmosis reactivation or infection is rare but can be life-threatening and usually occurs within the first year posttransplant. Toxoplasmosis prophylaxis is recommended for seropositive allogeneic recipients or those with a prior history of toxoplasmic infection.¹⁸² Oral TMP-SMX is the prophylactic agent of choice,¹⁸² but pyrimethamine-sulfadoxine (Fansidar) prophylaxis can be used.²¹⁷ For patients who are TMP-SMZ-intolerant, a combination of clindamycin,

pyrimethamine, and leucovorin can be substituted. Prophylaxis is recommended from the time of engraftment until 6 months after transplant.¹⁸² Pyrimethamine does not eradicate the cyst form of *T. gondii*.

STRATEGIES TO PREVENT INFECTIONS

Measures and practices to prevent nosocomial pathogen acquisition as well as the spread of infections play critical roles in the overall picture of managing febrile neutropenia as well as the well-being of all exposed to hospital settings.

Hand hygiene is the most effective means of preventing transmission of infection in the hospital.²¹⁸ All persons should sanitize their hands upon entering and leaving the rooms of neutropenic and other hospitalized patients.

No specific protective gear (e.g., gowns, gloves, and masks) is required during the routine care of neutropenic patients, but standard isolation and barrier precautions should be followed when specific infections occur or contact with body fluid is anticipated.²¹⁹ Single patient room occupancy is common practice, especially for HSCT.

Neutropenic diets are typically given to patients with neutropenia, though data are lacking. Studies comparing diets of cooked and uncooked foods indicate that avoidance of raw fruits and vegetables does not prevent major infection or death.^{220,221} While well-cooked foods are generally recommended, well-cleaned, uncooked raw fruits and vegetables are acceptable.

Many patients with neutropenia do not require specific room ventilation, but laminar airflow rooms and HEPA filtration are still considered important for certain high-risk patients, such as those undergoing HSCT. The use of laminar flow and HEPA filtration has been reported to decrease the incidence of *Aspergillus* infections.^{222,223} However, the use of reverse isolation has not been shown to significantly reduce the acquisition of nosocomial pathogens.²²⁴

Molds, including *Aspergillus* and *Fusarium* species, have been isolated from plants and dried or fresh flowers and therefore these should not be allowed in the rooms of neutropenic patients.^{225,226} Pets should also not be allowed in the area with neutropenic patients.²¹²

Prevention of Infections

Infection prophylaxis in cancer patients involves broad-spectrum antimicrobial therapy against the common bacterial, viral, and fungal pathogens in high-risk patients. Knowing the spectrum of infection-causing pathogens at individual hospitals or treatment centers is key to appropriate prophylaxis. A summary of prophylactic strategies in this patient population is provided in Table 69.6.

Antibacterial Prophylaxis

Historically, TMP-SMX has been used for many years for prophylaxis against bacterial infections. Initial studies showed efficacy in preventing PJP, whereas later studies demonstrated benefit in reducing the incidence of bacterial infections in patients with hematologic malignancies.^{227, 228, 229, 230} and ²³¹ Fluoroquinolones are the most commonly used antibiotics for prophylaxis against bacterial infections in neutropenic patients. They are broad-spectrum derivatives of nalidixic acid that are orally bioavailable with a broader spectrum of activity, preserve colonization resistance, and are well tolerated.

Quinolone-based prophylaxis has been successful in reducing the risk of aerobic gram-negative infections in neutropenic patients undergoing cytotoxic chemotherapy for AL and HSCT in several studies.^{232,233} An increased frequency of breakthrough gram-positive bacteremias, predominantly by viridans streptococci (*Streptococcus mitis*, *S. sanguis*) and coagulase-negative staphylococci, has been observed.^{71,233, 234} and ²³⁵ The newer fluoroquinolones (ciprofloxacin, levofloxacin) have broader gram-positive activity and have been variably effective in preventing infection with α -hemolytic streptococci when coadministered with roxithromycin or amoxicillin-clavulanate.²³⁶ Viridans group streptococcal bacteremia breakthroughs have been reported with ciprofloxacin prophylaxis.⁷¹ In comparison to placebo, fluoroquinolone prophylaxis significantly reduced the incidence of gram-negative infections.¹⁹¹ Fluoroquinolone prophylaxis was also associated with a statistically nonsignificant, yet clinically relevant, decrease in mortality in neutropenic patients.^{191,237} Gram-positive and fungal infection rates were not significantly affected by fluoroquinolone prophylaxis.¹⁹¹

Prophylactic levofloxacin in neutropenic patients with intermediate or high risk of infection has been shown to lead to a reduction in infections,¹⁷⁶ whereas the major benefit in low-risk neutropenic patients relates to the reduction in febrile episodes.²³⁸

Both the IDSA and NCCN recommend the consideration of fluoroquinolone prophylaxis (levofloxacin is preferred) in patients with an expected duration of neutropenia of more than 7 days. TMP/SMX should be used in specific patients at high risk for *P. jirovecii*. No antibiotic prophylaxis is recommended for patients with neutropenia expected to last 7 days or less and who are not receiving immunosuppressive regimens.^{3,239}

Emergence of secondary resistance remains a valid concern regarding the use of antibiotic prophylaxis. Gram-negative bacteremias in patients who receive fluoroquinolone prophylaxis are often caused by resistant *P. aeruginosa*, but infections that are caused by non-*P. aeruginosa* species, especially *E. coli*, and *Enterobacter* species, are being increasingly reported.^{240,241} The potential risks of quinolone prophylaxis regarding the development of *Clostridium difficile* colitis also warrants consideration^{77,164} and underscores the importance of judicious use of antimicrobial prophylaxis.

Prophylaxis against Pneumococcal Infection

Pneumococcal prophylaxis should be considered in asplenic patients and in allogeneic HSCT recipients with chronic GVHD. The risk of pneumococcal sepsis is greatest within the first 2 years after splenectomy, but a third of events may occur up to 5 years out, and cases of fulminant sepsis have been reported at more than 20 years.²⁴² Pneumococcal disease among allogeneic HSCT recipients typically occurs in the later transplant period, from 3 months to several years after transplant. Pneumococcal

P.1446

P.1447

prophylaxis with an oral penicillin or TMP/SMX is recommended for at least 6 months post-HSCT or until discontinuation of immunosuppressive therapy.²⁴³ Vaccination against *S. pneumoniae* is recommended for all HSCT recipients, preferably with pneumococcal 7-valent conjugate vaccine.²⁴³

TABLE 69.6 PROPHYLAXIS OF INFECTIONS IN HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS AND HEMATOLOGIC CANCER PATIENTS

Prophylaxis	Indication	Agent	Duration/Comments
BACTERIA			
Antibacterial prophylaxis	Patients who are expected to be neutropenic for >7 days	Levofloxacin 500 mg orally daily or TMP/SMX may be used for those allergic to or intolerant of fluoroquinolones	Start when ANC < 1.0 × 10 ⁹ /L and continue until resolution of neutropenia
FUNGAL AND MOLDS			
Antifungal prophylaxis	Induction therapy for AML and MDS	Posaconazole 200 mg orally tid is drug of choice if high risk for aspergillosis. Alternatives include itraconazole, voriconazole, lipid formulation of amphotericin B, or an echinocandin (may choose to use fluconazole prophylaxis if incidence of aspergillosis is low.)	Begin with initiation of chemotherapy and continue until resolution of neutropenia.
	Acute lymphoblastic leukemia	Fluconazole ^a or an echinocandin Azoles are inhibitors of cytochrome P-450 isoenzymes, and are	Continue prophylaxis for duration of neutropenia

		expected to interfere with metabolism of vinca alkaloids and other drugs; close monitoring is recommended	
	Autologous HSCT recipient during neutropenia	Fluconazole ^a or echinocandin	Continue prophylaxis for duration of neutropenia
	Allogeneic HSCT recipient during neutropenia	Fluconazole, ^a itraconazole, voriconazole, and micafungin have each been evaluated in this setting	Continue prophylaxis for duration of neutropenia
	Allogeneic HSCT with significant GVHD receiving intensive immunosuppressive therapy ^b	Posaconazole 200 mg orally tid is drug of choice. Alternatives include voriconazole, itraconazole, lipid formulation of amphotericin B, or an echinocandin	Continue prophylaxis for 16 wk and for at least the duration of intensive immuno-suppressive therapy, ^b whichever occurs later
<i>Pneumocystis jirovecii</i> Prophylaxis	Acute lymphocytic leukemia, allogeneic HSCT recipients, alemtuzumab recipients, fludarabine recipients, or patients receiving corticosteroids (≥ 20 mg of prednisone equivalent) for ≥ 1 mo in the presence of other immunosuppression or myelotoxic chemotherapy.	TMP/SMX 1 DS (TMP 160 mg + SMX 800 mg) orally daily or 3 days per week OR dapsone 100 mg orally daily OR inhaled pentamidine 300 mg every 4 wk OR atovaquone 1,500 mg/d.	In allo-HSCT, continue prophylaxis for 2 mo after stopping immunosuppression. In patients treated with alemtuzumab, continue prophylaxis for 2 mo after the last dose or until the CD4 count is >200 .
VIRUSES			
Prophylaxis for HSV	HSCT recipients (HSV-seropositive recipients) Induction chemotherapy for acute leukemia (HSV-seropositive) Patients treated with alemtuzumab, or in patients with recurrent HSV reactivation following chemotherapy	Acyclovir 400 mg orally bid or tid OR 800 mg orally bid OR 250 mg/m ² /12 h or valacyclovir 500 mg orally once or twice (higher doses have been used up to 1,000 mg tid) or famciclovir 250 mg orally tid	Continue prophylaxis for HSV until resolution of neutropenia and mucositis. In patients treated with alemtuzumab, continue prophylaxis for 2 mo after the last dose or until the CD4 count is >200
Prophylaxis for VZV	Allogeneic HSCT recipients with a history of chicken pox or shingles	Acyclovir 800 mg orally bid OR valacyclovir 500 mg orally daily	
Prophylaxis for CMV (preemptive)	Patients requiring CMV surveillance 1. Allogeneic HSCT	Induction for 1 wk followed by maintenance for 1 wk as follows:	CMV surveillance: 1. Allogeneic HSCT recipients: day 30 to at least

therapy)	<p>recipients who are CMV⁺ or whose donor is CMV⁺ (standard of care)</p> <p>2. Autologous SCT recipients receiving a CD34-enriched autograft</p> <p>3. Patients treated with alemtuzumab</p>	<p>Ganciclovir 5 mg/kg IV q12h for 7 days (induction), followed by Ganciclovir 5 mg/kg IV daily 5 times a week (maintenance) OR Foscarnet^a 60 mg/kg IV q12h times 7 days (induction) followed by Foscarnet^c 60 mg/kg IV daily (maintenance) Oral valganciclovir (900 mg bid) is an acceptable alternative to IV formulations in patients who do not have severe gut GVHD (see text)</p>	<p>6 mo after allogeneic HSCT, during periods of GVHD, and until the CD4⁺ count is >100 μL.</p> <p>2. Recipients of CD34-enriched autologous grafts: day 30 to day 100 and until the CD4⁺ count is >100 μl.</p> <p>3. Alemtuzumab recipients: time of initiation until at least 2 mo after completion of therapy and until the CD4 count is >100 μl.</p> <p>The level of CMV reactivation that triggers preemptive therapy varies with the method. The CDC recommends any positive CMV antigenemia (pp65) or two consecutive qualitative PCR results within the first 100 days, and five cells per slide after the first 100 days</p> <p>Treatment is given for the first 100 days, then weekly or biweekly monitoring and preemptive management is initiated</p>
Prophylaxis against CMV		<p>Ganciclovir or foscarnet at the same dose as in preemptive regimen</p>	

ANC, absolute neutrophil count; AML, acute myelogenous leukemia; bid, twice daily; CDC, Centers for Disease Control and Prevention; CMV, cytomegalovirus; DS, double strength; GVHD, graft-versus-host disease; HSCT, hematopoietic stem cell transplant; HSV, herpes simplex virus; IV, intravenous; MDS, myelodysplastic syndrome; tid, 3 times a day; PCR, polymerase chain reaction; SCT, stem cell transplant; TMP/SMX, trimethoprim/sulfamethoxazole; VZV, varicella zoster virus.

^a Fluconazole is effective as prophylaxis against candidal, but not mold, infections. If prophylactic fluconazole is used in patients with prolonged neutropenia, a strategy of empirical modification to a mold-active drug in patients with persistent neutropenic fever should be considered. Doses apply to adults with normal renal function.

^b Criteria include acute grade II to IV GVHD, or extensive chronic GVHD, or treatment with intensive immunosuppressive therapy consisting of either high-dose corticosteroids (1 mg/kg of body weight per day for patients with acute GVHD or 0.8 mg/kg every other day for patients with chronic GVHD), antithymocyte globulin, or a combination of two or more immunosuppressive agents.

^c Doses apply to adults with normal renal function.

Adapted from the NCCN Clinical Practice Guidelines in Oncology. Prevention and Treatment of Cancer-Related Infection. NCCN. Version 1.2012, the clinical practice guideline for the use of

antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America (IDSA), and the comprehensive guideline cosponsored by the Center for International Blood and Marrow Research, the National Marrow Donor program, the European Blood and Marrow Transplant Group, the American Society for Blood and Marrow Transplantation, the Canadian Blood and Marrow Transplant Group, the Infectious Diseases Society of America (IDSA), the Society for Healthcare Epidemiology of America, the Association of Medical Microbiology and Infectious Disease Canada, and the CDC makes evidence-based recommendations for HSCT that may be applicable to other cancer patients. Tomblyn M, Chiller T, Einsele H, et al. *J Am Soc Blood Marrow Transplant* 2009;15:1143-1238.

Antifungal Prophylaxis

Antifungal prophylaxis should be based on risk stratification and should target specific pathogens in different patient groups. Patients with hematologic malignancies or HSCT recipients have several risk factors for fungal infections: defects in cellular immunity, prolonged profound neutropenia, immunosuppressive therapy, use of broad-spectrum antibiotics, use of parenteral nutrition, and use of indwelling vascular devices. The Transplant Associated Infections Surveillance Network (TRANSNET) prospectively analyzed HSCT recipients with proven or probable invasive fungal disease. Aspergillosis (43%), candidiasis (28%), and zygomycosis (8%) were the most common.²⁴⁴ Preventive efforts should be directed toward the reduction of *Candida* and *Aspergillus* species, as they have traditionally been the most common causes of fungal disease in immunocompromised patients.^{196,244} Patients should be counseled to avoid dust or soil exposure when traveling to areas that are endemic for organisms such as *Blastomyces dermatitidis*, *Coccidioides immitis*, and *Histoplasma capsulatum* when possible. Most other pathogens such as *Aspergillus* species, *C. neoformans*, and the Mucorales order (Zygomycetes class) are ubiquitous in the environment. Hospital outbreaks of *Aspergillus* are more likely to occur during periods of construction or renovation.^{245,246} HEPA filtration, regular maintenance of ventilation systems, and floor-to-ceiling barriers around construction sites are important measures in reducing the risk of invasive aspergillosis.²⁴⁷

Prior to the development of the triazole class of drugs, few effective antifungal agents other than amphotericin B were available. Nystatin and clotrimazole may prevent oropharyngeal candidiasis but are not well tolerated in patients with severe mucositis. Oral polyenes (nystatin and oral amphotericin B) are not orally bioavailable and have failed to demonstrate a reduction of systemic fungal infections.^{248,249} Inhaled amphotericin B has shown promise in preventing colonization and infection with *Aspergillus* but tolerability remains a concern and direct comparison to systemic mold-active azoles has not been studied.^{250, 251} and ²⁵²

Multiple randomized trials in patients with leukemia and patients undergoing allogeneic HSCT have demonstrated that fluconazole prophylaxis at a dosage of 400 mg/day reduces the incidence of superficial and invasive candidal infections, excluding *C. krusei*.^{211,253,254} Fluconazole prophylaxis has also been found to confer improved survival in HSCT recipients,^{189,255} but may increase the risk of colonization by azole-resistant *Candida* strains.¹⁸⁹ Itraconazole prophylaxis for candidiasis has been shown to provide similar efficacy and may additionally reduce the risk of aspergillosis. However, itraconazole has also demonstrated higher toxicity (drug-drug interactions due to cytochrome P450 3A4 inhibition) and gastrointestinal intolerance. It is also contraindicated in patients with a decreased cardiac ejection fraction or a history of congestive heart failure.²⁵⁶ Micafungin appears to be as effective as fluconazole in prevention of candidiasis in HSCT recipients²⁵⁷ and may also reduce the risk of *Aspergillus*.

Prevention of aspergillosis requires prophylaxis with broader spectrum antifungals. Comparison of standard prophylaxis (fluconazole or itraconazole) versus posaconazole in AML/MDS patients receiving myelosuppressive induction therapy revealed that posaconazole prophylaxis led to fewer invasive fungal infections, including aspergillosis, and to improved survival.¹⁴² A similar comparison in HSCT recipients with severe GVHD demonstrated that prophylactic posaconazole also led to fewer cases of invasive aspergillosis but failed to impact overall survival.¹⁴² Comparison of voriconazole versus fluconazole prophylaxis in allogeneic HSCT recipients showed a trend toward reduction of aspergillosis infections in voriconazole recipients, but no difference in overall or fungal infection-free survival.³

Fluconazole is a well-studied agent and remains the standard drug of choice to prevent invasive candidiasis, but it has no activity against molds.²⁵⁸ Mold-active agents should be considered when there is significant risk of aspergillosis. Posaconazole is an oral agent with antimold activity and requires administration with food or enteral preparations to enhance bioavailability. The mold-active azoles (i.e., itraconazole, voriconazole, posaconazole) are potent inhibitors of cytochrome P450 3A4 isoenzymes and may lead to reduced clearance of other drugs, such as calcineurin inhibitors and vinca alkaloids. Close monitoring of drug-drug interactions and appropriate dose modifications are required.¹⁰⁹

P.1448

Histamine blockers and proton pump inhibitors, such as omeprazole, should be avoided, and serum levels must be monitored during therapy.²⁵⁹

Antiviral Prophylaxis

Opportunistic viral disease may occur by primary infection or by reactivation of latent infection. Herpesviruses, including CMV, VZV, and HSV-1 and -2, are by far the most common infection-causing viruses. Antiviral prophylaxis (acyclovir, valacyclovir, or famciclovir) against HSV is advised during the period of neutropenia in seropositive patients receiving chemotherapy for acute leukemia, and during neutropenia and at least 30 days after HSCT for both allogeneic and autologous transplant recipients.^{3,239} Prolonged prophylaxis should be considered in allogeneic HSCT recipients with GVHD or with frequent HSV reactivation before transplantation.²¹⁰ Acyclovir is an effective prophylaxis against reactivated HSV infections (gingivostomatitis, esophagitis) in patients who are receiving intensive chemotherapy for acute leukemia or BMT.^{260, 261} and ²⁶² Acyclovir or valacyclovir are each commonly used as prophylaxis, treatment, and suppressive therapy against HSV and VZV in immunocompromised patients.^{263,264} Although acyclovir has proven to be highly effective as prophylaxis, there are reports of acyclovir-resistant HSV developing while on therapy.^{265,266} Treatment with foscarnet or cidofovir is recommended in the setting of acyclovir-resistant HSV. Foscarnet-resistant HSV strains have been reported in allogeneic stem cell transplant patients and such patients have been treated with cidofovir.²⁶⁷ Newer nucleoside analogs (such as BV-ara U, Brovavir) are being studied. Acyclovir-related prodrugs (valacyclovir, famciclovir) appear as effective as acyclovir for HSV and VZV prophylaxis.^{160,172,268} Avoidance of close contact with infected or exposed individuals is advisable for immunocompromised seronegative patients. Prophylaxis should also be considered in patients receiving T cell-depleting agents (e.g., fludarabine, calcineurin inhibitors, and proteasome inhibitors).

Prevention of Viral Hepatitis

Reactivation of latent hepatitis B virus occurs in various settings (e.g., HSCT, cytotoxic chemotherapy, anti-CD20 monoclonal antibodies treatments). The immunosuppressive effect of the chemotherapy allows virus reactivation in the liver, and the subsequent immune reconstitution may result in hepatocellular damage.²⁶⁹ Patients with lymphoma, or who use steroids or receive anthracycline chemotherapy, seem to be at higher risk.²⁷⁰ Fulminant hepatitis and death may occur following HBV reactivation in immunocompromised patients. Evaluation of HBV surface antigen, core antibody, and surface antibody should be considered for those in whom intensive immunosuppressive therapy is planned.²⁷¹ Lamivudine prophylaxis has been shown to be relatively effective in the prevention of hepatitis B reactivation, though randomized trials are still needed.^{204,270,272}

Baseline quantitative PCR for HBV DNA should be obtained in HBsAg-positive individuals. Antiviral therapy should be strongly considered in patients with active HBV infection undergoing HSCT or other intensive immunosuppression therapies, but an optimal antiviral treatment regimen remains unclear.

Augmentation of Host Defense

Optimization of patients' immune status via prophylactic immunization is another consideration to assist in the reduction of infection risk. Table 69.7 summarizes the recommended vaccine schedule of patients with hematologic malignancies and HSCT recipients as per the Advisory Committee on Immunization Practices (ACIP), ASBMT, and EBMT.^{182,212,239,273,274}

Active Immunization

Patients with hematologic neoplasms are at increased risk for infection with polysaccharide-encapsulated bacteria, viruses, and fungi due to impaired T cell, granulocyte, and reticuloendothelial cell function, as well as to defective antibody responses. Immunization as a means of preventing infectious morbidity has been best studied in children with ALL or solid tumors, patients with HL with or without splenectomy, and marrow transplant recipients. Although the optimal timing of immunizations in these patients and specific recommendations for each type of cancer are still unclear, general guidelines have been established.

If indicated, the administration of inactivated vaccines should be completed more than 10 days before initiation of chemotherapy or 3 months after completion of chemotherapy in adults with hematologic malignancies, including acute leukemia and myeloproliferative diseases.²³⁹ CDC recommendations require all infants to be vaccinated for *Haemophilus influenzae* type B (Hib) and thus almost all adults in theory should possess adequate immunity against this organism. However, splenectomized Hodgkin's disease patients who were receiving antineoplastic therapy were found to have a significantly greater decrease in Hib titer at a 6- to 12-month period after the primary vaccination (given before starting chemotherapy) as compared to normal controls.²⁷⁵ Most children who receive maintenance chemotherapy for leukemia

or lymphoma are able to generate protective antibody responses to a single dose of conjugate polysaccharide Hib vaccine, although responses are less than those that are seen in healthy children.²⁷⁶ Recommendations for children are therefore to continue the primary series of Hib-conjugate vaccinations during chemotherapy treatment and to administer a booster immunization 1 year after completion of chemotherapy.²⁷⁷ For adults with hematologic malignancies, it is recommended that a dose of Hib vaccine be given before initiation of chemotherapy or before splenectomy, if one is planned.²⁷⁸ The need for a booster a year after chemotherapy in adults has yet to be determined, and further studies are warranted.^{275,278,279}

Pneumococcal vaccines are available as either a conjugate vaccine (PCV-7, PCV-13) or a polysaccharide vaccine (pneumococcal polysaccharide vaccine 23-valent, PPSV23). Conjugated vaccines elicit improved immune responses in HSCT recipients compared with pure polysaccharide vaccines, and are therefore preferred.^{274,280, 281, 282} and ²⁸³ Conjugated vaccines induce a robust T cell-dependent immune response and generate long-term memory loss. It is recommended that HSCT recipients receive 3 sequential doses of PCV-13 starting 3 to 6 months after transplant. A fourth vaccination with PPSV-23 is given 8 weeks after the third dose of PCV-13 to broaden the immune response to include serotypes not included in PCV-13. Given that patients with active chronic GVHD are likely to have a poor response to PPSV-23, a fourth dose of PCV-13 should be considered in these patients.¹⁸² One-time revaccination with PPSV-23 at 5 years after the first dose is currently recommended for immunocompromised patients.²⁷⁸ The ACIP recommends that adults 19 years of age or older with immunocompromising conditions who have not previously received PCV13 or PPSV23 should receive a dose of PCV13 first, followed by a dose of PPSV23 at least 8 weeks later. Complete protection might not be achieved if the vaccine is given within 3 years after antineoplastic therapy.^{284,285}

Immunization for *N. meningitidis* by using a polysaccharide vaccine is recommended in cancer patients requiring splenectomy.²⁸⁶ However, this vaccine offers no protection from serogroup B (which is responsible for one-third of cases). Ongoing studies are being conducted to test new meningococcal serogroup B vaccine.²⁸⁷

Children undergoing chemotherapy and who have not completed all of the diphtheria-tetanus (DT) (or diphtheria, pertussis, and tetanus; pertussis is included if the child is <7 years of age)

P.1449

and polio immunization series should complete the boosters as scheduled, although aggressive and prolonged chemotherapy may blunt the response. Only the inactivated polio vaccine (IPV) should be given to immunocompromised patients because of the risk of acquiring polio from the live attenuated oral polio vaccine. Booster doses of DT or diphtheria, acellular pertussis, and tetanus and the IPV should be administered 1 year after chemotherapy completion. It is recommended that adult cancer patients receive DaPT immunization boosters in the same dose and schedule as for healthy individuals, as responses can be elicited in immunocompromised patients.²³⁹

TABLE 69.7 RECOMMENDATIONS FOR ACTIVE IMMUNIZATION OF ADULTS WITH MALIGNANCIES

Vaccine	Persons Who Should Receive Vaccine	Timing in Relation to Chemotherapy	Regimen^a
<i>Haemophilus influenzae</i> type b	Lymphoma patients	Before staging splenectomy, >10 d before initiation of chemotherapy, or 3 mo after completion of chemotherapy	Single-dose
Hepatitis B ^b	Cancer patients with hepatitis B surface antigen (+) household contacts	Not during immunosuppressive therapy	3 doses: second dose 1-2 after the first, third dose 4-6 mo after the first
Influenza	All cancer patients	>2 wk before initiation or between cycles of intermittent chemotherapy	Annually each fall/winter
Measles, mumps, rubella	Nonimmune leukemic patients in remission and household contacts of all immuno-	For leukemic patients in remission, >3 mo after completion of therapy;	Once

	suppressed individuals	otherwise contraindicated in patients with leukemia, lymphoma, or those undergoing immunosuppressive therapy	
Meningococcal (<i>Neisseria meningitidis</i>)	Lymphoma patients	Before staging splenectomy	2 doses; second dose 3-5 y after the first
Poliomyelitis (inactivated poliovirus vaccine only) ^c	Adults at increased risk of infection; all susceptible household contacts of cancer patients	No data available; recommend each dose >10 d before initiating chemotherapy	3 doses; second dose 4-8 wk after the first, third dose 6-12 mo after the second
23-Valent polysaccharide pneumococcal (<i>Streptococcus pneumoniae</i>)	Any nonimmune cancer patient, especially lymphoma and multiple myeloma patients	Before staging splenectomy, >10 d before initiation of chemotherapy, or 3 mo after completion of chemotherapy	2 doses; second dose at least 5 y after the first
PCV13 (Pneumococcal Conjugate) Vaccine	19 yr of age or older with immunocompromising conditions who have not previously received PCV13 or PPSV23; 19 y of age or older with immunocompromising conditions, who have previously received one or more doses of PPSV23	Give a dose of PCV13 first followed by a dose of PPSV23 at least 8 wk later. Subsequent doses of PPSV23 should follow current PPSV23 recommendation. Give a dose of PCV13 one or more years after the last PPSV23 dose was received	
Tetanus and diphtheria toxoids combined	All cancer patients	No data available; recommend administration >10 d before initiating chemotherapy	Primary 3-dose series if not previously immunized; second dose 4-8 wk after the first, third dose 6-12 mo after the second; booster doses at 10-y intervals throughout life or with dirty wound if >5 y since last dose
Varicella	Nonimmune household contacts of cancer patients	Not applicable—contraindicated in patients with leukemia, lymphoma, or those undergoing immunosuppressive therapy	For persons >13 y of age, 2 doses separated by 4-8 wk

^a Adapted from the Centers for Disease Control and Prevention.

^b May be used in conjunction with hepatitis B immunoglobulin prophylaxis. ^c Live oral polio vaccine is no longer available for general use in the United States and is contraindicated in immunosuppressed

persons or their household contacts.

The inactivated influenza vaccine is generally recommended in immunocompromised patients on a yearly basis.²⁷⁸ Several studies have evaluated the efficacy of this vaccine in cancer patients; there is definite efficacy in patients with solid tumors, but the response may be blunted in patients with hematologic malignancies.²⁸⁸ Despite a lack of a clear-cut benefit in immunocompromised patients, the likelihood of at least partial protection has urged physicians to vaccinate all cancer patients with the inactivated influenza vaccine.

The live attenuated measles, mumps, and rubella (MMR) vaccine may be considered in previously unimmunized children with leukemia who are in remission, or who have been off or not received chemotherapy for at least 3 months; but it is otherwise contraindicated in immunocompromised individuals.^{239,277} The live attenuated varicella vaccine is not recommended for use in immunocompromised patients, except in seronegative children with HIV.^{239,289,290}

Protective antibodies to common childhood diseases (polio, tetanus, diphtheria, mumps, measles) wane after ablative therapy and autologous or allogeneic transplantation and thus necessitate revaccination.^{291, 292} and ²⁹³ All HSCT patients should be vaccinated with combined tetanus-diphtheria toxoids at 12, 14, and 24 months after transplant.^{243,292,294, 295} and ²⁹⁶ Antibody levels against *H. influenzae* gradually decline after transplant, and revaccination using the Hib-conjugate vaccine is recommended at 12, 14, and 24 months after transplant to restore immunity.²⁴³ The oral polio vaccine is contraindicated in all immunocompromised individuals.²⁷⁸ IPV and hepatitis B vaccines are recommended at 12, 14, and 24 months after transplant, owing to the loss of immunity against

P.1450

the virus by 1 year after transplant in the majority of transplant recipients.^{297,298} Vaccination against Meningococci, rabies, and hepatitis A is not routinely recommended in this patient population.¹⁸² Annual seasonal administration of inactivated influenza vaccine is recommended following 6 months posttransplant.¹⁸² The MMR vaccine, a live attenuated vaccine, may be given to BMT patients about 2 years after transplant and may be administered to household contacts before then. Patients with GVHD who are continuing to receive immunosuppressive therapy should not be given the MMR vaccine.²⁹¹ The varicella vaccine is a live attenuated vaccine and is contraindicated in transplant recipients. Use of the Bacille Calmette-Guérin vaccine is contraindicated during the first 2 years posttransplant.^{299,300}

Passive Immunization

Intravenous immunoglobulins (IVIG) therapy for prevention of infection has been evaluated primarily in patients with lymphoproliferative disorders and multiple myeloma and SCT recipients. Currently available IVIG preparations are safe, well tolerated, and consist primarily of IgG, although small amounts of IgA and IgM are present.³⁰¹ IgA-poor preparations must be used to prevent anaphylaxis in patients with known or suspected congenital IgA deficiency and/or those with high anti-IgA titers. IVIG (400 mg/kg given every 3 weeks) has been shown to reduce frequency of moderately severe bacterial infections in patients with CLL who have hypogammaglobulinemia or a history of recurrent infections.^{302, 303} and ³⁰⁴ However, this practice has not been proven to be cost-effective, to prolong survival, or to demonstrably improve the quality of life of patients with CLL.¹⁹⁴ Reduction in the number of symptomatic and life-threatening infections has also been reported in patients with multiple myeloma receiving monthly infusions of IVIG.^{201,305} A meta-analysis of multiple trials involving prophylactic IVIG in patients with CLL and MM illustrated a significant decrease in occurrence of major infections and reduction in clinically documented infections, but no survival benefit.³⁰⁶ Thus, prophylactic use of IVIG for patients with CLL or MM with hypogammaglobulinemia and/or recurrent infections should be considered on an individual basis.

In allogeneic HSCT patients, prophylactic use of IVIG has been shown to prevent grades II-IV acute GVHD,^{307,308} decrease gram-negative septicemia, and decrease local infections; but it does not improve mortality.^{309,310} Decisions to use IVIG in allogeneic transplant patients should be made on an individual basis because of the cost of IVIG and the availability of suitable antimicrobial alternatives. Autologous transplant recipients do not appear to benefit from prophylactic globulin therapy, and its use may actually lead to increased incidence of fatal hepatic venoocclusive disease in these patients.³¹¹

TABLE 69.8 DEFINITION OF CATHETER-ASSOCIATED INFECTIONS

Localized catheter colonization	•Significant growth of a microorganism (greater than 15 CFU) from the catheter tip, subcutaneous segment of the catheter, or catheter hub.
Exit site infection	•Erythema, or induration within 2 cm of the catheter exit site, in the absence of concomitant bloodstream infection (BSI) and without concomitant purulence.

Tunnel infection	•Tenderness, erythema, or site induration of more than 2 cm from the catheter exit site along the subcutaneous tract of a tunneled catheter (i.e., Hickman or Broviac) in the absence of concomitant BSI.
Pocket infection	•Purulent fluid in the pocket of a totally implanted intravascular catheter that may or may not be associated with spontaneous rupture and drainage or necrosis of the overlying skin in the absence of concomitant BSI.
Catheter-related bloodstream infection (CRBSI)	<ul style="list-style-type: none"> •Bacteremia or fungemia in a patient with an intravascular catheter with at least one positive blood culture obtained from a peripheral vein, clinical manifestations of infections (e.g., fever, chills, or hypotension) and no apparent source for the BSI except the catheter. •One of the following should be present: a positive semiquantitative (greater than 15 CFU/catheter segment) or quantitative (greater than 10² CFU/catheter segment) culture whereby the same organism (species and antibiogram) is isolated from the catheter segment and peripheral blood; simultaneous quantitative blood cultures with a 3:1 ratio for CVC versus peripheral; or differential period of CVC culture versus peripheral blood culture positivity of more than 2 hours.

IVIg and CMV hyperimmune globulin can confer passive immunity against CMV infection, but other methods of CMV prophylaxis, such as leukofiltration of blood products, may be more cost-effective.³¹²

Passive immunization with varicella zoster immune globulin is indicated in seronegative immunosuppressed patients who are exposed to an active case and should be given within 72 to 96 hours of the exposure.³¹³ Patients who are exposed to measles, mumps, or rubella may benefit from passive Ig prophylaxis if it is given within 6 days of exposure.^{314,315}

Intramuscular Ig is recommended for patients who travel to areas that are endemic for hepatitis A or for postexposure prophylaxis.³¹⁶ Two doses of hepatitis B Ig, given 1 month apart, are recommended for postexposure prophylaxis.

MANAGEMENT OF CATHETER-RELATED INFECTIONS

Catheter-related bloodstream infections (CRBSI) are associated with prolonged hospitalizations, increased healthcare costs, and increased morbidity and mortality.^{317,318} The incidence of device-associated infection varies depending on the type of device inserted, its length of use, and the extent of the patient's immunosuppression. Neutropenic patients, particularly those with a hematologic malignancy, have a greater risk for developing CRBSI and bacteremia.^{317,319,320}

Overall, the incidence of port-associated infections is low at 0.1 per 1,000 port-days, and that of tunneled catheters is approximately 1 to 3 per 1,000 days of patient use. Cumulative incidence of PICC-related blood stream infections is 1.1 per 1,000 PICC-days (range 0.9 to 1.3), but higher in the inpatient setting (2.1 per 1,000 PICC-days).³¹⁸ Number of lumens is an independent risk factor for CRBSI and multiple-lumen catheters have higher infection rates.^{142,321} Standardized infection control procedures as recommended by the CDC are increasingly being used to help reduce catheter-related bloodstream infections.³²²

Several types of catheter-related infections have been defined: exit site infection, tunnel infection (or pocket infection in the case of ports), septic phlebitis, and CRBSI (Table 69.8).⁵⁵ The majority of these infections are caused by gram-positive pathogens, with coagulase-negative staphylococci recovered most frequently.

P.1451

Catheter-related infections with *S. aureus*, gram-negative bacteria, corynebacteria, bacillus species, and mycobacterial and fungal organisms have also been reported.

Simultaneous cultures from peripheral sites and all catheter ports are helpful in distinguishing infection of the catheter itself from infection arising from another source. Successful treatment of CRBSIs caused by coagulase-negative staphylococcal or even gram-negative organisms does not always require catheter removal. Infections of the skin pocket of an implanted port also resolve in ~70% of patients without removal of the device.⁵⁵ Appropriate intravenous antibiotics should be administered for 1 to 3 weeks and should be rotated through all lumens. If clinical improvement is observed and surveillance cultures from each lumen remain negative after 3 days of antibiotic therapy, the catheter sterilization is likely.⁵⁵ Uncomplicated exit site infections will also usually resolve with aggressive local care and systemic antibiotic therapy. However, some bacterial infections (e.g., *S. aureus*, some *Bacillus* species, *Corynebacterium* group, and

Stenotrophomonas species) will require catheter removal in order to increase the likelihood of successful treatment. Other indications for immediate removal of the catheter include evidence of complicating endocarditis, osteomyelitis, septic thrombosis, septic pulmonary embolism, or sepsis with signs of shock/end-organ dysfunction. Certain organisms, such as Candida and fungi, are extremely difficult to eradicate and necessitate prompt catheter removal to avoid the complications of disseminated infection. Fungemia caused by *Malassezia furfur* (*Pityrosporum orbiculare*) tends to occur in patients who receive parenteral lipids and may be resistant to amphotericin B. This infection often manifests as fever, pulmonary infiltrates, and thrombocytopenia; discontinuation of the lipid, as well as removal of the catheter, is needed.³²³

Occlusion and Venous Thrombosis of Catheters

Although a clot is the most common cause of occlusion, inability to aspirate blood from the port or catheter does not always suggest clot formation. Other causes of impaired catheter flow include a malpositioned Huber needle, catheter compression on the wall of the vein, catheter kinking, catheter pinch-off, precipitation of drug solutions in the catheter lumen, development of fibrin sheaths, and catheter migration resulting in a malpositioned tip.³²⁴ Fibrin blockage is common, and simple repositioning of the patient and/or Valsalva maneuvers may allow blood to be withdrawn. If these strategies fail, the catheter position should be confirmed by chest radiograph after injection of contrast dye through the catheter. Patients in whom there is no contraindication to thrombolytic therapy may be given an infusion of urokinase at 200 U/kg/hour for as long as 12 hours to reopen the catheter. Otherwise, 5,000 U of urokinase (in 2 ml of sterile water) may be injected into the catheter, and a blood draw may be attempted again in 30 minutes. This procedure may be repeated twice in 24 hours if necessary. Recombinant tissue plasminogen activator (alteplase) at a dose of 2 mg/2 ml instilled for 30 minutes may also restore function in occluded venous catheters.^{325,326}

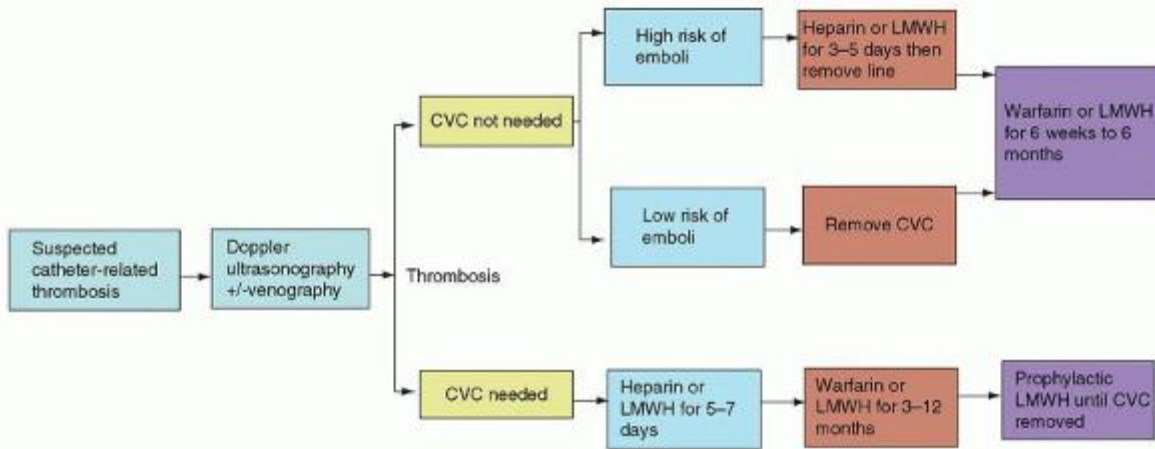

FIGURE 69.8. Algorithm for diagnosis and management of catheter-related thrombosis. (CVC, central venous catheter; LMWH, low-molecular-weight heparin.) Ultrasonography (U/S) can be used as the initial screening test for thrombosis, whereas venography may be required if U/S is negative or inconclusive. The duration of anticoagulation depends upon clinical factors, including the need for the CVC, the size of the clot, and the presence of a prothrombotic state. In patients with cancer, LMWH is preferred over warfarin, and duration of anticoagulation should be 6 months or longer. (Adapted from Baskin JL, Pi C-H, Reiss U, et al. Management of occlusion and thrombosis associated with long-term indwelling central venous catheters. *Lancet* 2009;374:159-169.)

Contrary to early reports, data from two randomized studies failed to demonstrate a benefit of low-dose warfarin³²⁷ or LMWH³²⁸ to reduce the incidence of symptomatic catheter-associated thrombotic events in patients with cancer. Prophylactic use of urokinase (5,000 IU/ml) every 1 to 2 weeks into long-term CVADs has shown reduced incidence of thrombosis and also of catheter-related infections.³²⁹

Thrombosis can occur in the catheter itself or in the superior vena cava or veins of the upper extremity. While asymptomatic thromboses have been reported in rates up to 60%, recent studies show a variable incidence of symptomatic catheter-related thrombosis of 4% to 5% up to 28% of adults and 12% of children with a CVC.^{325,330,331} Almost all central indwelling venous access devices become coated with a fibrin sheath within days of insertion and the majority of CVC-related thrombi arise within 30 days of initial placement.³³² Pain, ipsilateral extremity edema, and superficial venous dilation require evaluation with venography or noninvasive contrast imaging techniques. The catheter should be removed if it is no longer needed or if treatment with systemic anticoagulation fails. If the catheter remains functional and needed for clinical use, then the recommendation from the 2012 American College of Chest Physicians is to keep the catheter in place and to continue systemic anticoagulation with warfarin or low molecular weight heparin (LMWH) as long

as the catheter remains indwelling. If the catheter is removed, it is recommended to continue systemic anticoagulation for a total of 3 months regardless of diagnosis.³³³ Another recommendation has a variable length of anticoagulation, from 6 weeks to 6 months depending upon the size of the clot and whether the patient is considered prothrombotic³³¹ (Fig. 69.8).

P.1452

CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

Chemotherapy-induced nausea and vomiting (CINV) is a common adverse effect of cancer therapies. Nausea and vomiting can be very distressing to both patients and their caregivers. Nausea can have a negative impact on quality of life, both physical and cognitive functions, and may lead to critical delays in the administration of potentially curative therapy.^{334,335} Nausea and emesis can be induced by a number of factors besides chemotherapy, and thus it is important to investigate the underlying etiology. Radiation therapy, especially in those undergoing total body irradiation (TBI) prior to HSCT, infections, metabolic derangements, electrolyte abnormalities, metastases (especially brain and liver), medications (antibiotics, antifungals, opiates), and other psychological factors can all lead to nausea and vomiting in patients with cancer.³³⁶ Based upon the emetogenic potential of the chemotherapy administered and specific patient characteristics, personalized therapeutic decisions can be made to try to prevent CINV.³³⁷ A breakdown of the relative emetogenicity of commonly used chemotherapeutic agents can be found in Chapter 68, Table 68.2. Patient characteristics associated with increased risk for CINV include: age < 50, female gender, history of motion sickness, history of low prior chronic alcohol intake, and emesis during pregnancy.³³⁵ Coadministration of chemotherapeutic agents and repeated cycles of chemotherapy can also increase the potential for CINV.³³⁸

CINV can be broken down into 5 distinct yet related syndromes: (1) acute CINV, (2) delayed CINV, (3) anticipatory CINV, (4) breakthrough CINV, and (5) refractory CINV.³³⁸ Acute CINV is typically defined as occurring within the first 24 hours of chemotherapy administration. Delayed CINV is typically defined as occurring 1 to 5 days after chemotherapy administration. Anticipatory CINV occurs prior to the chemotherapy administration, and has been associated with just one episode of nausea and vomiting with a prior regimen. Breakthrough CINV occurs despite the use of appropriate preventative strategies, and refractory CINV occurs due to failure of preventative and rescue therapies.³³⁸

To understand the rationale behind different strategies for the prevention and treatment of CINV, it is helpful to understand the physiology of the emesis response. The current model of the emesis response (Fig. 69.9) is primarily mediated through neurotransmitters in the gastrointestinal (GI) system and the central nervous system (CNS).³³⁸ Afferent signals from the chemotherapy trigger zone (CTZ), cerebral cortex, and GI tract converge on the vomiting center (VC) within the medulla oblongata. Ultimately, the VC sends out efferent signals to the organs responsible for completing the motor events of emesis (esophagus, stomach, abdominal musculature).³³⁹ Serotonin and substance P are the main neurotransmitters implicated in CINV; however dopamine, histamine, endorphins, acetylcholine, and GABA have also been shown to be involved. Based upon the identification of active neurotransmitters and their receptors within the VC, control of CINV may depend ultimately upon blocking the neurotransmitter receptors in the VC from afferent inputs of the GI tract and CNS.³³⁸

FIGURE 69.9. Model of the emesis response. (With permission from Navari RM. Pathogenesis-based treatment of chemotherapy-induced nausea and vomiting—two new agents. *J Support Oncol* 2003;1:89-103.)

Prevention is the key treatment of CINV. Development of effective preventative antiemetic regimens requires consideration of the emetic potential of the chemotherapy, dosing and duration of the chemotherapeutic regimen (1 day vs. multiday), single vs. multi-drug regimens, personal risk factors, and the mechanism of action of the prescribed antiemetic therapy. Maximum benefit from antiemetic therapy is achieved when it is initiated prior to chemotherapy and continued throughout the duration of the emetic response to each chemotherapeutic agent. Multiple organizations, including ASCO, NCCN, and MASCC, have developed guidelines for antiemetic prevention, and a summary of these recommendations is listed in Table 69.9.

Agents

5-HT₃ Receptor Antagonists

Perhaps the most significant advance in antiemetic therapy, as well as supportive therapy in general, has been the development of the 5-HT₃ receptor antagonists. Agents in this class (e.g., granisetron, ondansetron, palonosetron, and dolasetron mesylate) have all shown efficacy in controlling acute nausea associated with chemotherapy.^{340, 341 and 342} As well, both IV and PO routes of administration of these medications are effective when appropriate doses are given.³⁴³ While all 5-HT₃ receptor antagonists have been shown to be effective in controlling acute nausea and vomiting caused by chemotherapy, palonosetron has recently been shown to be much more effective than other available 5-HT₃ receptor antagonists in preventing delayed nausea and vomiting.^{344,345,346} A recent meta-analysis of randomized controlled trials comparing palonosetron with other 5-HT₃ receptor antagonists revealed that it was significantly more effective in preventing acute and delayed nausea and vomiting for highly emetogenic and moderately emetogenic chemotherapy.³⁴⁷ Palonosetron's half-life of 40 hours is much longer than that of the other 5-HT₃ receptor antagonists and it has an approximately 100-fold higher binding affinity to the 5-HT₃ receptor. These qualities likely explain palonosetron's superiority in preventing chemotherapy-induced nausea and vomiting, especially delayed onset nausea and vomiting.³⁴⁸ Palonosetron is currently FDA approved for use as a single infused dose on day 1 for the prevention of acute and delayed nausea and vomiting associated with highly and moderately emetogenic chemotherapy. While repeat dosing is considered safe based on NCCN guidelines, the additional benefit of repeated dosing for multiple-day chemotherapy regimens is unknown.

Adverse effects of 5-HT₃ receptor antagonists are usually mild and transient. Headache is the most common side effect, followed by gastrointestinal side effects of abdominal discomfort, diarrhea, and constipation, which occur less frequently.³⁴⁹ Association of IV dolasetron with increased risk for cardiac arrhythmias has been reported by the FDA, and thus IV dolasetron is not recommended.

Neurokinin 1 Receptor Antagonists

Substance P is a mammalian tachykinin found in vagal afferents that send impulses to the vomiting center and thus are involved in the vomiting response. Substance P induces emesis through its binding to neurokinin 1 (NK-1) receptors in the brainstem nucleus tractus solitarius, the area postrema, and the abdominal vagus nerves.^{338,350} Two randomized, double-blind, multicenter

P.1453

P.1454

controlled studies found the addition of aprepitant (125 mg po on day 1 and 80 mg po daily on days 2 and 3) to standard therapy (5-HT₃ receptor antagonist on day 1) and dexamethasone (prechemotherapy on day 1 and daily on days 2 to 4) improved rates of acute N/V and delayed N/V when compared to standard therapy alone in patients receiving cisplatin chemotherapy.^{351,352} Thus, in 2003, aprepitant became the first neurokinin-1 receptor antagonist to be approved for the prevention of acute and delayed nausea and vomiting with highly-emetogenic chemotherapy. Fosaprepitant, a parenteral NK-1 receptor antagonist, has since become available for the prevention of CINV associated with highly emetogenic chemotherapy. Unlike aprepitant, fosaprepitant is given at a dose of 150 mg IV 30 minutes prior to chemotherapy on day 1 only.³⁵³ Important to note is that NK-1 receptor antagonists are moderate inhibitors of the enzyme CYP3A4, the enzyme responsible for glucocorticoid metabolism, and thus in clinical trials the dosing of concurrent dexamethasone was reduced to 12 mg on day 1 and 8 mg on days 2 and 3.^{351,352}

TABLE 69.9 SUMMARY OF GUIDELINES FOR THE PREVENTION AND TREATMENT OF CINV

Group	High		Moderate		Low	Minimal
	Acute CINV ^a	Delayed CINV	Acute CINV	Delayed CINV	Acute/Delayed CINV	Acute/Delayed CINV
NCCN ¹	-5-HT ₃ RA ^c (palonosetron preferred) + dexamethasone + (fos)aprepitant ± lorazepam ± H ₂ d blocker or PPI ^e	± 5-HT ₃ RA (unless palonosetron given day 1) +Dexamethasone (8 mg po daily days 2-4 with aprepitant or fosaprepitant 150 mg IV day 1) (8 mg po day 2, then 8 mg po BID days 3 and 4 with fosaprepitant 150 mg IV	-5-HT ₃ RA (palonosetron preferred) +Dexamethasone ± Aprepitant or Fosaprepitant 150 mg IV day 1 ± lorazepam ± H ₂ blocker or PPI	-5-HT ₃ RA on days 2 and 3. (unless palonosetron given day 1) Or Dexamethasone Daily day 2-3 Or Aprepitant 80 mg po day 2-3 (if aprepitant given day 1)	(repeat daily for multiple-day regimens) - Dexamethasone 12 mg po/IV daily Or - Metoclopramide 10-40 mg PO/IV Or - Prochlorperazine	No routine prophylaxis before or after chemotherapy is recommended

		day 1)		±	10 mg PO/IV	
		+ Aprepitant 80mg po days 2 and 3 if aprepitant given on Day 1			dexamethasone ± lorazepam ± H2 blocker or PPI	
		± lorazepam day 2-4				
ASCO ²	-5-HT3 RA + Dexamethasone +(fos)aprepitant ±Lorazepam ±diphenhydramine	- Dexamethasone Day 2-3, or day 2-4 + Aprepitant day 2-3 if Fosaprepitant is NOT used day 1.	-5-HT3 RA (palonosetron preferred) + Dexamethasone ±aprepitant ±lorazepam ±diphenhydramine	- Dexamethasone day 2-3 ± aprepitant (if used on day 1)	- Dexamethasone 8 mg PO/IV prior to chemotherapy	No antiemetic should be administered routinely before or after chemotherapy
MASSC/ESMO ³	For HEC ^h and ACi regimens: -5-HT3 RA + Dexamethasone + (fos)aprepitant	- Dexamethasone day 2-4 + aprepitant day 2-3 if aprepitant given day 1	Non-AC regimens: -Palonosetron + Dexamethasone	- Dexamethasone day 2-3 RA or Dopamine antagonist prior to chemo	- Dexamethasone or 5-HT3 RA or Dopamine antagonist prior to chemo	-No routine prophylaxis is recommended

Olanzapine

Olanzapine is an atypical antipsychotic with an affinity to multiple neurotransmitter receptors involved in the emetic response, including: dopaminergic, serotonergic, adrenergic, histaminergic, and muscarinic receptors, thus suggesting a potential benefit for the prevention and treatment of nausea and vomiting.^{354,355} In a pilot study, Passik et al. explored the antiemetic activity of olanzapine in patients with advanced cancer, with their results suggesting benefit. Subsequent trials, including a randomized phase III trial, confirmed these results.^{356, 357} and³⁵⁸ Navari et al. conducted a randomized phase III trial comparing the efficacy of olanzapine vs. aprepitant, both in combination with palonosetron and dexamethasone, for the prevention of CINV in patients receiving highly emetogenic chemotherapy. Complete response rates, no emesis, and no need for rescue medications were similar results for both groups during the acute and delayed period; however, nausea was better controlled in the olanzapine group.³⁵⁸ The total dose of dexamethasone was also less in the olanzapine group, as this group received only a one-time dose of dexamethasone on day 1 vs. 4 days of dosing in the aprepitant group. This finding led the authors to conclude that the use of olanzapine for the prevention of CINV with highly emetogenic chemotherapy may be more beneficial, since the exposure to steroids and potential adverse effects of their use with multiple rounds of chemotherapy would be much less.

An increase in extrapyramidal symptoms (EPS) associated with olanzapine use has not been seen in studies evaluating olanzapine's efficacy in the prevention of CINV, and this lack of increase in EPS as compared to other neuroleptic drugs used for the treatment of nausea (e.g., prochlorperazine and metoclopramide) is another reason to consider its use. These preliminary studies also found an improvement in mood and appetite in patients who were treated with olanzapine.³⁵⁴ At this time, expert guidelines recommend the use of aprepitant along with 5HT-3 receptor antagonists and steroids for the prevention of CINV associated with highly emetogenic chemotherapy; however, further studies evaluating olanzapine's benefit in this group of patients are ongoing and the results of these studies may alter recommendations in the future.

Chemotherapy-induced Nausea and Vomiting with High-dose Chemotherapy/Hematopoietic Stem Cell Transplant

Controlling nausea and vomiting in patients undergoing HDC with HSCT rescue is a challenge. Many factors, including HDC, total body irradiation (TBI), medications to prevent graft-versus-host disease, antimicrobials, and opioids, can induce nausea and vomiting.³⁵⁹ Multiple studies have shown a benefit of 5-HT₃ receptor antagonists along with steroids in the prevention of CINV in patients undergoing HDC; however, complete responses with these regimens were seen in only 15% to 50% of patients.^{360, 361, 362} and³⁶³ Given the suboptimal rate of control seen with 5HT-3 receptor antagonists and steroids, studies examining the addition of aprepitant, an NK-1 antagonist, to 5HT-3 receptor antagonists have been conducted.

The role of newer agents, such as aprepitant, in the prevention and treatment of CINV in patients undergoing HDC with stem cell rescue is less clear. There is data to support the efficacy and safety of aprepitant along with 5HT-3 receptor antagonists and steroids, albeit from small, single institution studies. Despite the small sample sizes, these studies have shown efficacy for a number of preparative regimens, including: BEAM (BCNU [carmustine] + etoposide + ARA-C [cytarabine] + melphalan), T-ICE (paclitaxel + ifosfamide + carboplatin + etoposide), BuCy (busulfan + cyclophosphamide), Cy/TBI (cyclophosphamide + total body irradiation), Cy/TBI/VP16, and BCV (BCNU + cyclophosphamide + VP16). The data so far has looked at multiple different dosing regimens for aprepitant, including the traditional 3-day regimen (125 mg po on day 1 followed by 80 mg po on days 2 and 3) and a 12-day regimen (125 mg po on day -7 followed by 80 mg po daily thereafter until day +4) conducted in a pilot study by Bubalo et al.³⁶⁴ As aprepitant is a moderate inhibitor of CYP3A4, busulfan doses need to be followed closely, and in pilot studies all patients required dose adjustments.^{365,366,367,368,369} These studies support the added benefit of aprepitant to standard antiemetic therapy without increasing toxicity. Because of the limited amount of data, ASCO guidelines currently recommend considering the use of aprepitant in patients undergoing HDC with HSCT until the results of larger phase III studies become available.

Miscellaneous

Multiday chemotherapy regimens and highly emetogenic radiation regimens are both commonly used in the management of hematologic malignancies. ASCO guidelines recommend the use of antiemetics appropriate for the emetogenic risk class of the chemotherapy being administered for each day of chemotherapy and for 2 days after, if appropriate.³⁷⁰ Both MASCC and ASCO guidelines recommend the use of a 5HT-3 receptor antagonist along with steroids for the treatment of highly emetogenic radiation therapy, such as TBI, with ASCO guidelines recommending a minimum of 5 days of steroid therapy.^{343,370}

CANCER-RELATED FATIGUE

Fatigue is one of the most common symptoms reported by cancer patients, and has a reported incidence of 60% to 90% among patients with cancer. Cancer-related fatigue (CRF) is defined as an unusual sense of tiredness that is persistent and not improved with rest, that can occur with cancer or cancer treatment, and that may affect physical and/or mental functioning.³⁷¹ Fatigue can negatively impact a patient's quality of life by interfering with their ability to perform activities of daily living, keep employment, and maintain financial stability.³⁷² CRF is more intense and more unpredictable than fatigue that was experienced before the cancer diagnosis.³⁷³

Multiple etiologies for CRF are often present in patients with cancer and include anemia, sleep disorders, depression, endocrinopathies, nutritional deficiencies, and uncontrolled pain. Anemia is likely the most common reversible cause of fatigue during active cancer treatment. Although CRF is often attributed to the initiation of cancer therapies, this fatigue may persist long after the completion of treatment with up to 30% of cancer survivors reporting loss of energy years after completion of treatment.^{372,374} Escalante and Manzullo recommend using the question "How

P.1455

would you rate your fatigue on a scale of 0 to 10 over the past week?" along with a simple visual analog scale from 0 to 10 (with 0 as no fatigue and 10 as the worst imaginable fatigue) to screen patients and to follow response to interventions. Specific causes for fatigue should be sought out, and once specific therapies for fatigue are initiated, then assessments for response should take place as the identified cause is being corrected.³⁷²

Multiple pharmacologic and nonpharmacologic interventions have been employed to treat CRF. Nonpharmacologic interventions include exercise programs, nutritional assessments, and sleep analysis. Exercise has been the most studied nonpharmacologic strategy for treating fatigue.³⁷² Schwartz et al. evaluated the effect of a moderate-intensity home exercise regimen in women with newly diagnosed breast cancer receiving active treatment with chemotherapy. Low- to moderate-intensity exercise significantly decreased fatigue in these patients, and the intensity of fatigue declined as exercise tolerance increased.³⁷³ Initiation of an exercise program should begin at low intensity levels and shortened intervals with gradual increase in intensity and duration based on the patient's physical conditioning. Patients with severe debilitation and extensive disease may require consultation with a physical therapist or a physical medicine and rehabilitation specialist to assist in developing a safe and effective exercise program.³⁷²

Pharmacologic strategies that have been used to combat CRF include stimulants, antidepressants, and low-dose steroids. Well-designed clinical trials evaluating the efficacy of these pharmacologic interventions to guide treatment decisions are unfortunately lacking. Methylphenidate, a stimulant, has been studied in CRF and may have a beneficial effect. Sarhill et al. studied the efficacy of methylphenidate for the treatment of fatigue in patients with advanced cancer. In this open labeled pilot study, 9 of 11 patients studied achieved benefit regardless of whether anemia was present. Only 1 patient stopped treatment because of adverse effects.^{375,376} Therapy is typically initiated at 5 mg in the morning and 5 mg in the early afternoon. Methylphenidate should not be administered in the late afternoon as it may interfere with sleep patterns. Patients may require titration of dosing over time in order to maintain a clinical benefit because of the potential development of tolerance. Tachycardia and hypertension are known adverse effects of methylphenidate and it is therefore not recommended for use in patients with known coronary artery disease, uncontrolled hypertension, or tachyarrhythmias.³⁷²

Modafinil, a nonamphetamine psychostimulant, has been studied in a randomized phase III trial to evaluate its effectiveness in the treatment of cancer-related fatigue.³⁷⁷ Jean-Pierre et al. reported a benefit from modafinil 200 mg daily in patients with severe fatigue at baseline; however, there was no statistically significant improvement in fatigue in patients with mild to moderate fatigue at baseline. Thus, it is recommended that intervention with modafinil be limited to those with severe fatigue at baseline.³⁷⁷

The inability of current pharmacologic interventions to produce significant improvements in CRF for the majority of cancer patients underscores the importance of a multidisciplinary approach to CRF that incorporates assessments for fatigue, recognition of underlying etiologies, coping strategies, nonpharmacologic therapies, and intervention with pharmacologic therapy only when necessary.

CANCER PAIN

Pain is one of the most feared symptoms of cancer by patients and family members.³⁷⁸ Sixty to eighty percent of patients with advanced cancer experience moderate to severe pain on a monthly basis, and control of cancer-related pain is one of the most important goals of supportive care. Management of cancer pain can be quite complex because the etiologies are

diverse and can adversely affect multiple domains of quality of life, including activities of daily living, psychological well-being, physical functioning, and social interactions.³⁷⁹ Coexisting cancer symptoms, such as weakness, fatigue, nausea, dyspnea, constipation, and impaired cognition, can magnify the perception of and exacerbate cancer pain. Modifying the source of the pain, altering the perception of pain, and blocking the transmission of pain to the central nervous system can effectively treat cancer pain in 85% to 95% of cases.³⁸⁰ A comprehensive patient-centered approach to pain management that assesses the patient's pain, barriers to pain control, concurrent medical problems, response to pharmacologic interventions, and psychosocial status is key to achieving adequate pain control.^{381, 382, 383} and ³⁸⁴

Types of Cancer Pain

To adequately address and control pain, it is imperative that the treating physician understand the pathophysiology of cancer pain. The majority of cancer-related pain can be classified as nociceptive, neuropathic, or both. The distinction between these 2 types of pain is important, as neuropathic pain is often refractory to opioid therapy. Nociceptive is the term used to describe pain that is propagated by continual tissue injury, and it is classified into somatic or visceral pain. Nociceptive pain is termed somatic when the continual tissue injury is relayed via primary afferent nerves in somatic tissues such as those of the musculoskeletal system. Somatic pain is classically described as being sharp or aching and localized to the area of tissue damage. Nociceptive pain is termed visceral when tissue injury is relayed via primary afferents of the viscera. Visceral pain tends to be poorly localized and intermittent, many times described as dull or aching.^{378,385,386} Neuropathic pain is a result of injury to peripheral or central nerves and typically causes paroxysmal burning, shooting, or aching sensations that may or may not be associated with paresthesias. In patients with malignancy, neuropathic pain can be caused by a number of different etiologies, such as direct nerve injury from the tumor itself, or the result of anticancer treatments such as surgery, radiation, and chemotherapy. Identification of neuropathic pain often indicates that nontraditional adjuvant therapies may be required to achieve adequate pain relief.^{385,387}

Barriers to Pain Control

Up to 50% of patients with cancer have uncontrolled pain.³⁸⁸ Several reasons for inadequate treatment of pain exist and can be classified as physician barriers or patient barriers to pain control.

Multiple studies have identified physician-related barriers to cancer pain management, and all have a recurring theme.^{389,390} Two large studies surveying US medical oncologists' attitudes and practices in cancer pain management have been undertaken over the past 20 years.^{391,392} Despite the almost 20-year time between the 2 studies, both concluded that knowledge deficits, inadequate training in pain management, inadequate opioid prescribing as recommended by established guidelines, and poor pain assessment are the main physician-related barriers to adequate pain management. The potential for addiction, the development of tolerance, scrutiny by regulatory agencies, and inadequate side effect management are other potential reasons for nonadherence to established pain management guidelines.

There are also many patient-related barriers that hinder patients' use of appropriate analgesics for cancer pain. Reluctance of patients to report pain and take pain medications have been shown to be the most prominent patient-related barriers to cancer pain management.^{393,394} The Barriers Questionnaire, a tool designed to identify patient-related barriers to cancer pain management, has identified 9 areas of concern that patients may have in reporting and taking pain medications. (1) Fatalism, belief that cancer pain is inevitable; (2) fear of addiction; (3) "desire to be a

P.1456

good patient" and not complain; (4) fear of distracting one's physician from treating the disease; (5) concern that increasing pain signifies disease progression; (6) concerns about drug tolerance; (7) concerns about side effects; (8) religious fatalism, the religious belief that pain is caused or given by a deity and that patients have to tolerate the pain in order to avoid carrying the pain into their next life; and (9) concerns that pain medications are better when given on an as needed basis.³⁹³

Patient education is one way to overcome patient barriers to cancer pain management. Multiple studies have proven the effectiveness of pain education programs in improving patient adherence to analgesic therapy and ultimately decreasing pain intensity.^{395, 396} and ³⁹⁷ Educational interventions for both physicians and patients will likely lead to more appropriate guideline-based analgesic prescribing and patient adherence to prescribed therapies.

Pain Assessment

A comprehensive pain assessment is crucial to adequate pain control and includes a detailed pain history that evaluates pain intensity, location, and type, as well as an assessment of psychological stressors and the patient's network of social support. A detailed physical exam paying close attention to impending oncologic emergencies is also important in

determining the etiology of pain so that timely and appropriate interventions can be initiated. Pain is subjective, and thus patient report is the “gold standard” for measurement. In order to try and make pain measurement objective and reliable, a number of scales have been developed.

Pain intensity has been shown to have an inverse correlation with quality of life and functioning. Pain intensity can be measured by a number of validated scales.^{398,399} Some scales are available to assess pain intensity for those with limited literacy as well as those who are cognitively impaired.^{378,400, 401} and ⁴⁰² Other scales, such as the Memorial Pain Assessment Card and the Wisconsin Brief Pain Inventory, have been developed to assess pain intensity as well as psychological distress. These two scales are not only multidimensional but also practical, given the efficiency in which they can be completed in a clinical setting.^{403,404} Numerical ratings of pain intensity obtained from the different scales can then be used to guide analgesic therapy.

Analgesic Management: World Health Organization Analgesic Ladder

The World Health Organization (WHO) “three-step analgesic ladder” (Fig. 69.10) developed in the 1980s continues to provide the framework for the management of cancer-related pain. The analgesic ladder introduced a stepwise approach to pain management and selection of appropriate analgesia based on pain intensity. Based on WHO recommendations, mild pain, rating 1 to 4, is treated with nonsteroidal antiinflammatory drugs (NSAIDs) and acetaminophen plus adjuvant analgesics; moderate pain, rating 5 to 6, is treated with weak opioids such as codeine and tramadol; and for severe pain, rating 7 to 10, strong opioids such as hydromorphone, morphine, fentanyl, oxycodone, and methadone are recommended.^{405,406} Additional principles endorsed by the WHO for optimal pain management include: (1) oral administration of pain medications if possible; (2) around-the-clock dosing for chronic pain; (3) pain severity should determine drug choice; (4) individualized treatment plans because of variability of response to analgesic agents among patients; and (5) frequent reassessments of patient's pain.⁴⁰⁶

NSAIDs and acetaminophen are the initial nonopioid step 1 analgesics recommended for use by the WHO guidelines for mild pain. NSAIDs block cyclooxygenase 1 and cyclooxygenase 2 enzymes (COX-1 and COX-2), thus decreasing prostaglandin synthesis. Prostaglandins and other inflammatory cytokines are produced within the tumor microenvironment and are responsible for pain associated with local tumor growth and infiltration.^{406,407} The benefit and role of NSAIDs in the treatment of cancer-related pain has been shown in two large meta-analyses.^{407,408} There does seem to be a ceiling effect for analgesia with NSAIDs and doses beyond the daily recommended maximum dose are not advised. Doses of nonopioid analgesics should be titrated to maximal daily doses or until adverse effects emerge, as long as mild to moderate pain persists. NSAIDs do carry a risk for GI toxicity, and cancer patients may be particularly susceptible to these toxicities, given concurrent medications that can lead to mucositis, gastritis, and anorexia. Selective COX-2 inhibitors are available and have been associated with less GI toxicity than nonselective NSAIDs; however, there have been reports of adverse GI effects with their use in cancer patients.⁴⁰⁹ For acetaminophen, it is not recommended to dose more than 6 g per day; however, for those with underlying

P.1457

hepatic dysfunction or those taking concomitant potentially hepatotoxic medications, 4 to 6 g per day may be more appropriate.

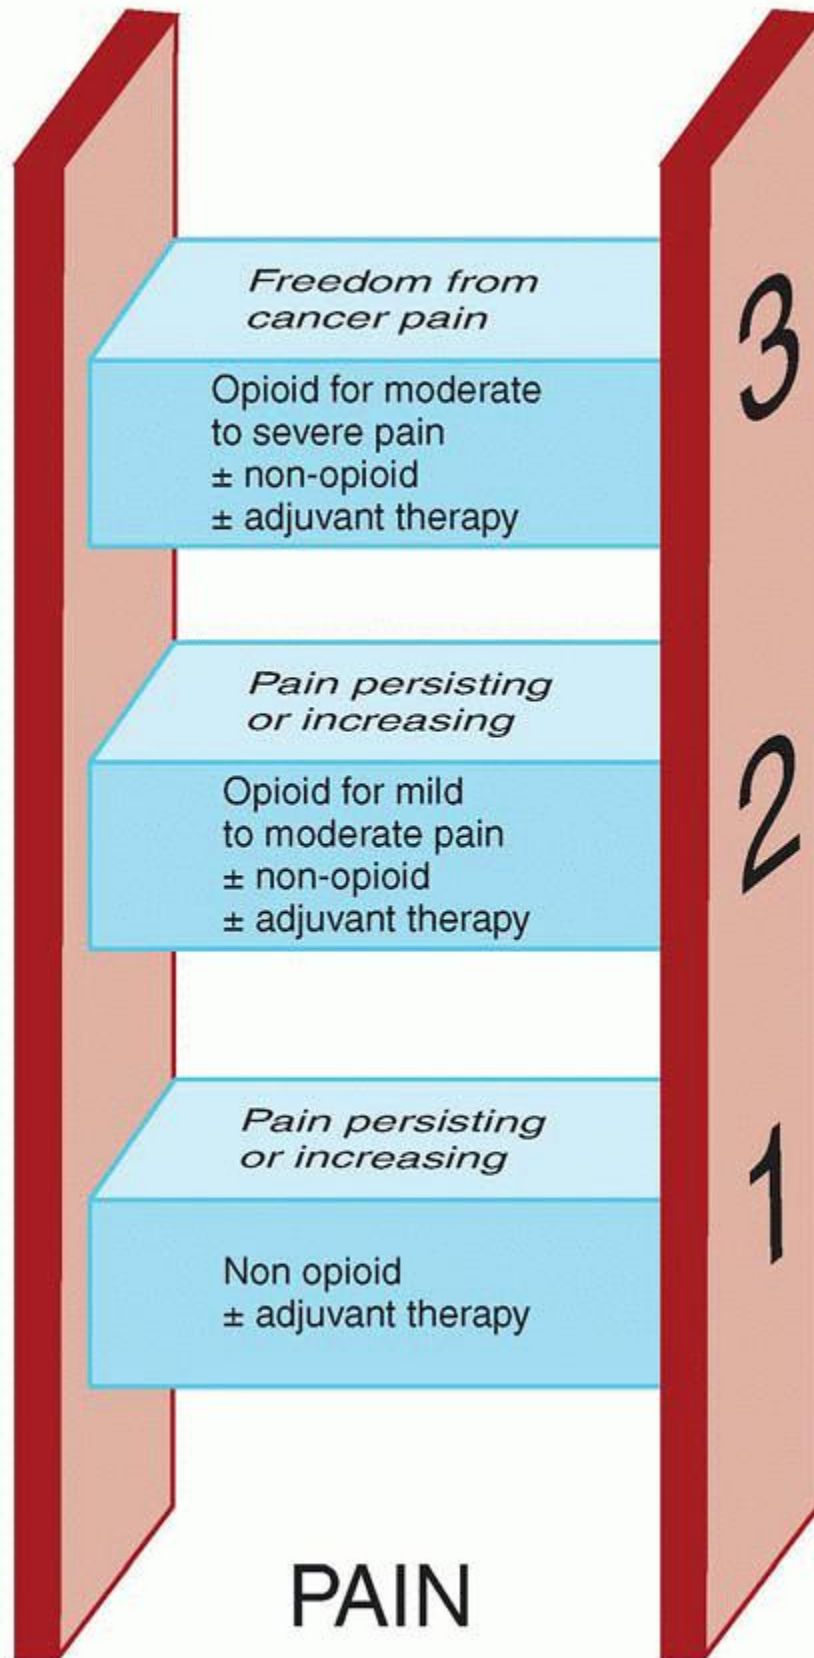

FIGURE 69.10. The WHO “three-step analgesic ladder.”

If pain remains uncontrolled with appropriate step 1 interventions, then the introduction of opioid therapy into the management of cancer pain is recommended by step 2 of the WHO analgesic ladder. Opioids are the backbone of pain management in patients with cancer. Interindividual variation in opioid receptors (polymorphisms of the mu, kappa, and/or delta receptors), absorption, intensity of the painful stimulus, administration of concurrent medications, and enzymes responsible for opioid metabolism underscore the importance of an individualized approach to opioid prescribing for patients experiencing cancer pain.^{410,411,412} Step 2 opioids, previously referred to as “weak opioids,” include codeine, tramadol, hydrocodone, and oxycodone. These opioids are typically combined with nonopioid analgesics such as NSAIDs or acetaminophen which limit their total daily dose. Codeine has a weak affinity for mu opioid receptors and its analgesic activity requires metabolism to morphine by CYP2D6. The time-to-peak effect for codeine is typically 1 to 2 hours, and it has an effective half-life of approximately 3 hours. Like many other opioids that require CYP2D6 metabolism to produce active metabolites, medications that induce or inhibit the CYP2D6 enzyme can alter the analgesic effects of codeine. In addition, some patients are “fast” or “slow” metabolizers, further adding to the variability in effectiveness.⁴¹³ Tramadol, a synthetic analog of codeine, is also considered a “weak opioid.” Tramadol is unique because it not only has analgesic properties that are mediated through mu receptor activation, but it also has serotonin and norepinephrine reuptake inhibitor activity. This dual mechanism is felt to be responsible for its effectiveness, especially in selected patients with chemotherapy-induced neuropathic pain.^{414,415} O-desmethyl tramadol, the active metabolite of tramadol, requires metabolism via the CYP2D6 enzyme and is thus subject to interactions to CYP2D6 inducers and inhibitors. Maximal daily dose is 400 mg per day, as doses above this can lead to neurotoxicity and seizures. Hydrocodone is an oral opiate that is indicated for the treatment of moderate pain and is available only as a combination product with an NSAID or acetaminophen. The metabolism of hydrocodone is through the CYP2D6 enzyme as well; however, its active metabolite, hydromorphone, is a very strong mu receptor agonist.⁴¹⁶ Given hydrocodone's prodrug properties, analgesic response is affected by different polymorphisms in the CYP2D6 gene, as well as inducers and inhibitors of this enzyme.⁴¹⁰

If pain persists at a level of 5 or greater after achieving the maximal daily dose of the step 2 analgesic, then the addition of a step 3 analgesic is recommended. Morphine, fentanyl, oxycodone, and hydromorphone are the most commonly used step 3 analgesics used for the management of moderate to severe cancer pain.

Morphine has classically been the opioid of choice for the treatment of moderate to severe cancer pain. Due to morphine's multiple routes of administration (oral tablets, oral solutions, parenteral, and rectal), formulations are available to appropriately treat acute pain crisis, chronic stable pain, and those in a terminal condition. Morphine can cause adverse effects that are classic for all opioids; however, it can also produce adverse effects that are unique to itself. Morphine can cause a histamine release, which can lead to bronchospasm and rash. Morphine can also decrease sympathetic tone that leads to peripheral vasodilatation and resultant orthostatic hypotension.^{410,413} It is metabolized through glucuronidation, producing active metabolites morphine-6 glucuronide (M6G) and morphine-3 glucuronide (M3G). M3G is associated with neurohyperexcitability and hyperalgesia. Both metabolites are excreted in the urine; thus, renal insufficiency can lead to an accumulation of these metabolites and result in oversedation and increased adverse effects.^{417,418}

Oxycodone is available in its pure form as well as in combination with acetaminophen or an NSAID. Combination products limit oxycodone's titration due to maximal daily doses of the nonopioid analgesic partner medication, thus limiting its efficacy to that of other step 2 analgesics. In its pure form, oxycodone has no ceiling effect, the same as the other step 3 opioids. Oxycodone is metabolized by CYP2D6 to oxymorphone, thus making it susceptible to drug-drug interactions that induce or inhibit CYP2D6.⁴¹⁰

Hydromorphone is a semisynthetic opioid that is approximately 5 times more potent than morphine once steady state oral and parenteral dosing is reached.⁴¹⁹ Hydromorphone has multiple routes of administration: intravenous, intramuscular, subcutaneous, oral, and rectal, and is extensively metabolized by the liver; thus its use may be preferred in patients with renal failure.⁴¹⁰

Fentanyl is another step 3 opioid that is a very strong opioid agonist, approximately 80 times more potent than morphine. Fentanyl is unique in that it not only has a parenteral form, but also has transdermal and transbuccal formulations. These preparations are particularly useful for patients with stable chronic pain who are unable to swallow pills, are noncompliant, or are in the terminally ill phase when swallowing may be difficult. When transitioning to transdermal fentanyl preparations it is important to note that there is a delay of 8 to 16 hours until the onset of analgesia, and thus initial overlap with other opioid medications may be required. Steady state of transdermal fentanyl is not reached until approximately 72 hours.^{410,420}

Fentanyl undergoes extensive metabolism in the liver, thus making it an attractive option for use in those with renal failure. There is some controversy as to the appropriate relative potency ratio to be used when converting oral morphine

to transdermal fentanyl. Donner et al. showed that an oral morphine to transdermal fentanyl ratio of 100:1 was safe and effective in converting patients with cancer pain from oral morphine to fentanyl; however, they noted that this ratio was too low and that the true ratio determined by their study was 70:1. Thus, if one uses 100:1 as a conversion ratio, then one should be aware that this will likely lead to insufficient dosing, and supplemental breakthrough medications will likely be necessary until appropriate doses can be achieved.⁴²¹

Oxymorphone, a newer strong opioid multireceptor agonist, is available in oral preparations and is 10 times more potent than morphine. Oxymorphone is not metabolized by CYP2D6 and thus is not as susceptible as some of the other aforementioned opioids to drug-drug interactions.⁴²²

Methadone is another effective opioid receptor agonist that has been used to treat chronic cancer pain. Due to its long half-life, erratic metabolism, and propensity for drug-drug interactions, it is recommended that methadone only be managed by providers with knowledge of its pharmacology and experience in its prescribing.⁴¹⁰

The oral route of administration is the most preferred as long as patients are able to swallow, and this route of administration is controlling the pain. Acute pain exacerbations should be treated with short-acting medications around the clock along with breakthrough dosing in order to ultimately come up with a total 24-hour opioid dose that will control the pain. As long as patients are experiencing severe unrelieved pain, the total opioid dose should be increased by 50% to 100% every 24 hours until the pain is controlled. If patients are experiencing unrelieved moderate pain, the total opioid dose should be increased by 25% to 50% every 24 hours until the pain is controlled. Once the patient's pain is adequately controlled, then long-acting preparations of oral opioid therapy can be incorporated. Appropriate doses of long-acting opioid medications can be calculated by taking the 24-hour total oral opioid requirement to control the pain and converting this into a long-acting opioid dose. Because of the individualized nature of the metabolism of different formulations of opioid pain medications, as a general rule it is safe to start with 75% of the total dose of the previous opioid when transitioning between opioids, and titrate the dose up as necessary. Once scheduled long-acting opioids are instituted, short-acting breakthrough

P.1458

medications should be made available to the patient on an as needed basis with dosing intervals determined by the medications' time to peak effect. Again, frequent reassessment of pain control is of paramount importance, especially during times of transition between different formulations of opioid medications.³⁸⁶

Despite aggressive and appropriate management with opioid and other adjuvant analgesic medications, a minority of patients will continue to have uncontrolled pain related to their malignancy. In these circumstances, a referral to an anesthesiologist or a neurosurgical pain specialist is warranted. Epidural nerve blocks, spinal cord stimulation, or implantable epidural catheters with opioid pain pumps may be needed to achieve adequate pain control.^{423,424}

Adjuvant Therapies

Opioid therapy alone may not be adequate to control all types of cancer-related pain, and thus throughout all steps of the WHO analgesic ladder adjuvant analgesic treatments are recommended when they are felt to benefit the patient (Table 69.10). Corticosteroids have long been used to treat pain due to spinal cord compression associated with metastatic disease; however, their benefit has been shown in the treatment of bone and neuropathic pain as well.^{425, 426} and ⁴²⁷ Anticonvulsants such as gabapentin and lamotrigine, as well as antidepressants such as amitriptyline and nortriptyline, have been shown to improve neuropathic pain and can be used in combination.^{428,429,430} As pain can be exacerbated by depression, and depression can be influenced by pain, it is crucial that prompt recognition and treatment of depressive symptoms occur when identified.⁴³¹ Pain that is caused by malignant bone involvement may respond to therapy with agents that limit osteoclast activity, such as bisphosphonates and Miacalcin, as well as agents such as NSAIDs and corticosteroids, which can decrease local inflammation caused by tumor invasion.^{432,433} There is some evidence to suggest that complementary therapies such as massage, acupuncture, and yoga are beneficial in the treatment of cancer-related pain; however, larger studies are needed to confirm these possible benefits.^{434, 435} and ⁴³⁶

TABLE 69.10 ADJUVANT ANALGESICS

Indication/Drug Class	Examples
Multipurpose Analgesics	
Tricyclic Antidepressants	Amitriptyline, Nortriptyline, Desipramine

Selective Serotonin Reuptake Inhibitors	Paroxetine, Citalopram
Noradrenaline/serotonin Reuptake Inhibitors	Venlafaxine
Others	
Corticosteroids	Dexamethasone, Prednisone
Neuroleptics	Olanzapine
For Neuropathic Pain	
Anticonvulsants	Gabapentin, Topiramate, Lamotrigine, Levetiracetam, Pregabalin
<i>N</i> -methyl-D-aspartate receptor antagonists	Ketamine, Dextromethorphan
Topical Drugs	Lidocaine/Prilocaine
For Bone Pain	Corticosteroids Dexamethasone, Prednisone
Calcitonin	Calcitonin
Bisphosphonates	Pamidronate, Zoledronic Acid
For Musculoskeletal Pain	
Muscle Relaxants	Cyclobenzaprine, Orphenadrine, Carisoprodol, Metaxalone
Baclofen	
Tizanidine	
Benzodiazepines	Diazepam, Lorazepam, Clonazepam

Adverse Effect Management

Despite the efficacy of opioids in the treatment of pain, almost all patients who use opioids for analgesia will experience side effects. The most common adverse effects of opiates are listed in Table 69.11. Prevention is the key to the management of these adverse effects; however, once side effects emerge, aggressive measures to abate these undesired effects, along with opioid titration and possible rotation, are necessary. Constipation is one of the most psychologically distressing side effects from opioid therapy that patients may experience and can lead to anorexia and bowel obstruction.⁴³⁷ All patients taking opioids should be on a prophylactic bowel regimen to try and prevent constipation. Methylnaltrexone, a peripheral opioid antagonist, has been demonstrated in multiple studies to be effective in relieving opioid-induced constipation. Weight-based subcutaneous dosing can be given as needed, however not to exceed 1 dose per 24-hour period. Inclusion criteria for randomized clinical trial enrollment were either < 3 bowel movements within the preceding week or >2 days without a bowel movement.^{438, 439, 440} and ⁴⁴¹ As methylnaltrexone is unable to cross the blood-brain barrier, it is able to reverse peripheral inhibition of opioid receptors of the GI tract without affecting analgesia.⁴⁴² Respiratory depression is a potentially fatal yet uncommon adverse effect of opioid treatment. Naloxone, a non-selective opioid antagonist, is the only therapy currently available for the reversal of opioid-induced respiratory depression.⁴⁴³ Due to its low bioavailability, naloxone is given by intravenous infusion. The extent and duration of naloxone's effect depends on the receptor affinity of the opioid being reversed. Due to its rapid elimination, naloxone many need to be dosed repeatedly or by continuous infusion to maintain reversal of respiratory depression.

Since naloxone is a nonselective opioid antagonist, reversal of respiratory depression results in reversal of analgesia, and thus research into therapies that can reverse respiratory depression while preserving analgesia are currently underway.⁴⁴⁴ Urinary retention can be relieved with insertion of a Foley catheter into the bladder. Excessive sedation can be combated by dose reduction of the opioid or with addition of a psychostimulant such as caffeine or methylphenidate.⁴⁴⁵ There is preliminary data that opioid-induced neurotoxicity, specifically hyperexcitability, can be managed with medications such

as lorazepam, baclofen, valproic acid, and midazolam. Small studies have shown improvement in opioid-induced nausea with centrally acting antiemetics such as

P.1459

metoclopramide and phenothiazines, as well as antipsychotics such as olanzapine and chlorpromazine.^{354,446}

TABLE 69.11 ADVERSE EFFECTS OF OPIOID TREATMENT

Common Adverse Effects of Opioid Therapy

Constipation	Hallucinations
Respiratory Depression	Impotence
Hyperexcitability	Fatigue
Urinary Retention	Sweating
Nausea	Vomiting
Pruritus	Myoclonus
Sedation	Xerostomia

MUCOSITIS

Mucositis is a common toxicity related to systemic chemotherapy, especially in those patients receiving HDC and HSCT, in which mucositis affects 80% to 100% of patients undergoing preparative regimens.⁴⁴⁷ Mucositis can make the host susceptible to infection, modulate the intensity of treatment able to be given, and hinder the ability for oral intake, all of which can have a negative impact on quality of life (QOL).⁴⁴⁸ The choice of chemotherapeutic agent (e.g., methotrexate, bleomycin, infusional 5-FU, cytarabine, etoposide), preexisting oral disease, and concurrent use of radiation therapy are all factors that can increase the likelihood of a patient developing treatment-related mucositis.^{449,450}

As with nausea, prevention is key; unfortunately, the data for effective preventative interventions is sparse. Pretreatment prophylactic oral care, consisting of a comprehensive oral examination that includes caries treatment, endodontic therapy, and tooth extraction if necessary, has been shown to decrease the frequency of treatment-related oral complications.⁴⁵¹ Other preventative therapies such as cryotherapy, palifermin, and low-level laser therapy have data to support their use in patients undergoing treatment for hematologic malignancies. The strongest data supporting oral cryotherapy (ice chips swished around the mouth for 30 minutes) for the prevention of treatment-related mucositis has been in patients receiving bolus 5-FU treatments.⁴⁵² There is also data supporting the use of oral cryotherapy in patients receiving high-dose melphalan and stem cell transplantation, and thus MASCC guidelines recommend the use of oral cryotherapy for the prevention of oral mucositis in this patient population.⁴⁵³

Palifermin is a recombinant human keratinocyte growth factor that stimulates the growth and differentiation of epithelial cells. Spielberger et al. evaluated the effectiveness of palifermin in preventing the development of severe mucositis in patients undergoing HDC and TBI followed by autologous HSCT in a double-blind phase III randomized controlled trial.⁴⁵⁴ Palifermin (60 µg/kg of body weight per day intravenously for 3 days before the initiation of conditioning therapy and for 3 days after autologous HSCT) was shown to decrease the incidence of WHO grade 3 or 4 mucositis, duration of mucositis, use of opioid analgesics, and need for total parenteral nutrition (TPN). These results led to clinical practice guidelines recommending the use of prophylactic palifermin in patients with hematologic malignancies who are undergoing high-dose chemotherapy with autologous HSCT.^{453,455} Palifermin's utility in allogeneic HSCT is not as well defined. Retrospective data from Goldberg et al. evaluated the safety and efficacy of palifermin in patients who underwent T cell-depleted allogeneic HSCT and found a benefit in those patients undergoing TBI-based conditioning regimens but not those undergoing chemotherapy-based conditioning regimens.⁴⁵⁶ Prospective studies to evaluate palifermin's role in allogeneic HSCT are currently underway and thus guideline-based recommendations currently advocate for palifermin's use in patients undergoing HDC with autologous HSCT.^{453,455,456}

Low-level laser therapy (LLLT) has also been reported to be an effective treatment for the prevention of oral mucositis associated with HDC and TBI conditioning regimens prior to HSCT. This type of low energy radiation therapy has been

shown to have analgesic, antiinflammatory, and wound healing properties.⁴⁵⁷ MASCC guidelines currently recommend the use of LLLT to reduce the incidence of oral mucositis associated with HDC or TBI conditioning regimens and HSCT. Unfortunately, LLLT requires expensive equipment and expert training, and thus few centers have the capability to support such therapy.⁴⁵³

Supersaturated calcium phosphate rinses (SCPRs) have been evaluated in the prevention of treatment-related oral mucositis. In a small randomized single-institution study of patients undergoing allogeneic HSCT comparing SCPR 4 times daily to a control group consisting of a solution made of saliva leaf extract, iodine-povidone, and fluconazole administered at the same frequency, SCPRs were found to decrease the incidence, severity, and duration of oral mucositis, as well as the need for analgesic and TPN interventions. Larger multicentered trials are needed to confirm these results.⁴⁵⁸

Once oral mucositis occurs, treatment is supportive and consists of appropriate oral care, mucosal protectants, and analgesia (topical and/or systemic); however, data to validate these interventions is limited. Routine oral care should focus on limiting trauma which could further damage the oral mucosa. Soft toothbrushes and gentle cleansing rinses such as salt and soda rinses (½ teaspoon of salt and 1 teaspoon of baking soda in a quart of water every 4 hours) should be used. In an open labeled pilot study conducted by Innocenti et al., Gelclair, a mucosal protectant, was found to be beneficial in reducing oral pain. Of note, only 3 of the 30 patients in this trial had chemotherapy-related mucositis.⁴⁵⁹ Studies of analgesic mouthwashes have documented pain relief with topical lidocaine and morphine preparations; however, if these preparations do not control the mucositis-related pain, patients should be treated with systemic analgesia by the oral route if possible, and if unable, through parenteral routes.^{460,461}

ANOREXIA

Cancer-related anorexia (CRA) leads to weight loss as a result of decreased appetite from the systemic effects of advanced cancer.⁴⁶² Anorexia is one of the most frequent and troubling symptoms experienced by patients and their family members, occurring in more than half of patients with advanced cancer.^{463,464} CRA and cachexia are provoked by metabolic changes induced by advanced malignancies in the host, with a milieu of proinflammatory cytokines felt to be responsible.⁴⁶⁵ Dramatic changes in weight and body habitus can occur when the hypermetabolic state of malignancy is coupled with decreased caloric intake associated with CRA. The resultant changes in body habitus can be quite psychologically distressing to patients and their families, and thus patient education and attempts to improve anorexia are of utmost importance.⁴⁶⁶

There are multiple nonpharmacologic and pharmacologic interventions that are effective in the treatment of CRA; however, the first step in the management of CRA is to evaluate for any reversible causes. Reversible causes of anorexia in patients with advanced cancers and those receiving directed therapies for advanced cancers include constipation, uncontrolled pain, nausea, vomiting, gastroparesis, depression, stomatitis, mucositis, and delirium. Evaluation for a possible reversible cause and its treatment should be the first step in management of CRA.⁴⁶⁶ If no reversible cause can be identified, then interventions directed toward management of CRA should be initiated. Nonpharmacologic measures include nutritional counseling, increasing physical activity, and encouraging the intake of caloriedense foods and supplements.

Corticosteroids, megestrol acetate (Megace), and cannabinoids have all been evaluated in the treatment of anorexia. Megestrol acetate at doses of 800 mg/day have been the most extensively studied and have been shown to be effective in treating anorexia associated with advanced malignancy and acquired immune deficiency syndrome (AIDS).^{467, 468, 469, 470, 471} and ⁴⁷² Jatoi et al. performed a large randomized controlled trial of more than 400 patients with advanced cancer, comparing the effectiveness of megestrol acetate (800 mg/day) vs. dronabinol (2.5 mg twice a day) vs. a combination of both agents for the treatment of cancer-associated anorexia. Megestrol acetate was found to improve appetite and induce weight gain more than dronabinol. Combination therapy did not provide an additional benefit over megestrol acetate therapy

P.1460

alone.⁴⁷¹ A study conducted by Navari et al. found that the addition of olanzapine (5 mg/day) to megestrol acetate (800 mg/day) led to improvements in weight gain, anorexia, and quality of life (QOL) when compared to megestrol acetate alone. No additional grade III or IV toxicities were observed in the group receiving megestrol acetate and olanzapine.⁴⁷³ Megestrol acetate is fairly well tolerated, with increased risk for thromboembolism being the most worrisome adverse effect. A prospective study of dexamethasone 4 to 16 mg daily has been shown to be effective in treating anorexia; however, given the multiple potential adverse effects of corticosteroids, the lowest effective dose should be used and treatment discontinued if no benefit is observed within 3 to 5 days of starting treatment.^{466,474} For patients unable to

consume all of their caloric needs by mouth, enteral tube feedings are the treatment of choice, as this method of delivery can help prevent mucosal atrophy of the gastrointestinal tract.

COMPLICATIONS OF HEMATOLOGIC MALIGNANCIES

There are numerous complications secondary to hematologic neoplasms, and selected topics on thrombocytopenia, anemia, and tumor burden are described in the subsequent section. Neutropenia was addressed in the preceding sections on neutrophil defects, febrile neutropenia, and myeloid colony-stimulating factors. Problems due to tumor burden include hyperleukocytosis, acute tumor lysis, hypercalcemia, and cord compression.

Thrombocytopenia

Thrombocytopenia may develop as a result of direct marrow infiltration, chemotherapy, infection, DIC, immune-mediated platelet destruction, and hypersplenism, as well as other idiopathic etiologies, and is considered the most common cause of serious hemorrhagic events in patients with acute or chronic leukemia.⁴⁷⁵ The relationship between spontaneous bleeding events and decreased platelet counts in the setting of induction chemotherapy or HSCT has been well described.^{476,477} As a result, prophylactic and/or therapeutic platelet transfusion to reduce bleeding risk is a generally accepted practice in these settings.^{478, 479, 480} and ⁴⁸¹ The optimal threshold for prophylactic platelet transfusion remains controversial, but levels in the 10 to $20 \times 10^9/L$ range have commonly been utilized with no major differences in outcome demonstrated between these levels.^{476,477,482} However, the risk of bleeding events in thrombocytopenia has been estimated to be increased 8-fold when counts are $< 5 \times 10^9/L$ and 2-fold with counts from 5 to $15 \times 10^9/L$ compared to platelets in the 20 to $29 \times 10^9/L$ range.⁴⁸³ Therapeutic (in the presence of bleeding) versus prophylactic (platelet count $< 10 \times 10^9/L$) platelet transfusion strategies have been compared in patients undergoing intensive chemotherapy for AML or autologous HSCT.⁴⁸⁴ The therapeutic platelet transfusion strategy led to a reduced number of platelet transfusions without an increased risk of major hemorrhage in autologous HSCT patients. However, nonfatal grade 4 (mostly CNS) bleeding was increased among AML patients, suggesting a continued role for prophylactic strategies in this population. Clinical practice guidelines set forth by ASCO currently recommend a threshold of $10 \times 10^9/L$ for prophylactic platelet transfusion in adult patients receiving therapy for acute leukemia.⁴⁸⁵

Patients with either chronic or recurrent thrombocytopenia requiring multiple platelet transfusion exposures are at increased risk for experiencing platelet refractoriness due to alloimmunization. The presence of fever is also associated with increased refractoriness to platelet transfusions⁴⁸⁶ and further compounds the risk of bleeding in this setting. When administering platelet transfusions to this population, the use of ABO-compatible platelet products is important in reducing alloimmunization as well as improving the incremental response to a given platelet transfusion.^{487,488} Platelets are generally available in the form of either single-donor apheresed products or pooled from multiple random donors. Each of these products may also be modified by either leukoreduction or irradiation. Reduction of leukocytes from platelet products by filtration has been demonstrated to be equally as effective as irradiation in the prevention of alloimmunization-related platelet refractoriness.⁴⁸⁹ Similarly, there is no difference in alloimmunization risk to support empiric use of leukoreduced single-donor (apheresed) platelet products compared to random donor platelets in this setting.⁴⁸⁹ Leukoreduction provides additional benefits by preventing CMV transmission⁴⁹⁰ and by reducing the incidence of febrile transfusion reactions.⁴⁹¹ The benefit of platelet irradiation for the prevention of transfusion-associated graft-versus-host disease (GVHD) appears limited. Use of irradiated platelet products should be restricted to patients receiving allogeneic HSCT, those receiving blood products from related donors, and those who are severely immunocompromised.⁴⁹²

Thrombocytopenia caused by accelerated platelet consumption can occur in patients with hematologic malignancies. ITP has been well described in the setting of CLL^{493, 494} and ⁴⁹⁵ and has been reported in patients with HL, NHL, MM, and ALL.^{494, 495, 496, 497} and ⁴⁹⁸ The mechanisms that contribute to the initiation of ITP in each of these situations are largely unknown, but it is presumed that pathogenic autoantibodies are produced and react to antigens present on the platelets. The prognostic significance of ITP in the setting of the various hematologic malignancies is unclear. Standard therapeutic interventions for ITP (Chapter 47) with steroids, intravenous immunoglobulin (IVIG), and/or splenectomy are typically employed in addition to definitive treatment for the underlying malignancy.

Diffuse intravascular coagulation (DIC) is well recognized to cause a consumptive thrombocytopenia associated with hematologic malignancies, most notably APL (Chapter 78). DIC is characterized by widespread intravascular activation of coagulation, intravascular fibrin deposition, and simultaneous consumption of coagulation factors and platelets which increase bleeding risk.⁴⁹⁹ APL-associated DIC is characterized by marked hyperfibrinolysis with a clinical presentation of severe bleeding and laboratory parameters consistent with hypofibrinogenemia, elevated fibrin split products, elevated fibrinogen degradation, quantitative D-dimers, and consumption of plasminogen and α_2 -antiplasmin.⁵⁰⁰ It is suspected

that the hyperfibrinolytic state in APL-associated DIC is superimposed on the prothrombotic characteristics known to occur in DIC as a result of coagulation activation and fibrin deposition, providing concurrent risk for both thrombotic and hemorrhagic complications. Chemotherapy administration to treat an underlying malignancy may transiently increase thrombotic risk by causing endothelial damage as well as release of procoagulant factors, cytokines, and proteases from damaged malignant cells.^{501,502,503,504} Therapeutic intervention for DIC remains largely supportive, with the focus on treatment of the underlying malignancy in these situations. Limited data exists to provide recommendations for the management of DIC-related complications. Transfusion support of platelets or plasma products is typically determined by active bleeding and/or the risk of hemorrhagic complications.⁵⁰⁵ The use of therapeutic heparin should be considered on an individual patient basis and may benefit those at risk for thrombotic complications.^{503,506}

Thrombocytopenia as a direct result of the malignant condition, or the aggressive chemotherapy that may be required, poses significant challenges in the treatment of patients. Recombinant human IL-11 (Oprelvekin) has been approved for the treatment and prevention of chemotherapy-induced thrombocytopenia in nonmyeloid malignancies.⁵⁰⁷ Randomized placebo-controlled testing in breast cancer patients receiving chemotherapy demonstrated reduced platelet transfusion events.⁵⁰⁸ Use of rIL-11 has

P.1461

also been shown to improve platelet nadirs and shorten duration of thrombocytopenia in patients receiving chemotherapy for hematologic malignancies.⁵⁰⁹ It is not indicated for use in children or in patients receiving myeloablative chemotherapy. Despite its proven effectiveness, the use of rIL-11 has been limited in part because of the potential for hypersensitivity reactions, ventricular arrhythmias, and papilledema associated with visual field defects and possibly blindness. Genetically modified recombinant human IL-11 (mIL-11) is under active investigation, but early reports suggest that it is able to provide equivalent thrombopoietic activity with an improved safety profile.⁵¹⁰

Romiplostim is a thrombopoietin (TPO) peptide mimetic which increases platelet counts by binding to and activating the TPO receptor (Chapter 47). Although approved for use in chronic ITP, off-label use has been reported for chemotherapy-induced thrombocytopenia⁵¹¹ and romiplostim's role in this setting is under active investigation (NCT01676961; NCT01516619). Eltrombopag is a nonpeptide TPO agonist also approved for chronic ITP. Eltrombopag increases platelet production by binding to and activating the TPO receptor, but also increases proliferation and differentiation of marrow progenitor cells by activation of intracellular signal transduction pathways. Increased platelet numbers have been reported with its use in patients with radiation-induced thrombocytopenia,⁵¹² patients receiving chemotherapy for advanced solid tumors,⁵¹³ and patients with refractory aplastic anemia.⁵¹⁴ Eltrombopag use in patients undergoing chemotherapy for hematopoietic malignancies is also an area of active investigation (NCT01656252, NCT01488565).

Anemia

Anemia commonly occurs as a result of the presence of a hematologic malignancy and/or the subsequent therapeutic interventions. Marrow infiltration and replacement with neoplastic cells is the primary cause, but other mechanisms must be considered.

Patients with inflammatory and/or malignant conditions commonly present with normocytic, normochromic or microcytic, hypochromic anemia. Laboratory findings are typically suggestive of a hypoproliferative state characterized by low reticulocyte counts and the absence of appropriate erythroid hyperplasia in the marrow in response to the anemia. Serum erythropoietin (EPO) levels tend to be inappropriately low in response to the malignancy-associated anemia,⁵¹⁵ which is suspected to result from proinflammatory cytokines that interfere with the regulation of EPO gene expression.⁵¹⁶ Erythroid marrow response to EPO is blunted, and higher doses of EPO supplementation are often required to improve anemia associated with hematologic neoplasms.^{475,517} The use of EPO stimulating agents has been curtailed because of an inferior survival in randomized trials for cancer patients and an increased risk for thrombosis.⁵¹⁸

Inflammatory cytokines have been demonstrated to increase hepcidin production,^{519,520} causing decreased intestinal iron absorption and impaired iron release from the reticuloendothelial system.⁵²¹ Increased IL-6 levels have been implicated in stimulating hepcidin production in patients with HL, MM, ALL, and AML, and provides insight into the pathophysiology of anemia commonly found in patients with various malignancies.^{522, 523} and ⁵²⁴ Targeting IL-6 in the treatment of cancer-related anemia has shown promise and remains an area of active investigation.^{525,526}

Macrocytic anemia is often seen in association with MDS and AML and is also commonly caused by exposure to cytotoxic chemotherapy. Agents such as cytarabine, hydroxyurea, methotrexate, and 6-mercaptopurine inhibit DNA syntheses and are frequently associated with the development of macrocytic anemia in exposed patients. In the absence of exposure to these types of agents, abnormal nucleated red cells may occur in AML or as part of the terminal phase of

myeloproliferative disorders. Certain morphologic features allow their differentiation from the megaloblasts resulting from vitamin deficiencies. The nuclear chromatin is typically not as fine as in true megaloblasts, and a greater proportion of the erythroid precursors are more immature in most patients with erythroleukemia than in those with vitamin B12 or folate deficiencies. In addition, the neutrophils characteristic of these vitamin deficiencies, such as hypersegmentation, giant metamyelocytes, and macropolycytes, are usually absent in the macrocytic anemia seen in AML/MDS.

Hemolytic anemias have been observed in association with various hematologic malignancies and may precede diagnosis of the malignant condition. While their presentation may be dramatic, concomitant hemolytic anemias do not carry prognostic significance. Warm antibody-mediated hemolytic anemia has been classically described to occur in 10% to 20% of patients with CLL but has also been observed in association with various other hematologic cancers.^{527, 528, 529} and ⁵³⁰ Therapy is directed at decreasing the production of antibody and the splenic destruction of red blood cells (Chapter 29). Glucocorticoids, transfusion support, and/or splenectomy are used in autoimmune hemolytic anemia of warm antibody type, in addition to therapy directed toward the underlying neoplasm. Anemia is usually mild in cold agglutinin disease, and intervention with steroids and splenectomy is of little benefit. Avoiding cold exposure, plasmapheresis, and treatment of the underlying lymphoproliferative disorder may be effective in improving the anemia associated with cold agglutinin disease. Microangiopathic hemolytic anemia is seen most often as part of the DIC syndrome but has been reported in patients with hematologic neoplasms without evidence of DIC. Erythrocyte trapping and/or destruction in the spleen may contribute to anemia in hematologic cancers such as low-grade lymphomas and CLL. Splenectomy has been used for treatment of nonautoimmune hemolytic anemias in lymphoid malignancies when this hypersplenism occurs.^{531,532}

Hemophagocytic syndrome is a rare but often dramatic cause of anemia in patients with a variety of hematologic malignancies. Its presence has been described in association with acute leukemias, lymphomas, and myeloma,^{533, 534, 535, 536} and ⁵³⁷ as well as a result of infectious complications of both bacterial and viral origin.^{538,539} The mechanism by which this potentially devastating macrophage activation occurs is poorly understood, but is felt to result from the inability to turn off the inflammatory response of the immune system to the particular inciting factor (malignancy, infection, etc.).⁵⁴⁰ Prognosis in these patients is quite poor.

Hyperleukocytosis and Leukostasis

Hyperleukocytosis has been variably defined as a white blood cell (WBC) count greater than $50 \times 10^9/L$ or $100 \times 10^9/L$ (Table 69.12).

P.1462

It is typically associated with increased morbidity and mortality in patients with leukemic diagnoses as a result of associated leukostasis and/or tumor lysis syndrome. The absolute count at which the hyperleukocytosis becomes clinically relevant is somewhat dependent on the specific underlying leukemic process. For instance, patients with AML may develop severe complications at a WBC count of $50 \times 10^9/L$, whereas patients with CLL may tolerate WBC counts above $400 \times 10^9/L$. Hyperleukocytosis has been estimated to occur in approximately 5% to 13% of AML and between 10% to 30% of ALL,⁵⁴¹ and has historically been associated with a poor prognosis when occurring in patients with acute leukemia.^{542, 543} and ⁵⁴⁴ Supportive care measures such as aggressive intravenous fluid support, allopurinol, and hydroxyurea are typically employed as temporizing measures until some form of cytoreductive therapy can be initiated.

TABLE 69.12 MANAGEMENT OF HYPERLEUKOCYTOSIS

1. Risk of leukostasis depends upon disease and level of WBC ($\times 10^9/L$). AML (monocyte variants) and CML, blast crisis ($>50-100$) $>$ ALL ($>150-300$) $>$ CML ($>150-250$) $>$ CLL (300-500)
2. Target organs for leukostasis are: brain (stupor, blurred vision), lungs (dyspnea), kidneys (azotemia), penis (priapism), heart (arrhythmia)
3. Spurious lab may occur with hyperleukocytosis: elevated platelet count, pseudohypoxemia ("leukocyte larceny"), pseudohyperkalemia, pseudohypoglycemia, prolonged coagulation tests
4. Transfusion: limit red cells due to risk of increasing viscosity; transfuse platelets due to increased risk of bleeding and loss of platelets with leukapheresis
5. Therapy: hydration, allopurinol or rasburicase, hydroxyurea, consider leukapheresis if symptomatic, dexamethasone, institute chemotherapy, manage tumor lysis

Leukostasis is a symptomatic manifestation of hyperleukocytosis which qualifies as a medical emergency caused by the “sludging” of the leukemic cells within the capillaries, leading to vascular obstruction and resultant tissue hypoxia (Fig. 69.11). Presenting symptoms of leukostasis are reflective of the location where this tissue hypoxia is occurring. CNS manifestations of confusion, headaches, visual disturbances, somnolence, delirium, or ataxia may occur. Respiratory findings may include bilateral infiltrates on chest imaging and associated dyspnea, tachypnea, hypoxia, and rhonchi on physical exam. Leukostasis remains a diagnosis of clinical suspicion rather than one confirmed by a laboratory test. Given the potential for catastrophic consequences, reasonable clinical suspicion of diagnosis should prompt emergent intervention. Hydroxyurea is an oral antimetabolite with the ability to rapidly lower leukocyte counts and whole blood viscosity.^{545,546} Definitive antileukemic therapy should be initiated as soon as possible. Some centers prefer to initiate leukapheresis prior to the initiation of chemotherapy in order to reduce the peripheral leukemic burden, ameliorate the symptoms of leukostasis, and minimize the risk of tumor lysis syndrome upon initiation of the chemotherapy.^{547,548} While retrospective data has shown that leukapheresis may reduce early mortality, it has failed to provide improvements in remission or overall survival.⁵⁴⁹

FIGURE 69.11. Hyperleukocytosis and leukostasis. A: An elevated leukocrit is present in this tube of centrifuged peripheral blood from a patient with T cell acute lymphoblastic leukemia who had a peripheral blood blast count of $250 \times 10^9/L$. B: Pulmonary alveolar capillaries are expanded by leukocyte aggregates indicative of leukostasis in patient with acute myeloid leukemia (hematoxylin and eosin stain). C: Ring-enhancing lesions on magnetic resonance imaging were attributed to hemorrhage in a patient with chronic granulocytic leukemia, hyperleukocytosis, and blurred vision (T1-weighted image).

Acute Tumor Lysis Syndrome

ATLS occurs most frequently in patients with rapidly proliferating neoplasms such as high-grade lymphomas (e.g., Burkitt) and acute leukemias (Fig. 69.12). ATLS may occur spontaneously and be observed at the time of initial diagnosis or in response to the initiation of cytotoxic chemotherapy. Tumor lysis results from the rapid breakdown of malignant cells and the subsequent abrupt release of the cellular contents (intracellular ions, nucleic acids, proteins, etc.) into the extracellular space. Laboratory evidence of tumor lysis is more commonly seen than the clinical manifestations.

Laboratory tumor lysis requires at least 2 of the following metabolic abnormalities occurring simultaneously within 3 days prior to or up to 7 days after the

P.1463

initiation of therapy: hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia.^{550,551,552} The clinical tumor lysis syndrome is defined as the above abnormal laboratory findings in combination with acute renal failure, seizures, cardiac dysrhythmias, or death.

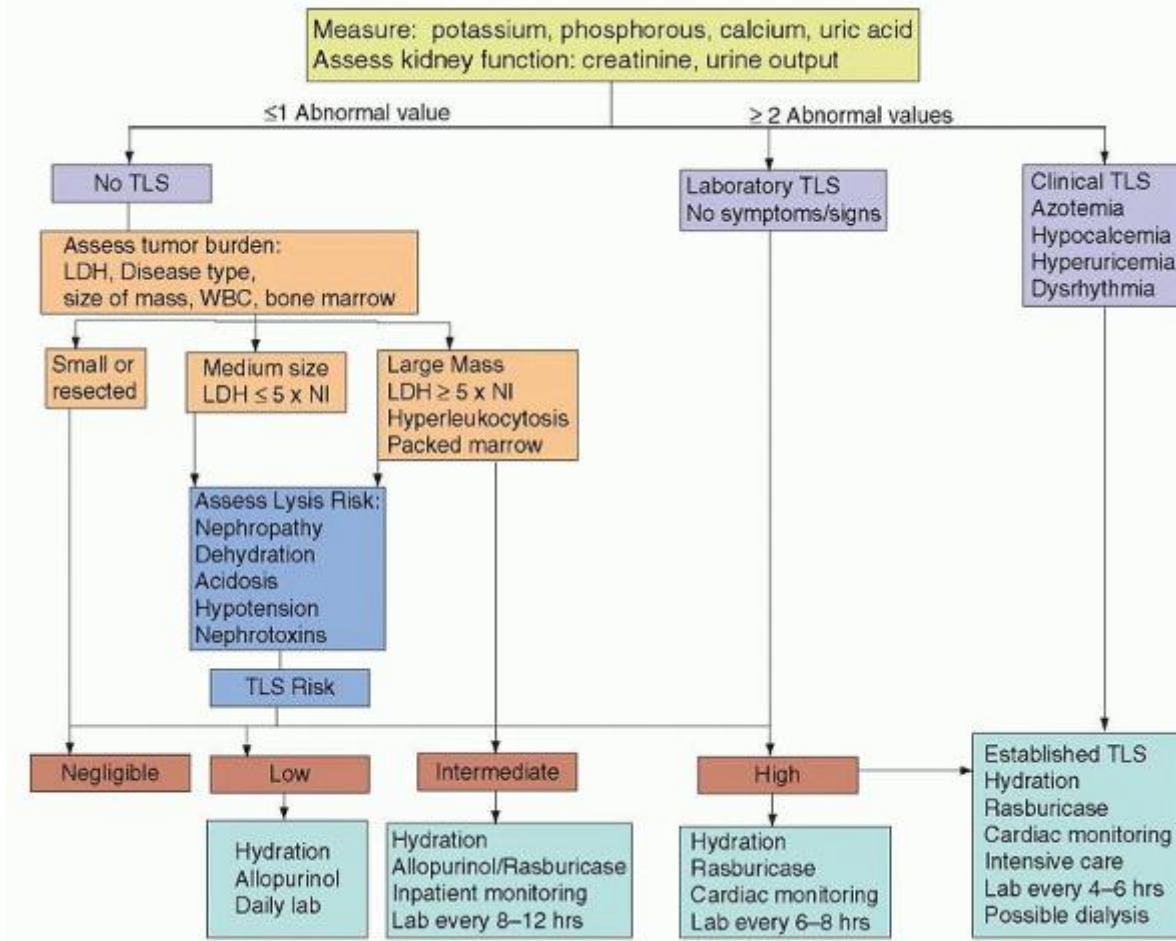

FIGURE 69.12. Management of tumor lysis syndrome (TLS). Serum chemistries and renal function are assessed when instituting therapy in any patient with a hematologic neoplasm. The risk of TLS is based on assessing laboratory values, disease type, and tumor burden. Patients at a high risk for TLS include the acute leukemias with hyperleukocytosis and the aggressive lymphomas with large masses or elevated LDH (lactate dehydrogenase). Volume repletion, agents to lower uric acid, and laboratory monitoring are warranted in all patients. As the risk of TLS increases, the interval of monitoring shortens and the level of care intensifies with cardiac monitoring and the possible requirement for dialysis. (Adapted from Howard SC, Jones DP, Pui C-H. The tumor lysis syndrome. *N Eng J Med* 2011;364:1844-1854.)

Hyperuricemia plays a major role in the development of the acute renal failure seen in ATLS. The etiology of the renal failure is presumably from crystal-induced tissue injury that occurs when calcium, uric acid, and xanthine precipitate in the renal tubules and lead to crystal-induced obstruction (Fig. 69.13). Allopurinol is commonly used in the prevention and treatment of ATLS. Allopurinol is a competitive inhibitor of xanthine oxidase and prevents the formation of uric acid. Allopurinol is available in both oral and IV preparations. If uric acid levels remain elevated despite allopurinol, rasburicase (recombinant uric acid oxidase) may be administered. Rasburicase converts uric acid to allantoin which is highly water soluble. Randomized data from high-risk pediatric patients receiving rasburicase versus allopurinol demonstrated reduction of uric acid levels by 86% within 4 hours of rasburicase administration versus only a 12% reduction in the allopurinol group ($P < 0.0001$).⁵⁵³ The FDA approved dosing schedule for rasburicase is 0.2 mg/kg intravenously over

P.1464

30 minutes daily for up to 5 days. Multiple reports in the literature suggest that lower fixed dose strategies may be sufficient and more cost-effective.^{554,555, 556} and ⁵⁵⁷

FIGURE 69.13. Tumor lysis: A: Karyorrhectic lymphoblast nuclei are present throughout the kidney in a patient with acute tumor lysis syndrome in whom cytolysis was initiated by administration of corticosteroids. B: Renal tubules contain calcium phosphate precipitates that contributed to acute lysis-associated renal failure (hematoxylin and eosin stain). (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.)

Patients with significant electrolyte imbalances and/or renal insufficiency may require therapeutic dialysis support until resolution of the ATLS. Prophylactic dialysis prior to initiation of chemotherapy should also be considered in high-risk patients such as those with bulky high-grade tumors.

Hypercalcemia

Hypercalcemia can occur in association with many various hematologic malignancies but is more commonly seen in patients with either MM or human T cell leukemia virus type-1 (HTLV-1)-associated adult T cell leukemia/lymphoma (ATL). Hypercalcemia in patients with cancer is primarily due to increased bone resorption and release of calcium from bone. The 3 main mechanisms leading to hypercalcemia are increased osteolytic activity, tumor secretion of parathyroid hormone-related protein (PTHrP), and ectopic production of calcitriol (1, 25-dihydroxyvitamin D). The symptoms of hypercalcemia are generally nonspecific and include fatigue, anorexia, nausea, constipation, pain, frequent urination, and altered mental status. Correction of the calcium levels typically leads to rapid and effective palliation of these symptoms.⁵⁵⁸

MM has an affinity for diffuse bone involvement and releases osteoclast activating factors leading to osteoclast-induced bone resorption that present as lytic lesions which may occur throughout the skeleton.⁵⁵⁹ Myeloma has also been associated with osteoblast inhibition leading to decreased bone formation.⁵⁶⁰ This impaired bone formation in the setting of increased destruction disrupts calcium homeostasis and results in the hypercalcemia. Numerous molecules have been implicated in the development of lytic disease and hypercalcemia, including interleukin (IL)-6, the receptor activator of nuclear factor kappa-B ligand (RANKL), macrophage inflammatory protein 1a, osteoprotegerin, and IL-3.

Calcium homeostasis in the normal host involves conversion of 1-OH vitamin D to calcitriol in the kidney. Calcitriol leads to increased calcium absorption from the gastrointestinal tract as well as increased bone resorption and results in hypercalcemia. Ectopic production of calcitriol has been described in both HL and NHL.^{561,562}

Normal calcium metabolism is mediated by parathyroid hormone. In cases of HTLV-1-associated ATL,⁵⁶³ as well as other hematologic malignancies (AML,⁵⁶⁴ CML,^{565,566} HL,⁵⁶⁷ NHL,⁵⁶⁸ and MM⁵⁶⁹), the secretion of PTHrP stimulates osteoclasts,

causing increased calcium release from the bone and resulting in a process known as humeral hypercalcemia of malignancy (HHM). Endogenous PTH is typically suppressed secondary to the hypercalcemia, and serum PTH levels will be very low. Unlike PTH, PTHrP does not typically stimulate production of calcitriol⁵⁷⁰ and thus does not increase intestinal calcium absorption. The uncoupling of bone resorption and formation that occurs in HHM results in the influx of calcium into the circulation and resultant hypercalcemia.

Regardless of the mechanism leading to the cancer-related hypercalcemia, successful treatment ultimately requires antineoplastic therapy directed toward the underlying malignancy. The severity of the patient's symptoms and the prevention of catastrophic consequences will typically require interventions with more rapid impact. Patients with hypercalcemia often experience significant volume depletion as a result of an osmotic diuresis. Thus, aggressive volume repletion with isotonic intravenous fluids (e.g., normal saline) should be initiated upon discovery of the hypercalcemia. Once the patient is appropriately volume replete, loop diuretics may be added to increase calciuresis. Thiazide diuretics increase calcium resorption and should be avoided.

The effectiveness and availability of bisphosphonates have made them a mainstay of hypercalcemic therapy. These agents inhibit calcium release by disrupting osteoclast-mediated bone resorption.⁵⁷¹ Multiple intravenous bisphosphonate choices are available for the treatment of malignancy-associated hypercalcemia: pamidronate, zoledronic acid, and ibandronate. Intravenous administration of the bisphosphonates is generally well tolerated, but patients may experience flu-like symptoms (fever, arthralgias, myalgia, fatigue, and bone pain), uveitis, hypocalcemia, hypophosphatemia, impaired renal function, and osteonecrosis of the jaw.⁵⁷² Calcitonin results in rapid lowering of serum calcium levels and may be combined with bisphosphonates,^{573, 574} and⁵⁷⁵ but calcitonin tachyphylaxis is common and limits the benefit of repeated dosing. Cases of renal insufficiency have been reported in association with bisphosphonates, and caution should be employed with their use in the treatment of hypercalcemia in patients with impaired renal function.⁵⁷⁶

Denosumab is a fully human monoclonal antibody that targets RANKL and inhibits osteoclast maturation, activation, and function, leading to reduced bone resorption. It is approved for the treatment of osteoporosis and prevention of skeletal-related events in at-risk patient populations. Its effectiveness has been reported in the treatment of malignancy-associated hypercalcemia refractory to bisphosphonates.⁵⁷⁷ Denosumab has also demonstrated less nephrotoxicity than bisphosphonates,^{578,579} and its use has been reported in the setting of renal insufficiency.⁵⁸⁰ Common side effects of denosumab include fatigue, headache, hypophosphatemia, hypocalcemia, nausea, weakness, dyspnea, and cough.

Cord Compression

Spinal cord impingement is a medical emergency requiring rapid recognition and intervention in the hopes of minimizing complications. It has been frequently reported in patients with MM and is also known to occur in association with HL and NHL. Cord compression as a result of a leukemia diagnosis is rare but has been reported.^{581, 582} and⁵⁸³ Pain is the most common presenting symptom of patients with cord compression and may precede neurologic symptoms by several weeks. Radicular pain, pain not relieved with lying down, and proximal muscle weakness are of particular concern for the possibility of an underlying cord impingement. The development of autonomic symptoms such as urinary retention and fecal incontinence typically occurs late in the course and is predictive of poor outcomes.

Patients with known hematologic malignancies that complain of severe back pain and/or any neurologic symptom warrant urgent imaging to rule out cord compression. Emergent referrals for the possibility of surgical intervention should be considered for patients in whom there is a reasonable index of suspicion. Empiric steroids may be appropriate in clinical contexts of concern, or if there are unavoidable delays in being able to obtain imaging. It should be noted, however, that the initiation of steroids may cause rapid necrosis of the tumor and impair the ability to make a tissue diagnosis. Magnetic resonance imaging (MRI) is the imaging modality of choice and should include the entire spine, as multiple areas of compression can occur simultaneously⁵⁸⁴ (Fig. 69.14).

Intervention for cord compression is directed at pain control, avoidance of complications, and the preservation or improvement of neurologic function. Frontline therapy typically consists of urgent initiation of corticosteroids (dexamethasone). The optimal dose of steroids is not known. High-dose dexamethasone (up to 100 mg) has been shown to improve neurologic recovery and ambulatory status,^{426,585} but carries the risk of serious adverse events such as psychosis and gastrointestinal complications.^{586,587} In general, it is recommended that patients with suspected or confirmed cord compression be started on dexamethasone at an

P.1465

initial dose of 10 to 100 mg followed by at least 16 mg daily (in divided doses).⁵⁸⁸ Following the initiation of steroids and confirmation of cord impingement, definitive treatment with surgical intervention, radiation therapy, and/or

chemotherapy should be initiated.^{588,589} Surgery should be considered in those who are medically and surgically appropriate and/or those in whom a tissue diagnosis has not yet been established. Radiation therapy should be administered to those who are not candidates for surgical intervention.

FIGURE 69.14. Spinal cord involvement shown by magnetic resonance imaging. Epidural mass on sagittal view with evidence of cord compression and cord impingement at &7 level (T1-weighted image). The diagnosis by biopsy was multiple myeloma.

SUMMARY

This chapter has addressed selected aspects of supportive care in hematologic malignancies. The improved prognosis for leukemias, lymphomas, and myeloma has been attributed to better drugs, including targeted therapy and immunotherapy; however, progress could not have occurred without the concomitant advances in supportive care, particularly in the management of infections and in transfusions.

The goals of supportive care are to prevent and reduce the toxicities of therapy and the complications of the diseases. There is an emphasis on survivorship, including rehabilitation after therapy and recognition of the long-term risks of

therapy. When therapeutic options no longer offer survival benefit, access to palliative care and end-of-life issues take precedence over other components of supportive care.

HISTORY

There probably is no field in medicine that has provided as much hope, or as much disappointment, as the field of tumor immunology. A major relationship between the immune system and the oversight of neoplasms was postulated in the early part of the last century by Paul Ehrlich.¹ This theory of immunosurveillance envisioned that, in long-lived animals, inheritable genetic changes in somatic cells must be common, and some proportion of these changes must represent steps toward malignant transformation. It was considered an evolutionary necessity, therefore, that some mechanisms exist for eliminating or inactivating such potentially dangerous mutant cells. This mechanism was thought to be immunologic. The theory of immunosurveillance was restated in the 1950s by Lewis Thomas, then popularized and championed by Sir Macfarlane Burnet.² Supported by these powerful figures in medicine, the theory of immunosurveillance was so inherently appealing that it often was accepted uncritically, and evidence to the contrary often overlooked.³ For instance, although patients or animals who are immunosuppressed tend to have an increased incidence of tumors, these tumors are disproportionately of lymphoid origin or associated with an oncogenic virus. The development of common epithelial neoplasms (with the exception of certain skin cancers) in these patients occurs with much less impressive frequency.⁴

The most obvious evolutionary necessity of the immune system was to survey a variety of infections, especially viral infections. Early evidence seemed to indicate that immunity played a significant role in eradicating virally induced tumors.^{4,5} On the other hand, it appeared to play a less significant, or less effective, role in prevention of tumors induced by physical or chemical carcinogens.^{6,7}

Experimentation in the early part of the 20th century demonstrated that spontaneously arising tumors in outbred animals could occasionally be transplanted from one animal to another of the same species and propagated in that fashion. Attempts to immunize against transplantable tumors soon followed. Animals injected with a small number of tumor cells often were able to eliminate those tumor cells—that is, there appeared to be a threshold number of tumor cells required for tumor propagation. Animals that had eliminated a sublethal inoculum of tumor cells were often able to withstand inoculation with a large number of tumor cells that would have been lethal in a naive animal. Furthermore, preexposure to normal tissue of the donor often rendered the recipient resistant to challenge with a lethal number of tumor cells.⁸ These experiments brought into question the idea of tumor-specific antigens and ultimately led to the discovery of major histocompatibility complex (MHC) genes and their products.^{9,10}

Modern tumor immunology finds its roots in the classic experiments of Prehn and Main.¹¹ These investigators demonstrated, in genetically identical mice, that previous exposure to a chemically induced sarcoma rendered animals resistant to challenge with the same tumor, but that these animals would accept normal, nonneoplastic tissues transplanted from the tumor donor animal. Similarly, prior exposure to normal tissues from the donor animal did not render the recipient animal resistant to tumor challenge. These experiments revived the notion that tumor-specific (transplantation) antigens did exist. Subsequent experiments demonstrated that protection afforded by prior exposure to tumor cells was tumor specific.¹² Thus, the host response to transplanted tumors behaved like an adaptive immune response, demonstrating memory and specificity.

Tumor immunity could be passively conveyed from one animal to another by transfer of lymphoid cells.¹³ The relevant cells for protection were shown to be T lymphocytes.¹⁴ Thus, it should have been clear to workers in the field that the relevant tumor antigens were those that could be recognized by T lymphocytes. However, as this work was beginning there was little understanding of how T lymphocytes recognized antigens or how those antigens were processed and presented to the T lymphocyte by antigen-presenting cells (APCs) or the tumor target cells. Much time and effort were expended in search of membrane structures or tumor cell products that would distinguish the tumor from all others. Particularly after the description of monoclonal antibody technology,¹⁵ a fervent search was undertaken to define structures on tumor cells that would be tumor specific and potential targets for therapeutic intervention. Although many cell surface structures were defined, and the contribution to the understanding of biology cannot be overstated, this adventure produced only a single truly specific tumor antigen, the idiotype (Id) of clonally distributed immunoglobulin present on certain lymphomas.

Only recently has convincing evidence for an effect of immunosurveillance been produced.^{16,17,18} This new evidence relies, in great measure, on the availability of genetically manipulated animal systems. A variety of knockout mice with defects in components of immune activation or effector function develop, at high frequency, spontaneous tumors or tumors after carcinogen exposure. Interferon- γ receptor-deficient mice are more likely to develop methylcholanthrene-induced sarcomas and are more susceptible to spontaneous development of sarcomas and lymphomas after loss of p53 alleles.^{19,20} One in two aged perforin-deficient mice develops disseminated lymphomas.²¹ These tumors are rejected by histocompatible wild-type mice through a mechanism dependent on CD8⁺ T lymphocytes. A high incidence of lymphoma is also seen in aged mice deficient in Fas/Fas ligand interactions.²² Aged mice doubly deficient in signal transducer and activation of transcription (Stat) 1 and recombination activating gene (Rag) 2 develop adenocarcinomas (colon, breast, and lung) with high frequency.²³ The frequency and distribution of tumors are increased in the doubly deficient mice over the frequencies and distributions seen in singly deficient mice. Many of these observations have been interpreted as evidence that the primary (both first and predominant) mechanism underlying tumor immunosurveillance is the system of innate immunity.^{16,17,18}

INNATE IMMUNITY AGAINST TUMORS

The innate immune system is a widespread and evolutionarily ancient form of host defense against infection. In recent years, there has been an explosion of information regarding innate immunity, including its role in host defense and its regulation of inflammation and adaptive immunity.^{24,25,26} The innate immune system is made up of many cells. These include dendritic cells (DCs), macrophages, mast cells, neutrophils, eosinophils, natural killer (NK) cells, natural killer T (NKT) cells, and certain subsets of $\gamma\delta$ T cells. Each of these cell types has been implicated in immune responses against tumors.

Phagocytic Cells

Many cells of the innate immune system, including neutrophils, macrophages, and DCs, bear receptors that detect “danger”²⁷

P.1468

in the form of pathogen-associated molecular patterns (PAMPs). Examples of PAMPs include bacterial lipopolysaccharide, lipoprotein, peptidoglycan, and lipoteichoic acids; bacterial CpG DNA; and viral RNA and DNA. These PAMPs are recognized by a variety of pattern recognition receptors (PRRs) expressed by cells of the innate immune system.^{26,28} The innate immune system is said to distinguish “infectious nonself” from “noninfectious self.” The PRRs of the innate immune system are encoded in the germline. Unlike genes of the T cell antigen receptor and the immunoglobulins, these genes do not undergo rearrangement. They are fixed and detect critical microbial components. Engagement of PRRs with PAMPs can result in pathogen uptake and/or cellular activation.^{26,28} One important group of PRRs is the family of evolutionary conserved Toll-like receptors (TLRs), which are critically important for innate immune cell activation. Thirteen TLRs, each with specificity for a different PAMP, have been described in mammals. Other PRR families include the nucleotide-binding domain leucine-rich repeats (NLR) receptors and the caspase recruitment domain helicases.

Neutrophils and macrophages typically exert little antitumor activity, unless these cells are activated by bacteria, their products, or cytokines produced by tumor-specific T cells.^{29,30} Recent studies have suggested that dying tumor cells or damaged tissues can release damage-associated molecular patterns (DAMPs) that can interact with PRRs and thus serve as danger signals.³¹ NLR receptors such as NLRP3 (NLR family pyrin domain-containing 3), which form large cytoplasmic signaling complexes called inflammasomes, are thought to play a critical role in detecting DAMPs and might regulate the development of tumors either positively or negatively.^{32, 33} and ³⁴ Macrophages can kill tumor cells using the same mechanisms utilized for killing of microorganisms. These mechanisms include phagocytosis and release of cytotoxic molecules such as reactive oxygen intermediates and nitric oxide.³⁵ Activated macrophages also produce a variety of cytokines. Among these cytokines, tumor necrosis factor (TNF)- α plays a major role in the tumoricidal effects of macrophages in vitro.³⁶

Another important role of phagocytes in tumor immunity is to present tumor antigens to T lymphocytes. DCs (and other APCs such as macrophages) can phagocytose tumor cells and present tumor antigens in the context of MHC molecules and costimulatory signals to T lymphocytes.³⁷

Natural Killer Cells

It has been recognized for a long time that NK cells kill MHC class I-deficient tumor cells in vivo and in vitro.³⁸ However, the identity and characterization of receptors mediating NK activation proved elusive for many years. Activation of NK

cells now is understood to be dependent on the balance of activating and inhibitory signals emanating from activating and inhibitory receptors on the NK cell surface.^{39,40} These receptors fall into two major structural classes, those of the immunoglobulin superfamily (KIRs and LIRs) and those of the C-type lectin-like family (NKG2D, CD94/NKG2A, and Ly49). Most inhibitory receptors (e.g., CD94/NKG2A, KIR, and Ly49) recognize classic or nonclassic MHC molecules. An activating receptor on NK cells, NKG2D (also called KLRK1), has now been shown to recognize a variety of stress-induced MHC class I-like molecules (e.g., Rae-1, H60, and MICA/B). Of note, activated CD8⁺ T cells and mucosal $\gamma\delta$ T cells also express NKG2D. Another activation receptor on NK cells is Fc γ RIII, which can target NK cells to immunoglobulin G (IgG) antibody-coated tumor cells and induce antibody-dependent cell-mediated cytotoxicity.

NK cells can also discriminate between different allelic variants of MHC molecules.⁴¹ This phenomenon was originally identified in the context of the hybrid resistance transplant model in mice, where parental bone marrow grafts were rejected by a subset of host F1 NK cells. When faced with mismatched allogeneic targets, a subset of donor NK cells can sense the missing expression of self-human leukocyte antigen (HLA) class I alleles and mediate alloreactions. These alloreactive NK cells can improve engraftment and control the relapse of acute myeloid leukemia (AML) in mismatched hematopoietic transplants.^{41,42}

Natural Killer T Cells

NKT cells are a subset of T lymphocytes that share receptor structures and functions with the NK cell lineage.⁴³ Prototypical NKT cells, often referred to as invariant (i)NKT cells, express a semi-invariant T cell receptor (TCR), which is specific for glycolipid antigens presented by the MHC class I-like protein CD1d. Although NKT cells express an antigen-specific receptor that is generated by somatic DNA rearrangement, these cells belong to the innate rather than the adaptive arm of the immune system.⁴⁴ The invariant TCR expressed by NKT cells recognizes a limited set of self- and foreign antigens and, therefore, bears similarity to the PRRs expressed by cells of the innate immune system. Further, NKT cells have a natural, activated phenotype and are unable to generate classic memory responses against their cognate glycolipid antigens.

Mice that are deficient in NKT cells have increased susceptibility to MCA-induced sarcomas, indicating that these cells contribute to natural immunity against tumors.⁴⁵ NKT cells in mice and humans respond to the marine sponge-derived glycosphingolipid α -galactosylceramide (α -GalCer), which has potent antimetastatic activities in mice.⁴⁵ α -GalCer and related NKT cell antigens are being explored as potential cancer immunotherapies.⁴⁶

Mucosal $\gamma\delta$ T Cells

T cells expressing the $\gamma\delta$ TCR are enriched in mucosal tissues such as the mucosa of the gut and skin.⁴⁷ These mucosal $\gamma\delta$ T cells have a highly restricted TCR repertoire, suggesting specificity for a limited set of antigens selectively expressed in their respective epithelial compartments. Like NKT cells, mucosal $\gamma\delta$ T cells can be classified as being at the interface between innate and adaptive immunity.⁴⁴ Epidermal and intestinal $\gamma\delta$ T cells express NKG2D and become activated when NKG2D binds to stress-induced MHC class I-related molecules.

$\gamma\delta$ T cells play a crucial role in immune surveillance against malignant epidermal cells. The incidence of cutaneous malignancies after treatment with a combination of initiator and promoter carcinogens was substantially increased in mice lacking the TCR δ -chain.⁴⁸ Activation of $\gamma\delta$ T cells required both NKG2D and the $\gamma\delta$ TCR, suggesting that engagement of NKG2D with its ligand(s) synergizes with signals received through the autoreactive $\gamma\delta$ TCR.

ADAPTIVE IMMUNITY AGAINST TUMORS

The adaptive immune system is composed of B and T cells that express diverse antigen-specific receptors, immunoglobulins, and TCRs, respectively. Diversity of these receptors is generated by somatic DNA rearrangement, in a process referred to as VDJ recombination.^{49,50} Currently, there is little evidence that adaptive immunity plays a major role in natural immunity against tumors (with the exception of tumors induced by viruses). Although mice lacking T lymphocytes have increased susceptibility to the development of MCA-induced sarcomas, this might be largely due to the lack of iNKT cells and/or $\gamma\delta$ T cells.^{18,51} Nevertheless, it is clear that tumors can induce adaptive immune responses (Fig. 70.1), which can be exploited for the development of cancer immunotherapies.

FIGURE 70.1. Immune responses against tumors. A variety of cells and soluble factors of innate and adaptive immunity can participate in immune responses against tumors. Examples of mechanisms that can suppress immune responses against tumors (i.e., production of TGF- β by tumor cells and induction of T_{reg} cells) are also depicted. Ab, Antibody; FcR, Fc receptor; IFN, interferon; MDSC, myeloid-derived suppressor cell; MHC I, major histocompatibility complex class I; MHC II, major histocompatibility complex class II; NK, natural killer; NKT, natural killer T; PRR, pattern recognition receptor; TAA, tumor-associated antigen; TCR, T cell receptor; TGF, transforming growth factor; TNF, tumor necrosis factor; T_{reg}, regulatory T cell.

Antibodies and B Cells

The role of B cells in regulating tumor immunity remains poorly understood. In some tumor models, B cells appear to be important for priming of T cell responses and tumor resistance, whereas in other models, B cells have an inhibitory effect on the generation of cytotoxic T lymphocyte (CTL) responses and tumor rejection.⁵² Nevertheless, it is clear that tumor-bearing hosts can produce antibodies against a variety of tumor antigens.⁵³ However, strong humoral responses rarely correlate with tumor resistance. Nevertheless, antibodies can be utilized for immunotherapy of cancer, in particular tumors of hematopoietic origin. Antibodies may kill tumor cells by activating complement and promoting phagocytosis by macrophages. Alternatively, antibody-coated tumor cells may be killed by antibody-dependent cell-mediated cytotoxicity, in which Fc receptor-bearing NK cells, macrophages, or neutrophils mediate the killing. In addition, in certain cases, antibodies may directly interfere with the growth of tumor cells, as illustrated by the beneficial effects of anti-HER-2/neu antibodies against breast cancer, which likely involves downregulation of the HER-2/neu growth factor receptor.⁵⁴

T Lymphocytes

Classic studies with transplantable tumors have demonstrated a critical role of T lymphocytes in tumor immunity.¹¹ CTLs play a particularly important role in tumor rejection, as these cells can directly lyse malignant cells that display tumor antigens in association with MHC class I molecules.^{55,56} The importance of CD4⁺ T cells in tumor immunity is less clear. CD4⁺ T cells may secrete cytokines that promote the development of CD8⁺ T cell responses, increase the sensitivity of tumor targets to CTL lysis by inducing MHC class I expression, and activate macrophages. Because of their critical role for the development of tumor immunotherapies, we will briefly describe the mechanisms that lead to the induction of T cell responses to tumors.

Antigen Processing and Presentation

T lymphocytes recognize peptide antigens in the context of MHC molecules. These peptides are derived from two distinct pathways.⁵⁷ Peptides representing proteins sampled from the extracellular world are generally presented in the context of class II MHC proteins, whereas peptides resulting from intracellular synthesis of proteins are presented in the peptide groove of the class I MHC proteins (Fig. 70.2). The binding cleft of MHC molecules has a β -pleated sheet floor and α -helical sides. An immunogenic peptide must be capable of forming noncovalent attachments to key residues along the cleft and interacting with the T cell antigen receptor with other residues. The MHC contact residues of the peptide tend to be near the amino and carboxy terminal ends of the peptide. The cleft of the class I MHC molecule has closed ends and accommodates only a peptide of proper length, 9 to 11 amino acids. The cleft of the class II MHC molecule, on the other hand, is open-ended and can bind peptides of more diverse lengths, 10 to 30 amino acids, with most being 12 to 19.⁵⁸

Peptides located in class II MHC molecules are derived from proteins that have been consumed by APCs⁵⁹ (Fig. 70.2A). The proteins are taken up by phagocytosis, or receptor-mediated endocytosis in clathrin-coated pits, or engulfed by pinocytosis. Once internalized, the antigens are located in membrane-bound vesicles called endosomes. The endosomes then become continuous with lysosomes. The enzymology of the endolysosome has been described in some detail.^{59,60} There, in an acidic environment, disulfide bonds in proteins are first reduced by the enzyme GILT (gamma interferon-inducible lysosomal thiol reductase), and the resulting products are subsequently cleaved to peptides by proteases, predominantly cathepsins. The endosome fuses with an exocytic vesicle budding from the Golgi apparatus that contains newly made class II MHC molecules associated with invariant chain, which has been shown to play a critical role in the assembly, intracellular transport, and function of MHC class II molecules.⁶¹ In addition, a chaperone, HLA-DM, plays a critical role in the loading of peptides onto MHC class II molecules. HLA-DM is a peptide exchange factor that binds with empty and peptide-loaded class II molecules in endosomal and lysosomal compartments.⁶¹ In the fused vesicle, peptides are loaded into the class II MHC molecules. Fusion of the endosome with the plasma membrane ultimately displays the class II MHC molecule-peptide complexes on the cell surface.

P.1470

FIGURE 70.2. Presentation of peptides by major histocompatibility complex (MHC) molecules. A: MHC class II-restricted antigen processing and presentation to CD4 T cells. Exogenous protein antigens are taken up by antigen-presenting cells, disulfide bonds are reduced by the interferon (IFN)- γ -inducible lysosomal thiol reductase (GILT), and the proteins are then degraded in endosomal/lysosomal compartments by cathepsins (Cat). MHC class II α and β are synthesized in the endoplasmic reticulum (ER) and associate there with the MHC class II-associated invariant chain (Ii). The class II/Ii complexes then egress to endosomal compartments, where Ii is degraded by cathepsins, until only its class II-associated invariant chain (CLIP) region remains bound by class II. CLIP is then removed from class II by the human leukocyte antigen (HLA)-DM peptide exchange factor. Finally, class II is loaded with peptide and delivered to the cell surface for presentation to class II-restricted CD4 T cells. B: MHC class I-restricted antigen processing and presentation to CD8 T cells. Cytosolic proteins, derived from endogenously synthesized proteins or from cross-presented antigens (as indicated by the arrow), are degraded by immunoproteasomes that contain the interferon IFN- γ -inducible subunits LMP2 (2), LMP7 (7), and MECL-1 (M). Some of the resulting peptides are further processed in the cytoplasm by peptidases and then transported to the lumen of the endoplasmic reticulum (ER) by the transporter of antigen processing (TAP). Some of the peptides undergo

further processing in the ER by ER-associated aminopeptidases (ERAP). Peptide-receptive MHC class I heavy chain (HC)/ β_2 -microglobulin (β_2m) heterodimers in the ER associate with a variety of chaperones, including calreticulin (crt), ERp57, and tapasin (tpn). After binding with peptides, class I molecules undergo a conformational change, permitting their egress to the cell surface for presentation to class I-restricted CD8 T cells.

Peptides are prepared for presentation on class I molecules in a different fashion (Fig. 70.2B). These peptides are derived from intracellular protein synthesis.^{62,63} After protein synthesis, proteins introduced into the cytoplasm become the target of the proteasome, a cytoplasmic organelle whose major function is the degradation of proteins tagged for turnover by the addition of ubiquitin.^{64,65} During conditions of interferon- γ production such as infection, several proteasome subunits (LMP2, LMP7, and MECL-1) become upregulated and are incorporated into newly assembled proteasomes. Proteasomes that include these IFN- γ -inducible subunits are referred to as immunoproteasomes, whereas those that lack these subunits are called constitutive proteasomes. The IFN- γ -inducible proteasome subunits favor the generation of peptides that have increased affinity for MHC class I molecules.^{66, 67} and ⁶⁸ In addition to the proteasome, several cytoplasmic peptidases (e.g., TPPII, LAP, TOP) have been implicated in the generation of antigenic peptides, although they can cleave some epitopes as well.^{65,69} These peptides are then transported into the lumen of the endoplasmic reticulum (ER) by the transporter associated with antigen processing (TAP) proteins.⁶² Within the ER, peptides may be further trimmed by ER-resident aminopeptidases (i.e., ERAP1 and ERAP2).^{65,69,70} Assembly of class I MHC heavy chain molecules with β_2 -microglobulin requires the presence of peptides. Within the ER, empty MHC class I molecules are associated with a variety of chaperones, including calnexin, calreticulin, ERp57, and tapasin. Tapasin is a transmembrane protein that tethers empty class I molecules in the ER to TAP.⁷¹ Emerging evidence suggests that tapasin retains unstable MHC class I molecules within peptide-loading compartments until they bind with high-affinity peptides. The assembled MHC class I-peptide complex transits the Golgi apparatus, proceeds in a vesicle to the cell surface, and is displayed on the cell surface after fusion of the vesicle membrane with the plasma membrane.

There has been a lot of interest in the mechanisms whereby tumor cells initiate CD8⁺ T cell responses. Few tumors are derived from professional APCs and, therefore, do not effectively prime naive CD8⁺ T cells. It has now been established that tumor cells can be processed and presented by host APCs, particularly DCs, in a process that is referred to as cross-presentation (Fig. 70.2).^{72,73} Tumor antigens are then processed inside the APC, and peptides derived from these antigens are displayed on MHC class I molecules for recognition by CD8⁺ T cells. These APCs also express MHC class II molecules and can prime naive CD4⁺ T cells, which may be important for the generation of effective CD8⁺ memory responses. Once tumor antigen-specific CTLs are generated, they can kill tumor cells without the requirement for costimulation. While the precise mechanisms of cross-presentation remain poorly understood,⁷⁴ the concept of cross-presentation has important applications in the development of tumor vaccines.^{72,75}

T Lymphocyte Activation

The goal of antigen processing and presentation is the activation of appropriate T lymphocytes to proliferate, produce cytokines, and promote an immunologic reaction or become cytotoxic cells. Although the interaction of the T cell antigen receptor with antigen-MHC provides specificity of response and initiates the crucial events of activation, the interactions are few and have low affinity.⁷⁶ The interaction between T lymphocytes and APCs or target cells is initially stabilized by a number of nonspecific

P.1471

receptor-counterreceptor interactions, leading to development of an immunologic synapse with its central supramolecular activation cluster.^{77,78,79} Chief among these interactions is the coupling of CD2 on the T lymphocyte with lymphocyte function antigen-3 on the APC. Also involved is the interaction of the lymphocyte function antigen-1 molecule with intercellular adhesion molecule-1 and intercellular adhesion molecule-2. Once the cells have been apposed, the specific interaction of the T cell antigen receptor and the antigen-MHC can occur. It now appears that the T cell proceeds toward activation only if certain threshold numbers of TCR-MHC/antigen interactions occur.⁸⁰

The signal transduction pathways that result in T cell activation have been extensively reviewed,^{81, 82} and ^{83,84} and we will focus here on the most salient features (Fig. 70.3). Ligation of the TCR with an agonist peptide/MHC complex results in phosphorylation of the cytoplasmic portions of the CD3 and ζ components of the TCR. The cytoplasmic domains of CD3 and ζ contain several conserved peptide sequences called immunoreceptor tyrosine-based activation motifs (ITAMs) that are targets for intracellular protein tyrosine kinases that catalyze the phosphorylation of tyrosine residues in various protein substrates. The tyrosine kinase Ick interacts with the cytoplasmic domains of CD4 and CD8 and the tyrosine kinase fyn interacts with the TCR-CD3 complex. Binding of the TCR with peptide/MHC complexes results in receptor clustering,

bringing CD4/CD8 and Lck in close proximity of the ITAMs within the CD3 and ζ -chains. Lck and fyn subsequently phosphorylate tyrosine residues within the ITAMs, which become docking sites for the ζ -associated protein, ZAP-70, a member of the syk family of protein tyrosine kinases. The bound ZAP-70 then becomes a substrate for Lck, and phosphorylation of ZAP-70 results in its activation. Activated ZAP-70 phosphorylates several scaffolding proteins, including LAT (linker of activated T cells) and SLP-76, which, when phosphorylated, serve as docking sites for other proteins that, in turn, activate multiple signaling pathways. One of these signaling pathways involves changes in inositol lipid metabolism. Phospholipase C γ 1 (PLC γ 1) becomes tyrosine

P.1472

phosphorylated and activated as it associates with LAT. Activation of PLC γ 1 leads to the hydrolysis of a minor membrane lipid, phosphatidylinositol biphosphate (PIP₂), to yield inositol triphosphate (IP₃) and diacylglycerol (DAG). Each of these products activates downstream events. IP₃ induces a rapid increase of free Ca²⁺ by release from membrane-sequestered Ca²⁺ stores, whereas DAG and Ca²⁺ activate protein kinase C (PKC) θ . T cell activation also results in the activation of the ras and rac signaling pathways. Adapter proteins that are activated by phosphorylated LAT and SLP-76 result in the activation of the guanine nucleotide exchange factors SOS (son of sevenless) and vav, which activate the ras and rac signaling pathways, respectively.

FIGURE 70.3. Overview of signal transduction events involved in T lymphocyte activation. Interaction of the T cell receptor (TCR) and coreceptors with major histocompatibility complex (MHC)-peptide complexes on antigen-presenting cells (APCs) results in multiple signaling events that lead to the activation of several transcription factors that stimulate expression of numerous genes (e.g., the interleukin-2 [IL-2] gene). Note that the precise interactions between different adaptor proteins that participate in proximal TCR signaling events remain incompletely understood. AP, activated protein; DAG, diacylglycerol; Elk, Ets-like transcription factor; Erk, extracellular signal-regulated kinase; Grb, growth factor receptor-bound protein; IκB, inhibitor of κB; IP₃, inositol triphosphate; Itk, interleukin-2-inducible tyrosine kinase; Jnk, Jun N-terminal kinase; Jnkk, Jnk kinase; LAT, linker of activated T cells; Lck, lymphocyte-specific protein tyrosine kinase; Mek,

Mapk/Erk kinase; Mekk, Mapk/Erk kinase; NF, nuclear factor; NFAT, nuclear factor of activated T cells; PIP₂, phosphatidylinositol biphosphate; PKC, protein kinase; PLC, phospholipase C; RasGRP, Ras guanyl nucleotide-releasing protein; SLP-76, SH2 domain-containing leukocyte protein, 76-kD; Sos, son of sevenless; ZAP-70, ζ-associated protein kinase, 70-kD.

These signaling events ultimately result in the activation of a number of transcription factors, including NFAT, NF-κ B, and AP-1. Cytosolic Ca²⁺ binds with the Ca²⁺-dependent protein calmodulin, and Ca²⁺-calmodulin complexes subsequently activate several enzymes, including the serine/threonine phosphatase calcineurin. Calcineurin then dephosphorylates NFAT, which uncovers a nuclear localization signal that permits NFAT to translocate to the nucleus. Activation of NF-κB is dependent, at least in part, on activated PKCθ. NF-κB is normally found in the cytoplasm in association with a protein called inhibitor of κB (IκB). TCR signals result in phosphorylation of IκB, which is then targeted for degradation by the proteasome. Release of IκB uncovers a nuclear translocation signal in NF-κB that permits its translocation to the nucleus. AP-1 is a transcription factor composed of the proteins Fos and Jun, which are activated by the ras and rac signaling pathways, respectively.

The net result of this extremely complex activation system is the expression of new proteins, the acquisition of functional capacity, or the ability to proliferate. T lymphocyte activation is best understood as a culmination of events leading to IL-2 production.⁸⁵ The constraints on production of this cytokine are more rigorous than those relevant for production of other gene products (such as IL-2 receptor α-chain and transcription factors). The promoter of the IL-2 gene is made up of a number of binding sites for transcription factors, including two NFAT sites, an NF-κB site, and an AP-1 site.⁸⁶ The combination of production of IL-2 receptor α-chain and IL-2 provides an adequate stimulus for the T lymphocyte to successfully proliferate, giving rise to the antigen-specific clonal expansion of lymphocytes characteristic of immunologic responses. However, there are extraordinary controls against inappropriate activation of T lymphocytes.⁸⁷ In addition to a first signal delivered via the T cell antigen receptor complex, full activation of T cells also requires a second signal.⁸⁸ The best characterized origin of these second signals is the interaction of CD28 on the T lymphocyte surface with its cognate ligands CD80 (B7-1) and CD86 (B7-2) on the APC, the most potent of which is the DC. Failure to receive a second signal can lead the T lymphocyte to undergo anergy or apoptosis. Activation of T cells is also regulated by a variety of negative signals, including inhibitory receptors of the CD28 family such as CTLA-4 (cytotoxic T lymphocyte-associated protein 4), which interacts with CD80 and CD86, and PD-1 (programmed death-1), which interacts with PD-L1 and PD-L2.⁸⁸

TUMOR-ASSOCIATED ANTIGENS

Tumor antigens are like all other antigens of adaptive immunity. That is, with few exceptions, they are peptides that are presented to T lymphocytes in the cleft of an MHC-encoded protein.⁵⁵ The nature of peptide antigens responsible for immune responses to tumors has been described in a classic set of experiments.⁵⁵ In essence, two approaches were used. Neither made assumptions regarding the nature of the antigenic peptides. In the first approach, tumor-derived cloned CTLs were established. Next, a library of tumor complementary DNA or genomic DNA was constructed and used to transfect cells expressing appropriate MHC molecules but lacking the tumor-specific epitope. Transfected cells were tested for their ability to activate the tumor-specific CTLs. The transfected DNA was then recovered and sequenced, thus identifying the gene of origin. In the second approach, MHC molecules were isolated from tumor cells. Subsequently, peptides were eluted from the MHC molecules and fractionated chromatographically. These peptide fractions were then used to load APCs and presented to tumor-specific CTLs. Peptide fractions that stimulated T cell responses were then sequenced using conventional Edman degradation or tandem mass spectrometry. These approaches have revealed some surprising characteristics of tumor-specific antigens. Most tumor-specific antigenic peptides discovered thus far have been derived from proteins not usually expressed in any normal adult tissues⁸⁹ (with the exception of testis and ovary), such as P1A^{90,91} and MAGE-1,^{92,93} or they represent differentiation antigens characteristic of the cellular lineage of the tumor, such as tyrosinase,^{94, 95} and ⁹⁶ gp100,^{97, 98} and ⁹⁹ and MART1/Aa^{100,101} in melanoma.

Early definition of tumor antigens focused on MHC class I-restricted peptides.¹⁰² This seemed to be the obvious approach because most tumors express MHC class I structures, but few express MHC class II molecules. Also, the point of immunotherapy was to eliminate tumors—a job for cytolytic cells (i.e., for CD8⁺ cytotoxic lymphocytes that recognize antigen in the context of class I MHC molecules). Early clinical immunization trials^{103, 104} and ¹⁰⁵ demonstrated the feasibility and the potential efficacy of immunotherapy with peptides recognized by CD8⁺ T cells. However, immune responses were, in general, weak and short-lived. At the same time that the trials were being conducted, there was a growing realization of the importance of CD4⁺ T cells in the immune response against tumors.^{102,106,107} Techniques similar to those used to define antigens recognized by CTLs have been used to define antigens for CD4⁺ T cells. However, these techniques are slow and labor intensive. A genetic targeting expression system has been designed to expedite antigen

screening.¹⁰⁷ It is likely that incorporation of both MHC class I- and II-restricted epitopes in tumor vaccines will be required to generate potent antitumor responses.¹⁰⁸

While this direct approach to tumor antigen recognition has proceeded, other investigators have asked whether certain appealing target proteins could be immunogenic. In particular, molecules involved in the process of malignant transformation provide attractive targets for therapeutic intervention.¹⁰⁹ Because loss variants of tumor cells bearing these oncogenic proteins would presumably be nonmalignant,¹¹⁰ an immunologic assault on these proteins might be particularly effective. Evidence has been provided that immune responses to both mutated and overexpressed oncogenic proteins can occur in patients with malignancy or can be elicited in animals. Target oncogenic proteins include mutated Ras,¹¹¹ HER-2/Neu,^{112,113} BCR-ABL,^{114,115} PML-RAR α ,¹¹⁶ and mutated p53.¹¹⁷

A newer approach to definition of tumor-specific antigen targets for humoral immunity, termed SEREX, has been introduced.¹¹⁸ In the SEREX approach, a complementary DNA library is prepared from a patient's tumor specimen, packaged into phage vectors, and expressed in bacteria. Recombinant proteins from bacterial clones are transferred to nitrocellulose membranes and identified as relevant antigens by reactivity with IgG antibodies present in the patient's serum. Early studies defined three classes of antigens: (a) known tumor antigens, such as MAGE-1, MAGE-4a, and tyrosinase; (b) products of known genes, such as restin; and (c) unknown gene products.^{119,120} Because the cellular and humoral arms of immunity work in concert, it is likely that targets of antibody production will also prove to be targets of cellular immunity. The SEREX method provides a direct approach to the definition of potentially relevant tumor antigens.

P.1473

TUMOR-HOST INTERACTIONS: BEYOND IMMUNOSURVEILLANCE

While the immune system can protect against the development of tumors, interactions between developing tumors and the host are complex. Tumors often develop means to evade immune responses, and tumors that develop in immunocompetent hosts are often more immunogenic than those that develop in immunodeficient hosts. Finally, it is now also well-recognized that the immune system can play both tumor-suppressing and tumor-promoting roles.

IMMUNE EVASION BY TUMORS

Many tumors have devised ways to evade immune responses.^{18, 56, 121} First, tumors may lose expression of the antigens that were recognized by antibodies or CTLs. Second, many tumors downregulate expression of MHC class I molecules, rendering these cells resistant to lysis by CTLs.^{122,123} Third, tumors may fail to induce effective CTL responses because of the absence of costimulatory molecules and/or resistance to uptake by APCs and cross-presentation.¹²⁴ Instead of inducing an effective immune response, some tumors may actively promote tolerance induction, by inducing anergy, exhaustion, or deletion of tumor antigen-specific T cells.^{125,126} This might involve the generation of tumor antigen-specific regulatory T cells (Tregs),¹²⁷ induction of inhibitory costimulatory molecules such as CTLA-4 and PD-1 on tumor antigen-specific T cells,¹²⁶ and/or expansion of myeloid-derived suppressor cells, a heterogeneous group of myeloid progenitor cells and immature myeloid cells that can inhibit lymphocyte function.¹²⁸ Fourth, tumor cells may actively suppress immune responses by secretion of suppressive cytokines such as TGF- β or by expression of the Fas ligand, which may engage with Fas on lymphocytes to induce apoptosis.¹²⁵ Fifth, the tumor microenvironment, most notably the tumor stroma, may be critical in preventing immunologic destruction of tumor cells by effectively generating an immune privileged site.

Immune Sculpting of Tumors

In 2001, an important study showed that the immune system not only can protect against the development of tumors, but also can influence the quality of tumors—that is, the immune system of the host in which a tumor develops influences the immunogenicity of the tumor.²³ These investigators showed that RAG2-deficient mice not only develop MCA-induced tumors at higher frequency, but that a substantial portion of these tumors was spontaneously rejected upon transplantation in syngeneic immunocompetent mice. In sharp contrast, tumors derived from immunocompetent mice usually grew progressively in immunodeficient mice. Thus, these findings demonstrated that the immune system not only protects the host from tumor formation but also sculpts the immunogenicity of the tumors, in a process that is now referred to as cancer immunoediting.^{17,18,129} Cancer immunoediting has been posited to proceed through three sequential stages: (a) an elimination phase where the immune system recognizes and destroys tumors before they become clinically apparent, (b) an equilibrium phase where tumor cells that escaped the elimination phase are continuously destroyed, with emergence of resistant tumor cell variants due to immune pressure, and (c) an escape phase where tumor cells that have

successfully evaded immune responses progressively grow. The cancer immunoeediting hypothesis represents an extension or modern version of the immunosurveillance hypothesis.

Tumor-promoting Immune Responses

Discussion of tumor-host interactions would not be complete without at least a mention of the tumor-promoting role of the immune system.¹³⁰ Many environmental factors, including chronic infections, tobacco smoke, and inhaled pollutants, as well as dietary factors and obesity, are associated with a low-level chronic inflammation and represent risk factors for cancer development. Chronic inflammation can contribute to tumor genesis at all stages, by generating nontoxic stress during the initiation of cancer, inducing cellular proliferation to promote cancer development, and enhancing angiogenesis and tumor invasion to promote cancer progression.¹³⁰

APPROACHES TO IMMUNOTHERAPY

Immunotherapy is the use of the immune system or its components to target and eradicate tumors. B cell lymphomas are considered to be the most immune responsive of all human cancers.¹³¹ They can undergo spontaneous regression,¹³² and partial responses have been elicited through the use of nonspecific immune activators, such as bacillus Calmette-Guérin and IL-2.^{133,134} Thus, follicular B cell lymphomas represent excellent candidates for immunotherapy.

Antibody Approaches

The most common form of immunotherapy employed in the treatment of cancer is passive immunotherapy, which involves the administration of manufactured antibodies that target a particular antigen (Table 70.1). Monoclonal antibodies have emerged as a potent and effective molecularly targeted therapy for human cancer, usually in combination with chemotherapy.^{135,136} Therapeutic mAbs, such as rituximab and alemtuzumab, are examples of a passive approach. Currently, several B lymphocyte antigens, including CD20, CD22, and CD52, have been utilized as targets for immunotherapy. These targets, while found uniformly on lymphoma cells, are also expressed on normal immune system components, such as normal B lymphocytes.^{134,137,138} Personalized immunotherapy, also referred to as Id vaccine therapy, is a patient- and tumor-specific approach. This modality targets unique protein determinants of the immunoglobulin molecules produced by the malignant B cell clone and does not appear to result in depletion of normal lymphocytes or subsequent impairment of the immune system. This technique stimulates the patient's immune system to attack the tumor through the use of both the humoral and cellular arms of the immune system. As a result, immunologic memory may be established which could translate into long-term remission. Some of these are being tested in phase II and III trials (Fig. 70.4).¹³⁹

TABLE 70.1 PERSONALIZED ACTIVE IMMUNOTHERAPY VERSUS PASSIVE IMMUNOTHERAPY

Personalized Active Immunotherapy	Passive Immunotherapy
Tumor-specific	Not tumor-specific
Stimulates host immuneresponse	Does not stimulate host immune response
Induces immunologic memory	Temporary antitumor effect
May produce long-term immunity	Requires retreatment
Induces both the cellular and humoral arms of the immune system	Induces the humoral arm of the immune system only (ADCC, CDC)
Requires patient tumor sample for production	Does not require patient tumor sample

ADCC, antibody-dependent cellular cytotoxicity; CDC, complement-dependent cytotoxicity.

FIGURE 70.4. Idiotype as a tumor-specific antigen for B-lymphoma cells. Each B lymphocyte expresses an immunoglobulin molecule on its surface, the idiotype (Id) protein, which is capable of recognizing and binding to a unique antigen. When B lymphocytes undergo malignant transformation, the Id sequences are maintained by the malignant clones and can thus serve as tumor-specific antigen. MHC, major histocompatibility complex; TCR, T cell receptor. (Adapted from Vose JM. Personalized immunotherapy for the treatment of non-Hodgkin's lymphoma: a promising approach. *Hematol Oncol* 2006;24:47-55.)

Unconjugated Antibodies

Unaltered antibodies have been used since the earliest trials of monoclonal antibody therapy in humans.^{140, 141} and ¹⁴² In early trials, success was limited by the absence of suitable tumor cell surface targets, antigenicity of first-generation (murine) mAbs in humans, modulation of the target structure from the tumor cell surface, and poor recruitment of immune effector mechanisms.^{143,144} However, enthusiasm for this approach was rekindled by the enormous success of genetically engineered, chimeric, or fully humanized versions of mAbs, most notably rituximab for lymphoid malignancies and trastuzumab in solid tumors.¹⁴⁴

Rituximab is a chimeric monoclonal antibody with humanized framework and Fc regions. It is directed against the CD20, pan B cell antigen. CD20 is present on pre-B cells and mature B cells, but not on precursor cells or terminally differentiated plasma cells. The function of CD20 remains poorly understood,¹⁴⁵ although it has been implicated in B cell activation, regulation of B cell growth, and regulation of transmembrane calcium flux. The antibody fixes human complement and elicits antibody-dependent cellular cytotoxicity (ADCC). Rituximab was approved for use as monotherapy in patients with low-grade or follicular CD20⁺ non-Hodgkin lymphoma (NHL) in 1997. In the pivotal trial involving 166 patients, reported by McLaughlin et al.,¹⁴⁶ patients had relapsed or chemotherapy-resistant disease. Patients received four weekly infusions of rituximab at 375 mg/m². Rituximab produced a tumor response in one-half of the patients, with a median duration of

response of 11.8 months, comparable to the patients' response duration on the last chemotherapy treatment. Human antichimeric antibody responses were uncommon. The most common adverse experience associated with rituximab was a constellation of acute infusion-related events, including chills, fever, headache, rhinitis, pruritus, vasodilation, asthenia, and angioedema. This syndrome can progress to hypotension, urticaria, bronchospasm, and, rarely, death. The risk is particularly great in patients with high circulating white cell counts.¹⁴⁷ Other toxicities were, in general, mild and infrequent.¹⁴⁸ Neutropenia and thrombocytopenia were unusual. Circulating B cells were depleted and remained low until recovery at a median of 12 months. Immunoglobulin levels, however, remained normal. No increased incidence of infections was seen. Rituximab was evaluated again in the relapsed, refractory, low-grade, or follicular NHL patient population, using eight weekly infusions rather than four.¹⁴⁹ This extended regimen produced a response rate of 57% and a time to progression (TTP) in responding patients of more than 19.4 months. Adverse event reporting was commensurate with the longer treatment period.

Davis et al.¹⁵⁰ reported a response rate of 43% and a TTP of 8.1 months in the patients with a significant poor prognostic factor, importantly in patients with low-grade or follicular NHL who had bulky disease, using the standard 4-infusion regimen. These investigators also showed an overall response rate (ORR) of 40% in patients who had progressed after an initial response to rituximab, with an estimated median TTP for responding patients of 17.8 months.¹⁵¹

Rituximab has been used in the first-line treatment of patients with indolent lymphoma, both as monotherapy and in combination with chemotherapy. Hainsworth¹⁵⁰ reported the results of rituximab as monotherapy in 39 previously untreated patients. Patients received rituximab \times 4 at the usual dose and schedule, with an ORR of 54%. Patients who had responded or who had stable disease were treated with an additional four weekly treatments of rituximab at 6 months intervals to a maximum of 4 treatment cycles. The ORR rose to 72% after the second course of treatment. Progression-free survival (PFS) at 1 year was 77%. The addition of rituximab to cyclophosphamide, hydroxydaunomycin, oncovin (vincristine), and prednisone (CHOP) chemotherapy produced impressive results. Patients were treated with six infusions of rituximab, one associated with each of six cycles of CHOP. In 40 patients with newly diagnosed ($n = 31$) or relapsed/refractory ($n = 9$) low-grade or follicular NHL, rituximab plus CHOP produced an ORR of 95% and complete response (CR) rate of 55%. With a median follow-up of 29 months, median duration of response and median TTP had not been reached. Eight of 18 patients tested for the BCL-2 [t(14;18)] translocation by PCR testing were positive at initiation of therapy. Seven of these 8 patients, after therapy, became negative for the translocation. The authors concluded that the addition of rituximab to CHOP produced benefits in efficacy parameters without significant additional toxicity. Elimination of PCR positivity for the t(14;18) translocation had not been previously reported with CHOP alone.

Rituximab also has been used with success in patients with more aggressive lymphomas. Vose et al.¹⁵¹ reported the results of rituximab plus CHOP chemotherapy (again using 6 infusions of rituximab in association with 6 cycles of CHOP) in 33 previously untreated patients with advanced aggressive B cell NHL. The combination produced an ORR of 94% and a CR rate of 61%. With a median observation time of 26 months, 29 of 31 patients achieving a remission were in continuing remission at the time of the report. Thirteen patients were BCL-2 positive at study entry. Eleven of these 13 patients became BCL-2 negative after treatment, and 10 of the 11 remained BCL-2 negative. The authors concluded that the results were achieved without significant added toxicities above those expected with CHOP. The Groupe d'Etude des Lymphomes de l'Adulte undertook a study to compare the utility of CHOP with that of rituximab plus CHOP in elderly patients with diffuse B cell lymphoma.¹⁵² Patients between the ages of 60 and 80 years with untreated, diffuse large B cell lymphoma were eligible for the study. Patients were randomly assigned to receive 8 cycles of CHOP chemotherapy (197 patients) or to receive 8 cycles of CHOP, each given after an infusion of rituximab (202 patients). Rituximab plus CHOP produced a superior rate of remission, 76% versus 63% ($P = 0.005$). With

P.1475

a median follow-up of 2 years, event-free and overall survivals (OSs) were significantly higher in the rituximab plus CHOP group ($P < 0.001$ and $P = 0.007$, respectively). These results were achieved without a significant incremental increase in toxicity. The addition of rituximab to CHOP reduced the risk of treatment failure (risk ratio, 0.54; 95% confidence interval [CI]: 0.44, 0.77) and the risk of death (risk ratio, 0.64; CI: 0.45, 0.89). The addition of immunotherapy to standard chemotherapy had accomplished what 25 years of chemotherapy manipulation had failed to do (i.e., improve on the results of CHOP chemotherapy).^{153,154} Maintenance rituximab has also been found to prolong event-free survival (EFS) and response duration in follicular lymphoma.¹⁵⁵ In subsequent ongoing randomized phase III studies,^{156,157} rituximab maintenance regimen provided significant PFS and OS at 3-year¹⁵⁶ and 4-year¹⁵⁷ follow-up assessments in both previously treated¹⁵⁶ and untreated¹⁵⁷ patients with follicular NHL, compared with no further treatment, though no difference in OS has been reported by other investigators.¹⁵⁸

The mechanism by which rituximab produces these impressive results is less clear. A number of possible mechanisms have been considered: initiation of complement-mediated cell lysis, induction of ADCC, and signaling via CD20 leading to programmed cell death and/or sensitization to cytotoxic drugs. Pretreatment lymphoma cells from 29 patients were examined by flow cytometry for expression of complement inhibitors CD46, CD55, and CD59.¹⁵⁹ Expression of these cell surface inhibitors of complement activation was not predictive of outcome to rituximab therapy. Considerable evidence suggests that induction of ADCC plays an important role in rituximab's antilymphoma effects. A rituximab-like antibody for which an IgG4 γ framework was substituted for the IgG1 framework of rituximab was incapable of producing B cell depletion in primates.¹⁶⁰ Rituximab was relatively ineffective in eliminating Raji B cell implants in FcR γ -/-/nu/nu knockout mice compared to nu/nu mice.¹⁶¹ These mice lack the activating receptor for Fc portions of antibodies, a critical component of the antibody-dependent cell-mediated cytotoxicity mechanism. In patients, response to rituximab has been shown to be associated with homozygosity for the high-affinity allotype of the Fc γ R1IIa receptor.¹⁶² Evidence also exists that rituximab signaling or interference with normal signaling via CD20 may directly induce apoptosis or sensitize cells to the deleterious effects of chemotherapeutic agents.¹⁶³ A direct, growth inhibitory effect of rituximab, with accompanying apoptosis, on cell lines cultured in the absence of complement was demonstrated.¹⁶⁴ Anti-CD20-associated apoptosis has been associated with upregulation of the proapoptotic protein, Bax¹⁶⁵ and downregulation of antiapoptotic protein BCL-2 through inactivation of STAT3.¹⁶⁶ Downregulation of STAT3 appears to be a result of downregulation of an IL-10 autocrine pathway.¹⁶⁷ These changes and/or others may be responsible for increased sensitivity to chemotherapeutic agents.¹⁶⁸

In the wake of the success of rituximab, a number of other antilymphoma mAbs have entered the clinic.¹⁶⁹ Alemtuzumab is a humanized IgG1 κ monoclonal antibody directed against the CD52 cell surface antigen.¹⁴⁴ CD52 is expressed on normal and malignant lymphocytes of B- and T cell lineage, as well as NK cells, monocytes, and macrophages. Alemtuzumab is indicated for the treatment of B cell chronic lymphocytic leukemia (CLL) in patients who have been treated with alkylating agents and who have failed fludarabine therapy. The pivotal clinical trial was carried out in 93 patients with fludarabine-refractory CLL.¹⁷⁰ Alemtuzumab produced a response rate of 33%. Virtually all of the responders were partial responders; the CR rate was 2%. Median duration of response was 7 months. Median TTP was 4.7 months for the group as a whole; 9.5 months for responders. The most common adverse events were infusion related—most were grade 1 or 2 in severity, including rigors in 90% of patients (grade 3 in 14%), fever in 85% of patients (grade 3 or 4 in 20%), nausea in 53% of patients, and vomiting in 38% of patients. Infusion-associated side effects declined with subsequent infusions. During the study, 28% of patients experienced dyspnea, 17% experienced hypotension, and 3% experienced hypoxia. Overall, 55% of patients developed an infection during the study. Approximately one-half of these infections were considered serious (grade 3 or 4). Septicemia occurred in 15% of patients, and two deaths resulted. Opportunistic infections occurred in 12% of patients. Ten percent of patients died during or within 30 days of treatment—one-third of these were attributed to progressive disease. Twenty-four percent of patients discontinued treatment because of a drug-related side effect. Most patients who discontinued had not responded to therapy. Serious infusion-related events associated with alemtuzumab appear to result from ligation of CD16 on NK cells resulting in what has been termed cytokine storm—release of IL-6, TNF- α , and interferon.¹⁷¹ Prolonged immunosuppression after use of alemtuzumab can result in opportunistic infections.¹⁷² Treatment schemas now include the routine use of prophylaxis with both antibiotics and antivirals.

To improve on the immunogenicity and efficacy of rituximab, the last few years have seen the development of new generations of anti-CD20 monoclonal antibodies (mAbs) with enhanced antitumor activity resulting from increased complement-dependent cytotoxicity (CDC) and/or ADCC and increased Fc binding affinity for the low-affinity variants of the Fc γ R1IIa receptor (CD16) on immune effector cells. These second-generation mAbs, such as ofatumumab, veltuzumab, and ocrelizumab, are in clinical development. They are humanized or fully human to reduce immunogenicity, but with an unmodified Fc region. Ofatumumab is a fully human anti-CD20 IgG1 mAb in clinical development for hematologic malignancies and autoimmune diseases. Ofatumumab specifically recognizes an epitope encompassing both the small and large extracellular loops of the CD20 molecule, and is more effective than rituximab at CDC induction and killing target cells. Veltuzumab (IMMU-106, hA20) is a humanized anti-CD20 mAb with complementarity-determining regions similar to rituximab. This antibody has enhanced binding avidities and a stronger effect on CDC compared to rituximab. Ocrelizumab is a humanized mAb with the potential for enhanced efficacy in lymphoid malignancies compared to rituximab because of increased binding affinity for the low-affinity variants of the Fc γ R1IIa receptor. Third-generation mAbs are also in clinical development. They are also humanized mAbs, but in addition they have an engineered Fc to increase their binding affinity for the Fc γ R1IIa receptor. Third-generation mAbs also in clinical development include AME-133v, PRO131921, and GA-101 (Table 70.2), with enhanced affinity for the Fc γ R1IIa receptor and an enhanced ADCC activity compared to rituximab.¹⁷³

Two other mAbs with potential utility in the treatment of lymphoma are in early clinical development.^{169,174} Epratuzumab is a humanized IgG1 monoclonal antibody directed against the CD22 antigen. CD22 is a pan-B cell antigen with distribution similar to that of CD20. Epratuzumab has a favorable safety profile in early trials. Approximately 50% of follicular

lymphoma patients and 25% of diffuse large-cell lymphoma patients responded in a small phase II trial. Some of the responses have been long-lived. A recent phase II trial testing the safety and efficacy of combining epratuzumab with R-CHOP (ER-CHOP) in untreated DLBCL showed that the addition to standard R-CHOP, E 360 mg/m² intravenously, administered for 6 cycles in 107 patients, showed similar toxicity to standard R-CHOP. ORR in the 81 eligible patients was 96% (74% CR/CR unconfirmed [Cru]) by computed tomography scan and 88% by positron emission tomography. By intention to treat analysis, at a median follow-up of 43 months, the EFS and OS at 3 years in all 107 patients were 70% and 80%, respectively. Comparison with a cohort of 215 patients who were treated with R-CHOP showed improved EFS in the ER-CHOP

P.1476

patients. ER-CHOP was well tolerated and results appear promising as a combination therapy.¹⁷⁵

TABLE 70.2 ANTI-CD20 MONOCLONAL ANTIBODIES (mAbs) APPROVED OR POTENTIALLY USEFUL FOR LYMPHOID MALIGNANCIES

mAb	Company	Antibody characteristics	Direct Comparison with			rituximab
			ADCC	CDC	effects	
Rituximab (Rituxan [®] , Mabthera [®])	Hoffman La Roche	Type I, first-generation mouse/human chimeric IgG1	++	++	+	
Rituximab (Rituxan [®] , Mabthera [®])	GlaxoSmithKline plc/Genmab A/S	Type I, first-generation, human IgG1	++	+++++		Binding to different CD20 epitope; more effective at CDC

Apolizumab is a humanized IgG1 monoclonal antibody that binds to a variant of the HLA-DR β -chain. The antibody induces complement-mediated lysis, ADCC, and tyrosine phosphorylation signaling events in cell lines *in vitro*. The antibody binds to approximately 70% of lymphoma specimens. Administration of the antibody to patients results in typical infusion-related side effects. Four of 8 patients with follicular lymphoma responded to apolizumab. A phase I/II dose-escalation study of thrice-weekly apolizumab (1.5, 3.0, 5.0 mg/kg/dose) for 4 weeks in relapsed CLL resulted in significant toxicity and lack of efficacy; thus, further clinical trials of apolizumab were discontinued, as were other trials in lymphoma and solid tumors.¹⁷⁶ Milatuzumab (hLL1, IMMU-115; Immunomedics) is a fully humanized mAb specific for CD74, a cell surface-expressed epitope of the HLA class II-associated invariant chain. CD74 plays an important role as an accessory signaling molecule and survival receptor in the maturation and proliferation of B cells by activating the PI3K/Akt and the NF- κ B pathways.¹⁷⁷ Milatuzumab demonstrated antiproliferative activity in transformed B cell lines, improved survival in preclinical models, and is presently being evaluated for the treatment of several hematologic malignancies.

Inroads are being made in other hematologic cancers. In multiple myeloma, it was recently reported that the cell surface glycoprotein CS1 (CD2 subset 1, CRACC, SLAMF7, CD319) was highly and universally expressed on myeloma cells while having restricted expression in normal tissues. Preclinical studies showed that elotuzumab (formerly known as HuLuc63), a humanized mAb targeting CS1, could induce patient-derived myeloma cell killing within the bone marrow microenvironment using a SCID-hu mouse model and that the CS1 gene and cell surface protein expression persisted on myeloma patient-derived plasma cells collected after bortezomib administration. *In vitro* bortezomib pretreatment of myeloma targets significantly enhanced elotuzumab-mediated ADCC, both for OPM2 myeloma cells using NK cells or peripheral blood mononuclear cells from healthy donors and for primary myeloma cells using autologous NK effector cells. In an OPM2 myeloma xenograft model, elotuzumab in combination with bortezomib exhibited significantly enhanced *in vivo* antitumor activity. Elotuzumab is currently in a phase I clinical trial in relapsed/refractory myeloma.¹⁷⁸ In AML, one strategy for the development of mAbs targeting human AML stem cells involves first identifying cell surface antigens preferentially expressed on AML LSC (leukemia stem cell) compared with normal hematopoietic stem cells. In recent years, a number of such antigens have been identified, including CD123, CD44, CLL-1, CD96, CD47, CD32, and CD25. Moreover, mAbs targeting CD44, CD123, and CD47 have demonstrated efficacy against AML LSC in xenotransplantation models. Hopefully, these antibodies will ultimately prove to be effective in the treatment of human AML.¹⁷⁹

Anti-idiotypic Therapy

Much time and energy were expended searching for tumor antigens, particularly after the development of mAb techniques.¹⁷ These brute-force immunization, hybridization, and screening procedures yielded little. They defined only a single truly tumor-specific antigen. That was the Id of clonally distributed antibody expressed on the surface of certain B cell lymphomas. Because it represents a unique protein structure within the combining site of the antibody, the Id can serve as an antigen for antibody production. This fact was demonstrated by Sirisinha and Eisen¹⁸⁰ in the early 1970s. Furthermore, they demonstrated that an immunologic response to Id could lead to tumor protection.¹⁸¹

Levy and Miller¹⁸² have explored the utility of anti-Id strategies in indolent B cell lymphoma over many years. Initially, these investigators raised custom-made anti-Id mAbs¹⁸³ for passive administration. A first patient with far advanced,

P.1477

chemotherapy-refractory disease received anti-Id mAbs. Gradual reductions in serum Id and tumor volume were noted. The patient then entered a long-term complete remission.¹⁸⁴ In an initial series of patients treated with anti-Id therapy, 11 patients were reported.¹⁸⁵ In this group, a second near-complete remission, four partial remissions, and five insignificant responses were seen. There was little toxicity associated with administration of the anti-Id antibodies. The most common side effects were chills and fever. Transient shortness of breath, headache, nausea, emesis, diarrhea, and myalgias were occasionally observed. Unusual toxicities included transient leukopenia or thrombocytopenia and transient elevations of hepatic enzymes. Several interesting problems of anti-Id therapy were noted in this early series: the interfering effect of

circulating Id, the development of human antimouse antibody, and the emergence of Id-negative tumor cell variants.^{186, 187, 188} and ¹⁸⁹ An attempt to reduce the incidence of emergence of Id-negative lymphoma variants with a short course of chlorambucil was unsuccessful.¹⁹⁰ The cumulative experience suggests that anti-Id therapy can result in a 15% CR rate and a 50% partial response rate. The mechanism of tumor response in these trials remains unclear. However, response in these trials correlated with anti-Id-induced signal transduction events in the lymphoma cells, suggesting that activation of apoptotic pathways may lead to lymphoma cell death after interaction of the anti-Id antibody with the lymphoma surface-bound immunoglobulin receptor.¹⁹¹ This group has turned to active immunization strategies in indolent lymphoma (see section "Immunization Strategies").

Radioimmunotherapy

The use of immunoglobulin-radionuclide conjugates in cancer treatment represents appropriation of a classic guided-missile strategy. In theory, the antibody homes to its antigenic target and delivers a cytotoxic assault on the cell to which it attaches. Radionuclides offer certain advantages over other cytotoxic agents. They do not have to be internalized. Radioactive particles can deliver their effects over distances of 1 to 5 mm, thus limiting collateral damage to normal tissues while still potentially providing antitumor effects against antigen-negative variants in the vicinity in what has been termed a cross-fire effect. The principles of radiation physics underlying radioimmunotherapy (RIT) have been reviewed by Press and Rasey.¹⁹² Radiolabeled antibodies deliver continuous, exponentially decreasing, low-dose-rate radiation. Traditional external beam radiotherapy delivers intermittent, fractionated radiation at higher dose rates. The most commonly used isotopes for RIT have been iodine 131 (I-131) and yttrium 90 (Y-90). These radionuclides kill cells primarily through emission of β particles, resulting in DNA strand breaks. The β particles of Y-90 are more energetic than those of I-131. They affect cells in a radius of approximately 5 mm compared to approximately 1 mm for those of I-131. I-131 also emits γ rays. This allows direct imaging of the distribution of the radioconjugate but raises issues regarding shielding and health care worker and family member safety.

Several recent reviews attest to the evolution of this field.^{193,194} A number of theoretical and experimentally generated concerns with RIT appear to have been overcome in the successful clinical studies described below. There had been concern that effective delivery of radioimmunoconjugates would be impeded by heterogeneous tumor vasculature, slow diffusion of these large molecules in interstitial spaces, heterogeneous biodistribution in tumor nodules, and high intratumoral pressures.

The two products in clinical use presently, Y-90 ibritumomab tiuxetan (Zevalin) and I-131 tositumomab (Bexxar), are both directed against the anti-CD20 antigen of B lymphocytes, the same structure targeted by rituximab. Both products are based on murine mAbs. Both are administered after infusion of unconjugated anti-CD20 antibodies—rituximab in the case of Zevalin and tositumomab in the case of Bexxar. Both have used nuclear medicine imaging as a preparatory step to administration, but it is no longer required for Y-90 ibritumomab. Simple dosimetry is accomplished for I-131 tositumomab by capturing whole-body gamma counts after infusion of a 5 mCi "dosimetric dose" of the agent. Imaging was carried out in Y-90 ibritumomab tiuxetan-treated patients to assure normal biodistribution. Whole-body dosimetry is carried out in I-131 tositumomab-treated patients to allow calculation of a patient-specific activity (mCi) to deliver a desired total-body dose of radiation (cGy). Both have been studied most extensively in indolent lymphoma and have been approved for treatment of patients with relapsed or refractory follicular, including rituximab refractory, or transformed B (CD20⁺) NHL.

The approval for ibritumomab tiuxetan rested primarily on two clinical studies. The first was a randomized controlled comparison of the effectiveness of Y-90 ibritumomab tiuxetan to that of rituximab in patients with relapsed or refractory, follicular, or transformed B cell NHL.¹⁹⁵ The study involved 143 patients; 73 randomized to Y-90 ibritumomab tiuxetan (single administration), and 70 randomized to rituximab (weekly \times 4). The median number of prior therapies was 2. Approximately one-half of the patients failed to respond to or had a TTP of less than 6 months to their last chemotherapy regimen. Y-90 ibritumomab tiuxetan produced a statistically superior response rate (using the response definitions of the International Workshop), 80% versus 56% ($P = 0.002$). The number of durable responders at 6 months favored Y-90 ibritumomab tiuxetan-treated patients, but the significance of the observation was lost at 9 months and 12 months. Median TTP (estimated by Kaplan-Meier methods) was 11.2 months for patients treated with Y-90 ibritumomab tiuxetan and 10.1 months for patients treated with rituximab ($P = 0.173$). Grade 3 and 4 nonhematologic adverse events were unusual in both groups. Y-90 ibritumomab tiuxetan produced grade 3 or 4 neutropenia in 57% of patients, grade 3 or 4 thrombocytopenia in 60% of patients, and grade 3 or 4 anemia in 2% of patients. One patient in the Y-90 ibritumomab tiuxetan-treated group developed myelodysplasia. One patient in the rituximab-treated group developed pancreatic carcinoma. The second trial was a phase II experience in 57 patients who had failed to respond to rituximab or had a TTP of ≤ 6 months.¹⁹⁶ These patients had a median of 4 prior therapies, and 74% had bulky tumors (greatest diameter ≥ 5 cm).

In this patient population, Y-90 ibritumomab tiuxetan produced a response rate of 74% and CR rate of 15%. The median TTP was estimated at 6.8 months. Grade 4 neutropenia occurred in 35% of patients, grade 4 thrombocytopenia in 9% of patients, and grade 4 anemia in 4% of patients.

The pivotal study for I-131 tositumomab enrolled 60 patients with refractory or transformed low-grade NHL who had been treated with at least two different qualifying chemotherapy regimens.¹⁹⁷ Patients must also have failed to achieve an objective response or relapsed within 6 months after completion of their last qualifying chemotherapy (LQC) regimen. Median age was 60 years, and other poor prognostic features included: median of 4 prior therapies, bulky disease, bone marrow involvement, elevated serum lactate dehydrogenase, advanced stage, and transformation from an initial low-grade histology to a higher-grade histology in 38% of the patients. A statistically significant improvement in the primary endpoint was achieved, with a longer duration of response (>30 days) after I-131 tositumomab therapy (n = 26) compared to patients after their LQC (n = 5; P < 0.001). Improvements in secondary efficacy endpoints after I-131 tositumomab compared to those after LQC were also achieved: overall response (47% vs. 12%; P < 0.001), duration of response (11.7 vs. 4.1 months; P < 0.001), and CR (22% vs. 2%; P = 0.002). Fifteen of 60 patients (25%) were classified as long-term responders (patients with a MIRROR Panel-assessed TTP of a year or more). Nine (15%) of the 60 patients remained in CR, with TTP ranging from 41+ to 57+ months.

P.1478

A second trial examined the incremental benefit of the radioconjugate (I-131 tositumomab) compared to the nonradioactive antibody (tositumomab).¹⁹⁸ This study was a randomized, two-arm, open-label, multicenter study that enrolled patients with chemotherapy-relapsed or refractory low-grade or transformed low-grade NHL. Patients were randomized to receive either I-131 tositumomab therapy or unlabeled tositumomab alone. The primary endpoint was a comparison of the rates of CR. Secondary endpoints included ORR, duration of responses, and TTP. A total of 78 patients (18% with transformation) participated in the study. Patients had been previously treated with one to three chemotherapy regimens. One or more therapies must have included an anthracycline, anthracenedione, or alkylating agent. A significant difference was observed for the primary efficacy endpoint. The CR rate was 33% (14 of 42 patients) for the patients treated with I-131 tositumomab compared to 8% (3 of 36) for patients treated with unlabeled tositumomab (P = 0.012). In addition, the ORR was greater after treatment with I-131 tositumomab: 23 of 42 patients (55%) compared to 7 of 36 patients (19%; P = 0.002). Nineteen patients initially treated with the unlabeled antibody crossed over to receive I-131 tositumomab after disease progression. A CR then was observed in 42% (8 of 19 patients) and an ORR in 68% (13 of 19 patients) in the crossover patient population. A total of 20 patients (33%) from the I-131 tositumomab-treated populations, including patients in the crossover arm, were classified as having a long-term response, including ten patients continuing in CR, with TTP ranging from 23+ to 59+ months.

The efficacy of I-131 tositumomab was also evaluated in patients who had progressed after rituximab.^{199,200} Patients must have had prior treatment with at least four doses of rituximab without an objective response, or to have progressed during or after treatment. Twenty-four patients did not respond to their last treatment with rituximab, and, of the 16 patients who did respond to rituximab, five patients had a duration of response exceeding 6 months. A response occurred in 27 of 40 patients (68%), with a median duration of response of 14.7 months (95% CI; 10.6 months no response). A CR occurred in 12 of 40 patients (30%); the median duration of CR had not been reached (95% CI; 11 months no response). Twenty-four patients had a longer (at least 30 days) duration of response after I-131 tositumomab than after rituximab; 5 patients had a longer duration of response after rituximab than after I-131 tositumomab; 9 patients had equivalent durations of response; and 2 patients were censored (P < 0.001). A total of 14 patients (35%) had a TTP of 12 months or longer. The median PFS was 10.4 months (95% CI, 5.7 to 8.6) for all patients and 24.5 months for confirmed responders (95% CI, 16.8 to not reached [NR]). PFS for 15 confirmed CR patients was NR with an estimated 3 years PFS of 73%. Prior response to rituximab did not significantly affect the confirmed OR rate, duration of response, or median PFS.

Radioiodinated tositumomab and Y-90 ibritumomab tiuxetan have also been used at myeloablative doses, with stem cell rescue in patients with relapsed B cell lymphomas.^{201,202,203,204} Radioiodinated tositumomab was used initially as a single agent.²⁰² Twenty-five patients were imaged after a tracer dose of radioiodinated tositumomab. Twenty-two of these 25 patients achieved favorable biodistributions (i.e., had tumor doses in excess of doses to normal organs). These 21 patients received therapeutic infusions of radioiodinated tositumomab (345 to 785 mCi) followed by reinfusion of autologous hematopoietic stem cells. All patients achieved bone marrow engraftment (19 with bone marrow stem cells, two with peripheral blood stem cells). However, two patients died before full neutrophil recovery; one of sepsis, one of progressive lymphoma. Nonhematologic toxicities included nausea in most patients, mild mucositis in five patients, and partial

alopecia in four patients. One patient experienced reversible cardiomyopathy and interstitial pneumonitis. Eighteen patients responded to this therapy; 16 patients experienced a CR. With a median follow-up of 2 years, 2 years PFS was estimated at 62%, with OS estimated at 93%. Press et al. then combined radioiodinated tositumomab with chemotherapy and autologous stem cell transfusion in a series of patients with relapsed B cell lymphomas.²⁰³ Fifty-two patients received the planned therapy. Patients were again given tracer doses of radioiodinated tositumomab and underwent sequential gamma camera imaging. Absorbed doses of radiation to tumor sites and normal organs were determined. Thereafter, patients received a therapeutic infusion of radioiodinated tositumomab calculated to deliver between 20 and 27 Gy to normal organs (e.g., liver, kidneys, and lungs). Patients then received etoposide, 60 mg/kg, and cyclophosphamide, 100 mg/kg, followed by reinfusion of autologous hematopoietic stem cells. The maximal tolerated dose of radioiodinated tositumomab to be combined with chemotherapy was determined to be that dose that delivered 25 Gy to normal organs. Eight patients experienced 13 grade 3 or 4 toxic events. These included 3 patients with acute respiratory distress syndrome, 3 patients with severe mucositis or gastrointestinal toxicity, 1 patient with venoocclusive disease, and 4 patients with fatal infections. At 2 years, the Kaplan-Meier estimates of OS and PFS for all treated patients were 83% and 68%, respectively. These findings were considered superior to results previously observed in patients who had undergone conventional external beam total-body radiation with etoposide/cyclophosphamide preparation for transplantation in the same institution. Thirty-one patients with CD20⁺ NHL were treated with high-dose Y-90 ibritumomab tiuxetan in combination with high-dose etoposide and cyclophosphamide and were followed by autologous hematopoietic cell transplantation (HCT).²⁰⁴ Treatment also was well tolerated; there were 2 deaths and 5 relapses. At a median follow-up of 22 months, the 2 years estimated OS rates are 92% and 78%, respectively. Retreatment with tositumomab and I-131 tositumomab, has also been found possible in patients with progressive disease after treatment with I-131 tositumomab, who were able to receive subsequent therapy, including cytotoxic chemotherapy and stem cell transplantation.²⁰⁵ In patients with prior response, I-131 tositumomab can produce second responses that can be durable.²⁰⁶

Use of RIT is also being investigated in the allogeneic HCT setting.^{207,208,209} RIT with β -emitters has been successfully used for further dose intensification of myeloablative conditioning regimens for HCT. Using a canine model of nonmyeloablative HCT, Bethge et al. used pretransplant RIT with the α -emitter bismuth-213 coupled to anti-CD45 or anti-TCR $\alpha\beta$ mAb together with postgrafting immunosuppression with mycophenolate mofetil and cyclosporine, which resulted in stable engraftment and long-term mixed chimerism.²⁰⁸ In 2 relapsed patients with NHL, Y-90 ibritumomab tiuxetan was given as part of the conditioning for an HLA-matched donor transplant. Rituximab 250 mg/m² was given on days -21 and -14, 0.4 mCi/kg Y-90 ibritumomab tiuxetan on day -14 and fludarabine (30 mg/m²) plus cyclophosphamide (500 mg/m²) on days -7 and -3, resulting in fast and reliable engraftment, offering an attractive new therapeutic option for relapsed lymphoma patients.²⁰⁹ A method of dose-intensified RIT called "pretargeting" RIT (PRIT) dissociates the slow distribution phase of the antibody molecule from the delivery of the therapeutic radionuclide. This might achieve improved outcomes with less toxicity, and is being explored in preclinical studies of hematologic malignancies.²¹⁰ In a preclinical study using an acute leukemia xenograft model, comparing conventional and pretargeted anti-CD45 RIT, investigators showed clearly that anti-CD45 PRIT provided rapid tumor localization and improved biodistributions of radioactivity with significant improvements in efficacy compared with conventional anti-CD45 RIT.²¹¹

In allogeneic HCT, RIT is being explored to reduce toxicity associated with external γ -beam radiation. RIT with an anti-CD45 mAb labeled with the α -emitter astatine-211 has been used as a conditioning regimen in dog leukocyte antigen-identical HCT, resulting in good engraftment and minimal toxicity.²¹²

P.1479

Immunotoxins and Fusion Toxins

This category of treatment reagents resembles those guided missiles of RIT. In this case, however, the warheads are chemical rather than nuclear, and the targeting is provided by antibodies or by lymphokines, growth factors, and so on, that specifically bind receptors on the surfaces of target tumor cells. Attached to the targeting moiety is the cytolytic moiety. This is usually a toxin, derived from plants or bacteria, which works by inhibiting protein synthesis. They kill either resting or dividing cells and require fewer than ten molecules in the cytosol to be effective.^{213,214} Toxins of this type tested in phase I trials include ricin A-chain, blocked ricin, saporin, pokeweed antiviral protein, *Pseudomonas* exotoxin A, and diphtheria toxin. Recently, calicheamicin, a highly potent antitumor antibiotic that cleaves double-stranded DNA at specific sequences,²¹⁵ has been successfully targeted to leukemia cells.²¹⁶

A number of factors influence the efficacy of immunotoxins. These include the binding affinity of the ligand for its target and the target density on the tumor cell surface.²¹⁷ The epitope to which binding occurs can affect the potency of the immunotoxin.²¹⁸ Membrane-proximal epitopes appear to confer greater efficacy. Immunotoxin binding must lead to internalization of the target structure and the attached immunotoxin.²¹⁹ Once internalized, the toxin moiety must translocate to the cytoplasm to be effective. This process is aided by certain translocation sequences in the toxin. The need for translocation signals provides the rationale for using blocked ricin toxin; targeting via the binding subunit is eliminated but translocation signals are preserved.²²⁰ The site of translocation may vary for different toxins. Increasing lysosomal pH protects cells from *Pseudomonas* exotoxin and diphtheria toxin but increases sensitivity to ricin,^{221, 222} and²²³ suggesting that ricin may undergo translocation in the Golgi apparatus. Finally, these toxins affect protein synthesis by ADP-ribosylating elongation factor 2²²⁴ in the case of diphtheria toxin and *Pseudomonas* toxin, or by alteration of the 60S ribosomal subunit in the case of ricin.²²⁵

A number of phase I clinical trials using ricin-based, anti-pan B cell antibody immunotoxins have been reported in B cell lymphoma.^{226, 227, 228, 229, 230, 231, 232} and²³³ These trials demonstrated that therapeutic doses of immunotoxins can be delivered with tolerable, reversible side effects. Toxicities include systemic symptoms of fever, nausea, vomiting, headache, and muscle aches; evidence of hepatocyte damage with transaminase elevations; and significant problems with capillary leak syndrome.²³⁴ Again recognized were the problems of human antimouse antibody formation and rapid clearance of immunotoxin in the presence of circulating antigenemia. Sporadic responses were seen in these trials, with response rates perhaps approaching 25% and CRs approaching 10%. There were hints that targeting via CD22 might be more useful than targeting via CD19.²³⁵ Some experts have suggested that these agents will not become useful clinical tools until problems of their immunogenicity have been solved.^{143,214}

However, recent success has been reported for two agents of this class. A recombinant immunotoxin containing the anti-CD22 variable domain (Fv) fused to a truncated *Pseudomonas* exotoxin has produced CRs in patients with hairy-cell leukemia (HCL).²³⁶ Sixteen patients whose disease was resistant to nucleoside analogs were treated by intravenous infusion every other day for three doses. Thirteen of 16 patients responded—11 had CRs. The treatment was generally well tolerated. Common side effects included transient elevations of liver enzymes and hypoalbuminemia. Median follow-up was 16 months, during which 3 of the 11 complete responders relapsed. These three patients were retreated with the immunotoxin. Two of the three developed hemolytic uremic syndrome. Moxetumomab pasudotox, is an improved, more active form of a predecessor recombinant immunotoxin, BL22 (also called CAT-3888), and is up to 50-fold more active on lymphoma cell lines and leukemic cells from patients with CLL and HCL. A phase I trial was recently completed in HCL patients, who achieved response rates similar to those obtained with BL22 but without dose-limiting toxicity. In addition to further testing in HCL, moxetumomab pasudotox is being evaluated in phase I trials in patients with CLL, B cell lymphomas, and childhood ALL. Moreover, protein engineering is being used to increase its activity, decrease nonspecific side effects, and remove B cell epitopes.²³⁷

Gemtuzumab ozogamicin (Mylotarg) is an immunotoxin composed of a recombinant human IgG4κ monoclonal antibody conjugated with a cytotoxic antitumor antibiotic, calicheamicin,²³⁸ and was previously approved for the treatment of elderly patients with CD33-positive AML in first relapse. The antibody is directed against the CD33 antigen found on the surface of leukemic blasts and normal immature cells of myelomonocytic lineage, but not on hematopoietic stem cells. CD33 is a sialic acid-dependent adhesion molecule. In a phase I dose-escalation trial, treatment with gemtuzumab ozogamicin resulted in elimination of leukemic cells from peripheral blood and bone marrow in 8 of 40 patients.²³⁹ The basis for approval of the drug was the experience in 142 patients participating in one of three similar trials designed to examine the efficacy and safety of gemtuzumab ozogamicin in patients in first relapse of AML.²¹⁶ Across the three studies, 80 patients were 60 years of age or older. The median duration of first remission for the group was 11.1 months. All 142 patients received a first dose of drug, 109 patients received two doses (the recommended treatment course), and five patients received three doses. Roughly 40% of patients were treated as outpatients. Median duration of hospitalization was 24 days. The ORR was 30%. This included patients achieving a CR (defined as [a] leukemic blasts absent from peripheral blood, [b] bone marrow blasts <5% of cellular elements, [c] recovery of neutrophils and platelets, and [d] rbc transfusion independence) and patients achieving a CRp (CR as defined, except delayed platelet recovery). Median survival for the group as a whole was 5.9 months. Median relapse-free survival for responders was 6.8 months. Essentially, all patients had grade 3 or 4 neutropenia and thrombocytopenia. Fifteen percent of patients experienced grade 3 or 4 bleeding events. Infusion-associated events occurred in approximately 10% of patients. Sepsis occurred in 16% of patients; pneumonia in 7%. Grade 3 or 4 hypotension was seen in 9% of patients. Twenty-three percent of patients experienced grade 3 or 4 elevation of serum bilirubin levels, and 17% of patients had grade 3 or 4 elevations of hepatic transaminases. Two deaths were associated with liver abnormalities. Eleven patients died during the treatment period of causes other than disease progression. There was no treatment-associated cardiotoxicity, cerebellar dysfunction, or alopecia.

Gemtuzumab ozogamicin was withdrawn from the United States market in 2010 due to lack of clinical benefit in subsequent trials, but it remains available in Japan and for selected investigator-initiated research. Inotuzumab ozogamicin is a similar immunotoxin linking calicheamicin to an IgG4 antibody against CD22, and is in phase III trials in B cell lymphoma.²⁴⁰

Neoplasms bearing the high-affinity IL-2 receptor have been approached with a genetically engineered, bacterially expressed IL-2-diphtheria toxin fusion protein, denileukin diftitox.²⁴¹ Denileukin diftitox was approved in 1998 for the treatment of patients with relapsed cutaneous T cell lymphoma (CTCL). This was the first approval for drugs of the recombinant fusion toxin class. The development of this molecule is detailed in a recent review.²⁴² The basis of approval was a pivotal trial conducted in 73 patients with disease that was refractory to other therapy (patients having received three or more previous treatments).²⁴³ Patients were randomized to either a low dose (9 µg/kg/day) or high dose (18 µg/kg/day) of the fusion toxin. Patients were treated on 5 consecutive days in 21-day cycles for up to 8 cycles.

P.1480

Seventy-one patients received a drug. The ORR was 30%, and CR rate was 10%. Rates and durations of response did not differ between the two treatment groups. Adverse events included flu-like symptoms, acute infusion-related events, and vascular leak syndrome. Approximately three-fourths of the patients experienced transient elevations of hepatic transaminase levels and hypoalbuminemia; approximately 15% of patients experienced grade 3 or 4 elevations of liver enzymes or hypoalbuminemia. The success of this trial, to some extent, allays concern that a major problem with this family of fusion toxins would be previous immunization of most of the American population with diphtheria toxoid in childhood. Although approximately one-half of patients had antibodies against diphtheria toxin at baseline and almost all patients had antibodies after treatment, these did not appear to affect treatment outcome.^{243,244}

An anti-CD30 antibody, brentuximab vedotin, an antibodydrug conjugate composed of the anti-CD30 chimeric IgG1 monoclonal antibody cAC10 and the potent antimicrotubule drug monomethylauristatin E connected by a protease-cleavable linker, is increasingly being used in hematologic malignancies.²⁴⁵ Several trials have shown durable antitumor activity with a manageable safety profile in patients with relapsed/refractory Hodgkin lymphoma,²⁴⁶ systemic anaplastic large-cell lymphoma, or primary cutaneous CD30-positive lymphoproliferative disorders.²⁴⁷ Treatment with single-agent brentuximab vedotin resulted in objective response rates and CR rates of 75% and 34%, respectively, in relapsed or refractory Hodgkin lymphoma; and of 86% and 57%, respectively, in relapsed or refractory systemic anaplastic large-cell lymphoma patients.²⁴⁷ Peripheral sensory neuropathy and neutropenia were observed with brentuximab vedotin but were generally grade 1 and 2 in severity and manageable. In August 2011, brentuximab vedotin was approved in the United States for the treatment of Hodgkin lymphoma after failure of autologous stem cell transplant (ASCT) or after failure of at least two prior multiagent chemotherapy regimens in ASCT-ineligible candidates, and for the treatment of systemic anaplastic large-cell lymphoma after failure of at least one prior multiagent chemotherapy regimen.

Bispecific Antibodies

Bispecific antibodies are antibody constructions that recognize a tumor-associated antigen (TAA) with one arm and recognize and activate an immune effector cell structure with the other arm.^{248,249,250} In theory, approximation of a tumor cell with an activated immune effector could result in tumor cell elimination. These bispecific antibodies can be obtained either by chemical heteroconjugation or by fusion of 2 hybridomas of desired specificity to yield a tetradoma. With either approach, chromatographic or other separation techniques are required to isolate the desired product.

Strategies using antibodies to activate phagocytic cells, NK cells, and T lymphocytes have been examined. In preclinical models, anti-Id × anti-CD3 bispecific antibodies have demonstrated the ability to inhibit tumor cell growth.^{251, 252} and ²⁵³ Recognizing the need for costimulation in T cell response, other investigators have used a combination of bispecific antibodies, anti-CD3 × anti-TAA and anti-CD28 × anti-TAA, with interesting results.²⁴⁸

Blinatumomab, a new novel class of T cell engaging bispecific single-chain antibody (BiTE[®] antibodies) engages T cells for redirected lysis of CD19 positive target cells.²⁵⁴ CD19 is stably expressed on the majority of B cell malignancies. A phase I trial in patients with indolent NHL showed efficacy.²⁵⁵ A phase II study of blinatumomab patients with B-lineage ALL, with persistent or relapsed MRD, resulted in an 80% MRD response rate. After a median follow-up of 33 months, the RFS of the whole evaluable study cohort of 20 patients was 61%, while 9 patients who received allogeneic hematopoietic stem cell transplantation (HSCT) after blinatumomab treatment had a hematologic RFS rate of 65% (Kaplan-Meier estimate). Amongst patients who were Philadelphia (Ph)-negative, 4/6 MRD responders with no further therapy after blinatumomab were in ongoing hematologic and molecular remission. Thus, blinatumomab may have a role in inducing long-lasting CRs in B-lineage ALL patients with persistent or recurrent MRD.²⁵⁶

Bispecific antibodies have been used in the treatment of patients with refractory Hodgkin lymphoma.^{257,258} In an initial phase I/II trial,²⁵⁸ 15 patients were treated with an NK cell-activating bispecific monoclonal antibody directed against the Fcγ-receptor III (CD16 antigen) and the Hodgkin-associated CD30 antigen. The antibody was administered every 3 to 4 days × 4. Dose-limiting toxicity was not encountered up to and including the highest dose administered, 64 mg/m². Side effects were unusual, but included fever, pain in involved lymph nodes, and maculopapular rash. Nine of 15 patients developed a human antimouse antibody response that resulted in allergic reactions in four patients who were retreated. Duration of one CR was 16 months, and partial responses endured for a median of 3 months. These results prompted a second trial to investigate the effects of different administration schedules and the concomitant administration of cytokines on the effectiveness of the bispecific antibody.²⁵⁹ Sixteen patients were treated with 25 mg of the construct four times, either as a continuous infusion for 4 days or a 1 hour infusion every other day. Patients who exhibited response were retreated at 4-week intervals, if possible. Patients with stable disease received retreatment after administration of IL-2 and granulocyte-macrophage colony-stimulating factor (GM-CSF). Four patients responded to the treatment (three partial remissions and one complete remission). Durations of response were from 5 to 9 months.

Bispecific antibodies, as an approach to immunotherapy, appear to have garnered more enthusiasm and engendered more activity in the treatment of solid tumors.²⁶⁰ This approach as an immunotherapeutic strategy is also being explored in overcoming drug resistance cell lines in B cell malignancies,²⁶¹ as well as the allogeneic HCT setting, to enhance the graft-versus-tumor effect, while minimizing graft-versus-host disease (GVHD).²⁶² Relatively minor results have not given rise to large-scale trials. Gupta et al. in a preclinical study showed that two bispecific HexAbs (IgG-[Fab]4 constructed from velutuzumab [anti-CD20 IgG] and milatuzumab [anti-CD74 IgG]) show enhanced cytotoxicity in mantle cell lymphoma (MCL) and other lymphoma/leukemia cell lines, as well as patient tumor samples without a crosslinking Ab, compared with their parental mAb counterparts, alone or in combination. They may thus constitute a new class of therapeutic Abs by invoking the juxtaposition and engagement of 2 independent targets on a cancer cell.²⁶³ A trifunctional bispecific antibody, FBTA05, is now in preclinical studies.²⁶⁴ It is designed to target human CD20 and human CD3, simultaneously binding B cells and T cells by its variable regions and recruiting FcγR-positive accessory immune cells by its intact Fc region. The cytotoxicity of FBTA05 on ex vivo cells from patients with CLL was comparable with that induced by alemtuzumab, exceeded the antineoplastic effects of rituximab, and was effective in elimination of malignant B cells even if CD20 surface expression was low. Importantly, a high grade of cytotoxicity was associated with the induction of T cell proliferation and the concomitant release of interferon-γ and IL-6, thus overcoming the detrimental effects of an unfavorable effector:target cell ratio.²⁶⁵ These unique approaches appear to further improve the antineoplastic efficacy of mAbs in hematologic malignancies.

Cytokines

Interferons

The interferons (IFNs) constitute a family of cytokines that were initially recognized by their abilities to interfere with viral replication.¹⁹⁹ Two major classes of IFNs exist: type I,

P.1481

consisting primarily of IFN-α and IFN-β; and type II, consisting of IFN-γ. Type I IFNs are produced by many cell types. Type II IFN is produced by T lymphocytes. Signaling in this system involves the janus kinase (JAK) family and the STATs.²⁶⁶ Transmission of IFN-specific signals results in induction of a number of genes, including several transcription factors, MHC class I and class II (primarily in response to IFN-γ) molecules, and a number of proteins that are responsible for the antiviral activity of the IFNs, including the (2' to 5') oligoadenylate synthase-nuclease system.²⁶⁷ Promoters for these genes share an IFN-stimulated response element that has a consensus structure of AGTTTCNNTTTCNC/T.²⁶⁸ The nature of the IFN antitumor action is as yet ill defined. Early observations involving virally induced tumors demonstrated that IFNs could inhibit tumor growth.²⁶⁹ These observations were later extended to nonvirally induced tumors.²⁷⁰ The marriage of molecular biology and the entrepreneurial biotechnology industry produced recombinant IFNs early on, and these molecules have been used extensively in clinical trials since the early 1980s. IFN-α has found its way into the therapeutic armamentarium, but IFN-γ has not. The most successful applications of these substances have been in chronic myelogenous leukemia (CML) and HCL.

In chronic-phase CML, IFN-α has demonstrated the ability to control blood counts and to induce complete hematologic response in perhaps 70% of patients, and complete cytogenetic responses in 25% of patients.^{271,272, 273, 274} and ^{275,276,277,278} Typical administration schedules have been 5 × 10⁶ U/m²/day or three times weekly. These results have been achieved with significant side effects, including initial flu-like symptoms that abate at approximately 2 weeks, then later fatigue,

weight loss, neurotoxicity, depression, and insomnia. Rare cardiac and autoimmune side effects have occurred, including arrhythmias and congestive heart failure as well as hemolytic anemia, thrombocytopenia, rheumatologic disorders, hypothyroidism, and nephrotic syndrome. The role of IFN- α in the treatment of CML and its effect on remission duration and survival are controversial. One large multicenter trial failed to demonstrate a correlation between cytogenetic response to IFN- α and remission duration or survival,²⁷⁴ but in a head-to-head comparison of IFN- α with hydroxyurea, significantly improved survival was seen in the IFN- α -treated group.^{276,279,280} In this study, most of the benefit of IFN- α appeared to accrue to the patients who achieved a major cytologic response, all of whom were in the IFN- α -treated group. In the era of imatinib mesylate, the role for IFN- α remains to be defined.^{277,278}

In HCL, IFN- α became the first effective, nonsurgical treatment; splenectomy was the first treatment approach. A number of studies conducted with partially purified, then recombinant IFN- α demonstrated that approximately 75% of treated patients achieved a complete or partial response.^{281, 282, 283, 284} and ²⁸⁵ Median durations of response were 12 to 24 months, with virtually all patients eventually relapsing. However, most patients responded to a second treatment course of IFN- α . The mechanism of IFN- α action in this disease is unknown. Both antiproliferative²⁸⁶ and immunomodulatory^{287,288} events have been demonstrated in treated patients. Although IFN- α is an active agent in HCL, the remarkable effectiveness of short courses of cladribine in inducing sustained complete clinical remissions in this disease make it the treatment of choice for most patients with the disease.

Interferon- α also has been used in the treatment of NHL.¹⁴³ As a single agent, interferon- α has modest activity in indolent lymphomas, but toxicities are significant (at the doses generally used) and remission durations are generally short, with little effect on response rates and perhaps a reduction in the rate of transformation to higher-grade lymphoma,²⁸⁹ moderate prolongation of remission durations, but, with one exception,²⁹⁰ no effect on OS.

IFN- α may also be a useful agent in the treatment of multiple myeloma.^{291,292} When used in combination with chemotherapy, IFN- α may improve initial response rate and PFS. A pilot trial conducted by the Eastern Cooperative Oncology Group suggested that IFN- α treatment in combination with chemotherapy led to increased response rates and prolonged disease-free interval by 12 months over that expected.²⁹³ In a large randomized trial of 256 patients,²⁹⁴ IFN- α maintenance treatment produced improved disease-free survival of 17.8 versus 8.2 months for the control group and OS of 50.6 versus 34.4 months. Both differences were statistically significant. Inclusion of IFN- α during induction therapy appeared to confer further benefit. However, in a large cooperative group trial,²⁹⁵ no benefit was seen to IFN- α maintenance therapy. A meta-analysis of 24 randomized studies involving more than 4,000 subjects indicated that IFN- α improves relapse-free survival to a moderate degree and OS to a marginal degree in multiple myeloma. Therefore, the role of IFN- α in the treatment of multiple myeloma remains controversial. Its cost and side effects must be considered when contemplating the use of IFN- α . Furthermore, its usefulness has been questioned in melphalanprednisone-treated patients,²⁹⁶ in patients receiving high-dose steroids,²⁹⁷ and in the elderly.²⁹⁸ Recombinant IFN- γ 1b has been used to enhance the immune system in high risk cancer patients treated with granulocyte transfusions, as well as to treat fungal infections in the allogeneic hematopoietic stem cell transplant setting.²⁹⁹ Type I IFN (HLBI, IFN- α 2b and IFN- β) has been shown to enhance antileukemic cytotoxicity of $\gamma\delta$ T cells in in vitro models.³⁰⁰ IFN- α is effective in polycythemia rubra vera, particularly in the young or pregnant patient.³⁰¹

Interleukin-2

IL-2 was first recognized as a growth factor for T lymphocytes.^{302,303} Its discovery allowed the cloning and long-term propagation of antigen-specific T cell clones.^{304,305} In addition, it was determined that IL-2 treatment led to gain of function, particularly increased cytotoxicity in T lymphocytes³⁰⁶ and NK cells.³⁰⁷ The possibility of generating or potentiating specific immune responses for clinical applications made the production of IL-2 one of the earliest targets of the biotechnology industry. Recombinant IL-2 was available for clinical application by 1983,³⁰⁸ only 5 years after the activity was first described.

IL-2 binds specifically to receptors (IL-2R) on target cell surfaces.³⁰⁹ Most resting lymphocytes display only intermediate-affinity receptors made up of IL-2R β and IL-2R γ polypeptide chains. A number of stimulatory signals lead to production of IL-2R α chains and the display of high-affinity heterotrimeric receptors of IL-2R α , IL-2R β , and IL-2R γ chains. IL-2R α contributes a rapid association rate with IL-2, whereas the IL-2R β and IL-2R γ chains provide a slow dissociation rate. The resulting rapid on rate and slow off rate results in an equilibrium dissociation constant ($K_d = 10^{-1}$ mol).³¹⁰ With approximately 750 receptors per cell surface, an endocytosis-related half-life of approximately 15 minutes, and an apparent requirement of 10,000 occupied receptors before commitment to cell cycle progression, it is likely that optimal treatment strategies will require prolonged, continuous administration of the cytokine.³¹¹

Early experience with IL-2 used increasing doses, seeking optimal effect. However, at high intravenous dose (greater than 10^{-8} mol peak concentration, attempting to saturate intermediate-affinity IL-2R on target cells), IL-2 produced significant, life-threatening toxicities.³¹² These side effects included fever and chills initially followed by a constellation of problems resulting from a capillary leak syndrome, including hypotension requiring pressor support in a majority of patients, significant weight gain, respiratory distress occasionally requiring intubation, oliguria, renal dysfunction, and death in approximately 1% of patients. Additional side effects included nausea, vomiting, diarrhea, cardiac arrhythmia, liver dysfunction, mental status changes, anemia, and thrombocytopenia. Because of

P.1482

these severe side effects, arbitrary ad hoc dose adjustments and well-controlled clinical trials have attempted to reduce dose while maintaining clinical efficacy. At doses approximately 300 to 500 times less than those initially used, marked increases in circulating levels of NK cells without induction of immune-mediated pathology have been demonstrated.³¹³ Continuous intradermal and intermittent subcutaneous administration schedules have been evaluated.³¹¹

IL-2 has been used in the treatment of AML. A few studies have been conducted in patients with active disease.^{314, 315, 316} and³¹⁷ Of these patients, a small minority had complete remissions, which were generally of brief duration. However, in several instances the IL-2-induced/maintained remission duration exceeded that of previous remission durations. This experience prompted an examination of IL-2's ability to prolong remission after chemotherapy.³¹⁸ Seventeen patients with AML were treated with IL-2 or IL-2 plus lymphokine-activated killer (LAK) cells after autologous bone marrow transplantation (BMT). Five of these patients relapsed between 2 to 10 months, one died in therapy, but 11 remained in complete remission 12 to 54 months after BMT. All of the surviving patients demonstrated remission inversion. Similar results were reported in seven patients treated with polyethylene glycol-conjugated IL-2 administered as the sole postremission therapy after induction of a second complete remission.³¹⁹ More recently, a pilot study of IL-2 in patients in first remission has been reported.³²⁰ The results suggest that more patients were alive at 3 years than would have been predicted by observations in historical controls. These results suggest that consolidative IL-2 administered early in remission induction can decrease relapse rate and suggest that prospective randomized comparisons are warranted.

Despite difficulty meeting accrual goals in several studies,³²¹ some experience has been gained using IL-2 in NHL, Hodgkin disease, and CTCL. In general, response durations in these diseases are brief and clinically insignificant.¹⁴³ However, a few remissions of prolonged duration have been reported. European investigators examined continuous-infusion high-dose IL-2 alone in patients with heavily pretreated lymphomas of various subtypes.³²² In 24 patients with low-grade lymphomas resistant to anthracycline-containing regimens, one CR was seen. In 23 patients with intermediate- or high-grade lymphomas refractory to primary therapy or salvage therapy, three complete remissions and two partial remissions were documented. No responses were seen in seven patients with Hodgkin disease. In seven patients with mycosis fungoides refractory to chemotherapy, one complete remission and four partial remissions were seen. These authors concluded that further testing with IL-2 in patients with aggressive lymphoma and CTCL was warranted. This experience with CTCL is particularly provocative because a direct effect of IL-2 on tumor cells, which often bear the IL-2R, is likely and may relate to the mechanism by which the IL-2 effect was manifest in this trial.

Use of IL-2 has been investigated in myelodysplastic syndrome (MDS).³²³ Its utility, in this setting, remains to be defined. IL-2 is critical for Treg cell development, expansion, activity, and survival.^{324,325} Investigators found that the administration of daily subcutaneous low-dose IL-2 in patients with active chronic GVHD rapidly induced preferential and sustained Treg cell expansion, reversed advanced manifestations of chronic GVHD, and permitted a substantial reduction in the glucocorticoid dose.³²⁶ Conversely, the binding of basiliximab and daclizumab, two IL-2 receptor antagonists (IL-2RAs) that bind to the α -subunit of the IL-2R (CD25), found predominantly on the surface of activated cytotoxic T cells, induced proliferation and provides selected immunosuppression, prevents GVHD efficiently and feasibly following unrelated donor-peripheral blood stem cell transplantation (URDPB SCT) and contributes to favorable outcome.³²⁷

Cellular Approaches

Graft-versus-leukemia Effect

Despite the fact that early studies in murine leukemia suggested that allogeneic HCT would confer a lower risk of relapse than syngeneic HCT,³²⁸ and this information was used as part of the rationale for early clinical HCT,³²⁹ the reality of a graft-versus-leukemia (GVL) effect in human transplantation was slowly recognized.^{330,331} Significant indirect evidence for a GVL effect can now be cited.³³² Anecdotal reports have documented remission reinduction after a flare of GVHD³³³ or on rapid withdrawal of immunosuppression.³³⁴ Furthermore, a number of studies have confirmed that syngeneic HCT is associated with a higher risk of relapse than allogeneic HCT.^{335,336} Other studies, including large retrospective analyses by the

International Bone Marrow Transplant Registry,³³⁷ have demonstrated a protective effect of GVHD. Non-T cell-depleted transplant recipients with acute, chronic, and acute plus chronic GVHD had a lower likelihood of relapse than did patients receiving non-T cell-depleted HCT who had no GVHD. Patients who received non-T cell-depleted HCT and experienced no GVHD still had a lower likelihood of relapse than patients receiving syngeneic HCT. These data have been interpreted to support the notion that graft-versus-leukemia effects can be seen in the absence of GVHD. Of note, it appears that the potency of the graft-versus-tumor effect differs among neoplasms.³³⁸ The graft-versus-tumor effect is obvious in AML and CML, has been suggested in lymphoma,³³⁹ but at least in one study was absent in ALL,³⁴⁰ and has been less apparent in myeloma.³⁴¹

The molecular and cellular mechanisms that underlie the GVL effect are becoming better understood.^{332,338,341,342} Furthermore, the relationship between the GVL effect and GVHD is becoming better defined. Some antigens relevant to these processes have been identified. Although MHC differences have long been associated with GVHD, the role of minor histocompatibility antigen expression in GVHD and the GVL effect is becoming apparent^{338,340,341,343,344,345} (Fig. 70.5). In a murine model, administration of allogeneic T cells specific for a single minor histocompatibility antigen resulted in an antileukemic response without a graft-versus-host response.³⁴⁶ Other antigens may be important as well.³⁴⁶ Immune responses against the neoantigens expressed from the BCR/ABL fusion in CML^{347,348} and the PML/Rα fusion in acute promyelocytic leukemia³⁴⁹ have been demonstrated. Their relevance is suggested by the disease-specific efficacy of DLI, but their true relevance in the clinical setting remains to be defined.

The immunologic effectors of GVHD and GVL are also being dissected. It is apparent that T lymphocytes must play a large role in these reactions, for their removal results in a marked decrease in GVHD and marked increases in relapse frequencies.³⁵⁰ The role of NK cells in mediating the GVL effect is increasingly being investigated.^{351,352} Preclinical studies in mice have shown that different combinations of activating and inhibitory receptors on NK cells can reduce GVHD, promote engraftment, and provide superior graft-versus-tumor responses. Emerging clinical data have shown that the use of KIR-ligand incompatibility produces a potent graft-versus-leukemia effect in patients with AML at high risk of relapse.³⁵² Recent evidence suggests that CD4⁺ T lymphocytes may be particularly important in the GVL effect.^{353,354} Allografts selectively depleted of CD8⁺ T lymphocytes (CD4⁺ T lymphocytes preserved) demonstrated a low incidence of GVHD yet a preserved GVL effect similar to that seen with unfractionated HCT in patients with CML. These clinical findings are supported by similar findings in animal models³⁵⁵ and by the demonstration of donor-derived, HLA-identical, cytotoxic CD4⁺ T cell clones of multiple specificities in a patient with severe GVHD after transplantation for CML.³⁵⁶ T-helper subset 2 and T-cytotoxic subset 2 may be particularly important in the regulation of GVHD and

P.1483

mediation of GVL effects.³⁵⁷ Development of MHC-tetramer technology has provided a means to visualize antigen-specific T cell responses.³⁵⁸ This technology can be used to correlate individual T cell responses with a clinical course. In an early application of the approach, Mutis et al.³⁵⁹ demonstrated that the frequencies of T cells specific for the HY and HA-1 minor histocompatibility antigens correlated with the severity of GVHD.

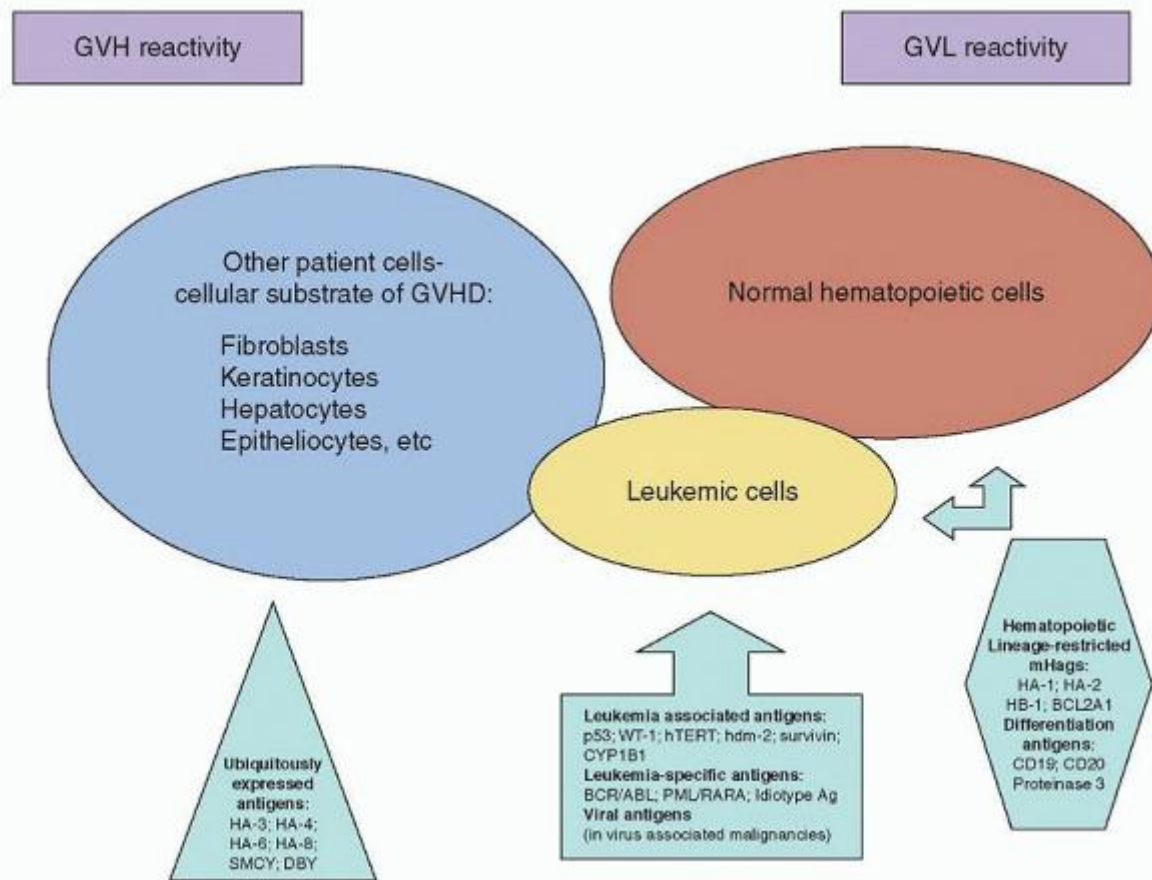

FIGURE 70.5. Antigenic basis of graft-versus-leukemia (GVL) and graft-versus-host (GVH) immune responses. Graft-versus-leukemia reactivity is mediated by immune responses specific to antigens with expression restricted to leukemic cells (leukemia-specific and certain viral antigens) and patient hematopoietic cells (hematopoietic lineage-restricted minor histocompatibility antigens, hematopoietic differentiation antigens). Reactivity to leukemia-associated antigens contributes to GVL mostly, although these antigens are expressed at low levels in normal tissues. Ubiquitously expressed antigens are a substrate of GVH disease. Ag, antigen; GVHD, graft-versus-host disease; mHags, minor histocompatibility antigens. (Adapted from Ivanov R, Hagenbeek A, Ebeling S. Towards immunogene therapy of hematologic malignancies. *Exp Hematol* 2006;34:251-263).

A number of strategies have been proposed to enhance the GVL effect and reduce GVHD.^{338,360} These include a reduction in the total number of T lymphocytes used in transplantation, delayed transfusion of donor lymphocytes,³⁶¹ CD8⁺ T lymphocyte depletion, ablation of thymidine kinase gene-transfected donor T lymphocytes with ganciclovir administration in case of GVHD,^{362,363} administration of IL-2³⁶⁴ and use of IL-2 receptor antagonists,³²⁷ functional depletion of antihost lymphocytes without depletion of antimyeloid lymphocytes,^{365,366} and ex vivo generation of leukemia-specific T lymphocytes.³⁶⁷

The approach that has garnered the most attention recently has been mini-allografting.^{368,369,371} High-dose chemotherapy with stem cell rescue has proven to be an effective, potentially curative approach to the treatment of several malignancies. However, this technique is associated with significant morbidity and mortality. The success of DLI (see section "Donor Leukocyte Infusions") for the treatment of CML and other hematologic malignancies has suggested that much of the benefit of allogeneic HCT is mediated by the graft-versus-malignancy effect. Several groups have evaluated the effects of safer, less toxic approaches to HCT. Shimoni et al.³⁶⁹ described their experience with allogeneic HCT using nonmyeloablative regimens in 116 patients. These low-dose regimens were designed, not to eradicate host hematopoiesis, but to allow induction of the GVL effect as the primary treatment mechanism. Forty-six patients with advanced age or significant organ dysfunction and diagnoses of CML, AML, or myelodysplasia, were treated with purine analog/cytarabine combinations to provide sufficient immunosuppression to allow engraftment of allogeneic progenitor cells. Thirty-six of 40 evaluable patients receiving related-donor HCT engrafted with donor cells—23 patients—achieved complete donor chimerism, and 13 patients were mixed chimeras. Death attributed to treatment-related causes occurred

in 8 patients. Twenty-eight of 31 evaluable patients with AML or MDS achieved a CR. Three patients died in remission. Fifteen patients relapsed. Six of the 15 patients received donor leukocyte infusion, but none responded. Eleven patients had CML. Eight of nine patients who received related-donor grafts achieved complete hematologic and cytogenetic remission. Two-thirds of patients treated in chronic phase were alive at 2 years. Seventy patients were treated with purine analog/melphalan nonmyeloablative regimens in an attempt to improve outcomes for patients with active chemorefractory leukemia at the time of HCT. Sixty-two of 64 evaluable patients had engraftment of donor hematopoietic cells. Treatment-related mortality was estimated at 45%. Median survival for the group was 4.5 months. Survival at 1 year was 37% and at 2 years was 31%. Investigators at the Center for International Blood and Marrow Transplant Research (CIBMTR) found that following HCT using myeloablative conditioning (MAC), GVHD had an adverse effect on transplant-related mortality (TRM) with early modest augmentation of GVHD-associated GVL. While following reduced-intensity conditioning (RIC), GVL may be important in limiting both early and late leukemia recurrence.³⁷²

Donor Leukocyte Infusions

A number of authorities consider the success of DLI to be the most compelling proof of a GVL effect.³⁷³ In 1990, Kolb et al.³⁷⁴ reported three patients with relapsed CML after marrow transplantation that were treated with infusion of buffy coat leukocytes from the donor and IFN- α . Complete hematologic and cytogenetic responses were seen in these patients. Since then, the phenomenon has been replicated and extended by many investigators.^{373,375,376} A broad experience of 25 North American transplant centers has been reported,^{377,378} confirming the remarkable efficacy of this approach in patients with relapsed chronic-phase CML and the less impressive response rates in advanced CML and acute leukemia. The collective experience suggests that in cytogenetic relapse or clinical chronic-phase relapse of CML,

P.1484

complete cytogenetic remission can be attained in 80% of patients. However, patients with more advanced disease have a much lower, perhaps 25%, chance of remission. When the technique has been applied to patients with AML relapsing after allogeneic BMT, response rates have been only 15% to 20%.³⁷⁶

The timing and application of DLI in other hematologic malignancies following hematopoietic stem cell transplant is still being explored. The clinical benefit of DLI in AML was explored in a retrospective analysis on the role of DLI in the treatment of relapsed AML after allogeneic HSCT by the European Group for Blood and Marrow Transplantation (EBMT) Acute Leukemia Working Party. They analyzed the data of 399 patients with AML in the first hematologic relapse after HSCT whose treatment did (n = 171) or did not (n = 228) include DLI. After a median follow-up of 27 to 40 months, respectively, estimated survival at 2 years was about 21% for patients who received DLI and 9% for patients who did not receive DLI. Improved outcome was associated with younger age (<37 years; P = 0.008), relapse occurring more than 5 months after HSCT (P < 0.0001), and use of DLI (P = 0.04). Among DLI recipients, a lower tumor burden at relapse (<35% of bone marrow blasts; P = 0.006), female sex (P = 0.02), favorable cytogenetics (P = 0.004), and remission at time of DLI (P < 0.0001) were predictive for survival in a multivariate analysis. Two-year survival was 56% if the DLI was performed in remission or with favorable karyotype, compared to 15% if the DLI was given in aplasia or with active disease.³⁷⁸ Anecdotal reports of responses have been generated in multiple myeloma, CLL, Fanconi anemia, and polycythemia vera.³⁷⁶ When applied to patients with ALL, Hodgkin lymphoma, and NHL, few responses have been seen.³⁷⁶

DLI are not without complications. The two most worrisome are GVHD and pancytopenia occurring weeks after infusion. Predictors of GVHD after donor leukocytes were T lymphocyte depletion in the original transplant marrow and concomitant IFN- α usage. The GVHD induced by DLI appears to respond more readily to immunosuppressive measures than does the GVHD seen with transplantation. Predictors of myelosuppression include frank hematologic relapse and T lymphocyte depletion.^{373,377,378,379}

The optimal dose and timing of DLI have yet to be determined.³⁸⁰ Administered dosage of leukocytes does not necessarily correlate with response,^{373,381,382} but there is some evidence that the incidence of GVHD does correlate with dosage,³⁸² making the notion of infusing fewer cells attractive. Regarding timing, the ability to detect relapse with molecular biologic techniques, such as PCR, allows definition of relapse long before it becomes hematologically apparent. Yet whether DLI should be used before hematologic relapse remains a matter for clinical investigation because transient molecular relapses have been documented.³⁷⁹ Similarly, the requisite concomitant use of IFN- α has been questioned. In the European trials, use of IFN- α did not appear to improve the response rate to DLI,³³⁷ and a number of studies have documented responses without the use of the cytokine.^{379,382}

Adoptive Cellular Immunotherapy

The field of immunotherapy was rejuvenated in the early 1980s by reports of clinical trials with transfer of antitumor cells to tumor-bearing patients.^{383,384} Rosenberg et al. pioneered the use of LAK cells plus IL-2.^{385,386} LAK cells were derived from resting, autochthonous, peripheral blood mononuclear cells by culture *ex vivo* in high concentrations of IL-2. After culture, these cells were capable of lysing fresh tumor cells in an MHC-nonrestricted fashion.³⁸⁷ They were returned to tumor patients with concomitantly administered high-dose IL-2. Although the tumor target structure remains undefined, these determinants appear to be broadly distributed on fresh and culture tumor cells and not expressed on normal cells *in vivo*. LAK cells appear to be derived from the NK subset of human lymphocytes bearing the NK markers CD16 and CD56, and usually lacking the CD3 structure.^{388,389} Initial reports with LAK plus IL-2 in patients suggested a significant response rate in NHL, but most emphasis has been given to solid tumors, particularly renal cell carcinoma and melanoma.^{390,391} Studies suggested that LAK cells do not consistently home to the site of tumor involvement, significantly limiting their therapeutic efficacy,³⁹² and have demonstrated no advantage for the administration of LAK plus IL-2 over administration of IL-2 alone.³⁹⁰

A search for more potent killer cells resulted in the description of tumor-infiltrating lymphocytes (TILs).³⁹³ These cells could be isolated and grown from single-cell suspensions of tumor specimens in IL-2. They have the phenotype of classical cytotoxic T cells and kill tumor cells in an MHC-restricted manner. In animal studies, TILs are approximately 50 to 100 times more potent killers than are LAK cells. TILs also more efficiently home to and accumulate in tumor deposits.^{394,395} Pilot trials^{386,396} have demonstrated a response rate of approximately 35% in patients with melanoma.

The rather modest response rates, the extremely laborintensive nature of these treatments, and the serious toxicity of systemically administered IL-2 have markedly limited enthusiasm for these approaches to treatment, but they stand as important milestones on the road to effective immunologic treatments for neoplastic hematologic diseases and solid tumors. The remarkable success of adoptively transferred, virally specific, *ex vivo* expanded T lymphocytes for control of cytomegalovirus infection in patients after allogeneic HCT³⁹⁷ and^{398,399} suggests that, if appropriate tumor cell antigens can be found and exploited, this form of therapy may become a useful modality in the treatment of hematologic malignancies.^{400,401}

Engineered cells, using autologous chimeric antigen receptor-modified T cells reinfused into a patient with refractory CLL, expanded to a level that was more than 1,000 times as high as the initial engraftment level *in vivo*, with delayed development of the tumor lysis syndrome and with complete remission. A specific immune response was detected in the bone marrow, accompanied by loss of normal B cells and leukemia cells that express CD19. Remission was ongoing 10 months after treatment. Hypogammaglobulinemia was an expected chronic toxic effect.⁴⁰² Also, transplants using lectin-separated, E-rosette-depleted (SBA-E-) allogeneic marrow- or granulocyte colony-stimulating factor-mobilized CD34⁺ peripheral blood progenitor cells, which were adequately depleted of T cells and administered without posttransplant immunosuppression, have been shown to induce consistent engraftment with low incidences of acute and chronic GVHD, both in HLA-matched and HLA-disparate recipients. Furthermore, the incidence of relapse posttransplant is not increased in patients transplanted for AML, MDS, or ALL.⁴⁰³

Immunization Strategies

The central hypothesis of active immunotherapy for cancer is that either the tumor cell itself or antigens derived from the tumor cell (which are specific, or at least selective, for the tumor cell) can be modified and injected back into the patient as a therapeutic vaccine. The desired result is activation of both major arms of the immune response, the host antibody response and a host T cell response, against the target tumor cell or antigen, to aid in the eradication of the disease (Fig. 70.6).

Active Immunotherapy for Lymphomas

Vaccine strategies targeting NHL have largely focused on using the tumor-specific Id as an antigen. The variable regions of the heavy and light chains of the immunoglobulin molecules expressed on the surface of B cells contain unique determinants termed Id that can be recognized as an antigen. Since malignancies of mature and resting B cells arise from clonal proliferation of cells that

P.1485

express immunoglobulins with unique variable region sequences on their surface, the Id of a given B cell malignancy can serve as a tumor-specific antigen and has been exploited as a target for active specific immunotherapy.

FIGURE 70.6. Therapeutic vaccination against cancer. Active immunotherapy against cancer typically involves the use of tumor cells or antigens derived from the tumor cells that are modified and injected back into the patients to elicit a potent host CD4⁺ and CD8⁺ T cell response and possibly a host antibody response against the targeted tumor to aid in the eradication of the disease. Ex vivo modification of tumor antigens or tumor cells may involve the use of conjugation to a carrier molecule, incorporation into viral vectors, transduction of tumor cells with cytokine genes, and/or administration with adjuvants. Ab, antibody.

Preclinical Studies of Idiotype Vaccines

In the early 1970s, Lynch and Eisen demonstrated in mice that active immunization with purified immunoglobulins from mineral oil-induced plasmacytomas induced Id-specific tumor resistance.^{180,181} This phenomenon has been reproduced subsequently in a number of lymphoma, myeloma, and leukemia models.^{404, 405, 406, 407, 408} and ⁴⁰⁹ In 1987, Kaminski et al. demonstrated that optimal immunization required conjugation to a strongly immunogenic carrier protein, such as keyhole limpet hemocyanin (KLH).⁴⁰⁷ Subsequently, Kwak et al. demonstrated that the use of GM-CSF factor as an adjuvant facilitated the induction of tumor-specific CD8⁺ T cells and enhanced the efficacy of the vaccine in a murine 38C13 lymphoma model.⁴⁰⁹ GM-CSF likely acts by recruiting and promoting maturation of professional APCs such as DCs, which may in turn activate pathways of antigen processing that allow exogenous proteins to be presented by class I molecules. Animal studies also demonstrated that idiotypic vaccination conferred protection against tumor challenge and could cause regression of established tumors. Taken together, these results provided the rationale for testing autologous tumor-derived idiotypic surface immunoglobulin as a therapeutic “vaccine” against human B cell NHL.

Pilot Clinical Trial of Idiotype Vaccine

The first human study of Id vaccination was pioneered by Kwak et al., in patients with follicular lymphoma (Table 70.3), which was a pilot study designed to determine whether it was possible to immunize against the Id portion of the protein.⁴¹⁰ Follicular lymphoma patients, in minimal residual disease or complete remission after chemotherapy, were immunized with subcutaneous injections of autologous purified tumor-derived immunoglobulin, conjugated to KLH. Because no Id-specific immune responses were observed before the addition of an immunologic adjuvant to the first group of patients, patients (9 patients) subsequently received the entire series of immunizations with a standard emulsion adjuvant (Syntex adjuvant formulation-1 [SAF-1]). In all, 41 patients were treated in this pilot study, and 41% demonstrated specific anti-Id antibody and 17% demonstrated cellular proliferative responses.⁴¹¹ Of the 20 patients with residual disease following chemotherapy, two patients had complete regression of the tumor in association with the development of a specific immune response. Thus, these results were important because they demonstrated that patients with lymphoma could be induced to make sustained Id-specific immune responses by active immunization with purified

autologous tumor-derived surface immunoglobulin conjugated to the immunogenic carrier KLH. Furthermore, the induction of Id-specific immune responses was demonstrated in the setting of minimal tumor burden after conventional chemotherapy. However, it is important to recognize that convincing T cell responses (CD8⁺) were not observed, and this single-arm trial was not designed to answer the question of clinical efficacy.

Idiotype Keyhole Limpet Hemocyanin + Granulocyte-macrophage Colony-stimulating Factor Vaccine-induced Molecular Remissions in Follicular Lymphoma

Based on the preclinical observation that the addition of GM-CSF as an adjuvant to the vaccine-induced tumor-specific CD8⁺ T cells,⁴⁰⁹ Bendandi et al. conducted a phase II clinical trial where 20 previously untreated follicular lymphoma patients were treated with autologous tumor-derived Id-KLH + GM-CSF vaccine (in normal saline) following induction of clinical remission with a uniform chemotherapy regimen (prednisone, doxorubicin, cyclophosphamide, and etoposide [PACE])⁴¹² (Table 70.3). This produced a homogeneous group of patients, all in first CR, who were given vaccine treatment in the setting of minimal residual disease. The vaccine was injected subcutaneously in 5 monthly doses starting approximately 6 months after completing chemotherapy to allow time for immunologic recovery. The vaccine was well tolerated, with the main adverse effects being injection site reactions such as erythema, induration, and pruritus. There were no long-term adverse effects due to the vaccine.

Following vaccination, anti-KLH antibody and cellular responses were induced in all patients. Anti-Id antibody responses were induced in 15 of 20 patients (75%) and Id-specific and/or tumor-specific CD4⁺ and CD8⁺ T cell responses were observed in 19 of 20 patients (95%).⁴¹² Further characterization of anti-Id cellular immune responses demonstrated that the T cells specifically recognized multiple unique immunodominant epitopes within the hypervariable complementarity-determining

P.1486

regions, but not framework regions of immunoglobulin heavy chain.⁴¹³

TABLE 70.3 KEY PHASE I/II CLINICAL TRIALS OF IDIOTYPE VACCINATION IN LYMPHOMA

Immune Responses (%)

Formulation	No.	Histology	T		Comments	Ref.
			Ab	Cell		
Id-KLH + SAF	41	FL	41	17	First human trial of idiotype vaccine	410,411
Id-KLH + GM-CSF	20	FL	75	95	Molecular remissions in 8 of 11 patients	412,414
Id-DC/Id-KLH-DC	35	FL	26	49	Clinical responses in 22% of patients	412,414
Liposomal Id/IL-2	10	FL	40	100	Sustained T cell responses beyond 18 mo	441
Id-KLH + GM-CSF	26	MCL	30	87	T cell responses induced in the absence of B cells	430,432
Id-KLH + GM-CSF	32	FL	20	67	Clinical responses observed in 4 patients	442
Id-KLH + GM-CSF	25	FL	52	72		487
Id-KLH + GM-CSF	92	FL	20	72	Improved disease-free survival	431
Id (Fab) + MF59 + GM-CSF	42	B cell lymphomas	46	56	Improved response rate Clinical responses observed in 6 of 15 FL patients	444

DC, dendritic cell; Fab, Fragment antibody binding; FL, follicular lymphoma; GM-CSF, granulocyte-macrophage colony-stimulating factor; Id, idiotype; IL-2, interleukin-2; KLH, keyhole limpet hemocyanin; MCL, mantle cell lymphoma; SAF, Syntex adjuvant formulation.

Monitoring of the patients for minimal residual disease showed that 8 of 11 patients with PCR-positive t(14;18) chromosomal translocation breakpoints converted to PCR negativity in their blood immediately after completing vaccination, and sustained their molecular remissions for a median of 18+ months (range: 8+ to 32+ months).⁴¹² Thus, these results provided the first convincing evidence for an antitumor effect of Id vaccination.

Analysis of time to relapse also provided an independent indication of clinical benefit. With a median follow-up of 9.2 years, median DFS is 8 years, and the OS rate is 95%.⁴¹⁴ While definitive statements cannot be made because this was not a randomized trial, the DFS appears superior to that of a historical, ProMACE chemotherapy-treated control group (median DFS, about 2.2 years).⁴¹⁵ Additional studies have also shown that Id vaccines may have potential clinical utility.

TABLE 70.4 PHASE III CLINICAL TRIALS OF IDIOTYPE VACCINATION IN FOLLICULAR LYMPHOMA

	NCI/Biovest	Genitope	Favrille
No. of patients randomized	177	287	349
Induction therapy	PACE	CVP	Rituximab
Randomized patients	CR/Cru	CR/CRu/PR	CR/CRu/PR/SD
No. of patients vaccinated	117	277	315
Vaccination	Id-KLH + GM-CSF or KLH + GM-CSF	Id-KLH + GM-CSF or KLH + GM-CSF	Id-KLH + GM-CSF or Placebo + GM-CSF
Id protein production method	Hybridoma technology	Recombinant DNA technology	Recombinant DNA technology
Isotype of vaccinated Id protein	IgM or IgG	IgG	IgG
Primary endpoint	Disease-free survival	Progression-free survival	Time to progression
Outcome	Positive	Negative	Negative
Reference	416	418	417

CR, complete remission; CRu, complete remission unconfirmed; CVP, Cyclophosphamide, Vincristine, Prednisone; GM-CSF, granulocyte-monocyte colony-stimulating factor; Id, idiotype; Ig, immunoglobulin; KLH, keyhole limpet hemocyanin; NCI, National Cancer Institute; PACE, Prednisone, Doxorubicin, Cyclophosphamide, Etoposide; PR, partial remission; SD, stable disease.

Idiotype Vaccine Improved Disease-free Survival in Follicular Lymphoma in a Phase III Trial

The encouraging immunologic and clinical outcome of the Id-KLH + GM-CSF vaccine in the phase II clinical trial led to the initiation of a randomized double-blind placebo-controlled multicenter phase III clinical trial sponsored initially by the National Cancer Institute (NCI) and later by Biovest International, Inc. to definitively answer the question of clinical benefit induced by Id vaccination in patients with follicular lymphoma (Table 70.4).⁴¹⁶ Patient population, induction chemotherapy, vaccine formulation, and trial design were similar to the phase II trial. Following induction of PACE chemotherapy, patients that achieved a CR or CRu were randomized 2:1 to receive either the specific vaccine, Id-KLH + GM-CSF, or the nonspecific immune stimulant, KLH + GM-CSF. Of 117 vaccinated patients, 76 received Id vaccine and 41 received control. After a median follow-up of 56.6 months, median DFS was 44.2 months for the Id vaccine arm and 30.6 months for the

P.1487

control arm (P = 0.047). Interestingly, in an unplanned subgroup analysis, the clinical benefit appeared to be restricted to the group of patients that had IgM isotype on their tumors. Median DFS for IgM-Id vaccinated group v control was 52.9 v 28.7 months (P = 0.001), and for IgG-Id vaccinated group v control was 35.1 v 32.4 months (P = 0.807). In summary, this

trial showed for the first time that therapeutic vaccination could induce meaningful clinical benefit in patients with lymphoma.⁴¹⁶

However, two other phase III clinical trials of Id vaccine in follicular lymphoma sponsored by Genitope and Favrilie failed to show clinical benefit (Table 70.4).^{417,418} Differences in the nature of vaccine products, trial design, and requirement for complete remission status after induction therapy may explain differences in outcomes between these 3 trials. For example, the NCI/Biovest study used the traditional hybridoma technology to generate the vaccine for each patient.⁴¹⁹ This results in production of the native IgM or IgG-Id, depending on the isotype of the Id on each tumor. In contrast, the Favrilie and Genitope studies used recombinant DNA technology to clone the variable regions of the tumor Id and fuse them to a common IgG Fc.⁴²⁰ Ids that have switched to IgG were previously shown to be tolerogenic, whereas Ids of their IgM progenitors were highly immunogenic.^{421,422} Moreover, the Fc fragment of IgG has been shown to have highly promiscuous MHC class II T cell epitopes that specifically activate Tregs and tip the immune responses toward tolerance rather than immunogenicity.⁴²³ The use of less intensive induction chemotherapy and vaccinating patients with partial remission and/or stable disease may also have contributed to persistence of tumor-induced immunosuppression at the time of vaccination in the Genitope and Favrilie studies.

Idiotype Vaccination in Combination with Rituximab

Although the NCI/Biovest study demonstrated that Id vaccination might improve clinical outcome, demonstration of vaccine efficacy after rituximab-containing induction therapy is necessary to integrate Id vaccination into standard of care for lymphomas. Rituximab is an anti-CD20 monoclonal antibody that depletes both normal and malignant B cells.^{146,424} Consequently, patients treated with rituximab are unlikely to have peripheral blood B cells and therefore unlikely to generate humoral immune responses following active immunotherapy. Animal studies have yielded conflicting results on the role of B cells in the priming of naive T cells.^{52,425, 426, 427, 428} and ⁴²⁹ To determine the effects of B cell depletion induced by rituximab on immune responses to Id vaccines, twenty-six previously untreated mantle cell lymphoma patients were treated with 6 cycles of dose-adjusted rituximab, etoposide, vincristine, doxorubicin, cyclophosphamide, and prednisone (EPOCH-R), followed 12 weeks later with 5 monthly cycles of autologous tumor-derived Id-KLH + GM-CSF vaccination (Table 70.3).⁴³⁰ As expected following EPOCH-R, peripheral blood B cells were completely depleted in all patients, began to recover at approximately 6 months, and returned to baseline levels by 1 year in most patients. In contrast, CD4⁺ T cell numbers decreased only slightly and recovered by the start of vaccination with a median time of 3 months; CD8⁺ T cell numbers did not change substantially.⁴³⁰

Unexpectedly, despite rituximab administration, antibody responses against the carrier molecule KLH and Id were detected in 17 of 23 (74%) and 7 of 23 (30%) evaluable patients, respectively. The humoral responses were delayed and correlated with B cell recovery, with most detected after the fourth or fifth vaccination, compared with after the first or second vaccination in the follicular lymphoma study in which rituximab was not administered.⁴¹² In contrast, vigorous CD4⁺ and CD8⁺ antitumor and KLH T cell responses were not delayed and were induced in 20 of 23 patients (87%) and 23 of 23 (100%), respectively, in the absence of circulating B cells,⁴³⁰ suggesting that professional APCs such as DCs may effectively present antigen to T cells in the absence of B cells. This result was independently confirmed in another clinical trial where induction of anti-KLH and anti-Id or tumor T cell responses was observed in >70% of follicular lymphoma patients vaccinated with autologous tumor-derived Id-KLH + GM-CSF vaccine following treatment with rituximab.⁴³¹ Although the median PFS of 24 months was not significantly different from historical controls of mantle cell lymphoma, the median OS of 104 months was markedly better. More interestingly, an antitumor T cell GM-CSF response but not antibody response was significantly associated with OS and time to next treatment, suggesting that antitumor cellular immune responses may significantly delay tumor growth.⁴³² Taken together, these results indicate that Id vaccines could be administered in the setting of B cell depletion induced by rituximab and may potentially improve clinical outcome.

The Relative Role of Humoral versus Cellular Immunity in Idiotype Vaccine Efficacy

While some murine lymphoma models have demonstrated that the antitumor efficacy of Id vaccine is dependent on the induction of an antibody response,^{407,433,434} other lymphoma models have shown that protection against tumor challenge or eradication of established tumors requires a CD4⁺ and/or a CD8⁺ T cell response.^{409,435,436} An analysis of 136 patients with follicular lymphoma treated with Id vaccination showed that the induction of specific anti-Id antibody responses was associated with significantly prolonged PFS.⁴³⁷ This study also demonstrated that patients with a favorable FcγRIIIa polymorphism that predicts stronger binding of the Fc of antibodies to effector cells had a longer PFS. Thus, patients with FcγRIIIa 158 valine/valine (V/V) genotype had a longer PFS than those with valine/phenylalanine (V/F) or phenylalanine/phenylalanine (F/F) genotypes. In contrast, no significant correlation was observed between the development of a cellular anti-Id immune response and PFS. However, it is possible that this study may have underestimated the value of an antitumor T cell response for several reasons. First, cellular responses on this study were

measured by a T cell proliferation assay, which is relatively insensitive, compared with assays such as ELISPOT and cytokine flow cytometry.⁴³⁸ Second, the proliferation assay detects primarily a CD4⁺ T cell response and may fail to detect a CD8⁺ T cell response. Third, immunologic assays that demonstrate recognition of native tumors (tumor-specific) may be more clinically relevant to assess T cell responses following cancer vaccination, compared with assays that demonstrate recognition of tumor antigens presented on appropriate APCs (antigen-specific). Finally, 86 of 136 patients (63%) in this study received a chemical adjuvant with the Id vaccine that predominantly induced a humoral immune response.^{410,411} In contrast, Id vaccine formulations using DCs^{439,440} or cytokines such as GM-CSF^{412,430} or IL-2⁴⁴¹ as adjuvants significantly enhanced the induction of cellular immune responses.

Following Id-pulsed DC vaccinations, clinical tumor regressions were associated with the induction of cellular responses, but without an antibody response^{439,440} (Table 70.3). Similarly, following Id-KLH + GM-CSF vaccination, patients achieved molecular remissions⁴¹² or CR⁴⁴² without a detectable antibody response, suggesting that cell-mediated antitumor immune responses are important for vaccine efficacy. Clinical tumor regression was also observed in a follicular lymphoma patient after administration of a novel liposomal Id/IL-2 vaccine (OncoVAX-Id/IL-2) in the absence of an antibody response.⁴⁴¹ The liposomal vaccine study also showed that the tumor-specific CD4⁺ and CD8⁺ T cell responses induced by the vaccine were sustained 18 months beyond the completion of vaccination and were associated with prolonged DFS⁴⁴¹ (Table 70.3). In another study, Nelson et al. demonstrated that the precursor frequency of tumor-specific CTL correlated with freedom from progression following Id vaccination.⁴⁴³ In treatment of naive indolent B cell lymphoma patients, cellular responses after immunization with Id Fab fragment correlated with tumor

P.1488

regression and PFS.⁴⁴⁴ As mentioned above, antitumor cellular but not humoral immune responses were associated with prolonged survival in mantle cell lymphoma.⁴³² Taken together, these results suggested that T cell responses could induce tumor regression independent of a humoral response and support the use of lymphoma vaccines in the setting of B cell depletion induced by rituximab-based induction regimens. However, because the relative role of cellular versus humoral immunity for vaccine efficacy is uncertain, it may be advisable to administer booster vaccinations following B cell recovery to optimize humoral responses.

Second-generation Lymphoma Vaccines

The results of clinical trials described above suggest that Id vaccination is safe, induces antitumor humoral and cellular immune responses, and is associated with improved disease-free survival in patients with follicular lymphoma. However, rapid progress in the development of active immunotherapeutic approaches for lymphoma has been hindered by the need to generate a custom-made product for each patient, by a process that is expensive, laborious, and time consuming. An alternative to Id protein vaccination is to directly extract selected membrane proteins from the tumor cells and incorporate them into liposomes along with IL-2. This novel membrane proteoliposome vaccine (Oncoquest-L) could be produced within 24 hours, was observed to be safe in a pilot clinical trial in follicular lymphoma patients, and induced tumor-specific CD4⁺ and CD8⁺ T cell responses.⁴⁴⁵ Other individualized tumor vaccine formulations in development for NHL include GM-CSF-transduced tumor/bystander cells,⁴³⁵ CD40-activated tumor cells,⁴⁴⁶ and tumor lysate-pulsed DCs.^{447,448} However, as with Id protein vaccination, these vaccine formulations also require generating a custom-made product for each patient and therefore may limit the broad applicability of this approach.

Identification of universally expressed lymphoma-specific antigens would lead to development of vaccine formulations that can be used in all lymphoma patients and are therefore easier and less costly to produce. Recently, T cell leukemia lymphoma 1 (TCL1), a coactivator of Akt that promotes cell proliferation and survival and has been shown to be aberrantly expressed in multiple B cell lymphomas, has been suggested as a possible shared TAA for common B cell lymphomas, including follicular lymphoma, CLL, mantle cell lymphoma, diffuse large B cell lymphoma, and splenic marginal zone lymphoma.⁴⁴⁹ TCL171-78 peptide-specific CD8⁺ T cells were shown to lyse autologous primary tumor cells in an HLA-A*0201-restricted manner, suggesting that TCL1 is naturally processed and presented on the surface of lymphoma cells for recognition by cytotoxic T cells. Additional preclinical studies are needed to determine the safety of TCL1 vaccine prior to evaluation in clinical trials.

Active Immunotherapy for Myeloma

Multiple myeloma is characterized by clonal proliferation of plasma cells, all of which secrete the same immunoglobulin molecule (M-protein). Similar to B cell lymphomas, the variable regions of the heavy and light chains of the immunoglobulin molecule secreted by the myeloma tumor cells contain unique idiotypic sequences that can be recognized as an antigen. Therefore, the Id of the myeloma can serve as a tumor-specific antigen and has been exploited

as a target for active specific immunotherapy in animal models.^{181,405} In addition, the M-protein can be easily isolated from human plasma and purified into a highly refined, safe protein vaccine. Id-specific CTL lines generated from myeloma patients by repeated in vitro stimulation with Id-pulsed DCs specifically recognized and lysed autologous primary myeloma cells,^{450,451} validating human myeloma cells as targets of an Id-specific T cell response.

Immunization of myeloma patients with Id vaccine following autologous stem cell transplantation was generally safe. However, Id-specific cellular immune responses were weak and clinical responses were transient or rare,^{452, 453} and^{454,455,456} possibly due to the immunocompromised state of myeloma patients from the underlying disease or treatment. Immunization with human telomerase reverse transcriptase and survivin-derived peptides similarly showed low immunogenicity.⁴⁵⁷ An alternative strategy is to immunize HLA-matched healthy donors prior to stem cell harvest and transfer the resulting tumor antigen-specific immunity to the patients by stem cell transplantation, with the goal of enhancing the graft-versus-tumor effect without increasing the risk of GVHD. This approach was tested in HLA-matched donor-recipient pairs in the setting of allogeneic stem cell transplantation.^{458, 459} and⁴⁶⁰ These studies demonstrated that immunization of healthy HLA-matched stem cell donors with the Id purified from the plasma of the myeloma patients conjugated to KLH was safe, induced KLH and Id-specific T cell immunity in the donors, and could be transferred passively to recipients. Interestingly, donor-derived KLH- and Id-specific humoral, and central and effector memory T cell responses were detectable relatively early after allotransplant, within the first 30 days, despite iatrogenic immunosuppression for GVHD prophylaxis, and were boosted by posttransplant vaccinations in most recipients.⁴⁶⁰ Furthermore, transfer of Id-specific immunity from the donors to the recipients was associated with prolonged DFS in the recipients.^{458, 459} and⁴⁶⁰ However, a randomized study is necessary to definitively determine whether Id vaccination of the donors is associated with improved clinical outcome in myeloma patients. Nevertheless, vaccination of stem cell transplant donors may represent a safe and novel strategy to improve outcomes of allotransplant by reducing relapse in malignancies for which tumor-specific antigens have been defined, and by protecting against infectious pathogens.

Recently, Dickkopf-1 (DKK1) has been suggested as a shared TAA for myeloma.^{461,462} DKK1 is highly expressed by the tumor cells of almost all myeloma patients, and is absent from normal tissues and organs except placenta, uterus, testis, and prostate.⁴⁶¹ DKK1 was shown to suppress osteoblast formation and increase bone destruction in myeloma; and inhibiting DKK1 activity by specific antibodies resulted in increased osteoblast number and bone formation, reduced osteoclast activity, and inhibited myeloma growth in a myeloma mouse model, suggesting a major role for DKK1 in the pathogenesis of myeloma.⁴⁶³ DKK1 peptide-specific T cell lines and clones generated from HLA-A*0201⁺ blood donors and myeloma patients effectively lysed primary myeloma cells in vitro and eradicated myeloma xenografts mice.⁴⁶¹ Furthermore, DKK1 vaccine protected mice from developing myeloma and had therapeutic effects against established myeloma in a murine myeloma model, suggesting its potential utility for myeloma patients.⁴⁶²

Active Immunotherapy for Leukemias

The identification of several leukemia-associated antigens has generated interest in developing vaccines for leukemia. One of the most studied leukemia antigens is the CML-associated BCR-ABL fusion protein resulting from the reciprocal translocation t(9;22). The demonstration of binding of the peptides derived from the fusion region to several HLA molecules and the induction of T cells that recognize peptide-pulsed target cells in vitro validated this fusion protein as a potential target for immunotherapy. Immunization of the CML patients with the peptides derived from the fusion region in clinical trials showed induction of specific BCR-ABL cellular immune responses and was associated with improved cytogenetic responses in some of the patients.^{464,465,466,467} However, additional trials are needed to determine the clinical efficacy of these vaccines, since most patients also received IFN and/or imatinib at the time of vaccination.

Active immunization strategies have also been evaluated in patients with AML and MDS using peptides derived from

P.1489

overexpressed proteins in leukemia cells such as the WT1, proteinase 3, and neutrophil elastase. A nonamer peptide PR1 derived from both proteinase 3 and neutrophil elastase that had high-affinity binding for the HLA-A*0201 molecule was tested in a phase I/II study in 66 patients with AML, CML, or MDS. Preliminary data suggest a significant increase in the PR1-specific T cells in 25 of 53 patients (47%) with measurable disease and clinical remission in 9 of 25 immune responder patients (36%), including durable molecular remissions in patients with refractory AML.⁴⁶⁸ Immunization of patients with AML or MDS with WT1 peptide-based immunotherapy showed a correlation between CTL immune responses and reduction of leukemic blast cells and/or WT1 transcripts.^{469,470,471,472,473}

FUTURE DIRECTIONS

The demonstration of induction of antitumor T cell responses by Id vaccination following B cell depletion induced by rituximab^{430,431} suggests that active immunotherapy strategies may be combined with passive immunotherapy strategies. Indeed, the use of passively administered antitumor mAbs such as rituximab with vaccines is likely to be complementary. Compared with mAbs, vaccines are likely to target different tumor antigens, can induce immunologic memory, and can induce polyclonal humoral and cellular immune responses, thereby minimizing the emergence of immune escape variants. However, with the increased use of rituximab for the treatment of B cell NHL, further improvement in the potency of the vaccines would require strategies to enhance the T cell responses, since rituximab depletes normal B cells and impairs the generation of antibody responses following vaccination. As described below, several strategies are being explored to achieve this goal.

Over the past two decades, preclinical studies have demonstrated that the induction of an optimal antitumor immune response requires the incorporation of tumor antigen, carrier molecule, and adjuvant as essential components of a cancer vaccine. Consequently, several cancer vaccine clinical trials were conducted to test and define a better tumor antigen, carrier molecule, and adjuvant. While such strategies were successful in enhancing the potency of the cancer vaccines and in inducing remissions in patients with minimal residual disease or small-volume disease, they do not appear to be effective for the treatment of patients with large tumor burdens. Although novel adjuvants such as TLR ligands may prove to be more potent than cytokine adjuvants,^{474, 475} and ⁴⁷⁶ further improvement of the cancer vaccines would probably also require disruption of the immunoregulatory pathways that modulate the magnitude and duration of the immune response.

Studies in animal models suggest that the T cell immune responses against foreign or self-antigens are regulated by several immunoregulatory pathways and/or peripheral tolerance mechanisms.^{121,477,478} For example, Tregs have been shown to downregulate T cell responses against foreign antigens as well as tumor antigens.⁴⁷⁹ Similarly, CTLA-4, a molecule that is expressed on activated T cells and Tregs, was shown to down-regulate T cell responsiveness and prevent the initiation and/or limit the magnitude of autoreactive T cell responses.⁴⁸⁰ A host of other mechanisms such as PD-1, B7-H1, and B7-H4 were recently described to negatively regulate T cell responses.^{121,481} These new insights have led several investigators to hypothesize that the potency of cancer vaccines can be further enhanced by concurrent suppression or blocking of peripheral tolerance mechanisms and/or suppressive immunoregulatory pathways. Dannull et al. have demonstrated that vaccine-mediated antitumor immunity is significantly enhanced in renal cell cancer patients after depletion of Tregs using denileukin diftotox⁴⁸² (a recombinant IL-2 diphtheria toxin conjugate; also known as Ontak), a Food and Drug Administration-approved drug for the treatment of CTCLs. Similarly, blockade of CTLA-4 in combination with peptide vaccination has resulted in enhanced cancer immunity and durable objective responses in patients with metastatic melanoma.^{483,484} Another strategy to enhance the potency of vaccines is to combine them with novel immunomodulatory agents. Lenalidomide, an immunomodulatory drug used for the treatment of myeloma, has been shown to enhance immune responses to pneumococcal vaccine in myeloma patients.⁴⁸⁵ Lenalidomide was also demonstrated to augment effects of Id vaccine by enhancing T cell responses and reversing systemic immunosuppression in a mouse model of lymphoma.⁴⁸⁶ Taken together, these preclinical and early-phase clinical results support the evaluation of combination immunotherapy strategies in future clinical trials with the cancer vaccine to stimulate an antitumor T cell response, and the simultaneous suppression of immune regulatory pathways to augment the induced T cell response. The existence of multiple immune regulatory pathways necessitates systematic evaluation of these approaches in clinical trials to determine the optimal combination immunotherapy regimen.

Chapter 71

Gene Therapy for Hematologic Disorders

Andre Larochelle

Cynthia E. Dunbar

John Tisdale

INTRODUCTION

The molecular characterization of congenital and acquired human disease over the past several decades has stimulated scientists and clinicians to envision genetic therapy as a new and exciting possibility.¹ By the 1990s, gene transfer technologies had progressed sufficiently to offer real hope for successful widespread clinical application.^{2, 3} and ⁴ The first replication-defective retroviral vector was described in 1983, offering a safe and feasible route for transfer of exogenous genes to nontransformed human cells.⁵ By 1989-1990, clinical studies using gene transfer began.^{6,7,8} Hundreds of clinical trials have been completed or are in progress (Fig. 71.1). Although surrounded by expectations, none of the early trials had even minimal evidence for clinical benefit, and in 1996 an expert panel convened by the director of the National Institutes of Health was critical of the premature initiation of clinical gene therapy trials and the subsequent overselling of results by investigators and the media.⁹ At the time of the report, no clinical gene “therapy” trial had shown clinical efficacy. The focus thus turned to rationally designed, small-scale clinical trials in diseases for which the pathophysiology is well understood, as well as the more important need for continued basic science investigations into vector systems and target cell biology.^{10, 11} and ¹²

FIGURE 71.1. Number of gene therapy clinical trials approved worldwide from 1989 through part of 2012. (From The Journal of Gene Medicine, © 2012 John Wiley and Sons Ltd, www.wiley.co.uk/genemed/clinical. Reproduced with permission of John Wiley and Sons, Inc.)

Hematopoietic stem cells (HSCs) and lymphocytes have remained central target cell populations for two major reasons: first, they are relatively easy to manipulate *ex vivo*, and second, many acquired and congenital diseases are potentially curable by their genetic correction.^{13,14} A significant fraction of ongoing human clinical trials target hematopoietic cells or are designed to treat congenital or acquired diseases of the hematopoietic or immune system (Fig. 71.2). Moreover, many important experimental advances in our understanding of hematologic physiology have resulted from the application of gene transfer techniques *in vitro* or in animal models.^{15,16,17, 18, 19} and ^{20,21} For instance, retroviral tagging of HSCs has allowed tracking and quantitative analysis of murine and nonhuman primate stem cell behavior, and experiments overexpressing oncogenes or cytokines in primary hematopoietic

cells using similar techniques has helped elucidate the *in vivo* role of these proteins. Significant advances in gene transfer technology have occurred through systematic preclinical testing in large animal models, and clinically relevant gene transfer levels have now been achieved in these models. These results predicted success in humans, at least for disorders for which modest transfer rates of genes not requiring complex regulation could be curative, and unequivocal efficacy has since been realized.^{22,23} These longanticipated results represented a significant advance for the field, providing not only restoration of immunity in children with severe combined immunodeficiency (SCID), but proof of principle in the context of a human disorder, and a great deal of enthusiasm for returning to the clinic for these and other disorders quickly developed. However, serious adverse events arising as a direct result of insertional mutagenesis have since been reported and efforts to understand these events more fully, develop additional safeguards, and adjust the risk-benefit assessment have now become necessary. Thus, it is particularly important for hematologists to have a general understanding of the field, even if widespread clinical applications may be a decade or more in the future. This chapter reviews the fundamental features of gene transfer technologies and their applications in preclinical and early clinical trials. The pace of the field is rapid, and many details may become obsolete, but the central concepts should remain relevant to any future gene therapy applications.

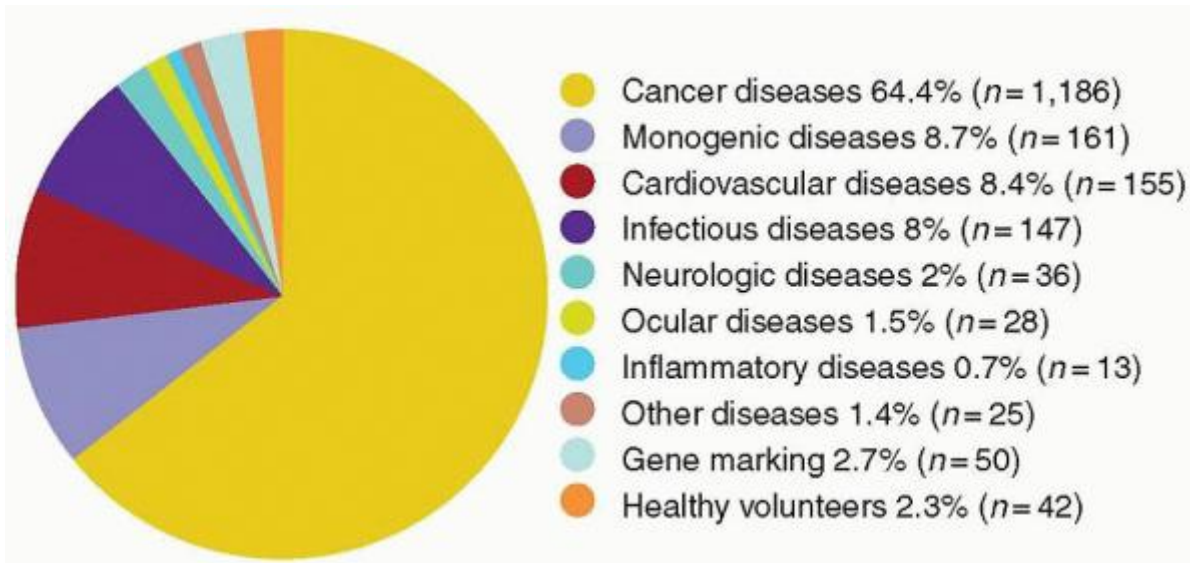

FIGURE 71.2. Indications for gene therapy clinical trials. (From *The Journal of Gene Medicine*, © 2012 John Wiley and Sons Ltd, www.wiley.co.uk/genemed/clinical. Reproduced with permission of John Wiley and Sons, Inc.)

OVERVIEW OF BASIC CONCEPTS

Gene therapy can be defined as the transfer of a gene or genetic material (DNA or RNA) into a cell with therapeutic intent (Fig. 71.3). The genotype of the cell is thus altered, with subsequent gene expression altering the phenotype of the cell. The therapeutic agent is the gene product, generally a protein, or less frequently RNA, for example, ribozymes or antisense molecules. This is in contrast to conventional therapies that act by directly altering the phenotype, even if the congenital or acquired defect is a genetic one. Three examples illustrate the conventional approach to underlying genetic disorders. Dietary avoidance of phenylalanine can prevent the consequences of phenylketonuria by circumventing the genetic deficiency of phenylhydroxylase. Cancer chemotherapy acts by preferentially killing tumor cells based on their cell cycle characteristics, thus removing cells with an acquired genetic defect. And factor replacement in hemophilia directly replaces the defective or missing gene product by infusion of an exogenously manufactured or isolated protein. Gene therapy strategies instead attempt to alter the underlying genetic abnormality to circumvent the need for these therapies.

The identification and cloning (isolation) of genes responsible for many congenital disorders, as well as of the cellular genes mutated in acquired disorders such as cancer has led to the concept of genetic correction of affected cell populations. Ideally, actual substitution of a defective gene with a therapeutic gene would be the most desirable method for returning target cells to a normal genotype and phenotype (gene replacement). However, this goal requires homologous recombination, a complex and inefficient process, and current gene transfer methods predominantly rely on either insertion of new genes into the chromosomes, or on extrachromosomal (episomal) maintenance of a newly introduced gene (gene addition).^{24, 25} and ²⁶ To date, efforts have focused on somatic (nongerm cell) therapy, with genotypic alteration of only the diseased target tissue. Manipulation of germ cells, with transmission of altered genetic

material to subsequent generations, is not yet feasible in humans, but the profound ethical and societal implications need to be addressed through the political process before the technology progresses much further.²⁷ The recent development of induced pluripotent stem cells (iPS cells), whose behavior is analogous to embryonic stem cells (ESCs) but can be derived from somatic cells, has introduced the possibility of genetic manipulation of autologous pluripotent stem cells, circumventing the ethical issues surrounding ESCs.

The vehicle for transferring new genetic material into a target cell is called a vector. At a minimum, a vector contains the gene or genes of interest along with regulatory elements such as promoters or enhancers that govern expression of the gene product.

P.1494

A vector may be a simple particle consisting of a fragment of DNA encapsulated within a liposome or conjugated to proteins that facilitate uptake into cells, or may be a more complex viral vector, capitalizing on the ability of viruses to enter cells easily and express genes robustly. Characteristics of the major vector systems are summarized in Fig. 71.4 and Table 71.1, and are detailed in subsequent sections. The successful interaction of a vector with a target cell, leading to an alteration in that cell's genotype, is termed transduction.

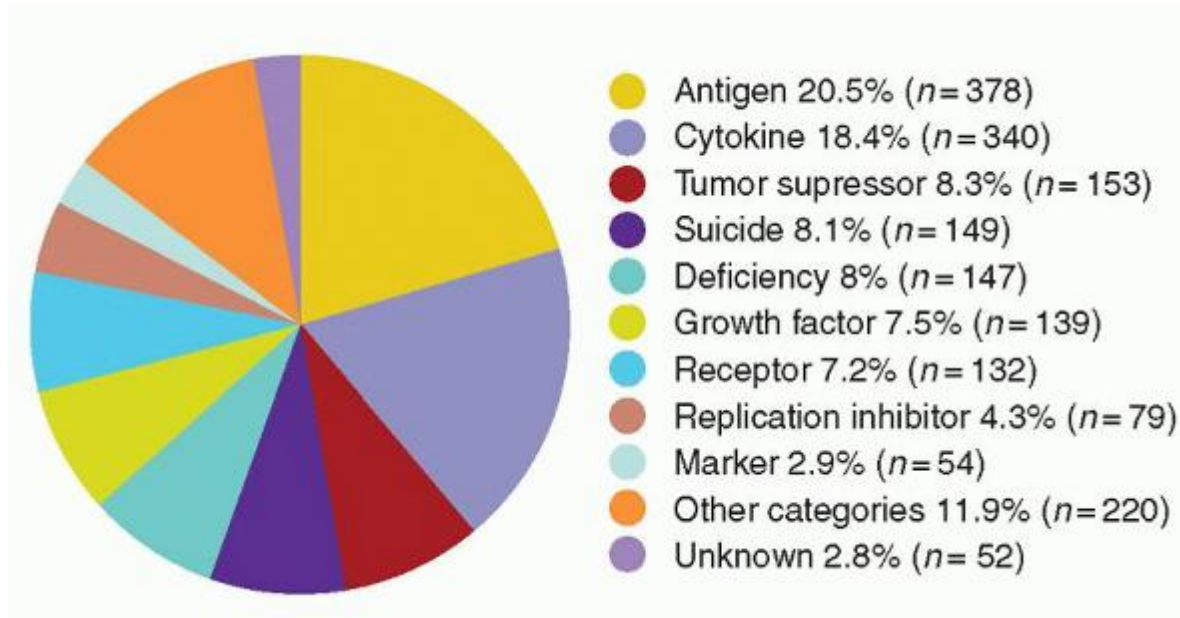

FIGURE 71.3. Gene types transferred in gene therapy clinical trials. (From The Journal of Gene Medicine, © 2012 John Wiley and Sons Ltd, www.wiley.co.uk/genemed/clinical. Reproduced with permission of John Wiley and Sons, Inc.)

Vector production procedures are unique to each system, but a number of considerations are common to all, especially those being developed for actual clinical use. A clinical vector must be feasible and practical to produce safely at pharmaceutical grade.^{28,29} To prevent indiscriminate spread of viral genomes, most viral vectors designed for clinical applications must be rendered replication-defective meaning that once a viral vector enters a target cell, the cell will produce no new viral particles. High-titer vector preparations, containing a high concentration of functional vector particles, are also very important, allowing exposure of target cells to the highest possible multiplicity of infection (MOI), defined as the ratio of vector particles to target cells; this increases the probability of successful vector-cell interaction.

Exposure of target cells to vectors can occur either *ex vivo* or *in vivo*. Autologous hematopoietic targets such as stem cells or lymphocytes are generally transduced *ex vivo*, because these cells can be easily collected, manipulated in culture, and then re-infused intravenously. *Ex vivo* transduction allows for a controlled exposure of only the desired target cells to large concentrations of vector, and is less likely to generate an inflammatory or immune response or be hindered by vector inactivation by complement. Other cellular targets for *ex vivo* transduction have included hepatocytes, keratinocytes, tumor cells, and muscle progenitor cells.

In vivo gene transfer has been used for applications involving cells that cannot successfully or easily be harvested and manipulated *ex vivo*, such as airway epithelium, vascular endothelium, differentiated muscle cells, retinal pigment

epithelium, and neurons. The ideal *in vivo* system would allow intravenous injection of a vector followed by rapid and safe specific transduction of target cells around the body.

A number of important steps must occur between exposure of a target cell to a vector and successful transduction of that cell, with persistence of the transferred genetic material in the correct cellular compartment and expression of the gene of interest or transgene. The vector must cross the plasma membrane efficiently and without damaging the cell. Most viral vectors enter cells via specific cell-surface receptors, and an important consideration is the number of functional receptors on the proposed target cell for the vector being used.³⁰ A process called pseudotyping can be used to redirect viral vectors to different cell-surface receptors by substituting alternative viral envelope proteins during the vector production process.^{31,32,33,34} Nonviral vectors may cross the plasma membrane without need for a specific receptor.

After crossing the plasma membrane, the vector must then travel through the cytoplasm and cross the nuclear membrane in order to enter the nucleus and utilize the cell's transcriptional machinery for expression of the transgene. Nuclear entry of some vectors may be dependent on mitosis, with temporary breakdown of the nuclear membrane; others carry nuclear localization determinants that result in specific conveyance across the intact membrane. The transferred genetic material may integrate permanently into the target cell's own chromosomal DNA, ensuring passage of the new gene to all daughter cells with every cell division. The need for integration depends on the target cell and therapeutic application: it is absolutely required for gene transfer into HSCs where the transgene must be transmitted to all progeny cells, but is superfluous for cellular targets such as neurons or muscle cells that are not mitotic.

FIGURE 71.4. Vectors used in gene therapy clinical trials. (From *The Journal of Gene Medicine*, © 2012 John Wiley and Sons Ltd, www.wiley.co.uk/genemed/clinical. Reproduced with permission of John Wiley and Sons, Inc.)

Alternatively, the gene may remain episomal, or nonintegrated. Some vectors are very stable as nuclear episomes, with prolonged persistence of transgene expression as long as the cell does not undergo mitosis. Unless the episome can reproduce itself, cell division will eventually dilute out episomal DNA, limiting the application of nonintegrating vectors to nonmitotic tissues or to situations requiring only transient expression.

The level of transgene expression and the ability to restrict expression to specific target cell types are also important factors to consider. Expression of the transduced gene is dependent on both vector and target cell determinants. Transcriptional promoters must be included along with the actual transgene protein coding sequences in the vector, and often lineage or tissue-specific promoter and enhancer elements are used to limit expression to a particular cell lineage derived from a target cell population.^{35, 36} and ³⁷ For instance, hemoglobin gene regulatory sequences are required to drive transgene expression specifically in erythroid cells in strategies targeting the globin disorders. In other situations, constitutive control elements that can drive transcription continuously in most cell types can be used. Genetic control elements that are inducible, or turned on by some exogenous manipulation such as the administration of an antibiotic, are also under development for inclusion in gene transfer vectors.^{38,39} Endogenous cellular factors may shut off expression of transferred genes in some situations.^{40,41} These factors have not been fully elucidated, and vary from vector to vector. Silencing of transferred genes via methylation of vector sequences is one possible mechanism.⁴² The level of expression

necessary for the desired therapeutic effect is very important to determine during in vitro and animal experiments and varies greatly depending on the target cell type and the proposed clinical application.

Nonviral Vectors

The simplest approach to gene transfer is to use only the DNA of the transgene, with the necessary control sequences, as the vector.^{29,43} Recombinant DNA production in bacteria can result in purified plasmids containing the gene(s) of interest along with regulatory elements. For over two decades, scientists have introduced purified DNA into target cells ex vivo by a variety of physical and chemical means. The least complex technique is direct microinjection into individual cells, which has little clinical

P.1495

utility due to the impossibility of injecting enough cells to produce most of the desired effects. One exception is the observation that direct DNA injection into muscle or skin can stimulate a very potent immune response against antigens introduced as plasmid transgenes.^{44,45} This observation led to preclinical and clinical development of genetic vaccination strategies against bacterial and viral pathogens.⁴⁶

TABLE 71.1 GENE TRANSFER VECTOR SYSTEMS

Vector System	Integration	Cell Cycle Dependence	Insert Size Limit	Clinical Experience	Advantages	Disadvantages	Major Applications
Murine retrovirus	Yes	Yes	8-10 kb	Extensive	Stable producer lines No viral genes in vector Low immunogenicity Well-understood biology Efficient entry and integration in many cell types Proven clinical safety	Low titer, fragile vector Requirement for cycling expression Erratic Insertional mutagenesis	Ex vivo—stem cells, lymphocytes, tumor cells, hepatocytes, myoblasts In vivo—producer cell or vector injection into tumors
HIV-based lentivirus	Yes	No		None	Faithful delivery of complex genes Well understood Efficient entry and integration Pseudotyping allows broad tissue range	Production labor-intensive Erratic expression Insertional mutagenesis Recombination with wildtype HIV	Ex vivo—stem cells, lymphocytes, tumor cells, nondividing cells
Adenovirus	No	No	8-10 kb	Moderate	High titer, stable vector High-level transgene expression Efficient entry	No stable producer lines Potential for recombination and replication-competent virus Multiple viral	In vivo—pulmonary epithelium, tumor cells, muscle, liver

					into many cell types	genes expressed from vector High immunogenicity (may be advantage as a vaccine vector!) Pre-existing immunity Inflammatory responses	
AAV	Yes— inefficient	Yes— controversial	4.5 kb	Minimal	Stable vector, extra- and intracellularly High titer High-level transgene expression No expressed viral genes in vector	No stable producer cell lines High percentage of defective particles Requirement for helper adenovirus during production Very limited insert size Pre-existing immunity	Undefined
Naked DNA	No	No	No	Moderate limit	Ease of production High level of safety No extraneous expressed vector genes No immunogenicity of vector	Inefficient cell entry, uptake into nucleus Poor stability within cell Low-expression level expression or vaccination	In vivo—tissues accessible to injection, for Low-transient expression or vaccination
Facilitated DNA (liposomes, polylysine conjugates, inactivated adenovirus, etc.)	No	No	No	Moderate limit	Same as naked DNA plus: Can be targeted to specific cell types More efficient uptake and intracellular	No mechanism for persistence	Same as naked DNA, plus in vivo tumor cells, vascular endothelium

stability

AAV, adeno-associated virus, kb, kilobases.

A number of other methods have been explored for getting plasmid DNA into cells. Liposomes, composed of phospholipid bilayers enclosing an aqueous space loaded with DNA, can directly fuse with the plasma membrane, releasing DNA into the cytoplasm.⁴⁷ The gene gun technique involves bombardment of the cell membrane with gold microparticles complexed to DNA.^{48,49, 50, 51} and ⁵² Electroporation and calcium phosphate precipitation are generally too toxic and inefficient for use in gene transfer strategies aimed at primary human cells.^{53, 54} and ⁵⁵

All of these methods lack mechanisms to stabilize intracellular vector DNA, nor do they allow transport into the nucleus; they therefore rarely result in chromosomal integration or long-term persistence and expression. The development of cationic liposomes has improved cellular uptake of plasmid DNA and has circumvented cytoplasmic degradation.^{56,57} In aqueous solution these positively charged liposomes bind with up to 100% of negatively charged DNA without size restrictions and can deliver DNA to the cell nucleus, albeit inefficiently, where it remains primarily episomal.⁵⁸ If administered *in vivo*, liposomes demonstrate no target cell tropism and are rapidly cleared by the reticuloendothelial system. However, after intravenous injection of cationic liposomes, long-term low-level persistence of vector sequences in many murine organs has been demonstrated.^{59,60}

Nonviral plasmid DNA transfer has been improved by conjugation of vector DNA to substances that improve cellular transport

P.1496

and allow target cell specificity via cell-surface receptors.^{61,62} For example, adenoviral capsid elements (especially the penton base protein) help disrupt endosomes, releasing DNA more efficiently into the cytoplasm, and inclusion of transferrin or other ligands in DNA-polylysine conjugates allows specific uptake via cell-surface receptors.^{63, 64, 65, 66} and ⁶⁷

Manufacturing nonviral vectors is much simpler than manufacturing viral vectors, and cannot generate potentially dangerous replication-competent infectious particles.^{29,68} Transduction is not dependent on target cell cycling, and no viral proteins are present to induce an antivector immune response. There are no size constraints. Limitations include a generally lower transduction efficiency than with viral systems. Most important, transgene integration is poor and persistent expression rare, limiting utility to situations allowing transient transgene expression.

Viral Vectors

Viral vectors are Trojan horses, taking advantage of the viral capsid or envelope and of the viral machinery to deliver nonviral transgene sequences efficiently to target cells.⁶⁹ In general, the external capsid or envelope of the virus is unaltered in a viral vector, but the genome of the virus is in large part replaced by a transgene or genes. This strategy is limited by the space available in a viral particle for new genetic material. Viral vectors also depend on the presence of a specific viral receptor on target cells. The efficiency of gene transfer utilizing viral vectors is the main advantage when compared to some of the physical and chemical cell entry methods described above. Furthermore, the relatively low toxicity of transduction of cells with certain viral vectors (e.g., retroviruses, lentiviruses, and adeno-associated viruses [AAV]) is another advantage when compared to physical or chemical methods. In order to modify a virus into a vector system, detailed understanding of the viral genome and life cycle is necessary to retain viral genome sequences required for packaging of vector nucleic acids into viral particles and for appropriate trafficking in the target cell, while removing sequences that might allow production of replication-competent viral particles.

Retroviral Vectors

The murine retroviruses exemplified by the Moloney murine leukemia virus (MLV) were the basis of the first practical viral vector system.^{70, 71} and ⁷² These retroviruses consist of two single strands of linear viral RNA bound to protein core and coated by a lipid envelope that is acquired from the plasma membrane of the infected cell upon viral release. The linear RNA genome can contain 2 to 9 kilobases (kb) of coding and regulatory sequences, flanked on each end by sequences termed long terminal repeats (LTRs) that permit integration into chromosomes and contain strong promoter/enhancer elements that normally drive expression of full-length viral RNA genomes, or via alternative splicing, the individual retroviral genes. These simple murine retroviruses contain only three genes necessary for viral replication and packaging: gag, pol, and env. The retrovirus enters a cell after binding to a specific cell-surface receptor via the env gene product. These receptors are large, widely expressed proteins involved in phosphate transport and other cellular homeostatic

functions.³⁰ The amphotropic receptor is found on both rodent and primate cells, and is the entry site for most murine retroviral vectors directed at human cells.^{73, 74 and 75}

After cell entry, the viral RNA is reverse transcribed via the pol gene product into proviral cDNA and enters the nucleus. The LTR sequences allow random integration of the viral cDNA into the host chromosomes. The integrated retroviral genome, or provirus, relies on the host cell's transcriptional machinery for expression of proviral genes and production of full-length viral RNA. The gag, pol, and env gene products are packaged along with the new viral RNA into viral particles, dependent on the presence of a packaging (ψ) sequence in the viral RNA, and viral particles are released from the cell via budding through the plasma membrane, without damaging the infected cell.

Recombinant retroviral vectors are constructed by removing the gag, pol, and env gene sequences from the viral nucleic acid backbone and replacing them with up to 7 to 8 kb of a gene or genes of interest, retaining only the LTRs and the packaging signal (ψ).⁵ The resulting recombinant viral vector can integrate and express the gene or genes of interest, but cannot replicate and produce new retrovirus once within a target cell, because of the lack of gag, pol, and env genes within its genome. Thus it is termed replication defective. Figure 71.5 diagrams the steps involved in making a retroviral vector. A packaging cell line is created by introducing a plasmid containing gag, pol, and env sequences but no ψ sequence into an immortalized cell line such as NIH3T3. The lack of the ψ sequence prevents these helper genes from being packaged into viral particles. A second plasmid containing the recombinant vector sequences (LTRs flanking the transgene or genes) is then introduced into these cells to create a producer cell line. Full-length vector RNA is transcribed from the vector plasmid sequences and packaged into viral particles using the gag, pol, and env proteins encoded by helper plasmid sequences. In this way, producer cell lines release helper-free replication-defective vector particles containing the recombinant genome into cell culture media at a titer of up to 10⁷ particles/ml. These particles contain the full-length vector RNA, consisting of the viral LTRs flanking the transgene or genes, and the env, gag, and pol proteins, but because they do not contain any actual gag, pol, or env viral gene sequences, no further infectious virus can be made once the vector infects the target cell.

The potential for generation of replication-competent virus through recombination events between the vector and helper sequences in the producer cell line is a significant safety concern.^{28,76} In order to allow packaging of replication-competent viral particles these recombination events must result in the transfer of an intact ψ packaging sequence being transferred into the helper sequences containing the gag, pol, and env genes. The presence of replication-competent virus could allow spread of vector and helper particles indiscriminately to nontarget cells in vivo, thus greatly increasing the risk of insertional mutagenesis by repeated infection of susceptible cell populations.^{76,77} The absolute need for avoidance of replication-competent viral particles in clinical vector preparations was inadvertently demonstrated when high-grade lymphomas occurred in rhesus monkeys transplanted with HSCs transduced with a vector preparation contaminated with high levels of replication-competent virus.⁷⁸ Over the next several years, a number of modifications in the organization of genetic sequences included in the packaging cell lines has greatly decreased the risk of recombination events, and sensitive systems for detecting replication-competent virus have been developed.^{28,79,80,81} A number of investigators have used packaging cell lines derived from human instead of murine cells to make producer cell lines, in hopes that lower levels of endogenous retroviral sequences in human cells would also decrease recombination events and thus replication-competent viral contamination.^{82,83}

As described below, retroviral vectors are capable of stable integrated transduction of a large number of cell types, including repopulating stem cells, but have a number of important limitations. Stable transduction and integration requires passage of the target cell through the S phase of the cell cycle, preventing transduction of quiescent cells.⁸⁴ The amphotropic receptor density on certain target cell types may be too low to allow efficient transduction.⁸⁵ Thus, redirection of receptor specificity via pseudotyping with alternative envelope proteins has been explored, with some success.^{32,86, 87, 88, 89 and 90}

Biophysical considerations may also limit vector-target interactions. Vector particles are very fragile, and degrade quickly in

P.1497

P.1498

solution or within cells if cell division allowing nuclear entry and integration does not occur. A number of investigators have tried to increase the likelihood of successful transduction by flowing vector solution continuously over target cells or

co-localizing vector and target cells using culture dishes coated with fibronectin fragments.^{91,92} New methods of concentrating and stabilizing vector preparations are also under development.^{33,87,93}

FIGURE 71.5. Schematic representation of transduction of a generic target cell by the four major gene transfer vector systems. The same “gene of interest” is shown being transferred with each vector. AAV, adeno-associated virus; Ad, adenovirus; ITR, inverted terminal repeat; LTR, long terminal repeat.

Lentiviral Vectors

There has been real progress toward the development of alternative retroviral systems that may overcome some of the limitations of the MLV vectors. HIV-derived lentivirus vectors have been most actively pursued. Relatively high-titer

vectors have been reported using production strategies with numerous safeguards against recombination events that could result in generation of wildtype HIV.^{94,95,96} Vectors retaining the HIV gp120 envelope protein could be used to transduce CD4⁺ T-cells, monocyte/macrophages, or glial cells, and pseudotyping with alternative envelope proteins such as vesicular stomatitis virus (VSV) or amphotropic leukemia virus envelope proteins could be used for transduction of a wider range of cells. Lentiviral vectors can traverse an intact nuclear membrane, requiring the HIV gag protein and an accessory VpR protein, thus allowing transduction of nondividing cells.^{97,98} The promise for more efficient HSC transduction using lentiviral vectors remains an attractive feature, however, other features of HIV-based vectors have also stimulated interest. Specifically, the faithful delivery of nonrearranged genes with complex regulatory elements appears superior, and success in delivering the human β -globin gene along with large portions of the locus control region has finally been achieved with HIV-based vectors.⁹⁹ A number of additional safety modifications have been employed, including deletions in the 3' LTR reducing the risk of insertional mutagenesis by self-inactivation of the integrated LTRs. Indeed, the first clinical trial employing lentiviral vectors for the treatment of HIV have been carried out,^{100,101} and subsequent trials have demonstrated clear efficacy in adrenoleukodystrophy (ALD)¹⁰² and thalassemia.¹⁰³

Human Foamy Viral Vectors

The other member of the retroviridae under consideration as a gene transfer vector is the human foamy virus (HFV). HFV, a poorly characterized retrovirus, has three potential advantages. It has never been associated with pathology in animals or humans, it infects a wide variety of primate cell types, and it has the capacity to package longer transgene(s).¹⁰⁴ It does not appear, however, to transduce nondividing cells, although it may be more stable than conventional retroviruses within a target cell, tolerating a more prolonged period before cell division and then integration.¹⁰⁵ Virologists are trying to define the packaging signal and other important elements necessary for engineering a replication-incompetent HFV vector,^{106,107} and a method for the production of helper-free vector stocks has recently been described.¹⁰⁸ Third-generation vectors have now been developed, and these foamy virus vectors appear efficient for transducing HSCs, with high gene transfer rates observed in human cord blood (CB) *in vitro*, and in murine BM (BM) *in vivo* after a single, overnight vector exposure.¹⁰⁹ Recently, HFV vectors have proven highly efficient in a canine model of leukocyte adhesion deficiency (LAD).¹¹⁰

Adenoviral Vectors

Adenoviruses are nonenveloped double-stranded large DNA viruses.¹¹¹ The linear adenovirus genome contains 36 kb with an inverted terminal repeat (ITR) of 100 to 165 base pairs at each terminus. A set of early genes encodes for regulatory proteins that serve to initiate cell proliferation, DNA replication, and down-modulation of host immune defenses, whereas the late genes encode for structural proteins. Adenovirus readily crosses the plasma membrane of many cell types, whether replicating or not, via receptor-mediated endocytosis¹¹² through the receptor, common to two distinct viral pathogens, coxsackie B and adenovirus 2 and 5, termed the coxsackie and adenovirus receptor.¹¹³ Adenovirus escapes the endosome by altering the pH and then enters the nucleus where it remains as a linear episome. In permissive cells, adenovirus replicates and then enters a lytic cycle, destroying the host cell and releasing daughter viral particles. Of the 42 adenovirus serotypes, most are known to cause mild respiratory, gastrointestinal, and conjunctival infections in immunocompetent humans; no associated malignancies in humans have been reported, although some serotypes can transform cells in culture. The human embryonic kidney cell line HEK293 was, in fact, immortalized by transfection of kidney cells with sheared adenovirus serotype 5 DNA; the E1 gene that is integrated into the cellular genomic DNA is apparently responsible for the immortalization of the cell line.

Recombinant adenovirus vectors have been engineered from adenovirus (usually serotype 5) by the removal of the E1 and E3 genes (regulating replication and immune recognition) and replacement by the gene or genes of interest, with space for 7 to 8 kb of new genetic material.^{114,115,116,117,118} High-titer adenovirus vectors, up to 10¹² plaque-forming units (pfu) per ml, can be reliably packaged through the use of a human embryonic kidney transformed cell line,²⁹³ which provide the helper or replication E1 genes, followed by purification and concentrating procedures. The final product is a replication-defective adenovirus vector which is free of helper or wildtype virus that can efficiently transduce nondividing cells.¹¹⁶ These vectors do not integrate into the target cell genome, avoiding insertional mutagenesis and resulting in only transient transgene expression in proliferative tissues. Because of the tropism of adenovirus for epithelial cells, these vectors were initially investigated for the treatment of pulmonary diseases and diseases in which liver gene transfer is desirable.^{119,120}

Transient transgene expression also may result from host cellular and humoral immune responses directed at either transgene-encoded antigens or adenovirus proteins expressed from the large portions of the adenovirus genome retained in these vectors.^{121,122} Another concern is inflammation resulting from *in vivo* transduction of certain cell types, especially airway epithelium.¹²³ *In vivo* use may also be compromised by pre-existing or new antiviral neutralizing antibodies,

limiting the efficacy of repeated dosing, which may be required for applications directed at mitotic tissues.¹²⁴ Nonessential adenoviral sequences are being gradually eliminated from the vectors.^{125,126} The use of adenovirus vectors in which essentially all viral genes are removed is the ultimate goal of such a strategy. Unfortunately, although these vectors have little except the capsid proteins to mark themselves as foreign, there is evidence that they can trigger innate immunity by recognition through the toll-like receptor 9 pathway in target cells.¹²⁷ Further technical issues that are important include the decreased efficiency of vector production as more viral genes are deleted, inasmuch as these functions need to be provided by accessory plasmids through transfection of vector-producing cells. Hence, these highly deleted vectors are often called “helper-dependent.” Specific dosage schedules (e.g., neonatal or embryonic exposure) or co-administration of immune modulators such as cyclosporine or IL12 may also prevent sensitization.^{128, 129, 130, 131} and ¹³² Another strategy being explored is use of different vectors based on adenovirus serotypes other than adenovirus 5. One survey of unusual group B and group D adenovirus serotypes that might be considered for use as HIV vaccines indicates that in a target population in sub-Saharan Africa the existing immunity to adenovirus serotypes 11, 35, and 50 from group B and adenovirus serotypes 26, 48, and 49 from group D are substantially less than that of the commonly studied adenovirus 5 serotype from group C.¹³³ By employing alternatives to adenovirus 5, it might be possible to get around the barrier of pre-existing antivector antibodies for vaccination

P.1499

efforts. Furthermore, it might be possible to alternate the vector type with subsequent vaccinations to thwart neutralizing antiadenovirus immunity to the vaccine vector. Recently, investigators developing HIV vaccination strategies have reported an adenovirus 41 serotype vector that can express HIV envelope protein.¹³⁴ The adenovirus 41 serotype virus is an enterotropic pathogen that causes diarrhea in its wildtype form; the use of a gene transfer vector with tropism for a mucosal surface may present advantages for vaccination against HIV, a pathogen that is normally encountered by the host in the mucosa. This vector has not yet been clinically tested.

In initial clinical trials, adenovirus vectors were used to transfer a normal cystic fibrosis transmembrane conductance regulator (CFTR) gene into airway cells (bronchial or nasal) of patients with cystic fibrosis.^{135, 136} and ¹³⁷ Despite the demonstration that airway cells could be transduced with these vectors in vivo with correction of the chloride transport defect, clinical utility has been precluded by the harmful immune and inflammatory responses noted above. However, the active immune response induced by adenoviral vectors is also being explored as a possible advantage for adenovirus vectors when they are used to transduce tumor cells with cytokines or other immune modulators for tumor vaccine protocols.^{138, 139} and ¹⁴⁰ The fact that most adenoviral gene transfer results in transient transgene expression (in contrast to retroviral-mediated gene transfer) has limited their use for congenital diseases in which permanent expression of a missing protein is desirable, such as hemophilia, ornithine transcarbamylase (OTC)-deficiency, or α -1-antitrypsin inhibitor deficiency. The use of alternating serotypes for repeated administration can only increase the number of administrations so much before immunity to the vectors neutralizes further administration. The powerful and often toxic immune reaction against viral vectors makes their use for vaccination or antitumor therapy more likely than for correction of metabolic disorders.¹⁴¹ The tragic death of a subject who received the OTC-adenovirus vector was mediated in a large part by the “cytokine storm” and resultant systemic immune response that led to widespread capillary leak multiorgan failure.¹⁴¹

Adeno-Associated Viral Vectors

AAV are small nonenveloped single-stranded DNA viruses in the parvovirus family, dependovirus subfamily, that require a helper virus (typically a double-stranded DNA virus such as adenovirus or herpes simplex virus) for production of new viral particles.^{142, 143} and ¹⁴⁴ The linear AAV genome is approximately 4.7 kb long and consists of two homologous ITRs of 145 bp flanking two groups of genes: the rep or nonstructural genes and the cap or structural genes. There are at least eleven serotypes of AAV that differ mainly on the basis of their external capsid proteins. AAV-2 is the best characterized serotype. AAV-2 enters host cells primarily through interaction with the heparin sulfate proteoglycan protein on the cell-surface, and by interaction with the α V β 5 integrin and fibroblast growth-factor receptor proteins. AAV has oncoprotective and HIV-suppressive properties, and is not known to cause disease in humans or other animals.^{145, 146} and ¹⁴⁷ Prior infection with AAV-2 in humans is common: seroepidemiologic studies demonstrate that 80% of the adult population has antibodies.^{143,148}

After cell entry mediated by the capsid protein, wildtype AAV integrates within the host chromosome.¹⁴⁹ Integration of multiple copies in tandem occurs in a site-specific manner within a relatively small area on chromosome 19: this site specificity appears to require rep protein.^{150,151} Specifics of replication and integration are less well understood than for retroviruses.

Recombinant AAV vector DNA contains the AAV ITRs flanking a gene of interest replacing the rep and cap genes. This plasmid is introduced into a cell line permissive for adenovirus, along with a helper plasmid containing the AAV rep and cap genes but no ITRs. Upon exposure to adenovirus or transfection with adenovirus genes such as E4 (particularly open reading frame 6), the cell line packages the recombinant vector sequences using the rep and cap gene products produced by the helper plasmid, and recombinant vector particles are released as the producer cell lyses.^{152,153, 154, 155} and ¹⁵⁶ Recombinant AAV vectors have size constraints: vector sequences longer than 115% of the wildtype length are not packaged or encapsidated efficiently. Very high titers of recombinant AAV particles can be produced, but often a significant percentage of capsids are empty or otherwise defective.

The need for replication-competent adenovirus during AAV vector production complicates the manufacturing and safety issues, inasmuch as the adenovirus must be inactivated or (preferably) removed before use. Some progress is being made toward introducing only the specific adenovirus genes necessary for AAV replication into producer cell lines, avoiding live adenovirus. The inability to harvest AAV vector without actual lysis and death of the producer cells also complicates production of pure and defined vector preparations. Generation of stable packaging cell lines is also hindered because the AAV rep gene product harms most cell types; but recently producer cell lines expressing rep from an inducible promoter have been isolated.^{157,158} Another approach to avoid the issue of helper-virus contamination is to transfect cells with multiple plasmids that separately encode the desired transgene nucleic acid as well as the structural and replication proteins.^{159,160}

Integration of the recombinant vectors into target cell chromosomes appears to be very inefficient, and thus these vectors prove more useful in situations not requiring integration, inasmuch as they have been shown to be stable as episomes for long periods.^{156,161,162} Site-specific integration in chromosome 19, very desirable to avoid random insertional mutagenesis, does not occur with the recombinant AAV vectors, presumably due to lack of rep protein in the vector particle.¹⁶² Many cell types can be efficiently transduced, including nondividing cells such as neurons, but integration and increased efficiency of transduction still appears to depend on cell division or other DNA-disrupting events, although this conclusion is very controversial.^{163, 164, 165, 166} and ¹⁶⁷

Recently, there has been a great deal of interest in the use of vectors based on serotypes other than AAV-2, especially AAV-6, AAV8, and AAV-9, although the work thus far has consisted of in vitro vector production development¹⁶⁰ and preclinical animal studies.^{168, 169} and ¹⁷⁰ It is possible that a number of other parvoviruses can be developed as vectors, including AAV-3, nonpathogenic strains of B19, or novel autonomous parvoviruses isolated from nonhuman primates or other animal species.^{171, 172} and ¹⁷³ These viruses are similar to AAV, but some, such as B19, never integrate. Self-complementary AAV vectors based upon serotypes with high-efficiency delivery to liver cells have been utilized recently to deliver factor IX as a potential treatment for hemophilia B in the canine model with correction of the bleeding abnormalities.^{174,175} These results supported the first successful clinical trials in humans described in detail below.¹⁷⁶

Miscellaneous Other Vectors

Herpes viruses are large DNA viruses with marked neurotropism, generating intense interest in their potential as vectors targeted at the nervous system.^{177, 178, 179} and ¹⁸⁰ They can accommodate very large DNA sequences (up to 30 kb). More recently, these vectors have been reported to transduce some types of hematopoietic cells, including monocytes, leukemic blasts, and progenitor cells.^{181,182} However, these vectors result in only transient expression in dividing cells, and cause cytotoxicity, limiting clinical utility, at least for hematologic applications.

Vaccinia virus, a large DNA virus that replicates cytoplasmically, has also been considered for gene therapy applications.^{183,184} It can accommodate very large transgenes (up to 30 kb) and expresses these genes at very high levels, but expression is

P.1500

transient, and production of replication-incompetent vectors has not yet been possible. Very high immunogenicity limits most clinical applications, but may be advantageous for in vivo vaccination with vaccinia-transduced tumor cells.^{184, 185, 186} and ¹⁸⁷

Genome Editing

Current vectors and protocols have attempted phenotypic correction or modification by gene addition, generally randomly in the genome. A different process, gene correction by homologous recombination, in hematopoietic tissues has been proposed as an alternative.¹⁸⁸ Correction of the genetic defect in lymphoblastoid cell lines derived from patients

with sickle cell disease was described¹⁸⁹ using a RNA-DNA oligonucleotide, yet the applicability of this approach remains elusive.

An alternative corrective approach for some disorders has recently been described. Constructs targeting aberrant splice sites in the form of oligonucleotides, morpholinos, or U7 snRNAs lead to increased levels of correctly spliced β -globin mRNA by effectively blocking the aberrant splice site through the use of sequences complementary to the corrected sequence.^{190, 191} and ¹⁹² A major problem with this approach has remained the difficulty in delivering such constructs in vivo with sufficient efficiency to correct the phenotype and recently, lentiviral vectors designed to deliver modified U7 snRNAs permanently have been tested in cell lines and in primary cells from individuals with thalassemia with encouraging early results.¹⁹³

Targeted DNA double-strand breaks through the use of artificial nucleases was recently shown to increase the efficiency of homologous recombination by several logs, renewing enthusiasm for this approach. The development of zinc finger nucleases (ZFNs) that allow cleavage of DNA in a sequence-specific manner allows the potential for genome editing at virtually any site. These artificial endonucleases mediate DNA cleavage at targeted sites and have been utilized successfully in a broad range of experimental systems including plants, flies, worms, rodents, ESCs, and primary human cells.¹⁹⁴ The ideal set of ZFNs would target double-strand DNA breaks at high efficiency, and more importantly, with high specificity. Specificity has thus far been difficult to achieve. ZFNs can also be utilized to modify normal genes, such as the CCR5 (required for HIV entry), and a clinical trial is now underway testing this approach as a potential therapy for HIV.¹⁹⁵ Transcriptional activatorlike effector nucleases are a new class of nucleases that allow tailored genome editing in a variety of cell types with the potential for increased specificity.¹⁹⁶ The advent of iPS cells that can be generated from individuals with genetic diseases raises the possibility of genome editing followed by differentiation to a cell type of interest as a form of therapy for a number of diseases, and proof of concept has already been achieved in a murine model of sickle cell disease in which iPS cells were corrected with homologous recombination and transplanted after differentiation into hematopoietic progenitors.¹⁹⁷

HEMATOPOIETIC STEM AND PROGENITOR CELLS AS TARGETS FOR GENE TRANSFER

Since the development of helper-free retroviral gene transfer technology, now decades ago, the HSC has been a primary target for gene therapy applications. The curative potential of HSCs carrying corrective genes has been well established through the use of allogeneic bone marrow (BM) transplantation in genetic disorders whereby an individual carrying a normal genotype serves as the stem cell donor, yet procedural toxicities and finite donor availability limit this approach. The prospect of a curative, one-time therapy using genetically modified autologous stem cells for the treatment of a wide variety of congenital disorders such as hemoglobinopathies, immunodeficiencies, or metabolic storage diseases, and of a new weapon against malignancies and HIV infection, has proven irresistible.^{13,14,198, 199, 200} and ²⁰¹ Gene therapy directed at HSCs must utilize an integrating vector, because ongoing self-renewal or proliferation/differentiation would rapidly dilute out an episomal vector in daughter cells. Initial preclinical studies in the 1980s reported the introduction of genetic markers and clinically relevant genes into mouse HSCs using integrating retroviral vectors, providing both conceptual and methodologic insights that led to first-, second-, and third-generation human gene therapy clinical trials (Fig. 71.6).

Gene Therapy Preclinical Evaluation Using Standard Mouse Transplantation Models

Retroviral gene transfer into murine hematopoietic repopulating stem cells has become routine in many laboratories.^{202,203,204} The isolation and availability of various hematopoietic growth factors has allowed ex vivo maintenance and increased retroviral gene transfer into hematopoietic target cells. Several different combinations of growth factors have been successful, including at least two or three cytokines that are active on primitive cells, such as interleukin-3 (IL-3), interleukin-6 (IL-6), and stem cell factor (SCF). Their mechanism of action probably includes both induction of cell cycling, a necessity for retroviral transduction and integration, and up-regulation of retroviral cell-surface receptors.^{85,205,206, 207, 208} and ²⁰⁹ Other manipulations that have been found to increase gene transfer efficiency to murine stem cells include co-culture of target cells directly on a layer of retroviral producer cells, use of high-titer ($>10^5$ viral particles/ml) vectors, induction of stem cell cycling by pre-treatment of donor mice with 5-fluorouracil, and co-localization of vector and target cells using fibronectin-coated culture dishes.^{92,210, 211, 212} and ²¹³ Using these techniques, successful gene transfer can now be achieved in virtually all mice transplanted with transduced syngeneic BM stem cells, with long-term persistence of the vector sequences in 10% to 100% of cells from all hematopoietic lineages.^{206,210,211,213,214} The continued presence of vector sequences in short-lived granulocytes for the lifespan of the mouse and in multiple lineages of the blood of serial transplant recipients indicates that murine repopulating stem cells can be successfully modified with retroviral vectors.^{15,17,206,215,216,217} Documentation of the shared single-cell ancestry of gene-modified cells from different lineages by examining retroviral integration sites among transduced cell progeny has also supported this contention.

The ability of retroviral vectors to introduce marker genes permanently into murine cells with lifelong repopulating ability led investigators to test whether this approach was feasible when clinically relevant genes were used. Genetic disorders with high morbidity and mortality and with no effective conventional treatments were considered prime candidates for preclinical evaluation.

Severe Combined Immunodeficiency Disease

SCID resulting from adenosine deaminase (ADA) deficiency was initially chosen and stable expression of functional human ADA was demonstrated in all hematopoietic lineages at levels near endogenous murine levels in reconstituted murine transplants.^{202,218, 219, 220, 221} and ²²² The efficiencies of gene transfer and ADA levels achieved in these preclinical models, together with the anticipated in vivo selective survival advantage of transduced T-cells, were thought to be predictive of successful correction of lymphoid dysfunction in patients with ADA deficiency.¹³ Retroviral vector-mediated gene transfer has also been used successfully to evaluate gene therapy strategies in several murine models of human immunodeficiencies, including those caused by deficiency

P.1501

of the common γ -chain expressed in T-cell cytokine receptors (X-SCID),²²³ and ^{224,225} JAK3 kinase deficiency,²²⁶ deficiency in the ZAP70 protein,²²⁷ and recombination-activating gene-2 (RAG-2) deficiency.²²⁸

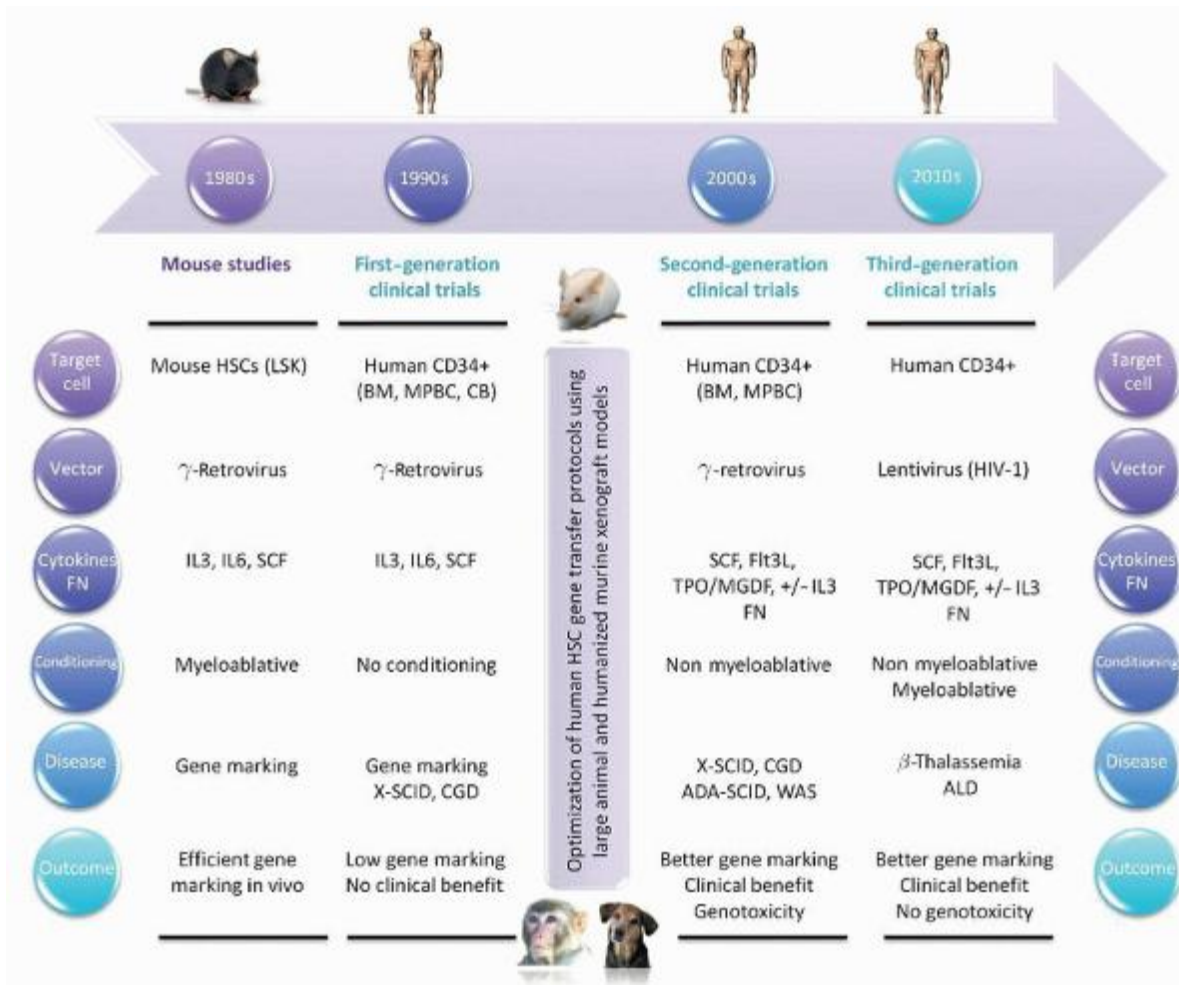

FIGURE 71.6. Timeline for the development of human gene therapy protocols targeting hematopoietic stem cells (HSCs). The main phases in the evolution of HSC gene therapy clinical trials are ordered chronologically. The six principal features defining each phase are outlined. ADA (adenosine deaminase); ALD (adrenoleukodystrophy); BM (bone marrow); CB (cord blood); CGD (chronic granulomatous disease); Flt3L (fms-related tyrosine kinase 3 ligand); FN (fibronectin); HIV (human immunodeficiency virus); IL3 (interleukin 3); IL6 (interleukin 6); LSK (Lin⁻, Sca1⁺, Kit⁺); MGDF (megakaryocyte growth and development factor); MPBC (mobilized peripheral blood cells); SCF (stem cell factor); SCID (severe combined

immunodeficiency disease); TPO (thrombopoietin); WAS (Wiskott-Aldrich syndrome).

Gaucher Disease

Gaucher disease is an inherited deficiency of the lysosomal enzyme glucocerebrosidase (GC) and the associated accumulation of glucocerebroside in the lysosomes of macrophages results in multisystem damage, including hepatosplenomegaly, gradual replacement of bone marrow (BM), skeletal deterioration, and neuropathology in some cases of Gaucher disease. Correction of enzyme deficiency in macrophages by HSC gene therapy has been considered an attractive therapeutic option for these patients. Mouse BM transplant models have been invaluable for initial evaluation of retrovirus-based gene transfer vectors developed for Gaucher disease.^{206,214,229, 230, 231} and ²³² These studies established the feasibility of efficient transfer of the GC gene to normal mouse HSCs and long-term expression in their progeny after reconstitution, strengthening the rationale for gene therapy as a treatment option for Gaucher disease.

Hemoglobinopathies

Hemoglobinopathies, including β -thalassemia and sickle cell disease, were also among the first diseases selected as targets for genetically based therapeutic approaches. Transfer of the human β -globin gene into murine HSCs proved more challenging due to the requirement to include specific endogenous regulatory elements from the β -globin locus that were obligatory to achieve clinically relevant expression. Early preclinical studies demonstrated that retroviral vectors containing the β -globin gene and its promoter could transduce murine HSCs. However, human β -globin gene expression was either absent or very low, usually varying between 0% and 2% of mouse β -globin RNA levels.^{205,233, 234, 235, 236, 237} and ²³⁸ As outlined below, it is not until new vector designs became available that successful genetic correction of β -thalassemia was first demonstrated in murine preclinical models, laying the foundation for a recent clinical trial of gene therapy for β -thalassemia.¹⁰³

P.1502

Chronic Granulomatous Disease

Chronic Granulomatous Disease (CGD) results from mutations in any one of four genes encoding the essential subunits of the phagocytic antimicrobial system NADPH phagocyte oxidase (phox),²³⁹ including gp91phox, p22phox, p47phox, and p67phox, rendering individuals born with CGD particularly susceptible to bacterial and fungal micro-organisms. Retrovirus-based gene transfer vectors have been tested in two CGD knockout mouse models.^{240, 241} and ²⁴² These studies indicated that gene transfer into murine HSCs is feasible and that partial reconstitution of NADPH oxidase activity achieved after retroviral gene transfer can improve host defense if an adequate number of phagocytes exhibit enzyme activity.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich Syndrome (WAS) is an X-linked complex primary immunodeficiency disorder caused by mutations in the gene that encodes the WAS protein (WASP).²⁴³ It is characterized by an increased susceptibility to recurrent infections associated with adaptive and innate immune deficiency, thrombocytopenia, eczema, and autoimmunity.^{244,245} The generation of two Wasp-deficient mice has facilitated preclinical safety and efficacy studies of retroviral vectors for the treatment of WAS. In one study,²⁴⁶ vector-mediated WASP expression was shown to correct the T-cell defect in Wasp mice. In another study, investigators demonstrated rescue of T-cell signaling and amelioration of colitis upon transplantation of transduced WAS HSCs in mice, supporting the development of gene therapy approaches for WAS.²⁴⁷

First-Generation Human Gene Therapy Trials

Because of the absence of *in vivo* assays that measure the repopulating capacity of human HSCs, gene transfer protocols employed in early clinical trials were adapted from the murine studies described above, and initially tested using human *in vitro* colony-forming cell (CFC) assays that detect committed progenitor cells, and long-term BM culture assays that detect a cell capable of maintaining production of CFC for at least 5 weeks on a layer of stromal cells. Notwithstanding the fact that progenitors do not have the same biologic properties as stem cells, investigators were initially encouraged when high gene transfer efficiency (up to 100%) was observed in these *in vitro* progenitor assays using gene transfer vectors and transduction conditions comparable to those employed in the mouse.^{248,249,250} Demonstration of correction of GC and ADA deficiency after retroviral vector-mediated gene transfer into progenitors from patients with Gaucher disease²⁵¹ and ADA-SCID,²⁵² respectively, provided even further impetus to regulators and investigators to initiate a first generation of human HSC gene transfer clinical trials, including gene marking studies and gene therapy trials with therapeutic intent (see Table 71.2).

Genetic Marking Trials

The first human clinical gene transfer trials used retroviral vectors carrying nontherapeutic marker genes, and were critical for establishing proof of principle and allaying safety concerns (Table 71.2).^{7,253} Patients already undergoing autologous transplantation as therapy for an underlying malignancy received genetically marked hematopoietic stem and progenitor cells to determine whether re-infused tumor cells contribute to relapse after autologous transplantation and to establish if transduced HSCs could contribute to long-term hematopoietic reconstitution.^{254,255,256, 257} and ²⁵⁸ Genetically marked tumor cells were unequivocally demonstrated in several patients at the time of relapse, suggesting that the re-infused marrow had contributed to progression, and that investigation of therapeutic purging strategies was worthwhile. The presence of the marker gene was also followed in nonmalignant hematopoietic cells. Gene-marked cells contributed only 0.1% to 1% of the total BM but detection of the marker gene in T-cells and B-cells for as long as 18 months after transplantation was consistent with low-level transduction of primitive hematopoietic cells with multilineage capacity.

In a similar marking study, investigators determined that autologous BM used for transplantation in patients with chronic myelogenous leukemia following intensive therapy also contained cells that contributed to relapse.²⁵⁹ Other gene marking trials involving patients with multiple myeloma,^{260,261,262} breast cancer,^{261,262} follicular lymphoma,²⁶³ and AML²⁶⁴ failed to show stable levels of marked cells of more than 0.1% after transplantation with autologous gene-marked grafts, contrasting with the high-level marking observed in preclinical mouse models. Although valuable in the early stages, the perceived level of risk related to retroviral-marking clinical trials was altered dramatically after the first report of leukemia in a patient receiving retroviral gene therapy for X-SCID,²⁶⁵ and given the lack of any possible benefit to the patient related to use of marking vectors, this type of trial has been completely abandoned.

Gene Therapy Trials with Therapeutic Intent

Despite the low efficiencies of gene transfer into long-term repopulating stem cells achieved in early human marking trials, several Phase I/II clinical trials investigating the transfer of potentially therapeutic genes were initiated (Table 71.2). Important information was obtained on both the safety and feasibility of stem cell engraftment without ablation, and although these initial trials were largely disappointing, there were glimmers of hope regarding clinical benefit.

Severe Combined Immunodeficiency Disease

SCID due to ADA deficiency has been a prototype target disease for gene therapy since the initial development of retroviral vectors over a decade ago,²⁶⁶ and children with ADA-deficient SCID were the subjects of the first clinical trial utilizing a vector carrying a therapeutic gene directed at T-lymphocyte targets (see below). HSCs would be theoretically preferable to T-cells as gene correction targets in this and other immunodeficiency disorders, because of the potential for permanent and complete reconstitution of the T-cell repertoire.

To address this hypothesis directly, two ADA-deficient children received autologous BM and mature lymphocytes transduced with two different retroviral vectors carrying the therapeutic ADA gene and the Neo gene and then repeatedly re-infused without conditioning.²⁶⁷ In the first year after initiation of these infusions, vector-containing T-cells originating from the transduced T-cells were observed, but with time, there was a shift to vector-containing T-cells originating from transduced BM cells. The proportion of gene-corrected clonable T-cells was 2% to 4%, and analysis of T-cell-receptor gene rearrangements indicated a wide repertoire of corrected clones. A surprisingly high number of marrow myeloid colonies resistant to neomycin were also reported, despite lack of conditioning, and an *in vivo* selective advantage for gene-corrected cells of all lineages was hypothesized.

For genetic disorders diagnosed *in utero*, the use of CB cells as targets for gene transduction represents an exciting alternative approach.^{268,269} CB may contain greater numbers of primitive reconstituting cells with higher proliferative potential that may prove more susceptible to retroviral transduction. Moreover, early treatment is crucial in diseases that progress to irreversible damage before a child is old enough to allow collection of mobilized peripheral blood or BM cells.²⁷⁰ Three infants diagnosed *in utero* with ADA deficiency allowed the testing of this concept, and CB was collected at the time of delivery. The cells were CD34-enriched and transduced with an ADA/Neo

P.1503

P.1504

retroviral vector and infused in the absence of conditioning.²⁷¹ Vector sequences were initially detected in circulating myeloid and lymphoid cells at low levels of <0.1% in all three children for >18 months. As expected if corrected lymphocytes have an in vivo advantage, 4 years after the newborns were given infusions of transduced autologous CD34⁺ cells, the frequency of gene-containing T lymphocytes rose to 1% to 10%, whereas the frequencies of other hematopoietic and lymphoid cells containing the gene remained <0.1%. Cessation of polyethylene glycol-conjugated ADA enzyme replacement in one subject led to a decline in immune function, despite the persistence of gene-containing T lymphocytes. Thus, despite the long-term engraftment of transduced HSCs and selective accumulation of gene-containing T lymphocytes, this study indicated that improved gene transfer and expression were needed to attain a therapeutic effect.²⁶⁷

P.1506

Fanconi Anemia

Fanconi Anemia (FA) is another genetic disorder of the hematopoietic system that appears to be an excellent candidate for gene therapy. This congenital syndrome is characterized by BM failure, physical anomalies, and an increased susceptibility to marrow failure and leukemias. Cells from these patients are abnormally sensitive to chemically induced DNA cross-linking. Many of the complementation groups have been cloned and sequenced, making a genetic approach feasible for this disorder.²⁷² Phenotypic correction of this abnormality in cells from one patient group was successful after

transduction with viral vectors carrying the Fanconi anemia complementation group C gene (FACC).^{273,274} A possible *in vivo* survival advantage for gene-corrected primitive cells and their progeny has made FA an attractive candidate disease for stem cell gene therapy. Even a very low efficiency of transduction might result in gradual *in vivo* expansion of corrected progenitor and stem cell populations. A clinical trial testing this hypothesis using granulocyte-colony stimulating factor (G-CSF)-mobilized peripheral-blood CD34⁺ cells as targets yielded disappointing results, in part because of the very poor mobilization in these subjects,²⁷⁵ yet engraftment with corrected progenitor cells was demonstrated.²⁷⁶

Gaucher Disease

Modeling preclinical murine transplantation models, gene therapy was also attempted for Gaucher disease.²⁷⁷ Akin to the previous gene therapy trials, no conditioning was used in these patients prior to infusion of G-CSF mobilized or BM CD34⁺ cells transduced with standard retroviral vectors carrying a normal GC cDNA. Unlike results obtained in the mouse, low numbers of gene-corrected cells were again detected, with little or no expression and no disease correction following transplantation.

Chronic Granulomatous Disease

Similar results were obtained in a clinical trial for an autosomal recessive form of CGD.²⁷⁸ Five patients received transduced G-CSF mobilized CD34⁺ cells without pre-conditioning. Corrected granulocytes were detected in the peripheral blood of all individuals for up to 6 months after infusion but the levels (0.004% to 0.05%) were below the desired 5% to 10% required for therapeutic effects.

Optimization of Human Gene Therapy Protocols

Although the first-generation human gene therapy trials established the proof of principle of transduction of primitive human repopulating hematopoietic cells, they uniformly failed to reach and maintain therapeutically relevant levels of genetically modified cells. This striking difference in outcome observed between mouse and human studies was proposed to result from intrinsic differences between mice and humans, resulting in a different susceptibility to retroviral transduction and a different ability of transduced HSCs to engraft. Other considerations included loss of stem cell activity by forced *ex vivo* division, immune recognition of cells expressing foreign transgene products, toxicity from the constitutive expression of the transferred gene products on HSC differentiation *in vivo*, lack of conditioning in the clinical settings, and the minimal expression of amphotropic surface receptors used by retrovirus-based gene transfer vectors on human HSCs.⁸⁵

The recognition of differences in HSC behavior between mice and humans and the disappointing results in the early human HSC gene therapy clinical trials underscored the need for alternative assays similar to those available in mice that permit direct identification and characterization of human long-term reconstituting cells and their susceptibility to gene transfer. These alternative assays provided the necessary platform for the optimization of human gene therapy protocols, leading to the first clinical trials with therapeutic benefits.

Development of Preclinical Animal Models for Investigating Gene Transfer into Human Hematopoietic Stem Cells

Large Animal Models

Inasmuch as prolonged follow-up of *in vivo* hematopoiesis is the most reliable parameter to identify human HSCs, large animals are more adapted than mice for evaluation of gene transfer to long-term repopulating cells, given their lifespan and their size, allowing repetitive blood and marrow sampling.

Fetal Sheep

The group of E. Zanjani, capitalizing on the immunologically tolerant environment of the fetal sheep between 50 and 60 days of gestation, successfully showed engraftment and persistence of human cells several years after intraperitoneal administration *in utero* of primitive human hematopoietic cells from CB or BM.^{279,280,281} Among fetuses reaching maturity, at least 50% showed long-term persistence of human cells and demonstration that retrovirally transduced human cells could be detected,²⁸² suggesting transduction of primitive human HSCs. However, the procedure was hampered by low-level engraftment, a high rate of fetal loss, and impracticality for most research groups.

Nonhuman Primates

Given their phylogenetic proximity to humans, nonhuman primates, including baboons and Old-World rhesus macaques, have been employed extensively for the preclinical testing of promising gene therapy strategies.^{283,284} The cross-reactivity of reagents employed for human application adds to the practicality of these models. In contrast to murine studies, much lower levels of gene-modified circulating cells than in the murine experiments were reported using similar vector systems and transduction conditions, generally <0.01% to 1%.^{285, 286, 287} and ²⁸⁸ These results were very similar to data obtained in

first-generation clinical trials, validating the importance of large animal models for the optimization of gene therapy strategies in humans. The value of these models for preclinical testing was also illustrated when aggressive T-cell lymphomas developed in 3 of 10 rhesus macaques as a result of insertional mutagenesis following transplantation with BM cells transduced with retroviral vector stocks contaminated with replication-competent helper virus capable of continued gene transfer in vivo.^{78,289} This setback led to a reassessment of safety issues and increased regulatory oversight of human clinical trials, with consensus that it is absolutely necessary to use producer cell lines and vector stocks that have been confirmed to be free of helper-virus contamination in any clinical application.

Canine Models

The canine autologous transplantation model has also been used to test retroviral gene transfer strategies. Successful transduction of G-CSF-mobilized peripheral-blood engrafting cells was first demonstrated in the dog, as was the importance of partially or fully ablative conditioning radiation or chemotherapy for detectable engraftment with transduced primitive hematopoietic cells.^{290, 291} and ²⁹² Cross-reactivity of human reagents has proven more problematic in the dog model, yet continued progress in this model has led to a clinically relevant gene transfer technique.^{293,294} Recently, further progress in this model has allowed the attainment of very high levels of genetically modified cells, approaching 100%.^{293,295, 296} and ^{297,298,299} The value of the dog model as a large animal model is further strengthened by the presence of several disease states that mimic those in humans, which could

P.1507

allow stringent preclinical testing, as recently shown in a canine model of LAD¹¹⁰ and pyruvate kinase deficiency.³⁰⁰

Large animal models thus became a focus, but outbred animals introduce significant experimental variability and the high costs limit the breadth of experiments that can be performed. For this reason, a competitive re-population model in which each animal serves as its own control has been utilized for the majority of subsequent comparative studies. In this model, hematopoietic progenitors are isolated and divided equally for transduction under two (or more) distinct experimental conditions using marking vectors that can be distinguished in vivo following reconstitution. Loss of stem cell activity during the ex vivo culture required to achieve gene transfer was a major concern generated by the early human clinical trials, a concern supported by studies in the mouse in which ex vivo culture of HSCs resulted in a significant engraftment defect.³⁰¹ Competitive experiments in the nonhuman primate tracking genetically modified cells subjected to either short or extended ex vivo culture supported this notion.³⁰²

Immunodeficient Mice

Although results from the large animal models have correlated better with results from early human clinical trials, the rhesus and canine experiments are expensive, slow, and technically difficult, not allowing large-scale testing of new approaches. Over the past 20 years, xenograft mouse models have gained in popularity, in part due to access, and investigators have begun to employ engraftment of transduced human hematopoietic cell populations in immunodeficient mice as an alternative experimental model.^{303, 304, 305, 306} and ³⁰⁷ Initially, large numbers of human BM cells were intravenously injected into sublethally irradiated mice lacking a functional immune system to prevent rejection of the injected human cells, including severe combined immunodeficient (Scid) and beige/nude/xid (bnx) mice.^{308,309} With regular treatment of engrafted Scid mice with a combination of human hematopoietic cytokines, human BM cells that migrated to the mouse marrow and spleen gave rise to a small but sustained pool of myeloid progenitors and B-cells for several months, indicating that the engraftment was long-term and multipotent, fulfilling two key criteria used to define HSCs.

The Scid mouse used in these initial studies can spontaneously generate murine T- and B-cells with age and has high levels of natural killer (NK) cell activity, both impeding efficient and prolonged xenograft. To improve upon the available immunodeficient mouse strains, the Scid mutation was backcrossed onto the nonobese diabetic (NOD) background.³¹⁰ The resultant NOD-Scid mouse had reduced innate immunity and superior engraftment of human hematopoietic cells. However, further improvements were sought due to the high incidence of spontaneous thymic lymphomas that shortened their lifespan, a striking preferential development of human B-cells after transplantation, and a persistence of murine NK-cells resulting in a lack of human T- and NK-cell differentiation in this strain. By reducing or abolishing NK activity in NOD-Scid mice a new strain, NSG or NOG mice, was developed and is currently the most widely used humanized mouse model for gene therapy preclinical testing.^{311,312,313,314}

The immunodeficient mouse model assays a human cell population, operationally defined as Scid repopulating cells (SRCs), that is distinct from hematopoietic progenitors identified using in vitro methodology, including long-term culture initiating cells and CFCs.²⁵⁰ Using a gene marking approach similar to that used in mouse transplant studies and early

clinical trials, Guenechea et al.³¹⁵ showed that individual engrafted and marked human SRCs could produce a large clone of differentiated progeny with engraftment potential in secondary NOD-Scid recipients, demonstrating the proliferative and self-renewal capacity of SRCs, respectively. Although this study did not contain a direct analysis of individual lineages, a recent investigation by the same group³¹⁶ successfully tracked self-renewal and multilineage output of single human cells purified using a complex set of markers (CD34+CD38-CD45RA-CD90+CD49f+Rhlo) for at least 8 months after transplantation in NSG mice. Together, these studies fulfilled the proliferative, self-renewal, and multipotential criteria previously used to define murine HSCs, providing a compelling characterization of human HSCs. Although, in practical terms, the above studies served to validate the murine xenotransplant model as a sound surrogate assay system for human stem cells, the predictive value of these xenograft models remains questionable, as a direct comparison of engraftment of genetically modified autologous baboon cells in both the baboon and the NOD/SCID mouse suggests distinct populations contributing to hematopoiesis, with short-term progenitors only read out in the immunodeficient mouse.³¹⁷

The development of better assays for evaluating gene transfer efficiency in human repopulating cells has culminated over the past two decades in various strategies to improve gene transfer protocols, including: (1) new retroviral vector designs, (2) optimized transduction conditions, and (3) use of conditioning regimens to favor engraftment of transduced cells.

Use of Alternative Gene Transfer Vectors

Standard retroviral vector systems have been used extensively in small and large animal models and have dominated clinical trials based on ex vivo transduction of autologous CD34⁺ cells. However, the dependence of these vectors on cell cycling for efficient transduction has limited their utility in quiescent HSCs. Thus, alternative viral vector systems have been explored, including AAV and retroviral vectors based on various members of the Retroviridae family (e.g., lentiviruses and spumaviruses). The need for integration has precluded extensive investigation of nonviral delivery systems for hematopoietic applications requiring long-term expression.

Adeno-associated Viruses

Despite a great deal of initial enthusiasm for the use of AAV as a clinical gene transfer vector, more recent data argue against the use of AAV for most applications requiring stable integration in hematopoietic cells and their progeny. Several laboratories have reported high transduction efficiency of both human and murine hematopoietic progenitors, as assayed by PCR or transgene expression analysis on individual CFC.^{162,318,319} These are difficult to interpret, however, given the stability of the AAV vector DNA and the very high efficiency of transient expression of transgenes for days to weeks without integration.^{161,318,319} Although these studies indicate no advantage over retroviral vectors in terms of gene transfer into repopulating stem cells, efficient transfer to hematopoietic cells can be obtained by using AAV vectors.^{320,321}

Human Foamy Viruses

HFV are retroviruses that specifically belong to the genera Spumavirus. The nonpathogenic nature of HFV makes vectors based on this virus more palatable. Because problems encountered in the production of replication-competent, retrovirus-free vector have been overcome, vectors based on the HFV have been used to transduce hematopoietic cells efficiently. They were employed to phenotypically correct CD18 integrin deficiency in a canine model of LAD,¹¹⁰ gp91phox deficiency in a mouse model of X-CGD,³²² and hemolytic anemia in a canine model of pyruvate kinase deficiency³⁰⁰ but it has not yet been used in clinical trials. However, they do not appear to transduce hematopoietic stem and progenitor cells more efficiently than standard retroviruses.

Lentiviral Vectors

Unlike vectors based on standard retroviruses, lentiviral vectors harbor a pre-integration complex that appears more stable and

P.1508

able to cross an intact nuclear membrane, thus allowing transduction of nondividing cells such as HSCs. However, it is also generally agreed that cells must exit G0 and enter G1 for efficient transduction by HIV-1 based vectors.

Self/inactivating Feature of Lentiviral Vectors

Because of safety concerns regarding recombination with endogenous HIV, a safety or "self-inactivating (SIN)" feature was incorporated in these vectors by eliminating a portion of the 3'-LTR, which on proviral integration replaces and thus inactivates the 5'-LTR. For these SIN vectors, the efficiency of transgene expression is highly dependent on the addition of ubiquitous internal promoters, such as the murine stem cell virus (MSCV), the human elongation -1a (EF1-a), human

phosphoglycerate kinase (PGK), spleen focus forming virus (SFFV), gibbon ape leukemia virus (GALV), or the hybrid chicken actin promoter containing the CMV enhancer region (CAG).

Altering Tropism of Lentiviral Vectors through Pseudotyping

Wildtype HIV-1 virions infect cells that express the CD4 receptor and an appropriate co-receptor. Expansion of the cellular tropism of HIV-1-based vectors can be accomplished by substituting the wildtype envelope protein with an envelope protein from a different virus, a process referred to as pseudotyping.³²³ The MLV amphotropic envelope used in most clinical gene therapy trials employing standard retroviral vectors was also chosen in early experiments with HIV-derived vectors.⁹⁵ However, its receptor, Pit-2, is only present at very low levels on HSCs, correlating with the low efficiency of lentiviral transduction in this cell type.⁸⁵ Screening of an extensive panel of pseudotyped MLV-based vectors using the xenograft murine and nonhuman primate models established the superiority of the GALV, the cat endogenous retroviral glycoprotein (RD114) and the VSV-G protein for the transduction of HSCs.^{89,324, 325} and ³²⁶ However, pseudotyping lentiviral vectors with alternate envelope proteins, namely GALV and RD114, has proven more difficult due to refractory residues within the cytoplasmic tail of both envelopes that limits their cleavage by lentiviral proteases. To improve the lentiviral packaging efficiency of GALV and RD114, chimeras of each envelope have been constructed by replacing the tail region of GALV and RD114 with the corresponding region from MLV. The resulting chimeras, GALV-TR and RD114-TR, have been shown to pseudotype lentiviral vectors with increased efficiency.^{327, 328} and ³²⁹

In contrast to native GALV and RD114, VSV-G is efficiently incorporated in HIV-1 virions. VSV-G pseudotyping confers high vector particle stability, allowing for repeated freeze-thaw cycles and concentration by ultracentrifugation to titers exceeding 10⁹ particles/ml.^{32,95,330} Pseudotypes based on VSV-G have broad tropism long thought to be conferred by interaction with phosphatidylserine (PS), a ubiquitous cellular lipid, but the role of PS as a cell "receptor" for VSV-G particles has been refuted.³³¹ When directly compared to amphotropic or RD114-pseudotyped lentiviral vectors using the NSG preclinical assay, vectors bearing the VSV-G envelope protein showed higher efficiency of transduction in human repopulating cells.³³² Toxicity of the VSV-G protein to cells in which it is expressed is perhaps the most significant shortcoming of this envelope protein. However, success has been obtained in deriving a stable packaging cell line by expressing VSV-G from a tetracycline-inducible promoter although this methodology has not yet been used clinically.^{333,334} Moreover, notwithstanding the observed toxicity of VSV-G and the demonstration that VSV-G-pseudotyped vectors produced in human cells were rapidly inactivated by human serum,³³⁵ two recent gene therapy trials^{102,103} have reported successful long-term transduction of human HSCs using HIV-1-based vectors pseudotyped with VSV-G.

Altering the Tropism of Lentiviral Vectors for Selective Targeting of CD34⁺ Cells

Envelope proteins made chimeric by the addition of a ligand, such as the early-acting cytokines SCF and thrombopoietin (TPO), have been explored as a mechanism for specifically targeting lentiviral vectors to primitive hematopoietic cells expressing the SCF receptor KIT. These vectors could be used for *in vivo* targeted gene delivery to HSCs, eliminating the risk of inducing cell differentiation and loss of the homing/engraftment potential of these cells as observed in *ex vivo* targeted HSC gene delivery approaches. The selective transduction of HSCs by VSV-G/TPO/SCF-displaying vectors was demonstrated by their capacity to promote selective transduction of long-term NOD/SRCs.³³⁶ However, the fusion glycoprotein VSV-G in VSV-G/TPO/SCF-co-displaying lentiviral vectors is sensitive to human immune/complement system, rendering these vectors unsuited for *in vivo* gene delivery.³²⁹ Recently, complement-resistant vectors capable of specifically targeting the very rare immature progenitor cells in an immunodeficient murine model were produced by substituting VSV-G for the complement-resistant glycoprotein mutant RD114-TR.³³⁷ Completely obviating *ex vivo* manipulation of HSCs may be of particular interest for gene therapy of BM failure syndromes for which the number of stem cells is limited.

Preclinical Evaluation of Lentiviral Vectors

Given the established lack of predictability of standard murine transplantation models for evaluation of HSC transduction efficiency in humans, investigators initially chose the murine xenotransplant assay to validate the ability of HIV-1-based vectors to efficiently transduce human hematopoietic cells, including CD34⁺ cells and the more primitive CD34⁺/CD38⁻ subset. Several groups reported efficient gene transfer of SRC derived from human CB,^{338,339,340,341,342} BM³³⁸ and mobilized peripheral blood^{343,344} under conditions where standard retroviral vectors were ineffective. High-level green fluorescent protein (GFP) transgene expression in SRC capable of secondary³⁴² and tertiary³⁴¹ multilineage re-population in NOD-Scid mice suggested transduction of primitive human HSCs with pluripotential, proliferative, and self-renewing capabilities. As outlined below, these preclinical data have recently been confirmed in the context of clinical trials for ALD¹⁰² and β -thalassemia.¹⁰³

Demonstration of the utility of HIV-1-based lentiviral vectors to transduce hematopoietic cells with long-term repopulating potential was initially met with limited success in rhesus macaques^{345,346} and baboons.³⁴⁷ These Old-World monkeys were found to possess cellular antiviral factors responsible for the observed resistance to HIV-1 infection. In contrast, HIV-1-based lentiviral vectors could mediate efficient gene transfer to long-term repopulating cells in the canine²⁹⁵ and pigtailed macaque models.³⁴⁸ The restriction to HIV-1 infection in rhesus macaques was alleviated by modification of HIV-1-based vectors^{349, 350} and³⁵¹ or by the use of an alternative lentiviral vector based on the simian immunodeficiency virus (SIV).^{352,353, 354, 355} and³⁵⁶

Despite the lack of predictability of standard murine transplantation studies for evaluation of gene transfer into human HSCs, mouse disease models developed by gene targeting or arising from spontaneous gene mutations may represent the only available option for preclinical testing of the impact of gene transfer vectors on disease phenotype; large animal disease models do not exist for most disorders treated by gene therapy, and for a number of orphan diseases that are common targets of gene transfer protocols, it is impractical to obtain biospecimens from a large cohort of patients to perform preclinical murine xenotransplant efficacy studies. All disorders with active HSC gene therapy clinical trials have employed murine models of human diseases to evaluate efficacy of lentiviral vectors for correction of disease phenotype, including ALD,¹⁰² WAS,^{357, 358, 359, 360, 361} and³⁶² β -thalassemia,^{363, 364, 365} and³⁶⁶ SCID,^{367, 368, 369, 370} and³⁷¹ and CGD³⁷².

P.1509

Gene Transfer Vectors with In Vivo Selectable Markers

One strategy to increase the efficiency of gene transfer entails the inclusion of selectable genes in vectors to confer an in vivo advantage to transduced cells. Successful in vivo selection has previously been documented in murine HSC transplantation models using several drug resistance genes, including multi-drug resistance protein-1 (MDR-1),^{213,373} dihydrofolate reductase (DHFR),³⁷⁴ and O6-methylguanine-DNA methyltransferase (MGMT)^{375, 376} and³⁷⁷ However, in more clinically relevant large animal models, in vivo selection using DHFR³⁷⁸ and MDR-1^{379,380} was variable and transient, with levels of gene-modified cells returning to baseline within a few weeks. MGMT is one of the most promising drug resistance genes that encodes for the DNA repair protein O6-alkylguanine-DNA-alkyl-transferase (AGT). This protein confers resistance to the cytotoxic effects of alkylating agents, including nitrosoureas (e.g., BCNU) and temozolomide. Incorporation of a mutant form of MGMT in the gene transfer retroviral vectors can facilitate a greater selective advantage for primitive hematopoietic cells containing the vector after in vivo administration of an alkylating agent. In vivo selection of HSCs using MGMT was successfully achieved in murine,^{376,377} nonhuman primate^{298,381} and canine models,^{297,298,382,383} and in human NOD/SRCs.^{384,385} However, results in large animals were not uniformly positive³⁵⁴ and, although no evidence of leukemic transformation was seen using this approach, the cumulative genotoxicity resulting from the combined use of alkylating agents and retroviral vectors needs to be considered.

Gene Transfer Vectors with Ex Vivo Selectable Markers

Positive selection of transduced cells in vitro before re-infusion is another strategy to increase re-population with gene-modified cells. Vectors containing genes for various cell-surface proteins have allowed flow cytometric sorting of successfully transduced cells. A number of studies have utilized the human cell-surface protein CD24, or the murine homolog heat-stable antigen (HSA). There is limited sequence homology between the murine and human forms, and noncross-reactive antibodies are available for selection. Their small size means they take up little space in the vector construct. Murine marrow cells transduced with a vector-containing human CD24 and sorted before re-infusion resulted in greatly increased long-term reconstitution with vector-containing cells.³⁸⁶ A vector expressing murine HSA allowed enrichment for transduced human progenitor cells.³⁸⁷ However, CD24 and HSA are GPI-linked surface proteins, a class of proteins that has been shown to be transferred from cell to cell both in vitro and in vivo, clouding the specificity of this marker and raising concerns about ectopic expression of these genes in vivo.^{161,386,387}

Retroviral vectors carrying a truncated nonfunctional form of the human nerve growth-factor receptor have also been developed as a selectable marker for use on hematopoietic targets, because hematopoietic cells do not express endogenous nerve growth-factor receptor. The introduction of new cell-surface proteins has the theoretical disadvantage of altering trafficking or cell-cell interactions upon infusion of transduced cells. Alternative cytoplasmic markers such as GFP and mutated murine protein are naturally fluorescent, avoiding the need for pre-selection antibody staining.³⁸⁸ However, prolonged stable expression of these proteins has proved difficult, and there is evidence that these proteins are toxic to primary mammalian cells.^{389,390} The use of selection for GFP after retroviral-mediated transduction in the nonhuman primate model to increase engraftment by genetically modified cells resulted in increased short-term

engraftment only, raising another concern that expression of transferred genes may be more efficient in differentiated rather than stem cells, effectively enriching for progenitors with only short-term potential.³⁹¹

Low transduction efficiency of primitive human HSCs may preclude post-transduction sorting for a marker gene if, after sorting, too few stem cells remain to allow safe and rapid hematopoietic reconstitution; this is especially problematic after ablative chemotherapy. A potential solution to this problem would be ex vivo expansion of selected transduced cells prior to re-infusion. However, when ex vivo cultured cells compete against endogenous stem cells in a nonablative model, a significant engraftment defect is evident,^{301,392} indicating that true long-term repopulating cells cannot be expanded efficiently or even maintained ex vivo using current culture conditions.^{302,393, 394, 395} and ³⁹⁶

Gene Transfer Vectors with Genes Promoting Selective Growth Advantage to Transduced Cells

In most diseases considered to be suitable targets for gene therapy, corrected cells do not themselves have an inherent growth advantage, providing an impetus to arm retroviral vectors with genes capable of conferring a selective growth advantage to transduced HSCs and their progeny. For example, mouse HSCs transduced with the homeobox gene, HOXB4, possess more than tenfold greater repopulating ability than that of nontransduced BM.³⁹⁷ Furthermore, transgenic overexpression of the antiapoptotic protein Bcl-2 results in increased HSC numbers,³⁹⁸ and expression of a truncated form of the human erythropoietin (Epo) receptor can augment HSC engraftment through the use of exogenous Epo.³⁹⁹ Blau et al. have utilized inactive monomeric signaling domains derived from receptors such as Epo or TPO to permit controlled growth of genetically modified cells through the use of chemical inducers of dimerization.^{400,401} Another approach involves selective enrichment of genetically modified cells using vectors encoding a fusion protein between the growth-signaling portion of the G-CSF receptor and the hormone-binding domain of the estrogen receptor. This approach allows controlled growth of genetically modified cells using exogenous estrogen, and preclinical testing in the nonhuman primate demonstrated the feasibility of this approach.^{402,403}

However, the risk of combining integrating vectors and growth-promoting genes for clinical applications has recently been highlighted in large animal model preclinical studies. Investigators transduced monkey CD34⁺ cells with either a HOXB4-expressing vector or a control vector expressing only a marker gene and analyzed the competitive repopulating ability of these cells in vivo. As hoped, there was an early very significant advantage for the HOXB4-transduced cells following engraftment of the monkeys, but in contrast to mouse studies, a much less significant advantage for the HOXB4-transduced cells was observed long-term after transplantation.⁴⁰⁴ However, approximately 2 years after transplant, they reported the first instances of leukemia linked to HOXB4 expression, both in the original group of monkeys and in dogs that received cells transduced with HOXB4-expressing vectors.⁴⁰⁵ Myelodysplasia in two additional nonhuman primates was subsequently reported in association with retroviral vector-mediated insertional mutagenesis and overexpression of HOXB4.⁴⁰⁶ Overall, these studies strongly indicated that overexpression of HOXB4 using integrating retroviral vectors is much too risky to be contemplated in any clinical settings.

Optimization of Transduction Conditions

Cytokine Combination

Various procedures have been refined by different laboratories to optimize retrovirus-mediated transduction in HSCs. A delicate balance must be reached to reconcile the needs for cell cycling for

P.1510

productive transduction without impairing the repopulating ability of HSCs. The current consensus based on large animal and murine xenograft models favors a transduction step in the presence of an early-acting cytokine cocktail composed of SCF, FLT-3L, and TPO, with the optional addition of IL-3. The mechanism of action of these early-acting cytokines is generally related to their effect on cell cycle status but they have also been proposed to enhance transduction by down-regulating proteasome activity in HSCs.^{407,408} Transduction with standard retroviral vectors is typically performed over 72 hours with an obligatory 24-hour cytokine-mediated prestimulation step to favor cell cycling. For lentiviral vectors, a 24-hour prestimulation followed by a single 24-hour transduction in serum-free medium with cytokines has been proposed as an optimal protocol for transduction of human CD34⁺ cells using the humanized NSG mouse xenograft model.^{409,410}

Use of Fibronectin during Transduction

The function of HSCs depends upon the signals from surrounding stromal cells (e.g., fibroblasts, osteoblasts) and extracellular matrix molecules (e.g., fibronectin) found within the highly specialized BM microenvironment. In murine studies, co-culture of the hematopoietic target cells with the fibroblast-derived retroviral producer cells has been shown

to be the most efficient gene transfer method. However, this approach is inappropriate for use in human clinical trials because of the risk of co-infusing the producer cells into patients along with the transduced hematopoietic cells.

To expand clinical applicability of murine gene transfer protocols, several investigators showed increased gene transfer to human hematopoietic cells adherent to autologous or allogeneic BM stromal cells using *in vitro* assays.^{411, 412} and ⁴¹³ Similarly, addition of autologous stromal cells during the transduction period promoted gene transfer into HSCs in the rhesus macaque model.³⁰² However, the technical difficulties associated with extensive scale-up have limited widespread clinical application of this approach. Moritz et al. took a different tactic by transducing human hematopoietic cells cultured in vessels coated with the chemotryptic 35-kd carboxy-terminal fragment of human fibronectin (FN35) and noted enhanced transduction by retroviral vectors.⁴¹⁴ A recombinant version of this fragment (CH-296), commercially available as Retronectin (Takara Biomedical, Otsu, Japan), was shown to enhance gene transfer in human CD34⁺ cells by co-localization of the cells with the vector,^{212,415,416} unless an excess of retroviral particles was used during transduction.⁴¹⁷ The co-localization of vectors and target cells can be enhanced using spinoculation, a neologism coined to describe low-speed centrifugation used at the start of transduction to augment gene transfer.⁹³ The enhancement effect achieved with fibronectin was also attributed to biologic effects on HSCs, such as preservation of repopulating potential^{212,418, 419} and ⁴²⁰ and decreased apoptosis.⁴²¹ Extensive preclinical studies showed successful gene transfer into murine long-term repopulating stem cells as well as into human and nonhuman primate CD34⁺ cells derived from BM, CB, or mobilized peripheral blood when transduction was performed *in vitro*^{421,422,423,424} or *in vivo*⁴²⁴ with retroviral vectors and Retronectin. Correspondingly, in all recent clinical gene therapy trials showing therapeutic benefits, retroviral transduction of human CD34⁺ cells was conducted in the presence of human recombinant fibronectin.

Conditioning Regimens to Enhance *In Vivo* Gene Marking

Engraftment of HSCs is a competitive process between endogenous and infused stem cells. For disorders such as SCID, a growth advantage conferred on genetically corrected cells enables engraftment without conditioning, yet for the majority of disorders in which HSC gene transfer may be applicable, no such advantage to the modified cells is conferred and most investigators have relied instead on toxic myeloablative conditioning to damage or destroy endogenous stem cells and thus provide a competitive advantage to the infused genetically modified stem cells. In preclinical models³⁰² and in patients with malignancies,^{254,261,262} myeloablative regimens have been used routinely to enable engraftment of gene-modified primitive hematopoietic cells. However, many of the diseases that could be targeted by gene therapy are chronic indolent disorders in which the risks of myeloablative regimens may outweigh the potential benefits.

Preclinical Evaluation of Nonmyeloablative Conditioning Regimen in Murine Models

Reduced intensity (nonmyeloablative) conditioning regimens were tested in preclinical models to assess engraftment of marked HSCs while reducing transplant-related toxicities. Engraftment of corrected cells can be achieved in mice in the absence of conditioning by using extremely large BM grafts but this approach is not clinically feasible.^{353, 354, 355, 356} and ³⁵⁷ Moderate-dose irradiation or antimetabolite-based nonmyeloablative conditioning allowed correction of CGD^{242,425, 426, 427} and ⁴²⁸ and X-SCID⁴²⁹ in mouse models of these disorders. Alternative conditioning strategies to promote engraftment of infused HSCs with increased safety have been investigated in mice and are of potential relevance for gene therapy applications. For instance, administration of an antibody that blocks c-kit, the receptor for SCF, transiently reduced endogenous murine stem cells, facilitating engraftment with donor HSCs in immunodeficient Rag2^{-/-}/γc^{-/-} mice but not in immunocompetent mice.⁴³⁰ Combination of this antibody with low-dose irradiation profoundly decreased endogenous repopulating activity, enabling efficient and durable engraftment of fresh or lentivirus-transduced BM cells in wildtype and CGD mice.⁴³¹ In another study, HSC mobilization with AMD3100, a CXCR4 antagonist with a favorable safety profile in clinical studies, was shown to vacate niches in the mouse BM microenvironment and thus could be used in this model as a preparative regimen for stem cell transplantation (SCT).⁴³²

Preclinical Evaluation of Nonmyeloablative Conditioning Regimen in Large Animal Models

In large animal models, no engraftment with genetically modified cells has been observed without conditioning. In one study using a nonmyeloablative regimen, 12% gene-marked leukocytes persisted in the peripheral blood of a rhesus macaque for up to 33 weeks after transplant.⁴³³ In other studies, autologous transplantation of transduced HSCs in nonhuman primates conditioned with low-dose irradiation or busulfan have generally resulted in low but measurable (~1%) long-term marking,^{355,434, 435, 436} and ⁴³⁷ providing proof of principle that partial marrow cytoablation allows engraftment of gene-modified cells without significant toxicity. A possible concern, however, is the unexpected finding that in partially ablated recipient mice, where the BM is a more competitive environment for re-population compared to the fully ablated marrow, HSCs carrying survival- or proliferation-activating lentiviral insertions had an advantage for engraftment, perhaps increasing the risk of leukemic progression.⁴³⁸

Conditioning Regimen in Gene Therapy Clinical Trials

Initial gene therapy efforts using HSCs did not administer preparative regimens to avoid potential toxicities from chemotherapy agents when benefits of the procedure were unproven.^{271,278,439} It was hypothesized that the low marking levels achieved in HSCs in these trials could only lead to clinical benefits if the cells derived from the transduced HSCs had a biologic selective advantage in vivo. Modeling conditioning protocols developed in preclinical models, subsequent gene therapy trials for ADA-SCID,^{23,440,441,442,443} X-CGD,^{444, 445} and WAS,⁴⁴⁶ and

P.1511

β -thalassemia¹⁰³ introduced partial myeloablation with busulfan or melphalan prior to infusion of the genetically corrected cells. As outlined below, in most cases, successes were detected after nonmyeloablative conditioning when augmented by a recognized biologic selection for successfully treated cells in vivo or by retroviral-mediated clonal expansion. It appears that reduced intensity regimens employed to date for disorders that lack a biologic selective advantage in gene-corrected cells, such as CGD, may be insufficient to mediate substantial HSC engraftment and that more ablative approaches may be necessary. The recent clinical success achieved in X-linked ALD using a conventional myeloablative conditioning (cyclophosphamide 200 mg/Kg and busulfan 16 mg/Kg) is a useful example of a suitable regimen that resulted in clinically relevant levels of HSC marking and long-term myeloid engraftment (10% to 15%).

Optimized Gene Therapy Protocols

The preclinical studies above, augmented by the clinical experience of the early gene therapy efforts, have led to an optimized protocol for ex vivo manipulation of HSCs that has been employed with success in recent clinical trials (Fig. 71.7). Hematopoietic stem and progenitor cells expressing the CD34 cell-surface marker are purified from BM harvests or G-CSF-mobilized peripheral blood cell collections. Following a brief (24 hours) ex vivo culture in conditions that favor cell cycle transition from G0 to G1 (e.g., culture medium supplemented with SCF, Flt3L, and TPO), the CD34⁺ cells are incubated on a surface coated with the C-terminal fragment of fibronectin in the presence of the same cytokines for an additional 72 hours with standard retroviral vectors or, preferably, for an additional 24 hours with VSV-G pseudotyped SIN HIV-1-based vectors expressing the desired therapeutic gene from an internal promoter. For disorders in which corrected cells do not have a competitive repopulating advantage over uncorrected endogenous HSCs and their progeny, the patient is conditioned with a reduced intensity or myeloablative regimen prior to intravenous re-infusion of the treated cells. After autologous transplantation, transduced cells home to the BM where they initiate hematopoiesis. Transduction efficiency and safety of the procedure are evaluated by periodic collection of peripheral blood samples over extended periods of time.

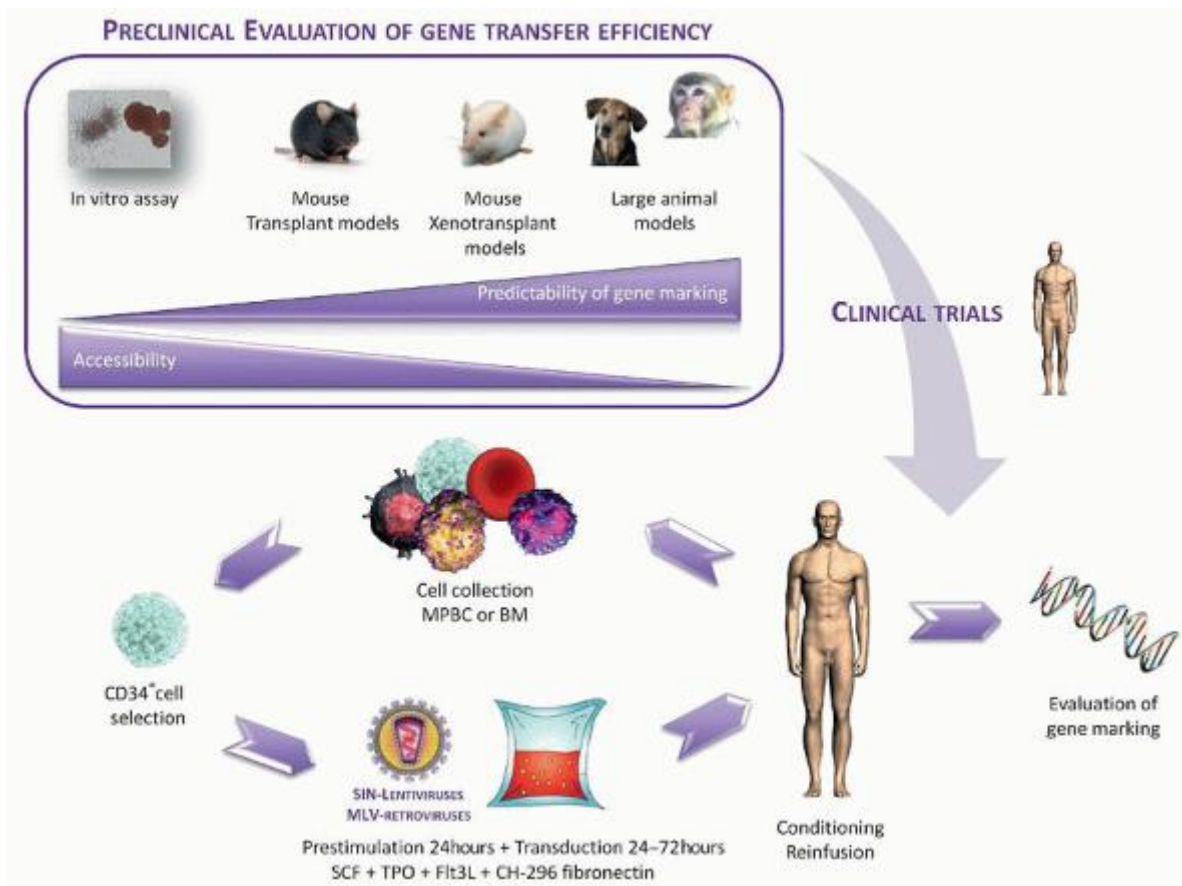

FIGURE 71.7. Approach for the genetic manipulation of hematopoietic stem cells (HSCs). The upper panel compares the predictive value and accessibility of various preclinical models in the evaluation of gene transfer efficiency of vectors used in HSC gene therapy trials. The lower panel depicts the optimized protocol for transduction of hematopoietic stem and progenitor cells, as used in recent clinical trials. BM (bone marrow); Flt3L (fms-related tyrosine kinase 3 ligand); MLV (murine leukemia virus); MPBC (mobilized peripheral blood cells); SCF (stem cell factor); SIN (self-inactivating); TPO (thrombopoietin).

Second-Generation Gene Therapy Trials

The advances derived from preclinical models were rapidly applied in a second generation of clinical trials, with actual therapeutic intent, for immunodeficiency disorders, including X-SCID, ADA-SCID, CGD, and WAS (Fig. 71.6 and Table 71.2). P.1512

Severe Combined Immunodeficiency Disease

The first HSC gene therapy trial demonstrating unequivocal clinical benefit was led by Fischer and Cavazzana-Calvo at the Necker Hospital in France.^{22,448,449} Eleven boys with X-SCID were treated, and each patient received autologous CD34⁺ BM cells, transduced with a standard retroviral vector expressing the corrective IL2R γ gene and re-infused without conditioning. Rapid functional B- and T-cell immune reconstitution and clinical improvement were observed in all but one child. The same vector insertion site could be detected in both myeloid and lymphoid cells, suggesting that at least some true HSCs had been corrected. Unfortunately, as outlined in details below, the elation after this success was short-lived; four subjects in the trial developed acute T-cell leukemia as a result of insertion of the gene therapy vector near proto-oncogenes resulting in increased expression of these genes through the vector's enhancer activity.^{265,450,451}

A similar gene therapy trial was also conducted in London on 10 children with X-SCID. All patients experienced substantial immunologic recovery and in most patients this was accompanied by recovery of humoral immunity and withdrawal of immunoglobulin supplementation.^{442,452,453} Similar to the first clinical study of gene therapy for X-SCID, a single insertion of the gene transfer vectors caused substantial overexpression of proto-oncogenes in 1 of 10 patients, resulting in

leukemogenesis.⁴⁵⁴ These data indicated that conventional murine retroviral vectors (based on MLV) present a high risk of leukemogenesis as a result of their powerful enhancer sequences in the intact LTR regions. Although gene therapy has been effective in infants with X-SCID, minimal clinical improvement was detected in 2 of 3 pre-adolescents despite effective transduction and engraftment of G-CSF mobilized CD34⁺ cells,⁴⁵⁵ and complete failure of gene therapy in 2 adult patients was reported after transplantation of transduced BM CD34⁺ cells.⁴⁵⁶

Bordignon's and Thrasher's group also reported sustained engraftment of engineered HSCs and good immune reconstitution in patients with SCID resulting from ADA enzyme deficiency following transplantation of BM-derived transduced CD34⁺ cells.^{23,440,441} No cases of leukemia have been reported to date in these trials consistent with the long-term analysis of integration sites revealing a polyclonal pattern along with a lack of *in vivo* skewing for risky insertions.

Chronic Granulomatous Disease

In an attempt to genetically correct the defect in CGD patients, investigators obtained G-CSF mobilized CD34⁺ cells from two CGD patients and, using a vector similar to that used in the X-SCID trials, inserted a corrective copy of one gp91phox gene needed to make a functional NADPH oxidase.⁴⁴⁶ Unlike other CGD trials,^{278,444,445} 3 weeks after the cells were re-infused into the patients, a surprisingly large fraction of circulating myeloid cells, more than 20%, carried the corrective gene. This sustained engraftment of functionally corrected cells with therapeutically relevant levels of NADPH oxidase was unexpectedly followed by further *in vivo* expansion of cell clones containing insertionally activated growth-promoting genes. Clinically, the patients were doing well, clearing chronic infections after engrafting with corrected cells. However, as outlined below, a progressive decline in blood counts was observed in both CGD patients at 15 and 28 months, respectively, after gene therapy as a result of genotoxicity from the gene transfer vectors.^{457,458}

Wiskott-Aldrich Syndrome

A German group has recently reported long-term (up to 5 years) correction of WAS in 9 of 10 patients through standard retroviral infection of G-CSF mobilized CD34⁺ cells transfused after busulfan-induced transient myelosuppression, as evidenced by a decreased frequency and severity of infections, and resolution of signs and symptoms of autoimmunity, including autoimmune hemolytic anemia, thrombocytopenia, neutropenia, and eczema.⁴⁴⁷ However, as described in more detail below, leukemia has now developed in several patients as a result of gene transfer vector activation of a growth-promoting gene.

Third-generation Gene Therapy Clinical Trials

Third-generation HSC gene therapy trials have recently emerged, supported by preclinical data suggesting that HIV-derived lentiviral vectors may be safer and more efficient for transduction of stem cells than vectors based on γ -retroviral vectors.^{340,348,353,459,460,461,462,463} This new generation of clinical trials has pioneered the use of SIN-lentiviral vectors for correction of ALD¹⁰² and β -thalassemia¹⁰³ (Fig. 71.6 and Table 71.2)

Adrenoleukodystrophy

The first use of a lentiviral vector for HSC gene therapy was reported for the treatment of two children with X-linked ALD.¹⁰² This is also the first study using a conventional myeloablative conditioning regimen before re-infusion of the genetically manipulated G-CSF mobilized CD34⁺ cells. Functional myelomonocytic cells derived from corrected CD34⁺ cells migrated into the patient's central nervous system to replace diseased microglia cells. At 24 and 30 months post-transplantation, both patients had highly polyclonal reconstitution of hematopoiesis and normal levels of ALD protein, which appeared to retard the progressive cerebral demyelination process. No evidence of genotoxicity has yet been reported in this trial.

β -Thalassemia

Cavazzana-Calvo and colleagues¹⁰³ have recently provided another example of the clinical potential of gene therapy using lentiviral vectors by treating an 18-year-old male patient suffering from transfusion-dependent β^E/β^0 -thalassemia. CD34⁺ cells were isolated from the individual's BM and transduced with an HIV-derived lentiviral vector containing a functional β -globin gene. Compared to previous trials, a conditioning regimen with higher doses of busulfan was used in this study. The levels of genetically modified cells gradually rose up to 11% at 33 months post-transplant with concomitant increases in levels of the normal β -globin protein and improved production and quality of normal RBCs. Remarkably, a year after treatment, the patient no longer needed RBC transfusions. This therapeutic benefit, however, was observed in the setting of clonal expansion resulting from integration of lentiviral vectors in the high mobility group AT-hook 2 (HMG A2) gene.⁴⁶⁴ Marked expansion of a single corrected clone, persisting without malignant transformation for many years, has been documented in an early ADA-SCID gene therapy trial,⁴⁶⁵ suggesting that clonal expansion does not irrevocably progress to

malignancy, but the known association between HMGA2 overexpression and benign/malignant neoplasias imposes further caution.^{464,466,467}

LYMPHOCYTES AS TARGETS FOR GENE TRANSFER

T lymphocytes have several features that make them potentially attractive targets for gene and cell therapies. T-cells circulate in large numbers and are easily harvested, functional subsets have been identified and can be purified via cell-surface antigen selection, and immune responsiveness against specific organisms or target cells can be enhanced via manipulation of culture conditions or genetic modification. A great deal has been learned in the past two decades regarding the optimal culture conditions

P.1513

for enhancing proliferation while retaining function and in vivo survival.⁴⁶⁸ Ablative conditioning is not necessary for persistence of infused T-cells, however, lymphodepletion and/or hematopoietic stem cell transplantation prior to lymphocyte infusion has been reported to improve the persistence and antitumor efficacy of adoptive T-cell therapies.^{469,470} These characteristics have stimulated investigators to target lymphocytes for many gene therapy applications. A series of in vivo human clinical trials have yielded very important and often surprising information on the lifespan of these "terminally" differentiated cells in the body, but also worrisome evidence of a strong immune response against exogenous genes expressed by these cells. Striking evidence for clinical efficacy has been obtained in studies redirecting immune reactivity of T-cells toward specific antigens.^{471,472}

Gene Marking Studies

The first infusion of genetically modified cells into a human enrolled in a clinical trial used genetic marking to monitor the fate of tumor-infiltrating T lymphocytes (TIL) in vivo. Persistence of low-level gene-marked T-cells was demonstrated, including within tumor deposits, although marking levels were too low to assess whether preferential trafficking of TIL cells to residual tumor occurred.⁷ More recently, gene marking studies in humans undergoing allogeneic SCT have helped to further characterize the behavior of lymphocytes that have been cultured ex vivo. Epstein-Barr virus (EBV)-specific donor T-cells from SCT donors used to transplant patients at high risk for post-allogeneic SCT EBV-lymphoproliferation were isolated, expanded, and gene-marked ex vivo during co-culture with EBV-transformed donor lymphoblasts.^{473,474} After transplantation, the EBV antigen exposed donor T-cells were infused into the patients, and gene-marked cells were detectable at levels suggesting expansion of two- to threefold in vivo. EBV-specific cytotoxicity in the peripheral blood was greatly enhanced after the infusions. Although circulating marked cells fell below the limit of detection 4 to 5 months later, the continued presence of memory cells derived from the infusion product was inferred in one patient who had an increase in marked lymphocytes in the blood after reactivation of latent EBV.⁴⁷⁴

Suicide Gene Modification of T-cells

The next iteration of genetically modified T-cell therapies in patients undergoing allogeneic SCT incorporated the herpes thymidine kinase (tk) gene into the retroviral vector.⁴⁷⁵ This "suicide gene" encoded viral protein converts the nontoxic pro-drug ganciclovir to a toxic metabolite that kills the cell by interfering with DNA synthesis.^{476,477} A major cause of morbidity and mortality post-allogeneic SCT is graft-versus-host disease (GVHD). By incorporating the tk suicide gene into donor T-cells, high doses of T-cells can be administered to confer antiviral or antitumor immunity. If and when significant GVHD occurs, donor T-cells can be destroyed by an infusion of ganciclovir. This strategy depends on inclusion of a cell-surface marker gene or a drug resistance gene within the vector to allow enrichment of transduced cells by flow cytometry or drug selection, before re-infusion, so that almost all infused cells will contain the tk suicide gene.^{475,478}

A landmark study demonstrating the safety and feasibility of this approach in patients following allogeneic SCT from matched donors was reported from Italy, and confirmed in several similar trials in Europe and the United States.⁴⁷⁹ Most recently, this approach has been shown to be very promising in haplo-identical SCTs, transplants with an extremely high risk of both severe GVHD and poor immune reconstitution.⁴⁸⁰

One issue that has arisen in these trials is development of immunity against the foreign tk protein, with eventual destruction of vector-containing cells even in the absence of ganciclovir in some.⁴⁸¹ Anti-tk immunity also developed in a subset of patients with HIV infection who received autologous HIV-reactive cytotoxic T-cells expanded ex vivo and transduced with a tk vector.⁴⁸² These observations serve as an important caveat that foreign proteins such as tk introduced via lymphocytes may stimulate immune recognition and rejection. Use of ganciclovir as the suicide activator is not ideal, given that this drug is a powerful antiviral agent and the drug of choice to treat some common viral infections in SCT- or HIV-infected patients. To circumvent both of these problems, the gene encoding the endogenous human cellular

proapoptotic protein caspase 9 was modified to allow dimerization and activation by the small molecule AP1903.⁴⁸³ In a recent trial, patients received a T-depleted haplo-identical stem cell transplant, followed by infusion of donor T-cells transduced with the inducible caspase 9 transgene. These cells persisted and expanded in vivo, but with the development of GVHD, more than 90% of T-cells were ablated within 30 minutes of AP1903 infusion, resulting in abrogation of GVHD.⁴⁸⁴

Therapy of Immunodeficiency Disorders

T lymphocytes were the targets in the first human clinical gene transfer trial utilizing a potentially therapeutic gene, initiated in 1990.^{8,485} Two children with SCID due to ADA deficiency received multiple infusions of autologous T-cells transduced with a retroviral vector encoding human ADA.⁶ Both patients showed improvements in circulating T numbers and some evidence for improvement in cellular and humoral immunity. In one child, over 30% of the circulating T-cells were positive for the transgene and ADA levels approached the normal range for more than 2 years. The second child had only 0.1% to 1% of circulating T-cells containing the vector even after multiple infusions, clouding interpretation of how much of the clinical improvement in the initial patient was due to the gene transfer, and how much to other factors, including the ex vivo lymphocyte expansion. The more convincing results and theoretical advantages of correcting HSCs as compared to T-cells, as detailed above, combined with the impossibility of obtaining target T-cells to correct in patients with many forms of SCID, has resulted in a shift to HSC instead of T-cell targets for the gene therapy of immunodeficiency disorders.

T-cell Gene Therapy for HIV Infection

A number of ongoing and completed human T-cell gene therapy clinical trials have enrolled patients with HIV disease, based on identification of a number of potential targets for genetic intervention.⁴⁸⁶ The concept of intracellular immunization against HIV, conceived more than two decades ago, hypothesizes that an effective gene therapy strategy for HIV could be to confer nonimmunologic HIV resistance to mature cell populations by introducing a gene that interferes with the HIV life cycle or prevents infection of progeny cells into HSCs or lymphocyte precursors.⁴⁸⁷ Striking proof of principle of this concept was reported when an HIV patient with leukemia received an allogeneic SCT from a donor with a CCR5 variant, preventing HIV cellular entry into all donor hematopoietic cells. The patient had complete disappearance of HIV post-transplantation.⁴⁸⁸ A second approach uses gene transfer to introduce genes that will result in killing of infected cells, either directly or via enhanced immunity, thus destroying the HIV viral reservoir.

A number of T-cell gene therapy approaches to HIV were tested in a unique clinical model pursued at the United States National Institutes of Health. A cohort of syngeneic twins with one infected and one uninfected twin was identified. T-cells from the uninfected twin were collected by apheresis, and then transduced with vectors encoding potential anti-HIV genes. Comparison of survival of these transduced cells in the infected twin with survival of cells transduced with a control vector was an elegant approach to testing various anti-HIV gene therapy strategies.⁴⁸⁹ Marked

P.1514

cells could be detected and studied in the HIV-infected twin.⁴⁹⁰ Unfortunately, none of the anti-HIV strategies tested in this model were shown to result in preferential survival of the genetically modified cells or clear improvement of viral control.⁴⁹¹

Mutant HIV Rev proteins have been reported to interfere with Rev function, either by binding to and inactivating wildtype Rev, or by competitively blocking binding of wildtype Rev to the RRE.^{55,492} Production of HIV either from normal lymphocytes exposed to HIV in culture, or from HIV-infected patient lymphocytes, was decreased after either retroviral or gene gun particle-mediated transduction of T-cells with a vector expressing the Rev M10 mutant, compared to a nontranslated inactive control Rev mutant.⁵⁰ A clinical trial used the gene gun to transduce autologous lymphocytes from HIV-infected patients with either the active Rev M10 vector or the inactive control Rev vector. These cells were then expanded in vitro and re-infused. The lymphocytes containing the active Rev M10 sequences survived preferentially in vivo, suggesting that the Rev M10 transgene improved T-cell survival in infected individuals.⁴⁹³ In another protocol, individuals with HIV infection and a refractory hematologic malignancy were offered allogeneic peripheral blood SCT and an aliquot of the allogeneic graft was CD34 selected, transduced with a transdominant Rev encoding vector, and infused along with the unmanipulated allograft. Overall marking was also low in the only recipient of genetically modified cells, however, rising vector copy number and nondetectable HIV over extended follow-up was encouraging.⁴⁹⁴

Another anti-HIV T-cell gene therapy strategy involved the use of "defective-interfering viruses" known to interfere with wildtype HIV replication and spread.⁴⁹⁵ The first lentiviral gene therapy trial in humans transduced T-cells with a "defective-interfering" vector that incorporated an antisense sequence targeting the HIV envelope gene.⁴⁹⁶ The use of a lentiviral vector in patients with HIV infection generated concern regarding the potential for recombination between the

vector and endogenous HIV virus in patients or HIV genes in the packaging cells, or the inadvertent transfer of a mobilized lentiviral vector to others via sexual or other modes of transmission, requiring further development of sensitive RCR testing development prior to clinical use and extensive safety testing of patients enrolled in the trial.¹⁰⁰ Preliminary results in the first five patients demonstrated the feasibility of this approach, with all patients tolerating the infusion well. In one subject, a sustained decrease in viral load was observed.⁴⁹⁷

T-cell Gene Therapies for Cancer

The most common clinical application for genetically modified T-cells has been for tumor immunotherapy. There are a number of challenges for cancer immunotherapies, most notably the low frequency of tumor-specific autologous T-cells, negative selection against high-affinity T-cell receptors (TCRs) binding to autologous tumor antigens during T-cell development, and the myriad mechanisms tumor cells have evolved to evade and cripple antitumor immune responses. Although early studies of the adoptive transfer of ex vivo expanded T-cells or in vivo stimulated T-cells with cytokines such as IL2 resulted in proof of principle that antitumor immunity existed and could be effective, investigators began searching for ways to enhance specific antitumor immunity via genetic modification.⁴⁹⁸

One approach begins by cloning high-affinity TCRs from cytotoxic T-cells shown to be reactive with tumor-specific antigens, generally from T-cells initially isolated from tumors (TILs), then further expanded and selected in vitro. The cloned transgenic α and β TCR subunit genes can then be incorporated into a retroviral or lentiviral vector and used to transduce patient T-cells, resulting in large numbers of T-cells reactive with a specific tumor antigen. Four of 31 melanoma patients receiving autologous T-cells transduced with a cloned high-affinity TCR reactive with a melanoma antigen (MART1) had objective tumor responses, as did one of three patients with colon cancer receiving T-cells transduced with a CEA-reactive TCR.^{470,499}

One major drawback of this approach is the HLA-restriction of TCRs, thus requiring a different TCR construct for each HLA class 1 target, and effectively limiting this approach to patients with common HLA haplotypes. There is also the potential for mispairing between the transgenic TCR and the endogenous TCR chains that are still expressed by the target T-cell, resulting in unpredictable adverse events such as autoimmunity/GVHD.⁵⁰⁰ Although this complication was observed in a murine model, there is no evidence to date for a similar phenomenon in hundreds of patients enrolled in transgenic TCR clinical trials.⁵⁰¹ However, administration of large numbers of high-avidity TCR-expressing T-cells reacting with tumor antigens that may also be expressed at low levels on normal tissues can result in toxicity such as colitis following anti-CEA T-cells given to target colon cancer, or skin/eye and ear toxicity following administration of TCR chimeric T-cells reactive with melanoma antigens.^{499,502}

A second and perhaps more promising approach to enhancing antitumor activity of T-cells was first conceptualized in 1993, and involves transduction of T-cells with genes encoding fusion molecules termed "chimeric antigen receptors" (CARs)^{503,504} (Fig. 71.8A). Engineered cell-surface molecules consisting of a specific antigen-binding domain from a monoclonal antibody, or some other specific ligand-binding domain, fused to intracellular signaling moieties from the T-cell receptor (generally the ζ chain) or the Fc ϵ RI receptor are introduced into T-cells via retroviral or lentiviral vectors. When the CAR binds to antigen or ligand, the T-cell signaling cascade is activated, resulting in cytotoxicity toward the antigen-bearing target cell. There are a number of advantages of CARs as compared to TCRs for genetic enhancement of T-cell antitumor immunity. Most important, the CAR approach is "universal" and not MHC-restricted, thus the same CAR can recognize the target in any patient. Second, tumors often down-regulate MHC molecules, and thus can evade TCR-dependent recognition, in contrast to CARs, which do not require MHC engagement for their activity. Third, nonprotein targets can be recognized by CARs. One disadvantage of CARs in comparison to TCRs is that intracellular antigens cannot be targeted by CARs, because these antigens require presentation as peptides on the cell surface via MHC molecules. A recent review catalogs the large diversity of CARs that have been developed for preclinical and clinical applications.⁵⁰⁵

Initial CAR clinical gene therapy studies were completed in the late 1990s, utilizing autologous or syngeneic T-cells transduced with constructs fusing the gp120 binding domain of CD4 to the TCR ζ chain, to promote killing of HIV-infected T-cells. Despite encouraging animal model and in vitro data, the infused cells were present at very low levels, disappeared over time, and were not associated with clinical benefit.^{491,506} A series of clinical trials in patients with cancer, targeting cell-surface proteins on ovarian cancer, neuroblastoma or lymphoma tumor cells were also disappointing, with no evidence for in vivo expansion and little persistence of infused CAR-modified cells.⁵⁰³ There was some evidence that CARs themselves could be immunogenic, and that ex vivo culture conditions used during transduction and expansion were suboptimal, but a more important difference between CAR-mediated and endogenous TCR-mediated signaling is the lack of co-stimulatory signaling during CAR engagement. T-cell stimulation in the absence of co-stimulatory signals, normally provided by antigen-presenting cells, results in T-cell death or tolerance, instead of expansion and a productive immune response (Fig. 71.8B). Therefore, a second generation of CARs was designed, incorporating co-stimulatory signaling

domains as part of the CAR fusion molecule itself, for instance, domains from CD28 or CD137. T-cells transduced with these enhanced CARs were found to be more effective in vitro and in animal models.⁵⁰⁷

P.1515

P.1516

A number of other strategies have also been pursued to enhance co-stimulation and in vivo survival of CAR-modified T-cells, including targeting CARs to T-cells already primed to respond to a common antigen such as EBV, administering T-cell supportive cytokines such as IL2, IL7, or IL15, or lymphodepleting the patient prior to CAR-T administration (Fig. 71.8A,B).⁵⁰³

FIGURE 71.8. Gene transfer of chimeric antigen receptors for tumor immunotherapy. A: The sources of components used to construct an artificial chimeric antigen receptor are shown. The signaling ζ subunit of the T-cell receptor is connected to the variable heavy chain(VH) and variable light chain(VL) domains of a monoclonal antibody generated against the desired tumor antigen. In the second-generation CARs, an additional transmembrane domain from CD28 or an alternative co-stimulatory molecule is added between the cytoplasmic signaling domain of the TCR ζ subunit and the extracellular VH/VL antigen-binding moieties. B: When a T-cell transduced with a first-generation CAR encounters a tumor cell bearing an antigen recognized by the VH/VL domain of the CAR, the ζ subunit is stimulated to signal (signal 1) but in the absence of a co-stimulatory signal, the T-cell is often diverted to an apoptosis or energy pathway. In contrast, the inclusion of a costimulatory signaling domain in the second-generation CAR ensures that when tumor antigen is encountered, both signal 1 generated from the ζ subunit and signal 2 generated from the CD28 domain are activated, and the T-cell proliferates and is stimulated to kill the tumor cell.

A series of clinical trials utilizing CARs targeting CD19 in patients with chronic lymphocytic leukemia (CLL) or other advanced chronic B-cell malignancies have provided proof of principle for the potential efficacy of this approach. A lentiviral vector expressing an anti-CD19 antibody domain fused to a CD137 co-stimulatory region and the CD3 ζ signaling component of the TCR was used to transduce autologous T-cells from a patient with CLL, and following re-infusion, there was rapid 1,000-fold in vivo expansion of the cells, tumor lysis, and complete remission of the CLL, persisting for at least 10 months to date.⁴⁷¹ A dramatic response was also reported in a patient with follicular lymphoma.⁵⁰⁸ Larger case series confirmed these encouraging results.^{509,510} However, the potent and persistent anti-CD19 response also resulted in profound depletion of normal B-cells and hypogammaglobulinemia. This very promising approach is now being developed for treatment of a variety of tumors.

GENE THERAPY FOR BLEEDING DISORDERS

The primary bleeding disorders most commonly result from genetic deficiencies of specific clotting factors. Classic hemophilia, or hemophilia A, results from a deficiency of factor VIII, which is normally produced by hepatocytes and vascular endothelial cells. Hemophilia B results from a deficiency of factor IX, which is normally made by hepatocytes. Thus, both diseases are hematologic disorders resulting from deficiencies of soluble plasma proteins synthesized by nonhematopoietic cells. Each of these coagulation factors may be found in circulating platelets' storage granules⁵¹¹ but the megakaryocyte is not likely a site of synthesis of either factor, and granule storage is likely to occur after uptake of the protein from plasma.

Hemophilia A and B have attracted a significant amount of attention from those interested in gene therapy, for a variety of reasons. First, they are monogenic diseases for which numerous mutations are known^{512,513} (<http://europium.csc.mrc.ac.uk/WebPages/Main/main.htm>, <http://www.kcl.ac.uk/ip/petergreen/haemBdatabase.html>) and their cDNAs were cloned decades ago.^{514,515} Second, functional factor VIII and factor IX gene products may be produced in nearly any cell type as long as the appropriate post-translational modifications are made and the protein is secreted into the circulation. Most important, epidemiologic data and experience with factor replacement therapy have demonstrated that the level of circulating factor VIII or factor IX required to prevent clinically significant bleeding may be as little as 1% to 2% of normal plasma levels. And finally, there may be a substantial margin for error with regard to overexpression of these factors, due to regulation of the "tenase" (factor VIII/factor IX) enzyme complex and "prothrombinase" (factor V/factor X) complex by the protein C/protein S anticoagulant proteins and antithrombin III. Epidemiologic analyses suggests that elevated factor VIII or factor IX levels may be risk factors for thrombotic diseases,^{516,517} but thus far it seems unlikely that overshooting to supraphysiologic levels of factor VIII or factor IX could occur following gene therapy.

Preclinical testing of hemophilia gene therapies have been facilitated by the existence of several animal models of hemophilia, including factor VIII and factor IX knockout mice^{518, 519, 520} and⁵²¹ and inbred dog colonies with spontaneous hemophilia A and B mutations.^{522, 523, 524, 525} and⁵²⁶ Furthermore, it has proved possible to detect epitope-tagged human factor VIII⁵²⁷ or normal human factor IX^{528, 529, 530} and⁵³¹ in normal rhesus macaques after gene transfer with various vectors, which permits not only safety testing of gene transfer, but also some assessment of gene expression in vivo.

Potential cell types targeted to become "cell factories" for gene transfer of factor VIII or IX include skin fibroblasts or keratinocytes, myocytes, hepatocytes, and BM stem and progenitor cells. Skin fibroblasts are readily propagated in tissue culture and can be transduced by vectors that may include selectable markers. Cells selected in vitro can then be re-introduced to the host, resulting in secretion of the therapeutic protein into the bloodstream. Preclinical studies utilizing skin fibroblasts transduced with factor IX or factor VIII retroviral vectors^{532, 533, 534, 535, 536, 537} and⁵³⁸ in rodents have achieved therapeutic levels of factor IX or factor VIII (>1% of normal). However, a recurring issue in these models has been lack of sustained expression of the transgene, which may be due to loss of transduced cells due to cell-mediated immunity or to promoter shutdown in implanted cells.⁵³⁹ One clinical trial has been performed in which factor VIII transfected skin fibroblasts were implanted in the omentum. The peak factor VIII levels achieved were marginally therapeutic and were not sustained.⁵⁴⁰

Gene transfer of secreted proteins to muscle cells can be performed using muscle-specific and/or nonspecific constitutive promoters to direct gene expression, with direct in vivo delivery of vectors to muscle cells via intramuscular injection. The most extensively studied and successful application of this approach has been through gene transfer utilizing adeno-associated virus vectors. AAV vectors can only package DNA with a total length of ~4.5 kb or less, which is sufficient for transfer of the small factor IX gene, but of limited use for transfer of the much larger factor VIII gene. AAV vectors form stable and long-lasting episomes, and in nondividing tissues such as muscle and liver, can produce long-term stable transgene expression. In vivo preclinical studies with AAV vectors in hemophilia B knockout mice and dogs have shown that it is possible to achieve clinically relevant levels of factor IX and correction of the bleeding phenotype for significant

periods of time following intramuscular injection of FIX-AAV vectors.^{541, 542, 543, 544, 545, 546, 547, 548} and ⁵⁴⁹ These encouraging animal results led directly to a clinical trial of AAV-factor IX gene transfer, involving multiple intramuscular injections of FIX-AAV particles in patients with severe hemophilia B. Plasma factor IX levels (~1% of normal) at doses of 2×10^{11} vector genomes per kg were achieved.⁵⁵⁰ Although the trial was an open label study and a placebo effect cannot be ruled out, there was a lower frequency of joint bleeds as reported by patients.⁵⁵⁰ Unfortunately, higher doses of the vector did not result in a greater therapeutic effect, perhaps due to binding of factor IX to type IV collagen present in muscle, and the intramuscular injection route, requiring very large numbers of individual injections, is impractical and potentially risky in patients with bleeding disorders, even with exogenous factor administration at the time of the procedures.⁵⁵¹ Very prolonged expression from the AAV vector construct was documented on muscle biopsy specimens obtained more than 3 years following the injection of vector.⁵⁵²

Liver hepatocytes synthesize most of the plasma proteins including factors VIII and IX, and synthesize certain proteins (e.g., albumin) in tremendous quantities, thus they are natural factories for secreted proteins. Hepatocytes are readily transducible by various vectors in vitro and in vivo, and gene transfer to liver is currently the most promising approach under investigation for gene therapy of hemophilia. Adenovirus vectors are capable of nearquantitative gene transfer to hepatocytes in vivo when administered intravenously and can accommodate large genes such as factor VIII. It is not surprising that adenovirus vectors have been used for in vivo gene transfer of factor VIII or factor IX to liver cells in various animal models, including mice,^{131,553, 554, 555, 556, 557, 558, 559, 560} and ^{561,562,563,564} monkeys,^{527,528,530} and hemophilic dogs.^{130,565, 566, 567} and ⁵⁶⁸ Unfortunately, adenovirus-mediated gene transfer is typically characterized by gradual loss of gene expression because these vectors do not

P.1517

form stable episomes and do not integrate, and the presence of the adenovirus vector proteins in immune-competent animals induces a cytokine cascade⁵⁶⁹ and has a significant adjuvant effect that may induce antibodies to the expressed gene.^{528,566,567,570} Based on the observation that deletion of adenovirus vector genes may result in longer periods of gene expression and a decreased immune response,⁵⁷⁰ efforts have been made to create and test vectors with most or nearly all of the adenovirus genes removed for gene therapy of hemophilia.^{558,561,571, 572, 573} and ⁵⁷⁴ Any clinical use of adenovirus vectors will be limited by neutralizing antibodies to most common serotypes that are routinely present in most humans and which would be boosted substantially with administration of an adenovirus vector.⁵⁷⁵

Vectors based on various serotypes of AAV have been studied for gene delivery to hepatocytes in hemophilia A and B mice and dogs, and in humans with hemophilia B. The earliest reports of AAV-mediated hepatocyte gene transfer focused on serotypes 1 and 2 vectors expressing factor VIII^{576, 577} and ⁵⁷⁸ and factor IX^{42,267,531,579,580,581, 582, 583, 584, 585, 586, 587, 588} and ⁵⁸⁹ in mice, dogs, and nonhuman primates. These preclinical studies demonstrated levels and duration of factor IX expression sufficient to justify clinical trials of hepatic artery infusion of AAV-2 factor IX vector in patients with severe hemophilia B. The initial trial was temporarily put on hold due to vector shedding in the semen of the first subject enrolled.⁵⁹⁰ After demonstration that the AAV vector was not incorporated in germline DNA, the trial was resumed. The results showed peak expression of 11% of normal factor IX levels in one of seven subjects who was treated with the maximum 2×10^{12} vector genomes/kg dose.⁵⁹¹ Unfortunately, although no inhibitor antibody to factor IX developed, factor IX expression declined and plasma factor IX activity levels returned to baseline within a period of 8 weeks. The decline in factor IX levels was associated with transient elevation of liver transaminases likely due to cell-mediated immune elimination of AAV-transduced hepatocytes. One other subject treated at the maximum achieved a factor IX plasma level of 3% of normal, but also had loss of factor IX expression and elevation of liver enzymes. T-cell responses to the AAV2 capsid protein but not to factor IX were documented in these patients, and it is likely that transient presence of the AAV-2 capsid, brought into the hepatocytes during transduction, stimulated a potent recall immune response in patients previously exposed to wildtype AAV2 viruses in the environment, resulting in immunologic elimination of transduced hepatocytes.⁵⁹² This finding had not been predicted from preclinical studies in large animals, which are not naturally infected by AAV2, underscoring the need for caution in predicting results of clinical trials from animal studies.

Alternative strategies to circumvent these problems tested in animal models have included transient immunomodulation at the time of vector administration, use of alternate AAV serotypes such as 6, 8, or 9 not known to normally infect humans and thus rarely associated with seropositivity, and design of optimized vectors able to express much higher levels of factor IX per genome.^{168, 169} and ^{170,593} The combination of all these strategies has finally resulted in what appears to be unequivocal clinical success. Six patients with hemophilia B received intravenous infusions of AAV8 vectors expressing codon-optimized and self-complementary factor IX genes.¹⁷⁶ All had sustained levels of factor IX of 2% to 11%, and four of the six were able to discontinue prophylactic factor IX infusions. Two patients had transient elevations of liver enzymes, in

one associated with detection of AAV capsid-specific T-cells, but a brief course of methylprednisolone in both led to rapid decrease in transaminases, and no loss of factor IX expression.

Although typical Moloney-based retroviral vectors are not particularly effective at *in vivo* gene transfer to hepatocytes due to the relatively low rate of cell division, lentivirus vectors (which do not require cell division for gene transfer) may prove to be useful for hemophilia gene therapy, and can accommodate larger transgenes and thus are more conducive to factor VIII gene therapy than AAV vectors, particularly B domain-deleted factor VIII, encoding a smaller but still functional protein. Several groups have used pseudotyped lentiviral vectors to transfer the factor VIII cDNA to liver.^{594, 595, 596} and⁵⁹⁷ The efficiency of *in vivo* gene transfer with lentivirus vectors has been far less than that of adenovirus or AAV vectors, but persistent expression has been achieved in some animal models. In some cases, injection of vector into the portal vein is employed to improve efficiency.⁵⁹⁸

Cells of hematopoietic origin are also logical targets for *ex vivo* gene transfer and re-introduction by marrow transplantation to treat hemophilia, because these cells circulate in the blood and, in the case of platelets, are concentrated at the site of vascular injury. This approach may be particularly relevant in patients with existing factor VIII or IX inhibitors, who have been excluded from all prior muscle and hepatocyte gene therapy trials. *Ex vivo* Moloney-based retroviral gene transfer of the human factor VIII gene into hemophilia A knockout mouse BM was not efficient enough to result in detectable plasma levels of human factor VIII after transplantation; however, the animals were rendered tolerant to human factor VIII.⁵⁹⁹ Expression of xenogenic or otherwise completely foreign genes in hematopoietic stem and progenitor cells via gene transfer is known to result in induction of tolerance.^{600,601} Investigators have been able to show expression of factor VIII in platelets produced from lentivirus-transduced BM in hemophilia A mice.^{602,603} The latter approach utilized a promoter for the α IIb glycoprotein (normally expressed on the surface of platelets) to restrict expression of factor VIII to the platelet, and to target expression of factor VIII to sites of vascular injury.

Future issues to be addressed in the field of hemophilia gene therapy include minimizing the risk of inhibitor formation or immune rejection of transduced cells (especially with viral gene transfer vectors), development of vectors capable of sustained high levels of coagulation factor expression, and avoidance of unintentional germline transmission of vector sequences. Strategies are being explored allowing expression of functional factor VIII despite its prohibitory large gene size, including deletion of certain nonfunctional domains (B domain deleted), splitting of the gene into two portions encoded by two independent AAV vectors with transcripts that are spliced *in vivo* prior to protein translation, or expression of the light and heavy chain of factor VII in two independent vectors.^{604,605}

SAFETY AND FEASIBILITY HURDLES TO CLINICAL GENE THERAPY

Immune Responses to Vectors and Transgenes

Immune responses against vector proteins or the transgene-encoded protein itself have only recently become the focus of intensive investigation. For *in vivo* vector administration, pre-existing immunity to a vector such as adenovirus is at least a theoretical concern. Repeated *in vivo* administration of complex vectors clearly stimulates an active immune response to vector proteins, and greatly hinders success. The expression of viral genes remaining in the vector sequences could also stimulate an immune response against transduced target cells. This is not a problem for retroviral vectors; as well, newer modifications of adenoviral vectors have been developed that no longer contain or express residual adenoviral genes.^{125,126} Nonhuman marker genes such as the neomycin resistance gene, or viral suicide genes such as tk included in vectors for positive or negative selection may also induce an immune response.⁶⁰⁶ Finally, the therapeutic gene product itself may induce an immune response if the patient completely lacks the endogenous gene product or the transgenic protein is processed or post-translationally modified.¹²¹

Rejection of the foreign transgene itself can be the primary problem, even when highly immunogenic adenoviral vectors are

P.1518

used. Recombinant adenoviral vectors encoding either murine or human Epo genes or a control vector without an expressed gene were injected into murine muscle and the mice were followed for several months for Epo expression and presence of the vector sequences in muscle.¹²¹ Mice expressing either human or murine Epo transgenes developed high hematocrits, but the effect was transient in those expressing human Epo, as profound anemia, surprisingly, developed after the transient polycythemia. Immune responses to both the vector-expressed human Epo and endogenous murine Epo were documented in these animals, indicating that the active immune reaction against the human Epo had also generated cross-reactivity toward endogenous Epo. Adenoviral genomes were detectable long term in the muscles of the

murine Epo and of the control mice, but not in the human Epo mice. This suggested that the immune response was elicited by expression of the foreign transgene, not by viral proteins.

In a murine model of allogeneic skin graft survival, foreign genes expressed by HSCs and their progeny may be capable of inducing tolerance even across MHC barriers.⁶⁰⁷ This evidence, and documentation in mice of very long-term persistence of expression of completely xenogeneic genes such as human GC, suggests that immune responses against genes introduced via repopulating stem cells will not induce immune responses.^{206,608} On the other hand, immune responses to a retroviral vector-introduced transgene in the canine MPS-1 autologous transplantation model have been shown to limit efficiency.⁶⁰⁹

In the murine model, tolerance to xenogeneic genes can be achieved by introduction through the hematopoietic compartment.⁶¹⁰ Long-term persistence of genetically modified cells at clinically relevant levels can be achieved after very low-dose irradiation with 100 cGy, even when highly immunogenic genes are transferred. Large animal testing in the nonhuman primate confirmed these observations, with equivalent levels of long-term engraftment of cells transduced with either a vector encoding the neomycin phosphotransferase (neo) or a vector carrying but not expressing this gene product, but the overall levels of engraftment were much lower.⁶¹¹ Transduction of lymphocytes in the absence of conditioning, however, resulted in rapid clearance of the neo expressing cells. However, if HSCs were transduced and transplanted first, long-term persistence of lymphocytes transduced with the neo expressing vector were observed.⁶⁰⁰

Various methods of immunosuppression have been at least partially successful in avoiding immune rejection of transduced cells. Neonatal exposure to vector has allowed repeated treatments with adenoviral vectors.¹³¹ Treatment with cyclosporine, cyclophosphamide, or IL-12 have all been reported to prolong survival of transduced cells.^{128, 129, 130, 131} and ¹³² But these general pharmacologic approaches are not desirable or practical for most gene therapy applications, which are attractive only if they prevent lifelong reliance on toxic pharmacologic agents. Instead, improved vector design and possible inclusion of antirejection mechanisms in the vectors themselves are more attractive approaches.

Safety Considerations

The number of individuals who have safely received genetic material in the form of vectors or vector-modified cells now numbers in the many thousands, suggesting that current gene transfer approaches generally carry a low risk to subjects, however, all but a small minority of these patients likely had no clinical benefit, and risks must therefore be considered in this context. Only recently have trials moved beyond safety testing into pilot studies of efficacy for a number of hematologic diseases. Pioneering trials, as detailed above, have provided encouraging results regarding efficacy of gene therapy for congenital immunodeficiency disorders, hemophilia, thalassemia, and metabolic disorders. However, very serious and in some cases fatal severe adverse events directly linked to gene therapy have occurred, and have had significant repercussions from regulatory, clinical, and scientific standpoints.

Phase 1 Gene Therapy Trial for Ornithine Transcarbamylase

Side effects of gene transfer can result from all aspects of the process, including those inherent to a specific vector system, vector production methodology, target cell identification and manipulation, vector integration, transgene expression, or selective pressure applied after transfer.⁶¹² The first reported serious complication of gene therapy occurred when an 18-year-old patient with relatively mild manifestations of OTC deficiency volunteered for a Phase 1 dose escalation gene therapy trial and received a catheter-directed infusion of a high dose of an adenoviral vector encoding the corrective gene into the hepatic artery. Within hours of the infusion, signs and symptoms of a systemic immune response syndrome appeared, and soon thereafter the patient died from multiorgan system failure. Studies infusing similar adenoviral vectors into nonhuman primates have shown evidence for activation of the innate immune response attributable to the adenovirus capsids as well as a vigorous proinflammatory IL-6 and IL-1 cytokine response, with evidence for endothelial damage and disseminated intravascular coagulation.^{528,530,613} The induction of acute phase reactants was anticipated from the preclinical data in nonhuman primates; however, the severity and duration of the fatal reaction observed in this patient was not expected at the dose level reached. As a result of the death, many clinical gene therapy trials were temporarily put on hold and the maximum doses of adenovirus (or other) vectors to be given to humans were scaled back as a precautionary measure. Furthermore, a number of issues with respect to the pace of clinical gene therapy trials, the informed consent process, subject eligibility, reporting of adverse events, and oversight of clinical gene therapy trials were raised, and measures to increase the protection of research subjects were uniformly instituted across all gene therapy trials.^{614,615}

Gene Therapy for X-SCID

Soon after the first unequivocal demonstration of clinical efficacy in a human gene therapy trial in which 10 of 11 children with SCID who received retrovirally transduced autologous BM cells were apparently cured,²² two patients developed a

precipitous rise in T-cell counts which progressed to overt leukemia 3 years following infusion of gene-corrected autologous CD34⁺ cells.²⁶⁵ Retroviral integration site analysis in the leukemia cells from both patients demonstrated vector insertions within or just upstream of the LMO2 gene activating expression.⁴⁵¹ LMO2 is a transcription factor required for fetal hematopoietic development and was already known to be activated by chromosomal translocations in some cases of spontaneous childhood T-cell leukemia.⁶¹⁶ Since that time, an additional two of the eleven X-SCID patients enrolled in the original French trial and one of ten patients enrolled in a similar trial in England have developed clonal vector-associated T-cell leukemias.^{448,454} Strikingly, four of the five patients had vector insertions activating LMO2, and the fifth had a vector insertion activating the CCND2 gene, encoding cyclin D, a protein known to control cell cycle entry and to be associated with cancer when dysregulated. One of the four patients has died of complications related to the leukemic process and its treatment, and the others have been successfully treated with chemotherapy.

The first report of these adverse events in 2003 resulted in a rapid response from investigators and regulatory agencies worldwide, with most gene therapy trials utilizing integrating MLV-derived retroviral vectors to transduce hematopoietic stem and progenitor cells put on hold. The occurrence of these events was not predicted. Prior to the sequencing of the murine and human genomes, retroviral insertion was thought to be random,

P.1519

based on the lack of any specific motif at the few insertion sites that had been mapped. It was predicted that just one or a few insertions into a cell's genome was unlikely to activate a proto-oncogene, based on the size of the genome and assumed random insertion.⁶¹⁷ Vector-containing leukemias and lymphomas had previously been reported in animal models utilizing HSC gene transfer, but were attributed to contamination by replication-competent viruses in a nonhuman primate study, resulting in multiple proviral insertions and eventual activation of a proto-oncogene, or overexpression of a signaling receptor in a murine model.^{78,618}

There was initially an intense focus on whether specific aspects of X-SCID patients themselves or constitutive expression of the IL2R γ transgene predisposed to vector-associated leukemia. One murine study suggested a greatly increased risk of leukemia when an IL2r γ transgene was overexpressed, and another reported a nonrandom relationship between activation of the Lmo2 and IL2r γ genes and leukemias and lymphomas in susceptible neonatal mice.^{619,620} Other unique aspects of the X-SCID clinical situation were proposed to have contributed to increasing risk, including the rapid expansion of lymphoid progenitors and mature T-cells into an "empty" lymphoid compartment, very high doses of transduced CD34⁺ cells, and impaired antitumor immunity. To date none of the patients enrolled in ADA gene therapy trials, even those receiving transduced CD34⁺ cells, have developed leukemia. A large survey of rhesus macaques, dogs, and baboons transplanted with CD34⁺ cells transduced with standard retrovirus vectors containing marker genes or drug resistance genes failed to document any hematologic abnormalities, or progression to clonal or oligoclonal hematopoiesis, with a median follow-up of over 3 years.⁶²¹ And it is of interest that there have been no vector-related clonal expansions or malignant transformations detected in patients receiving transduced T-cells, or undergoing in vivo gene therapy targeting hepatocytes, muscle cells, or other nonhematopoietic targets. It appears that HSCs are much more susceptible than differentiated cells to vector-related tumorigenesis.⁶²²

FIGURE 71.9. Mechanisms of gene dysregulation and oncogenesis via vector integration into genomic DNA. The reverse-transcribed retroviral or lentiviral DNA permanently integrates into the genome, and can disrupt endogenous gene expression via a number of mechanisms. The integrated vector consists of two identical long terminal repeats (LTR) that contain a strong enhancer (red) and a promoter (green). A: If the vector lands upstream, downstream, or within an intron of a proto-oncogene, the LTR enhancer can up-regulate expression of the proto-oncogene. B: If the vector integrates within the first exon of a proto-oncogene, a constitutively expressed fusion transcript can result, with loss of endogenous control of expression. C: Vector integration within an exon can completely inactivate expression of a tumor suppressor gene via production of a truncated or fusion transcript. D: Vector integration can disrupt normal exon/intron or isoform splicing, resulting in an aberrantly regulated transcript, and up-regulation of a proto-oncogene or down-regulation of a tumor suppressor gene.

Large-Scale Mapping of Gene Transfer Vector Insertion Sites

Concurrent with these adverse events, the entire human and murine genome sequences were published and new technologies were developed that permitted large-scale mapping of vector insertion sites. The insertion of a vector proviral form into the genome can affect gene expression and thus potentially promote malignant transformation via several different mechanisms, as detailed in Fig. 71.9 and discussed in detail in a number of reviews.^{462,623} The Moloney MLV proviral LTR contains a strong promoter and enhancer, able to activate expression of upstream or downstream genes at distances of up to 200 kb, or directly drive expression of gene via fusion or replacement of the endogenous promoter. Internal promoters or enhancers, included to enhance transgene expression, can also activate nearby genes. A proviral insertion can inactivate a tumor-repressor gene. Vector insertion can disrupt normal exon splicing and alter

P.1520

relative levels of transcript isoforms or stability. Detailed large-scale mapping studies in cell lines and in primary hematopoietic cells revealed clear biases in integration site preferences for both standard retroviral as well as lentiviral vectors. MLV retroviral vectors were more likely to integrate near transcription start sites of genes, and HIV and SIV vectors were likely to integrate in generic regions and within actual genes.^{624, 625} and ⁶²⁶

Integration patterns were also assessed over time in mice, large animals, and patients receiving transduced cells. Murine studies using high-titer retroviral vectors and performing much longer follow-up than previous studies documented a high rate of progression to clonal or oligoclonal hematopoiesis, specifically from clones with insertions into proto-oncogenes or other growth-altering loci, and frequent leukemias in secondary and tertiary recipients of transduced cells, associated

with insertions into proto-oncogenes.^{627, 628} A rhesus macaque transplanted 5 years previously with retroviral vector-transduced CD34⁺ cells developed a clonal myeloid leukemia containing a vector insertion in the antiapoptotic gene BCL2A1.⁶²⁹ A large-scale survey of retrovirus vector insertion sites in long-term repopulating cells of rhesus macaques uncovered one locus that was markedly overrepresented, with nine independent insertions into the MDS1/EVI1 proto-oncogene, accounting for 2% of all insertions mapped.⁶²⁶ Proviral insertions at this locus were also identified in immortalized myeloid cell lines generated in vitro from retrovirus vector transduced primary murine BM cells.⁶³⁰

Gene Therapy for Chronic Granulomatous Disease

Even more striking dominance of myeloid hematopoiesis derived from progenitors with vector insertions in the MDS1/EVI1 locus was reported in a clinical trial for CGD. As described above, two patients received CD34⁺ cells transduced with a retroviral vector expressing the corrective phox91 transgene. Initially the patients did very well but the level of vector-containing cells began to increase in the myeloid lineage beginning several months after transplantation, eventually reaching levels of 60% to 70%. This expansion was found to be almost entirely accounted for by contributions from clones with insertions in the MDS1/EVI1 locus.⁴⁴⁶ Both patients then progressed to clonal myelodysplasia/myeloid leukemia, derived from one of their MDS1/EVI1 clones, and associated with a secondary loss of chromosome 7 in the malignant cells.⁴⁵⁸ Despite the persistent high frequency of vector-corrected neutrophils, expression of NADPH oxidase dropped precipitously in both subjects over time. The silencing of NADPH oxidase occurred through progressive CpG methylation of the promoter contained in the LTR of the vector. These events led to a series of infections and eventual death of one patient. The second subject was referred for unrelated donor SCT while still infection free.

Gene Therapy for Wiskott-Aldrich Syndrome

In nine of ten patients with WAS treated by gene therapy, clinical improvement was initially demonstrated. However, in a subsequent report, two of nine patients who achieved an efficient correction of the disease developed T-ALL 5 years and 16 months after gene therapy, respectively. Two additional patients also developed T-ALL more recently (unpublished data). In three of four patients with T-ALL analyzed to date, an increase of a cell clone harboring an integration site upstream of LMO2 could be observed at the onset of leukemia, the same gene locus activated by vector insertion in most of the X-SCID patients that developed T-ALL. One patient underwent an allogeneic stem cell transplant and the other individuals have responded to chemotherapy with recovery of a polyclonal integration site pattern.

Approaches to Decreasing the Risk of Insertional Genotoxicity

The insertion pattern of lentiviral vectors based on HIV or SIV is potentially safer, given that transcription start sites are not targeted. HIV/SIV vectors also have all endogenous promoter/enhancer elements deleted from the LTR, and thus should be much less likely to activate an adjacent proto-oncogene. A lower rate of leukemic transformation or cellular immortalization with HIV as compared to standard MLV-based retroviral vectors has been reported using several preclinical models, and long-term follow-up of nonhuman primates receiving SIV-transduced cells has not revealed any clonal dominance.^{353,631,632} Highly polyclonal patterns have persisted long-term in several patients receiving HIV vector-transduced CD34⁺ cells on a clinical trial for ALD.¹⁰² However, a single patient enrolled in a lentiviral vector-based gene therapy trial for thalassemia has developed clonal expansion of cells containing an insertion in the HMG2A gene,¹⁰³ indicating that we do not yet fully understand the possible pathways to clonal dominance and associated risks with any integrating vector system.

The clinical adverse events and these laboratory findings strongly support the need for long-term toxicity assessment in predictive preclinical models, development of vector systems less likely to activate or otherwise alter the behavior of adjacent genes, and careful risk-benefit analysis of gene therapy target diseases and patient populations. Use of standard retroviral vectors with strong enhancers in their LTRs is no longer considered prudent for HSC-targeted gene therapy, but whether lentiviral vectors, enhancer-deleted retroviral vectors, novel vector systems such as HFV or avian leukosis sarcoma virus, or gene targeting approaches will be safer and sufficiently efficacious is not yet known, and may vary depending on patient, target cell, and disease-specific characteristics. Well-designed pilot clinical trials in patients with sufficient disease severity to justify participation in a potentially risky protocol and a level of understanding allowing authentic informed consent will in the end provide the relevant path forward for gene therapy, no matter how many careful preclinical studies have been performed.

CONCLUSIONS

A wide variety of imaginative approaches involving genetic manipulation of hematopoietic or other targets have led to the first clinical successes of gene therapy approaches to hematologic diseases such as the hemophilias and the immunodeficiencies and are certain to eventually revolutionize therapy for a number of currently fatal or disabling

conditions. Continued basic scientific investigation of target cell biology and vector systems along with carefully designed clinical trials will drive the eventual application of gene therapy on a large scale.

Molecular Genetics of Acute Leukemia

Mary Ann Thompson

Utpal P. Davé

INTRODUCTION

Acute leukemia results when a normal hematopoietic stem or progenitor cell sequentially acquires mutations which confer clonal growth advantage. This clonal evolution model of cancer development involves gain of function of oncogenes and loss of function of tumor suppressor genes that cooperate to induce fulminant disease. The earliest view of the genome of acute leukemia was provided by cytogeneticists who karyotyped leukemic blasts, revealing recurrent chromosomal translocations. Cloning these translocation breakpoints led to the identification of genes whose altered activity could be directly linked to leukemogenesis. More recently, the genomes of acute leukemias have been probed at an unprecedented depth, revealing various lesions at the base pair level, such as amplifications, deletions, insertions/deletions, and point mutations, that can deregulate oncogene or tumor suppressor gene function. Acute leukemias of either myeloid or B-cell origin (i.e., acute myeloid leukemia [AML] and B-cell acute lymphoblastic leukemia [B-ALL]) have been classified by the World Health Organization (WHO) by the presence of recurrent chromosomal rearrangements which affect the choice of therapy and have significant prognostic value. Acute leukemias without recurrent chromosomal rearrangement have been traditionally classified by their cell of origin, but recently these leukemias have been subjected to whole genome analyses, revealing the presence of novel recurrent molecular lesions. As clinical data matures, the list of oncogenes and tumor suppressors deregulated by mechanisms other than chromosomal rearrangement may be incorporated into a new classification schema. In this chapter, we focus on the more common recurrent genetic abnormalities found in acute leukemias, with special emphasis on how the genetic defects inform our concept of leukemia pathogenesis. We provide specific examples where the genetic lesions have led to the development of targeted therapies with fewer side effects than traditional cytotoxic chemotherapy. This is truly an exhilarating time for hematologic oncology, where laboratory findings have direct relevance to current treatment modalities.

Reasons for Studying Molecular Genetics of Acute Leukemia

A major reason for understanding the molecular genetics of acute leukemia is to develop novel molecular treatments for this disease. The paradigm for the translation of basic research knowledge to clinical treatment has been chronic myelogenous leukemia (CML). The first leukemia to be associated with a recurrent translocation, t(9;22)(q34;q11.2) (the Philadelphia chromosome),¹ CML was also the first leukemia where the product of the translocation, breakpoint cluster region (BCR-ABL1) was characterized.² In addition, CML was the first leukemia for which a specific molecular inhibitor, imatinib (Gleevec), was designed.³ Research and clinical trials are currently underway to increase the armamentarium of targeted molecular therapies. An additional benefit of being able to identify the molecular lesions in a given acute leukemia is the ability to carry out more accurate risk stratification of newly diagnosed patients. Numerous clinical studies have correlated clinical prognosis with the set of genes that are altered in a patient's leukemic blasts. Results from the initial cytogenetic and molecular studies on a patient's leukemic blasts are used to stratify the leukemia as favorable or unfavorable, as listed in Tables 72.1 and 72.2 for adult AML and pediatric B-cell ALL, respectively. Finally, the particular array of mutated genes in the leukemic blasts provides a very sensitive method for determining efficacy of treatment by using these aberrant molecular markers to quantify minimal residual disease after treatment.

A large number of the genes altered by translocation encode transcriptional regulatory proteins that often preserve the original DNA-binding specificity of one of the fusion partners, but have altered properties of transcriptional activation or repression. The search to understand these altered properties has led investigators to basic discoveries of how transcriptional regulatory proteins modify chromatin structure to open up or inhibit the transcription of target genes. However, the genes that are recurrently mutated in acute leukemias also belong to other functional classes of proteins. Kinases which are rendered constitutively active by mutation can deregulate the cell's signal transduction pathways and lead to uncontrolled proliferation. Mutations in genes encoding proteins involved in modification of histones or methylation of DNA can lead to altered expression of groups of genes that can have effects as dramatic as those caused by mutations in transcription factors. Additional functional categories of genes that are recurrently mutated in leukemia are inhibitors of apoptosis and nuclear pore proteins. This chapter will focus on the mechanisms by which mutations in genes in each of these major functional classes may contribute to the pathogenesis of leukemia. If we understand the mechanism by which "driver" mutations work, we may be able to reverse or inhibit their actions to develop novel treatment modalities for leukemia.

Multiple Hit Model of Leukemia

Another theme that emerges from the study of the molecular genetics of leukemia is that usually more than one genetic hit is necessary for the development of leukemia.⁴ This principle has been repeatedly demonstrated in mouse models, where introduction of the fusion gene found in acute leukemia by transgenic technology or retroviral transduction results in predisposition to acute leukemia with long latency, unless the accumulation of additional genetic hits is facilitated by treatment with a mutagenic agent. The multistep model of carcinogenesis is not limited to leukemias, and is reviewed in Hanahan and Weinberg's recent update⁵ of their original paper⁶ first outlining the six hallmarks of cancer. These hallmarks, now updated to eight, are properties that cancer cells must acquire through multiple mutations in order to become malignant: sustained proliferative signaling, evading growth suppression, enabling replicative immortality, resisting cell death, inducing angiogenesis, activating invasion and metastasis, avoiding immune destruction, and deregulating

P.1524

cellular energetics.⁵ In the field of leukemia research, attention has been focused on deregulation of proliferation (Class I mutations), and a block in differentiation (Class II mutations).⁴ The block in differentiation is visually striking under the microscope, as blasts have morphologic characteristics of hematopoietic stem cells (HSCs). However, what is relevant to leukemogenesis is that HSCs have self-renewal. Many of the well-characterized recurrent translocations in acute leukemia produce fusion genes that encode mutant transcription factors that can no longer activate the genes required for differentiation. However, some translocations (notably BCR-ABL1), and some of the genes most commonly affected by point mutations (FLT3) encode kinases that cause deregulated proliferation.⁴ Through new advances in technology outlined in the next section scientists have discovered a host of additional gene mutations that occur in leukemia, suggesting many more than two hits in the path toward leukemia. In addition, a further layer of regulation at the epigenetic level has been hypothesized due to the number of genes mutated in leukemia that are active in modification of histones or in regulation of DNA methylation.

TABLE 72.1 RISK GROUPS IN ADULT ACUTE MYELOID LEUKEMIA BASED ON CYTOGENETIC AND MOLECULAR ANALYSIS

Cytogenetic Classification	Cytogenetic Abnormality	Mutation in FLT3	Other Mutations	Overall Risk Profile

Advances in Technology: A Genomic Perspective of Acute Leukemia

The tremendous advances in technology in the few years since the previous version of this chapter have revolutionized our ability to analyze individual genomes (Table 72.3). As mentioned above, G-banding of chromosomes was our first view of the leukemia genome and is still highly informative in identifying translocations, aneuploidy, and other gross chromosomal rearrangements (>4 megabases).^{7,8} More focused analyses such as interphase fluorescence in situ hybridization (FISH) have improved the resolution of standard cytogenetics so that amplifications or deletions of 100 kilobases may be visualized.⁹ In the last 10 years, oligonucleotides covering the entire human genome have been printed onto arrays allowing hybridization of fluorescently labeled leukemic and control genomic DNA.^{10,11} This array comparative genomic hybridization (CGH) can identify copy number variation (CNV), and has been powerfully employed in identifying recurrent

P.1525

deletions and amplifications in acute leukemias. Similar microarrays were designed to cover common single nucleotide polymorphisms (SNPs) for genotyping purposes, but they too have been used to identify CNVs, particularly copy number neutral loss of heterozygosity (also known as uniparental disomy) in leukemia.¹² Array CGH and SNP arrays display the human genome as small probes and will not detect balanced translocations. Most excitingly, major advances in whole genome sequencing now provide single base pair resolution so that point mutations may be identified as well as chromosomal rearrangements.¹³ These powerful technologies are readily deployed in the diagnosis of acute leukemia and provide a complete genomic perspective of the disease; however, there are important caveats. Human genomes are full of rare and common structural variants and SNPs.^{14, 15, 16, 17} and ¹⁸ Therefore, mutations can only be interpreted as being

acquired in leukemogenesis if they are not present in normal somatic tissue. Thus, matched normal somatic tissue is frequently subjected to the same genomic analyses as leukemic blasts.

TABLE 72.3 RESOLUTION OF TECHNOLOGIES AVAILABLE TO IDENTIFY GENETIC ALTERATIONS IN ACUTE LEUKEMIA

Technique	Resolution	Molecular Lesion	References
Whole genome sequencing	1 bp	Point mutations, amplifications, insertions, deletions, translocations	13,325
Whole exome sequencing	1 bp	Point mutations, amplifications, deletions	326,327

Gene expression microarray	-	Gene expression	244,246,330
Interphase FISH	100 kb	Focal amplifications or deletions	9
Array comparative genomic hybridization	100 kb amplification 3-5 Mb deletion	Amplifications, deletions	10,11
SNP array	100 kb	Amplifications, deletions	11,12,331
Cytogenetics/karyotyping	3-4 Mb	Amplifications, deletions, translocations	8,332

FISH, fluorescence in situ hybridization; SNP, single nucleotide polymorphism.

The sequence of the human genome was completed in 2001 at 90% coverage after 10 years of collaborative and arduous work from multiple laboratories for a cost of 1 billion dollars; the draft genome sequence contained gaps that were filled in 2004, resulting in a highly accurate reference sequence currently at build 37(2012).^{19, 20} and ²¹ At this writing, a sample human genome can be sequenced in 6 weeks for approximately 40 thousand dollars.²² This remarkably short processing time and reduction in cost were made possible by massively parallel sequencing technologies, collectively known as next generation (or second generation) sequencing.²³ The original draft human genome sequence was generated by Sanger sequencing or dideoxynucleotide chain termination and capillary electrophoresis, first generation technologies. In second generation technologies, the addition of nucleotides occurs in parallel on multiple DNA strands and is multiplexed frequently on microchips or beads.²⁴ This has resulted in an incredible information glut. As DNA sequencing technologies race toward the \$1,000 genome, the burden has shifted toward efficient and timely informatics analysis. Some of the complexity of genome assembly can be avoided by targeted sequencing or whole exome sequencing. Here, capture technologies utilize DNA hybridization to purify all the exons of a given genome. These are then fully sequenced; of course, in this case the mutations discovered are limited only to the coding regions of the genome, and mutations within regulatory regions may also be present. Besides mutation analysis, next generation sequencing has expedited our ability to define whole genome chromatin marks,²⁵ CpG methylation,^{25,26} microRNAs,²⁷ and noncoding RNAs.²⁸ For chromatin analysis, immunopurification can enrich for genomic DNA that is associated with specific histone marks that denote active or inactive gene expression. These tools will be important in analyzing the effects of mutant leukemia proteins that modify histone residues.

In 2008 the entire genome sequence of a cytogenetically normal AML patient was completed for the first time.²⁹ In 2009 further refined techniques were used to sequence a second AML genome to a higher level of coverage (98%),³⁰ and in 2010 DNA from the first patient was subjected to deeper sequencing.³¹ In each patient multiple acquired somatic mutations were identified by comparison to normal skin from the same patient. Somatic mutations unique to the leukemia cells were found in coding sequences, as well as in conserved or regulatory portions of genes. All of the mutations were shown to be heterozygous and were present in the majority of the blasts. Screening of a large panel of AML samples for novel coding region mutations identified in the two sequenced genomes demonstrated two genes not previously thought to be involved in leukemogenesis that were recurrently mutated: IDH1, (mutated in 16% of cytogenetically normal AML samples),³² and DNMT3A (mutated in 22% of AML samples).³¹

A recent study greatly expanded this breakthrough work by deep sequencing the genomes of 12 patients with AML with a normal karyotype and 12 patients with acute promyelocytic leukemia (APL) with the t(15;17).³³ Again, bone marrow and skin samples were compared, and all single nucleotide variations (SNVs) were validated by Illumina sequencing. An average of 440 SNVs per genome were identified. The number of SNVs per genome was not different between the cytogenetically normal leukemia cases and the t(15;17) leukemia cases, and the number was proportional to age. Interestingly, the number of mutations detected in HSCs from normal patients was similar and also varied with age, suggesting that mutations randomly accumulate in stem cells and that the hundreds of mutations in the AML genomes most likely preexisted before the initiating mutation that gave growth advantage to the AML clone.³³ Thus only a few mutations may be relevant to the pathogenesis of the clone. An average of 11 mutations with translational consequences were present in cytogenetically normal AML genomes and 10 in APL (counting promyelocytic leukemia-retinoic acid receptor- α [PML-RARA] itself). Only a few were recurring in other AMLs, with an average of 3 recurring mutations in each cytogenetically normal AML genome and 2 recurring mutations, including PML-RARA, in the AML genomes with t(15;17).³³

The complexity of mutations that contribute to the leukemic phenotype is visually appreciated in Figure 72.1, a summary of coexpression of mutations in a cohort of 398 patients with AML that were screened for mutations of eighteen gene loci.³⁴

P.1526

FIGURE 72.1. Mutational complexity of acute myeloid leukemia (AML). The Circos diagram depicts the relative frequency and pairwise co-occurrence of mutations in patients with newly diagnosed AML who were enrolled in the Eastern Cooperative Oncology Group E1900 clinical trial. The length of the arc along the outer circle corresponds to the frequency of mutations in the first gene, and the width of the ribbon corresponds to the percentage of patients who also had a mutation in the second gene listed on the opposite end of the ribbon. Pairwise co-occurrence of mutations is denoted only once, going in the clockwise direction. The frequency of occurrence in the test cohort of the 18 genes in the test panel is listed to the right of the Circos diagram. From Patel JP, Gonen M, Figueroa ME, et al. ACUTE MYELOID LEUKEMIA

World Health Organization Classification

A subset of the new WHO classification of acute myeloid leukemia is entitled “acute myeloid leukemia with recurrent genetic abnormalities”³⁵ (see Table 72.4). These recurrent translocations occur most often in de novo acute leukemia, but are not restricted to this category. Another major category of acute myeloid leukemia is AML with myelodysplasia-related changes,³⁵ where genetic mutations and chromosomal deletions occur secondary to the mutator phenotype of the underlying myelodysplastic syndrome (MDS) in some cases.

TABLE 72.4 WORLD HEALTH ORGANIZATION CLASSIFICATION OF ACUTE MYELOID LEUKEMIA

AML with recurrent genetic abnormalities
AML with t(8;21)(q22;q22); <i>RUNX1-RUNX1T1</i>
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); <i>CBFB-MYH11</i>
Acute promyelocytic leukemia with t(15;17)(q24.1;q21.1); <i>PML-RARA</i>
AML with t(9;11)(p22;q23); <i>MLLT3-MLL</i>
AML with t(6;9)(p23;q34); <i>DEK-NUP214</i>
AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); <i>RPN1-EVII</i>
AML (megakaryoblastic) with t(1;22)(p13;q13); <i>RBM15-MKLI</i>

Whole genome sequencing has clarified our understanding of the clonal evolution from MDS to AML. Walter et al compared seven sets of samples from patients for whom there were paired samples of normal skin, preleukemic bone marrow diagnosed as MDS, and bone marrow involved by secondary AML.³⁶ In each genome there were 304 to 872 somatic point mutants in coding regions or consensus splice site regions, and those point mutations with translational consequences comprised an average of 24 mutations per genome. These functional mutations occurred in a total of 168 genes over the 7 genomes. The strength of the study was that the number of mutations allowed study of clonal evolution from MDS to secondary AML. The clonal evolution described by the sequential acquisition of mutations (defined as five mutation clusters by unsupervised clustering analysis) is visually shown in Figure 72.2. A majority of the cells in the MDS sample contained the same cluster of mutations, meaning that before blasts were even detected morphologically, the marrow was involved by a clonal process. At the secondary AML stage, all the samples contained several clones, all of which had the original set of mutations, but which were defined by acquisition of new sets of mutations as well. Presumably most of these somatic mutations are “passenger” mutations, but the multiplicity of mutations tracked adds credence to the description of clonal evolution.³⁶ The mutations that were in characterized genes ranged the gamut of genes involved in adhesion, cell death, cell cycle, differentiation, metabolism, motility, signaling, transcription, and transporters.³⁶ In the subsequent sections, we will discuss how alterations of genes that fall in these functional classes contribute to leukemogenesis.

FIGURE 72.2. Clonal progression of MDS to secondary acute myeloid leukemia (AML). This model summarizes the clonal evolution from MDS to secondary AML (sAML) in one patient. Cells in clone 1 (yellow) contain cluster 1 mutations, 323 somatic single nucleotide variants (SNVs) present in approximately 74% of the bone marrow cells. Cells in clone 2 (orange) originated from a single cell in clone 1 and therefore contain all cluster 1 and 2 mutations. This clone became dominant in the sAML sample, in which three subsequent subclones (red, purple, and black) evolved through serial acquisition of SNVs (clusters 3, 4, and 5). Transcription Factors

Promyelocytic Leukemia-Retinoic Acid Receptor- α

One of the most elegant examples of the interaction between clinical and molecular advances in the treatment of acute leukemia is APL. The association between the t(15;17)(q24.1;q21.1) translocation and the characteristic morphology of APL (hypergranular blasts with frequent Auer rods or microgranular variant with dumbbell-shaped nuclei) has been known for a long time. The ability to treat APL with retinoic acid (RA) and the understanding of the molecular basis for this treatment is a compelling example of the power of molecular medicine. The initial report from China³⁷ that all-trans retinoic acid (ATRA) could induce complete remission (CR) in APL patients actually preceded the discovery that the t(15;17) translocation involved the RARA gene on chromosome 17.^{38,39,40}

Of four translocations associated with APL, the most common is t(15;17)(q24.1;q21.1), in which the 5' portion of the fusion protein is encoded by the PML gene from 15q24.1 and the 3' portion is encoded by the RARA gene from 17q21.1. The RARA gene is a ligand-dependent steroid receptor that mediates the effects of the ligand, RA, on the cell. The breakpoint is invariant in intron 2 of RARA, yielding the C-terminal portion of the fusion protein, which includes the DNA-binding, ligand-binding, dimerization, and repression domains of RARA. There are three major breakpoints in the PML gene. The most common generates PML(L)-RARA, which includes the first six exons of PML encoding 554 amino acids of PML.⁴¹

The wild-type RARA is a nuclear receptor that acts as a transcription factor and binds to retinoic acid response elements (RAREs) in the promoters of many genes, including genes important in myeloid differentiation. RARA binds as a heterodimer with retinoid X receptor protein (RXR) and acts as a transcriptional repressor until ligand (RA) binding occurs, changing the conformation of the protein and resulting in transcriptional activation.⁴² Target genes important for myeloid differentiation include colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF]), colony-stimulating factor receptors (G-CSFRs), neutrophil granule proteins (leukocyte alkaline phosphatase, lactoferrin), cell-surface adhesion molecules (CD11b, CD18), regulators of the cell cycle, regulators of apoptosis (BCL2), and transcription factors (RARs, STATs, HOX genes) (reviewed in Ref. 43). Expression of a dominant negative RARA in either a murine hematopoietic cell

line or primary murine bone marrow cells, followed by stimulation with granulocyte-macrophage colony-stimulating factor (GM-CSF), results in arrest of granulocytic differentiation at the promyelocyte stage.⁴⁴

In the absence of RA, the wild-type RARA, present as a heterodimer with RXR on the RARE, binds to the corepressor proteins SMRT, N-CoR, mSin3, and histone deacetylases (HDACs). Deacetylation of the histones at the target gene promoter results in transcriptional repression. Ligand binding at physiologic concentrations of ATRA causes a conformational change that results in release of corepressors and recruitment of a coactivator complex (SRC-1), which associates with histone acetyltransferases (Fig. 72.3A).⁴⁵ Acetylation of the histones at the target gene promoter is associated with transcriptional activation (reviewed in Ref. 43).

Wild-type PML protein is normally localized in subnuclear PML oncogenic domains, also called nuclear bodies (NBs), in which other nuclear factors colocalize.⁴⁶ PML may act as a tumor suppressor protein and is involved in growth suppression as well as in induction of apoptosis (reviewed in Ref. 43). Although it does not bind DNA directly, it influences transcription by interacting with both CREB-binding protein (CBP),⁴⁷ a transcriptional activator, and HDACs, transcriptional repressors, possibly within the NBs. The protein encoded by the PML-RARA fusion transcript resulting from the t(15;17) is delocalized from the NBs to a microspeckled nuclear pattern.⁴⁸

In APL, the PML-RARA protein binds to RAREs with similar affinity to the RARA protein and is able to heterodimerize with RXR. It acts in a dominant negative manner, competing with wild-type RARA for binding to the RAREs. It binds corepressor proteins in the absence of ligand (via the RARA portion of the protein). However, physiologic levels of ATRA (10^{-8} M) are not able to convert PML-RARA into a transcriptional activator; pharmacologic concentrations are required (10^{-6} M; Fig. 72.3B).^{45,49} This provides the mechanistic basis for the efficacy of treatment of APL patients with ATRA to include differentiation of the promyelocytes.

Understanding of the mechanism of the response of APL to ATRA was furthered by studies of an alternative translocation, t(11;17)(q23;q21.1), which is rarely seen in patients with APL.⁵⁰ Patients with this translocation are resistant to treatment with pharmacologic doses of ATRA. The fusion partner gene on chromosome 11q23 encodes ZBTB16 (previously known P.1528

as promyelocytic zinc finger), a transcriptional repressor. The N-terminal portion of the fusion protein encoded by ZBTB16 includes the N-terminal POZ/BTB protein interaction domain, transcriptional activation and repression domains, and a variable number of zinc fingers important for protein and DNA interactions (reviewed in Refs. 43,45). ZBTB16 interacts with N-CoR, SMRT, mSin3A, and HDAC1 via the POZ/BTB domain,^{51,52} and therefore contributes a second binding site for corepressor proteins. Therefore, although pharmacologic doses of ATRA induce release of corepressors from the RARA portion of the fusion protein, the corepressors binding to ZBTB16 are unaffected (Fig. 72.3C).^{43,53} Significantly, concomitant treatment of cells with HDAC inhibitors such as trichostatin A (TSA) restores ATRA sensitivity, since TSA inhibits the deacetylase activity of the corepressors on the ZBTB16 moiety.^{49,52}

FIGURE 72.3. Model for the role of nuclear corepressors and retinoid acid receptor α (RARA) fusion proteins in the pathogenesis and treatment of acute promyelocytic leukemia. A: In the absence of all-trans retinoic acid (ATRA), RARA, promyelocytic leukemia (PML)-RARA, and promyelocytic leukemia zinc finger (PLZF; now known as ZBTB16)-RARA associate with N-CoR/sin3A/HDAC1 corepressor complex, which deacetylates histone tails, resulting in a compressed chromatin and transcriptional repression. Binding of ATRA at a physiologic concentration induces a conformational change in RARA, causing release of the corepressor complex and binding of coactivator (SRC-1) with histone acetyltransferase activity. Acetylation (Ac) of histone tails opens up the chromatin, facilitating transcriptional activation. B: In the case of PML-RARA protein, pharmacologic doses of ATRA are required to achieve dissociation of the N-CoR repressor complex. C: Because of additional interactions of the PLZF (ZBTB16) moiety of PLZF-RARA fusion protein with corepressors, they do not dissociate even in the presence of pharmacologic doses of ATRA. Therefore, the chromatin still remains in the repressed state. From Guidez F, Ivins S, Jhu J, et al. Reduced retinoic acid-sensitivities of nuclear receptor corepressor binding to PML- and PLZF-RAR α underlie molecular pathogenesis and treatment of acute promyelocytic leukemia. *Blood* 1998;91:2634-2642, with permission.

Subsequent studies have demonstrated that PML-RARA recruits the polycomb-repressive complex 2 (PRC2) to the promoters of its gene targets. The PRC2 has a H3K27 methylase activity and can initiate gene repression through trimethylation of H3K27.⁵⁴ ZBTB16-RARA additionally recruits polycomb-repressive complex 1 (PRC1); treatment with RA releases PRC2 from both PML-RARA and ZBTB16-RARA, but does not release PRC1 from ZBTB16-RARA.⁵⁵

Core-Binding Factor Translocations

The t(8;21) is present in approximately 15% of patients with acute myeloid leukemia,^{56,57} and the RUNX1 (runt-related transcription factor 1, formerly called AML1) gene, cloned from the t(8;21) (q22.3;q22) breakpoint,^{58,59} is mutated in another 3% of AML. The activity of the murine counterpart of RUNX1 was first described as part of the core-binding factor (CBF), which binds to a core enhancer sequence of the Moloney murine leukemia virus long terminal repeat.⁶⁰ Another component of CBF, the non-DNA-binding CBF β was found to be associated with inversion 16 in AML.⁶¹ Finally, the fusion partner of RUNX1 in t(8;21), named RUNX1T1, or ETO (eight-twenty-one), also encodes a transcriptional regulator.⁶² A gene related to RUNX1T1, CBFA2T3 (or MTG16), is involved in yet another translocation involving RUNX1, t(16;21).⁶³ The structures of the fusion proteins resulting from these CBF translocations are shown in Figure 72.4.

RUNX1 is located at chromosome 21q22.3 and is encoded by 12 exons over 260 kb of DNA. The N-terminal portion of the protein contains the runt homology domain (RHD), which is homologous to the *Drosophila* runt protein⁶⁴ and is responsible for the official HUGO name, RUNX1. This is the DNA-binding domain and it is mutated in familial platelet disorder (FPD) and in AML associated with RUNX1 mutations.^{65,66} CBF β interacts via this domain and changes the conformation of RUNX1 to increase DNA-binding affinity.⁶⁷ C-terminal to the RHD are potential MAP kinase phosphorylation sites, followed by three weak activation domains, a nuclear matrix target signal, a dimerization domain, and sequences that are recognized by corepressor proteins (reviewed in Ref. 68).

The CBFs are essential for hematopoietic development. Gene deletion of either Runx1⁶⁹ or Cbfb⁷⁰ in mice results in fetal death at E11.5 to 12.5. These embryos lack all fetal hematopoiesis. Further transgenic experiments have demonstrated that Runx1 is essential for development of HSCs in the aorta/gonadal/mesodermal (AGM) region, the source of definitive hematopoiesis.⁷¹ The essential role of RUNX1 in hematopoietic development appears to be through its function as a transcriptional activator. It regulates lymphoid genes such as B-cell tyrosine kinase, T-cell receptor α and β ,⁷² cytokines (interleukin-3 [IL3],⁷³ GM-CSF⁷⁴), and granulocyte proteins (myeloperoxidase and neutrophil elastase),⁷⁵ to name a few. In addition, RUNX1 acts as a transcriptional repressor of genes such as p21Waf1/Cip1 via interactions with the mSin3a corepressor⁷⁶ and with SUV39H1, a histone methyltransferase.⁷⁷

The ETO gene, now called RUNX1T1, was cloned from the t(8;21) fusion⁵⁸ and is the mammalian homolog of the *Drosophila*

P.1529

nervy gene.⁷⁸ The four homology domains shared with the *Drosophila* protein include a region of similarity to TAF110, a hydrophobic heptad repeat (HHR), an ND domain of undetermined function, and two zinc finger motifs that may be a protein-protein interaction domain (Fig. 72.4A).⁶⁸ RUNX1T1 does not appear to bind DNA specifically on its own. However, it may act as a corepressor protein.⁷⁹ It associates with N-CoR and mSin3A, and directly binds to the Class I HDACs, HDAC-1, HDAC-2, and HDAC-3 (Fig. 72.4A).⁸⁰

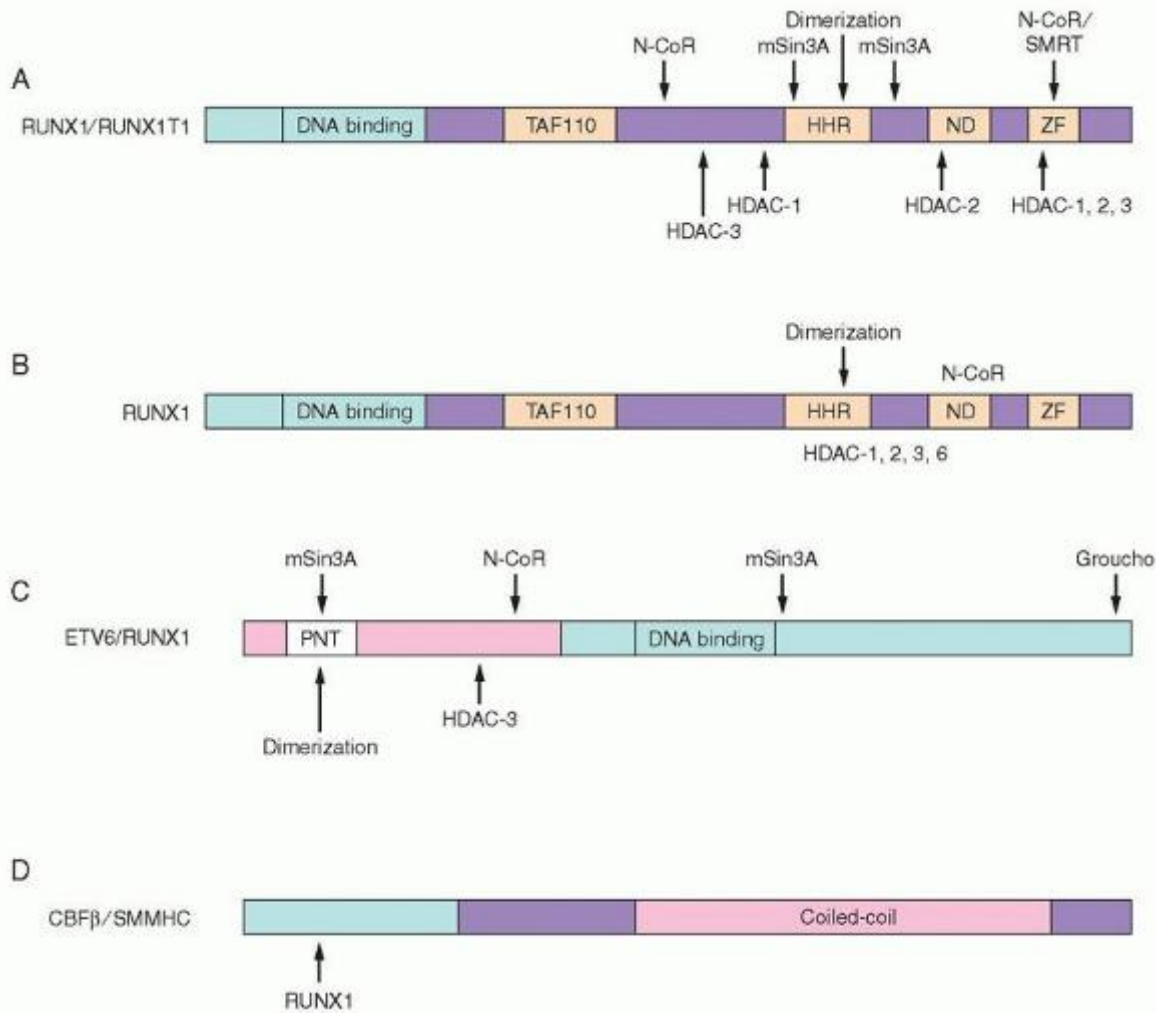

FIGURE 72.4. Schematic diagram of the t(8;21), t(16;21), t(12;21), and inv(16) fusion proteins with known corepressor contacts. A: t(8;21) RUNX1/RUNX1T1. The RUNX1 portion is shown in light pink, with the DNA-binding domain indicated. The RUNX1T1 portion is the dark pink box with domains conserved between RUNX1T1 and its *Drosophila* homolog in light gray boxes. Known contacts with corepressors and histone deacetylases are shown. B: t(16;21) RUNX1-MTG16 (now known as CBFA2T3). RUNX1 is shown as a light pink box, and MTG16 is shown in a similar manner to RUNX1T1 in A. C: t(12;21) ETV6-RUNX1. ETV6 is the dark pink box, with the conserved pointed (PNT) domain indicated. The RUNX1 portion is the light pink box. Interactions with corepressors and HDACs are shown. D: Inv(16) CBFβ-SMMHC (now known as MYH11). The CBFβ portion, which interacts with RUNX1, is light pink, and the SMMHC is dark pink, with the coiled-coil domain indicated as well as the C-terminal portion, which is necessary for interaction with mSin3A and HDAC8.⁷⁷ HHR, hydrophobic heptad repeat; ND, nery domain; TAF110, a domain with homology to the TAF110 coactivator; ZF, zinc finger domain. From Hiebert SW, Lutterbach B, Amann J. Role of corepressors in transcriptional repression mediated by the t(8;21), t(16;21), t(12;21), and inv(16) fusion proteins. *Curr Opin Hematol* 2001;8:197-200, with permission.

In the t(8;21) translocation, the RUNX1 gene is fused to the RUNX1T1 gene on chromosome 8. The breakpoint in the RUNX1 locus is between exons 5 and 6,⁸¹ yielding a fusion protein with the N-terminal 177aa of RUNX1.⁵⁸ In this fusion protein, the DNA-binding domain is present, but the C-terminal activation domains, corepressor interaction sites, and nuclear localization signals (NLSs) of the wild type are not present (Fig. 72.4A).⁶⁸ The breakpoint in the RUNX1T1 gene occurs in the introns between the first two alternative exons of RUNX1T1, resulting in the inclusion of almost all of the coding region for RUNX1T1 in the fusion transcript.⁵⁸

The RUNX1-RUNX1T1 protein specifically binds to the same DNA-binding site as RUNX1 and can heterodimerize with CBFβ.⁸² Therefore, the RUNX1-RUNX1T1 protein can act as a dominant negative inhibitor of wild-type RUNX1. However, cotransfection experiments demonstrated that RUNX1-RUNX1T1 can also function as an active transcriptional repressor, not only inhibiting activation of a reporter gene containing the GM-CSF receptor promoter by cotransfected RUNX1, but

also reducing the expression of the reporter gene below baseline.⁸³ The ability of RUNX1-RUNX1T1 to act as a transcriptional repressor depends on its association with HDACs (via RUNX1T1; Fig. 72.4A), since the HDAC inhibitor TSA can abrogate effects of RUNX1-RUNX1T1 on the cell cycle.⁸⁰ In addition, examination of the M-CSFR gene in Kasumi-1 cells (high expressors of RUNX1-RUNX1T1) reveals an increase in histone H3Lys9 methylation.⁸⁴ Targets of RUNX1-RUNX1T1 repression are presumed to include genes important for granulocyte differentiation. In addition, RUNX1-RUNX1T1 represses the tumor suppressor genes P14ARF and NF1.^{85,86} P14ARF stabilizes TP53 by antagonizing MDM2, an inhibitor of TP53.⁸⁷ Therefore, repression of P14ARF reduces the checkpoint control path of TP53, and may be a key event in t(8;21) leukemogenesis. The promoter of P14ARF has eight RUNX1 DNA-binding sites, and wild-type RUNX1 can activate P14ARF. However, transfection of RUNX1-RUNX1T1 into cells that have only low levels of RUNX1 and high endogenous levels of P14ARF results in repression of P14ARF. Samples of bone marrow from patients with t(8;21) leukemia have low levels of P14ARF transcript by quantitative real-time polymerase chain reaction analysis.⁸⁵ Surprisingly, expression of RUNX1-RUNX1T1 in myeloid progenitor cells inhibits cell cycle progression. However, this may contribute to leukemogenesis by allowing time for accumulation of mutations in a cell immune from TP53-induced apoptosis due to inactivation of P14ARF.⁸⁵

P.1530

Finally, inversion 16, present in about 8% of AML cases, involves the CBF complex member CBFβ and is associated with a morphologically distinct subset of AML, previously considered M4Eo in the French-American-British Cooperative Group Classification. This disease is a myelomonocytic leukemia with abnormal eosinophils that have dark purple as well as orange granules.³⁵ This cytogenetic abnormality in which the CBFβ gene is fused to the smooth muscle myosin heavy-chain (SMMHC) gene, MYH11, results in fusion of the first 165aa of CBFβ to the C-terminal coiled-coil region of SMMHC protein (Fig. 72.4D).⁶¹ A C-terminal region of SMMHC/MYH11 is necessary for the activity of CBFβ/MYH11 as a transcriptional corepressor, and this region also associates with mSin3a and HDAC8. Presumably CBFβ/MYH11, which cannot bind DNA on its own, interacts with RUNX1 to form a transcriptional repressor complex.⁸⁸

A number of experiments demonstrate that the CBF translocations are necessary but not sufficient for induction of leukemia. In order to determine whether expression of RUNX1-RUNX1T1 is sufficient to produce leukemia, mice were generated with a conditional Runx1-Runx1t1 knock-in allele using the Lox-Cre system. This obviates the embryonic lethality that results when Runx1-Runx1t1 is introduced into transgenic mice (recapitulating the phenotype of the Runx1 null mouse). No leukemia developed in 20 Runx1-Runx1t1+ mice in 11 months, and no hematologic abnormality was detected except for a slight increase in the number of hematopoietic colony-forming cells. Interestingly, expression of Runx1-Runx1t1 did not cause a significant block in differentiation of hematopoietic precursors. When the mice were mutagenized with the DNA alkylating agent, ethylnitrosourea (ENU), 31% of the mice developed granulocytic sarcoma or AML.⁸⁹ This supports the hypothesis that several genetic “hits” are necessary for the development of leukemia.

Another study used retroviral transduction of CD34⁺ human hematopoietic progenitor cells to investigate the effect of RUNX1-RUNX1T1 on proliferation and differentiation.⁹⁰ In mice reconstituted with RUNX1-RUNX1T1 expressing HSCs there was an expansion of the HSC population and immature myeloid cell populations, although the mice did not develop acute leukemia.⁹¹ Therefore, the expression of RUNX1-RUNX1T1 promotes accumulation of immature cells and prolongs the period of time during which progenitor cells may accumulate additional mutations.

Further support for the hypothesis that genetic mutations besides a mutant RUNX1 locus are necessary for development of acute leukemia comes from the study of patients with FPD with a propensity to develop AML (FPD/AML). These patients have mutations in one allele of RUNX1.⁹² They have defective platelets and progressive pancytopenia, and develop myelodysplasia and a high incidence of AML with age. However, second mutations appear to be necessary before progression to AML occurs. This implies that acquisition of additional mutations is necessary for development of leukemia.

CCAAT/Enhancer Binding Protein-α

CCAAT/enhancer binding protein-α (CEBPA) is a transcription factor that regulates granulocytic differentiation.⁹³ Cytogenetically silent mutations of CEBPA have been identified in about 10% of AML cases.⁹⁴ In addition, mutations in other oncogenes in leukemia often lead to CEBPA downregulation. For example, RUNX1-RUNX1T1 represses the CEBPA promoter.⁹⁵ FLT3-ITD activation of ERK leads to modification of CEBPA which reduces its activity.⁹⁶

In addition, the CEBPA promoter is methylated in half of AML cases.⁹⁷ The importance of CEBPA in granulocyte differentiation is demonstrated by the lack of mature granulocytes in Cebpa knockout mice,⁹⁸ while its conditional expression triggers granulocyte differentiation in bipotential precursors.⁹⁹ CEBPA transactivates the genes for G-CSF and

GM-CSF receptors and several granulocyte-specific proteins. The gene produces two proteins using alternative start sites. The larger and predominant 42-kD protein consists of two N-terminal transactivating domains, with a C-terminal bZIP domain consisting of a basic (b) region that mediates DNA sequence binding and a leucine zipper (ZIP) domain that mediates dimerization.¹⁰⁰ The shorter 30-kD protein is transcribed from an alternative internal start site, and retains its bZIP domain but lacks the first transactivation domain. Mutations in CEBPA are of two types: C-terminal bZIP domain mutations and N-terminal truncating mutations that lead to enhanced production of the 30-kD protein.^{101,102,103} The former type inhibits dimerization and DNA binding. The latter type dimerizes with the long form, but inhibits transactivation by the dimer, functioning in a dominant negative manner. In two-thirds of AML with CEBPA gene mutations, one allele has an N-terminal mutation and the other allele has a C-terminal variant. Several families with familial AML have been documented to have germline CEBPA N-terminal mutations, and progression to AML has been shown to correlate with a somatic mutation in the C-terminus.¹⁰⁴ CEBPA mutations most often occur in intermediate-risk AML with normal cytogenetics, and these patients have a significantly improved outcome.⁹⁴ Interestingly, mutation of CEBPA at both alleles is associated with a better overall survival than mutation of CEBPA at a single allele.¹⁰⁵ Approximately one-third of AML with CEBPA mutations also have FLT3 mutations, and the CEBPA mutation confers a more favorable prognosis in this group of AML patients as well.³⁴

GATA1

GATA1 is a zinc finger transcription factor that regulates erythroid and megakaryocytic differentiation. In the acute megakaryoblastic leukemia (AMkL) that occurs in children with Down syndrome (DS), mutations of GATA1 have been described in all tested cases.^{106,107,108} Familial missense mutations in GATA1 result in a syndrome of dyserythropoietic anemia and thrombocytopenia, while conditional knockout of Gata1 in megakaryocyte precursors in mice leads to thrombocytopenia and megakaryoblast proliferation. Approximately 10% of DS patients develop transient myeloproliferative disorder (TMD) in the neonatal period (usually in the first week, almost always within the first 2 months of life), and these patients have mutations in GATA1.^{106,109} About one-third of DS patients with TMD later develop AMkL within 5 years, and identical GATA1 mutations have been identified in the AMkL blasts as were present in the TMD. A large study demonstrated that there is no difference in the GATA1 mutations present in patients who just developed TMD compared to patients who went on to AMkL.¹¹⁰ The mutations in GATA1 result in transcription of a truncated form that lacks its N-terminal transactivation domain, GATA-1s. This shorter form has similar DNA-binding activity but reduced transactivation compared to wild-type, and it therefore can act in a dominant negative manner. By introducing the truncated GATA1 into GATA1-deficient fetal liver progenitor cells by retroviral transduction, Muntean and Crispino demonstrated that GATA-1s restored terminal differentiation but that abnormal proliferation occurred.¹¹¹ Interestingly, analysis of a knock-in mouse model where Gata-1s replaces wild-type Gata-1 demonstrates that fetal liver megakaryocytes abnormally proliferate, but that megakaryocyte proliferation is normal in adult bone marrow.¹¹² This may explain why TMD occurs in the neonatal period in DS patients. Research into the gene(s) on chromosome 21 that cooperate with mutant GATA1 to produce AMkL in DS children is ongoing; a recent mouse study reported evidence that Dyrk1a (dual-specificity tyrosine-phosphorylation-regulated kinase 1A) can cooperate with mutant Gata1 to promote megakaryoblast expansion.¹¹³

P.1531

AMkL in Down syndrome is sensitive to cytosine arabinoside/anthracycline-based chemotherapy, with event-free survival rates of 80% to 100%.¹¹⁴ Interestingly, a putative target of GATA1 regulation is cytidine deaminase (CDA), which inactivates ara-C by deamination to the inactive uridine arabinoside. Presumably failure of GATA-1s to transactivate CDA increases the efficacy of ara-C treatment.¹¹¹

Epigenetic Factors Modifying Chromatin and DNA

IDH1/2 and TET2 Mutations

In the whole genome sequencing of blasts from a patient with cytogenetically normal AML, mutations in isocitrate dehydrogenase 1 (IDH1) were detected and were found to be present in 16% of a panel of 80 cytogenetically normal AML samples.³⁰ IDH1 mutations had previously not been described in AML, though IDH1/2 mutations are common in gliomas.¹¹⁵ In a further screen of AML DNA, it was found that IDH1/2 mutations are mutually exclusive with mutations in TET2 (ten-eleven translocation 2) in de novo AML (Fig. 72.5). Additional findings suggesting a functional link between the products of these two genes are that AMLs with mutations in IDH1 have similar patterns of DNA hypermethylation as AMLs with mutations in TET2.¹¹⁶ In addition, these two mutational categories of AML share patterns of aberrant gene expression at

the level of 93%.¹¹⁶ The link became clear upon further investigation of the enzymatic activity of IDH1/2 and TET1/2. Wild-type IDH1/2 catalyzes production of α -ketoglutarate (α -KG), whereas the neomorphic enzymatic activity of mutant IDH1/2 produces 2-hydroxyglutarate (2-HG). α -KG-dependent enzymes such as histone demethylases and TET1/2 are inhibited by 2-HG, which is structurally similar enough to α -KG that it can bind in place of α -KG and inhibit these enzymes.¹¹⁷ The TET proteins catalyze the conversion of 5-methyl cytosine (5mC) to 5-hydroxymethyl cytosine (5hmC), which is thought to be a first step in demethylation of the cytosine.¹¹⁸ Experiments using a fluorescent-tagged antibody to 5hmC demonstrate that cotransfection of plasmids encoding IDH1 and TET2 result in a global increase in 5hmC, whereas cotransfection of plasmids encoding mutant IDH1 and wild-type TET2 fail to demonstrate an increase in 5hmC.¹¹⁷ Therefore, mutations in IDH1 and TET2 both produce increased DNA methylation: mutant IDH1 by inhibiting TET2, and mutant TET2 by loss of its ability to convert 5mC to 5hmC, and thereby promote demethylation.^{116, 117, 118} and ¹¹⁹ The significance of these changes for pathogenesis of AML is demonstrated by experiments in which either stable expression of mutant IDH1 or shRNA-mediated knock-down of TET2 in primary mouse bone marrow cells resulted in increased c-kit expression and decreased expression of the mature myeloid markers Mac-1 and Gr-1 by flow cytometric analysis.¹¹⁶ Therefore, the hypermethylation and resultant silencing of genes as a result of IDH1 and TET2 mutations presumably inhibit myeloid differentiation and thereby promote development of AML. This mechanism suggests new avenues of molecular therapy in that drugs that mimic α -KG or that inhibit the mutant IDH1/2 may restore proper enzymatic function to histone demethylases and TET2, promoting normal histone and DNA methylation patterns.¹¹⁷ In studies performed to date, mutations in IDH1 and TET2 have not been shown to have a significant impact on survival.¹⁰⁵

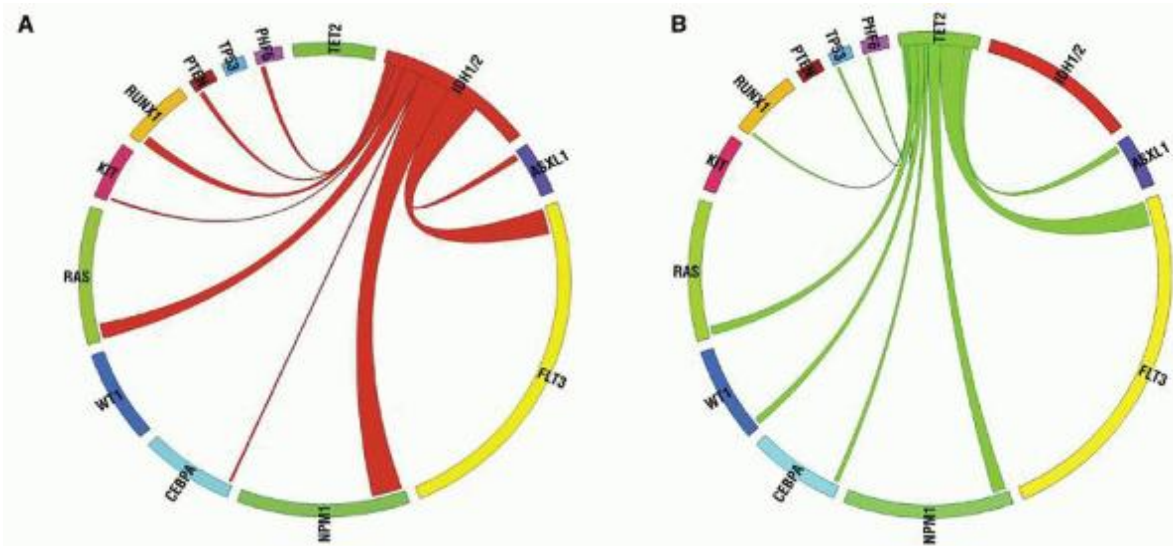

FIGURE 72.5. IDH1/2 mutations are mutually exclusive with mutations in TET2 in de novo AML. A: Circos diagram revealing relative frequency and pairwise co-occurrences of mutations in IDH1 and IDH2 in a cohort of 385 patients with de novo AML. B: Circos diagram revealing relative frequency and pairwise co-occurrences of mutations in TET2 in a cohort of 385 patients with de novo AML. Reprinted from Figueroa ME, Abdel-Wahab O, Lu C, et al. Leukemic IDH1 and IDH2 mutations result in a hypermethylation phenotype, disrupt TET2 function, and impair hematopoietic differentiation. *Cancer Cell* 2010;18:553-567, with permission from Elsevier.

DNMT3A

Deep sequencing of DNA from the first AML patient with a normal karyotype revealed additional mutations, including a mutation in DNA methyltransferase (DNMT3A). Sequencing of the DNMT3A gene in DNA from 281 AML patients revealed a mutation rate of 22.1%. The DNMT3A mutations were found in patients with intermediate-risk cytogenetics. As a group these patients had a mean overall survival significantly shorter than the patients with wild-type DNMT3A: 12.3 months compared to 41.1 months.³¹ The mutations detected in patients with AML map predominantly at the interface where they disrupt tetramerization of the DNMT3A molecules. Dimeric DNMT3A molecules still have methylase activity, but they dissociate from DNA more quickly than wild-type, so

P.1532

that fewer cytosines in a CpG island are methylated.¹²⁰ The effect on tetramerization explains why the DNMT3A mutations are dominant negative, usually occurring in just one allele. Global methylation does not seem to be affected in DNA from

AML with mutated DNMT3A, but analysis of DNA methylation by MeDIP-Chip (methylated DNA immunoprecipitation-Chip) analysis in a matched set of DNAs from 5 AML patients with mutated DNMT3A and 5 AML patients with wild-type DNMT3A demonstrated 182 genomic sites where the DNA from patients with mutated DNMT3A was hypomethylated.³¹ Studies of DNA methylation in Dnmt3a-null murine HSCs demonstrated a complex story with poor correlation between changes in methylation sites and changes in gene expression comparing wild-type to Dnmt3a-null HSCs. However, changes in gene expression patterns may be due to changes in methylation of regulatory regions of directly affected genes, whose expression then alters regulation of many other genes by mechanisms other than methylation. Transcriptional profiling of Dnmt3a-null HSCs did reveal that genes involved in the multipotency of normal HSCs were upregulated, whereas genes necessary for differentiation of the HSCs were downregulated. This suggests that the DNMT3A mutations may contribute to the block in differentiation that occurs in leukemic blasts. Interestingly the Dnmt3a-null mice have not yet developed leukemia, suggesting that DNMT3A mutation alone is not sufficient for leukemogenesis.¹²¹

Mixed Lineage Leukemia: 11q23 Translocations

A transcriptional activator that is characteristically rearranged in infant leukemia, therapy-related leukemia, and mixed phenotype acute leukemia is the mixed lineage leukemia gene (MLL), which maps to chromosome 11q23 (reviewed in Ref. 122). The MLL gene consists of 34 exons over 100 kb encoding a 3,969 aa protein.¹²² MLL is the mammalian homolog of trithorax, a Drosophila transcriptional regulator that positively regulates homeobox genes.¹²³ Homeobox genes are a large family of genes which are developmental regulators essential for growth and differentiation. They were first identified in Drosophila during the study of genes whose mutations led to developmental abnormalities involving misassignment of body segment identity.¹²⁴ The mammalian homologs consist of 39 HOX genes, which are important in mammalian development and cell fate determination.¹²⁵ Analysis of chimeric mice reconstituted with MLL-deficient embryonic stem cells demonstrates that MLL expression is required for definitive hematopoiesis and expansion of HSCs in the AGM region.¹²⁶ Wild-type MLL appears to be responsible for the regulation of homeobox gene expression during development, including HOXA9, HOXC8, HOXA7, HOXA10, HOXC6, and HOXC9.^{126,127,128,129} Wild-type MLL regulates HOX gene expression by methylation of histone H3 lysine (H3K4), requiring the SET domain. The SET domain is a protein domain shared by a number of transcriptional regulators that have histone methyltransferase activity.¹³⁰ H3K4 methylation is associated with transcriptional activation.

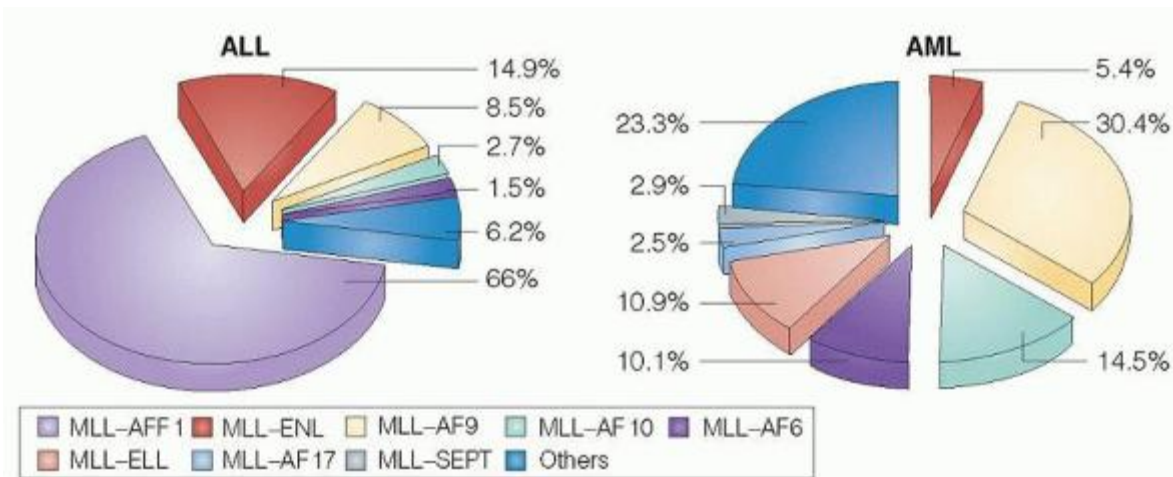

FIGURE 72.6. The distribution of the most common MLL chimeras in acute lymphoid and myeloid leukemias. In MLL-rearranged ALL, AFF1, AF9 (now known as MLLT3), ENL (now known as MLLT1), and AF10 (now known as MLLT10) account for 90% of all the translocations, and in AML 70% of MLL translocations involve AF9 (MLLT3), ENL (MLLT1), AF10 (MLLT10), ELL, and AF17 (now known as MLLT6). AFF1 is the most frequent translocation partner of MLL, which is typically associated with ALL. Reprinted by permission from Macmillan Publishers Ltd: Mohan M, Lin C, Guest E, Shilatifard A. Licensed to elongate: a molecular mechanism for MLL-based leukaemogenesis. *Nat Rev Cancer* 10:721-728, copyright 2010.

MLL rearrangements involve approximately 10% of chromosomal rearrangements overall in patients with ALL, AML, and MDS, and are associated with poor prognosis.¹³¹ More than 60 different partner loci have been identified¹³²; the 10 most common translocation partners are listed in Figure 72.6, along with a pie chart demonstrating the frequency of the translocation in pediatric vs. adult leukemia and AML vs. ALL. In pediatric and adult ALL, the most common translocation partners are the AFF1 gene (previously known as AF4) at 4q21.3 in t(4;11), the MLLT3 gene (previously known as AF9) at

9p22 in t(9;11), and the MLLT1 (ENL) or ELL genes at 19p13.3 and 19p13.1, respectively, in t(11;19). Interestingly, the t(9;11) and t(11;19) are also associated with AML¹³³; thus the name mixed lineage leukemia, since the gene is involved with leukemias of both myeloid and lymphoid origins. The breakpoints of 11q23 usually occur between exons 8 and 11 of MLL (Fig. 72.7),¹²² leaving approximately the N-terminal 1,400 amino acids of the MLL protein.¹³⁴ The retained protein contains three AT-hook sequences thought to bind DNA at the minor groove,¹³⁵ the CxxC domain that specifically binds unmethylated DNA, and a lysine-rich RD2 region. The conserved C-terminal SET domain is usually lost, though it is the domain that has the H3K4 histone methyltransferase activity that is the mechanism by which the wild-type protein activates HOX gene transcription (Fig. 72.7).¹²²

There has been much investigation as to the role of the multiplicity of fusion partners of MLL. Two of the most common fusion partners, MLLT10 (AF10) and MLLT1, associate with DOT1L, which is a histone methyltransferase with a different activity than wild-type MLL, as it methylates histone H3 lysine 79 (H3K79me).¹³⁶ This histone modification is also associated with transcriptional activation, however. DOT1L is one of many proteins in a Dot.com complex, which consists of DOT1L, AF10 (MLLT10), AF17 (MLLT6), and ENL (MLLT1) (Fig. 72.8).^{122,136} Thus the plethora of MLL fusion partners begins to make sense, as many of them normally associate together in complexes that regulate transcription. Therefore the fusion protein associates with its usual partners, but the H3K79me marking occurs at different sites than usual, as the N-terminal MLL protein has the DNA-binding sites that bring the activating histone methyltransferase activity to MLL target genes. Demonstration of an abnormal increase in the H3K79 methylation pattern at target HOXA genes confirms this hypothesis, and this increase was shown to be dependent on DOT1L function.¹³⁷ Dependence on functional DOT1L not only for the H3K79 methylation pattern but also for the development of leukemia has been demonstrated with a conditional knockout mouse model for Dot1L expression.¹³⁷ If cells

P.1533

are transduced by a retrovirus expressing MLL-MLLT3, smaller colonies of blast-like cells grow if the Dot1L is inactivated by the introduction of Cre. In addition, the colonies then demonstrate morphologic signs of differentiation. If the MLL-MLLT3 cells are transplanted into irradiated mice, in vivo colonies are also reduced if Dot1L is inactivated, and these colonies have more differentiation and fewer proliferating cells.¹³⁷ In addition, methylation analysis of HOXA and MEIS1, target genes of MLL, demonstrate reduced H3K79me2 modification after disruption of DOT1L. Even more dramatic is the effect of a small molecule inhibitor of DOT1L, EPZ004777, which specifically inhibits DOT1L and prevents its H3K79 methylase activity.¹³⁸ The growth of MLL-rearranged cell lines such as MV4-11 and MOLM-13 is inhibited by EPZ004777 after several days of exposure in cell culture, and levels of HOXA9 and MEIS1 expression are decreased. However, the growth of a leukemia cell line in which MLL is not rearranged (Jurkat) was not affected by EPZ004777. In addition, treatment of a mouse xenograft model of MLL with EPZ004777 resulted in a statistically significant increase in median survival. Therefore, inhibition of DOT1L holds promise for targeted treatment of MLL leukemia.¹³⁸

FIGURE 72.7. Structure of wild-type and leukemia-associated mixed lineage leukemia (MLL) proteins. Top: Domain architecture of wild-type MLL. Cleavage of MLL (denoted by the blue arrow) results in 320-kDa MLL^N and 180 kDa MLL^C fragments, which noncovalently associate. Domains within MLL^N include three AT-hooks (red), two subnuclear localization motifs (SNL1 and -2) (purple), a DNMT1 homology region (CxxC) (green), four plant homeodomain (PHD) fingers (blue), an atypical bromodomain (orange), and a FYRN domain (open circle). The breakpoint cluster region (BCR) spans an 8.3-kb region encompassing exons 7 to 13 (according to the new nomenclature) and is the site of chromosomal translocations involving MLL. Between the CxxC and the first PHD finger is repression domain 2 (RD2). A host cell factor-binding motif (HBM) (yellow) is found between the bromodomain and PHD3. MLL^C contains a transactivation domain (TAD) (filled oval), a FYRC domain (open square), and a C-terminal SET domain (dark blue). Middle: Chromosomal translocations involving MLL result in chimeric MLL-fusion proteins that include the N-terminal sequence of MLL up to the BCR (dotted vertical line), followed by one of several different fusion partners. Also shown are examples of fusion partner proteins. MLL-fusion proteins invariably retain AT-hooks, SNL and -2, and the CxxC domain of MLL^N, while losing the downstream PHD fingers and further C-terminal domains, including the SET domain. Bottom: MLL is also prone to internal partial tandem duplications (MLL-PTD), leading to duplication of MLL sequences comprising the AT-hooks, SNL1 and -2, and the CxxC domain, that are inserted at the BCR. Republished with permission of Annual Reviews, Inc. Muntean AG, Hess JL. The pathogenesis of mixed lineage leukemia. *Annu Rev Pathol Mech Dis* 2012;7:283-301.

Data also exists for participation of MLL fusion proteins with other transcriptional regulatory complexes. Purification of the proteins involved in the super elongation complex (SEC) revealed participation of several of the MLL translocation partners, including AFF1 (AF4), MLLT3 (AF9), MLLT1 (ENL), and ELL (Fig. 72.8).¹³⁹ The SEC complex also contains elongation factors such as ELL2, ELL3, P-TEFb, EAF1, and EAF2, and it functions to promote transcriptional elongation by RNA polymerase II. Therefore, interaction of this complex with the MLL fusion protein may provide another mechanism for increasing HOX target gene transcription.^{122,139}

The end result of the recruitment of these transcriptional regulatory complexes by the MLL fusion protein is thought to be abnormally sustained homeobox (HOX) gene expression. Usually HOX genes are expressed highly during early development, but then are downregulated during hematopoiesis. However, the MLL fusion protein inappropriately activates the HOX genes.¹²² Microarray analysis of MLL leukemia cells supports this hypothesis, as high levels of HOXA9,

HOXA5, HOXA4, and HOXA10, as well as MEIS1, characterize the gene expression profile of leukemias with MLL translocations.^{140,141}

MLL rearrangements are associated with several unique types of leukemia. First, in infant acute leukemia (birth to 1 year), there is a 60% to 80% incidence of 11q23 rearrangement.¹⁴² Second, in acute leukemias related to treatment with DNA topoisomerase II inhibitors, there is a 70% to 90% incidence of MLL rearrangements, particularly t(4;11)(q21;q23) and t(9;11)(p21-22;q23).^{143,144} Topoisomerase II is an enzyme involved in unwinding of DNA during replication and transcription. It does so by producing double-stranded in the DNA, after which (ds) breaks the ends are rejoined by a ligase activity of topoisomerase II. Topoisomerase II inhibitors such as epipodophyllotoxins inhibit this ligase function so DNA double strand breaks accumulate, triggering apoptotic events. In MLL there are 11 sites similar to topoisomerase II consensus binding sites in the breakpoint cluster area.¹⁴⁵ Therefore, if DNA ds breaks created by the topoisomerase II are incorrectly religated, translocations in MLL are likely to

P.1534

occur. Interestingly, infant leukemia with MLL translocations has a similar distribution of breakpoints, whereas sporadic cases of acute leukemia have more random breakpoints.¹⁴⁶ This observation has triggered speculation that in utero exposure to environmental topoisomerase II inhibitors such as flavonoids may have a role in the etiology of infant leukemia.¹⁴⁷

FIGURE 72.8. Proposed mechanism by which mixed lineage leukemia (MLL) fusion proteins increase transcription of HOXA9. MLL fusion proteins lose a large carboxy-terminal portion that includes the H3K4me3 writing methyltransferase SET domain, retain the chromatin-targeting property, and also acquire aberrant transactivation mechanisms through MLL fusion partners. On the left, a subset of MLL fusions MLL-AF10 (MLLT10), MLL-ENL (MLLT1), and MLL-AF9 (MLLT3), directly interact with DOT1L through the MLL fusion partner and induce the methylation of H3K79 at HOXA9. Some other MLL fusions, MLL-AF4 (AFF1), MLL-AF5q31 (AFF4), and MLL-ELL, interact with and recruit the P-TEFb transcription elongation complexes to HOXA9. On the right, DOT1L complexes (DOT1L-AF10-AF17-ENL [or AF9]) associate with P-TEFb complexes through the shared component ENL. Reprinted by permission from Macmillan Publishers Ltd: Chi P, Allis CD, Wang GG. Covalent histone modifications—miswritten, misinterpreted and mis-erased in human cancers. *Nat Rev Cancer* 2010;10:457-469, copyright 2010.

Recently a different type of MLL gene alteration involving an in-frame partial tandem duplication of exons 5 to 11 has been described in approximately 4% to 7% of patients with AML¹⁴⁸ (Fig. 72.7). This occurs in the absence of visible chromosome abnormalities and is often associated with FLT3 mutations.¹⁴⁸ This mutation retains the C-terminal SET domain, unlike all known MLL fusions resulting from balanced translocations. A mouse knock-in model replacing one copy of Mll with the Mll-PTD (MllPTD/WT mice) results in overexpression of Hoxa7, Hoxa9, and Hoxa10 in bone marrow, blood,

and spleen.¹⁴⁹ Inspection of the promoter of *Hoxa7* and *Hoxa9* by chromatin immunoprecipitation assay demonstrates an increase in H3K4 methylation, as would be predicted due to the retention of the SET domain (Fig. 72.7).

The latency of development of leukemia appears to be shorter for MLL rearrangements than for other leukemogenic rearrangements. In studies of twins who develop infant leukemia, those bearing a shared MLL rearrangement have a concordance of nearly 100% in the first year of life, whereas in twins sharing another rearrangement, the concordance is 25% and the time to development of leukemia may be years instead of months.^{150,151} Similarly, therapy-related leukemias based on MLL rearrangement occur sooner after therapy than those occurring after alkylating agents or radiation, usually with 7q- or 5q-cytogenetics.^{144,152} This suggests that the oncogenic fusion protein produced by the MLL rearrangement can deregulate the cell without the accumulation of many secondary mutations. However, in genetic experiments in mice where the MLL-Mllt3 fusion gene is knocked in, there is still a latency of 6 months before development of acute leukemia, suggesting that some secondary mutations are necessary.¹⁵³ An additional reflection of the potency of MLL rearrangements is that they are a poor prognostic indicator in infant leukemia, ALL, and most AML cases.¹⁴²

This section demonstrates that mutations in genes involved in epigenetic regulation have emerged as a significant mechanism of leukemic transformation. In addition to the genes discussed above, mutations in ASXL1 (addition of sex combs-like 1), a member of the polycomb-repressive deubiquitylase complex, and mutations in EZH2 (enhancer of zeste homolog 2), an H3K27 methyltransferase in the PRC2, have been found in AML that is secondary to MDS or myeloproliferative diseases. This enlarging group of genes has led Shih et al. to propose two additional categories of genes involved in the pathogenesis of AML besides the Class I genes promoting proliferation and the Class II genes promoting block in differentiation. These two additional categories are: (1) Mutations in genes involved in the hydroxymethylation pathway (IDH1/2, TET2), and (2) Mutations in genes involved in epigenetic modification (DNMT3A, ASXL1, MLL).¹⁵⁴

Kinases

FLT3 Mutations

FLT3 may be the single most commonly mutated gene in AML (reviewed in 155). Originally cloned from CD34⁺ HSCs, it encodes a type III receptor tyrosine kinase. FLT3 ligand (FL) is a type I transmembrane protein that is expressed on the surface of support and hematopoietic cells in the bone marrow. It normally stimulates growth of immature myeloid cells and stem cells.¹⁵⁶ When FL ligand binds to the FLT3 receptor, FLT3 dimerizes and autophosphorylates intracytoplasmic tyrosine residues. The phosphorylated, activated FLT3 then activates downstream signal transduction pathways, including PI3K/AKT, MAPK/ERK, and STAT5.^{157,158} Several types of mutations in FLT3 have been cloned from leukemic cells. The most common are internal tandem repeat (ITD) mutations, in which head-to-tail duplications of various lengths and positions occur in the juxtamembrane (JM) portion of the molecule (Fig. 72.9).¹⁵⁹ These elongation mutations may occur due to DNA replication errors as a result of a potential palindromic intermediate that may form at that site.¹⁶⁰ The JM domain is an autoinhibitory domain whose inhibitory function is usually relieved by autophosphorylation after ligand binding.¹⁵⁵ The in-frame insertions in the JM domain produce mutant proteins that are constitutively activated; they are able to dimerize

P.1535

and autophosphorylate in the absence of ligand.¹⁶⁰ Other types of mutations include activation loop mutations, usually an Asp825Tyr substitution resulting from a point mutation in the second tyrosine kinase domain (TKD), producing constitutive activation of FLT3.¹⁵⁵

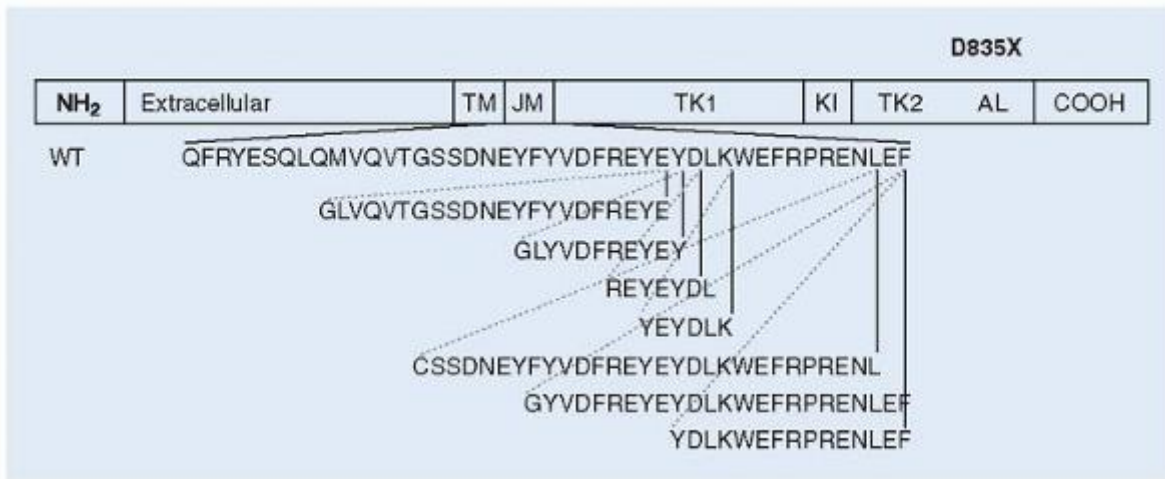

FIGURE 72.9. Schematic of the internal tandem repeat (ITD) and activation loop FLT3 mutations in acute myelogenous leukemia (AML). The structure of the FLT3 receptor tyrosine kinase is shown, with the position of the transmembrane domain (TM), the juxtamembrane (JM) domain, the kinase domains (TK1 and TK2), kinase insert (KI), and activation loop (AL). The amino acid sequence of the wild-type JM domain is listed, and underneath are the tandem duplication sequences found in individual patients with AML. These are always in-frame insertions. The position of the amino acid that is commonly substituted in activation loop mutations is indicated above the schematic of the protein domains. From Mizuki M, Fenski R, Halfter H, et al. FLT3 mutations from patients with acute myeloid leukemia induce transformation of 32D cells mediated by the RAS and STAT5 pathways. *Blood* 2000;96:3907-3914 and Kelly LM, Liu Q, Kutok JL, et al. FLT3 internal tandem duplication mutations associated with human acute myeloid leukemias induce myeloproliferative disease in a murine bone marrow transplant model. *Blood* 2002;99:310-318.

The overall frequency of FLT3-ITD in adult AML is 24% of patients, while in pediatric AML the frequency is somewhat lower at 10% to 15% (reviewed in Ref. 155). The frequency is very low in MDS and ALL. In contrast, the FLT3 activation loop mutation is reported in 7% of AML, 3% of MDS, and 3% of ALL patients.¹⁶¹ FLT3-ITD is detected most frequently in APL, but has been detected in all AML subtypes.¹⁵⁵ In addition, FLT3 is overexpressed at the mRNA and protein levels in many cases of AML and ALL.¹⁶²

The role of the FLT3-ITD in leukemogenesis has been investigated by retroviral transduction of murine bone marrow stem cells followed by transplantation into mice. These mice develop a myeloproliferative disease with predominantly maturing myeloid elements, but they do not develop acute leukemia.¹⁶³ Therefore, the FLT3 mutations may confer the proliferative signal in patients with acute leukemia, whereas a concomitant balanced translocation or other genetic defect confers the block in differentiation necessary for development of acute leukemia.¹⁵⁵

Mutation of FLT3 is a significant independent prognostic factor for poor outcome in patients younger than 60 years. In a study of 91 pediatric AML patients on the Children's Cancer Group (CCG) protocol, the remission induction rate was 40% in patients with FLT3-ITD compared to 74% with wild-type FLT3. The difference in event-free survival at 8 years was even more striking, at 7% for patients with FLT3-ITD compared to 44% for patients with wild-type FLT3.¹⁶⁴ In a study of 398 patients younger than 60 with AML, FLT3-ITD mutations were the primary predictor of outcome in patients with intermediate-risk cytogenetics and were associated with reduced overall survival.³⁴ As with BCR-ABL1 for CML, the implication of a mutant constitutively active tyrosine kinase receptor in the pathogenesis of AML opens up the possibility of identifying a selective kinase inhibitor as a specific treatment for AML patients with a mutant FLT3. Several kinase inhibitors have been identified by inhibition of IL3-independent growth of cell lines expressing FLT3-ITD in culture.^{165,166} Eight of these FLT3 inhibitors (FLT3-TKI) have been tested in phase I/II trials as single agents (reviewed in Ref. 167). In each study a majority of patients achieved >50% reduction in peripheral blast count, but these reductions were transient, lasting several weeks to months. The partial efficacy may be in part due to the refractory nature of the phase I/II patient population. However, a study performed by Piloto et al.¹⁶⁸ on resistant human cell lines developed through prolonged coculture with FLT3 tyrosine kinase inhibitors demonstrated that although FLT3 phosphorylation was still inhibited, downstream signaling pathways were activated. In two cell lines, activating NRAS mutations were detected. No mutations in FLT3 were detected. However, in other studies, SMRT sequencing was used to demonstrate secondary FLT3 kinase domain mutations in 4 of 8 patients who relapsed after treatment with FLT3-TKI. The mutation frequency in the patients' blasts was 20% to 50%, consistent with most of the leukemic blasts having a mutation on one allele. This degree of

mutation in relapsed patients supports the idea that FLT3 mutations are “driver” mutations necessary for growth of the leukemic clone. From the crystal structure of FLT3 several of the mutations would force the molecule into an active kinase confirmation which is not recognized by the AC220 type II kinase inhibitor used in the study.¹⁶⁹

Nuclear Pore Proteins

Nucleophosmin

Nucleophosmin (NPM) is a molecular chaperone that shuttles between cytoplasm and nucleus, with particular nucleolar concentration of protein.¹⁷⁰ While NPM appears to function to transport preribosomal particles from the nucleolus to cytoplasm, other functions have also been described, including regulation of centrosome duplication, regulation of p53, and functional regulation and stabilization of P19ARF (reviewed in Ref. 171). Cytogenetically silent mutations of NPM1 have now been identified in 35% of adult AML with normal karyotype. The frequency is less (9% to 27%) in pediatric AML with normal karyotype.^{171,172,173} The NPM1 mutation is stably expressed, being consistently present in leukemic blasts at relapse.¹⁷⁴ The wild-type NPM has two NLSs and two nuclear export signals (NES) that mediate the nuclear-cytoplasmic shuttling of wild-type NPM. Over 50 different mutations in NPM1 have been found in patients with AML; all of these mutations cause changes in the C-terminus of the NPM protein, including generation of a new NES motif, and loss of tryptophan residues 288 and 290, or 290 alone, causing unfolding of the C-terminal domain and disruption of binding to the nucleolus.^{174,175} The presence of a mutation correlates absolutely with abnormal subcellular localization of NPM, with relocation from its normal predominantly nucleolar location to the cytoplasm; this can be detected in tissue sections by immunohistochemistry. The mutation is always heterozygous, which may be related to the fact that the homozygous mutant is embryonic lethal.¹⁷⁶ The mutant NPM appears to function in a dominant negative manner through heterodimerization with normal NPM, to cause relocation of some of the normal NPM, as well as the mutant NPM, to the cytoplasm.¹⁷⁷ The mechanism by which the cytoplasmically located NPM promotes leukemia is under investigation. Conditional expression of mutated NPM in transgenic mice results in overexpression of HOX genes in Lin⁻ marrow progenitor cells.¹⁷⁸ Another mechanism by which mutant NPM1 may promote leukemogenesis is by destabilizing the tumor suppressor protein P14ARF, which regulates the TP53 response. P14ARF colocalizes with NPM to the nucleolus, and their interaction stabilizes P14ARF. Without this interaction and nuclear location, p19Arf (the mouse homolog) is more rapidly degraded by proteasomes. By this mechanism, mutant NPM may indirectly cause decreased amounts of the tumor suppressor protein P14ARF.¹⁷⁴ NPM1 mutations frequently occur in conjunction with IDH1 and IDH2 mutations and with DNMT3A mutations (see Fig. 72.1).^{34,173} Several studies have shown that patients with NPM mutations in the absence of FLT3 mutations have a favorable response to chemotherapy.^{173,175} Patients with intermediate-risk cytogenetics and mutations in NPM1 and either IDH1 or IDH2 mutations have an improved rate of overall survival and are considered to have an overall favorable risk.³⁴

Risk Stratification of Acute Myeloid Leukemia

A major purpose of molecular genetic testing performed on clinical AML samples in the molecular diagnostics laboratory is to have enough information to choose the optimal therapy and to assess the prognosis of the patient. Besides determining information about BCR-ABL1 or PML-RARA rearrangements that have an obvious impact on treatment decisions, the risk stratification of the patient helps the doctor determine whether it is best to treat with aggressive therapy, to adopt a gentler chemotherapy regimen, or to rush the patient to transplant. A recently published attempt to integrate the newly expanded knowledge of molecular defects, both mutations and translocations, that occur in AML reported the results of testing for mutations in a panel of 18 genes in 398 patients with AML at diagnosis. 97.3% of the patients had at least one somatic mutation. The frequency of each of the 18 mutations tested is demonstrated in Figure 72.1, as well as the Circos diagram depicting the interrelationships between the mutations.³⁴ The Circos diagram visually conveys the multiplicity of mutations that occur in most patients. This integrated mutational analysis demonstrated patterns of co-occurring mutations and

P.1536

also mutually exclusive mutations. Some of the more important co-occurrences are KIT mutations and CBF alterations, co-occurrence of IDH1/2 mutations and NPM1 mutations, and DNMT3A mutations with NPM1, FLT3, and IDH1 mutations. As mentioned previously, IDH1/2 mutations do not occur in patients with TET2 mutations (Fig. 72.5). In addition, IDH1/2 and WT1 mutations are mutually exclusive, as well as DNMT3A mutations and MLL translocations.³⁴ The effect of multiple mutations and the interplay with underlying cytogenetic changes on risk stratification are shown in Table 72.1.^{34,179} The most statistically significant predictors of overall survival are as follows: FLT3-ITD and MLL-PTD mutations are associated with reduced overall survival. CEBPA mutations and CBF translocations are associated with improved overall survival.

PHF6 and ASXL1 mutations are associated with reduced survival. IDH2 mutations (R140Q) confer a favorable outcome. In intermediate-risk AML, FLT3-ITD mutations are the primary factor influencing outcome. In this cohort of patients the group with favorable risk had a 3-year overall survival of 64%, whereas the group with intermediate risk had a 3-year overall survival of 42% and the group with adverse risk had a 12% overall survival. Multivariate analysis demonstrated that outcomes predicted from the risk stratification are independent of age, WBC, induction dose, transplantation status, and post-remission therapy.³⁴

Grossman et al.¹⁰⁵ developed a similar prognostic model based entirely on molecular mutational analysis rather than karyotype, in which they constructed an algorithm with 5 prognostic subgroups based upon analysis of 1,000 patients for mutations in: PML-RARA, RUNX1-RUNX1T1, CBFβ, MYH11, FLT3-ITD, MLL-PTD, NPM1, CEBPA, RUNX1, ASXL1, and TP53. The very favorable prognostic group (overall survival at 3 years of 82.9%) consisted of patients with PML-RARA rearrangement or CEBPA double mutations, and the very unfavorable group with an overall survival of 0% at 3 years consisted of patients with TP53 mutations. TP53, a well-characterized tumor suppressor gene, is mutated in many cancers, and mutations in TP53 are the basis of the cancer-prone Li-Fraumeni syndrome.¹⁸⁰ However, this study is the first to characterize the frequency of TP53 mutations in AML (11.5%) and its prognostic significance.¹⁰⁵

The particular combination of mutations and percentage survival will change with the discovery of additional mutations, new treatment trials, and additional patient cohorts, but the principle is important that risk stratification must take into account a multiplicity of genetic events, both translocations and mutations. The role of the molecular diagnostics lab will certainly increase; the difficult question will be what is the most prognostically significant and cost effective panel of molecular tests to perform on an AML patient at diagnosis.

B-ACUTE LYMPHOBLASTIC LEUKEMIA

Introduction

Table 72.5 outlines the WHO classification for B-ALL, which lists several of the major translocations that have been repeatedly seen in B-ALL. Recent genome-wide analysis of DNA from multiple B-ALL cases has demonstrated, as in AML, that there are multiple deletions and mutations in many other genes besides the well-characterized translocations. A recent survey of 242 cases of pediatric ALL using Affymetrix SNP arrays identified an average of 6.46 somatic copy number alterations per case, predominantly deletions.¹⁸¹ Interestingly, alterations in genes regulating B-lymphocyte differentiation were noted in 40% of B-ALL cases. The B-cell differentiation genes most commonly translocated or mutated include EBF1, PAX5, and IKZF1. Copy number changes in PAX5 occurred in 29.7% of this series, with the most common alteration being mono-allelic deletion of PAX5. PAX5 is essential for B-cell development, and it controls B-cell-specific transcription of B-lineage-specific genes such as CD19, CD79a, BLNK, and CD72.¹⁸¹ In Pax5^{-/-} mice, B-cell development is arrested prior to the B220⁺ pro-B-cell stage, and these pro-B cells are uncommitted lymphoid progenitors.¹⁸² Mutations in genes necessary for B-cell differentiation are a perfect example of Class II mutations that cause a block in cell differentiation in the classic model of acute leukemia pathogenesis.

Transcription Factors

PAX5

In the above-mentioned study, the PAX5 gene was altered by deletion or mutation in 31.7% of cases in a series of 242 B-ALLs.¹⁸¹ It is rearranged in 2.6% of pediatric B-ALL cases, with 17 different fusion partners documented. PAX5 is a paired box domain (PRD) transcription factor, encoded by the PAX5 gene at chromosome 9p13, and consists of 10 exons that encode a 391 amino acid protein. In all the fusion proteins, the paired box domain DNA-binding region and nuclear localization region are retained, but the C-terminal transactivation domain is deleted.¹⁸³ The C-terminal fusion proteins may act in contrast as transcriptional repressors, which would be brought to PAX5 target gene promoters by the retained PAX5 DNA-binding region. The PAX5 fusion proteins may act as dominant negative molecules in conjunction with the product of the wild-type PAX5 allele, and in this way may repress genes whose products are necessary for B-cell differentiation. The PAX5 translocations are correlated with a relatively normal karyotype, suggesting that they have a major role as a driver mutation; PAX5 deletions, however, are usually associated with a complex karyotype.¹⁸⁴

Core Binding Factors

RUNX1 is also involved in a translocation that is present in 25% of pediatric B-ALL, t(12;21)(p13;q22.3).¹⁸⁵ This translocation is associated with a good prognosis, although it is often missed by standard karyotype analysis. In this translocation, the N-terminus of ETV6, formerly called TEL (translocation-ETS-leukemia), is fused to most of the coding region of RUNX1.¹⁸⁶ ETV6 contains a DNA-binding ETS domain and a "pointed" domain homologous to the Drosophila development protein, pointed.¹⁸⁷ ETV6 is a transcriptional repressor and as such it contains a DNA-binding ETS domain and domains that interact with mSin3A (pointed domain), N-CoR, and HDAC-3 (Fig. 72.4C).¹⁸⁸ The functional significance of these interactions with HDACs was demonstrated by the ability of TSA to inhibit two properties of 3T3 fibroblast cells transformed with ETV6 and Ras: expression of the stromelysin-1 gene and aggregation.¹⁸⁸

P.1537

Another chromosomal alteration involving the RUNX1 locus that occurs in approximately 2% of pediatric patients with B-ALL is the intrachromosomal amplification of chromosome 21 (iAMP21). The significance of recognizing this cytogenetic abnormality is that it is associated with a dismal prognosis if treated with standard chemotherapy. There is a 6.6 Mbp common region of amplification (CRA) on chromosome 21, and in the majority of cases an associated 3.3 Mbp common region of deletion at the telomere. The average copy number of this CRA is 4.8, and the amplification is usually detected by FISH using the RUNX1 probe. Although RUNX1 is in the CRA, gene expression studies do not reveal increased transcription of RUNX1. This cytogenetic abnormality is associated with a complex karyotype and multiple mutations; however, clonal analysis indicates that the precipitating genetic event is the iAMP21 amplification.¹⁸⁹

TCF3 (E2A) Translocations

A common translocation in childhood B-ALL, present in 5% of pre-B-ALL cases,¹⁹⁰ is the t(1;19)(q23.3;p13.3) translocation, which fuses the TCF3 (E2A) gene on chromosome 19p13.3 with the PBX1 gene on chromosome 1q23.3 (Fig. 72.10).^{191,192} The TCF3 locus encodes three transcripts, E12, E47, and E2-5, which are generated by alternative splicing.¹⁹³ They belong to class I of the basic helix-loop-helix (bHLH) family of transcription factors which bind to specific E-box (CANNTG) sequences in promoters and enhancers, the first of which were identified in the enhancer regions of the immunoglobulin heavy-chain and κ -chain genes.¹⁹³ Usually the ubiquitous E2A proteins heterodimerize through the HLH domain with members of the class II bHLH proteins, most of which are tissue specific in expression. These heterodimers are crucial in transcriptional regulation of tissue-specific genes during development. Although E2A proteins are ubiquitous, they are preferentially expressed in B lymphocytes,¹⁹⁴ and E47 forms homodimers exclusively in B cells.¹⁹⁵ The requirement for E2A proteins in B-cell development is demonstrated by Tcf3^{-/-} null mice, which exhibit a complete block in B-cell differentiation at the pro-B-cell stage prior to immunoglobulin gene rearrangement, as well as defective thymocyte differentiation.^{196,197} These mice have an increased frequency of T-lymphoblastic lymphoma.¹⁹⁶

PBX1 (pre-B-cell leukemic homeobox 1), identified as the fusion partner of TCF3 in t(1;19),¹⁹⁸ encodes a member of the homeodomain family of transcription factors, encoded by homeobox (HOX) genes. The PBX1 gene is the mammalian homolog of the Drosophila gene Extradenticle, whose protein product cooperates with other homeodomain proteins

during development.¹⁹⁹ Likewise, PBX1 forms heterodimers with other homeodomain proteins via the homeodomain and the C-terminal HOX cooperativity motif (HCM).²⁰⁰ Cotransfection experiments with reporter genes containing DNA-binding sites for PBX1 have demonstrated that PBX1 is not a strong transcriptional activator.²⁰¹ The *Pbx1*^{-/-} mice have late embryonic lethality associated with multiple organ abnormalities,²⁰² supporting the hypothesis that PBX1 interactions regulate homeodomain protein function. PBX1 is not normally expressed in lymphocytes.

FIGURE 72.10. Structural features of E2A (TCF3) fusion proteins. The N-terminus of the E2A (TCF3) gene encodes a transcriptional activation domain that is translocated to hepatic leukemia factor (HLF) or pre-B-cell leukemic homeobox1 (PBX1) by chromosome translocations in acute lymphoblastic leukemia. In the case of E2A (TCF3)-HLF, the DNA-binding and dimerization domains of E2A (TCF3) are replaced by similar domains in HLF. For E2A(TCF3)-PBX1, the same DNA-binding and dimerization domains of E2A (TCF3) are replaced with the DNA-binding homeodomain of PBX1. AD, activation domain; b HLH, basic helix-loop-helix; bZIP, basic leucine zipper domain; H, homeodomain.

In the t(1;19) translocation, the breakpoint on chromosome 19 occurs within the intron between exons 13 and 14 of TCF3, so that the N-terminal two-thirds of TCF3 (E2A), aa1-483, are included in the fusion protein.¹⁹² This includes both of the transcriptional activation domains (AD1 and AD2), but excludes the bHLH DNA-binding and dimerization domains (Fig. 72.10). Therefore, the TCF3-PBX1 fusion protein depends on the homeodomain of PBX1 for DNA-binding specificity. The most straightforward model for how expression of the TCF3-PBX1 fusion protein results in the development of leukemia is that fusion of the TCF3 activation domains onto the PBX1 sequence results in abnormally strong transactivation of target genes recognized by the PBX1 homeodomain.²⁰³ These target genes would be activated in lymphocytes, where PBX1 is usually not expressed. Mapping experiments demonstrate that the activation domains AD1 and AD2 of TCF3 are necessary for transactivation of reporter genes containing PBX1 binding sites, and they are also necessary for transformation of NIH 3T3 cells.²⁰⁴ Gene expression profiling of a pre-B-cell line inducibly expressing TCF3-PBX1 demonstrated upregulation of BMI1,²⁰⁵ a gene which is expressed in normal HSCs, but whose expression normally decreases during hematopoietic development.²⁰⁶ *Bmi1*^{-/-} mice have a reduced number of HSCs, with defective adult self-renewal of HSCs.²⁰⁶ Cells from *Bmi1*^{-/-} mice are resistant to transformation by Tcf3-Pbx1,²⁰⁵ suggesting that the mechanism by which TCF3-PBX1 transforms cells is through overexpression of BMI1. Interestingly, BMI1 is a transcriptional repressor of the CDKN2A locus,²⁰⁵ which encodes the two tumor suppressor genes P16INK4A and P14ARF.²⁰⁷ P16INK4A binds to CDK4 and 6, preventing association with cyclins and phosphorylation of Rb. Therefore, repression of P16INK4A results in increased phosphorylation of Rb, which loses its affinity for the transcription factor E2F, increasing expression of E2F target genes necessary for progression to the S phase and proliferation.^{208,209} The tumor suppressor P14ARF inhibits MDM2, a repressor of TP53⁸⁷; therefore, inhibition of P14ARF results in increased MDM2, repression of TP53, and loss of the checkpoint functions of TP53 in preventing propagation of cells with DNA damage.⁸⁷ Therefore, activation of BMI1 by TCF3-PBX1 results in downregulation of two powerful tumor suppressor pathways.

Another translocation involving TCF3 occurs in approximately 1% of pediatric ALL, t(17;19)(q22;p13.3), which fuses TCF3 to HLF (hepatic leukemia factor).^{210,211} Clinically, these patients are adolescents; they may present with disseminated intravascular coagulation and hypercalcemia and usually have a poor prognosis. HLF encodes a transcription factor of the basic leucine zipper (bZIP) family, in which the basic region is the DNA-binding region and the leucine zipper refers to an amphipathic α -helical domain through which HLF can homodimerize or heterodimerize with other bZIP proteins. HLF is usually expressed in liver, kidneys, and central nervous system neurons, but not in hematopoietic cells.²¹²

The TCF3-HLF fusion protein is homologous to the TCF3-PBX1 fusion protein, in that the N-terminal 483 amino acids of TCF3, contributing the activation domains AD1 and AD2, are fused to the C-terminal portion of HLF, which contains the bZIP DNA-binding and dimerization domains (Fig. 72.10).²¹³ Unlike PBX1, wild-type HLF is a strong transactivator, but the alteration in cell type expression and alterations in DNA-binding affinity and protein interactions by virtue of fusion to TCF3 may contribute to the transforming properties of TCF3-HLF.²¹⁴

P.1538

Recent experiments using BaF3 cells inducibly expressing TCF3-HLF have implicated LMO2 and BCL2 as transcriptional targets of the abnormal TCF3-HLF transcription factor.²¹⁵ Microarray analysis was performed on RNA from the cell lines before and after induction of TCF3-HLF expression; subsequent CHIP experiments demonstrated that TCF3-HLF directly binds to the promoters of these two genes to transcriptionally activate them. Relevant to potential new therapies of this poor prognosis leukemia is the finding that knock-down of LMO2 expression or inhibition of BCL2 activity in the cells expressing TCF3-HLF reduces the proliferation of these immortalized cells.²¹⁵ LMO2 is a transcription factor expressed in hematopoietic progenitors and is known to play a role in development of T-ALL.²¹⁶ BCL2 is an antiapoptotic protein with a well-known role in the pathogenesis of B-cell lymphoma (reviewed in Ref. 217).

IKAROS

SNP array studies first demonstrated that IKZF1, encoding the transcription factor IKAROS, is deleted in 76.2% of pediatric Ph⁺ B-ALL and 90.9% of adult Ph⁺ B-ALL.²¹⁸ A subsequent study of adult B-ALL cases demonstrated that 75% of adult Ph⁺ B-ALL cases had alterations of the IKZF1 gene, compared to 58% of adult Ph⁻ B-ALL cases.²¹⁹ IKAROS is a zinc finger-containing transcription factor that is required for lymphoid lineage commitment. It is expressed in multipotent, self-renewing HSCs and is necessary for induction of genes important for the lymphoid lineage, as well as repression of genes responsible for self-renewal and multipotency in the differentiating progeny of HSCs.²²⁰ Deletions are usually of one allele, and in most cases the deletion involves a subset of exons, most commonly exons 4 to 7.²¹⁹ Sequencing of the deletion sites demonstrates the presence of heptamer recombination signal sequences that are recognized by RAG enzymes during immunoglobulin gene recombination.²¹⁸ These deletions result in loss of the DNA-binding domain but preservation of the dimerization domain of the protein, creating a dominant negative molecule.²¹⁹ Use of gene expression arrays to compare RNA from B-ALL cases with intact or mutated IKZF1 loci demonstrates that IKZF1 mutations are associated with downregulation of several genes in the B-cell differentiation pathway and upregulation of genes involved in cell cycle regulation, apoptosis regulation, DNA damage, and the JAK-STAT signaling pathway. In addition, in B-ALL with IKZF1 mutations, there is downregulation of RAG and EBF1, two genes whose products are involved in IgH VDJ recombination.²¹⁹ Downregulation of genes involved in normal B-cell differentiation may cause the arrest of B-cell maturation that occurs in B-ALL. As the gene expression patterns in B-ALL with mutations in IKZF1 are similar to gene expression patterns in BCR-ABL1 positive ALL, these cases are referred to as Ph-like ALL.²²¹ Though the prognosis of these cases is poor, discovery of frequent concomitant mutations in cytokine receptors such as CRLF2 and other signaling molecules such as JAK2 suggests that use of kinase inhibitors may play a role in treating this subset of B-ALL.²²²

Kinases

BCR-ABL1

The Philadelphia chromosome is the result of the t(9;22) (q34;q11.2) translocation in which the 5' domain of the BCR gene from chromosome 22 is fused with the 3' TKD of the ABL1 gene from chromosome 9.^{223,224} The Philadelphia chromosome is the resultant shortened chromosome 22. It is the most frequent recurring translocation in adult ALL, occurring in 15% to 30% of patients,²²⁵ and also is present in 5% of pediatric B-ALL.²²⁶ Unfortunately, it is an adverse prognostic factor in children and adults.

The BCR-ABL1 fusion gene is associated most commonly with CML. The pathogenesis of CML will be discussed in Chapter 81. A lymphoid blast crisis arising from CML may be difficult to distinguish from a Philadelphia chromosome-positive (Ph⁺)

ALL. The size of the BCR-ABL1 fusion protein and whether it is restricted in expression to lymphoid cells may be helpful in making this distinction. The most common breakpoint region, the major breakpoint cluster region (M-bcr), spans almost 6 kb between exons 12 and 16 of BCR and results in a fusion protein of 210 kD, referred to as p210bcr-abl.²²⁷ A minor breakpoint, the m-bcr, is farther 5', after exon 2 of BCR, resulting in a truncated fusion protein of 190 kD that contains only the first two exons of BCR (p190bcr-abl).² Interestingly, p210bcr-abl is much more common in CML and CML with lymphoid blast crisis, whereas p190bcr-abl is much more commonly expressed in Ph⁺ ALL. p190bcr-abl is present in 80% to 90% of pediatric Ph⁺ ALL and 50% of adult Ph⁺ ALL.²²⁵ However, some cases of Ph⁺ ALL contain both p190bcr-abl and p210bcr-abl. Transgenic mice expressing p190bcr-abl develop an aggressive leukemia restricted to pre-B cells, whereas transgenic mice expressing p210bcr-abl develop a more chronic disease involving B and T cells and myeloid lineages.²²⁸ In some cases of Ph⁺ ALL the aberrant fusion protein is present in lymphoid and myeloid marrow cells, whereas in other cases the aberrant fusion protein, usually p190bcr-abl, is restricted to lymphoid cells. Those cases in which p210bcr-abl is present in both lymphoid and myeloid cells are most likely to represent a CML lymphoid blast crisis.²²⁹

Studies of BCR-ABL1 expression in CML have demonstrated the leukemogenic properties of BCR-ABL1 as a constitutive tyrosine kinase.²³⁰ This constitutive kinase activates by phosphorylation multiple downstream signal transduction intermediates, including RAS, PLC γ , and PI3 kinase.²³¹ Activation of these pathways results in proliferation and resistance to apoptosis.²³² Presumably similar mechanisms are at work in Ph⁺ ALL. Restriction of expression of BCR-ABL1 to the lymphoid lineage would explain the development of ALL. However, in those cases of Ph⁺ ALL in which BCR-ABL1 is expressed in the stem cell compartment, it is unclear why ALL has resulted instead of CML. A high percentage of Ph⁺ ALL, as well as B lymphoid blast crisis of CML, have concomitant mutations in IKAROS, as described above.^{218,219,233}

Treatment of Ph⁺ ALL remains problematic. Initial response to chemotherapy is similar in Ph⁺ ALL and Ph⁻ ALL, but remissions tend to be short lived. Transplantation appears to be the best means of attaining a lasting remission. In a phase II trial of imatinib in relapsed or refractory Ph⁺ ALL, 60% of patients achieved a hematologic response, but it was usually short lived.²³⁴ However, trials using imatinib in conjunction with standard chemotherapy followed by bone marrow transplant in CR have proven more successful. The combination approach induces CR in 96% of patients with a 30% incidence of relapse and 65% overall survival rate at 18 months.^{235,236} Posttransplant BCR-ABL1 positivity has a poor prognosis; therefore in current protocols imatinib therapy is usually reinitiated 6 to 8 weeks after transplant.²³³

Secondary resistance to imatinib is common, however, and occurs in approximately 70% of relapse patients with CML blast crisis or Ph⁺ ALL. In 50% to 90% of relapse patients, point mutations have been identified in the adenosine triphosphate-binding pocket of BCR-ABL1 that is targeted by imatinib.²³⁷ New kinase inhibitors that can bind to the mutated as well as wild-type BCR-ABL1, such as dasatinib and nilotinib, are being utilized in patients who develop resistance to imatinib.²³³

T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA/LYMPHOMA

T-ALL is an uncommon acute leukemia but its genetics have been studied in considerable depth. The driver mutations in T-ALL were first identified by cloning the breakpoints at chromosomal

P.1539

translocations.^{238,239,240,241} These experiments revealed oncogenes whose expression was deregulated by rearrangement with the promoters and enhancers of T-cell receptor genes. Subsequently, it was shown that these same oncogenes are overexpressed by mechanisms other than translocation.^{242,243,244,245} Indeed, gene expression clustering based on these oncogene signatures has been highly informative in classifying T-ALL into distinct subtypes that relate to cell of origin.^{244,246,247} Whole exome sequencing and targeted sequencing have revealed numerous important mutations in T-ALL. As shown in Table 72.6, these oncogenes and tumor suppressor genes are divided into major gene classes. The CDKN2A locus encodes cell cycle regulatory genes P14ARF and P16INK4A, and is the most commonly inactivated gene in human T-ALL.²³⁸ CDKN2A is located on 9p21 which shows homozygous deletion in more 72% of patients.^{182,241} CDKN2A is also inactivated by other mechanisms.^{248,249} Deletions of 13q14.2 including the RB1 gene occur in up to 12% of T-ALL patients¹⁸²; these deletions are found in patients with intact CDKN2A, an expected finding since both of these tumor suppressors act in the same pathway.^{244,250} Mutations in TP53 and CDKN1B (p27) are uncommon, each occurring in less than 1% of T-ALL patients.

Notch

The NOTCH pathway is mutated in the majority of T-ALL patients. NOTCH1 is a regulatory protein that is important in many cell fate decisions, including commitment to T-cell lineage and choice of $\alpha\beta$ lineage.^{251,252,253} It was first cloned from a t(7;9)(q34;q34) translocation occurring in a T-ALL patient that involved NOTCH1 on chromosome 9q34 and the T-cell

receptor β -chain gene on chromosome 7q34.3.²⁵⁴ The t(7;9) translocation turned out to be rare in T-ALL but targeted sequencing revealed that over 60% of T-ALL patients have activating mutations in NOTCH1.²⁵⁵ NOTCH1 is synthesized as a single polypeptide protein that is cleaved in the Golgi at site S1 into two subunits, the ligand-binding NEC (extracellular) and NTM (transmembrane), which bind noncovalently at the heterodimerization domain. Upon ligand binding to NEC, NTM is cleaved at site S2 by a metalloprotease, and cleaved at S3 by regulated intramembrane proteolysis catalyzed by a multiprotein enzyme, the gamma (γ) secretase.²⁵⁶ The remaining intracellular portion, ICN1, translocates to the nucleus, where it acts as a transcriptional regulator with the DNA-binding protein CSL and with coactivators of the Mastermind-like family.²⁵⁷ The majority of the activating mutations in NOTCH1 found in T-ALL occur in the heterodimerization domain or in the PEST domain.²⁵⁵ The PEST domain regulates the turnover of NOTCH1. Therefore, the heterodimerization domain mutants uncouple NOTCH1 activation from ligand binding and the PEST domain mutants increase NOTCH1 protein stability.²⁵⁵ The NOTCH1/CSL complex has numerous transcriptional targets that affect diverse pathways required for cell transformation; among these, MYC and HES1 appear to be important for T-cell leukemogenesis.^{258,259,260,261} The FBXW7 gene is mutated in T-ALL and fits into the NOTCH pathway since it encodes a component of a multiprotein E3 ubiquitin ligase that targets NOTCH1, MYC, and CCNE for degradation.^{262,263,264} Inactivating mutations in FBXW7 are present in 9% to 16% of T-ALL patients.^{265,266} The unique proteolytic pathway leading to activated NOTCH1 can be targeted by small molecule inhibitors of the gamma-secretase enzyme that is required for S3 cleavage.^{267,268,269} These inhibitors have been used in clinical testing; however, since NOTCH1 regulates cell fate decisions for intestinal epithelial cells, patients have experienced significant gut toxicity.²⁶⁷

TABLE 72.6 FUNCTIONAL CLASSES OF GENES MUTATED IN T-LYMPHOBLASTIC LEUKEMIA

Gene Class	Frequency (%)	Oncogene or Tumor Suppressor
Cell cycle genes	85	<i>CDKN2A, RB1, TP53, CDKN1B</i>
Notch and its targets	70	<i>NOTCH1, FBW7, MYC</i>
bHLH and partners	35	<i>TAL1, TAL2, LYL1, OLIG2, LMO1-3</i>
Homeobox genes	35	<i>TLX1, TLX3, HOXA cluster, MLL, CALM</i>
Other transcription factors and chromatin modifiers	5-15	<i>MYB, BCL11B, PHF6, EZH2</i>
Cytokine and signal transduction	5-15	<i>ABL1, FLT3, IL7R, JAK1, LCK, NRAS, IGF1R</i>

The frequency shown is the estimated mean of all the frequencies reported for each individual gene mutation in a given class.

Transcription Factors

TAL1 and LMO Factors

Class B bHLH transcription factors, TAL (SCL) (T-cell acute lymphoblastic leukemia 1/stem cell leukemia), TAL2, LYL1, and OLIG2 are frequently deregulated in T-ALL.²⁴¹ The TAL1 gene is deregulated in 25% of T-ALL. TAL1 was originally cloned from a translocation, t(1;14)(p32;q11), present in 3% of patients with T-ALL.²⁷⁰ In the translocation, the breakpoint is 5' to the coding region of TAL1 on chromosome 1, and the translocation places TAL1 under the regulation of the T-cell receptor α/β genes on chromosome 14.^{271,272} A second series of rearrangements that occurs in 26% of patients with T-ALL results in deletion of 90 to 100 kb of DNA from the 5' upstream region of TAL1, placing the gene under the control of the upstream constitutively active SIL promoter.²⁷³ In both cases, the coding region of TAL1 is intact, unlike the fusion proteins that are usually expressed in other acute leukemias. Also, in some cases of T-ALL, overexpression of TAL1 occurs when there is no evident gene rearrangement by Southern blot analysis, suggesting a mutation in regulatory sequences.²⁷⁴

During development, TAL1 is expressed in early hematopoietic elements, in both the yolk sac blood islands and the definitive blood cells of the AGM region and fetal liver.²⁷⁵ Postnatally, it is expressed in erythroid, megakaryocyte, and mast cell lineages, but not in T cells. In nonerythroid cells, TAL1 is expressed in stem cells but is not expressed as the cells differentiate; however, in erythroid cells, TAL1 expression increases with early erythroid differentiation but decreases with terminal differentiation.²⁷⁶ The essential role of TAL1 in hematopoietic development is demonstrated by mice made

null for Tal1; embryonic lethality occurs due to a total deficiency in hematopoietic progenitors.^{277,278} Conditional gene targeting experiments using the *Lox-Cre* system to delete *Tal1* in adult mice demonstrate that continued expression P.1540

of TAL1 is not necessary for maintenance of HSCs, but it is necessary for erythrocyte and megakaryocyte differentiation.²⁷⁹

TAL1, like LYL1, OLIG2, and TAL2, binds E-box sequences in DNA by heterodimerizing with class I bHLH transcription factors TCF3. Tandem E boxes or E-box GATA sequences can be bound by two TAL1/TCF3 heterodimers that are bridged by LIM-domain-only 1 or 2 (LMO1/2) proteins. Interestingly, LMO1-3 genes are also important drivers of T-ALL which can be deregulated by chromosomal rearrangements with T-cell receptor genes and other mechanisms.^{216,280,281} Other TAL1 protein partners include GATA1, LDB1, coactivators p300 and pCAF, and corepressors mSin3A and HDAC1.^{282,283} Interestingly, LMO2 can be coimmunoprecipitated with TAL1 from T-ALL cell lines,²⁸⁴ and mice overexpressing both *Tal1* and *Lmo2* develop T-ALL with shorter latency than transgenic mice overexpressing either gene alone, providing evidence for cooperativity.^{285, 286} and ²⁸⁷ The transcriptional targets of activation or repression by TAL1 that are required for T-ALL have not been fully elucidated.^{288,289,290} Alternatively, TAL1 may act as a dominant negative inhibitor of the TCF3 transcription factors.^{291,292} Human and murine T-ALLs induced by bHLH or LMO gene overexpression show repression of TCF3 target genes.²⁹³ LYL1, OLIG2, and TAL2 may all behave similarly to TAL1 in that they cooperate with LMO proteins to regulate gene expression, although LYL1-overexpressing T-ALLs are more immature in the T-cell differentiation hierarchy than TAL1-overexpressing T-ALLs.^{294,295,296,297} The expression of these bHLH genes was quantified in a large panel of T-ALLs showing mutually exclusive expression patterns, which also argues for functional redundancy in leukemia pathogenesis. Interestingly, LYL1 and TAL1 are also functionally redundant in the maintenance of adult hematopoietic stem and progenitor cells.^{244,298}

Homeodomain Proteins

The homeobox genes are a major group of genes deregulated in T-ALL, mutually exclusive to the bHLH genes and LMO genes discussed above.²⁴⁴ TLX1 (HOX11) is overexpressed by chromosomal rearrangement or other mechanisms in 7% of T-ALL.^{242,299} TLX3 (HOX11L2) is deregulated most commonly by a t(5;14)(q35.1;q32) in 20% of adult T-ALL cases.^{300,301} Finally, the HOXA gene cluster is deregulated in 5% of T-ALL cases by inv(7)(p15.2q34) and other transcriptional mechanisms.^{302, 303} and ³⁰⁴ TLX1-overexpressing T-ALLs have a distinctive block at the cortical stage of T-cell differentiation. Recent data using transgenic mice overexpressing *Tlx1* show that the protein may repress mitotic checkpoint genes, leading to aneuploidy, and may disrupt the normal factors needed for T-cell receptor α rearrangement.^{305,306} MLL and its fusion partners PICALM and MLLT10 are rearranged and overexpressed in 5% to 10% of T-ALL cases and may function by deregulating the expression of the HOXA gene cluster.^{140,304,307,308}

Other transcription factors mutated in T-ALL include the MYB oncogene, which is duplicated in 8.4% of T-ALL cases as analyzed by array CGH and fiber FISH studies.^{309,310} Array CGH, SNP arrays, and sequencing revealed deletion or missense mutation in the BCL11B gene in 9% of T-ALL patients.³¹¹ Bcl11b knockout mice show major defects in T-cell differentiation consistent with a role in T-cell progenitor transformation.³¹² Loss of function mutations were found in PHF6, a transcription factor gene encoded on Xq26. This finding was very intriguing in that the mutations were 10-fold more prevalent in males than females, which correlates with the higher prevalence of the disease in males; however, the PHF6 mutations were highly concordant with TLX gene deregulation and uncommon in TLX-negative cases.³¹³ EZH2 and SUZ12 loss of function mutations occur in 25% of T-ALL cases. These two genes encode protein components of the PRC2. PRC2 is responsible for methylation of Lysine-27 on histone H3, a mark associated with silenced genes.³¹⁴

Mutations in Signaling Pathways

T-ALL, like most acute leukemias, harbors mutations predominantly in transcription factors. These proteins are difficult therapeutic targets in comparison to cytokine receptors and signal transducing tyrosine kinases. The latter group of genes was very recently implicated in T-ALL with targeted sequencing approaches. For example, gain of function mutations in the IL7R gene have been described in 5% to 10% of T-ALL patients.^{295,315,316} Some of the missense substitutions in IL7R introduce a cysteine residue in place of the wild-type amino acid in the JM domain. This creates a disulfide bond linking two receptors, resulting in constitutive phosphorylation of STAT5 and other downstream substrates.³¹⁶ The IL7R protein utilizes the nonreceptor tyrosine kinases, JAK1 and JAK3, for signal transduction, and these too are mutated in 5% to 10% of T-ALL cases.^{295,317,318,319} FLT3-ITD mutations similar to those found in AML are also found in T-ALL. NRAS mutations have also been described in ~10% of patients.^{181,320,321} The ABL1 gene is amplified involving simple translocations and complex rearrangements in 5% to 10% of T-ALLs.³²² Mutations in signaling pathways are more common in early T-cell precursor ALL, a form of T-ALL that is resistant to induction chemotherapy and prone to relapse.^{295,296} Some of the oncogenes and

tumor suppressor genes involved in T-ALL pathogenesis are also targeted by a group of microRNAs, offering yet another pathway toward regulation of expression.^{323,324}

SUMMARY

This chapter has reviewed the major translocations found in acute leukemia, with a focus on understanding the function of the fusion proteins encoded by the translocated genes. In addition, genes that are common sites of point mutations or deletions in acute leukemia are reviewed. A major theme has been alteration of transcriptional regulation. A major focus of future research will be identification of downstream targets of these aberrant transcription factors. Study of the aberrant transcription factors resulting from translocations and mutations has increased our understanding of the importance of histone acetylation, deacetylation, and methylation in transcriptional regulation. Study of mutated tyrosine kinases present in leukemia led to the first specifically engineered kinase inhibitor for the therapy of CML and Ph⁺ ALL. Kinase inhibitors have also been developed for the relatively common mutant FLT3 protein present in AML. This is a truly exciting time for hematologic oncology, where elucidation of the pathogenesis of acute leukemia is leading to development of new therapeutic agents. However, powerful genomic methods have revealed the incredible complexity of the mutational events necessary for the development of acute leukemia.

Chapter 73

Diagnosis and Classification of the Acute Leukemias and Myelodysplastic Syndromes

Daniel A. Arber

Attilio Orazi

INTRODUCTION

The diagnosis and classification of acute leukemias and myelodysplastic syndromes (MDSs) has grown increasingly complex.^{1,2} Cases can no longer be fully classified by the use of only morphologic evaluation and cytochemical studies. Historic information, such as the presence of Down syndrome, prior therapy, or prior MDS all impact the final diagnosis. Additionally, immunophenotypic studies are needed for many cases; and cytogenetic, with possible molecular genetic, studies are required for essentially all cases.

This increase in complexity in the evaluation of these neoplasms has resulted in more precise diagnostic categories and recognition that the broad categories of acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), and MDS actually represent heterogeneous groups of diseases. The newer disease categories are more predictive of outcome than older classification systems, in part because of their ability to separate disease groups within each category.^{3, 4, 5} and ⁶ Unfortunately, many physicians continue to use older terminology for these diseases, relying on terminology from the French-American-British Cooperative Group (FAB) classification^{7,8,9,10} of these neoplasms. While the FAB classification provided firm diagnostic criteria and useful terminology for communication of findings using the methods available at the time, its use is no longer appropriate. The third (2001) and fourth (2008) editions of the World Health Organization (WHO)

classification of hematopoietic tumors have dramatically changed the approach to diagnosis of many of these neoplasms, and the WHO system should be considered the current standard of care. Modifications from the LeukemiaNet group and others will certainly continue to aid in the refinement of our classification systems.^{11,12,13} This evolution from the FAB to the WHO is reminiscent of changes in lymphoma classification with evolution from the Rappaport¹⁴ and Kiel¹⁵ classifications to the Working Formulation¹⁶ to the REAL¹⁷ classification and finally to the WHO classification.^{2,18} Perhaps because the changes in lymphoma classification were more stepwise with shorter time intervals between the changes than the leukemia classification changes, they have been more widely adopted. We no longer refer to diffuse large B-cell lymphoma as histiocytic lymphoma and should no longer refer to AML with t(8;21)q22;q22) as M2, or to B-lymphoblastic leukemia with BCR-ABL1 as L2.

Several discoveries have impacted the classification of these neoplasms and many of them are covered in great detail in other chapters, but genetic discoveries associated with the acute leukemias and MDSs are probably the most significant. The finding of recurrent cytogenetic abnormalities with prognostic significance impacts all of these diseases.^{19,20,21, 22, 23} and²⁴ While balanced translocations are more common in the acute leukemias, the presence of single and complex abnormalities in the MDS has helped define disease prognosis as well as defining a specific disease category of MDS with isolated del(5q).^{5,6} The more recent discoveries of specific gene mutations have further impacted both acute leukemia and MDS diagnosis.^{13,25, 26, 27, 28, 29, 30} and³¹ While many of these mutations have their greatest frequency in AMLs with a normal karyotype, others offer prognostic significance that complements other morphologic and karyotypic features.

The classification of AML and MDS has also been impacted greatly by the understanding of similarities between the two. The so-called myelodysplasia-related AML and de novo AML described by Head³² helped lead to a new way of thinking about this disease; especially AML occurring in older patients.

This chapter will highlight key classification issues in the acute leukemias and MDSs, which are discussed in detail in the chapters that follow.

DIAGNOSTIC EVALUATION

The diagnostic approach to acute leukemia and MDSs still begins with a morphologic evaluation, but requires careful integration of the morphologic findings with clinical information and relevant laboratory data, including cytogenetic and molecular results.³³ Laboratory data, particularly results of a recent complete blood count (CBC) must be reviewed with the samples. Morphologic evaluation requires a well-stained (usually Wright-stained) peripheral blood (PB) smear prepared from a recent sample (less than 2 hours from procurement). A 200-cell manual differential count is required for PB smears. The bone marrow (BM) aspirate smears are best prepared at the bedside immediately after procurement and promptly stained. The review of BM aspirate smear includes a 500-cell differential count. In patients with inaspirable marrow, touch preparation of the BM biopsy can be used in lieu of an aspirate smear. The BM biopsy is usually stained with hematoxylin and eosin (H&E) or Giemsa and is useful in many settings.³⁴ The morphologic assessment allows for the appropriate use of ancillary tests in these disorders. Details of the ancillary tests used for the workup of the various diseases are provided in Chapters 2, 3 and 4 and will not be repeated here.

Cytochemical studies are still performed at many institutions and can often provide quick general information about the cell type of an acute leukemia (myeloid versus myeloperoxidase negative), but because more detailed information can now be obtained by flow cytometry in the same time frame, the use of these less specific cytochemical studies has decreased. Immunophenotyping, usually by multicolor flow cytometry, is now standard for acute leukemias and is absolutely required to accurately diagnose the lymphoblastic leukemias and some AMLs.^{7,11,12,35,36} In cases of acute leukemia with marrow fibrosis, as may occur with some acute megakaryoblastic leukemias and with acute panmyelosis with myelofibrosis (APMF) (see Fig. 73.1), paraffin section immunohistochemistry performed on a BM trephine biopsy is essential.³⁷ The use of flow cytometry immunophenotyping in the MDSs is the subject of much study, and many centers have incorporated this technique into the evaluation of patients with potential MDS not only to help quantitate blood and marrow blast cell percentages, but also to detect abnormal maturing cell populations.^{11,38,39} These methods, however, do not replace morphologic evaluation, including morphologic blast cell counts on smears.

Cytogenetic studies should also be performed on all cases of suspected acute leukemia or MDS.^{21,40,41} While specific gene mutations and some structural abnormalities will be missed by this method, karyotype analysis currently provides the best overall assessment of chromosomal abnormalities and should not be supplanted by other studies. Fluorescence in situ hybridization (FISH) or polymerase chain reaction (PCR) studies are often helpful to detect cryptic abnormalities that may be missed by karyotype analysis and are often added in panels for suspected

acute leukemia or MDS.⁴² Finally, molecular studies for specific gene mutations are now routinely performed on samples from patients with these disorders, but when each mutation is studied individually the specific tests performed should be ordered based on the findings of other studies. However, with the rapid growth of next-generation sequencing technology,⁴³ more cost-effective gene mutation panels will become available that may reduce the need for selective testing.

FIGURE 73.1 Acute panmyelosis with myelofibrosis illustrating the use of immunohistochemistry in diagnosis. The marrow is inaspirable due to marked marrow fibrosis (A) with a mixed cellular population that includes immature mononuclear cells. The cells show a mix of granulocyte precursors marking with myeloperoxidase (B), erythroid precursors marking with glycophorin B (C), and immature megakaryocytes marking with von Willebrand's factor (D).

Once this broad array of studies is complete, the results should be incorporated into a single report with a final diagnosis. Because they cannot always be completed in the time interval needed to begin therapy, this approach requires the use of preliminary and amended reports. Because the WHO classification relies on use of cytogenetic studies and some prognostic risk groups are defined by mutation analysis, the diagnosis often needs to be refined, and thus amended, when these studies are complete.

MYELOYDYSPLASTIC SYNDROMES

Patients with MDS typically show persistent (>6 months) unexplained cytopenias. The majority of MDS patients present with anemia. Neutropenia and thrombocytopenia are less common presenting symptoms. The cytopenias are defined by a hemoglobin level of less than 10 g/dL, an absolute neutrophil count of less than $1.8 \times 10^9/L$, and a platelet count of less than $100 \times 10^9/L$.^{33,44} Of note, CBC values higher than those listed above are not exclusionary for a diagnosis of MDS if definitive morphologic and/or cytogenetic findings are consistent with such a diagnosis. Since the presence of cytopenia(s) is required for the diagnosis, the most current and preferably previous CBCs have to be reviewed at the time of BM exam. Other pertinent data include medications, chemical exposure history, and previous and current illnesses, since all of these can cause morphologic dysplasia indistinguishable from MDS. Comorbidities associated with morphologic dysplasia are frequent in elderly patients affected by MDS, and include liver and kidney failure, autoimmune disorders, neoplasms, and systemic infections. In particular, morphologic evaluation is best performed when the patient is off medication.

Dysplastic features can be present in a single hematopoietic lineage (unilineage dysplasia) or involve all marrow populations (multilineage dysplasia) (Fig. 73.2). At least 10% of all cells in a given lineage (erythroid, myeloid, megakaryocytic) have to be dysplastic for establishing the presence of MDS-associated dysplasia. The majority of MDS subtypes show dyserythropoiesis. PB shows normocytic, normochromic, or macrocytic anemia with macroovalocytes. Microcytosis can be present in rare cases of MDS (e.g., cases associated with congenital or acquired alpha thalassemia).⁴⁵ The most common dysplastic features seen in erythroid precursors include nuclear abnormalities such as nuclear

P.1545

budding, nuclear fragmentation, irregular nuclear outlines, karyorrhexis, internuclear bridging, multinucleation, and megaloblastoid, coarsely condensed chromatin. Cytoplasmic vacuoles with coalescing vacuoles, defective hemoglobinization and increased numbers of ring sideroblasts can also be encountered. Similarly, dysgranulopoiesis is often manifested by abnormal nuclear features including hypolobation (pseudo-Pelger-Huët or monolobated neutrophils), hypersegmented and/or enlarged nuclei, nuclear sticks or fragments, macropolycytes, and abnormally condensed chromatin, which often coexists with nuclear hypolobation.

P.1546

Cytoplasmic features of neutrophil dysplasia include hypogranulation, pseudo-Chediak-Higashi granules, and rarely Auer rods. Hypogranulation occurs frequently and is related to the defective formation of secondary granules. However, the evaluation of this feature is highly subjective and dependent on the staining quality. A well-stained segmented neutrophil or neutrophilic precursor with well-developed secondary granules present, preferably in the same microscopic field, can be used as an internal control. Megakaryocyte morphology can be evaluated using both aspirate smear and the histologic sections (biopsy or clot section) with careful examination of at least 30 megakaryocytes.^{33,44} Dysplastic features include monolobated, hypolobated, and hyperlobated nuclei, and multiple, widely separated nuclei including "pawn-ball" forms. Normal size or small megakaryocytes with a single (nonlobated) eccentrically placed nucleus are common in 5q- syndrome and in cases with abnormalities of chromosome 3. The latter also shows typically numerous bilobated forms. Megakaryocytic dysplasia is often associated with thrombocytopenia and platelets of variable size, including large forms occasionally showing hypogranulation.

FIGURE 73.2 Dyspoietic changes in myelodysplastic syndrome and acute myeloid leukemia. Peripheral blood (A, B) and bone marrow (C, D) neutrophils may show cytoplasmic hypogranulation, clumped nuclear chromatin, and hypossegmentation, including pseudo-Pelger-Huët anomaly as shown in image A. Dyserythropoiesis may include nuclear-cytoplasmic asynchrony and irregular nuclear shapes in the marrow erythroid precursors (C, D). Megakaryocyte changes include hypersegmented cells (E) and smaller, hypolobated cells (F).

The biopsy allows for the evaluation of cellularity, architectural features, fibrosis, and the presence of previously undiagnosed focal lesions such as metastatic neoplasms or infections. In MDS marrows, the typical architectural organization is lost. Clusters of immature cells are frequently found in the center of the marrow space. This finding was originally termed abnormal localization of immature precursors and is more frequently seen in cases of high-grade MDS. The identification of blast clusters is facilitated by CD34 immunohistochemistry, which is also useful to determine the number of blasts in cases with inaspirable marrows. The presence of CD34 positive cell clusters is a prognostically significant finding that is predominantly seen in high-risk MDS.⁴⁶ The BM biopsy is necessary for the assessment of BM fibrosis by the Gomori silver impregnation method. Significant fibrosis occurs predominantly in high-risk and therapy-

related MDS; however, it may also occur in low-risk disease. Finally, BM biopsy is critical for the exclusion of other hematologic and also nonhematologic diseases associated with unexplained cytopenia(s) which can clinically mimic MDS.

In addition to dysplasia, the evaluation of blasts constitutes a cornerstone of morphologic diagnosis of MDS. The optimal quality of BM aspirate and PB smears cannot be overemphasized.³³ The blast percentage is derived from the 500-cell differential count of marrow aspirate smear and 200-cell PB manual differential count. Both differential counts are essential for the subclassification of individual cases. The agranular and granular (type II and type III blasts), and, if present, monoblasts, promonocytes, and megakaryoblasts are included in the blast category.⁴⁷ In the absence of adequate BM aspirate smears due to causes such as an inaspirable marrow, careful inspection of the histologic material aided by a CD34 immunohistochemical stain can be used. The latter is particularly helpful in cases with significant marrow fibrosis or in hypoplastic marrows, which often yield hemodilute marrow aspirates.^{48,49,50} Of note, blasts in MDS can be negative for CD34, therefore careful correlation with the visual blast identification is required in all cases. It is also important to emphasize that morphologic dysplasia is not equivalent to the diagnosis of MDS. Megakaryocytic and erythroid dysplasia are commonly seen in individuals in a variety of conditions. Nutritional deficiencies, heavy metal exposure, medications, and systemic diseases can produce morphologic changes resembling those seen in MDS. Therefore, as discussed previously, the correlation with clinical history is critical.

Cytogenetics is crucial and is also required for proper classification. The MDS-associated abnormalities are listed in Table 73.1. In addition, mutational analysis is becoming an important additional tool in the prognostic assessment of MDS^{30,51}; but mutation studies are not routinely performed in the evaluation for MDS at this time.

TABLE 73.1 RECURRENT CHROMOSOMAL ABNORMALITIES AND THEIR FREQUENCY IN MYELOYDYSPLASTIC SYNDROME

Abnormality	Frequency (%)
<i>Unbalanced</i>	
+8	10
-7 or del(7q)	10
-5 or del(5q)	10
del(20q)	5-8
-Y	5
i(17q) or t(17q)	3-5
-13 or del(13q)	3
del(11q)	3
del(12q) or t(12q)	3
del(9q)	1-2
idic(X)(q13)	1-2
<i>Balanced</i>	
t(1; 3)(p36.3;q21.2)	1
t(2; 11)(p21;q23)	1
inv(3)(q21;q26.2)	1
t(6;9)(p23;q34)	1

The 2008 WHO classification further refined the criteria for diagnosis and classification of MDS, and seven categories are now recognized (Table 73.2). Cases currently recognized as refractory cytopenia with unilineage dysplasia (RCUD) were considered as refractory anemia (RA) or MDS, unclassifiable in the 2001 WHO classification. Such cases encompass patients with one isolated cytopenia or bicytopenia associated with unilineage dysplasia. An advantage of the new category of RCUD is that one can further specify the lineage: refractory anemia, refractory neutropenia, or refractory thrombocytopenia. Regardless of the lineage involved in RCUD, blasts are absent or represent less than 1% of the PB differential count. Patients with 1% blasts in PB or patients with unilineage dysplasia associated with pancytopenia are

now classified as having unclassifiable MDS (MDS-U), owing to the uncertain but presumably more severe clinical significance of these findings.² Overall, the category of MDS-U is currently better defined and also includes cytopenic patients lacking significant dysplasia, but presenting with cytogenetic abnormalities considered presumptive evidence of MDS.

The 2008 WHO classification acknowledged a subset of pediatric patients with specific MDS features different from those commonly seen in adults, and included a separate category of childhood MDS termed refractory cytopenia of childhood. This category encompasses children with MDS that have persistent cytopenia with less than 2% blasts in the PB and less than 5% blasts in the BM.^{52,53}

Some subtypes or presentations of MDS are more challenging and will be discussed in more detail. MDS-U includes cases which do not fulfill criteria of other MDS subtypes. MDS-U can be diagnosed in patients fulfilling the following criteria: (1) patients who fit the criteria for a diagnosis of RCUD or refractory cytopenia with multilineage dysplasia (RCMD), but in whom 1% blasts in the blood are found on at least two consecutive occasions; (2) patients with MDS with pancytopenia and morphologic dysplasia limited to one hematopoietic lineage; (3) patients with persistent cytopenias, no increase in blasts, and lacking diagnostic morphologic features of MDS (less than 10% dysplastic cells in any lineage), but with clonal cytogenetic abnormalities considered as a presumptive

P.1547

evidence of MDS. According to the 2008 WHO classification, if characteristic features of a specific subtype of MDS develop later in the course of the disease, the case initially classified as MDS-U should be reclassified accordingly. The prognosis of MDS-U varies and close follow-up is warranted.

TABLE 73.2 THE WHO 2008 CLASSIFICATION OF MDS

Subtype	Blood findings	Bone marrow findings
Refractory cytopenias with unilineage dysplasia (RCUD)		Unilineage dysplasia;
Refractory anemia (RA)	Unicytopenia or bicytopenia ^a	≥10% of the cells of the affected lineage are dysplastic
Refractory neutropenia (RN)	No or rare blasts (<1%)	<5% blasts
Refractory thrombocytopenia (RT)		<15% ring sideroblasts
Refractory anemia with ring sideroblasts (RARS)	Anemia No blasts	Erythroid dysplasia only <5% blasts ≥15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenia(s) No or rare blasts (<1%) No Auer rods <1 × 10 ⁹ L monocytes	Dysplasia in ≥10% of cells in two or more myeloid lineages <5% blasts No Auer rods ±15% ring sideroblasts
Refractory anemia with excess blasts-1 (RAEB-1)	Cytopenias <5% blasts No Auer rods <1 × 10 ⁹ L monocytes	Unilineage or multilineage dysplasia 5-9% blasts No Auer rods
Refractory with excess blasts-2	Cytopenias	Unilineage or multilineage dysplasia

(RAEB-2)	5-19% blasts ±Auer rods <10-19% blasts ±Auer rods ^b × 10 ⁹ L monocytes	
Myelodysplastic syndrome, unclassified (MDS-U)	Cytopenias No or rare blasts (≤1%) No Auer rods	Unequivocal dysplasia in <10% of cells in one or more myeloid cell lines <5% blasts
MDS associated with isolated del(5q)	Anemia No or rare blasts (<1%) Platelet count usually normal or increased	Normal to increased megakaryocytes with hypolobated nuclei <5% blasts Isolated del(5q) cytogenetic abnormality No Auer rods

^a Bicytopenia may occasionally be observed. Cases with pancytopenia should be classified as MDS-U.

^b If the diagnostic criteria for MDS are fulfilled and Auer rods are present, the patient should always be categorized as RAEB-2.

MDS with fibrosis (MDS-F) is defined by the presence of significant fibrosis (at least 3+ reticulin fibrosis according to the Manoharan scoring system, or at least 2+ reticulin fibrosis according to the European consensus grading system).^{44,54,55} In the past, select cases with 2+ reticulin fibrosis according to Manoharan scoring may have been classified as MDS-F. Approximately 10% to 15% of MDS patients show a significant increase in reticulin fibers and/or collagen fibrosis at presentation.⁵⁴ These patients are diagnosed with an MDS subtype according to the 2008 WHO classification, with the annotation to indicate the presence of fibrosis. The majority of MDS-F cases fall into the category of refractory anemia with excess blasts (RAEB). Therapy-related MDS cases frequently show significant marrow fibrosis, but are excluded from the MDS-F category in favor of placing them in a special entity of therapy-related myeloid neoplasms. The majority of MDS-F patients present with severe pancytopenia. Organomegaly is minimal or absent. The patients with MDS-F are reported to have shorter overall survival and disease-free survival times than those without fibrosis, even in the absence of excess blasts.^{54,56,57} BM fibrosis is also associated with a poor outcome after BM transplantation.⁵⁸ BM and PB often show trilineage dysplasia with excess blasts. There is prominent dysmegakaryopoiesis, often associated with increased numbers of megakaryocytes. Cellular streaming is frequently seen on H&E biopsy section and is indicative of significant fibrosis. CD34 immunostaining may be helpful in assessing the number of blasts, since the aspirate smears are often inadequate in patients with fibrotic marrows. Differential diagnoses of MDS-F include other myelofibrotic myeloid neoplasms such as APMF, myeloproliferative, and myelodysplastic/myeloproliferative neoplasms. Similar to MDS-F, APMF, a subtype of AML-NOS (not otherwise specified), shows marked fibrosis, trilineage dysplasia, and dwarf megakaryocytes. The higher number of blasts (in the range of 20% to 25%), abrupt onset with fever and bone pain, and rapidly progressive course seen in APMF are helpful in establishing the definitive diagnosis.³⁷ Classic myeloproliferative neoplasms, such as primary myelofibrosis, can usually be easily distinguished from MDS-F by their morphologic characteristics (e.g., large-to-giant megakaryocytes with cloud-like nuclei, lack of other myelodysplastic features), and by the presence of significant splenomegaly.^{33,59} Myelodysplastic/myeloproliferative neoplasms such as chronic myelomonocytic leukemia may show morphologic features similar to MDS, yet demonstrate laboratory and clinical features of a proliferative process such as elevated WBC and monocytosis.

Hypoplastic MDS (h-MDS), which is defined by its low marrow cellularity (cellularity of less than 20% for patients older than 70 years of age and less than 30% for individuals younger than 70 years), accounts for 5% to 10% of MDS patients.^{2,60} Similar to typical cases of MDS, h-MDS is a disease of the elderly. It is more common in women. H-MDS has a prognosis and rate of transformation to AML similar to the corresponding

P.1548

WHO-classified MDS subtypes. The major differential diagnosis of h-MDS is aplastic anemia.^{60,61} The typically hemodilute

marrow aspirates obtained from hypoplastic marrow limit the evaluation of cytologic features, and in this context the information derived from BM biopsy/clot section is of paramount importance. The majority of patients with h-MDS present with dyserythropoiesis and no increase in blasts, and are classified as RA.^{60,61} Dysgranulopoiesis, dysmegakaryopoiesis, and increase in blasts occur less frequently. Patients with h-MDS can show mast cell hyperplasia, interstitial lymphocytosis, and lymphoid follicles. In the absence of significant multilineage dysplasia and/or increased blast population, the distinction from aplastic anemia can be challenging. The presence of megakaryocytes, increased reticulin fibers, and focally increased CD34 positive cells all suggest h-MDS. The immunohistochemical stains for CD34 and megakaryocytic antigens (CD42b and CD61) and reticulin stain are recommended to highlight the presence of these features.^{60,61} Additional findings such as immunophenotypic abnormalities by flow cytometry or the presence of select cytogenetic markers such as losses of chromosomes 5 and/or 7, which are uncommon in aplastic anemia, are also helpful. The applications of novel technologies may help to better differentiate aplastic anemia from h-MDS, and aid in early detection of transformation in the former entity.⁶² The diagnostic challenges might be related to the overlap in pathogenesis as demonstrated by the T-cell-mediated suppression of hematopoiesis or the coexistence of clones of paroxysmal nocturnal hemoglobinuria cells documented to occur in both diseases.⁶³

Erythroid-predominant MDS (MDS-E) can also cause diagnostic difficulties. By definition, these patients have less than 20% of blasts both as enumerated from the total marrow cellularity and from the nonerythroid BM population. The latter is necessary to exclude a diagnosis of erythroleukemia. In MDS-E, similar to other cases of MDS, blasts are enumerated as a percentage of all BM cells and their number is used to classify cases into one of the MDS subtypes.^{2,33} However, recent studies suggested that the alternative approach of calculating the percentage of blasts as a proportion of nonerythroid cells might provide a more accurate assessment of overall prognosis in MDS-E.⁶⁴ If blasts are calculated as a percentage of nonerythroid cells, the upgrade to a higher-risk subtype of MDS occurs mainly between the categories of RCMD and RAEB-1 and between RAEB-1 and RAEB-2. Changes from low-risk to high-risk MDS categories are exceedingly rare. Until more evidence is published, it is currently recommended to use the standard WHO criteria, using blast percentages based on all cells, to classify cases of MDS-E.

ACUTE MYELOID LEUKEMIA

The classification of AML has changed dramatically from the FAB classification^{7,8,10,65} to the WHO classification.² While the FAB classification was based primarily on morphologic and cytochemical features of the blast cells, the WHO uses a combined approach in an attempt to define prognostically significant and biologically relevant disease groups. While many of the WHO categories rely heavily on cytogenetic findings, most still retain distinctive morphologic and immunophenotypic findings. The specific AML disease categories are listed in Table 73.3, and some of the distinctive morphologic and immunophenotypic features of specific types are illustrated in Figures 73.1, 73.3, and 73.4 and described in Table 73.4.

For most cases, a blast cell count of 20% or more in either the PB or BM aspirate is necessary for a diagnosis of AML. For cases with one of three recurring cytogenetic abnormalities (t(15;17) (q24.1;q21.1) PML-RARA; t(8;21)(q22;q22) RUNX1-RUNX1T1; and inv(16)(p13.1q22) or t(16;16)(p13.1;q22) CBFβ-MYH11), however, a diagnosis of AML can be made with a lower blast count. These low blast count cases are uncommon and still have abnormal blood and marrow findings. The detection of the cytogenetic abnormality would indicate AML over a diagnosis of MDS in these cases. Acute erythroid leukemia (erythroid myeloid type) is also diagnosed with less than 20% blood or marrow blasts (see below).

TABLE 73.3 2008 WORLD HEALTH ORGANIZATION CLASSIFICATION OF ACUTE MYELOID LEUKEMIA AND RELATED PRECURSOR NEOPLASMS

AML with recurrent genetic abnormalities

AML with t(8;21) (q22;q22) (*RUNX1-RUNX1T1*)

AML with inv(16)(p13.1q22) or t(16;16) (p13.1;q22) (*CBFβ-MYH11*)

Acute promyelocytic leukemia with t(15;17)(q24.1;q21.1) (*PML-RARA*)

AML with t(9;11)(p22;q23) (*MLLT3-MLL*)

AML with t(6;9)(p23;q34) (*DEK-NUP214*)

AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2) (*RPNI-EVI1*)

AML (megakaryoblastic) with t(1;22)(p13;q13) (*RBM15-MKLI*)

Provisional entity: AML with mutated *NPM1*

Provisional entity: AML with mutated *CEBPA*

AML with myelodysplasia-related changes

Therapy-related myeloid neoplasms

AML not otherwise specified

AML minimally differentiated

AML without maturation

AML with maturation

Acute myelomonocytic leukemia

Acute monoblastic and monocytic leukemia

Acute erythroid leukemia

Acute megakaryocytic leukemia

Acute basophilic leukemia

Acute panmyelosis with myelofibrosis

Myeloid sarcoma

Myeloid proliferations related to Down syndrome

Blastic plasmacytoid dendritic cell neoplasm

AML, acute myeloid leukemia.

The WHO classification defines AML types by recurring genetic abnormalities,⁶⁶ by recognizing cases related to MDS,⁶⁷ and by separating diseases related to prior therapy⁶⁸ or associated with Down syndrome.⁶⁹ Cases that do not fall into any of those groups are placed in the AML-NOS group⁷⁰ and can be subdivided by morphologic features. Many of these cases, however, have normal karyotypes, and the search for predictive markers to better categorize them is ongoing.⁷¹

AML with recurring genetic abnormalities was expanded in the 2008 WHO classification to include more disease groups and to attempt to incorporate disease-defining mutations. AML with mutated *CEBPA* and AML with mutated *NPM1* are provisional disease categories based on the hypothesis that these mutations are disease-defining events,^{72, 73, 74, 75} and similar to the other recurring cytogenetic abnormalities in this category, and not merely secondary events that impact prognosis.

AML with myelodysplasia-related changes of the 2008 WHO classification (Table 73.5) is an expansion and revision of the category of AML with multilineage dysplasia in the 2001 classification.^{3,67} The use of multilineage dysplasia as the sole source of classifying AML is controversial. Certainly cases of AML arising from MDS can lack sufficient background cells to diagnose multilineage dysplasia and the expansion of this category now allows cases to be diagnosed as AML with myelodysplasia-related changes by demonstrating the presence of multilineage dysplasia, presence of an MDS-associated cytogenetic abnormality (Table 73.6), a history of prior MDS or a myelodysplastic/myeloproliferative neoplasm, or a combination of such findings. This combined approach captures more cases of AML and defines a group with a particularly poor prognosis in adults.

P.1549

Cases with a normal karyotype and no history, but the presence of multilineage dysplasia, defined as two or more cell lines with 50% or more dysplastic cells, is the major area of controversy. While some large series have failed to find prognostic significance for this group,^{77,78} other studies find multilineage dysplasia to still independently predict a worse outcome compared to AML-NOS.^{3,78}

FIGURE 73.3 Morphologic features of more common acute myeloid leukemia types with recurrent cytogenetic abnormalities. A: Acute myeloid leukemia with $t(8;21)(q22;q22)$ (RUNX1-RUNX1T1) with blasts containing abundant cytoplasm with large granules and perinuclear clearing (hofs). B: Acute myeloid leukemia with $inv(16)(p13.1q22)$ or $t(16,16)(p13.1;q22)$ (CBFB-MYH11) with an abnormal eosinophil containing large basophilic granules (lower right). C: Acute promyelocytic leukemia with $t(15;17)(q24.1;q21.1)$ (PML-RARA) typically shows blasts with bilobed nuclei, cytoplasmic granules and Auer rods (far right). D: Acute myeloid leukemia with $inv(3)(q21q26.2)$ (RPN1-EVI1) with background dyspoiesis and a small, monolobated megakaryocyte (center).

FIGURE 73.4 Acute erythroid leukemia, mixed myeloid erythroid type. Over 50% erythroid precursors are present in the bone marrow with dyspoietic changes that include cytoplasmic vacuolization (lower center). In addition, scattered blasts, which mark as myeloblasts, are present in the background (upper left and lower right) representing over 20% of the nonerythroid cells in the marrow.

Therapy-related myeloid neoplasms and the myeloid neoplasms associated with Down syndrome are also felt to be distinct from other AML types, and these also tend to show a continuum between cases with features of AML and MDS. For this reason, they are now considered separate disease entities, respectively, from the non-therapy or-Down-related leukemias.

The remaining cases are placed into the category of AML-NOS and this category includes many normal karyotype cases and cases that are diagnosed as AML with unique features. The subcategories of AML-NOS are probably of little significance, and mutation analysis is probably most important in this group. Selected mutations (FLT3 and KIT) are included as prognostic markers for different AML types in the WHO classification. While the utility of KIT mutations is primarily in the core binding factor leukemias (those with t(8;21)(q22;q22) RUNX1-RUNXT1; and inv(16)(p13.1q22) or t(16;16)(p13.1;q22) CBFβ-MYH11),⁷⁹ FLT3 and NPM1 mutations are prognostically predictive in most

P.1550

cases of AML-NOS.^{28,72,73,80, 81, 82, 83} and ⁸⁴ In addition to the mutations included in the 2008 WHO classification, other mutations have been described and validated as potential prognostic markers.^{27,85,86,87,88} Some of the most frequently occurring in AML include DNMT3A, IDH1, IDH2, TET2, RUNX1, NRAS, and WT1. Table 73.7 demonstrates one approach to combining cytogenetic studies and mutation analysis to develop prognostic categories in AML, but this approach will have to be frequently updated to include new discoveries.⁸⁵

TABLE 73.4 DISTINCTIVE CLINICAL, MORPHOLOGIC, AND IMMUNOPHENOTYPIC FEATURES OF ACUTE MYELOID LEUKEMIA CYTOGENETIC SUBTYPES

AML Subtype

Distinctive Features

AML with t(8;21) (q22;q22) (<i>RUNX1-RUNX1T1</i>)	Granular blasts with perinuclear hofs, large salmon-colored granules, aberrant CD19 expression on CD34 ⁺ myeloblasts
AML with inv(16)(p13.1q22) or t(16,16) (p13.1;q22) (<i>CBFB-MYH11</i>)	Presence of abnormal eosinophils with basophilic granules
Acute promyelocytic leukemia with t(15;17)(q24.1;q21.1) (<i>PML-RARA</i>)	Bilobed nuclei with blasts lacking HLA-DR and usually CD34-negative
AML with t(6;9)(p23;q34) (<i>DEK-NUP214</i>)	Multilineage dysplasia and associated basophilia
AML with inv(3)(q21q26.2) or t(3;3) (q21;q26.2) (<i>RPNI-EVII</i>)	Multilineage dysplasia and increased numbers of small mono- or bilobed megakaryocytes
AML (megakaryoblastic) with t(1;22) (p13;q13) (<i>RBM15-MKLI</i>)	Infant without Down syndrome with CD41+ and CD61+ blasts

AML, acute myeloid leukemia.

Categories of AML-NOS that offer the greatest diagnostic challenge are probably acute erythroleukemia and APMF. Acute erythroleukemia can be the pure erythroid leukemia with over 80% immature erythroid cells and no myeloblasts or a mixed myeloid erythroid type.⁸⁹ The latter type (Fig. 73.4) has 50% or more BM erythroid precursors; and of the nonerythroid marrow cells, 20% or more myeloblasts. The differential diagnosis of both types is with MDS, and both are probably closely related to aggressive MDS. APMF usually involves an inaspirable marrow with marked fibrosis and a mix of immature myeloid, erythroid, and megakaryocytic cells (Fig. 73.1).^{37,90} This rare disorder is also difficult to distinguish from MDS-F and may be related to such proliferations.

TABLE 73.5 CRITERIA FOR DIAGNOSIS OF ACUTE MYELOID LEUKEMIA WITH MYELOYDYSPLASIA-RELATED CHANGES

- 1) At least 20% blasts in the blood or bone marrow
- 2) No history of prior cytotoxic therapy for other disease
- 3) Absence of a recurring chromosomal rearrangement as delineated in [Table 73.3](#)

AND, one or more of the following features:

- 1) Previous history of myelodysplastic syndrome or myelodysplastic/myeloproliferative disorder
- 2) Multilineage dysplasia (dyspoiesis in at least 50% of the elements from two or more lineages)
- 3) Presence of an MDS-associated cytogenetic abnormality (see [Table 73.6](#))

MDS, myelodysplastic syndrome.

TABLE 73.6 CYTOGENETIC ABNORMALITIES SUFFICIENT TO DIAGNOSE ACUTE MYELOID LEUKEMIA WITH MYELOYDYSPLASIA-RELATED CHANGES WHEN ≥20% BLASTS ARE PRESENT IN BLOOD OR BONE MARROW IN THE ABSENCE OF PRIOR CYTOTOXIC THERAPY

Complex karyotype	≥3 unrelated chromosomal abnormalities, not including any rearrangements that would define a subtype of AML with recurrent cytogenetic abnormalities	
Unbalanced abnormalities	-7/del(7q)	del(11q)
	-5/del(5q)	del(12p)/t(12p)
	i(17q)/t(17p)	del(9q)
	-13/del(13q)	idic(X)(q13)
Balanced abnormalities	t(11;16)(q23;p13.3)	t(5;12)(q33;p12)
	t(3;21)(q26.2;q22.1)	t(5;7)(q33;q11.2)
	t(1;3)(p26.3;q21.1)	t(5;17)(q33;p13)

t(2;11)(p21;q23)

t(5;10)(q33;q21)

t(3;5)(q25;q34)

In addition to new gene mutations, gene expression (i.e., BAALC and ERG), often altered by epigenetic changes in AML, is now recognized to have a prognostic impact on this disease.^{91,92,93} Our understanding of the role of miRNAs and gene methylation in the diagnosis and prognosis of AML will also clearly grow in the near future.

ACUTE LYMPHOBLASTIC LEUKEMIA

The diagnostic approach to ALL has also changed dramatically over time. While the immunophenotype of ALL was not part of the FAB classification,¹⁰ it is now essential for diagnosing these disorders. Also, the relationship between lymphoblastic lymphoma and ALL is now recognized, and these disorders are grouped together in the WHO classification.⁹⁴ Cases diagnosed in the past as ALL with a mature B-cell phenotype (FAB L3) are no longer considered as ALL and are best classified as leukemic variants of the mature B-cell lymphomas.

While morphologic evaluation is important in ALL to identify a blast cell proliferation, immunophenotyping must be performed because lymphoblasts cannot be distinguished reliably from undifferentiated myeloblasts by morphology alone. In fact some

P.1551

lymphoblasts will contain cytoplasmic granules that may incorrectly suggest myeloid lineage.⁹⁵ Cytochemical studies are also not sufficient for such a diagnosis, because the absence of myeloperoxidase or Sudan black B by these methods does not exclude undifferentiated myeloblasts and the detection of PAS-positive granules in blasts is not specific for lymphoblasts.

B-lymphoblastic leukemia/lymphoma with hyperdiploidy

B-lymphoblastic leukemia/lymphoma with hypodiploidy

T-lymphoblastic leukemia/lymphoma

The 2008 WHO classification (see Table 73.8) introduced cytogenetic subtypes of B-lymphoblastic leukemia and these studies are also essential for a complete diagnosis of ALL.⁹⁶ There are no specific morphologic features for these ALL types (Fig. 73.5), with the exception that the very rare ALL with t(5;14)(q31;q32) (IL3-IGH@) is associated with a marked proliferation of normal appearing eosinophils.⁹⁷ While there are no specific morphologic features to most of these disorders, there are some characteristic immunophenotypic features that provide clues to the diagnosis, some of which are listed in Table 73.9. While many of these categories are defined by the detection of recurring cytogenetic abnormalities, the translocation of B-lymphoblastic leukemia/lymphoma with t(12;21)(p13;q22) (ETV6-RUNX1) is cryptic,⁹⁸ and FISH or PCR testing must be performed to detect this category. Because this cytogenetic abnormality primarily occurs in children, routine molecular or FISH testing for this fusion is indicated in all pediatric B-ALL cases. Similarly, there are no morphologic clues to reliably distinguish T-lymphoblastic leukemia/lymphoma from B-lymphoblastic leukemia/lymphoma. Although nuclear convolutions are described as more common with a T-cell immunophenotype, this finding is not sufficiently reliable to replace immunophenotyping studies.

FIGURE 73.5 Acute lymphoblastic leukemia with blasts containing scant, agranular cytoplasm. The morphologic features are not specific and may also be present in minimally differentiated acute myeloid leukemia. Part A is from a case of B-lymphoblastic leukemia, while part B is from T-lymphoblastic leukemia; both showing similar morphologic changes.

While mutations studies are not part of the 2008 classification of ALL, numerous genetic alterations have been described in recent years for this disease and will further impact classification. Interestingly, and in contrast to most mutations that are common in AML, many individual mutations in ALL have been shown not to have prognostic impact as a sole marker, but may define prognostic groups when they occur in combination.⁹⁹ PAX5 mutations at 9p13 occur in approximately 30% of B-ALL cases and often occur in combination with other abnormalities; but this mutation alone does not appear to be clinically significant, and routine testing for this abnormality is probably not indicated. In contrast, deletions of IKZF1 at 7p12 often occur in combination with PAX5 mutations and are seen in over 80% of patients with B-ALL with t(9;22)(q34;q11.2)(BCR-ABL1). Even in the absence of the Philadelphia chromosome, children with this deletion (representing almost 30% of all Philadelphia chromosome negative ALLs in one study) have a poor outcome that is similar to B-ALL with t(9;22)(q34;q11.2). The poor prognosis of IKZF1 deleted ALL appears to be independent of age, white blood cell count, or cytogenetic subgroup.^{100,101} Mutations of JAK2, found in approximately 8% of B-ALL cases, in combination with IKZF1 deletions are associated with an even worse prognosis.¹⁰²

A new recurring cytogenetic abnormality, not included in the WHO classification, involves CRLF2 located at Xp22.3/Yp11.3 and most often translocated with IGH@.^{26,103} These translocations occur in 7% to 14% of B-ALL cases, but are associated with either ALL of Down syndrome or ALL in Hispanic patients. They are commonly associated with JAK1 or JAK2 mutations and IKZF1 deletions and have a very poor prognosis.

In contrast to AML, there is no category of ALL for therapy-related disease. Despite this, it is now recognized that ALL may occur after cytotoxic therapy although the relationship to the prior therapy and the leukemia may be under-

appreciated.^{104,105} Most cases of therapy-related ALL are of precursor B lineage and some studies suggest that they are most often associated with MLL translocations involving 11q23.

Recurring cytogenetic abnormalities also occur in T-ALL, but are not included as diagnostic subcategories in the WHO classification. These translocations most often involve T-cell receptor genes at 7q32 (TRB@) and 14q11 (TRA@, TRD@) and TLX1, TLX3 and TAL1, but many other genes may be involved in a smaller percentage of cases.^{106,107} Prognostic significance has not been determined for many of these genetic changes, although TLX1

P.1552

translocations appear to confer a good prognosis. Mutations are also common in T-ALL, with mutations of NOTCH1 found in 50% to 60% of adult and pediatric disease.^{106, 107, 108, 109} and ¹¹⁰ Mutations of FBXW7, a gene involved in NOTCH signaling, occurs in 10% to 20% of cases.^{108, 109} and ¹¹⁰ Mutations of either gene appear to have some prognostic significance in children, at least predicting a favorable treatment response with protocols that include cranial irradiation, but appear to be of less significance in adult patients. FLT3 mutations are rare in T-ALL, found in about 4% of cases.^{111,112} However, these mutations are much more frequent in cases described as early T-cell precursor (ETP)-ALL. These cases are considered to represent a particularly high-risk type of T-ALL^{111, 112} and ¹¹³ that expresses CD7, but lacks CD1a and CD8, shows only weak expression of CD5, expresses CD34, HLA-DR, and CD117, and often expresses myeloid-associated antigens such as CD13, CD33, and CD65s. Some cases in the past were probably diagnosed as undifferentiated, mixed phenotype or biphenotypic acute leukemia. While often FLT3 mutated, ETP-ALL typically lacks mutations of NOTCH1 or FBXW7.¹¹¹

TABLE 73.9 DISTINCTIVE CLINICAL, MORPHOLOGIC, AND IMMUNOPHENOTYPIC FEATURES OF B-LYMPHOBLASTIC LEUKEMIA CYTOGENETIC SUBTYPES

B-ALL Subtype	Distinctive Features
B-lymphoblastic leukemia/lymphoma with t(9;22)(q34;q11.2)(<i>BCR-ABL1</i>)	Precursor B-cell lineage with aberrant expression of CD13, CD33, CD38, and CD25
B-lymphoblastic leukemia/lymphoma with t(v;11q23)(<i>MLL</i>)	CD10-negative precursor B-cell lineage with aberrant CD15 expression
B-lymphoblastic leukemia/lymphoma with t(12;21)(p13;q22) (<i>ETV6-RUNX1</i>)	Childhood leukemia with precursor B-cell lineage with CD34, bright CD10, and aberrant expression of CD13
B-lymphoblastic leukemia/lymphoma with t(5;14)(q31;q32) (<i>IL3-IGH@</i>)	Precursor B-cell lineage associated with marked eosinophilia
B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3) (<i>TCF3-PBX1</i>)	Precursor B-cell lineage lacking CD34 with cytoplasmic mu expression
B-ALL, B-cell acute lymphoblastic leukemia.	

FIGURE 73.6 Mixed phenotype acute leukemia with a bilineal appearance. A mixture of small lymphocytes, small undifferentiated blast cells and larger blasts with granular cytoplasm are present (A). The small blasts mark as B

lymphoblasts, while the larger cells are myeloperoxidase positive by flow cytometry and cytochemistry (B).

ACUTE LEUKEMIAS OF AMBIGUOUS LINEAGE

Despite extensive immunophenotyping studies, a small subset of acute leukemias cannot be definitely classified as being derived from myeloid or lymphoid lineage.^{114,115} These acute leukemias are either acute undifferentiated leukemias or mixed phenotype acute leukemias (MPAL) (Table 73.10). Acute undifferentiated leukemias have become extremely rare with modern immunophenotyping panels and are defined as lacking expression of markers specific for myeloid or lymphoid lineage. They often express non-specific markers such as HLA-DR, CD34, CD38, CD7 or TdT, but lack expression of cytoplasmic CD3, myeloperoxidase, cytoplasmic CD22, cytoplasmic CD79a, or strong expression of CD19, as well as markers of plasmacytoid dendritic cell tumors. No specific cytogenetic abnormalities are associated with these tumors.

The MPAL are slightly more common and are known by a variety of names that include mixed lineage acute leukemia, biphenotypic acute leukemia, and bilineal acute leukemia (Fig. 73.6). The diagnostic criteria for these disorders have been vague in the past, and the frequency of diagnosis has increased with the use of multicolor flow cytometry using large panels of antibodies. Lineage infidelity is common in acute leukemias, and determining how many aberrant markers are sufficient to make a diagnosis

P.1553

of MPAL creates a challenge in many cases. A variety of diagnostic criteria have been proposed for these disorders, but the criteria proposed by the European Group for the Immunologic Classification of Leukemia (EGIL)^{116,117} and the 2008 WHO^{118,119} criteria are most often used, with the WHO criteria currently preferred. The EGIL criteria (Table 73.11) provided the ability to weight the significance of different markers and reduced the number of cases diagnosed as MPAL. However, as new markers became available, the scoring system became less useful and it was not clear that the criteria resulted in a biologically distinct disease entity.

TABLE 73.10 2008 WORLD HEALTH ORGANIZATION CLASSIFICATION OF ACUTE LEUKEMIAS OF AMBIGUOUS LINEAGE

Acute undifferentiated leukemia

Mixed phenotype acute leukemia with t(9;22)(q34;q11.2)(*BCR-ABL1*)

Mixed phenotype acute leukemia with t(v;11q23)(*MLL*)

Mixed phenotype acute leukemia, B/myeloid, NOS

Mixed phenotype acute leukemia, T/myeloid, NOS

Mixed phenotype acute leukemia, NOS—rare types

NOS, not otherwise specified.

TABLE 73.11 EUROPEAN GROUP FOR THE IMMUNOLOGIC CLASSIFICATION OF LEUKEMIA (EGIL) SCORING SYSTEM FOR BIPHENOTYPIC ACUTE LEUKEMIA

Points/LineageB		T	Myeloid
2	CD79a	CD3 (membrane or cytoplasmic)Myeloperoxidase	
	Cytoplasmic IgM	TCR α/β	
	Cytoplasmic	TCR γ/δ	
	CD22		
1	CD19	CD2	CD117
	CD10	CD5	CD13
	CD20	CD8	CD33
		CD10	CD65s
0.5	TdT	TdT	CD14

CD24	CD7	CD15
	CD1a	CD64

More than two points for an individual lineage is required.

The WHO criteria (Table 73.12) are actually simpler to use, based on fewer markers, and specify two cytogenetic abnormalities [t(9;22)(q34;q11.2) BCR-ABL1; t(v;11q23) MLL rearranged] that are often reported in cases of MPAL. The WHO definition of MPAL does not separate cases with a single blast cell population showing a mixed phenotype (biphenotypic) from cases with two distinct blast cell populations (bilineal), since there is great overlap between these case types with some presenting with one pattern and relapsing with another. While the two cytogenetic categories are similar to other acute leukemia categories in the WHO classification, it is not clear these MPAL variants are distinct from other acute leukemias with the same cytogenetic abnormality (i.e., MPAL with t(9;22)(q34;q11.2) BCR-ABL1 versus ALL with t(9;22)(q34;q11.2) BCR-ABL1). The great variability of these disorders based on immunophenotype and recurring genetic changes suggests that immunophenotypic methods may not be the ideal means of classifying these tumors and future diagnostic methods may supplant this category in the future.

TABLE 73.12 2008 WORLD HEALTH ORGANIZATION CRITERIA FOR ASSIGNING LINEAGE FOR MIXED PHENOTYPE ACUTE LEUKEMIA

Lineage Criteria

Myeloid Myeloperoxidase

or

Monocytic differentiation (two or more: NSE, CD11c, CD14, CD64, lysozyme)

T lineage Cytoplasmic or surface CD3

B lineage Strong CD19 plus strong expression of at least one of CD79a, cCD22, CD10

or

Weak CD19 plus strong expression of at least two of CD79a, cCD22, CD10

SUMMARY

The diagnostic evaluation for acute leukemia and MDSs has become increasingly complex. It requires careful coordination between the treating hematologist and hematopathologist to ensure that all sample types needed for diagnosis are collected and appropriately tested. Because the various tests needed for diagnosis and prognosis will be resulted at different times, consolidated reporting of all results using amended reports is suggested to ensure that all results are interpreted in the context of the entire specimen.

Chapter 74

Acute Lymphoblastic Leukemia in Adults

Steven E. Coutre

Acute lymphoblastic leukemia (ALL) is a neoplastic disorder that is rapidly fatal if untreated. In children, ALL is the most common malignancy, and considerable advances have led to the cure of most children with the disease. Historically, treatment outcomes in adults have not been as favorable. Although improved prognostic stratification has led to a better understanding of the biologic heterogeneity of the disease, targeted therapies exploiting these differences have not yet emerged as part of standard therapy for most patients. However, dramatic advances in whole genome sequencing as well as the development of novel immunotherapies promises to improve both the fundamental understanding of the biology of the disease and treatment outcomes.

The clinical onset of ALL is rarely insidious, and presenting signs and symptoms reflect bone marrow as well as extramedullary involvement by leukemia. Examination of the peripheral blood smear is often sufficient to establish the diagnosis of ALL, but additional clinical and laboratory tests are essential for formulating a treatment plan and provide important prognostic information. Current therapy for adults involves a scheduled sequence that starts with remission induction chemotherapy, followed by one or more cycles of intensification, prophylaxis of the central nervous system (CNS), and prolonged maintenance lasting 2 to 3 years. With this multiagent, multicycle approach, between 25% and 40% of adults with ALL are cured of their disease. Modifications to this general scheme, based on an appreciation of the high risk for disease relapse, have improved outcome for adult ALL patients who have the mature B-cell phenotype as well as those with the Philadelphia (Ph) chromosome. Age remains a significant limitation to treatment intensity as one third of adults with ALL are over the age of 60 years.

Most adult patients with ALL experience relapse of their disease. Successful treatment options for relapsed or refractory ALL are few.

HISTORICAL BACKGROUND

Only a few decades ago, ALL was an incurable disease in all but a small minority of patients. Progress in the treatment of pediatric ALL has been substantial. This is clearly illustrated in the results reported from a series of successive clinical protocols from St. Jude Children's Research Hospital.^{1,2,3} Sequential treatment modifications in successive cohorts of children show a steady improvement in survival outcome as shown in Figure 74.1A. The initial clinical trials from 1962 to 1969 introduced multiagent chemotherapy regimens into pediatric ALL therapy. This proved superior to single-agent therapy, but, still, few children experienced long-term survival. The next era, from 1967 to 1979, saw effective prevention of leukemia relapse in sanctuary sites in the CNS through the use of cranial irradiation and intrathecal chemotherapy. Intensification of post-remission therapy with administration of non-cross-resistant drugs was responsible for improving survival in subsequent cohorts. With further refinements, as well as general improvement in supportive care, approximately 85% of children with ALL are now cured of the disease (Chapter 76).

The success demonstrated in the pediatric ALL trials led to similar approaches in the treatment of adults. As shown in Figure 74.1B, outcomes in consecutive cohorts of adults with ALL treated by the United Kingdom Acute Lymphoblastic Leukemia (UKALL) collaborative study group gradually improved as treatment was intensified and extended. Compared with the success in treating childhood ALL, however, the degree of improvement was only modest. The British Medical Research Council initiated the UKALL trials in 1971.⁴ The first trial, UKALL I, evaluated CNS prophylaxis but only enrolled 16 adults. Subsequent trials examined both the addition of active agents and more sustained intensive post-remission therapy, and participation of adult patients progressively expanded. Survival for adults with ALL was still only 20% at the

time the UKALL IX trial opened for patient accrual in 1980. It was the first trial in the series to enroll adults separately from children. UKALL IX and the subsequent trial, UKALL XA, saw further, although minor, incremental improvement in the survival rate but provided important systematic analyses of prognostic indicators based on clinical, immunophenotypic, and cytogenetic characteristics.⁵ The subsequent study, UKALL XII/ECOG 2993, was the largest treatment study of newly diagnosed ALL in adults. It compared post-remission chemotherapy with autologous or related donor transplant. The complete remission (CR) rate was 90% in the 1,646 Philadelphia chromosome negative patients; overall survival at 5 years was 43% and 39% if all 1,913 eligible patients were included.⁶ Patients up to age 50 were eligible for allogeneic hematopoietic stem cell transplantation (HSCT). Survival at 5 years was 54% for all Philadelphia chromosome-negative patients with a donor, versus 44% for those without ($P = 0.007$) and 63% versus 52% for standard risk patients ($P = 0.02$). There was no benefit to allogeneic transplant for high-risk Philadelphia chromosome-negative patients. Patients without a donor who underwent autologous transplant did no better than those who received chemotherapy alone. These series of studies, along with other national cooperative group studies have led to remarkably similar long-term survival rates among adults who receive chemotherapy without transplant. These outcomes are distinctly inferior to those achieved in the pediatric age group.^{7, 8, 9} and ¹⁰

PATHOPHYSIOLOGY

The cause of ALL is essentially unknown, and few clues can be derived from epidemiologic studies. The molecular pathogenesis of ALL is reviewed in Chapter 72. Points relevant to adult ALL concerning these issues are briefly highlighted here.

Epidemiology

The overall age-adjusted incidence of ALL in the United States based on the most recent National Cancer Institute (NCI) report (1975 to 2009) is 1.34 in 100,000.¹¹ The incidence of ALL in blacks is significantly less than in whites, 0.81 versus 1.34. There is a slight male predominance with a male to female ratio of 1.56:1.14. The majority of the approximately 6,000 new cases each year in the United States are diagnosed in persons younger than 20-years old with a peak between the ages of 2 and 5 years; the median age at diagnosis was 14 years in the NCI SEER Cancer Statistic Review between 2005 and 2009.¹¹ The incidence decreases sharply thereafter, a trend that continues through adolescence and adulthood until after age 50, when the incidence again starts to rise steadily (Fig. 74.2). Geographic differences in the incidence of ALL are reflected by higher rates in North America and Europe and lower rates in African and Asian populations.¹²

Etiology

The cause of ALL in adults is largely unknown.¹³ Inherited factors and genetic predisposition syndromes are more relevant to childhood ALL. Survivors of the nuclear fallout from the atomic bombing in Hiroshima and Nagasaki have an overall relative risk of 9.1 for ALL, greater among those exposed in childhood, with the peak incidence occurring 6 to 7 years after radiation exposure.¹⁴ Somewhat more relevant to adult ALL is the association between occupational exposure to low-dose ionizing radiation among nuclear workers in the United States and Europe and a slightly increased risk for leukemia, although findings were inconsistent across populations.^{15, 16 and 17}

Among chemical environmental exposures, high-level benzene exposure that occurred before contemporary occupational safety standards is generally accepted as a cause of bone marrow aplasia, chromosome damage, and leukemia.^{18,19} Cigarette smoking was linked to a small increase in risk for ALL among persons older than 60 years in one report.²⁰ Secondary acute leukemias occurring after exposure to chemotherapeutic agents are usually myeloid, although rare cases of therapy-related ALL have been observed.^{21, 22} and ²³

Molecular Pathogenesis

Molecular abnormalities can be grouped according to the functional consequence of oncogenic mutation. Acquired constitutive activation of the ABL protein kinase by rearrangement with the BCR gene is an example of a mutation that confers a proliferative advantage.²⁴ The fusion gene is the consequence of the t(9;22)(q34;q11) balanced chromosomal translocation,

P.1558

which is the most common cytogenetic abnormality in adult ALL. ABL is a nonreceptor tyrosine protein kinase that enzymatically transfers phosphate molecules to substrate proteins, thereby activating downstream signal transduction pathways important in regulating cell growth and proliferation.²⁵ Other gene rearrangements result in loss- or gain-of-function mutations involving transcription factors that are important for normal hematopoietic development.²⁶ An example is the t(12;21) (p13;q22) chromosomal translocation, which juxtaposes the ETV6 (TEL) and RUNX1 (AML) genes.²⁷ Excluding numerical aberrations, ETV6-RUNX1 is the most frequent cytogenetic abnormality in childhood ALL, although it is uncommon in adults. Another general mechanism of cancer formation involves loss or inactivation of tumor-suppressor genes, many of which have key regulatory functions in controlling cell cycle progression.²⁸ Examples are p16(CDKN2A) and p15(CDKN2B). Stock et al. investigated the incidence of cell cycle regulatory gene abnormalities in adult patients with de novo ALL treated by the Cancer and Leukemia Group B (CALGB) study group.²⁹ Deletions, microdeletions, and gene rearrangements involving p16(CDKN2A) and p16(CDKN2B) were common occurrences. Even more frequent was aberrant expression of RB1 and TP53, two other tumor-suppressor genes. Concurrent abnormalities involving two or more of these genes were found in one third of adult ALL patients.

FIGURE 74.2. Age-specific incidence rates of acute lymphoblastic leukemia (ALL) (dotted lines) and AML (solid lines) according to sex and race/ethnicity, SEER-17, 2001 to 2007. (With permission from Dores GM, Devesa SS, Curtis RE, et al. Acute leukemia incidence and patient survival among children and adults in the United States, 2001-2007. Blood 2012;119:34-43.)

Aberrant expression of NOTCH1 has also been linked to ALL leukemogenesis. NOTCH1 encodes a transmembrane receptor that regulates normal T-cell development. Upon proteolytic cleavage, NOTCH1 translocates to the nucleus and binds to a nuclear transcription factor, ultimately stimulating the transcription of target genes.³⁰ Although the association of a

previously described t(7;9)(q34;q34.3) translocation, which fuses part of NOTCH1 to the TCRB locus, is restricted to less than 1% of T-ALL, activating mutations of NOTCH1 that produce aberrant NOTCH1 signaling independently of t(7;9) have been reported in over 50% of human T-ALL.³¹ The exact mechanism for its role in leukemogenesis is not fully understood, although some evidence suggests that NOTCH contributes to TP53 suppression or nuclear factor-κβ pathway activation, promoting deregulated T-cell proliferation.^{32, 33 and 34}

CLINICAL FEATURES

Although the clinical presentation is variable and may develop insidiously, virtually all adults diagnosed with ALL present with symptoms of only a few weeks duration. The symptoms generally reflect bone marrow failure or involvement of extramedullary sites by leukemia (Table 74.1). Up to one-half of patients with ALL have fever or documented infections. One third have bleeding symptoms at diagnosis, which is less frequent than in patients presenting with acute myeloid leukemia. Severe hemorrhage is uncommon.³⁴ Fatigue, lethargy, dizziness, or even dyspnea and cardiac angina may reflect anemia in adults with ALL. Marrow expansion by

P.1559

leukemic blasts may produce bone pain and arthralgias, but marrow necrosis is much less frequently found in adults as compared with children who have ALL.³⁵ Approximately one half of adult patients have hepatomegaly, splenomegaly, or lymphadenopathy at diagnosis that can be appreciated on physical examination. Mediastinal masses are detected by chest radiographs or computed tomography scans primarily in patients with T-lineage ALL, who also frequently have pleural involvement and may complain of chest pain.³⁶ The fewer than 10% of ALL patients who have CNS involvement infrequently present with referable symptoms, such as headache, vomiting, neck stiffness, alteration in mental status, and focal neurologic abnormalities. Other sites of extramedullary involvement include testis, retina, and skin, although virtually any organ can be infiltrated by leukemic blast cells.

TABLE 74.1 CLINICAL FINDINGS AT DIAGNOSIS IN ADULTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA

Findings	Patients (%)
Male	59-63
Symptoms	
Fever/infection	3-56
Bleeding	33
Lymphadenopathy	40-57
Hepatomegaly	24-47
Splenomegaly	31-56
Mediastinal mass	10-15
Central nervous system leukemia	1-7

Retina	1.0
Skin	0.6
Tonsils	0.6
Testis	0.3

Data are based on collaborative trials reported by the CALGB,⁷ MRC,⁸ GIMEMA,⁹ and GMALL.¹⁰

LABORATORY FEATURES

In addition to a complete medical history and physical examination, patients with ALL should have a battery of diagnostic laboratory tests to confirm the diagnosis, subcategorize the patient's disease for prognostic classification, and plan for appropriate therapy (Table 74.2). These studies include a complete blood count with examination of the peripheral blood smear, electrolyte measurements, creatinine, hepatic enzymes, uric acid, calcium, and albumin. Therapy-related declines in anticoagulation factors, including fibrinogen, occur with L-asparaginase, a drug commonly used in the treatment of ALL, and baseline levels should therefore be obtained. A mediastinal mass may be detected with a chest radiograph. A lumbar puncture for examination of the CSF to assess for leukemic involvement should be performed if patients present with neurologic symptoms. A bone marrow examination is mandatory and should include a complete cytogenetic assessment and immunologic phenotyping. Morphologic, cytogenetic, and immunophenotypic characteristics of ALL are detailed in Chapter 73. This section emphasizes features pertinent to adults diagnosed with the disease.

Routine Laboratory Evaluation

Routine laboratory evaluation reveals that a substantial number of adult patients with ALL have normal or only modestly elevated white blood cell (WBC) counts at the time of diagnosis (Table 74.3). Hyperleukocytosis ($>100 \times 10^9/L$) occurs in approximately 15% of patients and may exceed $200 \times 10^9/L$. Some degree of anemia is present in the majority of adults. Approximately one third of patients have a platelet count less than $25 \times 10^9/L$, which is approximately the same proportion that present with bleeding symptoms. Circulating leukemic blasts may not be evident on examination of the peripheral smear in a significant number of patients. Coagulation parameters are typically normal, and disseminated intravascular coagulation is rarely observed.³⁷ Metabolic abnormalities, including hyperuricemia, can occur, especially in patients with rapidly dividing leukemia cells and high tumor burden.

TABLE 74.2 DIAGNOSTIC APPROACH FOR ADULT ACUTE LYMPHOBLASTIC LEUKEMIA

Medical history

Physical examination

Laboratory studies

Complete blood count, peripheral smear, coagulation studies, fibrinogen level, serum chemistry (renal and hepatic function, electrolytes, calcium, phosphate, uric acid, LDH), ABO and Rh blood group, HLA typing
Appropriate cultures in the setting of fever

Lumbar Puncture

A lumbar puncture is often performed at the time of diagnosis to examine the cerebrospinal fluid (CSF). CNS involvement is traditionally defined as greater than 5 WBC/ μ l of CSF with morphologically unequivocal leukemic blasts on the cytocentrifuged specimen.³⁸ Patients at risk for bleeding complications due to thrombocytopenia should be transfused to an adequate platelet count before the procedure. Whether to perform a lumbar puncture in patients with a high circulating blast count is controversial. This is due to concerns of iatrogenic "seeding" of the CNS with leukemic cells. Studies in pediatric ALL have shown that when the procedure is complicated by a traumatic tap, the finding of blast cells in the CSF occurs more frequently in children with higher presenting WBC count.³⁹ Among the patients who had traumatic lumbar punctures, those with leukemic blasts in the CSF were more likely to have subsequent CNS relapse.

P.1560

Bone Marrow Evaluation

All patients with ALL should undergo a bone marrow aspiration and core biopsy procedure. The specimens must be submitted for histologic, cytogenetic, and immunophenotypic analysis. Morphologically, the marrow space is usually densely packed with leukemic blasts, which account for greater than 90% of nucleated cells in many adult ALL patients. As a result, the marrow biopsy sections are generally hypercellular, and, in 7% of adult patients with ALL, the normal marrow is completely replaced by leukemic blasts. This may prevent a successful aspiration, and a touch imprint of the biopsy tissue then becomes useful in evaluating cytologic features. Although increased reticulin deposits are common, marrow fibrosis is rarely present.^{40,41}

Cytogenetics

Historically, poor chromosomal morphology in ALL made banding studies challenging, and karyotypic abnormalities were not reliably detected in early studies.⁴² The implementation of modern metaphase spreading, banding, and molecular cytogenetic techniques now reveals prognostically significant abnormal karyotypes in the majority of adult patients with

ALL.⁴³ These molecular techniques include fluorescent in situ hybridization using chromosome- and gene-specific probes for gene rearrangements that are difficult to identify, such as the t(12;21) chromosomal translocation.⁴⁴ Application of these sensitive methods has revealed, for instance, that the t(12;21) translocation is much less common in adults with ALL than in children.^{45,46} Other age-related differences include fewer occurrences of numerical chromosome abnormalities and a higher incidence of the Ph chromosome in adults (Table 74.4).

Because of the profound prognostic implication of the Ph chromosome, molecular testing for the BCR-ABL gene rearrangement should be performed for all patients diagnosed with ALL. The Ph chromosome was originally identified in a patient with chronic myeloid leukemia (CML), in whom the BCR and ABL genes juxtaposed within the so-called major breakpoint region.²⁴ This transcribes a 7-kb messenger RNA that is expressed as a 210-kd fusion protein, or p210BCR-ABL. In ALL, a variant breakpoint location, which results in the smaller p190BCR-ABL oncoprotein, is commonly found.⁴⁷ A polymerase chain reaction (PCR) -based laboratory test capable of detecting both the p210BCR-ABL and p190^{BCR-ABL} gene transcripts is now readily available to most clinicians and should always be performed in all newly diagnosed patients.

TABLE 74.4 CHROMOSOMAL ABNORMALITIES AT DIAGNOSIS IN ACUTE LYMPHOBLASTIC LEUKEMIA

Chromosomal Abnormalities	Gene(s)	Patients (%)	
		Adults	Children

t(8;22) (q24; q11)	<i>MYC-IGL</i>	Rare	
Immunophenotype			

The primary basis of initial treatment strategies for ALL depends on antigenic parameters, and, hence, all patients should have their leukemic blasts characterized by immunophenotypic analysis. By current World Health Organization classification, the majority of adult ALL cases involve the precursor lymphoid neoplasms.⁴⁸ Approximately 70% of cases are B-cell ALL, and 25% are T-cell ALL. The remaining 5% are a mature B-cell neoplasm, Burkitt leukemia.⁴⁹ Compared with adults, children less often present with T-lineage ALL. There is also a slightly higher incidence of myeloid antigen expression in adult ALL patients, with reported incidences ranging from 15% to 54% compared with 4% to 35% in children.^{50,51} Commonly detected myeloid antigens include CD13, CD15, and CD33.

Rare cases with co-expression of multiple lymphoid and myeloid antigens may be considered acute biphenotypic leukemia according to criteria suggested by a European group.⁵² The clinical course appears to be poor; however, there is no uniform consensus on whether to manage these cases as acute myeloid or lymphoid leukemia.⁵³ The Royal Marsden Hospital group identified 25 acute biphenotypic leukemia patients whom they treated over a 7-year period.^{54,55} The patients variably underwent remission induction with ALL-like regimens, AML-like regimens, or hybrid regimens containing elements of both with equal success, except for an excess of treatment-related mortality with the combined regimen. Overall survival was 39.4% at 2 years. They observed a high incidence of the Ph chromosome (41%) that partially accounted for the unfavorable outcome and emphasized the importance of aggressive risk-adapted therapy for these cases.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of ALL in adult patients is rarely difficult. Most commonly, patients are diagnosed after an acute symptomatic presentation. ALL can be distinguished from the lymphocytosis, lymphadenopathy, and hepatosplenomegaly associated with viral infections and from lymphoma by the presence of leukemic blasts in peripheral blood or bone marrow specimens. This is followed by definitive diagnosis with immunophenotypic studies.

Difficulty may arise when patients present with an antecedent or overlapping period of pancytopenia before developing ALL, as has been sporadically reported.^{56, 57, 58} and ⁵⁹ It may be impossible to distinguish "aleukemic" pancytopenic ALL from aplastic anemia based on examination of the peripheral blood smear. Bone marrow evaluation and vigilant observation of the patient's clinical course are mandatory in these instances.

Patients in lymphoid blast crisis of CML are usually initially diagnosed in the chronic phase and later progress to acute leukemia. Characterization of the breakpoint region for Philadelphia-positive (Ph+) ALL patients is of no use in distinguishing de novo ALL from CML lymphoid blast crisis, as both p190BCR-ABL and p210BCR-ABL are found in even distribution in patients with Ph+ ALL.⁶⁰

P.1561

PROGNOSTIC FACTORS

Many clinical and biologic characteristics previously identified as prognostic factors for adult patients with ALL have lost predictive value as therapy has evolved and become more intensive. In contrast, age, WBC count at presentation, and immunophenotype remain strong predictors of disease-free and overall survival for Ph-negative patients.⁶¹ (Table 74.5). More sophisticated assessment of the response to therapy, such as molecular detection of minimal residual disease (MRD), is becoming increasingly important in the management of adult ALL patients. The German Multicenter Study Group for Adult ALL (GMALL) prospectively assessed MRD evaluation in two consecutive trials.⁶² The complete response rate was 89% after induction, but the molecular CR rate was only 70% in 580 evaluable patients. After consolidation molecular CR was highly predictive of continuous complete remission (CCR; 74% vs. 35%; $P < 0.0001$) and of overall survival (80% vs. 42%; $P = 0.0001$) compared with patients with molecular persistence. These results justify the routine assessment of MRD in the treatment of adult ALL and define a new high-risk group based on molecular persistence of disease.⁶³

Clinical Features

Advanced age and high WBC count at the time of diagnosis have held up as significant adverse prognostic factors in all modern adult ALL multicenter collaborative trials.^{5, 7, 8} and ^{9,61,64 65, 66, 67, 68, 69, 70, 71, 72} and ⁷³ Both advanced age and high WBC count were inversely correlated with more frequent occurrences of CR, longer duration of CR, or better overall survival in either the majority or all of the collaborative studies. Advanced age was variably defined as greater than 30 or 35 years. When included in multivariate analysis as a continuous variable, increasing age predicted worse outcome across the entire age range, making it difficult to choose a cut-off separating standard-risk from high-risk patients. The cut-off for

high WBC count was either $30 \times 10^9/L$ or $50 \times 10^9/L$. In the trial conducted by the CALGB study group, patients with advanced age (30 to 59 years) and high WBC count had an overall survival of 39% and 34%, respectively, compared with 69% and 59% for patients without these adverse prognostic factors.⁷

TABLE 74.5 PROGNOSTIC FACTORS FOR REMISSION DURATION IN ADULTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA (ALL)

Patient Features	Prognostic Factor
Age (y)	
<25, <35	Favorable
>35, >55, >70	Unfavorable
White blood cell count ($\times 10^9/L$)	
<30	Favorable
≥ 30 (≥ 100 for T cell)	Unfavorable

Laboratory Features

Immunophenotype

The major immunophenotypic subgroup with prognostic value and therapeutic importance is the mature B-cell neoplasm, Burkitt leukemia. Burkitt leukemia is characterized by strong expression of surface immunoglobulin in addition to other markers common to B-lineage ALL, including CD10, CD19, CD20, and CD22.⁵² These patients respond poorly to standard ALL therapy, and outcome was dismal until brief, dose-intensified treatment programs were established as standard therapy.^{74,75,76} The substantial improvement in survival that resulted has negated the adverse prognostic value of this feature if patients are optimally managed.

T-cell ALL is another formerly unfavorable prognostic subgroup that, due to changes in treatment approach, is no longer a poor risk feature.⁷⁷ In fact, with many modern treatment programs, the T-cell immunophenotype has become prognostically favorable.^{7,68,78} High WBC count does not adversely affect survival in T-cell ALL unless the WBC is $>100 \times 10^9/L$.^{66,67,79} In addition, more detailed examination of prospective immunophenotypic data collected by the CALGB identified a subset characterized by expression of fewer than three T-cell markers that had an unfavorable prognosis.⁸⁰ Leukemic blasts from these patients also infrequently expressed mature T-cell surface markers such as CD1a, CD2, CD3, CD4, and CD8, and, hence, would be consistent with the "early" T-cell ALL immunophenotype also reported to be unfavorable by the GMALL.^{81,82} The distinction between early T-ALL (sCD3-, CD1a-), thymic T-ALL (sCD3-/+, CD1a+), and mature T-ALL (sCD3+, CD1a-) described by GMALL may serve as an example of a clinically significant, risk-adapted treatment stratification.⁸³

Other immunophenotypic markers have variably been shown to have prognostic value but are less well established. CD34 is expressed more frequently in adults with B-lineage ALL and was reported to affect outcome by the CALGB adversely.⁸⁰ However, CD34 expression overlapped with both a high WBC and the presence of the Ph chromosome, and findings from other smaller series have yielded conflicting results.^{84, 85, 86, 87} and ⁸⁸ Expression of myeloid antigen markers was slightly more frequent in B-lineage ALL than in T-lineage ALL but had no prognostic value in either instance.^{64, 80, 89}

Cytogenetics

Unfavorable cytogenetic abnormalities in adult ALL include t(9;22) [BCR-ABL], observed in up to 30% of cases, t(4;11)(q21;q23)[MLL-AFF1], rare in adult ALL, t(1;19)(q23;p13)[TCF3-PBX1], also rare, and a hypodiploid karyotype, seen in 5% to 6%. Translocations involving chromosomal band 14q11 and abnormalities of the short arm of chromosome 12, including t(12;21)[ETV6-RUNX1], observed in 3% of cases, are favorable cytogenetic abnormalities. Results from collaborative studies providing karyotypic data generally indicate disease-free survival rates less than 25% for P.1562

patients with unfavorable abnormalities, as opposed to greater than 75% for those with favorable cytogenetic findings.^{60,65,90, 91, 92, 93} and ⁹⁴ Additional reports from single institutions have provided similar outcome data.^{95,96}

Cytogenetic findings commonly identified in adult ALL with an intermediate prognosis include normal karyotype, hyperdiploidy, and abnormalities at 6q or 9p. The t(8;14) (q24;q32)[MYC-IGH] and other MYC gene rearrangements are associated with the Burkitt leukemia subtype and are not prognostically unfavorable markers with optimal treatment.

In the UKALL XII/ECOG 2993 trial, 41 patients (5%), without an established translocation, had a complex karyotype with 5 or more chromosomal abnormalities. Four patients were primary induction failures and 19 of 37 CR patients relapsed. All but 3 of these 19 patients relapsed within 2 years of diagnosis and 17 of the 19 died. EFS and OS were significantly inferior in this group. These results established complex karyotype as a poor prognostic indicator.⁹⁷

Adult Ph-positive patients achieve CR rates comparable to Ph-negative ALL patients, but the remissions are short and survival poor with standard therapy. The most frequent translocation in adults involving the MLL gene, located at chromosome band 11q23, is t(4;11) and is also associated with poor survival.⁹⁴ The t(1;19) translocation results in the TCF3-PBX gene rearrangement, and patients with this abnormality were found to have a 3-year disease-free survival rate of only 20%.⁹² Patients with hypodiploidy ranging from 30 to 39 chromosomes have a disease-free interval of only 2 to 4 months from the start of treatment.⁹²

Deletions and translocations involving 12p include the ETV6-RUNX1 gene rearrangement. ETV6 gene rearrangements are much less frequent in adults than in children but are prognostically favorable in both. Translocations involving the TCR- α/β

loci at chromosome 14q11 most frequently result in rearrangement with the TLX1 (HOX1) gene at 10q24.⁹⁸ Adult ALL patients with t(10;14)(q24;q11) experience long survival, but this may reflect an association with T-cell ALL subtypes.^{65,92}

Oncogenes

The absence of chromosomal abnormalities does not preclude the less conspicuous presence of aberrantly expressed oncogenes that promote leukemogenesis. Oligonucleotide microarrays, and more recently, next-generation sequencing technologies have led to a revolution in analysis of the leukemia genome and will undoubtedly add to cytogenetic profiling in the risk stratification of ALL. These are discussed in detail in Chapter 72. Using oligonucleotide microarrays, Ferrando et al. identified T-cell oncogenes—TLX1, TLX3, TAL1, and LYL1—that may have prognostic relevance in T-cell ALL.⁹⁹ These genes normally function as a homeobox gene (TLX1) or encode developmentally essential transcription factors (TAL1, LYL1) in normal thymocyte maturation. Their dysregulated expression is thought to foster leukemogenicity and can be detected as a signature genetic profile, which not only has the ability to provide insight into their pathogenetic heterogeneity, but also render important prognostic information. Overexpression of TLX1, present in approximately 30% of adult T-ALL cases, has been associated with a favorable prognosis, and in one study, demonstrated a leukemia-specific survival rate of 88% in TLX1-positive patients compared with 56% in TLX1-negative patients at a median follow-up of 4.7 years.¹⁰⁰ In contrast, the overexpression of TAL1 or LYL1 has been linked to poor response to treatment, and the predictive value of TLX3, another homeobox factor related to TLX1, is conflicting.^{101,102}

Another mechanism for ALL leukemogenesis is the constitutive activation of tyrosine kinase via the NUP214-ABL1 fusion episome. The juxtaposition of the two oncogenes leads to the familiar amplification of ABL1 on the chromosome band 9q34. However, the NUP214-ABL1 fusion escapes detection by conventional cytogenetics by virtue of its extrachromosomal position and requires molecular analysis for delineation. The fusion episome has been detected in approximately 6% of individuals with T-ALL.¹⁰³ Because of its sensitivity to abl tyrosine kinase inhibitors, the subset of T-ALL patients with this molecular feature is predicted to benefit from early identification.¹⁰⁴ The known presence of TLX1 or TLX3 may also merit exploration for the NUP214-ABL1 fusion given their tendency for co-expression.¹⁰⁵

Response to Therapy

Response to therapy can be assessed by determination of time to attainment of CR, quantitation of early leukemic blast clearance, or detection of MRD. These measurements provide a direct assessment of biologic susceptibility to antileukemic agents, and, as such, prognostic factors based on them have inherently high heuristic power. In addition, prospective evaluation of their utility as predictors of outcome in clinical trials has established that they also have high explanatory power. However, until recently, virtually all of the clinical studies measuring these outcomes have been performed in pediatric ALL. Assessments of response to therapy have become crucial prognostic factors in adult ALL, but remain underutilized in clinical practice. These should aid in refining prognostic models with the goal of improving outcome with risk-adapted therapy.

Early Complete Remission

Failure to achieve CR within 4 weeks of starting treatment or after one course of induction chemotherapy has been considered an independent unfavorable prognostic factor, confirmed in most adult ALL studies.^{7,73} An exception is the international, multicenter UKALL XII/ECOG E2993 trial, which could not confirm its importance in its 1,500 patient cohort.⁶¹ When significant, early CR held predictive value for standard ALL programs as well as for newer, dose-intensified treatment protocols.^{5,67,78,106,107,108} Patients requiring greater than 4 weeks to achieve CR were at least twice as likely to relapse, depending on the study. In one study, patients who did not achieve CR by week 4 of induction had a 5-year disease-free survival of 0% as compared with 46% for the remainder of the complete responders.⁷⁸ In this study, the number of weeks required to achieve CR was only marginally worse than the Ph chromosome as an unfavorable variable.

Early Leukemic Blast Clearance

Evaluation for persistence of leukemic blasts at even earlier time-points, between days 7 and 21 of induction, has been firmly established as an important prognostic indicator for outcome in pediatric ALL.^{109, 110} and ¹¹¹ Early persistence of leukemic blasts at 7 days after starting induction is thought to represent corticosteroid resistance.¹¹² In contrast, persistence at time-points after 21 days is considered a reflection of cytotoxic chemotherapy resistance. Numerous prospective studies in pediatric ALL have shown that a substantial unfavorable influence on outcome is associated with the morphologic detection of blood or marrow leukemic blasts persisting during induction therapy at day 7, day 21, or at other time-points in between. Persistence of leukemia was usually defined as the finding of greater than 1×10^9 /L blast cells in a peripheral blood sample or leukemic blasts greater than 5% of normal cells in a marrow specimen.

Although pediatric protocols already incorporate early treatment response assessment by a day 7 or day 14 bone marrow examination into risk classification, similar data in adult ALL are limited.¹¹³ Results from the few reported studies agree with findings from the pediatric experience. Sebban et al. prospectively evaluated persistence of marrow blasts, defined as greater than 5% of nucleated cells, at day 15 of induction for influence on outcome.¹⁰⁷ Among 437 adult ALL patients, one third were found

P.1563

to have persistent blast cells. These patients were less likely to achieve CR after 4 weeks of therapy. Even among only the patients who achieved CR within 4 weeks, an otherwise favorable feature, those who had persistent blasts at day 15 fared significantly worse. Among all complete remitters, the 5-year disease-free survival was 34% for those who cleared marrow blasts at day 15, compared with 19% for those who did not. Annino et al. and the Italian collaborative study group evaluated the early corticosteroid response by giving a 7-day course of prednisone immediately before induction.⁹ The pre-induction response was previously shown to have strong prognostic value in pediatric ALL.^{114,115} In the adult ALL study, prednisone response was defined by reduction of peripheral blood blasts to less than or equal to $1 \times 10^9/L$. Lack of a prednisone response was found to affect overall survival negatively, as it did in the pediatric ALL studies, and, among CR patients, it also adversely influenced remission duration.

Minimal Residual Disease

MRD refers to the post-remission persistence of leukemia that cannot be detected by histomorphologic assessment. Immunophenotypic, cytogenetic, or molecular techniques can be used to detect MRD.¹¹⁶ Samples from peripheral blood are generally one log₁₀ less sensitive than bone marrow, perhaps as post-treatment BCR-ABL transcripts from peripheral blood clear more rapidly,¹¹⁷ but may have comparable sensitivity in T-lineage ALL.^{118,119,120} Fluorescence in situ hybridization is better than conventional banding analysis for detecting chromosomal translocations and numerical abnormalities, but both techniques are limited by low sensitivity.^{121, 122, 123} and ¹²⁴ Flow cytometry, used in four or more color combinations and taking advantage of new reagents, detects aberrant antigen expression on leukemic cells and can unambiguously distinguish one leukemic blast among more than 104 normal cells in 90% of all patients.^{125,126} This level of sensitivity is sufficient for prognostically significant MRD detection.¹²⁷ Additionally, flow cytometry is rapid, reliable, and allows accurate quantitation, and the technical requirements for the assay are already in place at most centers, making it an attractive diagnostic tool. The most sensitive assays for detecting MRD, however, are based on PCR techniques, which can detect one leukemic blast in up to 106 normal cells. PCR targets using fusion gene transcripts such as BCR-ABL, ETV6-RUNX1, AFF1-MLL, and E2A-PBX are relatively standardized, but each alone can only be used for patient subsets.^{128, 129} and ¹³⁰ PCR targets based on immunoglobulin and T-cell receptor gene rearrangements can be used to detect MRD in theoretically all patients, but lose sensitivity if consensus rather than patient-specific primers are used.^{128,131} On the other hand, generating patient allele-specific primers requires DNA sequencing capability. Although a number of clinical studies have suggested the prognostic significance of threshold values of MRD,^{132,133} early experience with accurate quantitation of leukemia-specific residual disease with the PCR assay was fraught with technical challenges, and standardization of assay sensitivity among testing facilities was of major concern.¹³⁰ Where available, however, real-time quantitative PCR technology utilizing newer automated methods has proven to be technically simple, yielding precise and consistent quantitation of residual leukemic clones, and is gaining widespread acceptance.^{134,135} Information from pediatric ALL trials using PCR and flow cytometry in tandem may help determine more definitively the role of each for evaluating MRD.¹³⁶

The prognostic utility of MRD detection was first described in studies conducted on children with ALL.^{109,128,137} Three of the pediatric studies stand out for having large patient numbers, inclusion of both B- and T-lineage ALL, and for including patients with poor risk features.^{127,132,133} The European studies were multicentered and used PCR detection of patient-specific antigen receptor gene rearrangement, whereas Coustan-Smith et al. used multicolor flow cytometry in an unselected patient cohort treated at the St. Jude Children's Research Hospital. MRD was determined at the end of induction and at various time-points thereafter. The testing was technically challenging, as 1,254 of 1,914 (66%) combined patients treated during the study period did not have suitable PCR targets, serial PCR performed, or an immunophenotype suitable for MRD assessment. Nonetheless, all three studies demonstrated an unfavorable influence of persistent MRD on relapse-free survival. By multivariate analyses in the St. Jude study, sequential detection of persistent MRD remained a poor prognostic marker after controlling for age, WBC count, and adverse cytogenetics including the Ph chromosome and MLL gene rearrangement.¹²⁷ Detection of MRD during maintenance therapy tended to have the strongest positive predictive value for relapse. Conversely, absence of MRD at the end of induction negated the unfavorable influence of persistent leukemic blasts at day 7 as a prognostic factor.

Studies assessing the predictive value of MRD in adult ALL have generally echoed findings of pediatric studies.^{138, 139} and¹⁴⁰ Mortuza et al. reported results for 66 Ph-negative adult B-lineage ALL patients treated at a single institution, for whom MRD was assessed with PCR using consensus immunoglobulin heavy chain gene primers.¹³⁸ Detection of residual leukemia at the 10⁻³ level, the limit of sensitivity of the assay, independently correlated with inferior disease-free survival when measured 3 to 5 months after induction therapy. The kinetics of MRD clearance has also gained much attention with respect to predicting relapse risk. Among the 196 standard-risk ALL patients monitored by quantitative PCR during their first year of treatment in the German Multicenter Acute Lymphoblastic Leukemia (GMALL) study, the 3-year relapse rate was 0% if MRD declined rapidly to lower than 10⁻⁴ at day 11, or below detection threshold at day 24, compared with a relapse rate of 94% if the MRD was at a level of 10⁻⁴ or higher until week 16.¹⁴¹ Based on these results, they defined three risk groups based on MRD assessment in this otherwise homogeneous standard risk group. Scheuring et al. suggested that the magnitude and rate of BCR-ABL increase, as well as the absolute number of transcripts, could predict relapse within 2 months.¹⁴² Another large cooperative group study reported that a 2-log reduction of MRD after induction, and a greater than 3-log reduction after consolidation therapy were associated with a 2-year actuarial probability of overall, disease-free, and relapse-free survival of 48%, 27%, and 38%, respectively, compared with 0% survival with smaller reductions.¹⁴³ The increasingly recognized prognostic significance of MRD has prompted a large cooperative group study to evaluate prospectively the utility of MRD in selecting patients for stem cell transplantation in first CR as a model for risk-adapted treatment strategy.¹⁴⁴

PRIMARY THERAPY

Current management strategies for adult patients with ALL require a careful assessment of relapse risk at the time treatment is initiated. Most adult ALL patients have the precursor B-cell or T-cell subtype and can be managed with established treatment programs that start with remission induction, followed by blocks of intensification, CNS relapse prophylaxis, and prolonged maintenance therapy. With modern multiagent regimens, up to 90% of patients achieve CR, and 25% to 40% can be cured. The disease-free survival figure obviously needs improvement, and, hence, therapy should be tailored for patients who have an adverse prognostic profile. Risk-adapted therapy has proven remarkably effective for certain poor-risk groups, such as brief dose-intensive protocols for adult patients with Burkitt leukemia. Other patient groups known to have high risk for disease relapse should undergo allogeneic stem cell transplantation

P.1564

(SCT) in first remission, given an available donor and eligibility status. Considerable clinical data suggest that this strategy has been effective, particularly with Ph+ patients. The ECOG/MRCXII trial also demonstrated the benefit of transplant in standard risk patients under age 50. Elderly ALL patients pose special treatment considerations that are discussed in this chapter. General issues relating to supportive care of the patient with leukemia are discussed in Chapter 69.

General Principles

On presentation, certain pre-treatment considerations should be addressed before initiating therapy. Leukemia therapy is guided by an estimate of relapse risk, although there is no formal risk assessment tool for adult ALL. In reviewing the list of agents used to induce remission and protect against relapse, it can be appreciated that the individual superiority of one drug over another in many instances has not been established. Complicating management decisions are similarly conflicting outcome results for SCT in first remission for high-risk patients, although the general consensus is that allogeneic SCT from a sibling donor is best therapy.

Pre-treatment Considerations

Attention should be paid to metabolic, infectious, and hematologic issues before starting leukemia-specific therapy. Hyperuricemia, hyperphosphatemia, and secondary hypocalcemia may be pronounced with high leukemic cell burden and require intravenous hydration, alkalinization, and administration of allopurinol. In addition to myelosuppression during intensive treatment blocks, ALL therapy suppresses cell-mediated immunity, and some protocols have provisions for prophylaxis against herpes simplex virus and *Pneumocystis jiroveci* infections.¹⁰⁶ The clinical consequences of hyperleukocytosis ($\geq 100 \times 10^9/L$) in adult ALL patients are not well understood. Patients with MLL gene rearrangements and Burkitt leukemia are at higher risk for hyperleukocytosis at presentation.⁶⁰ In children, pronounced hyperleukocytosis involving lymphoid blasts are better tolerated than myeloid blasts, as reflected by fewer complications attributable to leukostasis or hemorrhage.¹⁴⁵ In one series, leukapheresis for pediatric ALL patients having blast counts greater than or equal to $2 \times 10^9/L$ led to outcomes equivalent to those for children who did not have this degree of hyperleukocytosis.¹⁴⁶ A similar policy is reasonable for adult ALL patients. Alternatively, immediate administration of prednisone or vincristine can rapidly reduce the circulating blast count. In an adult series, the WBC count dropped from greater than $100 \times 10^9/L$ to less

than 1×10^9 in 39% of patients given a 7-day course of prednisone immediately preceding remission induction chemotherapy.⁹

Risk Assessment Model

There are no useful clinical staging or prognostic scoring systems for adult ALL patients as there are for other hematologic malignancies, and there are no agreed-on uniform risk criteria as there are for pediatric ALL.^{147, 148, 149, 150} and ¹⁵¹ A prognostic model based on CALGB data suggested an additive effect of multiple adverse prognostic features on outcome, and, conversely, those without any poor prognostic factors did exceptionally well with few relapses.⁷ Others have described similar analyses.^{66,78} Based on these models and the current clinical evidence, a general framework for risk assessment may consider placing adults with ALL in different risk prognostic categories (Fig. 74.3). All patients with at least one established poor prognosis factor based on clinical, immunophenotypic, cytogenetic, or molecular features and response to induction therapy should be considered at high risk for relapse. Adding response to therapy, based on MRD detection, as a risk criterion for adapting therapy has been validated in several adult studies. In two consecutive GMALL trials (GMALL 06/99 and 07/03) involving 1,648 patients, prospective MRD evaluation was used at several time-points. MRD absence after consolidation therapy was highly predictive of continuous complete remission after 5 years (74% vs. 35%) as well as OS (80% vs. 42%). A multivariate analysis of prognostic factors, including age, immunophenotype, risk group, and MRD status after consolidation, found that only the MRD status was predictive of CCR after 5 years with a hazard ratio of 4.5 ($P < 0.0001$). Both age, with a hazard ratio of 1.3 ($P = 0.0007$), and MRD status, with a hazard ratio of 4.0 ($P < 0.0001$), influenced overall survival.⁶²

In addition, patients with persistent MRD undergoing HSCT in first CR experienced higher rates of CCR than those without HSCT (66% vs. 11%), which led to better survival (54% vs. 32%). The Northern Italian Study Group also reported an advantage for patients positive for MRD treated with HSCT ($n = 36$) compared with non-HSCT ($n = 18$) with approximately 50% compared with 10% long-term disease-free survival.¹⁵²

Remission Induction

The goal of remission induction therapy is hematologic complete remission (CR), as defined by the eradication of morphologically detectable leukemia cells in blood and bone marrow and the return of normal hematopoiesis. The importance of achieving CR after induction was highlighted in a study that demonstrated a 5-year overall survival rate of 45% in CR patients compared with 5% in patients who did not achieve CR.⁶¹ Remission induction chemotherapy for adults with ALL is most commonly built around a backbone of vincristine and prednisone. Remission induction with these two drugs in combination produces CR in approximately one half of patients with de novo ALL. The CR rate improves to 70% to 85% when an anthracycline is added, which was proven in a landmark CALGB trial to be superior to vincristine and prednisone alone.¹⁵³ Induction failures are evenly divided between refractory disease and toxicity-related mortality.^{5,7,9,66,78} The efficacy of various anthracyclines in adults, including daunorubicin, doxorubicin, zorubicin, and mitoxantrone, has been similar.^{77,154, 155} and ¹⁵⁶

Many alterations to the basic induction regimen have been evaluated.^{82,157, 158, 159} and ¹⁶⁰ A critical evaluation of the individual merits of these modifications is challenging. Improvement to CR rates that already exceed 80% would be difficult to detect at a satisfactory level of significance. Modern treatment protocols are complex, and it is difficult to attribute outcome results to any one component or to make comparisons of significant findings between any two trials. For example, some modern induction protocols also incorporate L-asparaginase, cyclophosphamide, or both, although neither has been proven by controlled trials to be beneficial in adult ALL when added to standard three-drug induction regimens. The one randomized trial with L-asparaginase found no improvement in frequency or duration of CR with the addition of L-asparaginase to doxorubicin, vincristine, and prednisone during induction.¹⁶¹ Nonetheless, L-asparaginase has a mechanism of action that is close to being ALL-specific, causes minimal myelosuppression, and has been shown to be efficacious in pediatric ALL.¹⁶² An Italian Gruppo Italiano Malattie Ematologiche dell' Adulto (GIMEMA) trial randomized adult ALL patients to induction with daunorubicin, vincristine, prednisone, and L-asparaginase with or without cyclophosphamide.⁹ The rate and durability of remission, as well as overall survival, did not differ between the two randomized treatment groups or for any subtype analyzed. In contrast, other studies have suggested a benefit with the inclusion of cyclophosphamide during induction, especially for patients with T-cell ALL, and, conversely, worse outcome with its omission.^{7,163}

Dose-intensified anthracycline and high-dose cytarabine induction regimens have been evaluated as alternatives to traditional

induction protocols. These treatment programs were intended to improve outcome by inducing rapid reduction of leukemic cell mass to achieve early CR.¹⁶⁴ Todeschini et al. generated considerable interest with reports from two sequential trials showing that dose escalation of daunorubicin to 225 mg/m² and, subsequently, to 270 mg/m² significantly improved disease-free survival.^{165, 166} and ¹⁶⁷ Multicenter implementation of this protocol by the GIMEMA group, however, failed to reproduce the earlier experience based on an interim analysis of 460 of 501 total patients enrolled.¹⁶⁸ Weiss et al. investigated a different approach using high-dose mitoxantrone given with high-dose cytarabine during induction.^{169,170} The results from their expanded randomized trial at seven study sites in the United States demonstrated improved remission (83% vs. 70%) and 5-year overall survival rates (35% vs.

P.1566

22%), as well as less resistance and more activity in Ph+ disease, compared with a standard regimen,¹⁷¹ establishing the activity of the combination of high-dose cytarabine and mitoxantrone in ALL. The standard L-20 regimen (vincristine, prednisone, cyclophosphamide, doxorubicin) used in this study did not use asparaginase during induction, and the results of the standard treatment arm are somewhat inferior to other contemporary regimens.

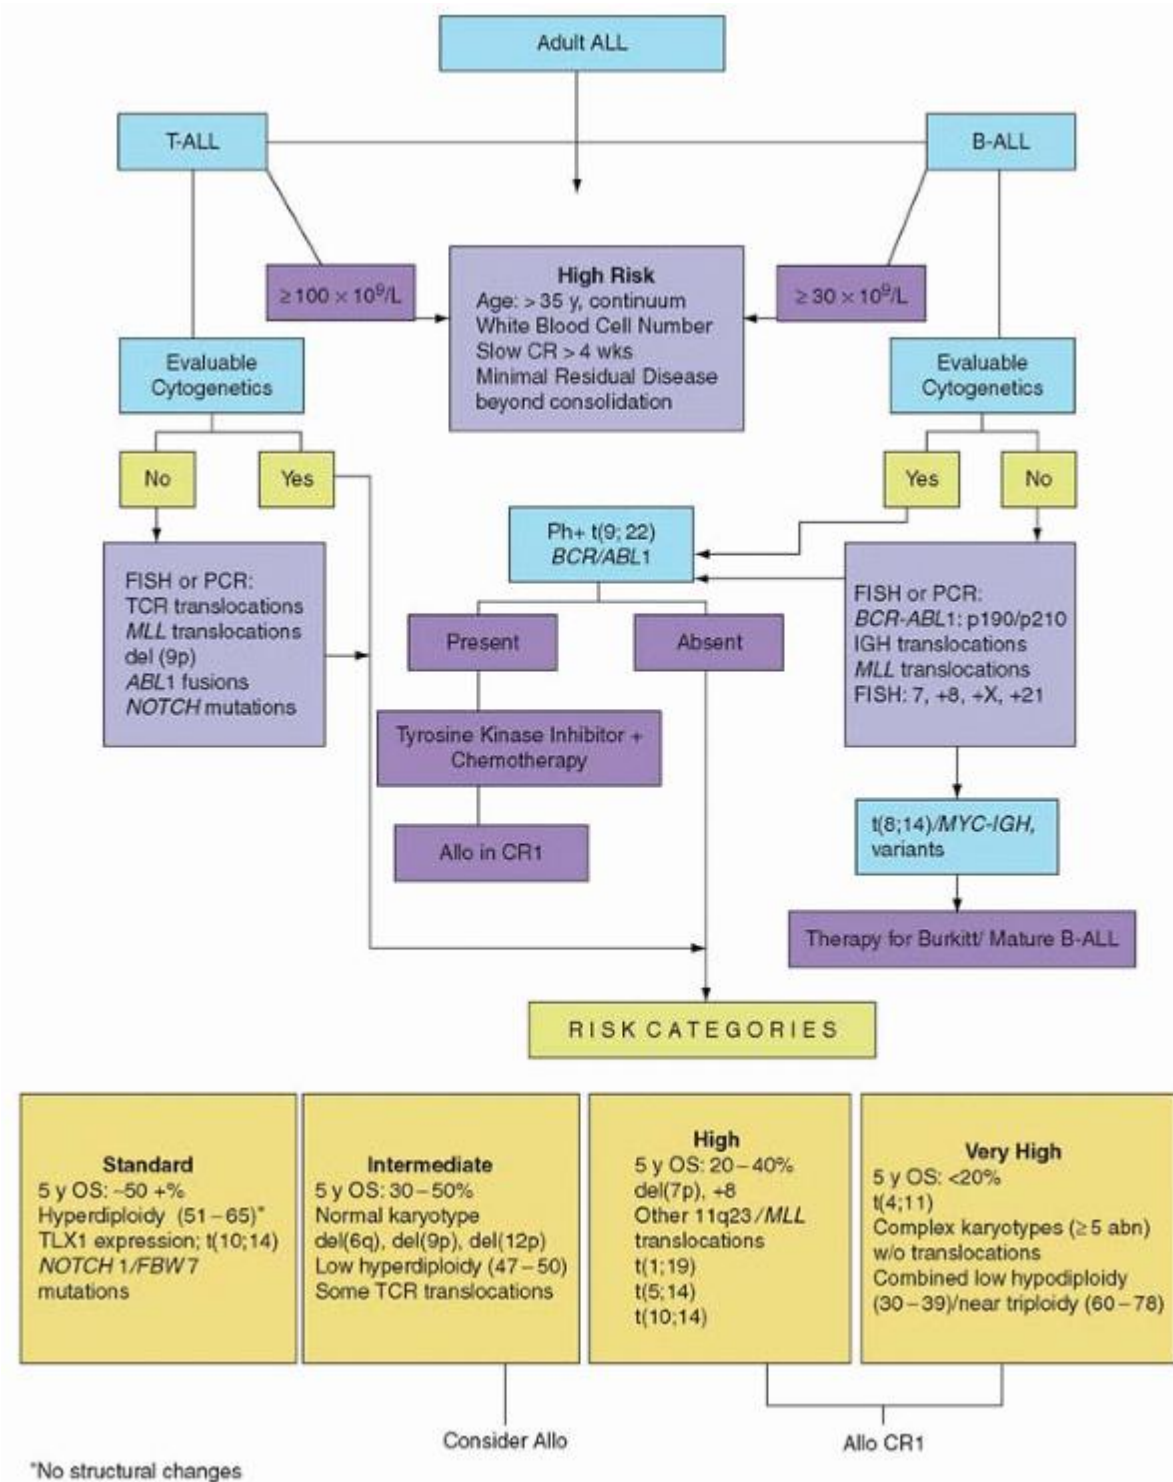

FIGURE 74.3. Risk assessment for adult acute lymphoblastic leukemia (ALL). Clinical, immunophenotypic, and cytogenetic features may be combined with the initial response criteria to classify patients into risk categories (Adapted from Pullarkat V, Slovak ML, Kopecky KJ, et al. Impact of cytogenetics on the outcome of adult acute lymphoblastic leukemia: results of Southwest Oncology Group 9400 study. Blood 2008;111:2563-2572.)

Dexamethasone has been substituted for prednisone in standard-risk pediatric patients in a large randomized trial.¹⁷² The use of dexamethasone achieved a 34% reduction in relapse risk as well as a significant decrease in isolated CNS relapse. However, dexamethasone is associated with an increased risk of avascular necrosis in children. Current pediatric protocols

use prednisone for all children >10 years old during induction and dexamethasone for those ≤10. This has not yet been studied in a comparable adult population.

Patients with Burkitt leukemia have poor initial responses to these conventional regimens and require special dose-intensified remission induction programs that are discussed below.^{74,75,173,174,175}

Granulocyte colony-stimulating factor started after completion of the first few days of ALL induction chemotherapy did not improve survival or ultimate outcome in randomized trials. It did, however, shorten the duration of neutropenia by 5 to 6 days and appeared to reduce the incidence of associated complications, particularly infections.^{64,176,177} and ¹⁷⁸

Intensification Therapy

Post-remission intensification or consolidation therapy after the attainment of CR is standard treatment for adult patients with ALL. This therapy refers to the administration of non-cross-resistant drugs aimed at eliminating residual leukemia to prevent relapse as well as the emergence of drug-resistant cells. Variably myelosuppressive doses of different drugs are given according to various schedules depending on the protocol. Due to the heterogeneity of approaches, it is difficult to assess the effect of any individual drug, and only a general assessment of the overall value of intensification can be made.

A randomized trial in childhood ALL clearly demonstrated that administration of both early (given immediately after CR) and late (week 20) intensification therapy was better than either early or late intensification alone and better than no intensification at all.¹⁷⁹ Two other pediatric trials confirmed the benefit of intensification.^{180,181} Results from comparative trials in adults have been less clear and again highlight the difficulty of comparing findings from discordantly designed studies. The pediatric study was conducted by the British UKALL study group, which also enrolled adult patients in a concurrent trial using essentially identical treatment regimens.⁵ There was a significant decrease in relapse incidence for adult patients who received the early intensification block, but this was not reflected by a statistically significant improvement in disease-free survival, possibly due to an increased number of deaths during remission. Likewise, two GIMEMA studies randomizing adult ALL patients to intensive versus standard consolidation and maintenance saw no advantage in disease-free survival for intensified post-remission treatment.^{9,72} No benefit was observed with extending consolidation started early in the post-remission period from 1 month to 4 consecutive months.¹⁸² Adding two myelosuppressive consolidation courses patterned after acute myeloid leukemia, "3 + 7" daunorubicin and cytarabine, to maintenance alone made no difference in the duration of remission.¹⁸³ Lastly, very late intensification given at 6 months or 11 months after CR, in two separate trials, led to no reduction in relapse compared with standard post-remission therapy alone.^{184,185}

In contrast, clinical data from nonrandomized trials provide evidence that adult ALL patients benefit from intensification.^{7,66,67} In the CALGB study, patients who achieved CR received two blocks of early intensification in addition to an 8-week late intensification therapy.⁵⁹ The reported medians of remission duration and survival, 29 months and 36 months, respectively, were substantially better than those observed in prior CALGB trials that did not use intensification blocks. Outcomes better than historical comparison groups were reported by the GMALL studies that consolidated remission patients with a late "re-induction" of drugs identical to initial therapy given 21 weeks after starting treatment.^{7,63}

Maintenance Therapy

As with post-remission intensification, the value of long-term, continuous maintenance therapy for adult ALL has not been established by randomized trials as it has for pediatric ALL.¹⁸⁶ Patterned after the childhood ALL experience, maintenance therapy usually consists of daily 6-mercaptopurine and weekly methotrexate for a total treatment period of 2 to 3 years. There is no information from adult ALL trials regarding the proper duration of maintenance therapy, but children who receive less than 18 months of therapy have worse outcome. The addition of monthly pulses of vincristine and prednisone reduced relapses in controlled childhood ALL studies and has been adopted in some adult maintenance therapy regimens. From a mechanism-of-action perspective, it may be that long-term drug exposure is required to eradicate residual, slowly dividing, or drug-resistant ALL clones.¹⁸⁷ This could explain why maintenance is not necessary for optimally treated patients with Burkitt leukemia, which is a highly mitotically active leukemia.^{2,74,75,173,174}

Relatively strong evidence that adult ALL patients benefit from maintenance therapy comes from a number of studies showing inferior outcome when prolonged maintenance was completely omitted.^{154,188,189} and ¹⁹⁰ The CALGB study was intended to evaluate the efficacy of mitoxantrone during induction and consolidation given over a 7- to 9-month period without maintenance.¹⁵⁴ Patient accrual on this trial was terminated at interim analysis because the median duration of remission (11 months) was much shorter than in previous protocols. Similarly, another American cooperative study group investigated high-dose cytarabine intensification followed by 8 cycles of multiagent consolidation.¹⁸⁹ Without maintenance, the median duration of remission was 10 months, and the disease-free survival at 4 years was only 13%.

Central Nervous System Therapy

CNS prophylaxis is essential in the treatment of ALL. Approximately one third of adult patients will eventually have CNS involvement at relapse without prophylactic therapy.^{191,192} The advantage of CNS prophylaxis in adult ALL was established by the Southeastern Cancer Group in a randomized trial comparing cranial irradiation plus intrathecal methotrexate versus no prophylaxis.¹⁹³ CNS prophylaxis may involve combinations of intrathecal chemotherapy, cranial irradiation, and systemic administration of drugs with high CNS bioavailability, such as high-dose methotrexate and high-dose cytarabine. Although the best combination of modalities and the preferred timing have not been established in controlled trials, a number of different approaches have all proved equally effective. Intrathecal chemotherapy alone or high-dose chemotherapy alone, however, has been associated with poor protection from CNS relapse.^{194,195} On the other hand, more aggressive approaches combining all three modalities do not yield clearly superior results.⁶⁶ Cranial irradiation between 1,800 and 2,400 cGy plus intrathecal methotrexate started after achievement of CR has been used as CNS prophylaxis in several studies, with CNS relapse rates between 0% and 11%.^{7,69,78,163} Similar results were achieved in other studies that were able to omit cranial irradiation by starting intrathecal chemotherapy concurrent with induction and incorporating high-dose methotrexate, high-dose cytarabine, or both.^{72,108,183}

P.1567

Adult ALL patients with CNS involvement at diagnosis require additional CNS-directed therapy, as it can adversely affect survival. In the UKALL XII/ECOG 2993 trial evaluating post-remission therapies, overall survival at 10 years was inferior in patients with CNS disease at diagnosis compared to those without (34% vs. 29%, $P = 0.03$).¹⁹⁶ Up to 10% of adults present with CNS leukemia at the time of diagnosis.^{7,67,156,195} Patients with Burkitt leukemia are at high risk for both CNS disease at presentation and subsequent CNS relapse.^{74,75} The treatment of CNS leukemia has generally involved early and repeated dosing of intrathecal chemotherapy started during induction therapy.^{67,78,106} Kantarjian et al. gave twice weekly alternating intrathecal methotrexate and cytarabine until the CSF showed no leukemic blasts, followed by the standard intrathecal prophylaxis regimen.¹⁰⁶ Linker et al. gave intrathecal methotrexate injections weekly for 10 weeks, then monthly for the remainder of the first year.⁷⁸ The cranial irradiation dose was also increased to 2,800 or 3,000 cGy when included as CNS prophylaxis during the treatment protocol.^{67,78} With either approach, the presence of CNS leukemia did not adversely affect subsequent outcome.

Hematopoietic Stem Cell Transplantation

Allogeneic SCT in first remission improves outcome for adult ALL patients with high-risk features and should be pursued for all eligible patients. Outcome data from most uncontrolled individual trials indicate disease-free survival between 40% and 60% with matched sibling allogeneic SCT.^{197, 198, 199} and ^{200, 201} Some centers reported exceptionally impressive results. In a transplant study performed by Stanford University and the City of Hope National Cancer Center, high-risk inclusion criteria were defined as age greater than 30 years, a WBC count greater than $25 \times 10^9/L$, failure to achieve CR within 6 weeks of starting induction, or the presence of unfavorable cytogenetic abnormalities. Blume et al. initially reported a disease-free survival rate of 63%, which held up at 61% with longer follow-up of an expanded patient cohort, as reported by Chao et al.^{197,198}

Registry data from the International Bone Marrow Transplant Registry (IBMTR) provide additional information. Registry data are useful in limiting the influence of selection bias and heterogeneity between patient groups at different institutions, especially when based on large patient numbers. Reporting on 243 adult patients with high-risk ALL undergoing sibling donor allogeneic SCT, the 5-year estimate of disease-free survival was 39%.²⁰² Treatment-related mortality (37%) exceeded disease relapse (30%) as the cause of treatment failure. In additional analyses by the IBMTR, patients were found to be half as likely to relapse if they developed either acute or chronic graft-versus-host disease.²⁰³ Others have also described similar evidence for a significant graft-versus-leukemia effect, which may have contributed to the relatively low relapse rate, although to a lesser degree in comparison to chronic and acute myeloid leukemias.^{204,205} Several comparisons of IBMTR data with outcome after standard therapy have been reported.^{206,207,208} In these indirect comparisons with historical control groups, allogeneic SCT in first CR proved superior for survival due to protection from relapse.

The first study providing controlled outcome data for allogeneic SCT versus standard therapy was the French Leucémie Aiguë Lymphoblastique de l'Adulte (LALA)-87.^{70,71,156} The study genetically randomized adult patients with ALL to sibling donor allogeneic SCT in first CR versus consolidation and maintenance chemotherapy, regardless of risk category. Risk categorization was based on criteria set by the German study group.^{67,68} Allogeneic SCT was found to be significantly

superior to standard therapy but only for high-risk patients. Disease-free survival at 10 years for these patients was 44% with allogeneic SCT versus 11% for conventional therapy. For standard-risk patients, disease-free survival with allogeneic SCT was similar (49%) but no better than conventional therapy (43%). The subsequent LALA-94 study also favored allogeneic SCT over standard chemotherapy for high-risk patients, with respective 5-year overall survival rates of 51% and 21%.²⁰⁹ The benefit of allogeneic SCT from a related donor in first CR even in standard-risk patients was demonstrated in the UKALL XII/ECOG 2993 trial.⁶

Allogeneic SCT from unrelated donors for adults in first CR can be successfully performed. Various individual trials have been reported, as well as results reported to the National Marrow Donor Program (NMDP). When 64 patients with high-risk features, including the t(4;11) and t(1;19) translocations, received matched unrelated donor allogeneic SCT in first CR, transplant-related mortality was 54%, but relapse at 4 years was only 19%. Only 1 of 17 patients surviving beyond the first year had relapsed at the time of last follow-up.²¹⁰ Subsequently, Weisdorf et al. reported the outcome of 517 patients, ranging in age from 0 to 51 years, with high-risk ALL, including relapsed status and the t(4;11) and t(1;19) translocations, who received matched unrelated donor allogeneic SCT in first or second CR.²¹¹ Transplant-related mortality was 42%, but relapse at 5 years was only 14% for those transplanted in first CR, and 25% for those in second CR. The 5-year probability of disease-free survival rates for those transplanted in first and second CR were 44% and 36%, respectively. Similarly, in a large European study, 5-year disease-free survival did not differ between patients receiving a graft from a matched related or unrelated donor as long as the SCT occurred in first CR (42% vs. 45%, respectively).²¹² Treatment-related mortality also did not differ between the two donor types of SCT.

The role for autologous SCT as an option for post-remission therapy in high-risk ALL patients is difficult to evaluate. The French LALA-87 group performed a trial, parallel to the allogeneic SCT study that randomly assigned patients younger than 50 years who did not have a matched sibling donor to autologous SCT versus standard therapy, regardless of disease risk.^{71,156} Conventional therapy was found to be equivalent to autologous SCT for standard-risk patients. For high-risk patients, autologous SCT and conventional therapy both proved equally ineffective, with 10-year disease-free survival rates of 10% and 16%, respectively. Patients on the SCT arm were transplanted after three consolidation courses, and the autografts were purged with monoclonal antibodies and complement or mafosfamide. The LALA-94 study compared the outcomes of high-risk ALL patients who were assigned to allogeneic SCT if they had an HLA-identical sibling, or randomized to autologous SCT versus standard therapy if they did not. Autologous SCT conferred no advantage over chemotherapy in this high-risk population, and the respective 5-year overall survival rates of 32% and 21% were not significantly different in statistical analysis.²⁰⁷ In the UKALL XII/ECOG 2993 trial, conventional chemotherapy was superior to autologous transplant, with a 46% versus 37% 5-year survival.⁶ Many autologous transplant studies compare individual trials with registry data and report significantly better results. Trials that compare registry data differ considerably from one another and from the French randomized studies with respect to timing of transplant, purging method, intensity of preparative regimen, and whether post-transplant maintenance therapy is given.^{213,214} Taken together, disease-free survival for autologous SCT in first CR from individual trials ranges from 26% to 65%, a wide degree of variability likely reflecting the above considerations.^{201, 215} In some studies, transplant-related mortality approached 20% and seems high relative to contemporary experience with autologous SCT.^{216, 217} and ²¹⁸

A comparative analysis of data from two registries—the NMDP and the Autologous Blood and Marrow Transplant Registry—reported the outcomes of 517 patients who received matched unrelated donor allogeneic transplants and 195 patients who underwent autologous SCT. Transplantation-related mortality was higher after unrelated donor SCT (42%) compared with

P.1568

autologous SCT (20%), but relapse rate was higher in the latter group (49%) compared with the former (14%). Five-year disease-free survival rates were similar (44% for unrelated donor SCT vs. 31% for autologous SCT) when transplanted in first CR or second CR (36% after unrelated SCT vs. 27% after autologous SCT). Net survival outcomes were, therefore, considered similar between the two transplant types, with the sole exception of a subset of patients with no high-risk features who enjoyed superior outcome with allogeneic compared to autologous SCT.²¹¹ In contrast, a trial genetically randomizing adult patients in first CR to sibling donor allogeneic versus autologous SCT found the former superior by a substantial margin.²¹⁹ The French Groupe Ouest-Est des Leucémies et Autres Maladies du Sang (GOELAMS) trial prospectively compared matched sibling allogeneic SCT in first CR with unpurged autologous SCT following sequential re-induction in patients who had no HLA-matched sibling donor or who were older than 50 years. Matched-sibling SCT significantly improved the 6-year overall survival (75% vs. 40% after autologous SCT).²²⁰

Tailoring post-remission strategies in a risk-adapted manner has become an accepted approach in the management of patients with ALL. There is general agreement that, at least in the high-risk patient population, in whom conventional therapies are known to be inferior, expeditious administration of allogeneic transplantation with a matched related donor, whenever possible, can afford the best chance for long-term survival. In contrast, autologous transplant does not seem to be superior to standard chemotherapy approaches.

Adult B-Cell and T-Cell Acute Lymphoblastic Leukemia

Adult ALL patients with the B-cell or T-cell immunophenotype should enter into chemotherapy treatment programs that start with multiagent remission induction chemotherapy. Prophylaxis against CNS relapse is indicated for all patients. Standard-risk patients who achieve remission, who are the majority, should continue with intensification and maintenance therapy or consider allogeneic SCT. Patients at high risk for relapse are best managed with allogeneic SCT in first CR.

Modern adult ALL treatment regimens that have been established by major collaborative study groups are illustrated in Figure 74.4.^{5,7,9,66,67} Clinical outcome results from adult trials are summarized in Table 74.6. Almost all modern multiagent, multiphasic adult ALL treatment protocols are variations on the same basic treatment theme.^{6,9,73,77,78 152 156,161,183 209 220 221, 222, 223, 224, 225, 226 and 227 228 229 230 231,232 233,234} Two exceptions are the GMALL B-NHL 86 and hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone) protocols, which are brief, intensive treatment regimens that have particularly improved outcomes for adult mature B-cell ALL. Although these protocols are further discussed separately in this chapter,^{74,75} the hyper-CVAD regimen also has high activity in non-Burkitt B-cell ALL subtypes.²²⁸ Maintenance therapy, delayed intensive cycles, and rituximab (if CD20+) are added to HyperCVAD in pre-B ALL.²³⁵

The remission induction regimens are built around the fourdrug combination of vincristine, prednisone, l-asparaginase, and an anthracycline, most commonly daunorubicin. The American CALGB 8811 and Italian GIMEMA 0288 protocols added cyclophosphamide to the induction regimen. For those who achieve remission, induction is followed by various intensification or consolidation treatment blocks, generally completed within 6 months of starting treatment. Prolonged maintenance with 6-mercaptopurine and methotrexate is continued for a total of 2 years of scheduled therapy. Intermittent pulses of vincristine and prednisone are also given during maintenance in the CALGB, GIMEMA, and the British UKALL protocols. Cranial irradiation is administered early in the German GMALL treatment program and during interim maintenance in the CALGB and UKALL programs, but omitted in the GIMEMA trial.

The CALGB 8811 trial was conducted between September 1988 and June 1991 at 25 institutions in the United States. Larson et al. reported the results of this study, which showed an 85% CR rate, median remission duration of 29 months, and disease-free survival of 46% but with relatively short median follow-up of 43 months.⁷ Of these patients, 6% failed therapy due to death during induction, and an additional 7% due to refractory disease. Intensification of standard induction with cyclophosphamide was felt to contribute to favorable outcome with T-cell ALL but contributed to myelosuppression, requiring dose reduction in patients older than 60 years and hospital stays averaging 26 days during the induction phase. Prospective karyotype and immunophenotypic data were collected from patients on this and subsequent CALGB protocols for analysis of prognostic markers and were reported separately.^{65,80}

The German GMALL 02/84 trial evaluated sequential blocks of intensive induction and consolidation therapy that extended for nearly a year before beginning maintenance. CNS therapy was aggressive and incorporated intrathecal chemotherapy and cranial irradiation, as well as systemic high-dose cytarabine and methotrexate. International application of this treatment protocol confirmed the high CR rate and disease-free survival of 39% that was reported by Hoelzer et al.^{66,67,194,219,236, 237 and 238}

The British UKALL XA trial was designed to evaluate the benefit of post-remission therapy with early and late intensification blocks. Results were reported by Durrant et al.⁴ CR was achieved in 88% of adult patients, and disease-free survival at 5 years was 28%. As previously mentioned, there was a reduction in relapse for patients randomized to receive the early intensification block, but this did not lead to a superior disease-free survival rate. Additional analyses of this patient cohort describing clinical, immunophenotypic, and cytogenetic prognostic factors were detailed in separate reports.^{69,93}

The GIMEMA 0288 trial tested the prognostic value of response to pre-induction prednisone and the efficacies of cyclophosphamide inclusion during induction followed by intensification of post-remission therapy. An 82% CR rate was observed in 794 adult patients with ALL, which was not better among patients randomized to receive cyclophosphamide during induction.⁹ The response to prednisone was shown to have prognostic significance. Prednisone responders had an overall survival rate of 33% at 8 years compared with 17% among nonresponders. The disease-free survival rate was 29%,

which was no better for patients who were randomized to an additional eight-drug consolidation after intensification, as opposed to proceeding directly to maintenance therapy.

In a single-institution study of 288 patients, dose-intensive hyper-CVAD courses alternating with high-dose methotrexate and cytarabine, with concomitant intrathecal CNS prophylaxis, achieved a CR rate of 92%. With a median follow-up of 63 months, the 5-year disease-free and overall survival rates were both 38%,²²⁸ demonstrating activity comparable with other established protocols. A smaller single-institution study evaluated the outcome of 84 patients using an intensified and shortened chemotherapy regimen consisting of an induction program with daunorubicin, vincristine, prednisone, and asparaginase, followed by cyclical post-remission therapy with high-dose cytarabine/etoposide, high-dose methotrexate/6-mercaptopurine, and the four drugs used in induction,²³⁹ along with intrathecal CNS prophylaxis. Despite eliminating prophylactic cranial irradiation and reducing the total dose of daunorubicin, the CR rate was 93%, and the 5-year disease-free survival rates for patients with B-lineage ALL, with and without high risk factors, were 34% and 66%, respectively.

P.1569

Adult Mature B-Cell Acute Lymphoblastic Leukemia (Burkitt Leukemia)

The mature B-cell phenotype is found in 5% of adult ALL cases, and most are not cured with the majority of conventional ALL regimens such as those just described. Diagnosis is made by morphologic and immunophenotypic features, as has been discussed. Compared with other ALL subtypes, there is a more pronounced male predominance and higher incidence of extramedullary disease, including CNS involvement.^{240, 241} and ²⁴² As is the case with other high-grade malignancies, the blast cells have a rapid doubling time, and vigorous supportive care must be pursued to prevent or treat tumor lysis syndrome.²⁴³ The high proliferative rate exhibited by the leukemic cells served as the rationale for a treatment strategy based on repeated administration (hyperfractionation) of high-dose cyclophosphamide plus methotrexate, also given at high dose, which proved highly successful in pediatric studies.^{173,244}

Adapted from Bassan R, Hoelzer D. Modern therapy of acute lymphoblastic leukemia J Clin Oncol 2011;29:532-543.

Studies performed by European and American groups have established that these brief, cyclical, dose-intensive protocols are the preferred approach to treating adult patients with mature B-cell ALL (Table 74.7).^{74,75,76,245, 246} and ^{247, 248, 249, 250, 251} and ²⁵² Adapted from the pediatric regimens, the B-NHL 86 protocol was used by the German study group (Fig. 74.4) and the hyper-CVAD treatment program was evaluated at the M.D. Anderson Cancer Center. Both use alternating blocks of intensive chemotherapy given monthly for a total of 6 or 8 months without subsequent maintenance. The hyper-CVAD regimen rotated fractionated high-dose cyclophosphamide with high-dose methotrexate. The B-NHL 86 protocol gave high-dose methotrexate with every treatment block and alternated cyclophosphamide with ifosfamide. CNS prophylaxis with intrathecal chemotherapy was started early, but cranial irradiation was omitted in the hyper-CVAD protocol. Similar outcome was reported by both studies. Remarkably similar results were also reported by the CALGB, which implemented the German protocol in a study involving 24 adult patients, with the exception that excess neurotoxicity was reported by the CALGB.²⁴⁶ By reserving intensive CNS prophylaxis for only high-risk individuals, however, the modified CALGB study was able to minimize neurologic toxicity without compromising efficacy.⁷⁶ Overall, with the use of such dose-intensive, short-duration combination chemotherapy treatment regimens, CR rates of 75% to 90% and overall survival rates of 50% to 70% have been achievable,^{175,253} substantially improving the outcome in a highly aggressive disease once considered incurable.

There are currently no effective treatment options for mature B-cell ALL patients who have refractory or relapsed disease. From the recent studies, predictors for relapse or poor outcome include high WBC count ($> 50 \times 10^9/L$), severe anemia, older age, elevated LDH, and poor performance status.^{74,75,245,247} In the report by Thomas et al., nine patients relapsed in

CR, for whom the median remission duration was only 7 months. Progression after relapse was rapid, with two deaths occurring before treatment could be initiated. The remaining patients were resistant to salvage therapy that included re-treatment with hyper-CVAD. After relapse, the median survival for the group was 1 month.

Philadelphia Chromosome-positive Acute Lymphoblastic Leukemia

Ph+ ALL accounts for at least 20% of adult cases^{60,254,255} and is associated with a poor prognosis.²⁵⁶ Patients tend to be older and have a higher WBC count and are more likely to present with

P.1571

hepatosplenomegaly and lymphadenopathy. Virtually all have the B-cell immunophenotype. Earlier experiences with standard ALL induction chemotherapy demonstrated that most achieved CR, but few were long-term survivors due to relapse. The median duration of survival ranged from 8 to 16 months, and disease-free survival did not exceed 10%.^{65,91, 92} and^{93,257} The hyper-CVAD regimen led to improved response rates and duration of CR, but not to advantage in overall survival.²⁵⁴ Incorporation of maintenance therapy to the regimen yielded potentially encouraging results for subtypes of adult ALL other than mature B-cell ALL but had no impact on survival for the 32 Ph+ patients in the series reported by Kantarjian et al.¹⁰⁶ In the LALA-94 and UKALLXII/ECOG 2993 trials the median OS was 5 months and the 5-year OS was only 3% to 6% in patients treated after relapse with Ph+ disease.²⁵⁸

Given the dismal prospect for long-term survival with combination chemotherapy alone, early allogeneic SCT in first CR has long been the recommended treatment for patients with Ph+ ALL. The benefits of transplantation derive from the intense myeloablative therapy combined with the graft-versus-leukemia effect.²⁵⁹ Results vary from center to center, but with allogeneic SCT, 30% to 65% of Ph+ patients can expect long-term survival.^{260, 261, 262} and²⁶³ Registry data from the IBMTR show rates at 2 years of 38% for disease-free survival and 34% for relapse.²⁶⁴ A large retrospective review of children who were Ph+, an equally unfavorable marker in pediatric ALL, suggested that allogeneic SCT substantially improved survival compared with chemotherapy alone.²⁶⁵ In the prospective, multicenter LALA-94 trial of 154 patients with Ph+ ALL, both the absence of MRD and presence of allogeneic SCT were independent predictors of disease-free and overall survival.²⁶⁶ In the study of 267 Ph+ ALL patients in the prospective multicenter trial UKALLXII/ECOG 2993, the actuarial 5-year relapse risk was lowest for those undergoing allogeneic SCT (32%) compared with those treated only with chemotherapy or with autologous SCT (81%).²⁵⁸ Recipients of allogeneic transplants experienced higher event-free and overall survival rates at 5 years (36% and 42%, respectively) compared to their counterpart (17% and 19%, respectively).

The probability of cure, although small in this patient population, further diminishes with advanced disease. Among 38 patients studied by Chao et al., the disease-free survival for Ph+ ALL patients transplanted in first remission was 46% at 10 years, compared with 28% in those transplanted after relapse.²⁶⁷ In another study of 127 patients with poor-risk cytogenetics, the National Marrow Donor Program reported that the overall survival at 2 years following matched unrelated SCT was 40% for patients in first CR, 17% in second or third CR, and 5% for primary refractory disease or relapse. The high treatment-related mortality associated with unrelated transplantation did not appear to overshadow the 37% disease-free survival at 2 years for patients in first CR.²¹⁰

A paradigm shift in the treatment of Ph+ ALL patients has occurred with the introduction of the oral tyrosine kinase inhibitor imatinib mesylate, with a reported response rate of 70% as a single agent.²⁶⁸ Although imatinib monotherapy in relapsed or refractory disease resulted in disappointingly poor durability,²⁶⁹ immediate post-remission SCT²⁷⁰ and integration into combination chemotherapy regimens have improved its therapeutic outlook. In the evaluation of concurrent hyper-CVAD and imatinib in 26 newly diagnosed Ph+ ALL patients, 96% achieved CR and five entered molecular remission, or RT-PCR negativity for the BCR-ABL transcript. Even without post-remission SCT, the 2-year disease-free survival rate was 87% for the combination imatinib-chemotherapy group compared with 12% to 28% with conventional chemotherapy regimens.²⁷¹ The value of incorporating imatinib into chemotherapy regimens in the treatment of newly diagnosed Ph+ or BCR-ABL-positive adult ALL patients was reiterated in another study that demonstrated a CR rate of 96%, molecular response exceeding 71%, and 1-year event-free and overall survival rates of 60% and 76%, respectively.²⁷² With a reduced risk of relapse compared with chemotherapy alone (3.5% vs. 42.3%)²⁷³ and no adverse impact on subsequent SCT,²⁷⁴ imatinib combined with chemotherapy can serve as a bridging strategy to SCT, the only known therapy with curative potential. When including imatinib, concurrent administration with chemotherapy appears to be superior to an alternating schedule,²⁷⁵ and attention to CNS prophylaxis remains paramount given its poor CNS penetrance.²⁷⁶

The second-generation BCR-ABL tyrosine kinase inhibitors dasatinib and nilotinib have also shown efficacy when used either as single agents or in combination with chemotherapy in this patient population.^{277,278} Dasatinib has been incorporated into

P.1572

treatment programs for adults with Ph-positive ALL. In a phase II study of dasatinib with hyper-CVAD in previously untreated Ph-positive patients 94% of 35 patients achieved CR.²⁷⁸ With a median follow-up of 14 months, median DFS and OS had not been reached. In another trial that involved initial treatment, dasatinib was given along with steroids to 53 newly diagnosed patients and all patients achieved complete hematologic response.²⁷⁷ Although these results show that significantly less toxic regimens that include TKIs can achieve very high CR rates and survival has improved, the general recommendation is for eligible adult patients with Ph-positive ALL to undergo allogeneic SCT.

Ponatinib is the newest approved BCR-ABL inhibitor with activity against all known abl mutations including the resistant T315I mutation. A phase II trial consisted of 94 patients with CML lymphoid blast phase or Ph+ ALL, resistant or intolerant to other TKIs.²⁷⁹ With a median follow-up of 12 months, the major hematologic responses were noted to be 35% and 33% in patients with resistance/intolerance to prior TKI and those with T315I mutation, respectively.

MRD following SCT for Ph+ ALL portends imminent relapse. Imatinib given in this setting was found to be effective in suppressing frank relapse in one study, inducing molecular negativity in 52% of 27 patients for the duration of

treatment.²⁸⁰ Relapse was observed if imatinib was unable to achieve molecular remission or in those who discontinued imatinib. Disease-free survival rates in those achieving molecular remission was 91% at 12 months and 54% at 24 months, compared with 8% at 12 months for those with remaining MRD.

Acute Lymphoblastic Leukemia in Elderly Patients

One third of adults diagnosed with ALL are older than 60 years according to US prevalence data.²⁸¹ Advanced age is itself an adverse prognostic factor for ALL, and survival decreases continuously with increasing age (Fig. 74.5). Although older age is independently predictive of inferior outcome, a number of factors can be identified that may account for the poor prognosis.^{282, 283, 284} and ²⁸⁵ Elderly ALL patients tend to have worse performance status, in part, reflecting co-morbid medical conditions. As a result, these patients have limited tolerance for intensive therapy, which may contribute to a high rate of treatment-related mortality. In addition, aspects reflecting the underlying biology of the leukemia likely have an influence as well. Elderly patients are more likely to be Ph+, be underrepresented in the favorable T-cell subgroup, and have disease refractory to standard chemotherapy drugs used to treat ALL.

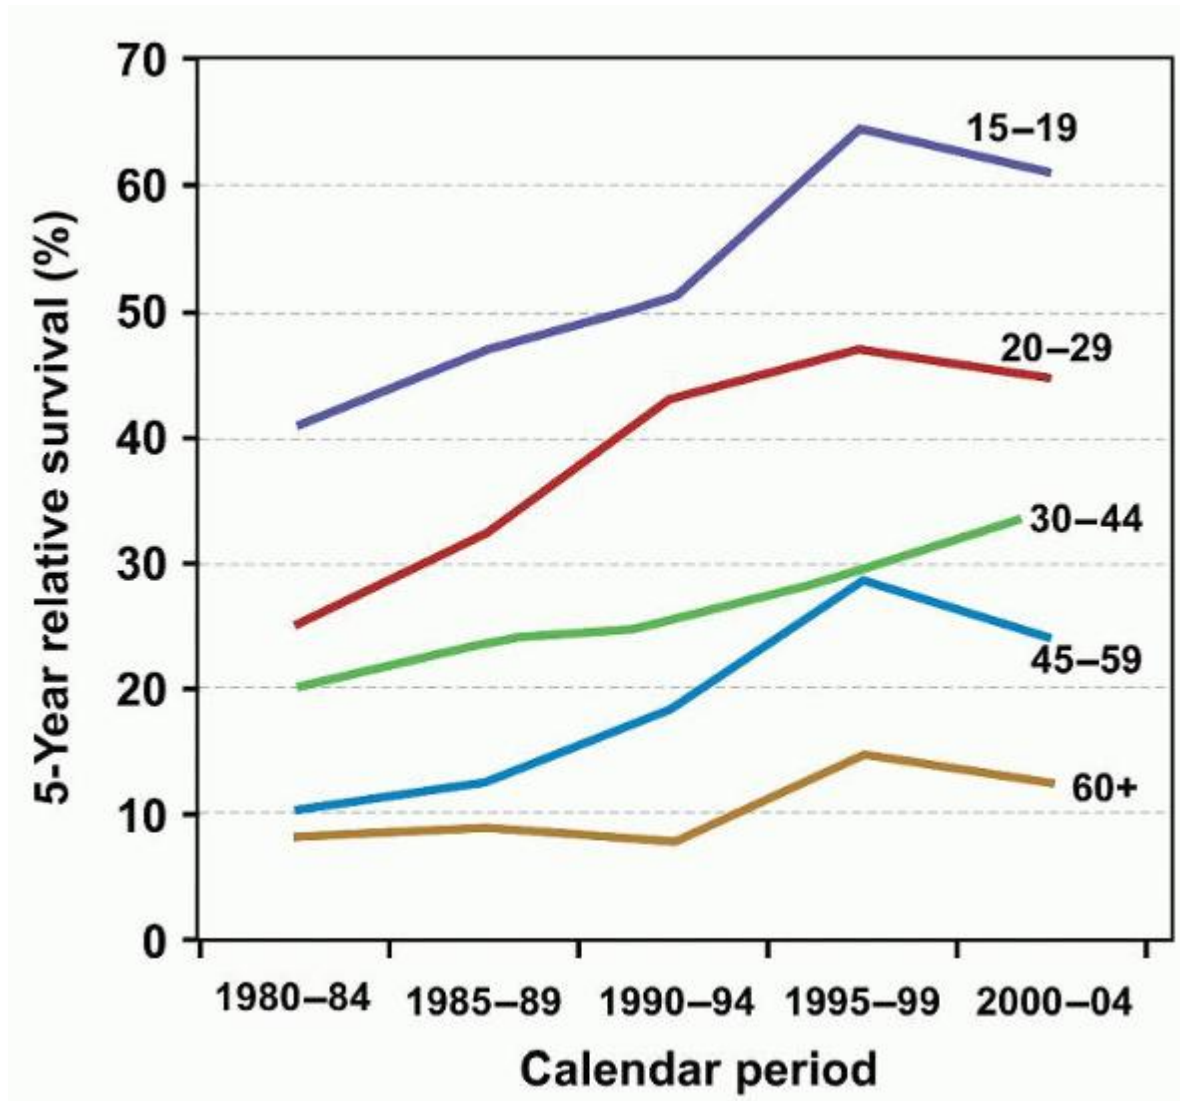

FIGURE 74.5. Five-year relative survival of patients with acute lymphoblastic leukemia (ALL) by major age groups in calendar periods from 1980-1984 to 2000-2004. (With permission from Pulte D, Gondos A, Brenner H. Improvement in survival in younger patients with acute lymphoblastic leukemia from the 1980s to the early 21st century. *Blood* 2009;113:1408-1411.)

At present, there is no satisfactory approach for managing elderly patients with ALL. Several groups have described treatment outcome for these patients, and the results are summarized in Table 74.8.^{284,286, 287, 288, 289, 290, 291, 292, 293, 294, 295} and ²⁹⁶ Elderly ALL patients given no therapy may not survive more than a few weeks.²⁸⁷ Palliative therapy, usually

moderate-dose prednisone and intermittent vincristine, has been used.²⁸⁶ Modest responses were observed, with survival extending to a few months. A retrospective review of one cooperative group member institution's 13-year experience revealed that only one half of their ALL patients older than 60 years were enrolled in their active study protocol.²⁸³ In these instances, risk-adapted therapy often meant limiting treatment intensity on a case-by-case basis. Many of these elderly patients were given ad hoc induction regimens of variably dosed vincristine and prednisone, with or without a third drug.^{288,289, 297} Complete responses were reported in up to 40%, but median survival remained only several months. Several groups uniformly treated fairly large cohorts (40 to 60) of elderly patients with "age-adjusted" chemotherapy programs.^{291,292,298} Impressive CR rates were sometimes observed, and median survival extended to 12 to 14 months. The patient numbers were still small, and it is difficult to evaluate the influence of patient selection bias, as conflicting results have been reported by the same institution treating patients with essentially the same protocol.^{291,292} Data from major collaborative groups treating selected, elderly ALL patients suggest that up to one half may achieve CR with intensive therapy.^{290,293} Resistant disease and toxic deaths were frequent, but a median survival of 10 months may be reasonably expected.

Although the prognosis remains generally grim for elderly patients with ALL, new therapeutic options are becoming available to the subset with the worst prognosis, that is, those with Ph-positivity. Given the generally favorable toxicity profile of imatinib, a number of studies have embarked on the evaluation of its efficacy in elderly patients with Ph+ ALL. In a study of 12 patients, who were older than 60 and not eligible for intensive therapy, treatment with daily imatinib at 800 mg and prednisone, followed by single-agent imatinib consolidation therapy yielded a CR rate of 92%, whereas 67% remained in CR at a median follow-up of 7 months.²⁹⁹ In the prospective, multicenter GMALL study, 32 elderly patients (median age, 67 years) with newly diagnosed Ph+ ALL were randomized to daily imatinib at 400 mg or ageadapted, multiagent induction chemotherapy followed by imatinib in consolidation and re-induction cycles. CR rates were 92% and 53%, respectively, with death and severe infectious complications during induction occurring only in the chemotherapy-assigned group.³⁰⁰

The accumulated literature is still sparse, and much remains to be learned about treating elderly patients with ALL. Ongoing evaluations of tyrosine kinase inhibitors, as well as the investigation of other new therapies, such as monoclonal antibodies and small molecule-based targeted approaches, are vital in the process of improving outcomes and the prognostic outlook for this growing demographic group. Elderly patients should be referred for investigational protocols at study centers whenever feasible.

SALVAGE THERAPY

The prospect of salvage therapy for refractory or relapsing disease will eventually have to be considered for most adult ALL patients. Primary resistance to induction chemotherapy reported by collaborative trials ranges from 8% to 15%.^{5,7,9,66,73,78} Although most

P.1573

patients achieve a first CR, only 20% to 40% become long-term survivors, and the principal cause of treatment failure is disease relapse. Although a second or salvaged CR can be obtained for a slight majority with chemotherapy, the durability of remission is likely short unless an allogeneic SCT is subsequently performed, and, even then, remission duration is limited for most patients.

TABLE 74.8 TREATMENT OUTCOME IN ELDERLY PATIENTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA

Author	Year	Patient (no.)	Median Age (y)	Complete Remission (%)	Refractory (%)	Toxic Death (%)	Median Survival (mo)

NA, not applicable; NR, not reported.

^a The top row involved induction with vincristine, daunoxome, and dexamethasone and was superior to the next row showing the results in elderly patients receiving GIMEMA ALL 0288 protocol.

^b CR% was from 40 patients evaluable after induction.

Recent studies yield some insight into the biologic and clinical features of disease relapse in adult ALL patients. Thomas et al. reviewed the presenting characteristics at relapse in patients referred for therapy at a single institution over a 17-year period.³⁰¹ The duration of CR was less than 1 year in 61%. Essentially all patients had marrow relapses, although one third had concurrent extramedullary involvement, including CNS leukemia in 16%. In other studies, the cytogenetic, immunophenotypic, and molecular changes at relapse compared with initial presentation were examined.^{302,303} Clonal cytogenetic changes were the most common finding. One half of the cytogenetic findings were believed to represent clonal evolution, and the remainder were karyotypic changes. Two entirely different abnormal karyotypes were never found. Immunophenotypic changes were twice as likely in patients with T-cell versus B-cell ALL and were marked by gain or loss of one or two antigens but no complete shift from B- to T-lineage ALL, or vice versa. Neither the presence of a karyotypic shift nor an immunophenotypic shift adversely influenced survival from the time of relapse. Patterns of persistence and clearance of BCR-ABL transcripts also characterize the assessment of MRD and appear to predict relapse in Ph+ ALL (see section on MRD).

Chemotherapy

Reinduction of remission, or attainment of a first CR for refractory patients, can be expected in slightly more than one half of patients with salvage chemotherapy. However, in the majority, remissions do not extend beyond 3 to 6 months, and long-term survival is well below 10% whether or not post-remission therapy is given. The numerous reports describing generally single-institution studies involving small numbers of patients have been exhaustively catalogued in excellent reviews.^{304, 305} and ³⁰⁶ In general, single-agent chemotherapy is inferior to multiagent protocols. Two or three drugs have been added to L-asparaginase or an anthracycline with good responses, but the best results are produced by combinations based on intermediate- to high-dose cytarabine. In one of the larger patient series, doxorubicin combined with vincristine and dexamethasone induced CR in 39% of 64 refractory patients.³⁰⁷ Treatment failure was due to resistant disease in 41%, whereas induction mortality was only 6%, reflective of a correlation between toxicity-related death and antileukemic activity.

Salvage regimens based on high-dose cytarabine, which have been much more extensively studied, produce CR rates that vary widely but have occasionally exceeded 70%. Additional drugs have included anthracycline, mitoxantrone, and fludarabine. The hyper-CVAD regimen, which incorporates doxorubicin and high-dose cytarabine in addition to fractionated cyclophosphamide, was used to salvage 66 relapsed patients and induced remissions in 44%.³⁰⁸ A separate study reported a more modest response, with a CR rate of 38%, in 29 patients with refractory or recurrent disease treated

with high-dose cytarabine and a single high dose of idarubicin,³⁰⁹ whereas standard-dose cytarabine and idarubicin led to a 30% CR rate in refractory patients in another study.³¹⁰ Hiddemann et al. reported a 50% CR rate in 24 refractory patients with the mitoxantrone and high-dose cytarabine two-drug combination.³¹¹ Other studies with these two drugs have reported CR rates of 17% to 80%. Fludarabine is a purine analogue that enhances bioavailability of the active metabolite of cytarabine, and, as a salvage regimen, the combination yields CR in 30% to 83%, with the higher response rates reported when cytarabine was used at high rather than intermediate dose.^{312, 313} and ³¹⁴

In a large single-institution review, Thomas et al. described treatment outcome for 314 adult patients with relapsed or refractory ALL who received various salvage therapy regimens. Overall CR was achieved in 31%.³⁰¹ Patients with long first remissions received the customary front-line study salvage regimen, which

P.1574

varied depending on the study period, whereas patients resistant to or relapsing on therapy were treated with new drug combinations. This approach to treatment regimen selection, based on timing of relapse and prior induction programs, can be regarded as reasonable recommendations for all adult ALL patients requiring salvage therapy. Patients with primary refractory disease and those with relapsed disease were found to achieve CR equally well. Death occurred without achieving remission in 21%. Patients with long first CR duration (>2 years) were more likely to achieve CR and have longer durations of second remission, a finding confirming observations made by other investigators.^{315,316} For the entire group, the median durations of remission and survival from the start of salvage therapy were 6 months and 5 months, respectively. Although salvage regimens in resistant or relapsed disease offer only modest effects with short duration, they allow a bridge to HSCT, which has curative potential for select patients who achieve remission.

Novel Agents

The emergence of newer agents has rejuvenated some optimism that incremental improvements can still be effected in certain patient subgroups. Nelarabine was approved for the treatment of refractory or relapsed T-ALL or T-cell lymphoblastic lymphoma (T-LBL) in patients who have undergone at least two prior chemotherapy treatments. As a prodrug, it is converted to the deoxyguanosine analogue, 9-β-D-arabinofuranosylguanine (ara-G), which selectively induces apoptosis in T-cells by incorporating its phosphorylated form into DNA and inhibiting synthesis. Following a phase I study, which showed significant cytotoxicity against T-cells,³¹⁷ two phase II studies of single-agent nelarabine demonstrated CR rates of up to 23% in patients with refractory or relapsed T-ALL or T-LBL.^{318,319} Neurotoxicity is the dose-limiting toxicity, for which close patient monitoring is strongly encouraged. There are ongoing trials incorporating nelarabine into frontline treatment protocols for T-cell disease including a very large Children's Oncology Group study, AALL0434.

Clofarabine is another deoxyadenosine analogue that was approved by the FDA for the treatment of pediatric patients (ages 1 to 21 years) with relapsed or refractory ALL. It demonstrated activity as a single agent, with a 30% overall response rate, in a phase II study of 61 heavily pre-treated children.³²⁰ Pilot studies combined with cytarabine, or with epratuzumab, an anti-CD22 antibody are being explored in adult ALL.

Two promising antibody therapeutics offer great hope for improving outcomes in ALL. Inotuzumab ozogamicin is an anti-CD22-calceamicin conjugate with significant activity, even in heavily pre-treated individuals.³²¹ In a phase II experience 49 previously treated patients received a 1-hour infusion of the study drug every 3 to 4 weeks for one to five courses. A CR was achieved in 9 patients with an additional 19 with a bone marrow complete response. Nineteen had resistant disease. Duration of response was short, with median overall survival of 5.1 months in all patients and 7.9 months in the 28 responding patients. Due to the significant efficacy observed, once-weekly dosing regimens are being pursued as are protocols incorporating inotuzumab in frontline regimens.

Blinatumomab is a bispecific single-chain antibody that binds both cytotoxic CD3 T lymphocytes and CD19 on the surface of the B-cell leukemic blast. In a phase II trial of B ALL patients with persistent or relapsed MRD, 80% of patients responded. With a median follow-up of 33 months, the hematologic relapse-free survival of the 20 evaluable patients was 61%.³²² These long-lasting remissions would be unusual for patients with MRD detectable disease. Another study included patients with overt hematologic relapse. Complete remission including MRD eradication was observed in 17 of 25 patients.³²³ On the basis of this promising activity, additional trials are planned not only for recurrent disease but also in combination with chemotherapy as part of initial treatment regimens.

Although imatinib mesylate has begun to change the landscape of treatment options for Ph+ ALL by dramatically improving remission rates and overall outcome, emergence of drug resistance warns against complacency.³²⁴ Among the several known mechanisms of imatinib resistance is the development of one of numerous kinase domain mutations of

BCR-ABL which prevent imatinib from engaging and competitively inhibiting the kinase at the ATP-binding site.^{325, 326, 327} and^{328,329} Three other tyrosine kinase inhibitor compounds have since been developed that are active against the majority of the imatinib-resistant BCR-ABL mutants and promise significant antileukemic activity against BCR-ABL-positive leukemias. All have significantly increased potency compared with imatinib, but differ from each other in that nilotinib is a selective inhibitor of BCR-ABL,³³⁰ whereas dasatinib and bosutinib are dual SRC-ABL kinase inhibitors.^{331,332} Early phase studies showed promising activity against BCR-ABL positive leukemia, with the exception of a single BCR-ABL mutation within the ATP-binding pocket of the tyrosine kinase, T315I, which confers a high degree of universal resistance to imatinib, nilotinib, bosutinib, and dasatinib.^{332,333,334} Safety profiles were generally favorable. The main adverse effects for nilotinib were dose-dependent grade 3 or 4 thrombocytopenia and neutropenia, transient indirect hyperbilirubinemia, pruritis, and rash. Side effects associated with dasatinib included grades 3 and 4 thrombocytopenia and neutropenia, pleural effusions, diarrhea, peripheral edema, and headache; none were dose-limiting. The US FDA approved dasatinib for Ph+ ALL.³³⁵ This approval included newly diagnosed patients, reflecting the unmet medical need in this difficult-to-treat population. Ponatinib was recently approved for these difficult-to-treat patients. Unlike the other abl inhibitors, ponatinib does not bind directly to the T315 abl active site.

Recent improvements in the outcomes for mature B-cell ALL do not obviate the need for novel salvage strategies for those with refractory or relapsed disease. In light of the highly expressed CD20 in mature B-cell ALL, recent studies have incorporated the monoclonal anti-CD20 antibody rituximab in intensive, multiagent chemotherapy regimens, yielding promising results (Fig. 74.4).³³⁶ A total of 31 newly diagnosed patients were given rituximab on each of two noncontiguous days in four cycles of hyper-CVAD. Of the 23 evaluable patients, the CR rate was 86% for those less than 60 years of age and 100% for older patients. Compared with historical controls treated on hyper-CVAD alone, inclusion of rituximab led to a 2-year overall survival rate of 89% (versus 58%).

Stem Cell Transplantation

Given the dismal outlook for relapsed disease, allogeneic SCT should be attempted for all eligible adult ALL patients as soon as possible after second or salvaged remission is achieved. The logistics may be difficult given the narrow window before impending relapse. This was examined by Davies et al., who described finding matched related donors for only 35% of 115 consecutive relapsed ALL referrals to a single institution over a 2-year period.³³⁷ An unrelated marrow donor search was initiated in most of the remainder, which was successful in another one third, but required a median of 10 weeks before a donor was identified. Overall, allogeneic SCT was not performed in the majority of the patients, and the reason in 19% was death before transplant despite all efforts to expedite SCT. This point was highlighted by a study at 12 GIMEMA institutions, which re-induced CR in 56% of adult ALL patients in first relapse with a combination of idarubicin and intermediate-dose cytarabine.³³⁸ This was to be followed by a scheduled SCT that could not be performed in 44% due to relapse and in another 26.5% due to persistent infection acquired during induction.

P.1575

Even if a patient is transplanted, the available data suggest that few will be effectively salvaged with allogeneic SCT. Outcome reported from individual trials indicates long-term disease-free survival in 15% to 45% after sibling donor allogeneic SCT in second or greater CR.^{200,339,340} Registry data from the IBMTR show a 5-year disease-free survival estimate of 26%.³⁴¹ Unlike allogeneic SCT for adult ALL in first remission, however, relapse (52%) outranked treatment-related mortality (36%) as the cause of treatment failure.

Allogeneic SCT for active disease appears to yield inferior results. Results for individual trials reporting sibling-donor allogeneic SCT for untreated refractory or relapsed disease indicate disease-free survival of 12% to 43%.^{340,342} The IBMTR reported a 4-year disease-free survival of 13% with 71% of patients relapsing.³⁴¹ In the study of imatinib therapy used as a bridge to SCT in relapsed or refractory Ph+ ALL patients, the disease-free survival at 12 months was 51% for patients transplanted in remission, compared with 8.3% at 7 months in those with active disease, further underscoring the importance of remission status at transplant on post-SCT survival.²⁷⁰ Not surprisingly, worse outcomes characterized transplantation performed for advanced disease (in or after second CR) or with highest tumor burden (in relapse).²¹²

Unrelated donor SCT is associated with a very high transplant-related mortality, compounding the difficulties of finding a matched donor. Based on registry data from the NMDP, transplant-related mortality was 75% for patients transplanted in second or greater CR and 64% for patients transplanted in relapse.²¹⁰ Another study, also based on NMDP data, demonstrated the significance of three factors in a multivariate analysis: unrelated donor transplantation, age greater than 20 years, and SCT performed between 1989 and 1995.²¹¹ Recent advances in histocompatibility antigen matching

based on molecular typing techniques may also improve transplant outcomes through a more precise selection of better-matched donors.³⁴³

A benefit from autologous SCT for patients in second or subsequent CR is difficult to determine. There are many individual studies, generally with short follow-up, reporting disease-free survival ranging from 10% to 31%.^{216,344, 345, 346} and ³⁴⁷ Almost all failures are due to treatment relapse, however, and no study has demonstrated a disease-free survival plateau.

SUMMARY AND FUTURE DIRECTIONS

Considerable progress has been made in the management of ALL in adult patients. Multiagent induction chemotherapy induces CR in over 85% of adult ALL patients. With the institution of post-remission therapy and prophylaxis against CNS relapse, up to 40% may be cured of the disease. There is no compelling reason to believe, however, that further modification of modern multiagent regimens with the addition of currently available chemotherapy drugs will lead to any substantial improvement in outcome for these patients, with the possible exception of nelarabine.

Tailoring therapy adapted for each individual patient on the basis of anticipated relapse risk is a strategy that has gained general acceptance. This approach has proved to be remarkably successful for two adult ALL subgroups, namely, those with Burkitt ALL and those with Ph+ ALL. Ongoing prospectively randomized clinical trials will establish the role of risk-adapted therapy for patients with high-risk features according to other criteria. Coupled with translational research, these trials will also help define the role of new technologies, such as whole genome sequencing and molecular MRD assessment, in refining and improving the ability to evaluate disease activity and relapse risk with greater accuracy.

Targeted molecular therapy, such as the small molecule inhibitors of the BCR-ABL tyrosine kinase, has emerged as an essential aspect of care in patients with Ph+ ALL. Whether the use of second-generation agents will translate into survival advantage remains to be seen. The success with improving outcomes for Ph+ ALL, although satisfying, is tempered by the fact that, at present, allogeneic SCT remains the only known viable intervention with curative potential for high-risk patients. Newer approaches with allogeneic SCT using dose-attenuated nonmyeloablative recipient conditioning are promising and can extend the procedure to patients who might otherwise not be eligible for conventional transplantation.^{348,349} Clinical outcome data are not mature, however, and, at present, the procedure is still investigational.

Other targeted therapies, including monoclonal antibodies directed against surface antigens expressed by malignant cells and chimeric antigen receptor-modified T-cells targeted to B-cell-specific CD19 antigen, have proven extremely effective for other lymphoproliferative disorders and are currently undergoing clinical trials to assess their utility in ALL.³⁵⁰

Discovery of additional, much-needed, state-of-the-art novel therapies depends upon the progressive understanding of the underlying biology and delineation of the critical molecular pathways that are responsible for ALL leukemogenesis.

Chapter 75

Acute Myeloid Leukemia in Adults

Ashkan Emadi

Maria R. Baer

Acute myeloid leukemia, acute myelogenous leukemia, and acute nonlymphocytic leukemia are equivalent terms for a hematopoietic neoplasm that is uniformly characterized by the presence of a malignant clone of myeloid cells in the bone marrow with maturation arrest at the level of blast. Acute myeloid leukemia (AML) is the term used in the World Health Organization (WHO) classification of the myeloid neoplasms^{1,2,3} and is the current recommended term.⁴

AML may follow a myelodysplastic syndrome (MDS) (Chapter 79) or a myeloproliferative neoplasm (MPN; Chapters 80, 81, 82 and 83). AML should be distinguished from acute lymphoblastic leukemia (ALL; Chapter 74), in which blasts are of lymphoid rather than myeloid lineage. AML should also be distinguished from chronic myelogenous leukemia (CML; Chapter 81), in which, in the initial phase of the disease, myeloid cells are expanded but do not exhibit maturation arrest. In addition, CML is a uniform disease, whereas AML has heterogeneous clinical, morphologic, immunophenotypic, cytogenetic, and molecular features. Chapter 77 addresses presentation and therapy of AML in children. Chapter 78 addresses the biology, presentation, and management of the acute promyelocytic leukemia (APL) subtype of AML in adults and children.

AML occurs at any age, but is more common in adults, with increased frequency as age advances. Patients typically present with manifestations of anemia, neutropenia, and/or thrombocytopenia resulting from impaired hematopoiesis due to replacement or suppression of normal marrow elements by malignant blasts. The total white blood cell count is variable, ranging from leukopenia to hyperleukocytosis with an elevated blood blast count that represents a medical emergency.

The malignant cell in AML is a blast that most often shows myeloid or monocytic differentiation, but shows erythroid or megakaryocytic differentiation in approximately 5% to 10% of cases. The myeloid blast can be identified by the presence of granules and/or Auer rods by Wright Giemsa staining, by Sudan black, myeloperoxidase (MPO), chloroacetate esterase, or nonspecific esterase cytochemical staining, and/or by an immunophenotype demonstrating expression of myeloid antigens. Immunophenotyping by flow cytometry is currently in widespread use^{4,5} and serves to define lineage in the absence of defining morphologic and cytochemical features.⁶ In addition, ultrastructural features characteristic of AML may be demonstrated by electron microscopy,⁷ although this modality is not generally a component of clinical diagnostics.

Immunophenotyping by flow cytometry has shown that AML is markedly heterogeneous, variably expressing antigens expressed on stem cells and on more mature myeloid cells, also with infrequent co-expression of lymphoid antigens.⁸ Moreover AML generally exhibits aberrant patterns of antigen expression or co-expression in relation to normal myeloid cells.^{9,10} Detection of aberrant phenotypes by flow cytometry has been applied toward monitoring of residual disease.¹¹

Cytogenetic abnormalities are present in leukemia cells of most patients with AML,¹² and are currently the most powerful predictors of treatment outcome.^{13,14} Because of the importance of cytogenetics in diagnosis and prognosis in AML, several recurrent cytogenetic abnormalities, including t(8;21)(q22;q22), inv(16) (p13.1q22), or t(16;16)(p13.1;q22), t(15;17)(q22;q12), t(9;11) (p22;q23), t(6;9)(p23;q34), inv(3)(q21q26.3), or t(3;3)(q21;q26.2) and t(1;22)(p13;q13), have been incorporated into the WHO classification of AML.² Moreover, cytogenetic abnormalities have been classified as favorable, intermediate, and unfavorable with regard to AML treatment outcomes,^{13,14} and this information is used to assist in the choice of initial and subsequent therapies. New diagnostic tools, including fluorescence in situ hybridization (FISH), polymerase chain reaction (PCR), comparative genomic hybridization (CGH), and microarray analysis, have improved the sensitivity of detection of genetic abnormalities and the ability to subclassify AML and to detect residual disease. Diverse molecular abnormalities are also being demonstrated in AML and predict treatment response,

particularly in AML with a normal karyotype. Molecular abnormalities are also serving as a basis for development of targeted therapies.

Advances in therapy have changed cure rates in AML from less than 20% in 1960 to 1980 to 40% to 70% for selected groups in the 2000s. The cure rate of APL is very high with the addition of all-trans-retinoic acid (ATRA) to chemotherapy and, in some regimens including in the relapse setting, use of arsenic trioxide (Chapter 78). For other types of AML, outcomes have improved significantly for younger, but not older, adult patients (Fig. 75.1). The highest cure rates have resulted from allogeneic stem cell transplantation (alloSCT) in first remission but, with improved survival of patients receiving high-dose cytosine arabinoside (cytarabine or ara-C) post-remission chemotherapy, the question of what is the best post-remission therapy in AML remains unanswered, and stratification based on patient and leukemia characteristics is indicated. Novel targeted approaches are currently being tested in AML, and their ultimate roles remain to be determined.

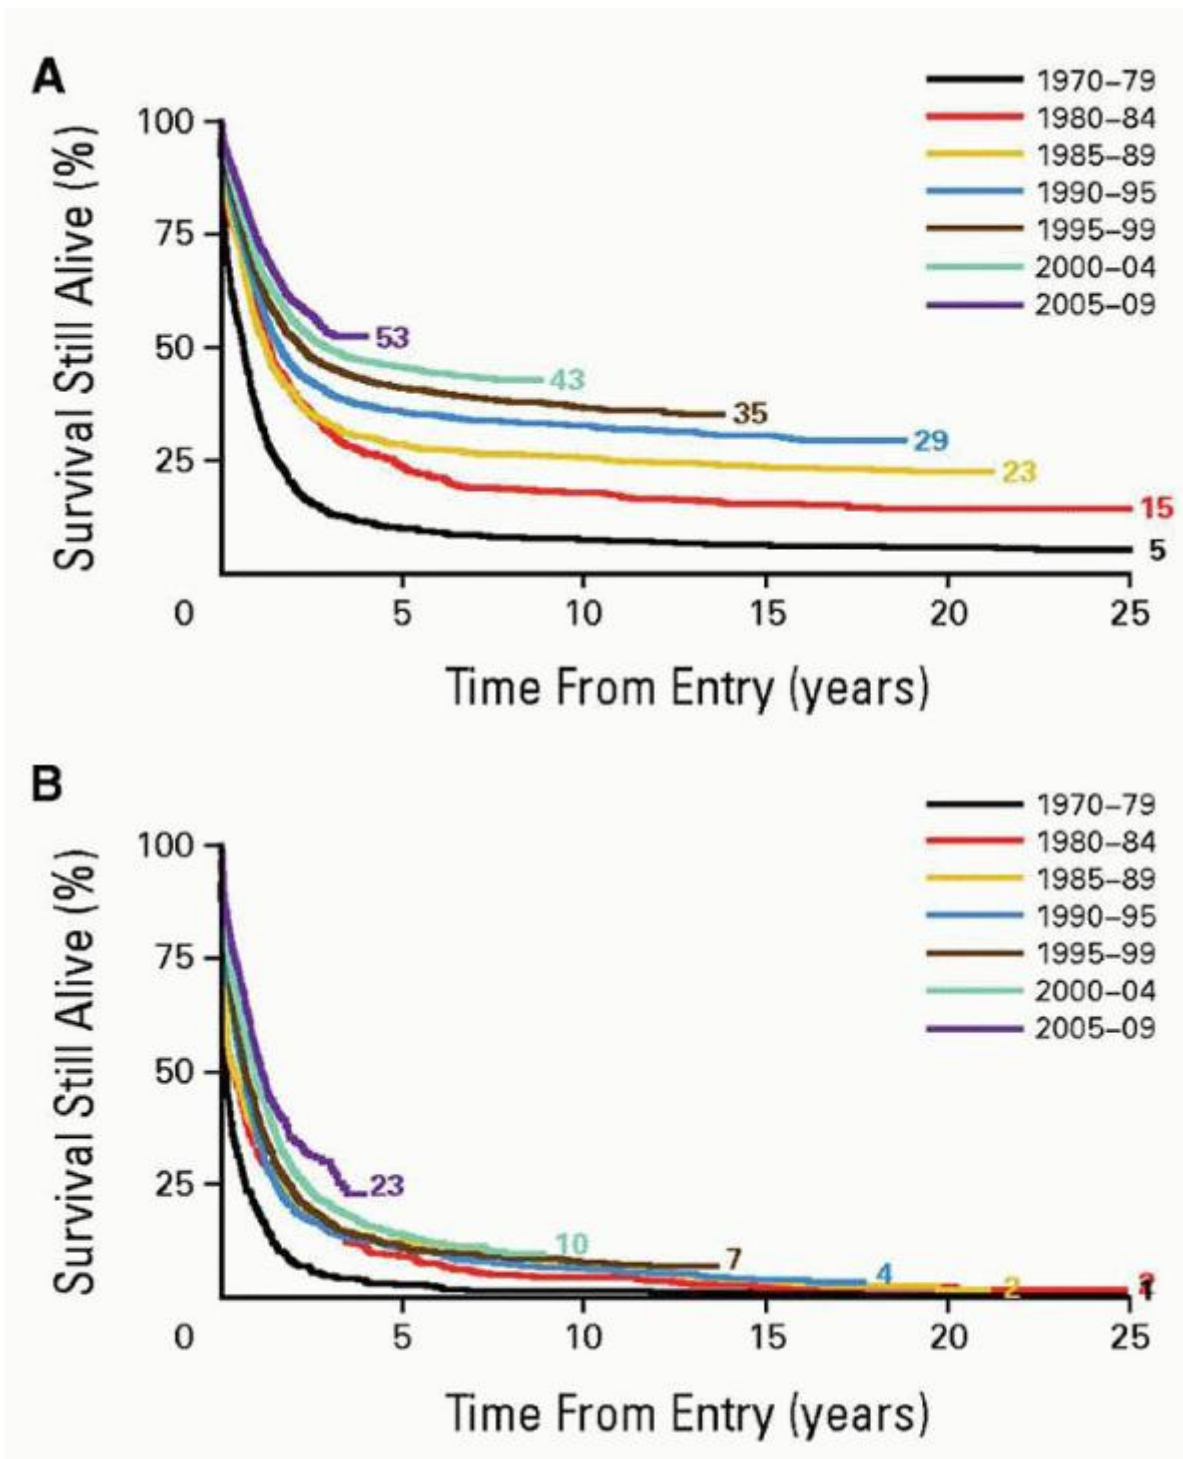

FIGURE 75.1. Change in overall survival of AML patients with time. A: Age 15 to 59 years. B: 60 or more years. (From Burnett A, Wetzler M, Löwenberg B. Therapeutic advances in acute myeloid leukemia. *J Clin Oncol* 2011;29(5):487-494.) P.1578

In this chapter, epidemiologic, clinical, biologic, cytogenetic, and molecular features of adult AML are addressed in the context of therapeutic principles and prognosis.

HISTORICAL PERSPECTIVE

The terms “weisses Blut” and “leukämie” were first used by Virchow in the middle of the 19th century, following initial descriptions of patients with an excess of white blood cells and splenomegaly at autopsy.^{15,16} Ebstein introduced the term “acute leukemia” in 1889 to differentiate rapidly progressive leukemias from more indolent “chronic” leukemias. Naegeli identified the myeloblast in leukemia in 1900¹⁷ and divided leukemias into “myeloid” and “lymphocytic.” During the first half of the 20th century, most of the subcategories of AML were identified by light microscopy with the aid of cytohistochemical stains and were described based on resemblance to normal hematopoietic precursors. Reschad and Schilling described acute monoblastic leukemia in 1913;¹⁸ DiGuglielmo described acute erythroleukemia in 1917;¹⁹ Von Boros and Karenyi described acute megakaryocytic leukemia in 1931;²⁰ and Hilstad described APL in 1957.²¹

The initial classification of AML developed by the French-American-British (FAB) cooperative group in 1976²² was based on morphology. It was subsequently expanded to include new morphologic and immunogenotypic subsets, notably minimally differentiated disease with myeloid antigen expression.⁶ The WHO classification, published in 1997 and updated in 2002 and 2008,^{1,2,23,24} incorporates clinical and cytogenetic data, distinguishes therapy-related AML and AML with MDS-related changes from de novo AML, and uses several recurring structural cytogenetic abnormalities to define AML subtypes.

Numerous cytogenetic abnormalities, both structural and numerical, have been identified in AML, beginning with the t(8;21)²⁵ and t(15;17)²⁶ translocations. Several of these recurring abnormalities were incorporated into the WHO classification, serving to define new subtypes.^{1,2,24} Cytogenetic findings in AML are the strongest predictors of treatment outcomes.^{13,14,27,28,29,30, 31, 32, 33} and ³⁴ Structural cytogenetic abnormalities have been characterized at the molecular level, resulting in increased understanding of AML pathogenesis, and establishment of potential therapeutic targets, as well as molecular markers for quantitative monitoring of residual disease.¹¹ Increasing numbers of gene mutations are also being described in AML, also enhancing our understanding of its molecular pathogenesis, providing new prognostic categories,^{35,36,37,38, 39, 40} and ^{41,42,43,44,45,46,47,48,49,50} and identifying new therapeutic targets.

The European LeukemiaNet has developed a new prognostic classification of AML incorporating cytogenetic and molecular data.^{51,52}

Full sequencing of cytogenetically normal AML genomes was first reported in 2008⁵³ and 2009,⁵⁴ demonstrating 10 and 12 genes with acquired mutations, respectively. Finally, microRNAs, or small noncoding RNA molecules that hybridize to target messenger RNA species and regulate their translation, have also been found to have distinct expression patterns in AML, with prognostic significance, and may represent new therapeutic targets.^{55,56,57}

EPIDEMIOLOGY

It is estimated that 13,780 individuals (7,350 men and 6,430 women) were diagnosed with AML and 10,200 died of AML in the United States in 2012.^{58,59} Lifetime risk of AML based on rates from 2007 through 2009 is 0.39%, which means that 1 in 254 men and women born today will be diagnosed with AML during their lifetime.

TABLE 75.1 AGE DISTRIBUTION OF ACUTE MYELOID LEUKEMIA (AML) AT DIAGNOSIS

Age (Years)AML Incidence (%)

<20	6.0
20 and 34	6.6
35 and 44	6.6
45 and 54	11.8
55 and 64	15.5
65 and 74	20.1
75 and 84	23.3
>85	10.2

The incidence of AML increases with age. AML accounts for 80% to 90% of cases of acute leukemia in adults, but less than 15% of cases of leukemia in children younger than 10 years and 25% to 30% in those between 10 and 15 years.^{60,61} From 2005 through 2009, the median age at diagnosis of AML was 66 years.⁶² Table 75.1 shows the age distribution for diagnosis of AML.⁵⁸

The increased incidence of AML in the elderly is likely related to a combination of improved diagnosis, recognition of AML after MDS, and longer life expectancy, with consequent increased environmental exposures. Based on the number of

patients diagnosed from 2005 through 2009 in 18 Surveillance Epidemiology and End Results (SEER) geographical areas, the age-adjusted incidence of AML is 3.6 per 100,000 subjects per year.⁵⁸ The incidence is higher in males than in females and higher in whites than in blacks (Table 75.2).^{58,61} There is an increased risk for Eastern European Jews and a decreased risk for Asian populations.⁶³

The overall 5-year relative survival for AML from 2002 through 2008 in 18 SEER geographic areas was 23.4%.⁵⁸ As with incidence, mortality rates in AML vary with age, gender, and race. Table 75.3 summarizes the age distribution of AML-related death.⁵⁸ The median age at death from AML was 72 years in 2005 to 2009,⁶⁴ and the age-adjusted mortality rate was 2.8 per 100,000 subjects per year.⁵⁸ Table 75.4 summarizes mortality rates by race and gender.⁵⁸ From 2002 through 2008, 5-year relative survival by race and sex was 21.3% for white men, 24.6% for white women, 23.2% for black men, and 24.8% for black women.⁵⁸

RISK FACTORS

Risk factors for AML include both exposures that result in DNA damage, and congenital diseases and gene polymorphisms associated with impaired repair of DNA damage. Epidemiologic studies

P.1579

have identified genetic, environmental, and occupational factors that may contribute to the pathogenesis of AML.^{60,63,65} In addition, AML arising following cytotoxic therapy for prior malignancies or benign conditions, termed therapy-related AML (t-AML), is an increasing problem in the face of successful therapy for lymphomas and solid tumors, as well as leukemias, and decreasing the risk of this devastating complication is an important goal in the evolution of oncology treatment regimens and strategies.

>85	12.4

Identified occupational, environmental, lifestyle-related, and medical risk factors for development of AML are discussed below. Multiple factors may contribute and interact. A recent case-control study of risk factors for de novo AML at MD Anderson Cancer Center demonstrated multiple factors, joint effects, and differences by sex and WHO subtype.⁶⁶ Heavy smoking (≥30 pack-years; odds ratio [OR], 1.86) and low-level (OR, 2.87) or moderate/high-level (OR, 4.13) occupational

solvent exposure increased the risk of AML in men, whereas obesity (OR, 1.62) and low-level (OR, 2.73) or moderate/high-level (OR, 3.90) occupational solvent exposure increased the risk in women.

Occupational Exposures

Occupational exposures are risk factors for the development of AML. In recent literature, an increased risk of AML has been reported in workers manufacturing, or exposed to, rubber, paint, embalming fluids, pesticides, ethylene oxide, petroleum, poultry, munitions, automobiles, nuclear power, plastics and electrical wiring, as well as gasoline station attendants, beauticians, barbers, and cosmetologists.⁶⁷ Most of these reports are based on retrospective and cross-sectional studies, which makes establishing causal relationships difficult. Older literature also implicated employment in shoe-making, painting, furniture manufacturing or repair, paper mill, clothing or textile industry, chemical manufacturing, printing, nursing, and biologic laboratories,⁶⁷ and it can be speculated that enforcement of regulations pertaining to occupational exposures has altered the occupational risk profile. Of note, an association with hobbies, including artistic painting, car repair, ceramics or pottery, furniture repair, model building, photography, shooting or hunting, or wood working, has not been reported.^{67, 68, 69, 70, 71 and 72}

TABLE 75.4 ACUTE MYELOID LEUKEMIA (AML)-RELATED DEATH RATES (PER 100,000 INDIVIDUALS) BY RACE AND BY GENDER

Race/Ethnicity	Male	Female
All Races	3.7	2.2
White	3.8	2.3
Black	2.7	1.9
Asian/Pacific Islander	2.4	1.6
American Indian/Alaska Native	2.6	1.2
Hispanic	2.3	1.5

The most fully characterized occupational exposure associated with AML is to the aromatic hydrocarbon benzene.^{73, 74} and ⁷⁵ Benzene is absorbed through the skin and lungs and can accumulate in the body fat and neurologic tissues. Toxicity is related to cumulative dosage, and the risk of leukemia was high before safety controls were put into place in the workplace. Chromosome damage can occur at 1 to 10 ppm, and leukemogenic risk is considerable at 124 to 200 ppm. In surveys of factories in China, the leukemogenic risk was four to seven times higher in workers exposed to benzene than in the general population, and the average latency was 11.4 years.^{76,77} A dose-response pattern was suggested, with the highest risk in Chinese workers exposed at constant levels of 25 ppm or higher.⁷⁷ Increased risk of AML with occupational exposure to benzene was confirmed in a recent systematic review and meta-analysis,⁷⁸ and occupational benzene exposure was found to be associated with specific aneuploidies.⁷⁹

Environmental Factors

Ionizing radiation is carcinogenic primarily via induction of double-strand DNA breaks. The risk of leukemia correlates with radiation dosage and age at exposure, with a more rapid peak early in life (<15 years), as well as a more rapid decline than in those exposed at older ages (Fig. 75.2).⁸⁰

Fallout from atomic tests and exposure to nuclear reactors has been a concern in the second half of the 20th century and the start of the 21st century. Atomic bombs were released over Hiroshima and Nagasaki in 1945, and an excess risk of leukemia was reported in 1952.⁸¹ The excess relative rate, per Gray (Gy), of AML among Japanese atomic bomb survivors was best described by a quadratic dose-response function that peaked approximately 10 years after exposure, but with the effect persisting for more than five decades.⁸² Whereas little radioactivity was released

P.1580

into the environment at Three Mile Island, there was extensive exposure to radioactivity after Chernobyl,^{83,84} and increased AML incidence has been reported in Chernobyl clean-up workers.⁸⁵ Of note, one Gray is the absorption of one joule of ionizing radiation energy, per kilogram of body matter.

FIGURE 75.2. Effect of age at exposure and temporal pattern of developing leukemia according to cell type (acute vs. chronic granulocytic leukemia). ATB, at time of bomb. (From Okada S, Hamilton HB, Egami N, et al., eds. A review of thirty years of Hiroshima and Nagasaki atomic bomb survivors. *J Radiat Res* 1975;16(Suppl):1-164.)

Radon, cosmic radiation, and nonionizing radiation have been implicated as possible etiologic factors in AML but are unlikely to contribute a major risk.

Lifestyle-related Factors

Lifestyle-related risk factors for AML include smoking, obesity, and use of some hair dyes. Smoking has been repeatedly identified as a risk factor for AML in an extensive literature.^{86, 87, 88, 89, 90, 91} and ⁹² Cigarette smoke contains more than 4,000 chemical compounds, of which 60 have been found to be carcinogenic and leukemogenic, including benzene, urethane, nitrosamines, and polyaromatic hydrocarbons such as benz[a]anthracene, benzo[a]pyrene, benzo[b]fluoranthene, benzo[c]phenanthrene, benzo[e]pyrene, and benzo[j]fluoranthene. Meta-analyses have estimated a relative risk for AML of 1.3 to 1.5 in smokers.^{87,93} The risk of developing AML is two to three times higher in male smokers who have exceeded 20 pack-years.^{86,94} Smokers of more than 40 cigarettes per day who develop AML have an increased incidence of unfavorable cytogenetic abnormalities, including -7/7q.^{88,92} In a recent case control study at MD Anderson Cancer Center, a history of heavy smoking was associated with AML in men, and current smoking was associated with an increased risk of AML in women, and there was a joint effect of smoking and solvent exposure.⁶⁶

Obesity has been reported as a risk factor for AML.^{66,95, 96} and ⁹⁷ In a large cohort of male US veterans, obesity was associated with a higher incidence of AML in both white and black populations.⁹⁶ Similarly, among over 40,000 women ages 55 to 69 years in the Iowa Women's Health Study, the risk of AML was increased among women who reported being overweight or obese (relative risk, 1.9; 95% confidence interval [CI], 1.0 to 3.4; relative risk, 2.4; 95% CI, 1.3 to 4.5;

P(trend) = 0.006, respectively), compared with women of normal weight.⁹⁷ Findings were similar in a Canadian population.⁹⁵

Finally, there is evidence of an association between use of permanent, but not nonpermanent, dark hair dye and AML.⁹⁸

Therapy-related Acute Myeloid Leukemia

Antineoplastic therapy is associated with an increased risk of subsequent development of AML, and AML diagnosed following cytotoxic therapy for a prior malignant or benign condition is considered to be t-AML.

AML most commonly develops following treatment with alkylating agents or topoisomerase II inhibitors, but nucleoside analogs, antitubulins, and radiation are also associated with t-AML.^{99,100,101}

Radiation used for medical purposes may be leukemogenic. Smith and Doll reported a fivefold increased risk of leukemia in patients with ankylosing spondylitis receiving a single dose of pelvic radiation; the risk peaked 3 to 5 years after radiotherapy.¹⁰² A twofold increased risk has been reported after pelvic radiation for menorrhagia, a treatment commonly used during the 1930s and 1940s.¹⁰³ Small increases in risk have also been reported after radiation for tinea capitis¹⁰⁴ and peptic ulcer disease.¹⁰⁵

t-AML presentation and treatment response differ based on the setting in which it arises and the likely causative agent. Most therapy-related leukemias occur 3 to 10 years after initial therapy, with a longer latency for alkylating agents (5 to 9 years) than for topoisomerase II inhibitors (6 months to 5 years).^{99,101} Alkylating agents cause point mutations, as well as chromosome deletions and unbalanced translocations.¹⁰⁰ Topoisomerase II inhibitors result in loss of a critical enzyme involved in DNA replication, leading to balanced chromosomal translocations usually involving 11q23, and less frequently 21q22, with the formation of fusion genes.¹⁰⁶

The prognosis for t-AML is poor, with a median survival of 7 to 10 months and usually less than 10% 5-year survival.¹⁰⁰ Patients with chromosome 5 and 7 abnormalities have the worst prognosis. Alkylating agent-associated t-AML, generally characterized by deletions or monosomies of chromosomes 5 and/or 7 or complex karyotypes, frequently evolves from t-MDS, and has a low complete remission rate and short disease-free and overall survival. In contrast, topoisomerase II-associated t-AML, most commonly with 11q23 translocations, is typically not preceded by t-MDS and has a high complete remission rate, but short disease-free and overall survival. More rarely, patients treated with antineoplastic agents may develop t-AML with t(8;21), inv(16), or t(15;17).^{101,107} An early report suggests similar prognosis for t-AML and de novo AML with t(8;21) or inv(16),¹⁰⁸ whereas a more recent report suggests a worse outcome for t-AML than for de novo AML with t(8;21).¹⁰⁹

Alkylating agent-associated t-AML has been extensively described. Cumulative drug dose is a primary determinant in causing leukemia, and alkylators differ in their leukemogenicity. Mechlorethamine and melphalan are more leukemogenic than cyclophosphamide. Germline mutations in tumor suppressor genes (NF-1, TP53), genetic variations in enzymes (cytochrome P450, glutathione S-transferase, and NAD(P)H: quinone oxidoreductase 1) that are involved in drug metabolism, and genetic variations in genes such as XRCC1 and hMSH2, encoding DNA repair proteins, can all contribute to an increased risk for t-MDS/t-AML.^{110,111} and ¹¹² Alkylating agent-associated t-AML was initially best characterized following treatment of Hodgkin lymphoma (HL), one of the first malignancies for which curative therapy was developed,^{113,114} and ¹¹⁵ but has now been described after therapy of multiple neoplasms, including but not limited to breast cancer, multiple myeloma, ovarian cancer, and non-Hodgkin lymphoma (NHL),^{101,116,117} and ¹¹⁸ as well as in nonneoplastic disorders such as collagen vascular diseases.¹⁰¹

In HL, radiation can be a contributing factor, but the risk in patients treated with radiation alone is usually less than 1.0%, compared to 1.5% to 5.0% for those who received both radiation therapy and chemotherapy, particularly when chemotherapy is administered as salvage therapy for relapse after radiation.^{119,120} The risk of leukemia after HL ranges from an 11- to a 136-fold increase over that in the general population.¹²⁰ With the increased use of autologous transplantation as salvage therapy for lymphomas, t-MDS/t-AML is being recognized in 5% to 15% of patients and is associated with a poor prognosis.^{101,121} The time of leukemia onset after alkylating agent exposure has ranged from 1 to 28 years and is most commonly in the 5- to 9-year range.¹²² The risk is greater and the latency is shorter in older patients with HL (>50 years of age).¹²³ Splenectomy has been suggested as a contributing factor to leukemia in some, but not all, studies.^{122,123} Elevation in the mean corpuscular volume (MCV) may be an early sign of development of myelodysplastic changes, and up to two thirds of patients who develop leukemia have a preceding myelodysplastic phase that lasts approximately 6 months.^{122,124} Clonal cytogenetic abnormalities are often complex; the most common single abnormality is monosomy 7 (-7), followed by del(5q) and -5.¹²²

Topoisomerase II inhibitors, particularly etoposide and teniposide, were recognized as leukemogenic agents in survivors of lung cancer,^{125,126} germ cell cancer,¹²⁷ ALL,¹²⁸ neuroblastoma,¹²⁹ and osteosarcoma¹³⁰ in the 1980s. Large cumulative doses and prolonged courses have been implicated as increasing the risk of leukemia. The latency period is short, with most cases occurring between 6 months and 5 years after initial therapy. There is no myelodysplastic phase, and the majority of cases are myelomonocytic (FAB M4) or monoblastic (FAB M5). The most common cytogenetic abnormality involves a translocation of

P.1581

the mixed lineage leukemia (MLL) gene at chromosome band 11q23.¹²² Over 40 partner genes that encode different proteins are involved in MLL translocations. Patients with AML and 11q23 abnormalities after topoisomerase II inhibitors tend to be chemosensitive but are rarely long-term survivors because of a high relapse rate.¹²²

Breast cancer is treated with both alkylating agents and topoisomerase II inhibitors, as well as antitubulins. Cytogenetic abnormalities in t-AML after breast cancer therapy are heterogeneous and include those associated with either alkylating agent or topoisomerase II inhibitor therapy.¹³¹ Use of G-CSF has been implicated in increasing the risk of t-AML following breast cancer adjuvant therapy^{131,132,133} and radiation therapy may also contribute.^{131,134, 135} and ¹³⁶

Nucleoside analogs have also been implicated in t-AML. Fludarabine in chronic lymphocytic leukemia is associated with t-AML, particularly when combined with chlorambucil¹³⁷ or mitoxantrone.¹³⁸ Nucleoside analogs are also associated with an increased risk of t-AML in Waldenström macroglobulinemia.¹³⁹ Azathioprine is associated with t-AML, frequently with chromosome 7 abnormalities, in patients with rheumatologic disorders and in solid organ transplant recipients.¹⁴⁰ 6-Mercaptopurine is also associated with t-AML.¹⁴¹ In addition, MDS/AML with dysplasia and chromosome 7 abnormalities has been seen in patients treated for de novo AML and may represent t-MDS/t-AML associated with cytarabine.¹⁴²

An increasing literature is also documenting t-MDS/t-AML occurring following therapy for APL with ATRA and diverse chemotherapy drugs. Many of these cases of t-MDS/t-AML have chromosome 5 and/or 7 abnormalities, but others have 11q23 translocations, and miscellaneous abnormalities are also seen.¹⁴³

Although less leukemogenic than chemotherapy, radiation therapy is leukemogenic, as evidenced by an increased leukemia risk in patients receiving radiation in the past for ankylosing spondylitis,¹⁰² menorrhagia,¹⁰³ tinea capitis¹⁰⁴ and peptic ulcer disease.¹⁰⁵ The risk of leukemia (latency period of 2 to 11 years) is approximately 2 times higher in patients who have received either radium implants or external beam radiation for cervical, ovarian, or endometrial cancer.^{144, 145} and ¹⁴⁶ Similarly, a twofold increase in risk has been reported in breast cancer patients receiving adjuvant radiotherapy, compared to a tenfold increase in risk after chemotherapy; combined radiation and chemotherapy resulted in a seventeenfold risk.^{131,136} Radiation therapy has been associated with only a small increase in risk of leukemia in patients with HL and NHL, unless the radiation is extensive and encompasses a large volume of bone marrow.^{115,147}

In a recent report, patients who developed MDS/AML following radiation alone were found to have a lower incidence of high-risk karyotypes and longer survival than those who developed MDS/AML following chemotherapy or chemotherapy and radiation. Karyotypes did not differ from those in de novo MDS/AML, suggesting that post-radiation MDS/AML may not represent a direct consequence of radiation toxicity and may warrant a therapeutic approach similar to de novo disease.¹⁴⁸

Medical exposure to radioactivity is leukemogenic. In a recent meta-analysis, the relative risk of leukemia in thyroid cancer survivors treated with radioactive iodine (RAI) was 2.5 (95% CI 1.13, 5.53, $p = 0.024$).¹⁴⁹ A standardized incidence ratio (SIR) of 5.68 (95% CI, 2.09 to 12.37) was recently reported in patients with low-risk (T1N0) well-differentiated thyroid cancer, with the excess risk of leukemia significantly greater in patients aged <45 years (SIR = 5.32; 95% CI, 2.75 to 9.30) than in older patients (SIR = 2.26; 95% CI, 1.43 to 3.39).¹⁵⁰ Increased leukemia risk has also been previously reported following therapy with radioactive phosphorus (³²P) for polycythemia vera, as well as following exposure to Thorotrast, a radioactive contrast agent containing thorium (²³²Th).¹⁵¹

Chromosome Instability or Defective DNA Repair

The incidence of AML is increased in patients with syndromes characterized by chromosome instability or defective DNA repair,¹⁵² notably Bloom syndrome,⁵⁹ an autosomal recessive disorder with excessive chromosomal breakage, including quadriradial formation, and increased sister chromatid exchanges, caused by alterations in a gene on chromosome 15q26.1 encoding a protein with helicase activity that is central to DNA repair.¹⁵³

An increasing recent literature also associates polymorphisms in genes encoding detoxifying enzymes and DNA repair proteins with incidence of AML, as well as with treatment outcomes. Glutathione S-transferases (GSTs), including GSTM,

GSTP, and GSTT, are detoxification enzymes involved in metabolism of carcinogens. A recent meta-analysis of the association of GST polymorphisms with risk of AML supported a significant risk of AML in the presence of null genotypes of GSTM1 and GSTT1.¹⁵⁴ Associations with treatment outcomes were also suggested.^{155,156}

Polymorphisms in the RAD51 and XRCC3 genes, encoding proteins involved in repair of DNA double-strand breaks via homologous recombination, have been associated with increased risk of development of AML, and the association is additionally strong for t-AML and in the setting of coincident polymorphic deletion of the GSTM1 detoxification gene.¹¹⁰ Other work implicates polymorphisms of the XRCC1 gene, encoding a protein involved in base excision repair,¹⁵⁷ and of RAD51¹¹¹ in the risk of t-AML, and of polymorphisms in the xeroderma pigmentosum group D (XPD) DNA repair gene, encoding a protein involved in nucleotide excision repair, in AML with 5q and 7q chromosome deletions.¹⁵⁸ Additionally, XPD polymorphisms have been associated with AML treatment outcome, and ERCC1 and XRCC3 polymorphisms with treatment toxicities.¹⁵⁹

Heritable Genetic Factors

Heritable syndromes associated with increased risk of AML are usually recognized in childhood and are discussed in Chapter 77. In addition to Bloom syndrome,⁵⁹ they include Fanconi anemia (FA),¹⁶⁰ familial platelet disorder (FPD),^{161, 162} and¹⁶³ Schwachman-Diamond syndrome,^{164,165} amegakaryocytic thrombocytopenia, which may be X-linked, as well as Blackfan-Diamond syndrome, familial aplastic anemia,¹⁶⁶ and Kostmann syndrome.¹⁶⁷ Severe congenital neutropenia (SCN), with mutations in the neutrophil elastase (ELA2) gene, when treated with G-CSF increases risk for AML, associated with acquired somatic mutations in the G-CSF receptor.¹⁶⁸

Inherited mutations of tumor suppressor genes predispose patients to malignancies, including those of myeloid origin. The Li-Fraumeni syndrome, described in 1969, is an autosomal dominant cancer family syndrome with an increased risk for sarcomas, breast cancer, and other neoplasms, including leukemia, due to germline mutations in the TP53 gene.^{169,170}

CLINICAL PRESENTATION

AML presenting symptoms and signs are related to failure of normal hematopoiesis, resulting in anemia, neutropenia, and thrombocytopenia. The most common complaint is nonspecific fatigue or malaise that may have been present for several months. Pallor and weakness are caused by anemia. Fever is common and is the presenting feature in 15% to 20% of patients, often associated with sweats, and may result from infection secondary to neutropenia or from leukemia itself. Hemorrhagic signs and symptoms, including petechiae, epistaxis, and easy bruising, may be found in up to one half of patients at diagnosis. Petechiae correlate with the severity of thrombocytopenia, and ecchymoses with the presence

P.1582

of disseminated intravascular coagulation (DIC), which is most common in APL, but also occurs in other AML subtypes. Weight loss is present in up to 50% of patients, but is usually not severe. Bone pain occurs in less than 20% of patients. Organomegaly and adenopathy have been reported in up to one half of patients with AML, but are less common than in ALL.

Leukemia Cutis

Leukemic skin infiltration, or leukemia cutis, occurs in up to 13% of patients with AML during the course of the disease, most commonly in those with a monocytic component. Skin lesions are often nodular and violaceous (Fig. 75.3), are painless, and may be widespread or localized. Widespread lesions are distinguished from other exanthems by being raised and palpable. Diagnosis is confirmed by biopsy. Skin lesions may precede the diagnosis of AML, or may occur concurrently with AML or as an extramedullary relapse. They are radiosensitive, but patients should usually be treated with systemic chemotherapy.¹⁷¹ Benign skin lesions associated with AML include Sweet syndrome¹⁷² and pyoderma gangrenosum.¹⁷³ These are painful and are responsive to corticosteroids. These diagnoses are also confirmed by skin biopsy. Leukemia cutis is frequently associated with involvement of other extramedullary sites, including the central nervous system (CNS).¹⁷¹ Gum infiltration is also characteristic of acute monocytic leukemia (Fig. 75.4).

Myeloid Sarcoma

Myeloid sarcoma, or granulocytic sarcoma, myeloblastoma, or chloroma is an extramedullary tumor that occurs in 2% to 14% of cases of AML.^{174, 175} and¹⁷⁶ The term chloroma derives from a green appearance due to expression of MPO. The tumors are usually localized, frequently in bone, periosteum, soft tissues, lymph nodes, or skin. Common sites are the orbit and the paranasal sinuses, but other sites reported include the gastrointestinal tract, genitourinary tract, breast, cervix, salivary glands, mediastinum, pleura, peritoneum, and bile duct.¹⁷⁵ Myeloid sarcomas may occur at diagnosis of

AML, may precede the diagnosis, or occur as an extramedullary relapse. They have also been seen in association with MDSs or MPNs and usually predict transformation to acute leukemia.^{174, 175} and ¹⁷⁶ The diagnosis is suggested by presence of eosinophilic myelocytes in hematoxylin and eosin-stained biopsy sections. Imprint preparations can be helpful. The diagnosis can be made if Auer rods are detected or if myeloid origin is confirmed by cytochemical or immunohistochemical methods. Although granulocytic sarcomas are radiosensitive, systemic chemotherapy is warranted in most cases.¹⁷⁷

Central Nervous System Leukemia

The incidence of CNS disease at diagnosis of AML is difficult to determine because lumbar puncture is not generally performed.¹⁷⁸ Meningeal disease has been reported to develop in up to 16% of adults with AML.¹⁷⁸ The increased use of high-dose cytarabine (HiDAC), which crosses the blood-brain barrier, lessens the risk of CNS leukemia in AML, as evidenced by a 2.2% incidence in a review of 410 patients from a single institution.¹⁷⁹ CNS disease is associated with hyperleukocytosis and the AMoL variants.¹⁸⁰ It is often asymptomatic, but may be associated with headache, nausea, and/or cranial nerve palsies, particularly V and VII. Ocular involvement may result in blindness and suggests meningeal involvement. Intracerebral masses were reported in FAB M4Eo in association with *inv(16)(p13q22)* and M5 subtypes,¹⁸¹ but also appear to be less common with increased use of HiDAC. Prophylactic central nervous system (CNS) therapy is not given routinely to adult patients with AML, but some clinicians advocate prophylaxis in patients with AMoL or with presenting white cell counts greater than 100,000 cells/mm³. Diagnostic lumbar puncture with prophylactic intrathecal chemotherapy may also be advocated prior to hematopoietic stem cell transplantation.

Other Organ System Involvement by Acute Myeloid Leukemia

Other organ systems may be involved. Cardiac abnormalities are usually related to electrolyte imbalances, particularly hypokalemia, but may result from direct involvement of the conduction system or infiltration of vessel walls.¹⁷⁵ Pulmonary symptoms occur in patients with leukostasis, infections related to neutropenia, or hemorrhage. Gastrointestinal symptoms also include infections, particularly perirectal abscesses and typhlitis, which is a necrotizing colitis related to leukemia infiltration of the bowel wall. Management of typhlitis is supportive, including antibiotics and nasogastric suction, but surgical intervention is sometimes unavoidable.¹⁸² Obstructive jaundice has occurred secondary to myeloid sarcoma.

Hypocellular Acute Myeloid Leukemia

Hypocellular AML occurs in 5% to 10% of patients with AML and is defined by the presence of AML in a hypocellular bone marrow, with the definition of hypocellularity varying between 5% and 40%.¹⁸³ Hypocellular AML is typically seen in older patients, and should be distinguished from MDSs and aplastic anemia. Howe et al.

P.1583

demonstrated a CR rate of 73% in a series of 29 patients with hypocellular AML.¹⁸⁴ Although hypocellularity alone should not exclude a patient from receiving chemotherapy, caution should be exercised in treating these patients, and transplantation strategies should be considered.

LABORATORY FINDINGS

Presenting blood counts vary widely among patients with AML.¹⁸⁵ The leukocyte count is elevated in more than half of patients, but is greater than 100,000 cells/mm³ in less than 20%. Blasts are usually present in the peripheral smear or in a buffy coat smear. Auer rods and Phi bodies are considered pathognomonic of AML. Phi bodies are fusiform or spindle-shaped rods similar to Auer rods that require special stains for hydroperoxidases.¹⁸⁶

Cytopenias result from hematopoietic failure and contribute to symptoms and signs. Anemia is common in AML and is predominantly normochromic and normocytic. Reticulocytopenia is generally present, but nucleated red blood cells may be seen. Neutropenia is present in most AML patients. A normal neutrophil count is more common in patients with monocytic variants of AML. Giant lysosomes are rarely noted in neutrophils of patients with AML; their presence has been called a pseudo-Chédiak-Higashi syndrome.¹⁸⁷ Thrombocytopenia is usually present and may be severe at diagnosis. Thrombocytosis is rarely identified, and is characteristic of AML with abnormalities of the long arm of chromosome 3, involving the EVI1 gene.

DIC is more common in AML than in ALL, and is most common in APL (Chapter 78). DIC is seen at presentation in nearly all patients with APL, and its incidence in AML other than APL is in the 10% to 30% range.¹⁸⁸ The cause of DIC is thought to be the release of tissue factor-like procoagulants from the azurophilic granules within the leukemia cells. DIC is manifested clinically by bruising and, when severe, by bleeding from multiple sites. Laboratory findings include thrombocytopenia, hypofibrinogenemia, elevated fibrin split products, and deficiency of coagulation factors, including factor V and factor VIII.¹⁸⁹ Other mechanisms, such as excessive fibrinolysis and secretion of interleukin (IL)-1 by AML cells, may contribute to bleeding.¹⁹⁰

Hyperuricemia is noted in up to 50% of patients with AML and can also be associated with tumor lysis, although the latter is more common in ALL.¹⁹¹ Hydration and administration of allopurinol and/or recombinant urate oxidase (rasburicase) for markedly elevated uric acid levels or elevated uric acid levels with renal insufficiency, can prevent complications of tumor lysis, which may occur during induction chemotherapy, most often in the setting of hyperleukocytosis.

Serum lactate dehydrogenase (LDH) levels may be elevated, particularly in monocytic (FAB M4/M5) subtypes, but to a lesser degree than is observed in ALL.

Levels of lysozyme are elevated, particularly in variants of AML with a predominant monocytic component (FAB M4/M5). Excess lysozyme (muramidase) may cause proximal renal tubular damage, which results in hypokalemia. Other factors that can contribute to hypokalemia in AML include potassium uptake by rapidly proliferating cells, as well as medications, particularly diuretics and the antifungal antibiotic amphoterecin. Hyperkalemia can occur in association with hyperuricemia and tumor lysis. With improved agents to treat hyperuricemia, hyperphosphatemia with or without hypocalcemia is the most common abnormality associated with renal failure during induction therapy. Patients with AML may have hypocalcemia,¹⁹² but hypercalcemia is very rare.¹⁹³

Hyperleukocytosis, arbitrarily defined as a blood blast count greater than 100,000/mm³, occurs most commonly in monocytic (FAB M4/5) AML and in AML with fms-like tyrosine kinase 3 internal tandem duplication (FLT3-ITD).^{174,194} Hyperleukocytosis is a medical emergency because it is associated with leukostasis in the lungs and the CNS,¹⁹⁵ causing respiratory failure and intracerebral hemorrhage,^{180,196, 197} and¹⁹⁸ which are usually rapidly fatal. Pulmonary leukostasis is manifested by dyspnea, tachypnea, rales, interstitial infiltrates, and respiratory failure.^{195,199} CNS leukostasis manifests as headaches, blurred vision, somnolence, obtundation, ischemic stroke, and intracerebral hemorrhage.²⁰⁰ Spurious laboratory data associated with hyperleukocytosis include a falsely elevated platelet count because blast fragments are counted as platelets, pseudohypoxemia caused by oxygen consumption by leukemia cells, pseudohypoglycemia caused by glucose consumption by leukemia cells, hypophosphatemia, and falsely prolonged coagulation tests due to low plasma volume.^{201, 202} and²⁰³ Artfactual lowering of the pO₂ and glucose may be prevented by placing blood samples on ice and performing the tests without delay.¹⁷⁴

To decrease the risk of leukostasis in patients with hyperleukocytosis, the white blood cell count must be rapidly lowered. Therapeutic measures include leukapheresis, administration of large doses of hydroxyurea, and immediate initiation of induction chemotherapy.^{174,198,204} Red cell transfusions should be minimized initially to avoid overcorrection of the

hemoglobin level, because this may produce an increase in blood viscosity that can worsen leukostasis. A hemoglobin goal of 8 g/dl, but not higher, is generally appropriate. In contrast, platelet transfusions are needed to decrease the risk of hemorrhage, because the platelet count may be overestimated, as discussed above. In addition, leukapheresis exacerbates thrombocytopenia and patients may also have DIC. An initial platelet count goal of 50,000/mm³ is generally reasonable. No controlled clinical trials have defined the optimal management of hyperleukocytosis, but retrospective data support the use of leukapheresis.²⁰⁵ Leukapheresis is indicated urgently if symptoms of leukostasis are present.¹⁹⁶ Moreover, leukapheresis should be considered early to decrease the risk of leukostasis in patients with hyperleukocytosis, as the onset of leukostasis may be abrupt, and, once initiated, it may be fulminant and irreversible.¹⁷⁴ Studies suggest that leukapheresis is associated with decreased early mortality and improved complete remission (CR) rates, but not with improved survival.^{197,198} Because leukapheresis is only a temporary measure to decrease the risk of leukostasis, hydroxyurea should also be administered, and chemotherapy should be initiated as rapidly as possible.¹⁷⁴

BIOLOGIC FEATURES

Heterogeneity

AML is a complex and extremely heterogeneous neoplasm in all respects, including cytologic features, stage of differentiation, antigen expression, cytogenetic findings, gene mutations, gene expression, activation of signal transduction pathways, and response to treatment. Significant advances have been made in our understanding of the complex biology of AML, including identification and characterization of multiple interdependent pathogenetic phenomena and pathways. Increasingly sophisticated research techniques are being applied toward elucidating the complex biology of AML and developing more effective therapies.

Aberrant Immunophenotypes

In the majority of cases of AML, leukemia cells have immunophenotypes that distinguish them from myeloid progenitor cells found in normal marrow. Compared to normal bone marrow myeloid cell populations, AML cells exhibit asynchronous myeloid antigen expression, antigen overexpression, loss of antigen expression and co-expression of nonmyeloid antigens.⁹ These findings are consistent with aberrant differentiation rather than arrest of normal differentiation. The ability to distinguish AML cells from normal marrow cells based on aberrant immunophenotypes has

P.1584

formed the basis for flow cytometric analysis of AML in peripheral blood or marrows of patients with AML, as well as for detection of residual disease by flow cytometry.^{206, 207} and ²⁰⁸ Immunophenotypes remain abnormal at relapse, but commonly exhibit gain or loss of one or more antigens and/or changes in antigen density.^{11,209}

Leukemogenesis

Leukemogenesis in AML is a heterogeneous, multistep process that results in maturation arrest, altered proliferation, and impaired apoptosis, mainly through genetic dysregulation. A "two-hit" model of leukemogenesis has been proposed for AML.²¹⁰ In this model, AML is the consequence of at least two classes of mutations. Class I mutations (e.g., BCR-ABL, K-RAS, N-RAS, KIT, FLT3) confer a proliferative and/or survival advantage, whereas Class II mutations (e.g., CBFβ-MYH11, AML1-ETO, TEL-AML1, and PML-RARα fusion genes) result in impaired cellular differentiation and apoptosis. Fusion genes such as AML1-ETO and CBFβ-MYH11, which are involved in the specific structural chromosomal abnormalities t(8;21) and inv(16), respectively, in AML, impair differentiation and apoptosis, but are insufficient to cause AML by themselves.^{211,212} A second class of genetic changes, such as mutations in the receptor tyrosine kinases FLT3,²¹³ KIT,^{214,215} or N-RAS,²¹³ which deregulate proliferation, are required for development of AML. The limitations of this hypothesis include: (1) lack of identifiable mutations in class I and class II in all cases of AML, (2) frequent epigenetic changes in AML, and (3) unexplained role of newly discovered alterations in metabolic pathways and enzymes such as isocitrate dehydrogenase (IDH) in AML pathogenesis.

Recent whole-genome sequencing of bone marrow and skin, paired with skin, from patients with AML evolving from MDS revealed persistence of an antecedent founding clone containing approximately 200 to 650 somatic mutations, accompanied by outgrowth or emergence of at least one subclone with several new mutations.²¹⁶

Clonality

The clonal nature of AML is confirmed by the presence of clonal cytogenetic abnormalities in the majority of cases,¹² and has also been demonstrated by analysis of G6PD isoenzymes²¹⁷ and of restriction fragment length polymorphisms (RFLP).²¹⁸ Clonal abnormalities may be demonstrated in either a single cell line or in more than one cell line (such as

myeloid and erythroid or myeloid and megakaryocytic), indicating that leukemic transformation can occur in either restricted-lineage or multipotential stem cells.^{217,219} Whole genome sequencing demonstrated that irrespective of blast count, more than 80% of bone marrow cells in MDS and s-AML are clonal.²¹⁶

Deep sequencing of genomes from AML patients at initial diagnosis and at relapse suggested two major clonal evolution patterns at AML relapse: (1) gain of new mutations by the founding clone in the primary tumor, or (2) expansion of a subclone of the founding clone surviving initial chemotherapy, with gain of additional mutations. Thus AML relapse is associated with new mutations and clonal evolution, perhaps due to the influence of chemotherapy on the founding clone.²²⁰

Leukemia Stem Cells

It is generally accepted that AML relapse is caused by survival and persistence of rare chemotherapy-resistant leukemia stem cells (LSC).²²¹ Transplantation of AML cells into immune-deficient mice demonstrated that LSCs are present at a frequency of one in 250,000 cells in the peripheral blood of AML patients, are usually enriched in the CD34⁺CD38⁻ cell fraction,²²² and lack expression of CD71 and human lymphocyte antigen (HLA)-DR,²²³ but express CD123.²²⁴ These cells are primarily in the G0 phase of the cell cycle.²²⁵ They are also characterized by activation of the transcription factor nuclear factor- κ B (NF- κ B), which is not activated in normal hematopoietic stem cells.²²⁶ Finally, they express multiple multidrug resistance proteins, including P-glycoprotein (Pgp; MDR1; ABCB1) and breast cancer resistance protein (BCRP; MXR; ABCG2), as do normal hematopoietic stem cells.^{227,228}

Substantial basic and translational research has been performed to better understand the biology of LSCs and ultimately to target them therapeutically.²²⁹ LSCs cannot be distinguished from normal hematopoietic stem cells (HSCs) based on the CD34⁺CD38⁻ phenotype,²³⁰ but intermediate levels of aldehyde dehydrogenase (ALDH) enzyme activity can distinguish CD34⁺CD38⁻ LSCs, capable of engrafting immunodeficient mice, from normal HSCs, which showed higher ALDH activity, and presence of CD34⁺CD38⁻ALDH intermediate leukemic cells in complete remission after induction chemotherapy was associated with subsequent relapse.²³¹ Moreover, using bioinformatic analysis, 42 and 121 genes were identified as LSC-related and HSC-related signatures, respectively, and 44 genes were found in both signatures and were designated as core-enriched HSC-LSC genes. When LSC- and HSC-related gene signatures were examined in 160 patients with cytogenetically normal AML, both signatures correlated negatively with overall survival even in patients with the prognostically favorable FLT3 wildtype and NPM-1 (nucleophosmin-1) mutant status.²³⁰

Hematopoietic Growth Factor Effects

The use of culture systems with phytohemagglutinin (PHA)-conditioned medium from peripheral blood leukocytes in the 1980s allowed growth of clonogenic cells in 80% to 90% of cases of AML,²³² likely because of the presence of hematopoietic growth factors. Leukemia cells, like normal cells, generally require growth factors for survival and proliferation. AML cells express receptors for a number of hematopoietic growth factors, including granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), interleukins 1, 3, 4, 6, and 9, Steel factor (KIT ligand), thrombopoietin (MPL ligand), and FLT3 ligand (FLT3L).^{233, 234, 235} and ²³⁶ Growth factors predominantly cause proliferation, but may also inhibit apoptosis²³⁵ and induce differentiation.²³⁷ Growth factors may be produced by stromal cells or by AML cells themselves, resulting in paracrine or autocrine stimulation, respectively.^{238,239} Patients whose AML cells exhibit autonomous growth in vitro have an inferior response to treatment,^{240,241} and autonomous growth of AML cells is associated with other adverse disease characteristics, including unfavorable cytogenetic risk group,²⁴² multidrug resistance²⁴³ and expression of antiapoptotic proteins.²⁴⁴

Proliferative Characteristics

The proliferative characteristics of AML cells, including the percentage of S-phase cells, the duration of S-phase, and the total cell cycle time, are highly variable,^{245, 246} and ²⁴⁷ and proliferation may be either slower or faster than that of normal myeloid cells. AML with a high or a low proliferative rate responds less well to chemotherapy than AML with an intermediate proliferative rate.²⁴⁵ A high proliferative rate may be associated with marrow aplasia after chemotherapy, but rapid regrowth of leukemia,²⁴⁶ whereas nonproliferative AML cells may be chemoresistant.²⁴⁸ S-phase and total cell cycle times are longer in relapsed than in newly diagnosed AML.²⁴⁵

Resistance to Apoptosis

Resistance to apoptosis contributes to both leukemogenesis and drug resistance in AML.²⁴⁹ Apoptosis occurs by two pathways,

both of which result in caspase activation: (1) receptor-mediated, involving the tumor necrosis factor (TNF) family of death receptors, and (2) mitochondrial-mediated, regulated by the BCL-2 family of proteins.²⁴⁹ Chemotherapy kills malignant cells through activation of mitochondrial-mediated apoptosis, and altered apoptotic pathways are a mechanism of resistance to chemotherapy. AML cells overexpress BCL-2 and other antiapoptotic proteins, including BCL-x(L), MCL-1, XIAP, and survivin,^{250,251} which may be up-regulated by the effects of stromal cells²⁵⁰ and cytokines.²⁵² Permeabilization of the mitochondrial outer membrane is blocked by higher levels of the antiapoptotic proteins BCL-2, BCL-x(L), and MCL-1, and facilitated by the proapoptotic proteins BAX or BAD. High BCL-2-to-BAX protein ratios in AML cells are associated with lower complete remission rates and shorter overall survival.²⁵³ Expression of APAF-1, an important protein in the apoptosis machinery, is commonly silenced by methylation in AML cells, and may be restored by treatment with DNA methyltransferase inhibitors.²⁵⁴ Expression of the multidrug resistance protein P-glycoprotein (ABCB1) may also inhibit AML cell apoptosis by a mechanism independent of drug efflux.²⁵⁵

Signal Transduction Pathway Activation

Activation of signal transduction pathways may result from mutations in gene encoding growth factor receptors such as FLT3, KIT, or RAS. In addition, aberrant activation of the PI3K/Akt/mammalian target of rapamycin (mTOR) signaling pathway is implicated in leukemogenesis in AML,^{256, 257, 258} and²⁵⁹ in the absence of consistent gene mutations. mTOR is constitutively activated in most AML cases,^{256, 257} and²⁵⁸ but not in normal hematopoietic stem cells,²⁵⁷ and P13K/Akt/mTOR pathway activation is associated with compromised apoptotic response mechanisms^{260, 261} and²⁶² and resistance to chemotherapy.^{256,258, 259, 260} and²⁶¹ Thus PI3K/AKT/mTOR inhibitors have the potential to be both effective and selective in AML.^{263,264} Multiple signal transduction pathways may be activated in AML and the number of pathways activated is associated with a progressively worse prognosis.²⁶⁵

Microenvironment

AML bone marrow exhibits increased microvessel density, compared to normal marrow,^{266, 267} and²⁶⁸ and AML cells express vascular endothelial growth factor (VEGF), mRNA, and protein,²⁶⁶ and may also express aberrant VEGF receptors.²⁶⁹ VEGF can act via multiple paracrine,²⁷⁰ as well as autocrine,²⁶⁹ mechanisms to contribute to AML cell expansion and survival in the bone marrow microenvironment.^{271,272} VEGF secretion is strongly correlated with expression of FLT3 and of FLT3 ligand.²⁷³ Inhibition of FLT3 signaling with a small molecule FLT3 inhibitor, an antibody that blocks FLT3 ligand binding or FLT3 receptor siRNA decreases VEGF secretion. FLT3 is likely to induce VEGF secretion through the MAPK (mitogenactivated protein kinase) pathway via its activation of ERK1/2 (extracellular-signal regulated kinase-1 and -2) phosphorylation, rather than through AKT (protein kinase B) or STAT5 (signal transducer and activator of transcription-5),²⁷³ suggesting novel treatment strategies.²⁷⁴

The chemokine stromal cell-derived factor-1 (SDF-1) regulates homing and engraftment of leukemia cells in the bone marrow microenvironment and stromal niche. SDF-1 and its receptor CXCR-4 (fusin, LESTR) are expressed by AML cells and promote AML cell survival²⁷⁵ and stroma-mediated chemoresistance. CXCR-4 represents a novel therapeutic target²⁷⁶ for AML, and CXCR4 inhibitors have been tested in combination with chemotherapy in preclinical and clinical studies, with the goal of inducing mobilization of AML cells into the circulation, with promising results.²⁷⁷

CYTOGENETIC AND MOLECULAR FINDINGS

Cytogenetics

Acquired chromosome abnormalities are present in AML cells in most patients and diverse recurrent abnormalities are strongly predictive of treatment outcomes. Cytogenetic abnormalities were first described in AML in the 1960s, and were found to be present in approximately one half of AML patients in the 1970s with development of chromosome banding techniques (Chapter 3). With technical improvements, recent series have reported abnormal karyotypes in 55% to 78% of adults with AML.^{32,278} Approximately 55% of patients with AML have a single cytogenetic abnormality, including 15% to 20% with gain or loss of a single chromosome as the only change; the remaining 45% have two or more changes. The most common recurring cytogenetic abnormalities in AML include t(15;17), t(8;21), inv(16), +8, +21, del(5q), -7, 11q23 translocations, and 12p11-13 abnormalities.^{32,278}

Correlation of cytogenetics and clinicopathologic data has led to the recognition of distinct subtypes of AML and has helped to identify prognostic groups (Table 75.5).^{32,278} Techniques such as PCR, FISH, and CGH have allowed characterization of cytogenetic abnormalities at the molecular level, demonstrating frequent involvement of oncogenes and tumor-suppressor genes (Chapter 72).

The best described subtypes of AML are defined by recurring structural chromosomal abnormalities, which primarily consist of balanced translocations, occur more commonly in younger patients, tend to correlate with morphology, and are predictive of treatment outcomes. These include t(8;21), inv(16) or t(16;16), and t(15;17) and their variants. AML with t(8;21) tends to have blasts with maturation, often with azurophilic granules and occasionally with very large granules (pseudo-Chédiak-Higashi granules).²⁴ AML with inv(16) or t(16;16) is usually associated with monocytic differentiation and abnormal marrow eosinophils.^{24,181} APL with t(15;17) and its variants is suggested by the presence of hypergranular promyelocytes in association with disseminated intravascular coagulopathy (DIC), but may also be present in a variant microgranular (hypogranular) subtype (Chapter 78). Other cytogenetic abnormalities associated with morphology in AML include 11q23 translocations with monoblastic features;^{24,279} t(6;9) with marrow basophilia;²⁸⁰; abnormalities of 3q21-26 with abnormal platelets and thrombocytosis²⁸¹ and t(9;22), 14q32, or 11q23 with mixed lineage antigen expression.^{282,283} t(8;21), inv(16) and t(15;17) are associated with favorable responses to chemotherapy, and 11q23 translocations, t(6;9), 3q21-26 abnormalities and t(9;22) with adverse treatment outcomes. AML with 11q23 abnormalities is associated with a high complete remission rate but short disease-free and overall survival, whereas the other unfavorable abnormalities are associated with low complete remission rates as well as short disease-free and overall survival.

11q23 translocations are common in t-AML arising following topoisomerase II therapy,^{99,122} but they also occur de novo, and are associated with monocytic differentiation. 11q23 translocations are characterized molecularly by rearrangement of the MLL gene at 11q23. The frequency of MLL rearrangements is sevenfold higher (5.3% vs. 0.8%) in patients younger than 60 years of age. The molecular pathogenesis of MLL gene rearrangements probably involves aberrant nonhomologous end joining of DNA double strand breaks. The normal MLL protein is proteolytically cleaved and functions as a transcriptional repressor or activator. Chimeric proteins that are generated from MLL rearrangements include the N-terminal region of MLL, which is involved in protein-protein interactions and transcriptional repression, and their leukemogenic effects appear to occur via activation of clustered

P.1586

P.1587

homeobox (HOX) genes.²⁸⁴ More than 40 different partner genes for MLL have been identified.²⁴ In t(9;11), t(10;11), and t(11;19), the amino terminus of the MLL gene is fused to one of three homologous genes, AF9, AF10, or ENL, from chromosomes 9q22, 10p12, and 19p13, respectively.²⁸⁵ Survival of patients with de novo t(9;11) has varied among studies, with some groups placing it in an intermediate prognostic group whereas others have reported it as unfavorable.^{29,278,286} De novo AML with t(6;11) (q27;q13) has a very poor prognosis.²⁸⁷ Additional cytogenetic aberrations have been shown to modify the outcome of pediatric 11q23/MLL-rearranged AML.²⁸⁸ AML patients with MLL gene rearrangement may have a better outcome with more intensive treatment regimens.

TABLE 75.5 SELECTED PRIMARY CHROMOSOME ABERRATIONS IN ACUTE MYELOID LEUKEMIA

Type of Rearrangement	Genes Involved	Hematologic Clinical Features	Prognosis
t(1;3)(p36;q21)	<i>MEL1</i>	Preceded by MDS, M1, M4, dysmegakaryopoiesis	Poor
t(1;7)(q10;q10)		Preceded by MDS, M1, M4, genotoxic exposure	Poor
t(1;11)(p32;q23)	<i>AF1P, MLL</i>	M0, M5	Poor
t(1;11)(q21;q23)	<i>AF1Q, MLL</i>	M4, M5, infants	Poor
t(1;22)(p13;q13)	<i>RBM15, MKL1</i>	M7, thrombocytopenia, hepatosplenomegaly, bone marrow fibrosis	Poor
inv(3)(q21;q26);t(3;3)(q21;q26)	<i>EVII, RPN1</i>	Preceded by MDS, M1, M4, M6, abnormal dysmegakaryopoiesis,	Poor

		thrombocytosis	
t(3;5)(q25, 1;q35)	<i>MLF1, NPM</i>	M6, megakaryocytosis, Sweet syndrome	Intermediate to poor
t(3;12)(q26;p13)	<i>MDS1, EVII-TEL</i>	Preceded by MDS, dysmegakaryopoiesis	Poor
t(3;21)(q26;q22)	<i>EVII, MDS1, or EAP; AML1</i>	No FAB preference, genotoxic exposure	Poor
+4		M1, M2, M4; subcutaneous tumors	Poor
-5/del(5q)		No FAB preference, genotoxic exposure	Poor
t(5;17)(q35;q12)	<i>NPM, RAR-α</i>	M3	Poor
t(6;9)(p23;q34)	<i>DEK, CAN</i>	Preceded by MDS; M2 and M4, bone marrow basophilia	Poor
t(6;11)(q27;q23)	<i>AF6, MLL</i>	M4 and M5; localized infections	Poor
-7/del(7q)		No FAB preference; genotoxic exposure; prior MDS	Poor
t(7;11)(p15;p15)	<i>HOXA9, NuP98</i>	M2 with Auer rods	Intermediate
+8		M2, M4, and M5; can be preceded by MDS; no impact on prognosis when associated with good-risk cytogenetics	Intermediate to poor
inv(8)(p11q13)	<i>MOZ TIF2</i>	M5, acute mixed-lineage leukemia, erythrophagocytosis	Poor
t(8;16)(p11;q13)	<i>MOZ, CBP</i>	M5, erythrophagocytosis, DIC; mainly children	Poor
t(8;21)(q22;q22)	<i>ETO, AML1</i>	M2 with Auer rods, eosinophilia, myeloblastoma	Good
t(8;22)(p11;q13)	<i>MOZ, P300</i>	M5, can be therapy-related	Poor
t(9;11)(p21-22;q23)	<i>AF9, MLL</i>	M5	Intermediate
t(9;22)(q34;q11)	<i>ABL, BCR</i>	M1 and M2; biphenotypic, rare	Poor
t(10;11)(p11-15;q13-23)	<i>AF10, MLL</i>	M5	Intermediate to poor
t(10;16)(q22;p13)	<i>MORF, CBP</i>	M5, can be therapy-related	Poor
+11	<i>MLL</i>	M1, M2	Poor
t/del(11q23)	<i>MLL</i>	M5, biphenotypic, genotoxic exposure	Poor
t(11;16)(q23;p13)	<i>MLL, CBP</i>	M4, M5, infants	Poor
t(11;17)(q23;q25)	<i>MLL, AF17</i>	M2, M4, and M5	Poor
t(11;17)(q23;p21)	<i>PLZF, RAR-α</i>	M3	Intermediate
t(11;19)(q23;p13)	<i>MLL, ENL, ELL</i>	M4 and M5; biphenotypic	Poor

t/del(12p)		No FAB preference, genotoxic exposure	Poor
i(12)(p10)		Concurrent germ-cell tumors	Poor
t(12;22)(p13;q11)	<i>TEL, MNI</i>	Preceded by MDS, M1, M4, M7	Poor
+13		No FAB preference	Poor
t(15;17)(q22;q11)	<i>PML, RAR-α</i>	M3, M3v, DIC, Auer rods	Intermediate to poor
inv(16)(p13;q22), t(16;16),	<i>MYH11, CBF-β</i>	M4Eo, central nervous system disease	Good

t(16;21)(p11;q22)			
i(17)(q10)		Preceded by MDS, no FAB preference	Poor
del (20q)		No FAB preference	Poor
+21		No FAB preference, MDS	Intermediate
+22		M4, can be associated with inv16; MDS	Intermediate

DIC, disseminated intravascular coagulation; FAB, French/Am British; MDS, myelodysplasia.

Note: See Chapter 72 for description of the genes and Mitelman F, Johansson B, Mertens F, eds., Mitelman database of chromosome aberrations in cancer.

<http://cgap.nci.nih.gov/chromosomes/mitelman>.

Structural abnormalities involving the long arms of chromosomes 5 and/or 7, monosomy 5 and/or 7, and complex karyotypes, defined by the presence of three or more unrelated numerical and/or structural abnormalities, are frequently seen in AML arising from prior MDS and in t-MDS/t-AML associated with alkylating agent therapy.^{100,122} These abnormalities, whether in de novo AML or t-AML, are associated with low complete remission rates and short disease-free and overall survival. Other numerical chromosomal abnormalities associated with poor treatment outcome include +11, +13, and +21.

The monosomal karyotype (MK), recently defined by the presence of at least two autosomal monosomies or a single autosomal monosomy in combination with at least one structural abnormality, is associated with a particularly dismal prognosis, with a 4% \pm 1% 4-year overall survival, whereas the 4-year OS of patients with complex, but nonmonosomal, karyotypes was 26% \pm 2%. In a subsequent Southwest Oncology Group study of 1,344 adult AML patients, MK was present in 13%, increased in incidence with age, being present in 4% of patients age 30 or younger, but 20% of those over age 60, comprised 40% of the unfavorable cytogenetic risk category, and was associated with a complete remission rate of only 18% and only 3% 4-year survival.²⁸⁹ Transplantation resulted in limited improvement in outcome, with 25% 4-year OS in patients transplanted at the Fred Hutchinson Cancer Research Center.²⁹⁰ Thus transplant is indicated when feasible, but improvement in outcome is modest.

Molecular Abnormalities

AML is characterized by recurrent gene mutations that confer constitutive or aberrant signaling through one or more pathways in the complex signaling network that regulates normal hematopoiesis. The therapeutic implications of targeting different signaling pathways have begun to be exploited in recent years, with several promising small molecules and biologic agents in development (see "Therapy" section). Moreover, prognosis in AML is increasingly able to be assessed by evaluating molecular markers including frequently detected gene mutations.²⁹¹ This can be particularly useful in dissecting the prognosis of AML with a normal karyotype.^{49,292} In addition, overexpression of specific genes is associated with unfavorable treatment outcomes. Assays for gene mutations are more readily standardized and more widely applicable than assays measuring gene expression levels. The number of gene abnormalities described in AML continues to increase.

FLT3 is a receptor tyrosine kinase that is expressed on hematopoietic progenitor cells and is activated by binding of FLT3 ligand (FL), stimulating proliferation.²¹⁰ FL binds to the receptor and induces dimerization, tyrosine kinase activation, and

receptor autophosphorylation, followed by initiation of the phosphorylation of downstream signaling proteins. FLT3 is expressed on AML cells in most cases of AML, and is mutated in 20% to 34% of patients with AML^{35,36,37,293,294} resulting in constitutive activation.^{210,293} FLT3 mutations can be detected by genomic PCR amplification and gel electrophoresis. The most common mutation is a small in-frame internal tandem duplication (ITD) in the FLT3 gene that results in duplication of an amino acid sequence within the juxtamembrane domain of the receptor, which disrupts the autoinhibitory activity of the juxtamembrane domain, resulting in constitutive tyrosine kinase activation (Fig. 75.5). Point mutations in the DNA sequence encoding the FLT3 activation loop, predominantly in the aspartic acid (D) residue at amino acid position 835, occur less frequently.³⁶

FLT3 mutations activate similar transduction pathways as binding of FLT3 ligand to the wildtype receptor, including signal transducer and activator of transcription (STAT) 5 and the RAS/MAPK and PI3K/Akt pathways.^{293,295, 296} and ²⁹⁷ Other effects include myeloid maturation arrest by virtue of suppression of the C/EBP α and PU.1 transcription factors,²⁹⁸ and antiapoptotic effects by virtue of phosphorylation of the proapoptotic protein BAD,^{298,299} resulting in inactivation of its proapoptotic function.

FLT3 mutations are associated with higher peripheral blast counts, normal karyotype and FAB M5 disease. Presence of FLT3-ITD does not affect CR rate, but predicts high relapse rate and poor survival and is useful in stratifying patients with AML with a normal karyotype into poor risk groups.^{35,37,293,300,301,302} FLT3 point mutations are less prognostically unfavorable than FLT3-ITD.³⁰³ FLT3-ITDs are of less prognostic significance in AML patients over age 70 years,^{300, 304} likely because they occur in different patient populations than expression of MDR1/Pgp,³⁰⁵ which is a strong adverse prognostic factor in older adult AML patients,³⁰⁶ and because the prognosis of all AML patients over 70 years is poor.³⁰⁷ Prognosis of patients with FLT3-ITD is further worsened by absence of the wildtype allele,³⁸ higher ITD to wildtype allelic ratio, larger size of the ITD³⁰⁰ or presence of the ITD in CD34+CD33-precursors.³⁰⁸ The role of transplantation

P.1588

in overcoming the adverse prognosis associated with FLT3-ITD is under investigation (see "Stem Cell Transplantation" section). Several FLT3 inhibitors are currently being evaluated in clinical trials in AML (see "Therapy" section).

FIGURE 75.5. Simplified diagram of the FLT3 receptor: it contains 993 amino acids and consists of an extracellular ligand-binding domain with five immunoglobulinlike domains, a single transmembrane domain, and a cytoplasmic domain, which is comprised of a juxtamembrane domain followed by the tyrosine kinase domain. Internal tandem duplications (ITD) in the juxtamembrane domain and point mutations at aspartate 835 within the activation loop constitutively activate FLT3. (Drawing by Tim Gilfilen, Medical Art Group, Vanderbilt University.)

Recently several groups have focused on the important role of the FLT3 ligand (FL) in AML with FLT3-ITD. FL expression increases significantly during induction and consolidation chemotherapy, and AML blasts remain highly responsive to FL at relapse, suggesting a potential role of FL in promoting relapse.³⁰⁹ A treatment strategy involving induction chemotherapy, stem cell transplantation, FLT3 inhibitors, and monoclonal antibodies against FL has therefore been proposed for AML with FLT3-ITD.³¹⁰

Mutations of exon 12 of the nucleophosmin (NPM or NPM1) gene are the most common single gene mutations in AML, present in up to half of AML cases with normal karyotypes.^{39,41,311} Nucleophosmin is a nucleocytoplasmic shuttling protein that regulates the p53 tumor suppressor pathway, and NPM1 mutations in AML cells result in cytoplasmic localization of the protein, which can be demonstrated by immunohistochemistry.³¹² NPM1 mutations are found at diagnosis and remain stable throughout the disease course. These mutations are typically found in AML with a normal karyotype,^{39, 40} and^{41,42,312,313} and are associated with prolonged event-free and overall survival.⁴² Co-occurrence of NPM1 with FLT3-ITD mutations, but not with other mutations, negates their favorable prognosis,^{39, 40} and^{41,45,302,314} (Fig. 75.6). The mechanistic role of NPM1 in the pathogenesis of AML has not been fully elucidated. Perhaps due to favorable prognosis of NPM1-mutated AML, targeted therapies have not been investigated. Mutant NPM1 transcript levels have been validated as a residual disease marker, with cumulative incidence of relapse after 4 years after double induction therapy 6.5% in patients who achieved RQ-PCR negativity compared with 53% in RQ-PCR-positive patients ($P < 0.001$); and with much better overall survival (90% vs. 51%; $P = 0.001$) in RQ-PCR-negative patients.³¹⁵

Mutations in the CEBPA (CCAAT/enhancer binding protein alpha) gene,³¹⁶ encoding a transcription factor that is essential for myeloid differentiation, are also a favorable prognostic factor in AML. These mutations are present in approximately 10% of AML patients overall and 15% of those with a normal karyotype,^{46,48} and are correlated with a distinct DNA methylation profile. Mutations at the CEBPA C-terminus generate dysfunctional proteins, and frameshift mutations in the CEBPA N-terminus create a dominant negative shorter protein. Biallelic CEBPA mutations in AML are associated with better prognosis than for unmutated or monoallelic mutated AML.^{50,317,318}

FIGURE 75.6. Clinical outcome in 550 AML patients with a normal karyotype according to FLT3/ITD and NPM1 mutant status. Both markers were prognostically significant predictors of survival ($p < 0.0001$), and together identified three prognostic groups: good (FLT3/ITD- NPM1+), intermediate (FLT3/ITD- NPM1- or FLT3/ITD+ NPM1+), and poor (FLT3/ITD+ NPM1-). (With permission from Gale RE, Green C, Allen C, et al. The impact of FLT3 internal tandem duplication mutant level, number, size, and interaction with NPM1 mutations in a large cohort of young adult patients with acute myeloid leukemia. *Blood* 2008;111:2776-2784.)

Partial tandem duplication of the MLL gene (MLL-PTD), which is the gene at 11q23 that is involved in 11q23 chromosome translocations, was the first molecular abnormality to be identified in cytogenetically normal AML and to be associated with short disease-free survival,^{319, 320} and³²¹ although outcomes are better with recent regimens incorporating more intensive post-remission therapies.³²²

Overexpression of ERG (ets-related gene) adversely affects outcome in AML with a normal karyotype and can be detected in AML with complex karyotypes that have a cryptic amplification of chromosome 21.³²³

When expression of the BAALC (brain and acute leukemia, cytoplasmic) gene is dichotomized into high and low levels, high expression is associated with a higher rate of primary resistant disease and is an adverse prognostic factor for

disease-free survival, cumulative incidence of relapse, event-free survival, and overall survival in AML with a normal karyotype, and predicts adverse prognosis independently from FLT3 mutations.³²⁴ High BAALC expression is also highly predictive of shorter disease-free and overall survival in normal-karyotype AML without FLT3 or CEBPA mutations.⁴⁹ High BAALC expression is associated with FLT3-ITD, absent FLT3-TKD, wildtype NPM1, mutated CEBPA, MLL-PTD, and high ERG expression, but high BAALC expression independently predicted lower complete remission rates when adjusting for ERG expression and age, and shorter survival when adjusting for FLT3-ITD, NPM1, CEBPA, and white blood cell count.³²⁵

Overexpression of the EVI1 (ectotropic viral integration site 1) gene on chromosome 3q26.2 has an incidence of approximately 11% and is seen not only in AML involving 3q26, including inv(3) and t(3;3), but also with other unfavorable karyotypes (e.g., -7/7q- and 11q23 abnormalities) and is associated with a poor prognosis.^{326,327,328} EVI1 is not overexpressed in AML with favorable-risk karyotypes or with NPM1 mutations. Stem cell transplantation in first complete remission has a favorable impact on relapse-free survival of patients with AML overexpressing EVI1 (20% to 40% versus 0%).

RAS mutations occur in 10% to 44% of AML, but rarely with FLT3 mutations, and have not consistently predicted outcome.^{36,329,300} Activation of the RAS/Raf/MEK/ERK pathway has also been demonstrated in AML, promoting AML cell survival and inhibiting apoptosis.^{330,331}

TP53 mutations have a frequency of 10% in de novo AML, but much higher frequency (40% to 50%) in t-AML. They have been associated with abnormalities of chromosomes 5 and/or 7 and with worse overall survival in older patients.³⁰⁰ TP53 mutations, or TP53 mutations and 17p-loss of heterozygosity combined, also have independent negative prognostic effects on survival in AML.³³²

Mutations in the WT1 (Wilms tumor 1) gene occur in 5% to 10% of AML patients, with equal distribution in cytogenetically normal and abnormal AML groups.²⁹¹ There are reports of both positive³³³ and negative³³⁴ prognostic effects of WT1 gene mutation in AML. WT1 mutation in AML was found to be associated with overexpression of CD96, a leukemia stem cell-specific marker, and of genes involved in regulation of gene expression (e.g., MLL, PML, and SNRPN) and in proliferative and metabolic processes (e.g., INSR, IRS2, and PRKAA1).³³⁵

The RUNX1 gene, located on chromosome 21 at band q22.12, encodes a transcription factor that is involved in benign and malignant hematopoiesis. The t(8;21) translocation, which is common in AML, results in a RUNX1 and ETO fusion protein. RUNX1 mutations are identified in 5.6% to 13.2% of AML patients, and are more common in older patients and in men. They are associated with lower lactic dehydrogenase, FAB M0/M1 subtypes, and expression of HLA-DR and CD34, and with lack of CD33, CD15, CD19, and CD56 expression. RUNX1 mutation is a poor prognostic factor, with resistance to chemotherapy and inferior event-free survival, relapse-free survival, and overall survival.^{336,337,338}

P.1589

The additional sex comblike 1 (ASXL1) gene encodes an enhancer of trithorax and polycomb proteins, which functions as a transcriptional activator or repressor in different cells. ASXL1 mutations are present in AML and were found to be five times more common in older (≥ 60 years) patients (16.2%) than those younger than 60 years (3.2%; $P < 0.001$), and to be associated with wildtype NPM1, absence of FLT3-internal tandem duplication and mutated CEBPA, and with inferior complete remission rate and disease-free, overall, and event-free survival in older patients.³³⁹

TET hydroxylase enzymes are involved in DNA hypomethylation and demethylation by α -ketoglutarate-dependent conversion of 5-methylcytosine to 5-hydroxymethylcytosine (alcohol moiety), followed by further oxidation to 5-formylcytosine (aldehyde moiety) and to 5-carboxylcytosine (acid moiety), Figure 75.7.^{340, 341} and ³⁴² Mutations in the 10 to 11 translocation 2 (TET2) gene were identified with frequencies of 22% of myelomonocytic leukemia, 24% in secondary AML, 19% in MDSs, and 12% in MPNs.³⁴³ Heterozygous TET2 mutations were found in 7.6% of younger adult patients with AML and were not associated with favorable or unfavorable response to chemotherapy or with overall survival.³⁴⁴

Chromatin conformation can be affected at the DNA level by addition of a methyl group to the C-5 position of cytosine. Cytosine methylation occurs when the cytosine (C) is followed by a guanosine (G) in CpG pairs (p indicates phosphodiester bond). When CpG dinucleotides in the genome cluster together, they form CpG islands, which are located in proximity to gene promoter regions or in other intergenic areas. DNA methylation is catalyzed by the DNA methyltransferase (DNMT) family of enzymes which transfer a methyl group from S-adenosyl methionine to DNA. Hypermethylation of CpG islands in the promoters of tumor-suppressor genes is common in many cancers.

In 2010, Ley et al. found that 22% of 281 de novo AML cases had mutations in DNMT3A that could affect translation.³⁴⁵ These mutations were seen predominantly in patients with intermediate-risk cytogenetic profiles, and not in patients with favorable-risk profiles. The precise effects of these mutations have not yet been elucidated. FLT3, NPM1, and IDH1 mutations were significantly enriched in samples with DNMT3A mutations. DNMT3A mutations were independently associated with poor prognosis. DNMT3A mutations were associated with significantly shorter median overall survival (12.3 months vs. 41.1 months, $p < 0.001$).

Several subsequent studies have shown that DNMT3A mutations are frequent (approximately 20%) in older patients with normal karyotype AML and are associated with higher WBC and platelet counts, and concurrent mutations in the NPM1, FLT3, and IDH1 or IDH2 genes, and that they independently predict a higher relapse rate and shorter overall survival, but are not associated with a lower CR rate.^{346, 347} and ^{348,349}

Mutations in isocitrate dehydrogenase genes, IDH1 and IDH2 (mIDH), are present in 10% to 15% of de novo AML,⁵⁴ are most common in normal karyotype AML, and are an unfavorable prognostic factor according to most, but not all, studies.^{350,351,352,353,354}

Although wildtype IDH in cytosol and mitochondria catalyzes the conversion of isocitrate to α -ketoglutarate (α -KG) with the production of NADPH, altered amino acids in mIDH1 (R132) and mIDH2 (R140 or R172) reside in the catalytic pocket and result in a neoenzymatic activity, converting α -KG to 2-hydroxyglutarate (2HG), with the consumption of NADPH.^{355,356,357} The primary source for α -KG for these cells is glutamine, which is first converted to glutamate by glutaminase and subsequently to α -KG (Fig. 75.8).³⁵⁸

FIGURE 75.7. DNA demethylation reactions mediated by the effect of TET enzymes and 2-HG. 5-methylcytosine in DNA is partially converted to 5-hydroxymethylcytosine by the TET (10 to 11 translocation) dioxygenases. In DNA 5-hydroxymethylcytosines are oxidized to aldehyde (5-formylcytosine) and acid (5-carboxylcytosine) by TET enzymes. TET enzymes use α -KG as co-enzyme. 2-HG, produced by IDH mutant enzyme, inhibit these reactions mediated by TET enzymes. The ultimate outcome is aberrant hypermethylation of DNA. (Drawing by Ashkan Emadi, University of Maryland Greenebaum Cancer Center.)

IDH1 and IDH2 mutations in AML associate with specific cytosine methylation, and aberrant DNA hypermethylation is the dominant feature of IDH1/2-mutant AMLs.³⁵⁹ 2HG, as the unique product of IDH-mutant enzymes, is a competitive inhibitor of multiple α -KG-dependent histone demethylases, prolyl hydroxylases, and TET hydroxylases (Fig. 75.7).^{360,361} Expression of mutant IDH1/2 and loss of TET2 increase expression of stem cell markers and impair myeloid differentiation.³⁵⁹

KIT is a receptor tyrosine kinase, as is FLT3. KIT mutations have been described in approximately a third of cases of AML with t(8;21) or inv(16) in adults and their presence is associated with short disease-free survival in this otherwise prognostically favorable cytogenetic subset.^{214,362,363,364,366} KIT mutations have been incorporated into the European LeukemiaNet prognostic classification.⁵¹ KIT overexpression is also described in t(8;21) or inv(16) cases without KIT mutations.²¹⁴ KIT inhibitors are beginning to be tested in conjunction with chemotherapy in t(8;21) or inv(16) AML.

Patterns of microRNA expression are beginning to be described in AML, with potential prognostic significance;^{55,56,57} microRNA expression may also be a future therapeutic target.

CLASSIFICATION OF ACUTE MYELOID LEUKEMIA

Morphologic Subtypes

The FAB classification identified eight subtypes of AML based on morphology and cytochemical staining, with immunophenotypic data in some instances (Chapter 73).⁶ Four types (M0, M1, M2, M3) are predominantly granulocytic and differ according to the extent of maturation. M4 is both granulocytic and monocytic, with at least 20% monocytic cells, whereas M5 is predominantly monocytic (at least 80% monocytic cells). M6 shows primarily erythroid differentiation with dysplastic features including megaloblastic changes, and M7 is acute megakaryocytic leukemia (AMgL) identified by

the presence of megakaryocyte antigens demonstrated by flow cytometry or immunohistochemistry, or of platelet peroxidase or a demarcation membrane system on ultrastructural studies. Problems with the FAB classification include interobserver variability, lack of definitive criteria for some cases of AML, and poor correlation with survival. In addition, correlations with immunophenotype, cytogenetic findings, and molecular abnormalities were not fully defined. Morphologic subtypes not precisely defined by the FAB include hypocellular AML and mixed lineage acute leukemia.³⁶⁷ Eosinophilic leukemia, basophilic

P.1590

leukemia, and mast cell leukemia are rare, overlap with myeloproliferative disorders, and are also not recognized by the FAB classification. The WHO classification recognizes chronic eosinophilic leukemia with the overlapping hypereosinophilic syndrome, and acute basophilic leukemia and the spectrum of mast cell disease, including mast cell leukemia.²⁴

FIGURE 75.8. Chemical reactions that link glutamine to IDH enzymes. In normal cells, IDH catalyzes loss of one carboxyl (CO₂, light blue) group from isocitrate and oxidizes its hydroxyl group (OH, pink) to ketone. The product is α-KG. Under certain conditions, this reaction can be reversible. In cells with mutant IDH, α-KG cannot be converted to isocitrate, instead it is converted to a new molecule 2-HG, and as a result, α-KG is siphoned by the mutant enzyme. Glutamine is the primary source for α-KG, which is replenished via conversion of glutamine to glutamate by glutaminase. Glutamate can be

converted to α -KG either by transamination or by oxidation processes. GOT, glutamate oxaloacetate transaminase; GLUD, glutamate dehydrogenase. (Drawing by Ashkan Emadi, University of Maryland Greenebaum Cancer Center.)

World Health Organization Classification

The WHO classification of acute leukemias and MDS evolved from the FAB classification, which is based on morphology, to also include clinical, immunophenotypic, and cytogenetic features.^{1,3,24} The WHO recognizes five major categories: (a) AML with recurrent genetic abnormalities; (b) AML with multilineage dysplasia; (c) AML and MDS, therapy-related; (d) AML not otherwise categorized; and (e) acute leukemia of ambiguous lineage (Table 75.6). Additionally, the WHO classification defines AML by presence of 20% or more blasts, thus including cases with 20% to 30% blasts, which had been categorized as the refractory anemia with excess blasts in transformation subtype of MDS in the FAB classification. This change was made based on evidence that survival of patients with marrows with 20% or more blasts is similar to that of patients with marrows with 30% or more blasts.³⁶⁸ In addition, in the WHO classification presence of recurrent cytogenetic abnormalities that are characteristic of AML, including (8;21)(q22;q22), inv(16)(p13;q22) or t(16;16)(p13q22), t(15;17)(q22;q12), or translocations or structural abnormalities involving 11q23 establishes the diagnosis of AML, even if the bone marrow contains less than 20% blasts.

AML with recurrent genetic abnormalities includes AML with t(8;21)(q22;q22), inv(16)(p13;q22), or t(16;16)(p13q22), t(15;17)(q22;q12), or translocations or structural abnormalities involving 11q23. t(8;21) and inv(16) or t(16;16) typically occur in younger patients, have a relatively favorable response to therapy, and define the favorable category in cytogenetic classifications of AML. AML patients with 11q23 translocations include two clinical subgroups in particular: AML in infants and therapy-related leukemia, usually occurring after treatment with DNA topoisomerase II inhibitors. AML with recurrent genetic abnormalities is discussed in the "Clinicopathologic Syndromes" section in the context of the FAB morphologic subtype with which the abnormalities correlate and is also discussed in the "Cytogenetic Classification" section.

AML with multilineage dysplasia must have dysplasia in 50% or more of cells of at least two lineages. It is more common in older patients, frequently exhibits aberrant expression of CD56, CD7, or both, and is associated with unfavorable cytogenetic findings, including -7/del(7q), -5/del(5q), +8, +9, +11, del(11q), del(12p), -18, +19, del(20q) +21, and, less often, translocations involving 3q21 and 3q26 and t(1;7)(q10;p10). Abnormalities in the 3q26 region may be associated with increased platelet production. AML with multilineage dysplasia has a poor response to therapy.

AML not otherwise categorized includes AML that does not fulfill criteria for the other groups and essentially reflects the morphologic and cytochemical features and degree of maturation used in the FAB classification, with the exception that AML is defined by 20% (rather than 30%) or more blasts in the marrow. The abnormal promyelocytes in APL and the promonocytes in AML with monocytic differentiation are considered blast equivalents. In addition, AML not otherwise categorized includes acute basophilic leukemia, acute panmyelosis with myelofibrosis, and myeloid sarcoma.

Acute leukemia of ambiguous lineage is diagnosed when blasts lack sufficient lineage-specific antigen expression to classify them as myeloid or lymphoid and is discussed in the "Immunophenotypic Classification" section.

Immunophenotypic Classification

The nonlymphoid derivation of AML is confirmed by the presence of antigens expressed during myelomonocytic differentiation,

P.1591

including CD13 (My7), CD14 (Mo2), CD15 (My1, LeuM1), CD33 (My9), CD117 (KIT), and MPO; erythroid antigens (glycophorin A, CD71); and megakaryocytic antigens, including CD41 (platelet glycoprotein IIb/IIIa), CD42b (platelet glycoprotein Ib), CD61 (platelet glycoprotein IIIa), and factor VIII antigen.³⁶⁹ The stem cell marker CD34 (My10, HPCA-1) is present on blasts in 40% to 65% of cases of AML.^{370,371} Surface markers in most cases have not correlated well with the FAB classification or with prognosis.³⁷² More than 90% of cases of AML express CD33 or CD13, 80% to 90% express HLA-DR, and less than 25% express CD15; CD11b and CD14 are more variably expressed and tend to be present in monocytic (M4/M5) subtypes.⁵¹ Some antigens have also been associated with morphologic and cytogenetic subsets: CD2 with M4Eo with 16q22 rearrangements;³⁷³ absence of HLA-DR (major histocompatibility complex class II) and of CD34 with M3 [t(15;17)]; and presence of CD19 and CD56 with M2 with t(8;21).^{10,374}

Acute Leukemia of Ambiguous Lineage

The morphologic associations and prognostic significance of surface markers have been variable; antigen expression should be interpreted only in the context of other clinicopathologic features. CD34 is expressed more often in less differentiated subtypes (M0, M1; M5, poorly differentiated) in many series,³⁷⁵ it has also been described as more common in monocytic (M4/M5) than in granulocytic (M1, M2, M3) subtypes.³⁷⁶ CD34 is generally a poor prognostic marker, particularly when observed in older patients, after MDS, or in association with expression of the multidrug resistance gene P-glycoprotein (Pgp; MDR-1; ABCB1),^{375,377} but CD34 is also expressed in FAB M2 AML with the t(8;21) chromosomal translocation³⁷⁸ and in FAB M4Eo with inv(16),³⁷⁶ both of which have a favorable prognosis.

Lineage-specific antigen expression in the WHO classification is demonstrated in Table 75.7. Lymphoid antigens are expressed on blasts in 10% to 30% of cases of AML, and their expression has often been implicated as having prognostic significance, but their presence should be interpreted in the context of all available information.³⁷⁹ Expression of CD19 (B-cell) is associated with a good prognosis when present in AML with t(8;21)²⁸³ and a poor outcome when co-expressed with CD34 in the absence of favorable cytogenetics findings. CD7 (T-cell) is present in 15% to 20% of cases of adult AML and has

been associated with a poor prognosis, usually with less differentiated subtypes (M0/M1) and expression of CD34, Pgp, or TdT.^{380,381} CD56, a cell-surface glycoprotein identical to the neural cell adhesion molecule, is more commonly observed in patients with AMoL, t(8;21), and trisomy 8, and with expression of CD11b, CD14, and CD19,³⁸² and has been associated with shorter disease-free survival in favorable AML subtypes.³⁸³

Acute leukemias of ambiguous lineage are divided into three groups. Undifferentiated acute leukemias, the first group, lack morphologic or immunologic differentiating features. The blasts often express HLA-DR, CD34, and CD38 and may express TdT and CD7. Bilineage acute leukemia, the second group, has two

P.1592

populations of blasts expressing distinct lineage markers of myeloid or lymphoid origin or, less frequently, B- and T-cell lineage. In the third group, biphenotypic acute leukemia, blasts co-express myeloid and lymphoid (B- or T-cell) antigens. Blasts very rarely express myeloid, B-, and T-cell antigens. Rearrangements of the T-cell receptor or the immunoglobulin chain genes are usually absent in AML with lymphoid antigen expression, although they have been described, usually in association with karyotypic abnormalities such as t(9;22), 11q23, or 14q32 translocations.^{384, 385} and ³⁸⁶ Up to 20% of patients with acute leukemia may have biphenotypic or mixed lineage features as detected by immunologic and molecular genetic techniques, but less than 4% of cases are unclassifiable.²⁴

TABLE 75.7 LINEAGE-SPECIFIC ANTIGEN EXPRESSION IN THE WHO CLASSIFICATION

Myeloid	MPO (by flow cytometry, immunohistochemistry or cytochemistry) <i>or</i> monocytic differentiation (at least two of the following: NSE, CD11c, CD14, CD64, lysozyme)
T-lymphoid	Cytoplasmic CD3 (flow cytometry with antibodies to CD3 epsilon chain; immunohistochemistry using polyclonal anti-CD3 antibody may detect CD3 zeta chain, which is not T-cell-specific) <i>or</i> surface CD3 (rare in mixed phenotype acute leukemias)
B-lymphoid	Strong CD19 with at least 1 of the following strongly expressed: CD79a, cytoplasmic CD22, CD10, <i>or</i> weak CD19 with at least two of the following strongly expressed: CD79a, cytoplasmic CD22, CD10

Cytogenetic Classification

Cytogenetic findings are the strongest predictors of AML treatment outcomes. AML has been divided into favorable, intermediate, and unfavorable subgroups based on cytogenetic findings in large series from multiple cooperative groups, with remarkably consistent findings. Cytogenetic classification of AML is discussed in the section, "Prognosis."

Molecular Classification

Cytogenetically normal AML is subdivided based on the presence of diverse mutations, which are detailed above and further discussed in the section, "Prognosis."

European LeukemiaNet Classification

In a 2010 publication, the European LeukemiaNet proposed a classification of AML that integrated cytogenetic and molecular data to define favorable, intermediate-I, intermediate-II, and unfavorable genetic groups.⁵¹ This classification is being widely adopted, and the significance of additional and newly discovered molecular abnormalities is being described in the context of this classification.

CLINICOPATHOLOGIC SYNDROMES

The WHO classification recognizes four major categories of AML defined by specific genetic abnormalities, with multilineage dysplasia, therapy-related, and a not otherwise categorized group that retains the morphology-based FAB classification. In addition, acute leukemia of ambiguous lineage is included. Clinicopathologic syndromes of AML are discussed below.

Minimally Differentiated Acute Myeloid Leukemia (AML M0)

Criteria for FAB M0 were developed in 1991.^{6,387} Immunophenotyping confirms the myeloid nature of blasts in M0, because morphology and cytochemistry are inconclusive. Blasts in M0 AML are agranular and lack Auer rods. By definition, the diagnosis of AML M0 requires less than 3% MPO-positive and Sudan black B-positive cells but more than 20% leukemia cells expressing myeloid antigens (CD13, 33, 117).^{6,387} Of note, lymphoid-associated antigens, particularly T-cell type (CD2

and CD7) and TdT (30 to 50%), are commonly expressed in AML M0, but T-lymphoid-specific cytoplasmic CD3 (cyCD3) and B-lymphoid-specific cytoplasmic CD22 and CD79 (cyCD22, cyCD79) are absent.³⁸⁸ M0 is characterized by a higher incidence of karyotypic abnormalities (70 to 75%) than other FAB subtypes.³⁸⁹ AML M0 tends to occur in older patients (>60 years).³⁹⁰ The CR rate and survival in AML M0 are generally poor, consistent with the association with unfavorable karyotypes.^{391, 392} and ³⁹³

Acute Myeloid Leukemia Without Maturation (AML M1)

AML M1 is defined by a predominance (>90%) of myeloblasts without evidence of maturation (<10% promyelocytes or other, more mature, cells). The presence of Auer rods is variable. At least 3% of the blasts are reactive with Sudan black or MPO. The blasts express myeloid antigens. AML M1 makes up 10% to 20% of cases of AML and is more common in adults than in children; the median age is 45 to 50 years.²⁴ Constitutional symptoms are common, and hepatosplenomegaly and lymphadenopathy occur in up to one third of patients.²⁴ No specific cytogenetic marker has been associated with AML M1, but trisomies 11 and 13 have been reported in the immature myeloid leukemias, AML M0 and M1.³⁸⁹

Acute Myeloid Leukemia with Maturation and with t(8;21) (AML M2)

AML M2 is associated with t(8;21)(q22;q22) in 30% to 40% of cytogenetically abnormal cases.²⁴ Approximately 10% of all AML patients present with this syndrome; most are children and young adults. Myeloid sarcoma is common in this syndrome. AML with t(8;21) is typically associated with prominent Auer rods, marrow eosinophilia, and cytoplasmic globules and vacuoles (Fig. 75.9).

P.1593

Immunophenotypic markers include the presence of myeloid antigens, increased expression of the natural killer cell-associated antigen CD56, and, less commonly, the B-cell antigen CD19.³⁹⁴

FIGURE 75.9. AML M2 with t(8;21), Wright-stained bone marrow smear. Blasts with maturing myeloid elements. (Courtesy of Dr. Qing Chen, Department of Pathology, University of Maryland.)

The two genes involved in t(8;21) are AML1 (also known as RUNX1, CBF α , and PEBP2 α B) at 21q22 and ETO (also called CDR and MTG8) at 8q22^{395,396} (Chapter 72). They form a fusion gene on the derivative 8 chromosome, which may be detected even in patients in long-term remission, indicating its low value as a marker for minimal residual disease.³⁹⁷ The AML1 gene is also involved in t(3;21)(q26;q22), a rare balanced translocation observed in blast crisis of CML and in t-AML, and in t(12;21) with the TEL gene in ALL.³⁹⁸

The t(8;21) usually occurs in de novo AML and generally predicts a favorable outcome, with a high remission rate (CR rate of 86% to 95%) and long survival (5 years DFS of 57% to 71%), particularly after high-dose cytarabine (HiDAC) consolidation therapy.³⁹⁹ Children and patients with leukocytosis (>20,000 cells/mm³) or with extramedullary disease may have high relapse rates and inferior survival.⁴⁰⁰ Mutations of the growth factor receptor KIT in AML1-ETO AML identify a subgroup of patients with a high white count (median 29,600/mm³), a higher incidence of extramedullary disease (33%), and a poor prognosis.³⁶⁴ Expression of the CD56 antigen on AML cells with t(8;21) is also associated with a shorter disease-free survival (DFS).³⁸³ Because of high survival rates after multiple cycles of HiDAC consolidation, alloSCT is usually reserved for relapse.

Acute Promyelocytic Leukemia (AML M3)

See Chapter 78.

Acute Myelomonocytic Leukemia (AML M4) and Acute Myelomonocytic Leukemia with Eosinophilia (AML M4Eo) and Pericentric Inversion of Chromosome 16

AML M4 and M4Eo is present in approximately 5% to 10% of patients with AML in association with monocytosis and a myeloblastic/monoblastic infiltration of the bone marrow (Fig. 75.10). Organomegaly is common, with splenomegaly in 30% of patients. Hyperleukocytosis (>100,000 cells/mm³) is present in 20% to 25% of patients.²⁴ Extramedullary disease with involvement of skin (scalp), ovaries, testicles, intestine, CNS, and particularly lymphadenopathy occurs in 20% to 30% of patients and may confer a worse prognosis.⁴⁰¹ The immature eosinophils have a monocytoid nucleus and a mixture of eosinophilic and large atypical basophilic granules. Staining with Sudan black, periodic acid-Schiff (PAS), and chloroacetate esterase with nonspecific esterase (double esterase) can identify the neoplastic cell. By flow cytometry, all cases of AML M4Eo express the panmyeloid marker CD13 and the stem cell antigen CD34, but there is variable expression of other myeloid/monocytic markers, including CD11b, CD11c, CD14, and CD33. There is also frequent expression of the T-lymphoid marker CD2, along with HLA-DR.

The syndrome associated with AML M4Eo was first described by Arthur and Bloomfield in 1983 in five patients with a deletion of the long arm of chromosome 16. In subsequent reports, the abnormality has been described in almost all patients as a pericentric inversion of chromosome 16, inv(16)(p13;q22), whereas a minority of patients have a balanced translocation between the two copies of chromosome 16, t(16;16)(p13.1;q22).⁴⁰² The prognosis of patients with t(16;16)(p13;q22) is similar to that of patients with inv(16)(p13;q22).⁴⁰³ Cloning of the 16p and 16q breakpoints has identified the two genes involved: MYH11, which codes for smooth muscle myosin heavy chain, and core-binding factor (CBF) β (also known as PEBP2 β), which codes for the β subunit of CBF, a heterodimeric transcription factor involved in murine leukemogenesis and in T-cell receptor gene expression.^{404,405} CBF β -MYH11 fusion transcripts are detected by RT-PCR in typical AML M4Eo, but also in approximately 10% of patients with AML M4 without eosinophilia.⁴⁰⁶

FIGURE 75.10. AML M4Eo with *inv(16)*, Wright-stained bone marrow smear. In addition to myeloblasts and monoblasts, abnormal eosinophils with large basophilic granules are characteristic of this type of AML. (Courtesy of Dr. Qing Chen, Department of Pathology, University of Maryland.)

The 81% to 93% CR rate and 48% to 63% DFS of AML with *inv(16)* or *t(16;16)* to conventional chemotherapy represent a better prognosis than for most other subtypes of AML.^{399,407} Allogeneic transplantation is usually considered only in patients who relapse. AML with inversion 16 previously had a high risk of CNS relapse, but the use of HiDAC as consolidation therapy decreases the incidence of CNS disease and may serve as CNS prophylaxis. Multiple cycles of HiDAC consolidation are associated with better relapse-free survival (RFS) than a single cycle.³⁹⁹ As with AML/ETO, the detection of KIT mutations is associated with an increased relapse rate.³⁶⁶ Minimal residual disease (MRD) can be monitored by quantitative RT-PCR to identify patients at risk for relapse.^{406,408,409} Carefully defined MRD cutpoints for persistent CBF β -MYH11 transcript positivity were shown to be able to distinguish patients with significantly increased risk of relapse.⁴¹⁰

Acute Monocytic Leukemia (AML M5a and M5b) and with 11q23 Abnormalities

AML M5 accounts for 2% to 10% of AML cases. M5 is subdivided into M5a, poorly differentiated (>80% monocytic cells including monoblasts), and M5b, well differentiated (80% monocytic, predominantly promonocytes and monocytes).¹⁷⁸ Patients with M5a tend to be younger (75% <25 years of age) than those with M5b, but both include a wide age range.²⁴ Monocytic precursors are recognized by their fluoride-inhibitable nonspecific esterase positivity and expression of CD14 and CD4 (dim expression) but not CD2. Monoblasts may be recognized by staining with antibodies to lysozyme and to CD68 (KP1).²⁴ There is cytogenetic heterogeneity in AML M5, but common findings include a normal karyotype (49%), 11q23 abnormalities (21%), and trisomy 8 (21%).⁴¹¹ The incidence of 11q23 abnormalities is higher in AML M5a (31% to 33%) than in AML M5b (12% to 16%) and AML M4 (5%); they are found in less than 1% of all other FAB subtypes ($P < 0.0001$).^{278,286,411} Trisomy 8 is more common in M5a than M5b, which has a normal karyotype in 71% of cases.⁴¹¹ FLT3 mutations are more common (29%) in M5b than M5a.⁴¹¹

Extramedullary disease occurs in over 50% of patients with AML M5 and is more common in AML M5 than in other subtypes of AML. It may include cutaneous lesions, gum infiltration,

testicular involvement, and CNS disease.^{412,413} CNS involvement has been reported in 3% to 22% of patients.⁴¹² Leukocytosis is a common finding, present in 10% to 37% of patients. The frequency of DIC is second only to that in APL, and DIC may be exacerbated when therapy begins. Elevated levels of lysozyme are found in more than two thirds of patients and may contribute to renal insufficiency or proteinuria. Results of several studies indicate that AML M5 is associated with poor prognosis, and specifically short disease-free survival.⁴¹² On the other hand, ECOG reported no difference in CR rates for M5 patients (62%) compared to non-M5 patients (60%) and no difference in 3-year overall survival (31% vs. 30%).⁴¹⁴

Erythroleukemia (AML M6)

Erythroleukemia accounts for 2% to 4% of cases of AML and is characterized by a prominent component of erythroblasts. Erythroid/myeloid leukemia (M6a) has 50% or more erythroid precursors in the nucleated population and 20% or more myeloblasts in the nonerythroid population. In the less common pure erythroid leukemia (M6b), 80% of the marrow cells are immature erythroblasts, without a significant percentage of myeloblasts. A third type (M6c) has been characterized by 30% or more nonerythroid blasts and 30% or more pronormoblasts.⁴¹⁵

Morphologic findings in the peripheral smear may include schistocytes, teardrop forms, pincerred red cells, and basophilic stippling.⁴¹⁶ Circulating erythroblasts are observed in one half of patients. The bone marrow is usually hypercellular with megaloblastic changes.⁴¹⁶ Erythroid precursors commonly have multinuclearity (65%), karyorrhexis (53%), morulae (25%), and/or cytoplasmic vacuolization (23%). The PAS reaction may stain abnormal erythroid cells in either a coarse globular (16%) or diffuse (57%) pattern. The most common immunophenotypic markers for erythroleukemia are glycophorin 7 and the transferrin receptor (CD71).

There is a bimodal age distribution for erythroleukemia, with a small peak below 20 years and a broader peak in the seventh decade.⁴¹⁵ In many series approximately one half of cases of erythroleukemia are therapy-related.⁴¹⁶ Cytogenetic abnormalities are found in over 70% of patients, and abnormalities of chromosomes 5 and 7 are common.^{417, 418} and ⁴¹⁹

The prognosis for erythroleukemia is generally poor, with a recent reported overall survival of 8 months,⁴²⁰ but depends upon age, secondary leukemia, cytogenetic abnormalities, and subtype of erythroid leukemia. One report had a CR rate of 62% for de novo erythroleukemia but most series have CR rates in the 10% to 40% range, particularly in secondary erythroleukemia.⁴¹⁵ The CR rate in patients with 5q or 7q abnormalities is approximately 20% and the median survival is 4 months, compared to 18 months in the absence of these abnormalities.⁴²¹ Median survival was inferior in M6b (1.8 months) compared to M6a (18.8 months, $P < 0.002$) and M6c (7 months, $P < 0.01$).⁴²² Allogeneic SCT appears to confer the best long-term survival in erythroleukemia, particularly with unfavorable cytogenetics and/or therapy-related.⁴¹⁵

Acute Megakaryocytic Leukemia (AML M7)

AML M7 was first described in 1931 and was added to the FAB classification in 1985.^{423, 424} and ⁴²⁵ There is a bimodal age distribution, with one peak in infancy and the other in older adults. Megakaryocytic AML represents 0.6% to 1.2% of cases of adult AML, compared to 3% to 10% of childhood AML. The median age for adult AML M7 is 51 to 58 years and there is a male predominance. Morphologically, AML M7 can be confused with the L2 subtype of ALL or with AML M1. Cytoplasmic blebs suggestive of megakaryocyte differentiation may be present on the blasts. The myeloid surface markers CD13 or CD33 may be expressed, and CD34 is often absent. The diagnosis depends on the expression of at least one platelet antigen (CD41, CD42b, CD61, or factor VIII-related antigen) on the leukemia cells. The bone marrow may be difficult to aspirate and over two thirds of patients will have significant fibrosis.

Cytogenetic abnormalities are more frequent (>90%) in AML M7 than in other subtypes of AML.⁴²⁶ They are heterogeneous but differ between children and adults,⁴²⁶ with adults typically having complex karyotypes.

Although data are limited, the clinical presentation of AML M7 is not substantially different from that of other subtypes of AML. Organomegaly is infrequent in adults. Cytopenias are usually present, but approximately 30% of patients have platelet counts above 100,000/ μ l.¹⁷⁸ Platelet function studies usually indicate impaired aggregation responses. Serum LDH levels are often elevated. Osteosclerotic and osteolytic lesions have been demonstrated radiographically.^{178,427}

Prognosis in adult AML M7 is poor.^{423, 424} and ⁴²⁵ The CR rate is 43% to 50% and the median DFS is 6 to 10 months.^{423, 424} and ⁴²⁵ The ECOG series reported an inferior DFS in M7 compared to non-M7 AML (23 vs. 52 weeks, $P < 0.001$), and found M7 AML to be an independent adverse prognostic factor for DFS.⁴²³ Because of the poor prognosis of adult AMGL, early allogeneic SCT should be considered.

Other Clinicopathologic Syndromes

Acute panmyelosis with myelofibrosis (APMF) was first described in 1963 by Lewis and Szur.⁴²⁸ APMF is rare, representing less than 1% of AML, and has replaced acute myelosclerosis or acute myelofibrosis in the WHO classification.⁴²⁸ The median age is 57 to 67 years and there is a male predominance. The onset is sudden and patients have pancytopenia with <5% blasts in the peripheral blood and no to minimal teardrop forms. There is no history of preceding myeloproliferative disorders and there is no, or minimal, splenomegaly. The marrow is hypercellular with various degrees of hyperplasia of the three cell lineages; clusters of late-stage erythroids may be prominent. Dysplastic changes, including hypolobated megakaryocytes with dispersed chromatin, are present. Clusters of immature cells are present, and the degree of marrow fibrosis is variable. If the proliferative process includes predominantly myeloblasts and fibrosis is present, the leukemia should be classified as AML of the appropriate cell types with “myelofibrosis.” The main differential diagnosis is between APMF and AML M7.⁴²⁸ There are fewer blasts in APMF and the blasts rarely express megakaryocytic antigens. Cytogenetic findings are not specific but are often complex and include abnormalities of 5q, 7, and 17p.⁴²⁹ The prognosis of APMF is extremely poor, with a median survival of less than 2 months in some series.^{428,430}

Acute basophilic leukemia is very rare, but is recognized as an independent entity by the WHO classification.⁴³¹ Cutaneous disease, organomegaly, lytic bone lesions, and symptoms of hyperhistaminemia may be present. Blasts have oval, round, or bilobed nuclei and variable numbers of coarse basophilic cytoplasmic granules. The characteristic cytochemical staining is metachromatic positivity with toluidine blue, diffuse acid phosphatase positivity, and, in some cases, block PAS positivity. Blasts often do not stain with Sudan black B, MPO, or nonspecific esterase. Blasts express the panleukocyte antigen CD45, the myeloid antigens CD13, CD33 and CD11b, and usually also CD9 and CD17, CD34, and HLA-DR. Involvement of 12p or t(6;9), which can occur in AML with increased basophils, has been reported.⁴³¹ Some cases may represent blast crisis of CML or de novo Ph+ acute leukemia. Prognosis is uniformly poor.⁴³²

The t(6;9)(p21;q34) is a rare variant of AML (<1%) that was initially described in a young age group (20 to 30 years of age) with basophilia and a poor response to therapy. It is usually of the FAB M2 or M4 subtype.⁴³³ The genes involved are the DEK gene on chromosome 6p23 and the nucleoporin protein, NUP214 (previously CAN) gene on chromosome 9p34.⁴³⁴

P.1595

AML with abnormalities of the long arm of chromosome 3, inv(3)(q21q26) and t(3;3)(q21;q26), typically presents with a normal platelet count or thrombocytosis.⁴³⁵ The critical gene involved at 3q26 is EVI1 (ecotropic viral integration site 1),^{436,437} and overexpression of EVI1 is found in 9% of AML without 3q26 abnormalities.⁴³⁸ GATA2 (3q21) may also be overexpressed. The inv(3)(q21;q26) syndrome represents 1% to 3% of de novo AML, may also follow MDS, and has a poor prognosis. Abnormal megakaryocytes may be present.⁴³⁹ Other rare balanced rearrangements involving 3q26 include t(3;21)(q26;q22), t(3;12)(q26;p13), and t(2;3)(p15;22;q26).⁴⁴⁰

AML with t(3;5)(q25.1;q35) has been reported in approximately one fourth of patients with erythroleukemia (M6), and the marrow often has trilineage dysplasia and abnormal megakaryocytes. Unlike patients with inv(3), patients with t(3;5) do not have thrombocytosis.⁴⁴¹ The genes involved are NPM on chromosome 5 and myelodysplasia/myeloid leukemia factor 1 (MLF1) on chromosome 3.⁴⁴²

TABLE 75.8 PROGNOSTIC FACTORS IN ACUTE MYELOID LEUKEMIA

Factor	Favorable	Unfavorable
Clinical		
Age	<45 y	<2 y, >60 y
ECOG performance status	0-1	>1
Leukemia	De novo	Antecedent hematologic disorder; myelodysplastic syndrome, myeloproliferative disorder
Infection	Absent	Present
Prior chemotherapy	No	Yes
WBC count	<25,000/mm ³	>100,000/mm ²
Serum LDH	Normal	Elevated

Extramedullary disease	Absent	Present
CNS disease	Absent	Present
Cytoreduction	Rapid	Delayed
Morphology		
Auer rods	Present	Absent
Eosinophils	Present	Absent
Megaloblastic erythroids	Absent	Present
Dysplastic megakaryocytes	Absent	Present
FAB type	M2, M3, M4	M0, M6, M7
Surface/Enzyme Markers		
Myeloid	CD34 ⁻ , CD14 ⁻ , CD13 ⁻	CD34 ⁺
HLA-DR	Absent	Present
TdT	Absent	Present
Lymphoid	CD2 ⁺	CD7 ⁺ , CD56 ⁺ Biphenotypic (two or more lymphoid markers)
MDR-1	Absent	Present
Cytogenetics		
(see Tables 75.4 and 75.6)	t(15;17), t(8;21), inv(16)	-7, del(7q), -5, del(5q), 3q21 and 3q26 abnormalities, complex karyotype
Molecular Markers		
FLT3 mutation	Absent	Present
EVI1 overexpression	Absent	Present
MLL partial tandem duplication	Absent	Present
NPM1 mutation	Present	Absent
CEBP- α mutation	Present	Absent
BAALC overexpression	Absent	Present
VEGF overexpression	Absent	Present

ECOG, Eastern Cooperative Oncology Group; FAB, French-American-British; HLA, human lymphocyte antigen; LDH, lactate dehydrogenase; MDR, multidrug resistance gene.

PROGNOSIS

Prognosis Is Multifactorial

A number of clinical and biologic features, detailed below, predict prognosis in AML, and prognosis is actually determined by interactions between these factors (Table 75.8). As an example,

structural cytogenetic abnormalities involving the genes encoding the core binding factor transcription factor subunits, including t(8;21), inv(16), and t(16;16), define the favorable cytogenetic subgroup of AML, but treatment outcome is significantly worse in older patients with these cytogenetic abnormalities,⁴⁴³ and in patients whose AML cells have mutations of the growth factor receptor KIT.^{364,365,366} As another example, in a Southwest Oncology Group study of older AML patients, secondary AML, unfavorable karyotype and expression of the MDR protein MDR1 (Pgp) were each independently significant associated with lower CR rates, but CR rates ranged from a high of 81% to a low of only 12% depending on how many of these three adverse prognostic factors were present.⁴⁴⁴

Clinical Factors

Age is a powerful prognostic factor, with older adult patients having worse outcomes than younger adults.⁴⁴³ The clinical state of the patient, as reflected in performance status and co-morbid conditions, also affects outcome.⁴⁴⁵ Patients with secondary AML, defined by a preceding bone marrow disorder, including MDS or MPN, or with t-AML, have an inferior response and survival compared to those with de novo AML.^{446,447} Hyperleukocytosis correlates with shorter overall survival⁴⁴⁸ due to both increased induction deaths⁴⁴⁹ and an association with FLT3 mutations.³⁶ Extramedullary disease is unfavorable.⁴⁴⁸ Finally, one report demonstrated lower CR rates and shorter overall survival in African American males, in relation to whites and African American females.⁴⁵⁰

Morphology

Favorable morphologic features include presence of Auer rods (M1-M4) and of eosinophils (M2 and M4Eo), the latter because of the association with the favorable cytogenetic abnormalities t(8;21) in M2 and inv(16) in M4Eo. The eosinophils in M2 show only minor abnormalities such as faint green-blue/yellow granules, whereas in M4Eo they are dysplastic and often have large, irregular deeply purple granules (Figs. 75.6 and 75.9). Morphologic dysplasia is unfavorable,⁴¹⁵ likely by virtue of association with unfavorable karyotypes.⁴⁵¹ In regard to FAB types, patients with M0,³⁹³ M6⁴⁵² and M7^{423,424} generally have lower survival rates. FAB M5 is associated with extramedullary disease and with FLT3 mutations³⁵

Immunophenotype

The effect of surface markers on prognosis is variable and is interdependent with other factors. Although CD34 has been reported as an adverse factor,^{379, 448} in some studies it has had no impact on outcome.^{453,454} CD34 expression is a poor prognostic factor when it is associated with the multidrug resistance gene (MDR1).⁴⁵⁵ CD34 expression is associated with prognostically adverse karyotypes, including abnormalities of chromosome 5 (-5/5q-) and 7,⁴⁵⁴ but it is also expressed in favorable AML subtypes, including AML with t(8;21)^{378, 454} and inv(16).³⁷⁶ The lack of HLA-DR reactivity as observed in APL (M3) has been associated with a good prognosis in some,⁴⁵⁶ but not all,⁴⁵⁷ series, whereas absence of CD33 expression may be unfavorable.⁴⁵³ CD7 expression is prognostically unfavorable.⁴⁵⁸ CD56 expression correlates with extramedullary disease, which is unfavorable.⁴⁴⁸ Both CD19 and CD56 are frequently expressed on AML cells in t(8;21) AML; CD19 does not have prognostic significance, and CD56 is associated with shorter disease-free survival in these patients.³⁸³ Finally, detection of residual or recurrent blasts by multiparameter flow cytometry at diverse time points following therapy predicts adverse outcome.^{206,208,459, 460 and 461}

Multidrug Resistance

Expression of multidrug resistance (MDR) genes has been identified as having adverse prognostic significance in AML.^{377,462,463} The best described MDR gene is MDR1, whose gene product, P-glycoprotein (Pgp), is a 170-Kda cell membrane ATP-binding (ABC) protein (ABCB1) that functions as a drug efflux pump for naturally occurring substances, including anthracyclines, epipodophylotoxins, vinca alkaloids, and taxanes,^{463,464} as well as the calicheamicin moiety of gemtuzumab ozogamicin.⁴⁶⁵ Pgp expression can be detected on the surface of AML cells by flow cytometry using specific antibodies such as MRK16 and can be correlated with functional efflux of substrate fluorescent dyes by AML blasts. Expression of MDR-1/Pgp on blasts is more commonly found in older AML patients, often in conjunction with adverse cytogenetic findings, and is associated with a lower CR rate.³⁷⁷ Moreover, MDR-1/Pgp overexpression and FLT3-ITDs occur largely in different AML patient populations.³⁰⁵

Other transport proteins that mediate cellular drug efflux and appear to mediate drug resistance in AML include the ABC proteins multidrug resistance-associated protein 1 (MRP-1; ABCC1) and breast cancer resistance protein (BRCP; ABCG2).^{377,462,466} MRP-1 has adverse prognostic significance in AML,⁴⁶⁷ especially when co-expressed with MDR-1/Pgp,^{462,468} and BCRP also has adverse prognostic significance.⁴⁶⁹ The major vault protein lung resistance protein (LRP) is not an ABC protein, but rather an intracellular protein that affects cytoplasmic-nuclear drug transport; its expression in AML cells has been associated with adverse treatment outcome in some series.^{463,470}

Cytogenetics

Cytogenetic subgroups identify prognosis better than any other factor in both younger and older adult AML patients,^{28,29,31,32,471,472} and stratification of therapy based on cytogenetic prognostic group has become the standard of care in AML.⁴⁷³ Criteria that subdivide AML patients into favorable, intermediate and unfavorable cytogenetic risk groups vary only minimally among cancer cooperative group studies (Table 75.9). Studies of cytogenetics in AML are important not only in terms of defining prognostic subgroups, but also in terms of defining the features and optimal management of AML with uncommon individual karyotypes.^{278,474} A representative survival curve according to cytogenetic findings is illustrated in Figure 75.11.⁴⁷⁵

APL [t(15;17)] and AML with either of two core binding factor (CBF) abnormalities, t(8;21) and inv(16) or t(16;16), are regarded as favorable types of AML. AML with either of the two CBF abnormalities has both a high CR rate and a high rate of disease-free survival, particularly when treated with high-dose cytarabine-based post-remission regimens.^{399,476} Nevertheless, favorable cytogenetic prognosis may be modified by other factors. For example, when t(8;21) is present in older patients⁴⁴³ or when t(8;21) AML cells express the neural cell adhesion molecule CD56³⁸³ or have mutations of the growth factor receptor KIT,^{364,365} and ³⁶⁶ prognosis is worse. The standard of care for AML with favorable karyotypes is post-remission chemotherapy with high-dose cytarabine, rather than transplantation in remission.⁴⁷³

Unfavorable cytogenetic groups are consistently defined by del(5q)/-5, -7/del(7q) and/or complex karyotypes (defined by either ≥3 or ≥5 unrelated abnormalities), or inv(3)/t(3;3), t(6;9) or t(9;22). There is some variability in additional karyotypes included in unfavorable cytogenetic groups among different cooperative groups^{28,29} and within cooperative groups, when considering induction outcome, cumulative incidence of relapse or overall survival.²⁹ Additional karyotypes predicting adverse outcomes in different series include abnormalities of 9q, 11q, 12p, 17p, 20q, and 21q, +8, and +21. 11q23 abnormalities have adverse significance with regard to survival, except for t(9;11).²⁷⁸ The standard of care for AML with unfavorable karyotypes is

P.1597

allogeneic hematopoietic stem cell transplantation when this option is available, or clinical trials.⁴⁷³

CALGB, Cancer and Leukemia Group B; GERMAN AMLCG, German AML Cooperative Group; GIMEMA/AML10, Gruppo Italiano Malattie Ematologiche dell'Adulto; MRC, Medical Research Council; SWOG/ECOG, Southwest Oncology Group/Eastern Cooperative Oncology Group.

^aPatients with t(15;17) or t(9;22) were not included in this analysis. Trisomy 8 with core-binding factor or t(9;11) was not adverse; del(5q) was intermediate if sole abnormality (Byrd JC, Mrözek RK, Dodge AJ, et al. Pretreatment cytogenetic abnormalities are predictive of induction success, cumulative incidence of relapse, and overall survival in adult patients with de novo acute myeloid leukemia: results from Cancer and Leukemia Group B (CALGB 8461). Blood 2002;100:4325-4336).

The intermediate-risk cytogenetic group is defined as AML with a normal karyotype or with cytogenetic abnormalities not defined as favorable or unfavorable, although the Southwest Oncology Group classification also includes an "other" group for uncommon abnormalities not specifically listed as favorable.²⁸ Patients with normal karyotypes represent a heterogeneous group that is increasingly able to be further categorized by molecular abnormalities.

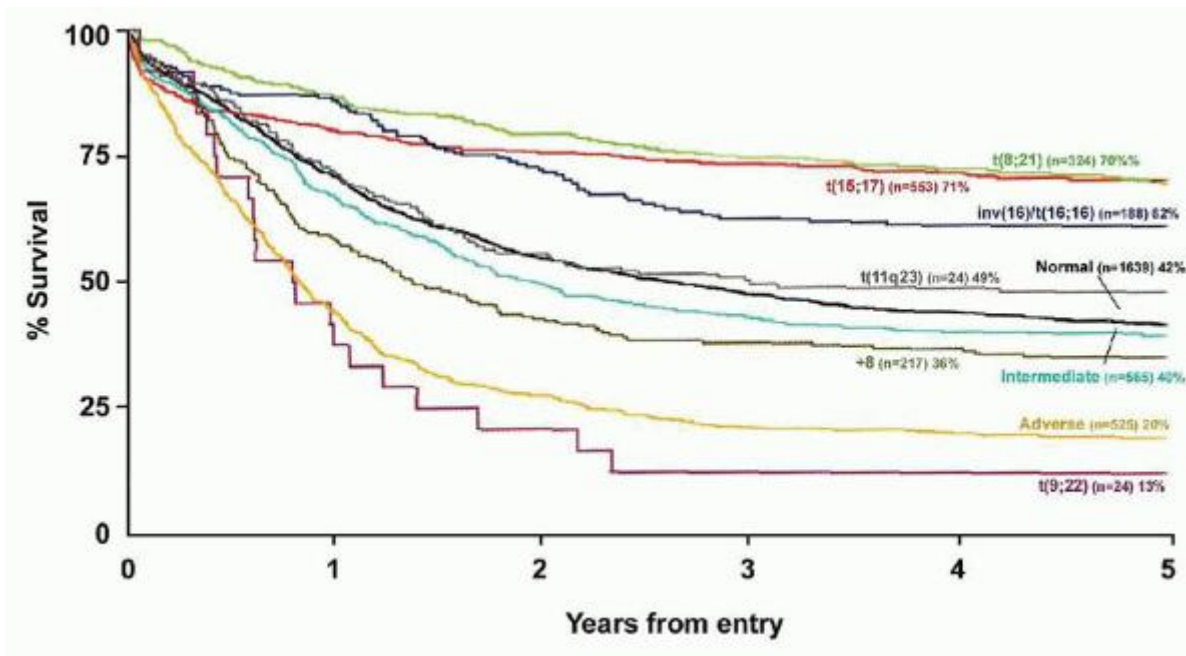

FIGURE 75.11. Overall survival of patients up to 60 years treated in UK Medical Research Council AML 10 and AML 12 trials according to cytogenetics. (With permission from Grimwade D. Impact of cytogenetics on clinical outcome in AML. In: Karp J, ed. Acute myelogenous leukemia. Totawa, NJ: Humana Press, 2007:181.)

Cytogenetic analysis at the time of assessment of response to remission induction therapy is prognostically significant because the relapse rate is higher and both disease-free and overall survival is shorter in patients with persistence of abnormal metaphases following induction chemotherapy.⁴⁷⁷ Cytogenetic risk groups remain prognostically significant following alloSCT for primary refractory AML,⁴⁷⁸ but not for AML in CR.^{479,480}

Molecular

Molecular studies are particularly helpful in subdividing the group of AML patients with a normal karyotype, and in guiding their management.^{49,292} Individual molecular abnormalities and their prognostic significance are detailed above. Prognosis is best determined by combinations of cytogenetic and molecular findings, and this approach was recently formalized by the European LeukemiaNet.⁵¹ The European LeukemiaNet classification is shown in Table 75.10.

Biologic Parameters

Diverse parameters reflecting leukemia biology have been found to have prognostic significance in AML. Increased expression of antiapoptotic proteins such as BCL-2 and/or decreased expression of proapoptotic proteins in AML cells is associated with resistance to chemotherapy and adverse prognosis.^{481, 482, 483} and ⁴⁸⁴ Overexpression of vascular endothelial growth factor (VEGF) and other proteins associated with angiogenesis correlates with increased angiogenesis and has been associated with a worse prognosis in AML.^{485, 486, 487} and ⁴⁸⁸ Expression of the chemokine receptor CXCR-4 on AML cells has also been found to be prognostically unfavorable.^{489,490} Finally, activation of signal transduction pathways in AML cells is associated with a poor prognosis,²⁶⁵ although much remains to be elucidated in this area.

Gene Polymorphisms

Polymorphisms in genes encoding proteins involved in drug detoxification, such as glutathione S-transferases,^{155,491} drug resistance, such as MDR1,⁴⁹² and DNA repair, such as XPA,⁴⁹³ XPD, ERCC1, and XRCC3,¹⁵⁹ have been variably associated with treatment toxicities and treatment outcome. The ultimate goal of these studies is stratification of chemotherapy based on genotypes.

TABLE 75.10 EUROPEAN LEUKEMIANET GENETIC CLASSIFICATION INTEGRATING CYTOGENETIC AND MOLECULAR DATA IN ACUTE MYELOID LEUKEMIA (AML)⁵¹

Genetic Subgroup	Subsets
Favorable	t(8;21)(q22;q22); <i>RUNX1-RUNX1T1</i> inv(16)(p13.1q22) or t(16;16)(p13.1;q22); <i>CBFB-MYH11</i> Mutated <i>NPM1</i> without <i>FLT3-ITD</i> (normal karyotype) Mutated <i>CEBPA</i> (normal karyotype)
Intermediate I	Mutated <i>NPM1</i> and <i>FLT3-ITD</i> (normal karyotype) Wildtype <i>NPM1</i> and <i>FLT3-ITD</i> (normal karyotype) Wildtype <i>NPM1</i> without <i>FLT3-ITD</i> (normal karyotype)
Intermediate II	t(9;11)(p22;q23); <i>MLL3-MLL</i> Cytogenetic abnormalities not classified as favorable or adverse
Adverse	inv(3)(q21q26.2) or t(3;3)(q21;q26.2); <i>RPNI-EVII</i> t(6;9)(p23;q34); <i>DEK-NUP214</i> t(v;11)(v;q23); <i>MLL</i> rearranged -5 or del(5q); -7; abn(17p); complex karyotype

THERAPY

Overview of Treatment

Treatment for AML is divided into two phases, remission induction therapy and post-remission therapy (Fig. 75.12). The goal of induction therapy is attainment of a complete remission, which, except in APL, usually requires a period of marrow aplasia, or a “morphologic leukemia-free state,” following induction chemotherapy. Serial changes in peripheral blood

counts during induction therapy include clearance of blasts from the blood, followed by pancytopenia requiring red blood cell and platelet transfusion support and management of complications of neutropenia, followed by increases in neutrophil and platelet counts and then resolution of anemia in patients with favorable responses to treatment. Table 75.11 outlines the management of AML at diagnosis and during induction therapy.

Post-remission therapy is therapy administered after patients achieve complete remission. Its goal is to prolong complete remission by delaying or preventing recurrence of AML, called relapse, and to maximize the chance of cure. Post-remission therapy may consist of intensification, consolidation, and maintenance therapies. Intensification may include allogeneic or autologous hematopoietic stem cell transplantation, whereas consolidation involves either regimens similar to those used in induction or the use of drugs at higher dosages than in induction; maintenance therapy is less intensive and less myelosuppressive than induction.⁴⁹⁴ Maintenance therapy is standard for ALL and for APL, but not for AML, although new approaches are being tested.⁴⁹⁵

Endpoints of Acute Myeloid Leukemia Treatment

Early assessment of the efficacy of remission induction chemotherapy is by sampling of the bone marrow approximately 14 days following initiation of chemotherapy, during pancytopenia. The morphologic leukemia-free state⁴ desired at this time-point is defined by the presence of less than 5% blasts in an aspirate sample with marrow spicules and with a count of at least 200 nucleated cells and absence of blasts with Auer rods. A bone

P.1599

marrow biopsy performed at the same time allows more bone marrow tissue to be examined and allows identification of clusters of blasts. Patients with clear residual AML at the time of early assessment are unlikely to go on to achieve remission, and additional or alternative therapy should be considered. Persistent detection of cells with the phenotype of the patient's pre-treatment leukemia cells by flow cytometry in marrow that is morphologically leukemia-free is viewed as persistence of leukemia, although therapeutic decisions about re-induction therapy in clinical trials have generally not been based on flow cytometry findings. If presence of residual leukemia is questionable, a bone marrow aspirate and biopsy should be repeated a week later. A morphologic leukemia-free state also requires absence of extramedullary disease.

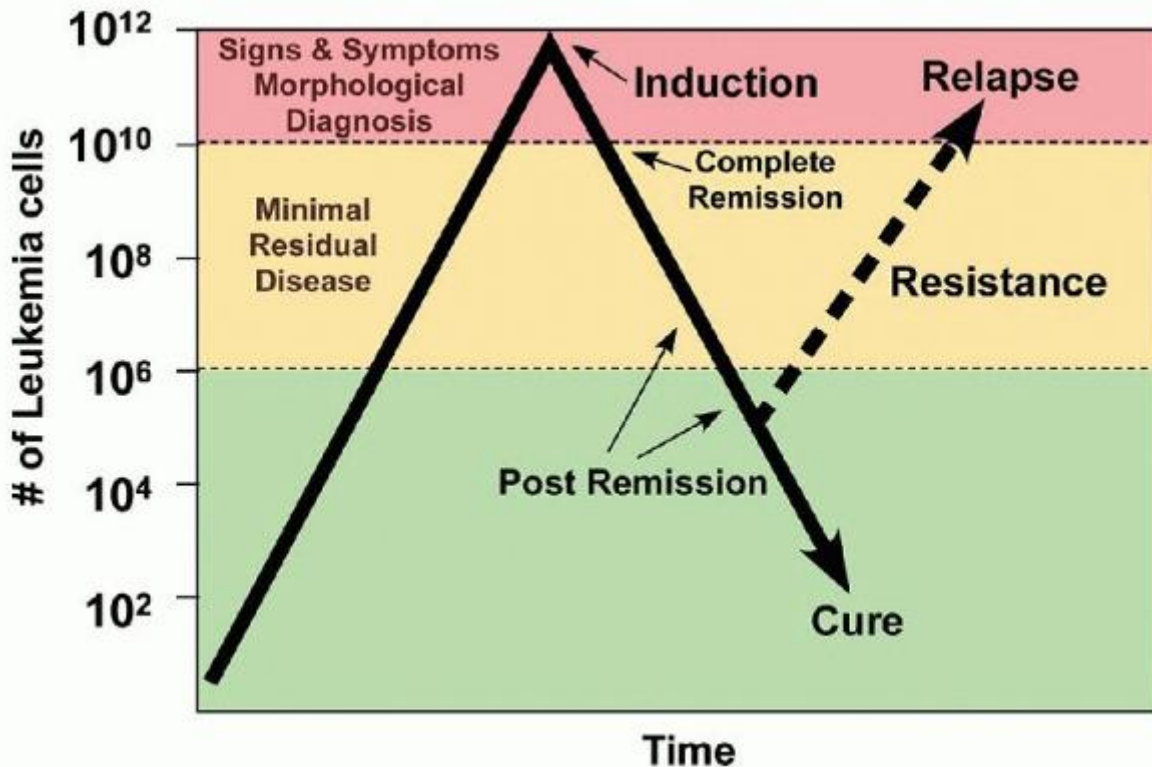

FIGURE 75.12. Phases of therapy. The diagnosis of acute myeloid leukemia can be made when the leukemia cell number is

$>10^{10}$. Induction therapy achieves a clinical complete remission and is followed by post-remission therapy with a goal of cure. If cells develop mechanisms of resistance, relapse occurs.

Patients are then assessed for response to induction therapy at the time of blood count recovery. The definition of complete remission has evolved.⁴ The term complete remission generally refers to morphologic complete remission, defined by red blood cell transfusion independence, an absolute neutrophil count of more than 1,000/ μ l and a platelet count of 100,000/ μ l or greater and the presence of less than 5% blasts in a bone marrow aspirate sample with marrow spicules and with a count of at least 200 nucleated cells, absence of blasts with Auer rods, and absence of extramedullary leukemia. The currently recommended International Working Group (IWG) criteria do not include requirements with regard to bone marrow biopsy cellularity or duration of response, but persistent detection of AML cells with the phenotype of the patient's pre-treatment leukemia cells by flow cytometry in marrow that is morphologically leukemia-free is considered persistence of leukemia.⁴

TABLE 75.11 MANAGEMENT OF ACUTE MYELOID LEUKEMIA AT DIAGNOSIS

Patient History

Review preceding myelodysplasia, prior diagnosis of cancer, previous chemotherapy, occupational exposure, family history, number of full siblings.

Physical Examination

Assess performance status.

Screen for infection: dental, nasopharyngeal, lung, perirectal.

Search for extramedullary disease: skin, neurologic, adenopathy, organomegaly, testicular.

Baseline Laboratory

Complete blood count with differential; type and screen.

Bone marrow examination: include cytogenetic analysis and save sample for molecular diagnostics if applicable.

Screen electrolytes, liver and renal function, tumor lysis parameters.

Screen for DIC.

Viral serologies, particularly HSV, CMV, hepatitis, and HIV.

HLA-A, -B, -DR type.

Chest radiograph: rule out pneumonia, leukostasis, mediastinal mass.

Cardiac status: ejection fraction by echocardiogram or MUGA.

Supportive Care

Transfusions: platelets, packed red blood cells (unless hyperleukocytosis), cryoprecipitate with or without fresh-frozen plasma in DIC.

Central line placement.

Hydration.

Allopurinol. Rasburicase (after checking G6PD).

Treat ongoing infections.

Infection prophylaxis: acyclovir (if HSV-positive), antifungal agents (fluconazole or voriconazole), antibacterial agents (usually to cover Gram-negative and Gram-positive organisms).

If hyperleukocytosis, hydroxyurea, and leukapheresis, uncertain role of CNS radiation.

Therapy

Induction chemotherapy cytarabine and anthracycline; possible role of etoposide or mitoxantrone;

possible role for high-dose cytarabine.

Monitor for DIC and tumor lysis, infection, drug toxicities.

APL, acute promyelocytic leukemia; CMV, cytomegalovirus; CNS, central nervous system; DIC, disseminated intravascular coagulation; HIV, human immunodeficiency virus; HLA, human lymphocyte antigen; HSV, herpes simplex virus; MUGA, multiple uptake gated acquisition scan.

Cytogenetic complete remission (CRc) has been proposed as a separate category of CR, indicating reversion to a normal marrow karyotype at CR in patients with an abnormal karyotype at presentation of AML.⁴ Persistence of abnormal metaphases in morphologically normal marrows of patients following recovery from induction chemotherapy is associated with shorter survival in AML patients.⁴⁷⁷ It is important to specify how many metaphases were examined.

Molecular complete remission (CRm) is also relevant in some subtypes of AML.⁴ Quantitative reverse transcriptase polymerase chain reaction (RT-PCR) may detect residual disease in AML cases with fusion genes resulting from chromosomal translocations [e.g., PML-RAR α in t(15;17), AML1/ETO fusion in t(8;21), CBF β -MYH11 fusion in inv(16), and others]. The prognostic significance of CRm achievement is clearly established for APL^{496,497} and CRm is recognized as a therapeutic objective in APL, whereas the significance of CRm in the other subsets of AML is still controversial, particularly in AML with t(8;21), a prognostically favorable subtype of AML in which AML1/ETO transcripts may continue to be detected in patients in long-term morphologic complete remission.⁴⁹⁸ It is important to establish and specify the sensitivities of assays used in assessing CRm.

Another category of response to induction chemotherapy is morphologic complete remission with incomplete blood count recovery (CRI), defined by fulfillment of all of the criteria for CR except for residual neutropenia (<1,000/ μ l) or thrombocytopenia (< 100,000/ μ l).⁴ This category of response was particularly evident in clinical trials of gemtuzumab ozogamicin,⁴⁹⁹ in which patients commonly met all criteria for complete remission except for platelet count recovery. The term CRp was used to indicate complete remission with incomplete platelet recovery following gemtuzumab ozogamicin treatment,⁴⁹⁹ but CRI is a broader term also incorporating incomplete neutrophil recovery, but not both. Survival of patients with CRp appears to be better than for those with treatment failure due to resistant disease, but not as good as those with morphologic CR. In a retrospective study of more than 6,000 patients with AML treated on ECOG, SWOG, and MD Anderson Cancer Center clinical trials, patients who achieved CR had longer relapse-free survival than patients who achieved CRp, after adjustment for covariates, whereas achieving CRp had a positive impact on survival, compared with resistant disease.⁵⁰⁰ Moreover, favorable pre-treatment prognostic factors predicted a higher likelihood of achieving a CR rather than CRp.⁵⁰⁰

Partial remission is defined by attainment of the blood count criteria for complete remission, and a decrease of at least 50% in the percentage of blasts in the bone marrow aspirate, to 5% to 25%, or less than 5% blasts in the marrow with presence of Auer rods.⁴

Remission induction treatment failure can be divided into at least three categories⁴ (Table 75.12). Patients who survive at least 7 days after completion of treatment and have persistent AML in marrow and/or blood are said to have treatment failure due to resistant disease. Patients who survive at least 7 days after completion of treatment and die while cytopenic and with a post-treatment bone marrow within 7 days of death demonstrating aplasia or hypoplasia are said to have treatment failure due to

P.1600

complications of aplasia. Finally, patients with treatment failure of indeterminate cause include those who die less than 7 days after completion of treatment, those who die 7 or more days after completion of treatment whose blood did not show persistent leukemia and whose marrow was not examined post-treatment, and those who die without completing treatment.

TABLE 75.12 TYPES OF FAILURE IN THERAPY OF ACUTE MYELOID LEUKEMIA

Drug Resistance

No response based on persistence of blasts and absence of hypocellularity (usually day 14)

Hypocellular or partial marrow with subsequent regrowth of leukemia

Complications of Aplasia

Hypoplastic death (within 4 wk)

Regeneration failure: marrow remains hypocellular for >4 wk

Indeterminate Cause

Death within 2-3 wk of initiating therapy (marrow either negative or not tested)

Hematologic Remission but Persistent Disease

Myelodysplasia, extramedullary disease; cytogenetic, flow cytometric, or molecular disease

Remission Induction Therapy

Table 75.13 outlines active agents in AML and includes their cell cycle specificity, major toxicities, response rates, and clinical uses. Cytarabine and anthracyclines have been the subject of most intense study. Cytarabine is incorporated into DNA during DNA synthesis and is only effective in cells in the S-phase of the cell cycle. Anthracyclines are not cell cycle-specific and appear to be the most active single agents. Synergy exists between agents with different mechanisms of action, and combination chemotherapy produces better results in AML. Particular considerations with regard to choice of treatment in older AML patients are discussed below, as is AML diagnosed during pregnancy.

Conventional Induction Therapy

The most common induction chemotherapy regimens in AML involve the use of cytarabine (ara-C) and an anthracycline. Cytarabine is usually administered as a continuous infusion of 100 to 200 mg/m²/day for 7 days, with an anthracycline given by intravenous push daily on the first 3 days of ara-C therapy, a combination called "7 + 3." Studies performed by CALGB in the 1980s established the efficacy of this regimen for newly diagnosed AML and since then has been the most commonly used induction regimen for treatment of adult patients with AML.^{501, 502, 503} and ⁵⁰⁴

Continuous infusion of ara-C at a dosage of 100 mg/m² has been shown to be superior to pulse doses of 100 mg/m² every 12 hours.⁵⁰¹ "7 + 3" has been shown to be superior to the same drugs given over 5 days and 2 days (5 + 2), respectively,⁵⁰¹ and appears equivalent to "10 + 3."⁵⁰³ Increasing the ara-C dose in "7 + 3" from 100 mg/m²/day to 200 mg/m²/day or prolonging the infusion to 10 days, in combination with daunorubicin, increased the toxicity with no to minimal improvement in efficacy.^{503, 504} and ⁵⁰⁵

The addition of oral thioguanine 100 mg/m² twice on days 1 to 7 (7+ 3 + 7) did not improve the results. The anthracycline most commonly used in 7 + 3 is daunorubicin, and its dose has ranged between 30 and 90 mg/m² in different studies. In early studies, daunorubicin 45 mg/m² daily was compared to 30 mg/m² daily in the 7 + 3 regimen, and resulted in higher CR rates in patients younger than age 60 years.⁵⁰² A single course of 7 + 3 ara-C and daunorubicin (45 mg/m²) therapy produces a CR rate in the range of 40% to 50%. When a second course of ara-C and daunorubicin (either 5 + 2 or 7 + 3) is administered to patients with morphologic evidence of persistent leukemia in the bone marrow on day 14, the overall CR rate increases to 50% to 85%. Higher response rates (70% to 85%) are seen in patients under 60 years of age with de novo AML.

Two recent phase 3 randomized clinical trials from the United States and South Korea have confirmed the clinical benefit of daunorubicin dose intensification (90 mg/m² vs. 45 mg/m²) in the context of the 7 + 3 regimen in patients younger than 60 years of age with previously untreated AML.^{506,507} In the US study, 90 mg/m² daunorubicin, as compared with 45 mg/m² of the drug, resulted in a significantly higher CR rate (70.6% vs. 57.3%) and, most important, better overall survival (median, 23.7 vs. 15.7 months). The rates of serious adverse events including heart failure and other cardiac toxicities were similar between the two groups.⁵⁰⁶ In the study conducted in South Korea,⁵⁰⁷ the CR rates were also significantly higher (82.5% vs. 72.0%) in the group who received 90 mg/m² daunorubicin compared to the group receiving 45 mg/m² group. With approximately 4.5 years of median follow-up, both overall survival (46.8% vs. 34.6%) and event-free survival (40.8% vs. 28.4%), were significantly better in the 90 mg/m² arm, compared to the 45 mg/m² arm. The advantage of higher-dose daunorubicin was observed in patients with an intermediate-risk cytogenetics but not in those with an unfavorable karyotype or a high-risk molecular profile. The toxicities were similar in the two groups.

Another clinical trial tested the potential benefit of high-dose daunorubicin in older patients receiving intensive chemotherapy.⁵⁰⁸ Newly diagnosed AML patients 60 years of age and older received the 7 + 3 regimen, consisting of cytarabine 200 mg/m² and daunorubicin either 45 mg/m² or 90 mg/m², followed by a second cycle of 1,000 mg/m² cytarabine every 12 hours for 6 days. Complete remission rates (64% vs. 54%) and rates of complete remission after the first cycle of induction treatment (52% vs. 35%) were significantly higher in the group who received 90 mg/m² daunorubicin, compared to the 45 mg/m² group. There was no significant difference between the two groups in 30-day

mortality rates, hematologic toxicities or moderate, severe, or life-threatening adverse events. The OS rates were similar between the two groups. Patients 60 to 65 years of age had higher rates of CR (73% vs. 51%), EFS (29% vs. 14%), and OS (38% vs. 23%) in the 90 mg/m² group as compared with the patients in the same age group who received 45 mg/m² daunorubicin, however, a difference was not seen in those over 65 years, with the exception of the favorable cytogenetic group, who benefited from daunorubicin dose intensification regardless of age.

Modifications of Standard Induction Therapy

The anthracycline idarubicin and the anthracenedione mitoxantrone have been used instead of daunorubicin in 7 + 3. In three randomized trials, idarubicin, given as 12 mg/m² daily for 3 days with ara-C, tended to produce a higher CR rate than daunorubicin and ara-C, more often required only one cycle to induce remission, and was associated with a better survival in some trials.^{509, 510} and ⁵¹¹ The long-term follow-up of the aforementioned three randomized studies suggested better OS for idarubicin compared with daunorubicin in only one study.⁵¹² However, superiority of idarubicin (10 to 12 mg/m²) over daunorubicin (45 to 60 mg/m²) in the achievement of CR when used in the 7 + 3 regimen was confirmed in a meta-analysis.⁵¹³ In a randomized trial in AML patients between 50 to 70 years, idarubicin produced a higher CR rate than high-dose daunorubicin (80 mg/m²/day for 3 days).⁵¹⁴

P.1601

P.1602

Substitution of idarubicin with either fludarabine or topotecan in combination with ara-C for treatment of newly diagnosed AML, refractory anemia with excess blasts in transformation (RAEB-t), or RAEB resulted in lower CR rates and shorter EFS and OS.⁵¹⁵

TABLE 75.13 STANDARD SINGLE AGENTS IN ACUTE MYELOID LEUKEMIA

Class of Agent	Route of Delivery	Cell-Cycle Specificity	Mechanism of Action	Plasma Half-Life (h)	Main Route of Excretion	Response Rate (%)	Major Toxicities Other Than Myelosuppression	Comments
Cytarabine Pyrimidine analog	IV, SC	S	Active form ara-CTP inhibits DNA polymerase and is incorporated in DNA (S phase).	1-2	Renal	15-35	Cerebellar, gastrointestinal, hepatic, skin and	Antileukemic effect is dose-dependent. Cerebellar toxicity occurs in patients >50 y receiving high doses (3 g/m ²).
Daunorubicin, doxorubicin, idarubicin, epirubicin	IV	NS	Inhibits DNA replication by intercalation of base pairs; inhibits	15-30	Hepatic	40-50	Cardiac, gastrointestinal	Cumulative, dose-dependent cardiomyopathy in patients receiving >500 mg/m ² for

				topoisomerase II.				daunorubicin. (cardiomyopathy uncommon <290 mg/m ²). Increased gastrointestinal toxicity with doxorubicin (idarubicin has longer half-life and probably better efficacy).
6-Thioguanine	Purine analog	PO, IV	S	Ribonucleotide form is incorporated into DNA, leading to strand breaks.	6-12	Renal, 10 hepatic	Hepatic, gastrointestinal	Synergistic with cytarabine; unlikely to add to combination of cytarabine and anthracycline.
Mitoxantrone	Anthracenedione	IV	NS	Intercalates into DNA; induces topoisomerase II-mediated damage.	25-50	Hepatic > renal	Cardiac, gastrointestinal	Probably less cardiotoxic than anthracycline antibiotics.
VP-16 (etoposide)	Epipodophyllotoxin	IV, PO	S	Forms complex with DNA and topoisomerase II, leading to strand breaks (G2 phase).	6-12	Renal > hepatic	Gastrointestinal, hepatic, stomatitis	Effects are dose- and schedule-dependent. Oral dose usually twice IV dose. Efficacious in acute monocytic leukemia of infancy. Etoposide phosphate is a water-soluble

Amsacrine (m-AMSA)	Acridine derivative	IV	S	Intercalates into DNA, produces strand breaks (G2 phase).	7-8	Hepatic > renal	30-50	Cardiac, including QT prolongation; gastrointestinal	prodrug of etoposide. Most effective when combined with high-dose cytarabine.
5-Azacytidine, decitabine	Pyrimidine analogs	IV, SC	S	Phosphorylated form incorporates into RNA and DNA.	3-6	Renal	10-20	Gastrointestinal, hepatic, skin, neurologic	No cross-resistance with cytarabine; limited by neurologic toxicities. Approved agents for MDS.
Carboplatin	Platinum analog	IV	NS	Covalent binding to DNA.	0.2-40	Renal	20-28	Gastrointestinal	Less nephrotoxicity, ototoxicity, and emesis than cisplatin, but more myelosuppression.
Fludarabine, cladribine, pentostatin, clofarabine	Purine analogs	IV	NS	Inhibit DNA polymerase, incorporate into DNA and RNA, nicotinamide adenine dinucleotide depletion.	Biphasic: α , <30 min; β , 6-20 h	Hepatic > renal	5-25	Neurotoxicity, pulmonary (fludarabine); immunosuppression (T-cell depletion)	Synergism with cytarabine, can potentiate the accumulation of ara-CTP if given before cytarabine. SC and PO under development.

IV, intravenous; MDS, myelodysplasia; NS, nonspecific; PO, orally; S, specific; SC, subcutaneous.

Historically, mitoxantrone has been used more often to treat relapsed AML, and it may have less cardiotoxicity than the anthracyclines.⁵¹⁶ A randomized trial of daunorubicin, idarubicin, and mitoxantrone with standard-dose ara-C as induction therapy in older AML patients showed no differences in clinical outcome.⁵¹⁷

Daunorubicin (50 mg/m²) on days 1 to 3 plus ara-C (25 mg/m² bolus followed by 160 mg/m² as a continuous infusion daily for 5 days) and 6-thioguanine (100 mg/m² orally every 12 h daily for 5 days) (DAT) was compared with amsacrine (190

mg/m², IV on days 1 to 3) plus ara-C and 6-thioguanine at the similar doses (AAT) in a trial involving approximately 100 adult patients with de novo AML. Patients who achieved CR received two courses of the same chemotherapy regimen as consolidation therapy. Stratified by age, CR rate and OS were better in the AAT group compared to the DAT group.

Other studies have tested the addition of a third agent to the 7 + 3 regimen. The addition of etoposide to 7 + 3 at 75 mg/m²/day for 7 days (7 + 3 + 7) did not improve CR rates and was associated with more mucositis, but it did improve median remission duration (12 months for 7 + 3 vs. 18 months for 7 + 3 + 7). Overall survival was similar between the two groups.⁵¹⁸ A three-drug induction regimen known as ADE, consisting of ara-C 100 mg/m²/day for 7 days and both daunorubicin 90 mg/m² and etoposide 100 mg/m² daily for 3 days, was tested by CALGB in previously untreated de novo AML patients less than 60 years, without excess cardiotoxicity, and with a complete remission rate of 75% and a median disease-free survival of 1.34 years and median overall survival of 1.86 years.⁵¹⁹ Moreover, ADE consisting of ara-C 100 mg/m²/day for 7 days and both daunorubicin 60 mg/m² and etoposide 100 mg/m² daily for 3 days was used in previously untreated older AML patients, with rates of CR, nonresponse, and death of 46%, 34%, and 20% with median disease-free survival of 7 months; these results were not superior to historical results.⁵²⁰

Because Pgp overexpression and function in AML cells are strongly associated with adverse treatment outcome, clinical trials of Pgp modulators, or noncytotoxic competitive inhibitors of drug transport by Pgp, were undertaken in AML. Addition of PSC-833, a cyclosporin derivative which is a potent Pgp inhibitor, to induction regimens containing the Pgp substrates daunorubicin or mitoxantrone and etoposide did not show clinical benefit,^{521,522} nor did addition of zosuquidar, another potent Pgp inhibitor.⁵²³ In contrast, addition of cyclosporin A to chemotherapy was beneficial in some trials.^{524,525} Cyclosporin A blocks drug transport by multiple MDR proteins known to be expressed in AML.⁵²⁶

High-dose Cytarabine

The antileukemic effect of cytarabine depends on dosage and schedule. Cytarabine is effective at both high and standard dosages. Although at plasma concentrations greater than 10 μM, which are achieved with high-dose ara-C (2 to 3 g/m² daily), the drug diffuses freely into cells,⁵²⁷ at concentrations less than 1 μM, which are achieved with 100 to 200 mg/m² daily, ara-C influx into cells is strongly correlated with the number of nucleoside transporters per leukemic blast.⁵²⁸ High-dose cytarabine (HiDAC) (1 to 3 g/m² every 12 to 24 hours, for 4 to 12 doses), with or without either an anthracycline, mitoxantrone, or etoposide, is particularly effective as intensification therapy or as therapy for relapsed disease.^{529, 530} and⁵³¹ HiDAC crosses the blood-brain barrier and can help prevent CNS leukemia, but cerebellar toxicity may develop, particularly in patients 50 years of age or older.⁵³² Lengthening the duration of administration from 1 hour to 3 hours or decreasing the dose from 3 g/m² to 1.5 g/m² may lessen the risk of cerebellar toxicity and is common practice in patients over 50 years of age. Patients receiving HiDAC must be tested for cerebellar toxicity before each dose, and subsequent doses of HiDAC must be withheld if cerebellar toxicity is documented or suspected; the ara-C dose must then be decreased, and HiDAC also cannot be administered as part of any subsequent therapy. Conjunctivitis and a painful, blistering erythematous rash involving the palms and soles are common side effects following HiDAC. Administration of corticosteroid eyedrops may prevent conjunctivitis, which is caused by secretion of cytarabine administered at high doses into tears.

Although HiDAC has most often been given as consolidation therapy or for relapsed disease, high CR rates (up to 90%) were observed when HiDAC was given during induction in some studies in the early 1990s.⁵³³ In a randomized trial by the Australian Leukemia Study Group in newly diagnosed AML patients less than 60 years old,⁵³⁴ the CR rate was similar with HiDAC (6 g/m² per day) and standard-dose (100 to 200 mg/m² daily administered as a 7-day continuous infusion) ara-C-based remission induction and post-remission therapy, but HiDAC was associated with a significantly longer estimated median remission duration (45 vs. 12 months) and higher percentage of 5-year relapse-free survival (48% vs. 25%), but also with greater hematologic and nonhematologic toxicities. Another randomized trial of high-dose (4 g/m² per day) versus standard-dose ara-C in newly diagnosed AML patients less than 65 years old by the Southwest Oncology Group⁵³⁵ demonstrated slightly better relapse-free survival (33% vs. 21% at 4 years for patients less than age 50 and 21% vs. 9% for ages 50 to 64 years), but a significantly higher risk of fatal toxicity with high-dose ara-C. The efficacy of HiDAC, as part of a double induction strategy, was tested against standard-dose ara-C in a large randomized trial.⁵³⁶ Two courses of standard-dose cytarabine, daunorubicin, and 6-thioguanine (TAD) were compared with one course of TAD followed by high-dose cytarabine (3 g/m² every 12 hours for 6 doses) with mitoxantrone (HAM) starting on day 21 regardless of the presence or absence of leukemic blasts in the bone marrow. CR rates (65% vs. 71%) and survival were similar between the two groups. Recently, another randomized clinical trial in more than 800 AML patients younger than 60 years tested the efficacy and toxicity of different doses of cytarabine in the setting of a double-induction chemotherapy regimen.⁵³⁷ Patients were randomly assigned to receive either intermediate doses of cytarabine (200 mg/m² for cycle 1 followed by 1 g/m² twice daily for cycle 2) or HiDAC (1 g/m² twice daily for cycle 1 followed by 2 g/m² twice daily for cycle 2), with idarubicin in cycle

1 and amsacrine in cycle 2 in all patients. If patients achieved a CR, they received consolidation therapy that did not contain cytarabine. This trial showed no efficacy advantage for HiDAC when compared to intermediate-dose cytarabine. The rates of CR (80% vs. 82%), CR after the first cycle 1 (60% vs. 66%), 30-day mortality (10% in both groups), event-free survival (34% vs. 35%), and overall survival (40% vs. 42%) at 5 years were similar for intermediate dose and HiDAC, respectively.⁵³⁷ Patients in the HiDAC group experienced higher rates of grade 3 and grade 4 toxicities (51% vs. 61%) in cycle 1, and prolonged hospitalization, and delayed neutrophil and platelet recovery in cycle 2. On the basis of these data, the use of HiDAC for induction chemotherapy for newly diagnosed AML is not generally recommended, unless in special circumstances.

Other Nucleoside Analogues

Nucleoside analogues including cladribine (2-CdA), fludarabine, clofarabine, gemcitabine, pentostatin, troxacitabine, and sapacitabine have also been tested in AML.^{538, 539, 540} and ^{541,542,543}

Fludarabine has been extensively studied in AML because of pre-clinical⁵⁴⁴ and clinical data demonstrating that its administration prior to ara-C sensitizes leukemic blasts to ara-C by enhancing ara-CTP formation.⁵⁴⁵ The observation that administration of

P.1603

G-CSF with fludarabine further enhanced this effect⁵⁴⁶ led to the design of a regimen consisting of fludarabine with high-dose cytarabine and G-CSF (FLAG).^{547, 548} and ⁵⁴⁹ Derivative regimens incorporating idarubicin with (FLAG-IDA)^{550,551} or without G-CSF (FLAI)⁵⁵² are also active in AML.

Clofarabine is a second-generation nucleoside analog that has activity in AML by itself or when administered prior to ara-C.^{553,554} In a phase II trial in hematologic malignancies, an overall response rate of 48% was reported; AML patients with a short first CR (≤ 1 year) had a response rate of 18%, compared to 87% in those with a longer first CR.⁵⁵³ Clofarabine combined with ara-C produced a response rate of 60% and a CR rate of 52% in untreated AML, and a response rate of 38% and a CR rate of 22% in relapsed AML.^{554,555} In two single-arm studies, single-agent intravenous clofarabine (30 mg/m² daily for 5 days) demonstrated a CR + CRi rate of approximately 46% to 48%, with CR rates of 32% to 38% in high-risk older patients, including those with an unfavorable karyotype.^{556,557}

Recently, a 652-patient Polish Adult Leukemia Group (PALG) randomized multicenter trial in patients age 60 years or younger with AML demonstrated that cladribine, but not fludarabine, added to 7 + 3 induction chemotherapy prolonged survival.⁵⁴² Patients received 7 + 3 alone (AraC 200 mg/m² on days 1 to 7 as a continuous infusion plus daunorubicin 60 mg/m² daily infusion on days 1 to 3) or 7 + 3 plus a 3-h infusion of cladribine (5 mg/m² daily on days 1 to 5), or 7 + 3 plus a 30-min infusion of fludarabine (25 mg/m² daily on days 1 to 5). Consolidation chemotherapy included high-dose cytarabine and stem cell transplantation or 2 years maintenance chemotherapy, based on relapse risk. Both the CR rates (68% vs. 56% vs. 59%) and 3-year overall survival rates (45% vs. 33% vs. 35%) were significantly improved by addition of cladribine to the 7 + 3 regimen, compared to 7 + 3 alone and 7 + 3 + fludarabine, respectively. Toxicity was not significantly different in the three arms. Patients with an unfavorable karyotype also benefited from 7 + 3 + cladribine.

Hematopoietic Growth Factors

A variety of purified cytokines has been investigated as modifiers of cytopenias and of leukemia growth in vitro and in vivo. The best studied are the myeloid hematopoietic growth factors GM-CSF and G-CSF. Due to in vitro data demonstrating proliferative effects on AML blasts and based on clinical trial data outlined below, routine use of the myeloid growth factors in AML is not recommended.

Despite concerns about proliferative effects of myeloid CSFs on AML cell growth, studies were initiated in the 1990s to determine their clinical efficacy in AML. Two studies evaluated Escherichia coli-derived G-CSF in patients with relapsed or refractory leukemia and yeast-derived GM-CSF in older patients with de novo AML. Both reports indicated that the CSFs could be administered safely, with a statistically significant reduction in the duration of neutropenia and in early deaths, and trends toward an improvement in the CR rate, but not in survival.^{558,559}

Subsequently, a number of phase III trials of GM-CSF and G-CSF consistently showed more rapid neutrophil recovery, which usually results in fewer infections and shorter hospitalizations, but no improvement in CR rates, relapse rates, or overall survival.^{560, 561, 562, 563, 564, 565, 566} and ⁵⁶⁷ Two randomized trials evaluating the role of G-CSF after consolidation therapy showed decreases in the duration of severe neutropenia and a decreased rate of infection, but no effect on CR duration or OS.^{566,568}

There were also attempts to exploit the proliferative effect of myeloid growth factors on leukemia cells to recruit AML cells into S-phase in order to increase chemosensitivity to ara-C, an S-phase-specific agent. In these clinical trials, G-CSF or GM-CSF was administered prior to and/or during chemotherapy, so-called "growth factor priming." These clinical trials have generally not demonstrated clinical benefit,^{517,563,569, 570} and⁵⁷¹ with some exceptions.^{572,573} One possible reason is that, although G-CSF administered to untreated AML patients prior to chemotherapy did increase the percentage of blasts in S-phase, this percentage remained low.⁵⁷⁴ Hematopoietic growth factor priming is not recommended, outside of clinical trials.⁵⁷⁵

Post-remission Therapy

In the absence of post-remission therapy, the probability of cure is approximately zero⁵⁷⁶ with all patients relapsing within a median of 6 months, so post-remission therapy is essential, with the goals of decreasing and attempting to eliminate residual disease, delaying relapse and increasing the likelihood of cure.

Although additional therapy clearly is required beyond induction therapy, utilizing drugs at similar doses to those used in induction therapy, with or without maintenance therapy, has not had a major impact on survival in AML. With a CR rate of 60% to 75%, 15% to 25% of adults could be expected to have prolonged survival after consolidation or maintenance therapy administered through 1980.

Studies involving the use of HiDAC at different dosages and schedules as post-remission therapy suggested that survival in AML could be improved by dose escalation (Table 75.14).^{577,578,579,580} Wolff et al. reported the efficacy of HiDAC/daunomycin intensification in AML, with a projected 49% survival that was age-dependent (83%, 50%, and 23% for age groups 25 or less, 26 to 45, and more than 45 years, respectively).⁵⁷⁹

Randomized trials were performed to confirm the value of HiDAC consolidation.^{581,582,583} In an ECOG trial of 143 patients in first CR after daunorubicin, cytarabine, and 6-thioguanine, patients were randomly assigned to 24 months of low-dose maintenance therapy or one course of HiDAC (3 g/m² every 12 hours for 6 days) plus amsacrine.⁵⁸² Although HiDAC caused more toxic deaths, the 4-year DFS in patients less than 60 years of age was 28%, compared to 15% for those receiving maintenance therapy. In contrast the Leukemia Group for the Swiss Society for Cancer randomly assigned 137 patients in first CR after ara-C, daunorubicin, etoposide, and AMSA to standard-dose ara-C at 100 mg/m²/day for 7 days or HiDAC at 3 g/m² every 12 hours for 6 days and found no difference in DFS.⁵⁸⁴

In a landmark clinical trial, the CALGB randomly assigned 596 patients in first CR after 7 + 3 to one of three different ara-C dose schedules: HiDAC at 3 g/m² over 3 hours every 12 hours on days 1, 3, and 5 (6 doses); intermediate-dose ara-C at 400 mg/m²/day for 5 days by continuous infusion; or lower-dose ara-C at 100 mg/m² for 5 days by continuous infusion.⁵⁸³ The estimated probabilities of remaining in CR at 4 years for patients less than 61 years of age were 44%, 29%, and 24% for the three treatments, respectively (Fig. 75.13, P = 0.002), but there were no differences among the arms in patients over the age of 60, with a probability of 16% or less of remaining in CR. These results clearly show that consolidation with HiDAC improves DFS in younger patients in first CR. Multiple cycles may be required to obtain the maximum benefit of HiDAC consolidation.^{535,583}

The efficacy of HiDAC consolidation therapy also varies by cytogenetic group. In an analysis of cytogenetic correlates in the CALGB three-arm consolidation study referred to above,⁵⁸³ Bloomfield et al. found that the impact of HiDAC consolidation was greatest in the favorable cytogenetic group, with 78% of patients remaining in remission at 5 years, compared to 40% of those with a normal karyotype, and 21% of those with other abnormalities.⁵⁸⁵ The favorable impact of repetitive cycles of HiDAC in AML with the favorable karyotypes t(8;21) and inv(16) was confirmed in series focusing on patients with those abnormalities.⁴⁷⁶ In addition, patients less than 60 years old with a normal karyotype had 5-year disease-free survival rates of 41% and 45% following four cycles of HiDAC or ara-C 400 mg/m² consolidation or one cycle of

P.1604

HiDAC/etoposide followed by autologous hematopoietic stem cell transplantation.⁵⁸⁶ Of note, these studies antedated the availability of molecular data.

TABLE 75.14 TRIALS EVALUATING HIGH-DOSE CYTARABINE (HiDAC) IN POST-REMISSION THERAPY

Source	Post-remission	Duration (mo)	CR No. of Patients (%) in	Median Age (y)	Median Follow-up (y)	Median Duration of CR (mo)	Complete Response (%)	Toxic Death (%)

Z, zorubicin. CR duration data for controlled studies presented for patients <60 years of age.

A recent, large (n = 781) prospective randomized trial from Japan compared four courses of conventional multiagent chemotherapy to three courses of HiDAC (2 g/m² twice daily for 5 days) alone as post-remission therapy for AML in adult patients younger than 65 years in first complete remission.⁵⁸⁷ Five-year DFS (43% vs. 39%) and 5-year OS (58% vs. 56%) were similar for the HiDAC group and the multiagent chemotherapy, respectively. In patients with favorable cytogenetic risk, 5-year DFS (57% vs. 39%) and 5-year OS (75% vs. 66%) were significantly better in the HiDAC group compared with the multiagent chemotherapy group. The frequency of infections was higher in the HiDAC group. Another recent clinical trial (n = 237) from France compared HiDAC with timed-sequential chemotherapy in patients 15 to 50 years of age with AML in first remission.⁵⁸⁸ No significant difference was reported between the two arms with respect to 5-year EFS, cumulative incidence of relapse, or treatment-related mortality. Finally, a clinical trial (n = 933) from Germany compared two HiDAC regimens (36 g/m² vs. 12 g/m²) as a first consolidation in untreated AML patients age 15 to 60 years.⁵⁸⁹ In the intention-to-treat analysis, there were no significant differences in the 5-year OS (30% vs. 33%) or DFS (37% vs. 38%).

Data with regard to administration of hematopoietic growth factors after post-remission therapy are similar to those on administration after induction. Two randomized trials evaluating the role of G-CSF after consolidation therapy both showed decreases in the duration of severe neutropenia and a decreased rate of infection, but no effect on complete response duration or overall survival.^{566,568}

In summary, for younger adults with favorable cytogenetic and molecular findings, HiDAC intensification alone (four cycles using CALGB doses and schedule) is often considered the best treatment choice. For younger adults with intermediate-prognosis cytogenetic and molecular findings, reasonable choices include HiDAC consolidation alone (four cycles using CALGB doses and schedule), or allogeneic transplantation. For older patients with good performance status and who have an available donor and meet age and health criteria, allogeneic transplantation should be considered, and a modified HiDAC regimen can be used for those without transplant options or opting not to pursue transplant. Because there is no post-remission chemotherapy regimen established as superior to others in older patients, participation in a clinical trial is recommended. For all patients who have adverse prognostic features including, in particular, prognostically unfavorable karyotypes or molecular findings (see section "Prognosis") and who have an available donor and meet age and health criteria, allogeneic hematopoietic SCT is the treatment of choice in first remission (see "Stem Cell Transplant" section).

In contrast to the approach in ALL, maintenance chemotherapy does not play an important role in AML. Randomized trials showed that maintenance therapy may prolong initial remissions,^{200,590} but has no benefit in improving the cure rate of AML.^{591,592} Moreover, maintenance chemotherapy appears unwarranted in AML if post-remission therapy is of adequate intensity.^{591,592} Novel approaches to maintenance therapy are being explored,⁴⁹⁵ but their ultimate benefit is unknown.

Novel Agents

New agents with novel mechanisms of actions are being investigated for the treatment of AML. Table 75.15 shows some of these agents with their chemical structures. Also see the section on “Other Nucleoside Analogs.”

Several pre-clinical and early-phase clinical trials have been conducted to test the potential antileukemic activity of novel agents that target molecular mutations, epigenetic gene silencing, and aberrant signal transduction. Targets include, but are not limited to, the FLT3-ITD mutation, the epigenome (DNA methylation and histone acetylation), kinases (Pim, aurora, RAS/RAF/MAP), metabolic pathways (PI3K/AKT/mTOR), cellular reduction/oxidation (redox) states, mitochondria and reactive oxygen species, the WNT/ β -catenin signaling pathway, Hedgehog signaling, TP53, angiogenesis, ubiquitin-proteasome pathways, cell surface farnesylation, and anti- and proapoptotic proteins such as MCL-1, BCL-2, and BAX.

DNA methylation may contribute to leukemogenesis by silencing tumor suppressor genes, and the DNA methyltransferase inhibitors azacitidine and decitabine inhibit DNA methylation and have had activity in phase I-II trials in patients with AML as well as MDS, as do histone deacetylase inhibitors such as phenylbutyrate, valproic acid, depsipeptide, suberoylanilide hydroxamic acid (SAHA), and MS-275.^{593, 594, 595, 596, 597} and⁵⁹⁸ DNA methyltransferase inhibitors are being evaluated as initial therapy for AML in older adults.^{599, 600, 601, 602} and⁶⁰³

FLT3 Inhibitors

Because of the importance of FLT3-ITD resulting in constitutive FLT3 signaling as an adverse prognostic factor in AML, as outlined above, inhibitors of FLT3 signaling have been developed and are being tested in clinical trials in AML (Fig. 75.14). FLT3 inhibitors that have been tested include midostaurin,⁶⁰⁴ lestaurtinib,⁶⁰⁵ sorafenib,⁶⁰⁶ sunitinib,⁶⁰⁷ tandutinib,⁶⁰⁸ and AC220.⁶⁰⁹ CEP-701 (lestaurtinib) is an orally administered indolocarbazole derivative that is cytotoxic to AML blasts with FLT3-ITD in vitro⁶¹⁰ and in vivo⁶¹¹ and has clinical activity in AML.^{612, 613} It was tested in combination with chemotherapy, with the design of the combination regimen based on pre-clinical data,⁶¹⁴ but unfortunately no clinical benefit was seen.⁶⁰⁵ Clinical trials of other agents are recently completed or in progress. Resistance to FLT3 inhibitors may occur by activation of other signaling pathways⁶¹⁵ or by progressive up-regulation of FLT3 ligand.³⁰⁹ FLT3 inhibitors also have in vitro activity in AML without FLT3 mutations.⁶¹³

Gemtuzumab Ozogamicin

In early studies in AML, unconjugated monoclonal antibodies targeting CD14, CD15, and CD33 produced low response rates (<10%).^{616, 617} Consequently, investigators turned to conjugated antibody therapy, with CD33 being the best studied target, as it is present on AML cells in 90% of cases²⁰⁹ and is expressed on normal hematopoietic cells but not on normal hematopoietic stem cells. The best studied anti-CD33 antibody conjugate is gemtuzumab ozogamicin (Mylotarg), which uses a recombinant humanized anti-CD33 monoclonal antibody to deliver calicheamicin, an antibiotic that binds to the minor grooves of DNA, causing double-strand breaks and apoptosis.⁶¹⁸ Calicheamicin is a substrate for Pgp-mediated efflux.⁶¹⁹

When two 9 mg/m² gemtuzumab ozogamicin doses were given over 4 h 14 days apart to patients with CD33⁺ AML in untreated first relapse in phase II trials, the overall response rate was 26%, including 13% CR, and 13% CRp.^{620, 621} Response rates did not differ based on age or length of first remission. The median overall survival was 4.9 months for all patients and 12.6 months for responders. Severe myelosuppression was uniformly present, reflecting expression of CD33 on mature myeloid cells, but sepsis (17%) and pneumonia (8%) were relatively uncommon.⁶²¹

Gemtuzumab ozogamicin was subsequently also tested as frontline therapy. A 33%/5% CR/CRp rate was seen in AML patients 61 to 75 years of age who were not candidates for standard chemotherapy, but toxicity was excessive in patients older than 75 years.⁶²² In a randomized trial, the addition of gemtuzumab ozogamicin to different induction and consolidation chemotherapy regimens resulted in no difference in CR rate or survival,⁶²³ but survival benefit was demonstrated for patients with favorable-risk cytogenetic findings.

Gemtuzumab ozogamicin was approved by the United States Food and Drug Administration in May, 2000 under the accelerated approval regulations for the treatment of patients 60 years of age or older with CD33-positive AML in first relapse. Post-marketing reports of fatal anaphylaxis, tumor lysis, adult respiratory distress syndrome (ARDS), and hepatic veno-occlusive disease (VOD) required labeling revisions and the initiation of a surveillance program.⁶²⁰ Tumor lysis and ARDS were primarily observed in patients with leukocyte counts above 30,000/ml. VOD was also observed.^{620, 624}

Under accelerated approval, additional clinical trials after approval are required to confirm the drug's benefit. If those trials fail to confirm clinical benefit to patients, the FDA can withdraw the drug from the market. For gemtuzumab ozogamicin, a confirmatory clinical trial was designed and begun in 2004 to determine whether adding gemtuzumab ozogamicin to standard chemotherapy would improve survival of patients with AML. The trial was stopped early when no

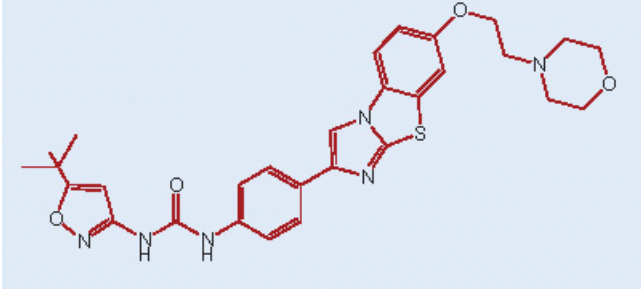

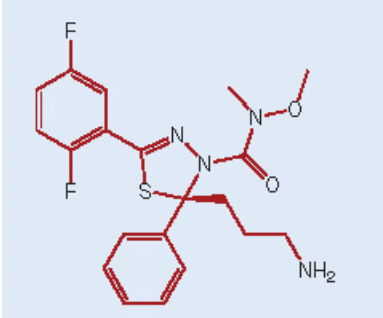

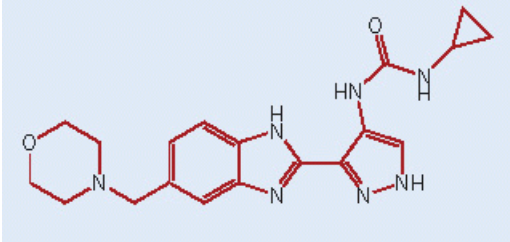

clinical benefit was observed, and after a greater number of deaths occurred in patients who received gemtuzumab ozogamicin compared with those who received chemotherapy alone. Gemtuzumab ozogamicin was withdrawn from the P.1606

P.1607

P.1608

market in June, 2010. Nevertheless other subsequently published studies have shown benefit.⁶²⁵

TABLE 75.15 NEW AGENTS IN DEVELOPEMENT FOR TREATMENT OF ACUTE MYELOID LEUKEMIA

Compound	Chemical Structure	Mechanism of Action
AC-220		Flt3 kinase inhibitor
Aflibercept	Fusion Protein	Angiogenesis inhibitor, VEGF antagonist
ARRY-520		Kinesin spindle protein inhibitor, cell cycle inhibitor, mitotic inhibitor
AT-9283		Aurora kinase inhibitor, Janus kinase 2 inhibitor, cell cycle inhibitor, mitotic inhibitor

Azacitidine

DNA methyltransferase inhibitor

AZD-1152

Aurora kinase inhibitor

Belinostat

Histone deacetylase inhibitor

Bortezomib

Proteasome inhibitor, transcription factor NF-κB inhibitor

CP-4055
(Elacyt)

Antimetabolite, DNA/RNA synthesis inhibitor ara-C-5'-elaidic acid ester

CSL-360

Monoclonal antibody

Monoclonal antibody against leukemia stem cells

Decitabine

DNA methyltransferase inhibitor

17-DMAG

Hsp90 inhibitor

Entinostat

Histone deacetylase inhibitor

Everolimus

mTOR inhibitor,
angiogenesis inhibitor

Flavopiridol

Cyclin-dependent kinase (Cdk) inhibitor

Lenalidomide

Immunomodulation,
angiogenesis inhibition,
tumor necrosis factor α
antagonist

Lintuzumab Monoclonal antibody

Monoclonal antibody
against CD33

Midostaurin

Protein kinase C inhibitor,
Flt-3 kinase inhibitor, cell
cycle inhibitor

Mocetinostat

Histone deacetylase
inhibitor

Obatoclax
mesylate

Mcl-1 antagonist, Bcl2
antagonist

Sapacitabine

Antimetabolite, DNA
synthesis inhibitor

Sirolimus

mTOR inhibitor,
angiogenesis inhibitor

Sorafenib

Flt-3 kinase inhibitor, RET
tyrosine kinase inhibitor, B-
raf kinase inhibitor, EGF
receptor kinase, inhibitor,
PDGF receptor kinase
inhibitor, angiogenesis
inhibitor

Sunitinib

Flt-3 kinase inhibitor, c-kit
inhibitor, EGF receptor
kinase inhibitor, PDGF
receptor kinase inhibitor

Temsirolimus

mTOR kinase inhibitor

Tandutinib

Flt-3 kinase inhibitor, c-kit
inhibitor, PDGF receptor
kinase inhibitor

Tipifarnib

Farnesyltransferase inhibitor

Voreloxin

DNA Topoisomerase II inhibitor, DNA-dependent protein kinase inhibitor

Vorinostat (SAHA)

Histone deacetylase inhibitor

FIGURE 75.14. Signal transduction pathways downstream to FLT 3 and other tyrosine kinase receptors include Ras/Raf/MEK and PI3K/Akt. FT, farnesyl transferase. (See text for description of targets and inhibitors.) (Drawing by Tim

Gilfilen, Medical Art Group, Vanderbilt University.)

Other Novel Agents in Acute Myeloid Leukemia

Lenalidomide has antiangiogenic effects and other effects on the marrow microenvironment, has been approved for MDS with 5q-, and is under investigation in AML.^{626,627} Angiogenesis is targeted by several other novel agents: SU5416 (Semaxinib) in an example of a small molecule receptor tyrosine kinase inhibitor directed at the vascular endothelial growth factor pathway; early trials with SU5416 indicate activity in AML.⁶²⁸ The anti-VEGF monoclonal antibody bevacizumab also has activity in AML.⁶²⁹ Bortezomib (Velcade) is a small molecule proteasome inhibitor that has activity in vitro in AML and is in clinical trials.⁶³⁰ Tipifarnib (Zarnestra) is an orally administered nonpeptidomimetic enzyme-specific inhibitor of farnesyl protein transferase, an enzyme that promotes RAS processing and transduction of proliferative signals.^{626,631} Inhibitors of mammalian target of rapamycin (mTOR) signaling have activity in AML.^{632,633} Heat shock protein 90 (Hsp 90) is a molecular chaperone involved in signaling pathways for cellular proliferation and survival, and a small molecule inhibitor of Hsp 90, the benzoquinone antibiotic 17-allylamino-17-demethoxygeldanamycin (17-AAG), suppresses the chaperone function of Hsp 90.⁶³⁴

Immunotherapy

Immunotherapeutic interventions are being explored in the setting of minimal residual disease following post-remission therapy in AML. Post-consolidation immunotherapy with interleukin-2 and histamine dihydrochloride, both administered subcutaneously, significantly improved 3-year leukemia-free survival.⁶³⁵ In addition, diverse novel vaccines and vaccine strategies are being developed and are beginning to be tested clinically in AML.^{636,637} The ideal vaccine strategy is to identify leukemia-associated antigens that are absent in hematopoietic stem cells or normal tissues and can elicit a cytotoxic T-cell response.⁶³⁷ The ability of AML blasts to differentiate into dendritic cells that can present target antigens is a method of vaccination under investigation.⁶³⁶ Peptide vaccination trials in AML have targeted different epitopes of the Wilms' tumor gene 1, the proteinase 3-derived epitope peptide, and the receptor for hyaluronic acid mediated motility (RHAMM/CD 168)-derived epitope R3. Other AML targets include preferentially expressed antigen of melanoma (PRAME), G250/CA9, BCL2, laminin receptor 1 (LamR1), and telomerase reverse transcriptase (hTERT).⁶³⁷ WT1 has been the target in recent promising clinical trials.^{638,639}

Therapy of Acute Myeloid Leukemia in Older Patients

Older patients with AML, usually defined as those 60 years of age and greater, have a worse outcome than younger patients.⁴⁴³ Reasons include differences in performance status and comorbidities, but also in biology, including cytogenetics and other parameters associated with drug resistance.⁶⁴⁰ The biology of AML may differ in older patients, with the malignant cell originating in an earlier stem cell than in younger patients.²¹⁷ Prior MDS and t-AML are more common. Unfavorable cytogenetic findings are more common in the elderly, whereas the favorable abnormalities are less common. Increased expression of the MDR1 protein on AML blasts is more common in older patients.^{377,463} In addition, older patients are more likely to have defects in the MSH2 protein which is involved in DNA repair and is associated with microsatellite instability and TP53 mutations.⁵⁹⁵

Although the overall prognosis of AML patients over 60 years of age is poor, CR rates approaching those of younger patients can be observed, so chemotherapy should not be withheld on the basis of age alone. Patients with favorable and intermediate karyotypes and with good performance status may respond well to chemotherapy,⁴⁴³ and CR rates with chemotherapy in older patients are usually in the 35% to 60% range. Unfortunately, however, median remission duration is less than one year in older patients regardless of post-remission chemotherapy regimen. Therefore, for older patients who achieve complete remission, reduced-intensity allogeneic hematopoietic stem cell transplantation should be strongly considered. In general, because of poor long-term DFS with chemotherapy (5% to 15%), it is important to discuss the poor prognosis with patients and families, to enroll patients on clinical trials, and to implement low-intensity therapies for patients unlikely to benefit from intensive chemotherapy. For older patients unlikely to benefit from chemotherapy because of disease- and/or patient-related factors, a number of novel agents and approaches are being pursued in clinical trials and as standard therapies. These currently include the DNA methyltransferase inhibitors decitabine and azacitidine, the nucleoside analogs clofarabine and sapacitabine, the immunomodulatory agent lenalidomide, and the farnesyl transferase inhibitor tipifarnib. Some of these agents, such as the DNA methyltransferase inhibitors, may be administered in the outpatient setting.

In summary, for older AML patients, the critical decision is whether to administer intensive induction chemotherapy. This decision should not be solely based on age, but also on performance status, co-morbidities, and AML risk profile including primarily cytogenetics.^{307,443} It has been shown to be feasible to wait for and use cytogenetic results in choosing initial treatment for older AML patients.⁶⁴¹ In older patients who achieve complete remission, the option of reduced-intensity

allogeneic hematopoietic stem cell transplantation should be considered.⁶⁴² Older patients with poor performance status, advanced age, and unfavorable-risk AML should optimally be treated on clinical trials of novel therapies.

Acute Myeloid Leukemia in Pregnancy

Although development of AML during pregnancy is rare, occurring in less than 1 in 10,000 pregnancies, it represents a major quandary in patient management.^{643, 644} and ⁶⁴⁵ Transmission of leukemia from mother to fetus is extremely unusual.^{646,647} Diagnosis of AML is less common in the first trimester than in the second or third trimesters, occurring in 14% in a series of 59 patients.⁶⁴⁸ Teratogenic effects of chemotherapy are more common in the

P.1609

first trimester and appear to be minimal in the second or third trimester.^{645,649,650} Options in the first trimester include therapeutic abortion and supportive therapy until the second trimester. Chemotherapy with intensive supportive care can result in a successful outcome for the fetus and the mother with leukemia in the second or third trimester^{644,645,650,651} usually without a need to terminate pregnancy. Fetuses exposed to antileukemia therapy in utero may have slight fetal growth retardation as well as transient myelosuppression if treatment is given near delivery, but generally have normal growth and development in childhood.^{652,653} The choice of induction chemotherapy is similar to that in nonpregnant patients. In addition to close monitoring of the mother and the fetus, delivery should optimally occur during a noncytopenic period.⁶⁵⁴

Relapsed and Refractory Acute Myeloid Leukemia

Approximately half of younger patients and a large majority (>85%) of older patients will either not achieve a complete remission or will relapse. The percentage of patients who have refractory AML (i.e., never obtain a complete remission) is at least 20%, but varies depending upon age, cytogenetics, and other prognostic factors. The definition of refractory AML includes patients who do not achieve complete remission with induction chemotherapy, those with a short (less than 6 to 12 months) first complete remission and patients who have relapsed twice or more.⁶⁵⁵ Prognostically relevant variables at first relapse include length of relapse-free interval after first complete remission, cytogenetics at diagnosis, age at relapse, and whether stem cell transplantation was performed previously.⁶⁵⁶ All patients with relapsed or refractory AML are candidates for clinical trials with novel therapies (see "Therapy" section).

AlloSCT is superior to chemotherapy for patients with relapsed or refractory disease, but many patients do not have a donor, or are too old or too ill for alloSCT (see "Stem Cell Transplantation" section). Although patients with a matched related donor can be offered an alloSCT in early relapse, there is an advantage and sometimes a necessity to receive additional chemotherapy to lessen the leukemia burden before a transplant, particularly if there is a delay in obtaining an alternative (i.e., unrelated) donor or if a nonmyeloablative approach is utilized (see "Stem Cell Transplantation" section). Autologous SCT is also an alternative for patients in second remission, but it is probably inferior to alloSCT and is not universally recommended.

Second remissions can be obtained in 30% to 80% of patients who had an initial first remission, are generally shorter in duration than first remissions, and are achieved more readily in patients with initial remissions longer than one year or with favorable cytogenetics.^{657, 658} and ⁶⁵⁹ Second CR was achieved in 55% to 60% of patients with initial CR > 1 year, compared to 33% to 46% with CR < 1 year.^{655, 658} Second CR was obtained in 80% to 88% of patients with favorable cytogenetics, 18% to 49% with intermediate, and 0% to 30% with poor risk.^{657,660}

To date, there is no standard regimen for induction of a second CR. Dose escalation and use of noncross-resistant regimens have been helpful in inducing second remissions. Cytarabine has been used in doses ranging from 500 mg/m² to 3 g/m² every 12 to 24 h for 3 to 6 days, alone or in combination with other agents, including anthracyclines, etoposide, clofarabine, fludarabine, gemtuzumab ozogamicin, irinotecan, L-asparaginase, mitoxantrone, and topotecan.^{661, 662, 663, 664, 665, 666, 667, 668, 669, 670} and ⁶⁷¹ HiDAC alone resulted in a CR rate of 40%, compared to 56% in patients receiving HiDAC with an anthracycline,⁶⁶¹ but two large randomized trials have not shown a benefit to adding a second agent to cytarabine.^{531,672}

A liposomal formulation of ara-C and daunorubicin with specific molar ratio (CPX-351) has shown promising activity in in vitro and in vivo studies.^{673,674} Preliminary results from a randomized trial (n = 126) showed no significant differences in CR/CRi rates for CPX-351 compared to other salvage chemotherapy (51% vs. 41%), but there were 2 months overall survival advantage for AML patients with unfavorable prognostic risk disease who received CPX-351 compared to other therapies (6.6 months vs. 4.2 months).

Reversal of drug resistance may be accomplished through the use of drugs that compete with chemotherapy agents for binding sites on p-glycoprotein. A randomized trial comparing cyclosporine A with chemotherapy versus chemotherapy

alone in poor-risk AML favored the cyclosporine A arm;⁵²⁴ however, trials evaluating the cyclosporine D derivative PSC-833 (valsopodar) and zosuquidar, a third-generation MDR modifier with less effect on pharmacokinetics of chemotherapy drugs, in initial therapy have been disappointing, as discussed above.^{521,522}

The DNA methyltransferase inhibitors azacitidine and decitabine have been used for the treatment of relapsed or refractory AML with generation of anecdotal evidence to support their use in this setting.^{675,676,677}

Single-agent clofarabine resulted in 30% CR rate in a phase 2 single-arm clinical trial in patients with relapsed or refractory leukemias.⁵⁵³ A combination of clofarabine with ara-C generated a response rate of 38% in another single arm study.⁵⁵⁴ A phase 3 prospective randomized trial (n = 320) in patients older than 55 years of age with relapsed/refractory AML compared the combination of clofarabine plus ara-C (clofarabine at 40 mg/m²/day × 5 days, ara-C 1 g/m²/day × 5 days) versus ara-C alone.⁶⁷⁸ Overall survival as the primary endpoint was not different between the two arms (6.6 months for the combination vs. 6.4 months in the ara-C arm), but CR rate (41% for the combination vs. 16% for ara-C alone, P = 0.001) was higher with the combination regimen.

Novel molecules as single agents are warranted and have been commonly used in the context of phase I and II clinical trials in relapsed patients who have short first remissions or have failed an initial salvage regimen (see “Therapy” section).

STEM CELL TRANSPLANTATION

AML has replaced CML as the most common disease to be treated with alloSCT due to the success of tyrosine kinase inhibitors in treating CML. AlloSCT is thought to have excellent efficacy in treatment of AML due to both the effect of high-dose chemotherapy with or without whole body irradiation utilized in the conditioning regimen and the immunologic graft-versus-leukemia (GVL) effect.⁶⁷⁹ AlloSCT is associated with the lowest relapse rates and can be effective in chemotherapy-refractory acute leukemia. Patient age, disease status, cytogenetics, prior therapy, co-morbidities, performance status, timing, and type of transplant determine its outcome.

AlloSCT is recommended for AML in second remission, but its benefit needs to be assessed against its risk for patients in first remission. Randomized trials in the 1990s comparing alloSCT to autoSCT and chemotherapy produced mixed results; there tended to be better disease-free survival with allogeneic SCT, but no improvement in overall survival^{680,681} (Figs. 75.15 and 75.16). Primary problems with alloSCT have been lack of suitable donors and a high early mortality caused by organ toxicity, infections, and graft-versus-host disease (GVHD).

The landscape of SCT is constantly changing (Chapters 104 and 105), and overall survival after allografts is gradually improving.^{682, 683} and ⁶⁸⁴ Major improvements in alloSCT have included: (1) high-resolution DNA typing for HLA matching; (2) improved prevention and treatment of GVHD; (3) improved supportive care, including molecular monitoring of CMV and use of pre-emptive antiviral therapy and improved antifungal therapy; (4) the development of reduced-intensity (nonmyeloablative) conditioning regimens;

P.1610

and (5) the use of co-morbidity indices to predict prognosis and to select patients and type of transplant.^{685, 686} and ⁶⁸⁷ The donor pool is expanding with the increased availability of unrelated donors and umbilical cord transplants in adults and with innovative immunosuppression to allow HLA-mismatched donors.^{688, 689, 690} and ⁶⁹¹ The HLA-haploidentical 2 or 3-loci mismatched related donor is an important and viable alternative stem cell source for patients who do not have matched donors, and it has been used in many transplant centers with outcomes that appear not to be inferior to transplantation from matched unrelated donors.⁶⁹²

FIGURE 75.15. Impact of different post-remission therapies on survival. A: Disease-free survival (DFS). Allogeneic bone marrow transplantation (BMT) has the best DFS, versus randomization between autologous BMT and intensive chemotherapy ($p = 0.05$). B: Overall survival (OS): There were no differences in OS among the three. (With permission from Zittoun RA, Mandelli F, Willemze R, et al. Autologous or allogeneic bone marrow transplantation compared with intensive chemotherapy in acute myelogenous leukemia. *N Engl J Med* 1995;332:217-223.)

Age is no longer an absolute contraindication to alloSCT with the use of nonmyeloablative conditioning regimens (Fig. 75.17),⁶⁸⁵ which allow older patients and those with comorbid illnesses to undergo alloSCT with low early mortality, albeit with a higher relapse rate. Because nonmyeloablative SCT has less antileukemic effect, it relies on the graft-versus-

leukemia (GVL) effect. Transplant-related mortality with nonmyeloablative conditioning regimens is reduced to the 10% to 20% range, but the relapse rates of 30% to 65% are higher than for myeloablative SCT. Overall survival appears to be equivalent following reduced-intensity and myeloablative conditioning regimens in patients in remission or with low tumor burden.^{693,694} The 3-year DFS for AML utilizing reduced intensity conditioning has been 30% to 66%.⁶⁹⁵

AutoSCT is associated with lower transplant-related mortality than alloSCT, but with higher relapse rates. In vitro purging with cyclophosphamide derivatives or by positive stem cell selection has been associated with a lower relapse rate, but the role of purging remains controversial because it can delay engraftment and it has not been validated in a large randomized trial.⁶⁹⁶ A randomized trial comparing alloSCT to autoSCT in first CR, the EORTC-GIMEMA AML-10 trial, favored the allo (donor) arm over the auto (no donor) arm, but only in patients with poor-risk cytogenetics.⁶⁹⁷ Other reports have favored autoSCT over alloSCT.^{698,699} In a retrospective comparison of autoSCT and matched unrelated donor (MUD) SCT, the 3-year survival probabilities were: 57% \pm 4 versus 44% \pm 7 (P = 0.002) in CR1 and 46% \pm 7 versus 33% \pm 5 in CR2 (P = 0.006).⁶⁹⁹ However, cytogenetic data were unavailable for most patients and it is likely that alloSCT would have had better outcomes than autoSCT in patients with poor-risk cytogenetics. Due to a leukemia-free stem cell source and a lower relapse rate, alloSCT from a matched related donor (MRD) tends to be preferred over autoSCT.

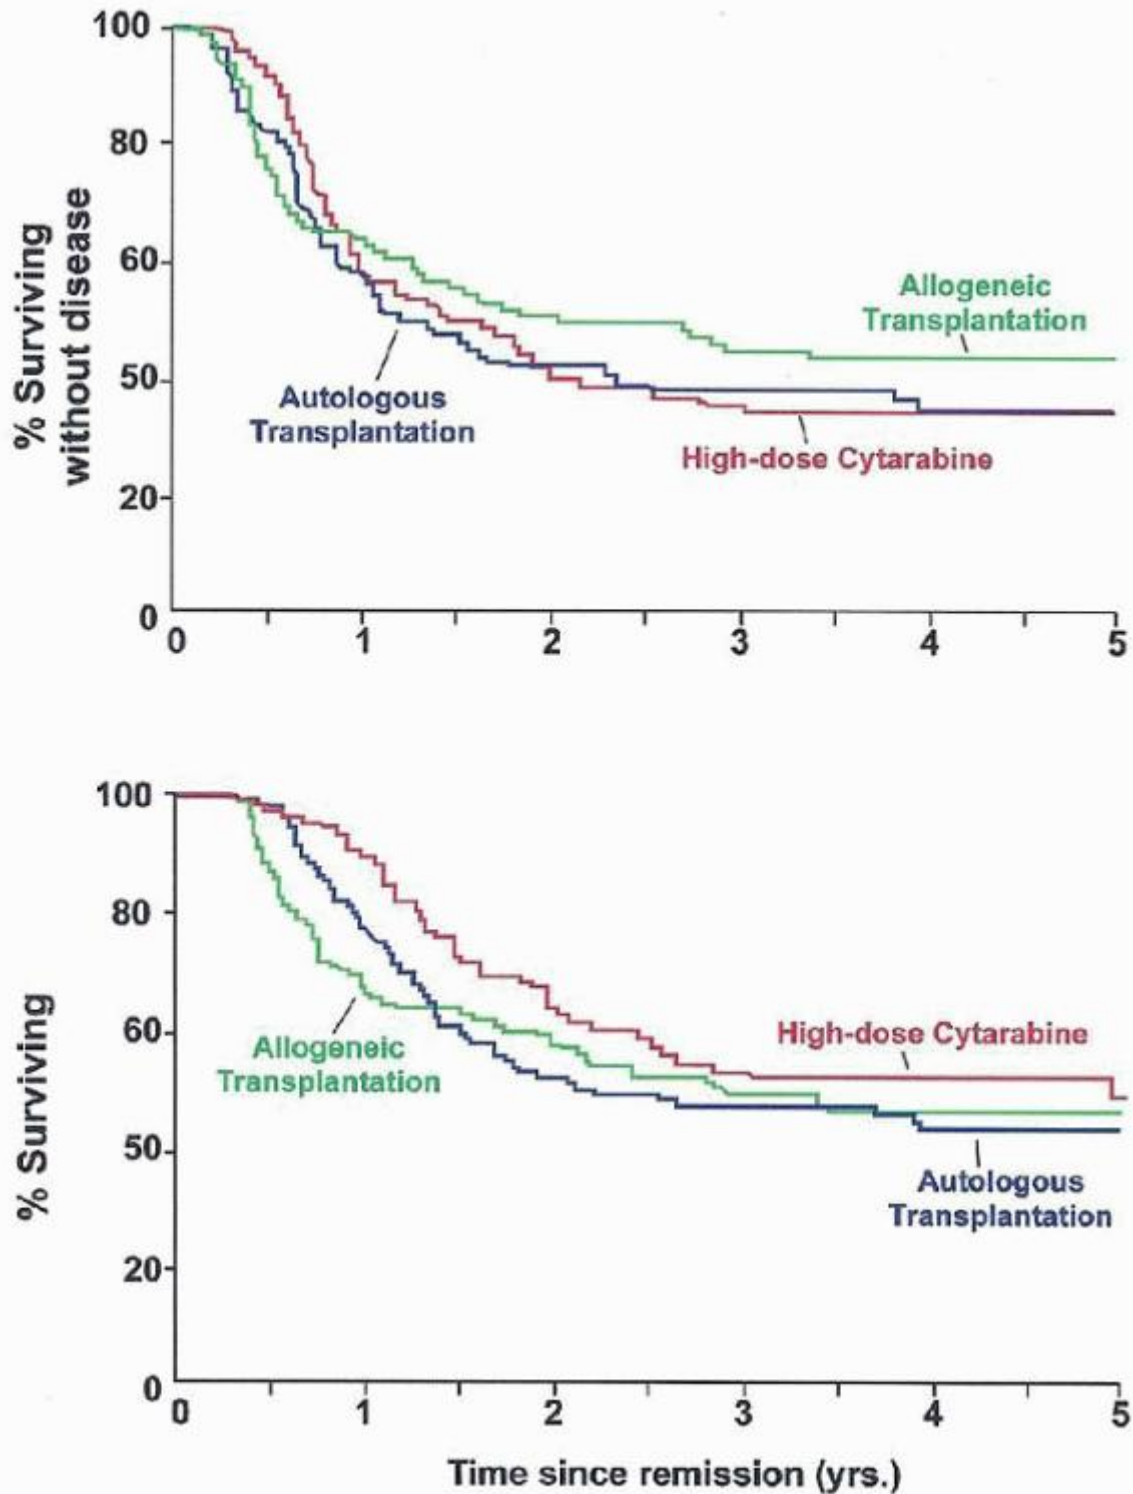

FIGURE 75.16. A: Disease-free survival according to post-remission therapy was not statistically significant at 4 years: autologous bone marrow transplantation (autoBMT), 35.6%; allogeneic bone marrow transplantation (alloBMT), 43.6%; high-dose cytarabine, 35.6%. B: Overall survival at 4 years was better for high-dose cytarabine, 52 ± 9%, than for either alloBMT, 46 ± 10% (p = 0.04) or auto BMT, 43 ± 9% (p = 0.05). (With permission from Cassileth PA, Harrington DP, Appelbaum FR, et al. Chemotherapy compared with autologous or allogeneic bone marrow transplantation in the management of acute myeloid leukemia in first remission. *N Engl J Med* 1998;339:1649-1656.)

Transplant in first CR is generally not recommended for patients with favorable-risk cytogenetics, including t(8;21) and inv(16), but gene mutations may identify patients with good-risk cytogenetics who are unlikely to be cured by chemotherapy and should be considered for early transplantation. KIT mutations are associated with an inferior survival for favorable-risk core-binding factor AML.^{364,365,366}

FLT3 mutations, particularly of the internal tandem duplication (ITD) type, are the most important adverse prognostic factor in cytogenetically normal AML. A retrospective, single-institution study suggested that performing alloSCT in early first complete remission could improve long-term outcomes for FLT3/ITD AML,⁷⁰⁰ with 4 years overall survival for the 31 FLT3/ITD patients comparable to the 102 patients with WT FLT3. Patients with normal karyotype and FLT3 mutations also appear to benefit from autoSCT.⁷⁰¹ In addition, patients with a normal karyotype who had NPM-1 mutations and did not have FLT3-ITD did not

P.1611

benefit from alloSCT, whereas those with other combinations of the mutations did benefit in a retrospective evaluation.⁴⁵

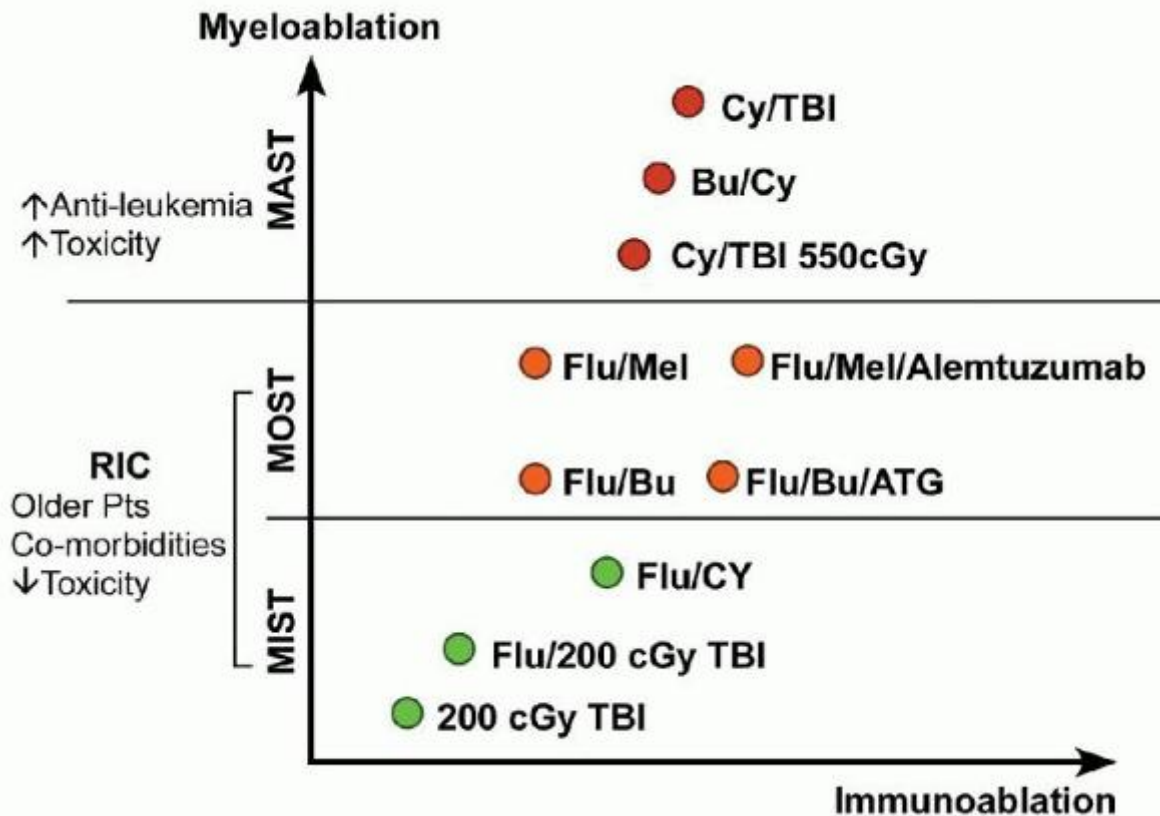

FIGURE 75.17. Diagram showing intensity of different regimens. The horizontal axis indicates the degree of immunoablation, and the vertical axis that of myeloablation. ATG, antithymocyte globulin; Bu, busulfan; CY, cyclophosphamide; Flu, fludarabine; MAST, myeloablative SCT; Mel, melphalan; MIST, minimal-intensity SCT; MOST, moderate-intensity SCT; RIC, reduced-intensity stem cell transplantation (SCT); TBI, total-body irradiation. (Adapted from Kassim AA, Chinratanalab W, Ferrara JLM, Mineishi S. Reduced-intensity allogeneic hematopoietic stem cell transplantation for acute leukemias: “what is the best recipe?” Bone Marrow Transplant 2005;36:565-574.)

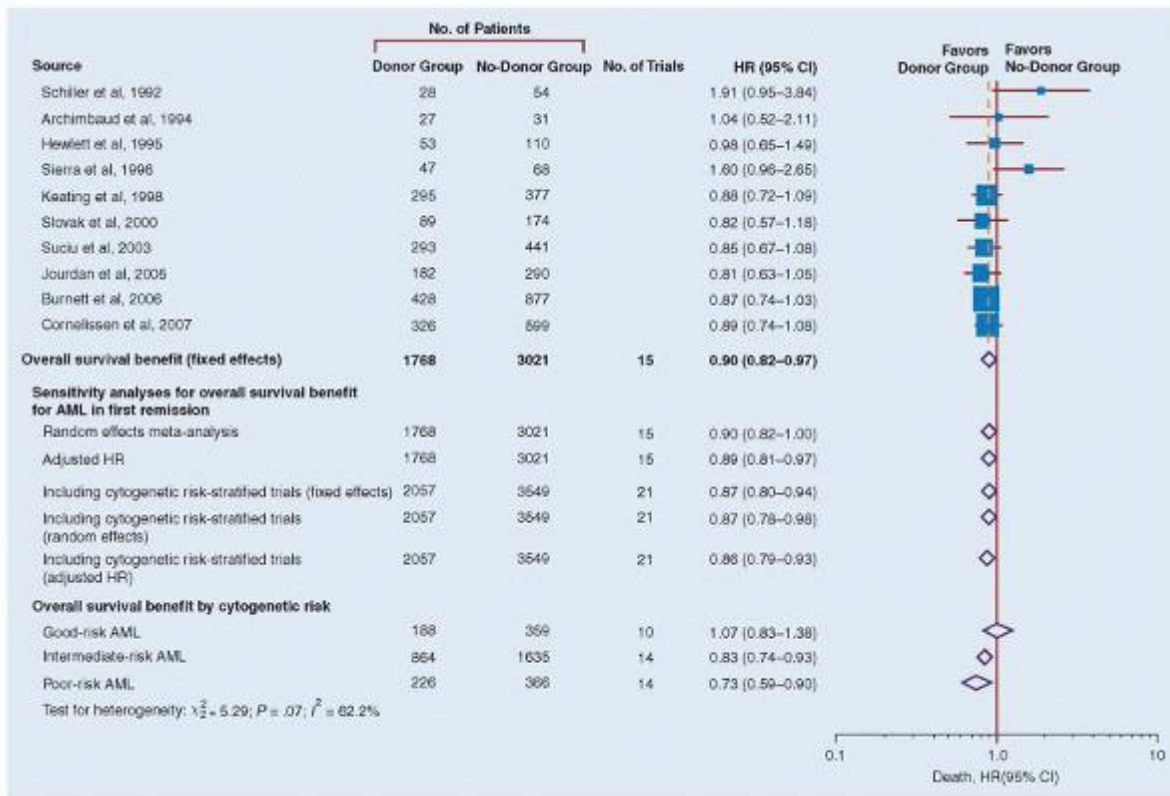

FIGURE 75.18. Overall survival benefit of allogeneic SCT for AML in first complete remission. Black rectangles indicate summary effects estimates (hazard ratios [HRs]) for individual study reports. Sizes of data markers are proportional to the study weights. Error bars indicate 95% confidence intervals (CIs). AML indicates acute myeloid leukemia. (From Koreth J, Schlenk R, Kopecky KJ, Honda S, Sierra J, Djulbegovic BJ, Wadleigh M, DeAngelo DJ, Stone RM, Sakamaki H, Appelbaum FR, Döhner H, Antin JH, Soiffer RJ, Cutler C. Allogeneic stem cell transplantation for acute myeloid leukemia in first complete remission: systematic review and meta-analysis of prospective clinical trials. JAMA 2009;301(22):2349-2361.)

The role of SCT in the treatment of AML has been investigated in several prospective clinical trials.^{680,681,697,702, 703} and ⁷⁰⁴ In four major prospective trials, involving approximately 2,700 AML patients in first CR, only 71% of eligible patients received alloSCT, and only 47% of the remainder were randomized.⁷⁰² Intent-to-treat analyses comparing survival between donor versus no-donor are recommended to assess the impact of alloSCT in prospective trials. In three large prospective trials, EORTC-GIMEMA favored the donor arm for poor-risk cytogenetics, the MRC 10 favored the donor arm for intermediate-risk cytogenetics, and the HOVON-SAKK favored the donor arm for both risk groups.^{697,702,704} A systematic review and meta-analysis of clinical trials involving more than 3,500 patients with AML in first complete remission including prospective biologic assignment reported a significant survival advantage of alloSCT compared to non-alloSCT in the treatment of AML patients with intermediate and unfavorable cytogenetics, but not with favorable cytogenetics (Fig. 75.18).⁷⁰⁵

Although there is general agreement that alloSCT offers the best option for preventing relapse in patients with AML with intermediate- or poor-risk cytogenetics, its overall impact on survival and the optimal timing and method of SCT (related vs. unrelated; myeloablative vs. reduced intensity) remain unresolved issues. In most trials utilizing alloSCT in first CR for patients

P.1612

without favorable cytogenetics, 5-year DFS is 45% to 75% using an MRD.^{706,707} There has been a significant decline in transplant-related mortality to less than 10% for patients in first CR in some reports due to a decrease in deaths from GVHD, infections, and organ toxicity; this decline in transplant-related mortality has led to improved survival in first remission patients but not in patients in relapse or second remission⁷⁰⁸ (Fig. 75.19).

FIGURE 75.19. Probability of survival in adults (age ≥ 18 years) after HLA-identical sibling transplants for AML, 2000-2009, by disease status. (From the Center for International Blood and Marrow Transplant Research (CIBMTR), Pasquini MC, Wang Z. Current use and outcome of hematopoietic stem cell transplantation: CIBMTR Summary Slides, 2010. Available at: <http://www.cibmtr.org>.)

Despite improvements in HLA matching and supportive care, results of transplants from unrelated donors are usually inferior to those from matched siblings in first CR.⁷⁰⁹ In contrast, recent reports have indicated equivalent survival for sibling and unrelated transplants for AML, particularly for patients in early relapse or second CR, for whom DFS is in the 20% to 40% range (Fig. 75.20).⁷¹⁰ Fortunately approximately one third of patients who fail induction therapy but achieve remission with subsequent therapy and proceed to alloSCT can have prolonged DFS.⁷¹¹ For patients with refractory or advanced AML, the salvage rate is 5% to 30%.^{478,712}

Patients with acute GVHD (grades II-IV) or chronic GVHD and patients transplanted from unrelated donors have had lower relapse rates than patients without GVHD or transplanted from matched related donors, respectively.⁷¹³ However, GVHD and the therapy of GVHD can be debilitating or fatal, especially for the older patient. There are ongoing trials with different nonmyeloablative regimens and different immunosuppressive agents to control GVHD without losing GVL.^{714,715}

FUTURE DIRECTIONS

Further studies will identify and characterize additional gene mutations, epigenetic changes, patterns of microRNA expression, and aberrant signal transduction that will serve to further refine prognostic subsets and provide new therapeutic targets. Refined approaches to transplantation will increase its safety and efficacy, and its applicability in older patients, who are in great need of more effective therapies to prolong disease-free and overall survival. Novel immunotherapeutic approaches may also favorably affect outcomes in the future. The detection of residual disease is an ongoing area of study that should come into increasing use in the management of AML, and measurable minimal residual disease may serve as a target for innovative therapies.

FIGURE 75.20. Survival of adult (age ≥ 18 years) unrelated bone marrow transplants with myeloablative preparative regimens for AML by disease status, 2000-2009. Five-year survivals were approximately 40% in first and second CRs, and less than 20% for advanced disease. Survival is significantly increased for transplants in CR1 or CR2 compared to transplants for patients with more advanced disease. (From the National Marrow Donor Program.)
