Chapter 35

Hemoglobins with Altered Oxygen Affinity, Unstable Hemoglobins, M-Hemoglobins, and Dyshemoglobinemias

Martin H. Steinberg

More than 1,100 mutations affecting the globin subunits of hemoglobin have been described (<http://globin.cse.psu.edu/>), and among these, sickle cell disease along with hemoglobinopathies associated with HbE, HbC, and the β - and α -thalassemias are mankind's most common single-gene disorders (see Chapters 33 and 34). Much less common are hemoglobin mutations discussed in this chapter that affect the ability of the molecule to bind and release oxygen, that reduce its stability, and that allow its heme iron to be oxidized. Exogenous agents can also oxidize hemoglobin, interfering with oxygen transport.

HEMOGLOBINS WITH ALTERED OXYGEN AFFINITY

The affinity of hemoglobin for oxygen is characterized by the amount of oxygen bound at any given oxygen tension. Oxygen affinity is usually designated by the P_{50} , which is the partial pressure of oxygen at which hemoglobin is 50% saturated. Oxygen affinity can be modified by pH, temperature, and organic phosphates. The normal co-operativity of hemoglobin, or heme-heme interactions in the hemoglobin tetramer, determines the sigmoidal shape of the hemoglobin-oxygen dissociation curve. This is a result of the fact that the deoxygenated T (tense) form of hemoglobin has a lower affinity for oxygen than the oxygenated R (relaxed) form (see Chapter 6). Consequently, globin gene mutations that alter areas of the molecule involved with T-R interactions can lead to alterations in oxygen affinity. Both high- and low-oxygen-affinity hemoglobin variants are encountered and all globin genes have been affected.

High-oxygen-Affinity Hemoglobins

Globin gene mutations can increase the affinity of the hemoglobin molecule for oxygen and cause erythrocytosis. More than 90 high-oxygen-affinity variants have been reported in <http://globin.cse.psu.edu/> and Wajcman and Galacteros.¹ Familial erythrocytosis is a valuable clue to the presence of a high-oxygen-affinity hemoglobin variant; isolated cases are caused by new mutations. These α - or β -globin chain mutations are dominant disorders, expressed clinically in the heterozygote. They may be lethal in homozygotes if they affect the α -globin chain and are expressed in utero. One γ -globin variant (HbF-Monserrato-Sassari, HBG2 cys93arg) in a normal newborn and a possible δ -globin variant (Hb Noah Mehmet Oesteurk, HBD his143tyr) have been described.

Several homozygotes for β -globin high-oxygen-affinity variants have been described and these individuals can have more severe disease.^{2, 3, 4, 5} Compound heterozygotes with a high-oxygen-affinity hemoglobin and β^0 -thalassemia have also been described, mimicking the homozygous state as normal adult hemoglobin A (HbA) is not present.

Pathophysiology

Stabilization of the R state of the hemoglobin tetramer ($\alpha_2\beta_2$), with its high affinity for oxygen, or destabilization of the low-oxygen-affinity T state is caused by globin gene mutations in critical areas that can effect the R \rightarrow T transition (Table 35.1).⁶ The increased avidity for oxygen (low P_{50}) of these variants reduces oxygen delivery to tissues, thereby stimulating erythropoietin production and increasing red cell mass. Patients with high-oxygen-affinity hemoglobins with erythrocytosis usually have normal urine erythropoietin levels. However, erythropoietin levels increase when they are phlebotomized to a normal red cell mass.^{7, 8} Individuals with these hemoglobin variants appear to be reasonably compensated for the low P_{50} by the increased red cell mass. Oxygen consumption and arterial pO_2 are normal, but in some cases there is reduced mixed venous pO_2 and decreased resting cardiac output.

Not unexpectedly, the JAK2 V617F mutation found in some individuals with polycythemia vera is absent in patients with high-oxygen-affinity hemoglobin variant induced erythropoiesis.⁹

Diagnosis

The differential diagnosis of increased red cell mass is discussed in Chapter 44. The diagnosis of high-oxygen-affinity hemoglobins is suspected by finding isolated erythrocytosis without accompanying leukocytosis, thrombocytosis, and splenomegaly, as might be expected in cases of polycythemia vera. A family history of erythrocytosis is also suggestive of a high-oxygen-affinity hemoglobin variant. Other disorders expressed in the erythrocyte that cause isolated erythrocytosis include 2,3-diphosphoglycerate (2,3-DPG) mutase mutations that reduce the synthesis of this modulator of hemoglobin-oxygen affinity, some instances of methemoglobinemia, and chronic carbon monoxide (CO) poisoning.

Determination of the red cell oxygen equilibrium curve is the benchmark for the diagnosis of erythrocytosis due to high-oxygen-affinity hemoglobins. The oxygen-binding characteristics of hybrid tetramers ($\alpha_2\beta^A\beta^{var}$) are likely to be intermediate between purified HbA and purified variant, and the shape of the hemoglobin-oxygen dissociation curve can at times be biphasic. Measurement of blood P_{50} confirms the shift in the hemoglobin-oxygen dissociation curve. Rarely, the whole-blood P_{50} is normal, requiring study of dialyzed purified hemoglobin. An accurate P_{50} value is difficult to "calculate" from pO_2 data, and it is best to measure the pO_2 and hemoglobin saturation directly. P_{50} measurements are not widely available but can be done with several instruments.

High oxygen affinity is observed in both erythrocytes and purified dialyzed hemoglobin. The concentration of 2,3-DPG is normal, indicating that altered oxygen affinity is not caused by reduced levels of this modulator of hemoglobin function. This is in contrast to what is seen in the rare instance of red cell 2,3-DPG mutase deficiency, where both erythrocytes and whole blood have high oxygen affinity, and the oxygen affinity of the purified hemolysate stripped of 2,3-DPG is normal.¹⁰

High-performance liquid chromatography (HPLC) studies may reveal an abnormal hemoglobin, but normal studies do not exclude the possibility of a high-affinity hemoglobin that migrates with normal HbA. As with all evaluations for abnormal hemoglobins, determining the DNA sequence of the globin genes provides the definitive information.

Examples of high-oxygen-affinity hemoglobins that illustrate the varying mechanisms and heterogeneous clinical findings seen with these variants are discussed in the following. A detailed

P.915

understanding of the structure of hemoglobin and the importance of each residue in determining function allows a molecular explanation of most of the clinical abnormalities observed.

TABLE 35.1 SITES OF GLOBIN MUTATION ASSOCIATED WITH INCREASED OXYGEN AFFINITY^a

Heme pocket mutations

Miscellaneous

^aOther than single amino acid substitutions, these mutations can include small deletions and insertions of amino acids, reading frameshifts, fusion globins, and elongated globin chains.

α -Globin Chain Variants

Because there are four α -globin genes, most stable α -globin variants form 25% or less of the total hemoglobin, compared with 40% to 50% for β -globin variants. As a result, the clinical effects of α -globin variants are less striking than those of β -globin variants. However, the coincident inheritance of a β -thalassemia gene can modulate the concentration of high-affinity α -variant hemoglobins and homozygosity for a high-oxygen-affinity variant affecting α -globin chains has been described.

Hb Chesapeake (HBA arg92leu) was the first reported high-affinity hemoglobin variant.¹¹ It was discovered in an 81-year-old patient with erythrocytosis, an abnormal hemoglobin detected by hemoglobin electrophoresis, and erythrocytes with increased oxygen affinity. Fifteen members of the proband's family were similarly affected. Hb Chesapeake represented ~20% of the total hemoglobin. With a P_{50} of 19 mm Hg (normal ~26 mm Hg), Hb Chesapeake produced moderate erythrocytosis. The mutation affected an invariant residue that stabilizes the R state at the $\alpha_1\beta_2$ area of contact, making the T conformer less favored.

Hb Nunobiki (HBA1 arg141cys), is one of four mutations of this invariant residue, all of which exhibit high oxygen affinity and moderate to mild erythrocytosis.¹² This group of mutations represents an interesting cluster of variants that illustrates the effects of different mutations at the same amino acid residue. As a mutant of the 3'-HBA1 gene that is expressed to a lesser extent than the 5'-HBA2 gene, Hb Nunobiki makes up ~13% of the hemolysate and is accompanied by only mild erythrocytosis. High oxygen affinity is a result of the breaking of the C terminal-to-C terminal salt bridge that is indispensable for the stabilization of the T state, favoring the R state.

β -Globin Chain Variants

All possible single-base mutations of the $\beta 99$ site disturbing the $\alpha_1\beta_2$ area of contact have been described and include Hb Kempsey (HBB asp99asn), Hb Yakima (asp99his), Hb Radcliffe (asp99ala), Hb Ypsilanti (asp99tyr), Hb Hotel-Dieu (asp99gly), Hb Chemilly (asp99val), and Hb Coimbra (asp99glu). As expected for stable β -globin chain variants, all are present at 40% to 50% of the hemolysate, exhibit moderately high oxygen affinity, and are characterized clinically by erythrocytosis. Hbs Kempsey, Radcliffe, and Hotel Dieu have a decreased response to 2,3-DPG. Hbs Ypsilanti and Radcliffe form stable hybrid tetramers in the hemolysates in which the abnormal β chains coexist with normal β chains.

Six of the possible seven mutations of the C-terminal CAC (tyr) codon have also been described. One of them, Hb Cochin-Port Royal (tyr146arg), has nearly normal oxygen affinity but decreased 2,3-DPG interaction and Bohr effect.¹³

Three mutations of β 82 lys have been described: Hb Rahere (lys82thr), Hb Helsinki (lys82met), and Hb Providence (lys82asn). All have moderately high oxygen affinity and moderate erythrocytosis.

These mutants have drastically reduced 2,3-DPG binding as a result of the elimination of one of the normal binding sites for this allosteric effector. Hb Porto Alegre (HBB ser9cys) has high oxygen affinity and a tendency to aggregate, but erythrocytosis is not present.¹⁴ Polymerization of Hb Porto Alegre is based on the formation of disulfide bonds in oxygenated samples and is different from HbS polymerization. Polymerization of this mutant diminishes heme-heme interaction and increases the oxygen affinity.

Hb Tak (HBB 147(+AC), modified C-terminal sequence: 147thr-lys-leu-ala-phe-leu-leu-ser-asn-phe-157tyr-COOH), is elongated by 11 amino acid residues.^{15, 16} It forms 40% of the hemolysate, has a very high oxygen affinity with no cooperativity, and no allosteric interaction with pH or 2,3-DPG. The C terminus of the β -globin chain is actively involved in the conformational changes of the hemoglobin molecule by stabilizing the T state. By having these stabilizing interactions disrupted, Hb Tak is totally frozen in the R state. Hb Tak is also slightly unstable. In spite of these severe functional abnormalities, a heterozygous patient did not have erythrocytosis. The extreme biphasic nature of the hemoglobin-oxygen affinity curve observed in mixtures of Hb Tak and HbA suggests that hybrid tetramer ($\alpha_2\beta^A\beta^{\text{Tak}}$) formation is absent. The top portion of the oxygen equilibrium curve is normal, and it begins to be abnormal only at <40% saturation. Because physiologic oxygen exchange occurs most commonly above that level of saturation, the tissues may not be hypoxic, removing the stimulus for increased erythropoiesis.

Clinical Features

Patients with high-affinity hemoglobins and erythrocytosis have a benign clinical course and rarely have complications, apart from a ruddy complexion. Splenomegaly is typically absent. Hemoglobin concentration and hematocrit are increased variably, and usually only moderately, suggesting that modulation by variations in other genes might affect the physiologic response to hypoxia. Some patients with Hb Malmo (HBB his97gln) have been reported to be symptomatic and to benefit from phlebotomy and the transfusion of normal blood, but this clinical course is an exception.¹⁷

Many cases of high-oxygen-affinity hemoglobins are diagnosed during a routine hematologic examination or when the family of a proband known to have erythrocytosis is examined. In very limited studies, exercise capacity in the laboratory and the indices of working capacity and cardiac tolerance were similar in patients with high-oxygen-affinity hemoglobins and in controls.¹⁸ It has been suspected that carriers of these variants may have enhanced athletic performance under some circumstances, and this has led to the unfortunate and sometimes fatal use of erythropoietin or transfusion to enhance performance in competitive athletics.

In a population-based study of erythrocytosis, high-oxygen-affinity variants accounted for 3% of all cases.¹⁹ By early diagnosis of high-affinity hemoglobins, unnecessary invasive diagnostic procedures and inappropriate therapeutic interventions, such as cardiac catheterization, can be avoided. Patients have received ³²P treatment based on a mistaken diagnosis of polycythemia vera.

Increased morbidity or mortality in mothers with high-oxygen-affinity hemoglobins or their offspring has not been observed, suggesting that the affinity of the mother's hemoglobin is irrelevant with respect to oxygen delivery to the fetus.¹⁸ Low ambient pO_2 , as in unpressurized airplanes and ascent to altitude, do not represent a risk, because high-affinity hemoglobins are avid for oxygen.

Hypothetically, carriers should be less prone to "the bends" during deep sea diving, because of slower oxygen release during ascension.

P.916

Treatment

Patients with high-oxygen-affinity hemoglobins have reasonable compensation for their abnormality, with adequate tissue oxygen delivery despite increases in blood viscosity. Intervention is therefore rarely required. Exercise studies before and after phlebotomy in patients with Hb Osler (HBB tyr145asn), a variant with a P_{50} of 10 to 11 mm Hg and a hemoglobin concentration of ~22 g/dl, did not show an impairment after phlebotomy.¹⁸ Limited studies have suggested that phlebotomy generally does not improve exercise performance. However, rare individuals appear to have benefited from

phlebotomy, and thus other unknown factors may be interfering with their normal compensation for high hemoglobin - oxygen affinity, and increased blood viscosity may have become a burden. Prudence dictates that before embarking on a regimen of chronic phlebotomy, one should be conservative and review the hematologic and physiologic findings at 6-month intervals during the first few years after diagnosis. In older patients, special attention should be directed to blood flow to the heart and central nervous system. Thrombosis has been reported in individuals with high-oxygen-affinity variants but a causal relationship has not been established. In an example of a patient with a high-oxygen-affinity hemoglobin with concurrent β -thalassemia, treatment with hydroxyurea reduced the PCV from 61% to 39%, increased HbF from 3.6% to 30%, and P_{50} from 6 to 10 mm Hg.²⁰ This case should not be a recommendation for routine treatment of erythrocytosis due to high-oxygen-affinity hemoglobins with cytostatic agents.

Low-oxygen-Affinity Hemoglobins

Hemoglobin variants with reduced affinity for oxygen are in many respects the converse of high-oxygen-affinity variants. About half as many low-oxygen-affinity variants have been described compared to high-oxygen-affinity variants. They are expressed in the heterozygote, with homozygosity likely to be embryonic lethal. A major clinical feature is anemia that, at times, is accompanied by cyanosis.

Pathophysiology

Alterations of critical molecular regions involved directly in the R-T transition result in the stabilization of the deoxy T state or destabilization of the oxy R state. Low-oxygen-affinity hemoglobins deliver more O_2 to the tissues per gram of hemoglobin, and this is reflected by an oxygen-hemoglobin dissociation curve shifted toward the right of normal and an increase in P_{50} . When hemoglobin has a right-shifted or low-affinity curve, the difference between oxygen binding in the lungs at PO_2 levels of 100 mm Hg and unloading in the tissues at 40 mm Hg can be twice as great as the differences in a hemoglobin with a normal oxygen equilibrium curve. Patients with a moderately right-shifted oxygen equilibrium curve (P_{50} between 35 and 55 mm Hg) may be mildly anemic, but some individuals with very right-shifted oxygen equilibrium curves ($P_{50} \sim 80$) are not anemic. A right-shifted oxygen equilibrium curve leads to an increase in the synthesis of 2,3-DPG and a decrease in its destruction.

Diagnosis

The first report of a low-oxygen-affinity hemoglobin was Hb Kansas (HBB asn102thr), which presented with asymptomatic cyanosis without anemia or hemolysis.²¹ Detection of a lowoxygen-affinity hemoglobin is part of the differential diagnosis of patients with cyanosis (see later). Before undertaking extensive diagnostic procedures in cases of cyanosis that are not clearly the result of cardiovascular or pulmonary disease, fractionating hemoglobin by HPLC and measuring blood P_{50} is advisable. A search for low-affinity hemoglobins as an explanation for anemia without cyanosis is less compelling, but if other investigations prove fruitless, unexplained normocytic anemia without reticulocytosis might be evaluated by measuring P_{50} .

A simple bedside test can distinguish cyanosis resulting from low-oxygen-affinity hemoglobins or cardiopulmonary cyanosis from that occurring with methemoglobinemia, M hemoglobins, or sulfhemoglobinemia. When blood from carriers of low-oxygen-affinity hemoglobins or patients with cardiopulmonary disease is exposed to ambient oxygen, it will turn from purple-greenish to bright red. In contrast, blood of patients with methemoglobinemia, sulfhemoglobinemia, or M hemoglobins will remain abnormally colored.

Clinically apparent cyanosis is observed only in carriers of low-oxygen-affinity variants with greatly right-shifted curves and where the variant comprises a substantial portion of the hemolysate. Cyanosis is present from birth in some low-oxygen-affinity hemoglobins due to α -globin chain mutants. In carriers of β -globin chain mutants, cyanosis may appear from the middle to the end of the first year of life as γ -globin gene expression and HbF synthesis wanes and is replaced by β -globin gene expression and HbA. Neonatal cyanosis has been associated with γ -globin variants that have low oxygen affinity.²² Globin gene sequencing is the sole means of definitive diagnosis.

Clinical Features

Three low-oxygen-affinity variants have been described at $\beta 102$. Hb Kansas, the best-studied variant, has a whole-blood P_{50} of ~ 70 mm Hg, decreased co-operativity, and a normal Bohr effect.²¹ The $\beta 102$ asn residue is invariant among β -globin chains and participates in the only hydrogen bond between asn 102 and asp 94 across the $\alpha_1\beta_2$ interface in oxyhemoglobin. This bond is broken when the molecule assumes the T state. The new thr residue is incapable of forming this bond, and low oxygen affinity results from destabilization of the R conformer. The changes induced by this substitution at the $\alpha_1\beta_2$ interface allow Hb Kansas to dissociate into $\alpha\beta$ dimers, the near opposite of the high-oxygen-affinity Hb Chesapeake.

Hb Beth Israel (HBB asn102ser) was found in a patient with cyanosis of the fingers, lips, and nail beds.²³ The P_{50} was 88 mm Hg, and arterial blood was only 63% saturated despite a normal pO_2 . The hemolysate also had a low oxygen affinity and a normal Bohr effect. Erythrocyte 2,3-DPG was mildly elevated. The molecular mechanism of reduced oxygen affinity is the same as for Hb Kansas, although the defect may be more disruptive locally, because the serine side chain is shorter than that of threonine.

Hb Bologna (HBB lys61met) is informative because it was present as a compound heterozygote with β^0 -thalassemia and comprised 90% of the hemolysate.²⁴ Adults were neither cyanotic nor anemic despite having a P_{50} of 37.6 mm Hg. During gestation, the high concentration of HbF makes it doubtful that this mutation would have an effect on fetal development.

Hb Bruxelles (HBB phe42del) is a deletion of the most conserved amino acid residue of hemoglobin.^{25, 26} Phenylalanine residues at $\beta 41$ and $\beta 42$ are conserved in all normal mammalian non- α -globin chains and are indispensable for the structural integrity and oxygen-binding functions of the molecule. From age 4 years, the index case of Hb Bruxelles had severe hemolytic anemia and cyanosis, requiring blood transfusion once. Later in life, her hemoglobin concentration stabilized at 10 g/dL. Reasons for this "switch" of phenotype are unknown. Other mutations of $\beta 41$ and $\beta 42$, which are predominately unstable hemoglobins, are discussed later.

Treatment

Treatment is not needed for these variants. The importance of early diagnosis is to avoid unnecessary work-up and to alleviate concern for the patient and family.

P.917

UNSTABLE HEMOGLOBINS

The unstable hemoglobins result from globin chain mutations that cause hemoglobin tetramer instability and intracellular precipitation of its globin subunits. These intraerythrocytic precipitates are detectable by supravital staining and appear as globular aggregates called Heinz bodies. These inclusions reduce the life of the erythrocyte by binding to the membrane, decreasing cell deformability, and increasing membrane permeability. The resultant hemolytic disorder is sometimes called congenital Heinz body hemolytic anemia. Heinz bodies and hemolysis also occur with certain hereditary erythrocyte enzyme deficiencies (see Chapter 28). More than 140 unstable variants of both the β - and α -globin chains with widely varying clinical severity have been reported, almost always as heterozygotes for the mutation, although some homozygous cases have been reported. The major clinical features are anemia, reticulocytosis, pigmenturia, and splenomegaly.

Pathophysiology

The pathophysiology of unstable hemoglobins relates to the specific mutations leading to altered heme-globin interaction, the process of Heinz body formation, and destruction of red cells containing denatured hemoglobin.

Mutations That Alter Heme-Globin Interaction

Mutations that change the primary structure (amino acid sequence) of globin, depending on the substitution and its location, can alter the secondary structure (α -helical), the tertiary structure (folding of the globin chain), or the quaternary structure (interactions within the hemoglobin tetramer). The mechanisms that can lead to this hemoglobin instability are listed in Table 35.2.

Heme-globin interactions are vital for oxygen delivery but also contribute to molecular stability and intracellular solubility. For example, introduction of a charged amino acid residue into the heme pocket, a site normally formed by residues with nonpolar side chains, results in hemoglobin instability (e.g., Hb Bristol). Mutations involving residues that interact directly with heme, such as those near the (F8) proximal histidine that reacts with heme-iron (e.g., Hb Köln), are associated with hemoglobin instability. Also, mutations associated with nontyrosine substitutions of the (E7) distal histidine (e.g., Hb Zürich) cause molecular instability. An interesting effect of this is that the ligand-binding properties of iron are changed, and Hb Zürich has a much higher affinity for CO.^{27, 28}

Disruption of the secondary structure reduces subunit solubility and is often a result of the introduction of proline residue that cannot be accommodated into the α -helix except in its first two positions. α -Helices comprise ~70% of a globin subunit and must be folded into a globin motif. Introduction of water into the molecule destroys its stability, and this can be caused by substitution of a charged residue, for example, alanine, for a nonpolar residue, such as proline (e.g., Hb Brockton).²⁹

TABLE 35.2 SITES OF GLOBIN MUTATION ASSOCIATED WITH UNSTABLE HEMOGLOBINS^a

Weakening or modification heme-globin interactions

Interference with the secondary structure of a globin subunit

Interference with the tertiary structure of the subunit

Altered subunit interactions interfering with the quaternary structure

^aOther than single amino acid substitutions, these mutations can include small deletions and insertions of amino acids, reading frameshifts, fusion globins, and elongated globin chains.

Loss of intersubunit contact hydrogen bonds or salt bridges in the $\alpha_1\beta_1$ contact area will interfere with hemoglobin quaternary structure and also reduce stability. Dissociation of $\alpha_1\beta_1$ contacts normally does not occur in red cells, whereas dissociation of $\alpha_1\beta_2$ contact does take place. Dissociation of $\alpha_1\beta_1$ dimers into monomers is normally minimal, as it generates methemoglobin and consequent instability. Dissociation of chains along the $\alpha_1\beta_1$ contact generates α - and β -globin chains that uncoil, loosening their heme-globin interaction and favoring methemoglobin formation. Mutations affecting the $\alpha_1\beta_1$ interface tend to be more unstable than those affecting the $\alpha_1\beta_2$ contact. Examples of unstable hemoglobin mutations that are due to decreased $\alpha_1\beta_1$ contact include Hb Philly,³⁰ Hb Peterborough,³¹ and Hb Stanmore.³²

α -Hemoglobin-stabilizing protein (AHSP) binds free α -globin chains, protecting them from precipitation (see Chapter 6). In vitro studies suggest that the impaired interaction of AHSP with α -globin variants when the mutation lies in the molecular sites where AHSP binds α -globin might affect the stability of the variant. In these studies, recombinant Hb Groen Hart (HBA pro119ser), Hb Diamant (HBA pro119leu), and α -globin termination mutants had impaired interactions with AHSP. These observations suggest an additional mechanism for unstable α -globin variants.^{33, 34}

Heinz Body Formation

Heme loss is inhibited by maintaining heme iron in the reduced ferrous (Fe^{2+}) state by the action of methemoglobin reductases and detoxification of oxygen radicals. Therefore, dimerization and the dispersion and precipitation of free heme is minimized. Hemoglobin dimers autoxidize and lose heme more readily than tetramers. Generation of methemoglobin increases the thermostability of hemoglobin, suggesting that the pathways and events accompanying the conversion of ferrous to ferric heme are important for hemoglobin stability.

Heinz bodies are the product of hemoglobin denaturation. First suggested to be heme-depleted globin chains, these inclusions were subsequently identified as hemichromes, derivatives of ferric hemoglobin that have the sixth coordination position occupied by a ligand provided by the globin. Hemichromes are generated when heme is dissociated from the heme pocket and rebinds elsewhere in the globin after the α - or the β -chains have denatured. Irreversible hemichromes are a stage in the formation of Heinz bodies (also see Chapter 6). Membranes prepared from the red cells of patients with Hb Köln (HBB val98met) who have had splenectomies contain aggregates composed of disulfide-linked spectrin, Band 3, globin, and high-molecular-weight complexes composed in part of denatured spectrin.

Red Cell Destruction

Red blood cells containing Heinz bodies have a shortened lifespan. Hemichrome can bind to Band 3 of the erythrocyte membrane. Decreased deformability of the erythrocyte leads to preferential trapping in the spleen, where Heinz bodies are removed. The coincident loss of small amounts of membrane gradually converts discoid cells into spherocytes that are eventually removed from the circulation. Membrane damage might also result from lipid peroxidation and protein cross-linking because of free-radical formation that is a result of Fenton chemistry.

Hyperunstable hemoglobins are an uncommon class of variants in which the mutation, usually in the third exon of the globin gene, leads often to a truncated globin that is barely detectable or is undetectable.^{35, 36} These hemoglobins, presumably synthesized normally, are rapidly destroyed, creating the phenotype of dominantly inherited thalassemia.

P.918

Diagnosis

Patients with unstable hemoglobins may have characteristically dark urine or pigmenturia. This is a result of the presence of dipyrroles that are also present in Heinz bodies. The absence of pigmenturia does not exclude the diagnosis of unstable hemoglobin, and the severity of the hemolysis is unrelated to pigmenturia. For example, carriers of Hb Köln and Hb Zürich

(HBB his63arg) both can have pigmenturia, but hemolysis with Hb Köln can be severe whereas it is usually very mild with Hb Zürich. The P_{50} of unstable hemoglobins is variable and can be normal, low, or high. This is a result of different mutations variously affecting heme-globin interaction, and the tertiary and quaternary structures of the molecule.

Blood Smear

Abnormalities of the blood smear are nonspecific. They can include anisocytosis, basophilic stippling, Howell-Jolly bodies, nucleated red blood cells, and microspherocytes. Fragmented cells appear to have had a "bite" taken from them and are thought to result from the phagocytosis of Heinz bodies during passage of the cell through the spleen. The mean corpuscular hemoglobin concentration may be as low as 25 g/dl because of heme loss or Heinz body formation. Some reported values for reticulocytes may be factitiously high, as inclusion bodies are mistaken for reticulocytes.

Heinz Body Preparation

Heinz bodies in circulating red cells are usually seen only after splenectomy or during an acute hemolytic episode. Under such circumstances, >50% of the cells typically contain one or more large, spherical inclusions. Heinz body detection requires the incubation of erythrocytes with a supravital stain such as new methylene blue or crystal violet. The Heinz bodies appear as single or multiple inclusions of 2 μm in diameter or less and often appear attached to the membrane. Heinz bodies may be found in fresh blood, but usually, incubation for 24 hours without glucose is required for their formation. A normal control should always be run simultaneously.

Hemoglobin Stability Tests

The isopropanol test is a good screening test for unstable hemoglobins, but it can give false-positive results when the sample contains >5% HbF.³⁷ In the heat denaturation test, a hemolysate is incubated for 1 or 2 hours at 50°C, and hemoglobin instability is suggested by the development of a visible precipitate.³⁸ Although the test is simple, the results can vary because of different concentrations of the abnormal variant and different temperatures needed for denaturation. Controls with a normal stable hemolysate must be run simultaneously.

Hemoglobin High-performance Liquid Chromatography

When the mutation is such that heme dissociates from the abnormal globin chain, as in the example of Hb Köln, the partially heme-deficient molecule is susceptible to reversible and irreversible hemichrome formation with subsequent denaturation. Precipitates tend to be pale, and the pattern found during hemoglobin separation is characterized by lack of discrete peaks and multiple diffuse bands when electrophoresis is used, unless stabilized by the addition of hemin. Dipyrroluria is present, suggesting that free heme was converted to dipyrroles rather than bilirubin.

About a quarter of unstable hemoglobins are not detectable by commonly used methods of hemoglobin separation. On HPLC, some unstable hemoglobins such as Hb Köln, Hb Zurich, and Hb Hasharon demonstrate characteristic elution times.

Detection of the Variant Hemoglobin and Mutation Analysis

If clinical and hematologic studies suggest an unstable variant, the determination of the molecular defect becomes the final step in diagnosis. DNA analysis is the ultimate approach to defining the globin mutation. New mutations are common, so a family history need not be present.

Clinical Features

The presence of an unstable hemoglobin should always be considered when hemolytic anemia is present and its cause is not clearly defined. Chronic hemolysis as a result of unstable hemoglobins can be associated with all of the known complications of hemolysis, including aplastic crisis, jaundice with cholelithiasis, leg ulcers, splenomegaly, and hypersplenism and pulmonary hypertension.³⁹ A special feature of unstable hemoglobins is pigmenturia. Similar to glucose-6-phosphate dehydrogenase (G6PD) deficiency, increased hemolysis often is associated with fever, infections, and ingestion of certain drugs (see Chapter 28). Dusky cyanosis has been described in some patients with unstable hemoglobins predisposed to methemoglobin formation. In one case in which the γ -globin chain of HbF was affected (HbF-Poole; HBG2 trp130gly), hemolytic anemia was present in the newborn but disappeared as the γ - to β -globin switch was completed.⁴⁰ Sometimes the disease is seen in early childhood; it can be found in adults incidentally, or when fever or drug treatment induces hemolysis.

Many unstable hemoglobin variants produce mild hemolytic disease with minimal or no anemia. In the steady state, reticulocyte counts range between 4% and 10%. Splenomegaly may be present. Most patients with mild disease are first seen during a hemolytic crisis induced by drugs or infection. More than one half of the unstable variants are associated with no hematologic abnormality and are detected through screening programs (<http://globin.cse.psu.edu>).

Just as in all other chronic hemolytic anemias, B19 parvovirus infection can temporarily shut down erythropoiesis, rapidly worsening the anemia and resulting in an aplastic crisis. Anemia may also increase during infection and after treatment with oxidant drugs such as sulfonamides. The intensity of hemolysis is variable and is dependent on the mutation and fraction of abnormal hemoglobin present.

Hb Köln, described in multiple kindreds, is the most common unstable hemoglobin and is characterized by anemia, reticulocytosis, splenomegaly, and 10% to 25% Hb Köln.⁴¹ It is not associated with oxidant-drug-induced hemolysis. The independent occurrence of this variant in so many apparently unrelated individuals suggests that the Hb Köln mutation, located at a methylated CpG dinucleotide sequence of the β -globin gene, can act as a "hotspot" for mutation through the deamination of the methylcytosine nucleotide to form thymine.

Hb Zürich has also been reported on multiple occasions.⁴² This variant, forming ~25% of the hemolysate, is accompanied by mild anemia exacerbated by oxidant drugs, pigmenturia, and, as discussed previously, an increased affinity for CO. The latter protects the β -globin heme group from oxidation and increased instability. Carriers have a special susceptibility to sulfonamide-induced hemolytic crisis. Investigation of the basis for variation in drug-related hemolysis of family members with Hb Zürich disease suggested that tobacco smoking ameliorated hemolysis, probably because the high affinity of Hb Zürich for CO stabilized the hemoglobin tetramer.^{43, 44}

Hb Hasharon (HBA2 asp47his) is another more common variant affecting the α -globin chain, found in Ashkenazi Jews and P.919

causing hemolysis in newborns but not in most adults.^{45, 46} This variant comprises 15% to 20% of the hemolysate, and inclusion bodies are not found.

Some unstable hemoglobins are linked to α - or β -thalassemia genes: the α -chain mutants Hb Suan-Dok (HBA2 leu109arg) and Hb Petah Tikva (HBA ala110asp) coexist in cis with α -thalassemia and some β -chain mutants such as Hb Leiden (HBB glu6 or 7del), Hb Duarte (HBB ala62pro), and HbG-Ferrara (HBB asn57lys) coexist with a β^0 -thalassemia mutation in trans.

Pulmonary Hypertension

Altered nitric oxide (NO) bioavailability has become recognized as a common occurrence in hemolytic anemia and might account for a commonality of clinical findings in what are very different pathophysiologic entities.^{47, 48} Because a variable fraction of hemolysis occurs within the vasculature, heme and arginase released from the erythrocyte into blood consume NO and deplete supplies of arginine, the substrate of the NO synthases. Pulmonary hypertension and priapism, common complications of hemolytic anemia, have been described in patients with unstable hemoglobins.^{49, 50}

Miscellaneous

In a case of hemolytic anemia resulting from Hb Bristol-Alesha (HBB val68met), moyamoya and transient ischemic attacks occurred in a 10-year-old girl.⁵¹ The authors suggested that chronic hypoxemia may be the cause of occlusive moyamoya in unstable hemoglobinopathies or in hemoglobins with altered oxygen affinity.

Hyperunstable Hemoglobin

Some uncommon globin mutations are hyperunstable. Although these mutants are synthesized in normal amounts, they are unable to form stable tetramers or even dimers and are rapidly catabolized. These variants therefore have features of both unstable hemoglobins and thalassemias, and they have been called thalassemic hemoglobinopathies. The phenotype is that of severe, dominantly inherited β -thalassemia rather than unstable hemoglobin disease, because the affected globin chain fails to accumulate and participate in tetramer formation. In the first recognized example of this phenotype, three generations of a family had a dominantly transmitted hemolytic anemia with splenomegaly, gross abnormalities of the erythrocytes, dyserythropoiesis, and large inclusion bodies in bone marrow erythroblasts and in nucleated red cells of the peripheral blood.^{35, 36}

Dominantly inherited β -thalassemias (sometimes the α -globin chain is similarly affected) have been identified in many ethnic groups and are caused by missense mutations, deletions or insertions of intact codons, single-base substitutions leading to premature termination of translation (nonsense mutations), and mutations causing frameshifts or aberrant splicing. Most of the mutations are in exon 3 of the affected gene, and this location might permit globin mRNA to escape nonsense-mediated decay and allow enough denatured protein, along with the uninvolved globin chain, to accumulate and damage the developing erythroblast.

Treatment

Unstable hemoglobinopathies are generally mild disorders and do not require therapy except supportive and preventive measures. As with other hemolytic anemias, Parvovirus B19 infections can cause the development of severe acute anemia. Administration of folic acid to prevent megaloblastic arrest of erythropoiesis might be warranted, although access to a nutritious diet is probably satisfactory. The possibility of fever-associated hemolysis should be recognized, and avoidance of oxidant drugs, including acetaminophen and sulfonamides, are other management considerations. Chronic hemolysis is associated with a high incidence of cholelithiasis.

Severe hemolysis raises the question of splenectomy because the spleen undoubtedly plays an important pathophysiologic role in the destruction of Heinz-body-containing red cells. As in other chronic hemolytic anemias, the decision to perform a splenectomy must be balanced with the role of the spleen as a defense against pneumococcal infections early in life and the need for antipneumococcal vaccines and prophylactic penicillin in cases where splenectomy is performed in childhood. On balance, splenectomy might be beneficial for individuals with severe unstable hemoglobinopathies, and partial correction of the anemia is sometimes achieved. Nevertheless, predicting the response to splenectomy is difficult. Hydroxyurea has been used to stimulate HbF production and help repair anemia in two cases of unstable hemoglobin disease.⁵²

M HEMOGLOBINS

The M (met) hemoglobins are characterized by heme-iron oxidation. Heme iron is more stable in the ferric than the ferrous state. Erythrocyte methemoglobin reductive capacity cannot effectively compensate for this instability of ferrous heme. The major clinical feature of these disorders is cyanosis. They are not noted for clinical severity. The misdiagnosis of other causes of cyanosis and unneeded treatment are the major hazards of these rare variants.

Pathophysiology

In the M hemoglobins, the mutant globin chain creates an abnormal microenvironment for the heme iron, displacing the equilibrium toward the oxidized or ferric (Fe³⁺) state. A combination of Fe³⁺ and its abnormal coordination with the substituted amino acid generates a visible spectrum that resembles, but is clearly different from, methemoglobin that is not due to a globin gene mutation, in which the heme iron is oxidized but there is no associated amino acid substitution.

In the Iwate prefecture of Japan, “black children” had been observed for more than 160 years, and this was associated with a brownish-colored hemoglobin in the hemolysate of a patient that was eventually characterized as HbM Iwate (HBA his87tyr).⁵³ Six β-, two α-, and two γ-globin HbM variants have been reported. In five of the eight described HbM variants, the mutation involves the substitution of the distal (E7) or proximal (F8) histidine interacting with the heme iron via tyrosine (<http://globin.cse.psu.edu>). With HbM Milwaukee (HBB val67glu), the longer side chain of the glutamic acid residue can reach and perturb the heme iron. In two novel variants that form methemoglobin, an amino acid deletion was suspected to alter the orientations of the distal and proximal histidine residues.⁵⁴ Properties of some M hemoglobins are shown in Table 35.3. The strength of attachment of ferric heme to globins differs among M hemoglobins.

HbM Milwaukee is an example of an M hemoglobin that is not caused by mutation of the proximal or distal histidine residues, but by the nearby β67 (E11) val (<http://globin.cse.psu.edu>). When this residue is replaced by a glutaminy residue, it perturbs the heme iron and generates an M hemoglobin. Of interest, other mutations of that site, such as Hb Bristol (val67asp) or Hb Sidney (val67ala), are unstable or have low affinity but do not lead to heme-iron oxidation. X-ray crystallography shows that the carboxylic group of the new glutaminy residue in Hb Milwaukee occupies the sixth coordination position of the iron, and that the proximal histidine maintains its role as the tenant of the fifth coordinating position, stabilizing the abnormal ferric state of HbM Milwaukee.

P.920

TABLE 35.3 HEMATOLOGIC FEATURES OF SOME HβM VARIANTS OF THE α- AND β-GLOBIN GENES

Variant	PercentHb (g/dl)	Reticulocytes (%)	P₅₀	Bohr Effect
HbM Hyde Park (Milwaukee-2)(β)	23-32	10-13	4-6	Normal Present

HbM Chile (β)	17	13.2	1.2	—	—

Oxygen-binding Properties and the R \rightarrow T Transition of M Hemoglobins

HbM Milwaukee, HbM Hyde Park (HBB his92tyr), and HbM Boston (HBA his58tyr) all adopt deoxy or deoxylike conformation upon the deoxygenation of the two normal chains, although the abnormal chains cannot off-load oxygen. This, and crystallographic, electron paramagnetic resonance, and nuclear magnetic resonance (NMR) spectroscopy, and 2,3-DPG-binding studies affirm that after two heme groups become deoxygenated, the entire molecule adopts the deoxy T conformation.

With HbM Milwaukee, Hb M Saskatoon (HBB his63tyr), and HbM Hyde Park, a normal Bohr effect and P_{50} strongly suggest that the hemoglobin adopts the R state when the two normal chains are oxygenated. NMR studies of HbM Milwaukee support the notion that the conformational changes take place when the normal heme groups are oxygenated. In contrast, HbM Iwate is in the crystallographic T configuration when its normal heme groups are in the ferric state, explaining its decreased oxygen affinity; the molecule does not shift to the R state when the normal heme groups are liganded and remains in the low-affinity T state. A similar situation probably exists in HbM Boston, as the habit of the deoxy crystal remains intact after oxygenation, suggesting that no conformational change has occurred that would require a different crystal structure.

HbM Saskatoon and HbM Boston have different properties despite the common substitution of the distal histidine. This occurs because HbM Saskatoon does not change its conformation when oxygenated, whereas the latter variant does. Why properties of the β -globin chains differ from those of the α -globin chain when their distal histidine is substituted is unresolved.

Iron Oxidation and Spectral Characteristics

In M hemoglobins, the affected heme groups are stabilized in the ferric state and have an abnormal microenvironment. They exhibit an abnormal visible absorption spectrum that is easily distinguished from methemoglobin. This characteristic separates these variants from some unstable hemoglobin mutants that also have a tendency to form methemoglobin.

Heme iron in the abnormal subunits of the M hemoglobin exhibit abnormally low redox potential. They are oxidized more rapidly by molecular oxygen and are resistant, to a variable degree, to reduction by dithionite. Differences also exist in the rate of reduction of the five M hemoglobins with NADH-cytochrome b_5 reductase (CYB5R3). HbM Iwate, HbM Hyde Park, and HbM Boston are not reduced at all, whereas HbM Milwaukee is reduced slowly and HbM Saskatoon is reduced normally by this reductase. These last two variants might be less oxidized in vivo than expected. Full ferric conversion might occur only in vitro, because of the high autoxidation rate of these abnormal hemoglobins. Older red cells might, nevertheless, have fully oxidized abnormal chains consistent with the presence of clinically apparent cyanosis.

Clinical Features and Diagnosis

Clinically, the skin and mucous membranes of HbM carriers have an appearance similar to, but not identical with, cyanosis, sometimes called pseudocyanosis. Pseudocyanosis is not associated with dyspnea or clubbing. Skin and mucosal surfaces are brownish/slate-colored, more like methemoglobinemia, but not as slate blue-purple as true cyanosis. This distinction is subtle and might not be apparent without comparing the two conditions at the same time. Skin reflects hemoglobin molecules with an abnormal ferric heme and abnormal spectrum, whereas cyanosis is caused by the presence of more than 5 g/dl of deoxyhemoglobin. Pseudocyanosis is present from birth in α -globin-chain abnormalities and from the middle of the first year of life in the β -chain mutants. The γ -globin gene HbM variants, HbF-M Osaka (HBG2 his63tyr) and HbF-M Fort Ripley (HBG his92tyr), have been associated with neonatal "cyanosis" that disappears as γ -globin-chain synthesis wanes.^{55, 56} A mixture of the abnormal pigment and true cyanosis, resulting from hemoglobin desaturation of the normal chains, is observed in the low-oxygen-affinity HbM Boston and HbM Hb Iwate.

A mild hemolytic anemia and reticulocytosis have been observed in HbM Hyde Park and can be explained by the instability of the hemoglobin induced by partial heme loss.

HbM should be considered in all patients with abnormal homogeneous coloration of the skin and mucosa, particularly if pulmonary and cardiac functions are normal. The diagnosis can be suspected by observing an abnormal brown coloration of the blood in a tube. To distinguish this coloration from methemoglobin, the addition of KCN to the hemolysate is useful. KCN will turn blood containing methemoglobin red but has little if any effect on HbM-containing hemolysates. Lack of color conversion with KCN is diagnostic of HbM.

A spectrophotometric recording of the visible spectrum of the hemolysate is critical for the diagnosis, and the mutation is confirmed by DNA analysis. M hemoglobins do not have an absorbance peak at 630 to 635 nm which is typical of methemoglobin. In the presence of HbM, accurate measurement of oxygen saturation and CO hemoglobin is difficult with most instruments. Absorption maxima at different wavelengths of all hemoglobin M variants have been reported.

Treatment

Treatment for individuals with HbM is neither necessary nor possible. A correct diagnosis is most important, because this will forestall therapeutic and diagnostic misadventures.

P.921

METHEMOGLOBINEMIA UNRELATED TO GLOBIN GENE MUTATIONS

Normally, small amounts of hemoglobin are continually being oxidized by endogenous agents, including oxygen itself (autooxidation). When oxygen reacts with deoxygenated hemoglobin to produce oxyhemoglobin, one electron from heme-iron (Fe^{2+}) is transferred to the bound oxygen, thereby forming a ferric-superoxide anion complex ($\text{Fe}^{3+}\text{-O}_2^-$). Subsequently, when hemoglobin is deoxygenated, most oxygen is released as O_2 , but a small amount leaves as superoxide anion (O_2^-). The partially transferred electron is not returned to iron, leaving the heme-iron as Fe^{3+} (methemoglobin). Increased temperature and low pH promote auto-oxidation.⁶ Usually, methemoglobin levels are <1% of the total hemoglobin, because erythrocytes contain cytochrome b5 reductase that catalyzes its reduction (see Chapter 6). Genetically determined methemoglobinemia, unrelated to globin gene mutations, occurs in individuals with hereditary deficiency of cytochrome b5 reductase. Acquired methemoglobinemia occurs in normal individuals exposed to drugs and chemicals that oxidize hemoglobin iron at a rate that exceeds the capacity for enzymatic reduction.

Cyanosis

Cyanosis most often is due to cardiac or pulmonary disease, but genetic and acquired disorders of hemoglobin can result in significant arterial desaturation. In the M hemoglobins and with sulfhemoglobin and methemoglobin, the altered visible spectrum of the abnormal pigments is responsible for the brownish/slate skin color. The spectral properties of sulfhemoglobin versus methemoglobin are such that patients can be markedly "cyanotic," with 0.5 g/dl of sulfhemoglobin; 1.5 g/dl of methemoglobin is required to produce "cyanosis"; true cyanosis requires 10 times this concentration of deoxyhemoglobin.

Although dyspnea is not a feature of M hemoglobins, it can be present even with relatively low levels of methemoglobinemia. Because the altered hemes in HbM, sulfhemoglobin, and methemoglobin do not transport oxygen, affected individuals with all three conditions may have normal hemoglobin concentrations but are functionally anemic, simply because of insufficient operational heme groups. This effect is clinically significant only in extreme cases of methemoglobinemia and sulfhemoglobinemia or when the overall hemoglobin level is low. With HbM, the proportion of normal to abnormal heme is genetically determined and fixed, so that decreased oxygen delivery is problematical only when superimposed on underlying anemia.

The clinical effects of nonfunctional heme groups are not limited to an inability to transport oxygen. Small amounts of nonfunctional heme can have clinical significance if their presence produces a physiologically dysfunctional shift in the oxygenation of neighboring unmodified subunits. This is the molecular basis of the left-shifted oxygenation curve, the impaired oxygen delivery to the tissues, and the resulting respiratory distress seen in relatively mild degrees of methemoglobinemia. This phenomenon, called the Darling-Roughton effect, occurs as oxidized subunits in partially oxidized tetramers are held in an R-like conformation, increasing the oxygen affinity of the remaining subunits. Although mixed venous blood is unusually saturated, the abnormal spectrum of the methemoglobin dominates this effect, causing cyanosis. An analogous left shift in the oxygenation curve, but to a more pronounced degree, is present with CO poisoning and impaired oxygen delivery exacerbates dyspnea.

Cytochrome b5 Reductase Deficiency

Mutations of the cytochrome b5 reductase 3 gene (CYB5R3; 22q13) cause decreased activity of the soluble form of this erythrocyte enzyme and hereditary methemoglobinemia. CYB5R3 is a transferase that facilitates electron transfer from NADH to cytochrome b5, which then directly reduces methemoglobin. A second erythrocyte enzyme is NADPH-methemoglobin reductase, which by itself is unable to reduce methemoglobin effectively, and individuals lacking this

enzyme do not have methemoglobinemia. However, in the presence of redox compounds such as methylene blue, NADPH methemoglobin reductase rapidly reduces methemoglobin. Thus this agent is useful in treating methemoglobinemia.

Cytochrome b5 reductase enzyme deficiency is a recessive trait, and only homozygotes or individuals who are compound heterozygotes for two different gene mutations express the disease. Of interest, however, heterozygotes can be at risk for acquired methemoglobinemia when exposed to oxidant drugs.^{57, 58} Two forms of cytochrome b5 reductase deficiency are recognized, types I and II.

Type I deficiency is limited to erythrocytes and is manifested by methemoglobinemia only. Patients are more cyanotic than sick, in the worst cases complaining of fatigue with strenuous exercise. They have normal survival and have normal pregnancies. Methemoglobin levels vary from 20% to 40%. When exposed to methemoglobin-inducing drugs or chemicals, these patients are at risk for developing further methemoglobinemia symptoms. Enzymatic activity of the NADH-dependent methemoglobin reductase system is reduced in the erythrocyte.

Type II deficiency is a generalized form cytochrome b5 reductase deficiency, affecting 10% to 15% of patients. It is a severe and lethal disease, with a strong neurologic component. Although the methemoglobinemia can be treated, the neurologic syndrome is refractory. The disease is secondary to homozygosity or compound heterozygosity for defective cytochrome b5 reductase in all tissues.

At least 33 mutations of CYB5R3 have been associated with methemoglobinemia.⁶² Seventeen exon mutations were associated with type 1 disease, 15 with type II, and 1 with both types of disease. Missense, nonsense, deletions, and other classes of mutation have been described.

A high incidence of hereditary methemoglobinemia is found among Alaskan Eskimos, Northwest Indians, Navajo Indians, and natives of Yakusk, Siberia, groups that might have common ancestry. In one report from Alaska, the gene frequency was 0.07, but these results were based on enzyme assay and not detection of the gene. Cytochrome b5 reductase deficiency has also been observed sporadically among Puerto Ricans and in Mediterranean populations.

Acquired (Toxic) Methemoglobinemia

Many chemical agents and drugs can induce methemoglobinemia in normal people (Table 35.4). Dapsone- and primaquine-induced methemoglobinemia, at levels of 15% to 33%, have been reported in human immunodeficiency virus (HIV)-infected patients. Nitrites also are common offenders, and recreational use of amyl, butyl, or isobutyl nitrites is a cause of acquired methemoglobinemia. Infections that release toxins (including nitrites) can produce methemoglobin. Aniline dyes and aniline reduce molecular oxygen and generate methemoglobin. Phenylhydroxylamine, after reducing oxyhemoglobin, can generate nitrosobenzene, which is reduced again to phenylhydroxylamine by red cell enzymes. The cycle can then, in turn, generate more methemoglobin. Henna, a natural product used worldwide as a hair dye and to stain skin and nails, contains a chemical, 2-hydroxy-1,4-naphthoquinone, that can increase methemoglobin production, especially in G6PD-deficient individuals. Use of benzocaine as a topical anesthetic is often associated with methemoglobinemia. Certain medications used to treat diaper rash that contain benzocaine and resorcinol have been reported to produce methemoglobin levels as high as 35%.^{57, 58, 59, 60, 61, 62, 63, 64}

Acetaminophen/phenacetin

Newborn infants are at increased risk for methemoglobinemia because of a transient decrease in NADH cytochrome reductase activity during the neonatal period; normal adult enzyme activity is present by 3 to 4 months of age. Infantile methemoglobinemia has occurred in association with nitrate contamination of the water supply.⁶⁰ Children with septic shock also can have methemoglobinemia, presumably because of increased circulating nitrite/nitrate levels. In children with *Plasmodium falciparum* malaria, mean methemoglobin levels are increased, and this is related to disease and anemia severity.⁶¹ Because malaria itself produces hypoxia, the additional reduction in oxygen-carrying capacity because of the presence of methemoglobinemia might be particularly critical for the subgroup of patients who are anemic or acidotic.

Diagnosis

The possibility of acquired methemoglobinemia should be considered in anyone with recent or sudden apparent cyanosis who is unresponsive to 100% oxygen and without cardiopulmonary pathology. Sulfhemoglobinemia (see later) should also be considered in these cases. Acquired methemoglobinemia is not rare; it is much more common than any of the genetic causes of methemoglobinemia. In a retrospective study of acquired methemoglobinemia (methemoglobin level >2%), 138 cases were encountered over a period of 28 months.⁶⁴ Patients' ages ranged from 4 days to 86 years, and there was one fatality and three near-fatalities. Dapsone was the most common etiology of acquired methemoglobinemia, accounting for 42% of all cases. The mean peak methemoglobin level among these individuals was 7.6%. In five of the patients with the most severely elevated levels, 20% benzocaine spray was the causative agent and was associated with a mean peak methemoglobin level of 44%. Eleven pediatric patients developed methemoglobinemia either from exogenous exposure, such as drugs, or because of serious illness, such as gastrointestinal infections with dehydration. Ninety-four percent of patients with methemoglobinemia were anemic.

Long-standing symptoms, or symptoms in siblings, is suggestive of a hereditary methemoglobinemia. Because the enzyme deficiency is inherited as a recessive trait, clinical disease is not expected in the parents. The differential diagnosis includes the HbM variants and low-oxygen-affinity hemoglobins. Because of the "dominance" of the HbM genes, one parent often has the same symptoms.

The diagnosis of cytochrome b5 reductase deficiency is made by direct assay of the enzyme. Genetic ascertainment is available for the known mutations. Pre-natal diagnosis is available for type II congenital methemoglobinemia.

Treatment

Acquired methemoglobin is treated by stopping the offending agent once it is identified. Direct drug intervention with intravenous methylene blue is indicated in patients with 40% to 60% methemoglobin, particularly when symptoms are present. Methemoglobin levels of 70% can be fatal. The usual dose of methylene blue is 1 to 2 mg/kg, and the maximum dose is 7 mg/kg. It can be given intravenously in acute methemoglobinemia. For intravenous administration, it should be given slowly over 35 minutes to avoid high concentrations and paradoxical methemoglobin production. Rapid

improvement in cyanosis and normalization of methemoglobin level usually occurs 30 to 60 minutes after methylene blue injection. If there is coexistent G6PD deficiency, methylene blue is not effective, because of the lack of NADPH production, and its use may result in hemolysis. A transient drop of pulse oximeter arterial oxygen saturation can be seen following methylene blue injection, a result of interference by methylene blue with the light-wave emission of the pulse oximeter. Methemoglobin levels can increase again following successful treatment.⁶⁵ In type I cytochrome b5 reductase deficiency, treatment is mainly for cosmetic purposes. Oral methylene blue, 100 to 300 mg daily, can maintain methemoglobin levels of 5% to 10%. Ascorbic acid, 200 to 500 mg daily, also can reverse cyanosis in patients with type I methemoglobinemia.

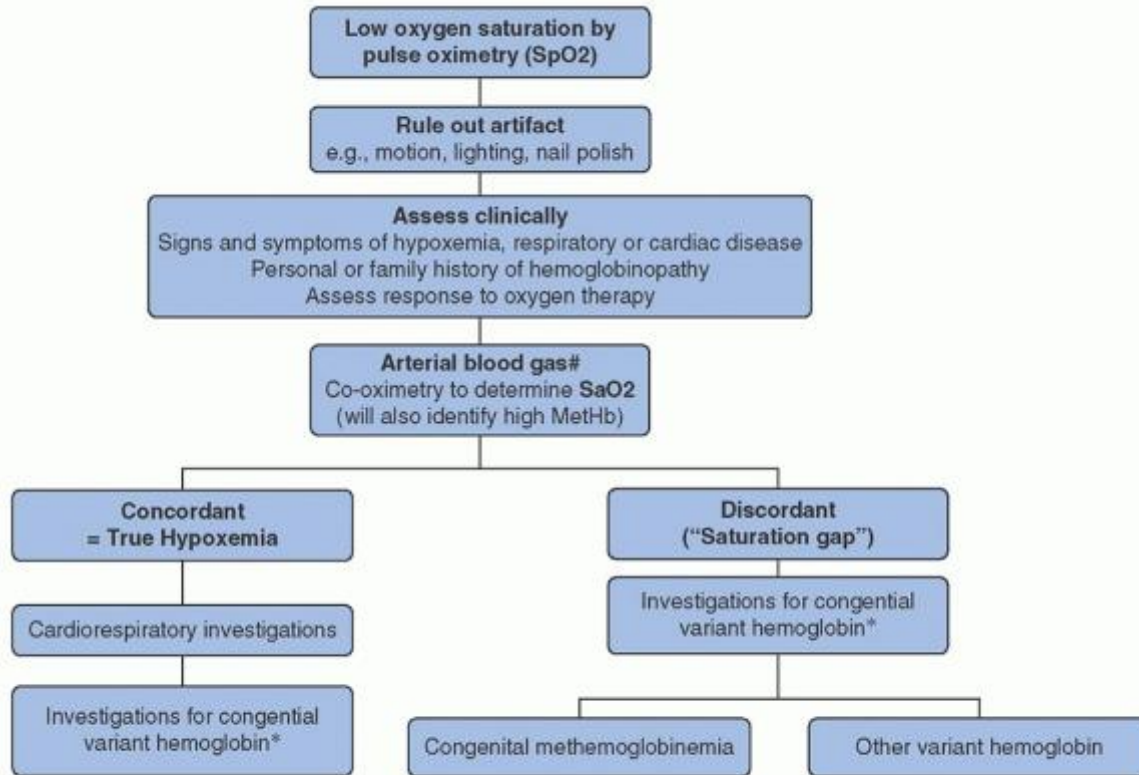

In aniline-induced methemoglobinemia, methylene blue can couple with oxyhemoglobin to generate free radicals and has sometimes produced hemolysis. In these cases, dosing should be limited.

Automated red blood cell exchange has been used successfully when methylene blue is ineffective and may be superior to manual exchange transfusion.⁶⁶

PULSE OXIMETRY

Virtually all of the classes of hemoglobin variants and methemoglobinemia discussed above have been associated with unexpected low oxygen saturations when this is measured by pulse oximetry. Some low-oxygen-affinity variants have both a low pulse oximeter measured oxygen saturation and a low arterial oxygen saturation although the arterial oxygen pressure was normal.^{67, 68, 69, 70} These anomalies are due to the altered absorption spectrum of the hemoglobin variant that confounds the settings of the pulse oximeter which uses set wavelengths of light to calculate oxygen saturation. Attention should be paid to measurement of blood oxygen saturation when any hemoglobin variant is present. Blood oxygen saturation can be measured using an arterial blood gas analyzer, by pulse oximetry, or by using a CO-oximeter. The first method measures blood partial pressure of dissolved oxygen and provides the PaO₂ and SaO₂. The convenient pulse oximeter provides a transcutaneous measure of absorbance at two wavelengths (660 and 940 nm) but is inaccurate when dyshemoglobins, such as methemoglobin (hemoglobin with oxidized [Fe³⁺] heme iron), carboxyhemoglobin, and sulfhemoglobin, are present. CO-oximetry, the most accurate of all the methods, can be inaccurate in cases of M hemoglobins.

P.923

* Evaluation for variant hemoglobins are discussed in Chapters 33–35.

FIGURE 35.1. An algorithm for evaluation of low SpO₂. Arterial blood gas should be done on room air and with simultaneous SpO₂ measurement. (Redrawn from Ref. 70.)

Oxygen saturation calculated from pH and PO₂ should be interpreted with caution, because the algorithms used assume normal hemoglobin oxygen affinity, normal 2,3-DPG concentrations, and no dyshemoglobins such as methemoglobin or hemoglobinopathies. CO-oximeter reports should include the dyshemoglobin fractions in addition to the oxyhemoglobin fraction. In cases of increased methemoglobin fraction, pulse oximeter values trend toward 85%, underestimating the actual oxygen saturation. Hemoglobin M variants may yield normal methemoglobin levels and increased carboxyhemoglobin or sulfhemoglobin fractions measured by CO-oximetry.

In a systematic review, 25 publications and 4 unpublished reports representing 45 patients with low SpO₂ and a confirmed variant hemoglobin were identified.⁷⁰ Fifty-seven family members of patients had a confirmed or suspected variant hemoglobin. Three low-oxygen-affinity variant hemoglobins had concordantly low SpO₂ and SaO₂. Eleven variant hemoglobins were associated with unexpectedly low SpO₂ measurements but normal SaO₂. Most variant hemoglobins were associated with spuriously low SpO₂. The differential diagnosis of possible variant hemoglobin should be considered in asymptomatic patients found to have unexpectedly low SpO₂. Otherwise these patients might be subjected to unneeded extensive cardiopulmonary investigations in search of the cause of their “hypoxemia.” A approach to the evaluation of low oxygen saturation is shown in Figure 35.1.

DYSHEMOGLOBINEMIAS: CARBOXY-, SULF-, AND NITROSOHEMOGLOBINS

CO and NO are present in normal red cells in very low concentrations, and both can bind to hemoglobin to form carboxyhemoglobin (CO hemoglobin) and nitrosohemoglobin (NO hemoglobin), respectively. Carboxyhemoglobin avidly binds oxygen and cannot release it to the tissues. Nitrosohemoglobin may have critical physiologic functions. In addition to these normally occurring liganded hemoglobins, sulfur compounds can bind to the pyrrole ring of heme, forming a thiochlorin, referred to as sulfhemoglobin (see Chapter 6). Mutations or environmental conditions can increase the concentrations of all these liganded or oxidized hemoglobins, thereby producing dyshemoglobinemias. Sometimes, increased levels of dyshemoglobins are life-threatening, and because effective treatments are available, their presence should be identified promptly.

Carbon Monoxide Poisoning: Carboxyhemoglobinemia

CO, a toxic gas, is odorless, colorless, and tasteless, has a low solubility in water, and is relatively inert. It combines with hemoglobin heme with high affinity and with lesser affinities to myoglobin and cytochrome heme. Under physiologic conditions, its affinity for hemoglobin is ~240 times greater than that of oxygen. Once CO is bound to heme, its "off" rate is very slow, producing a very high affinity constant of CO for heme and a life-threatening danger for organisms exposed to high levels of CO.

Further endangering those exposed to CO, once two molecules of CO are bound to hemoglobin, the molecule switches to the R state, and the two globin chains that can bind oxygen will be in their high-affinity conformation. This high ligand affinity makes the delivery of oxygen to the tissues by the remaining oxygen-binding sites more difficult (Darling-Roughton effect). Consequently, the oxygen equilibrium curve of blood is shifted to the left with increasing CO levels.

In the absence of increased environmental CO, the blood of adults contains ~1% to 2% CO hemoglobin. This endogenous CO is derived from heme catabolism, specifically, the first enzymatic reaction catalyzed by heme oxygenase (see Chapter 6). Caloric restriction, dehydration, and Japanese

P.924

and Amerindians seem to generate higher endogenous levels of CO. Hemolytic anemia, hematomas, and infection tend to increase CO production up to threefold. Fetuses and newborns have double the normal adult levels of CO hemoglobin, and this increases further in the presence of neonatal hemolysis. Exogenous sources of CO include atmospheric CO, which is a product of incomplete combustion and oxidation of hydrocarbons, and natural sources.

The most commonly used instrument for the detection and quantification of carboxyhemoglobins is the CO-oximeter, which also provides the levels of oxy-, deoxy-, and methemoglobin.

Chronic CO Intoxication

It has been estimated that CO intoxication is responsible for upward of 50,000 emergency room visits yearly.⁷¹ Symptoms of CO hemoglobinemia can include irritability, nausea, lethargy, headache, and sometimes a flulike condition. A study of more than 1,000 CO-poisoned patients suggested that symptoms might not correlate well with blood levels of CO hemoglobin.⁷² Higher CO hemoglobin levels produce somnolence, palpitations, cardiomegaly, and hypertension, and might contribute to atherosclerosis. Long-term neuropsychological symptoms can persist and even be permanent.⁷¹ Chronic CO poisoning can produce erythrocytosis, the magnitude of which varies with the level of CO hemoglobin. By increasing red cell production, chronic CO poisoning can mask the mild anemia of thalassemia trait or other acquired or genetic hemolytic disorders.

The most frequent exogenous source of CO is cigarette smoking, which can increase carboxyhemoglobin to 15%. Waterpipes have also been associated with CO hemoglobinemia. Pregnant women, fetuses, neonates, and infants are particularly susceptible to CO poisoning from smoking. Because CO hemoglobin increases hemoglobin-O₂ affinity, this may cause erythrocytosis, especially in smokers. The second most common cause of chronic CO exposure is defective heating exhaust systems and vehicles that leak CO into the passenger compartment. Occupational exposure is seen in garage workers, toll booth attendants, tunnel workers and other situations and occupations with poor ventilation, firefighters, and workers with industrial exposure.

Acute CO Intoxication

Carboxyhemoglobin levels >20% are usually required before symptoms appear. Accidental exposures to high environmental levels of CO or suicide attempts by deliberate exposure to a CO source are the most frequent causes of acute poisoning in the United States, responsible for ~4,000 adult deaths a year. Acute CO intoxication in children is responsible for ~400 deaths a year, is more severe, and sometimes has unique symptomatology. Children are more likely to have severe sequelae such as leukoencephalopathy, white-matter destruction, and severe myocardial ischemia. Carboxyhemoglobinemia has been associated with high doses of sodium nitroprusside in children, with levels of 5.5% to 7.7%.⁷³ The mechanism is unclear but is hypothesized to be the induction of heme oxygenase, the first enzyme in heme catabolism that generates CO.⁷⁴

CO rapidly affects the central and peripheral nervous system and cardiopulmonary functions. Cerebral edema is common, as are alterations of sensory and peripheral nerve function. CO induces increased permeability in the lung, resulting in acute pulmonary edema. Cardiac arrhythmia, generalized hypoxemia, and respiratory failure are the common causes of CO-related death. Carboxyhemoglobin levels >40% are present in these cases. In survivors, considerable neurologic deficits may remain.

Less severe acute cases present with the same types of symptoms as patients with chronic intoxication. Arrhythmias, myocardial ischemia, lactic acidosis, convulsions, and coma also can occur. An interesting complication observed several days after the exposure to CO are patches of necrotic skin induced by localized hypoxia. The levels of carboxyhemoglobin that can elicit any of these symptoms vary widely among patients.

Treatment

Treatment of chronic exposure is principally rapid removal of the patient from the source of environmental CO and if needed, breathing 100% O₂ will increase the rate of CO removal. Hyperbaric oxygen, whose efficacy is unproven,^{71, 74} perhaps because of the almost inevitable delay in its institution, should be reserved for exceptional cases of CO intoxication.⁷⁴ In acute exposure, after identification and removal of the source of CO, 100% O₂ should be administered.

Sulfhemoglobinemia

Sulfhemoglobin is a green-pigmented protein with a sulfur atom incorporated into the heme ring. It is first suspected in a cyanotic patient with near-normal oxygen tension who is felt to have methemoglobinemia but does not respond to therapy with methylene blue. Although it shares a similar absorption peak with methemoglobin, the absorption peak of methemoglobin, unlike that of sulfhemoglobin, is abolished by cyanide. At low concentrations, sulfurated tetramers are shifted toward the deoxy or T form, producing a right shift of the oxygen equilibrium curve. This shift in the hemoglobin-oxygen dissociation curve reduces the likelihood of dyspnea unless the concentrations of sulfhemoglobin are exceptionally high.

Sulfhemoglobin has been associated with the use of certain "oxidant" medications, although mostly when used in doses higher than recommended, during drug abuse, with occupational exposure to sulfur compounds and with exposure to polluted air.⁷⁵ Sulfhemoglobin and methemoglobin have been reported to coexist in some cases of drug-induced hemoglobinopathy, and chemicals and drugs reported to produce these syndromes are similar. Congenital sulfhemoglobinemia is rare and has been described with an unstable hemoglobin. It is likely, that, because of drug-related and industrial exposure to sulfur, this condition is underdiagnosed. For equivalent amounts of abnormal pigment, the patient with sulfhemoglobinemia appears bluer than the patient with methemoglobinemia, and concentrations of 0.5 g/dl can produce cyanosis. These individuals are less symptomatic than those with methemoglobinemia, as cyanosis occurs at a sulfhemoglobin concentration 10 times lower than the methemoglobin level needed to cause cyanosis. Treatment is rarely required in addition to withdrawal from the putative offending agent. Exchange transfusion is the sole therapeutic option for symptomatic cases.

Nitrosohemoglobins

NO is generated from L-arginine by nitric oxide synthases (see Chapter 6). NO diffuses out of the originating cells and into nearby target cells, where it binds the heme groups of enzymes and hemoglobin. The reaction of free NO with erythrocytes is diffusion-limited. It has been proposed that S-nitrosylhemoglobin is formed in the lungs, whereas in tissues NO is liberated from hemoglobin leading to vasodilation. It is hypothesized that by sensing the physiologic oxygen gradient in tissues, hemoglobin exploits conformation-associated changes in the position of β93 cys to bring local blood flow into line with oxygen requirements.^{76, 77, 78, 79, 80, 81} This hypothesis is controversial, however, and there is little direct evidence that NO is liberated from the β93 cys site as hemoglobin assumes the T state.

Chapter 36

Megaloblastic Anemias: Disorders of Impaired Dna Synthesis

Ralph Carmel

HISTORICAL BACKGROUND

The story of megaloblastic anemia, its causes, and how they were decoded is a wonderfully instructive chapter of medicine. Clinical observations set the stage for a series of insightful clinical investigations that converted a dreaded “pernicious” condition into one that is now easily treated.

A puzzling illness with anemia, debilitation, languor, and, finally, torpor and death was described by Addison¹ in 1849. Although possibly similar cases were reported earlier and Addison believed the anemia to be related to adrenal dysfunction, this is generally taken as the first description of pernicious anemia. Neuropathy was noted by Osler and Gardner in 1877, and Lichtheim associated it with myelopathy 10 years later. In 1880, Ehrlich identified megaloblasts and proposed them as the precursors of the “giant blood corpuscles” described in the peripheral blood by Hayem.

The clinical breakthrough occurred in 1926 when Minot and Murphy,² using the then new technique of reticulocyte assessment, showed that the manifestations could be reversed and held in abeyance by eating prodigious amounts of liver; for this, they shared the Nobel Prize. Three years later, Castle,³ building on earlier descriptions of achylia gastrica, demonstrated that gastric juice contains an “intrinsic factor” (IF) that combines with an “extrinsic factor” in meat and allows it to be absorbed. Several decades later, the extrinsic factor, vitamin B₁₂, was synthesized,^{4, 5} and its structure was demonstrated by Hodgkin,⁶ who was awarded a Nobel Prize for her crystallographic work.

Studies by Wills,⁷ who treated macrocytic anemia with yeast, and by many others defined the need for folate, which was isolated and characterized by 1948.⁸ The ability of nutritional folate deficiency to cause megaloblastic anemia was proven in a notable selfexperiment by Herbert.⁹ The stories of these and other discoveries are available in several highly readable books and articles.^{10, 11, 12, 13}

Cure is so simple now that the once deadly diseases are considered domesticated. That gratifying development has been so successful that the potential for clinical neglect has emerged,^{14, 15, 16} even as major metabolic and molecular advances

continue. The definitions of insufficiency have expanded,¹⁷ and accurate and accessible biochemical tools have facilitated exploration of potential impact on public health. This has not been free of controversy.

NORMAL PHYSIOLOGY AND PATHOPHYSIOLOGY

Megaloblastic anemia is, most often, a product of folate or cobalamin (vitamin B₁₂) deficiency. These metabolically intertwined vitamins, whose disorders are sometimes difficult to differentiate, require very distinct diagnostic and therapeutic approaches. The two are discussed separately throughout this chapter, which signals the need to always differentiate between them.

Biochemistry and Metabolism

Folate

Folate, or pteroylglutamate, consists of a pteridine ring, paraminobenzoate, and one or more glutamate side chains (Fig. 36.1). Folates vary in their reduction states, one-carbon moieties, and glutamation states. Polyglutamated folates, with three or more γ -carboxyl-linked glutamate residues, predominate intracellularly; they are better retained in cells than monoglutamated forms, which traverse membranes more easily.¹⁸ Polyglutamated forms are also more effective participants in enzymatic reactions, although N5-methyltetrahydrofolate (methylTHF), the major folate in the body, tends to be a poor substrate for polyglutamation.

Folic acid is pharmacologically stable but must be reduced to be active. Folates reduced to tetrahydrofolate (THF) at positions N5 through N8 (Fig. 36.1) function as one-carbon group donors, acceptors, or modifiers. THFs with varying one-carbon moieties at the N5, N10, or both positions, attach to enzymes and serve as co-substrates in cytoplasmic or mitochondrial one-carbon group transfers involving amino acids (Fig. 36.2, reactions 4, 5, and 7),

P.928

purines (reactions 10 and 11), and pyrimidines (reaction 2). By indirectly contributing to S-adenosylmethionine (AdoMet) generation, folate is linked to important methylations, including methylation of DNA cytosine (Fig. 36.2, reaction 13). Cellular folate metabolism and its compartments are reviewed elsewhere.^{18, 19}

FIGURE 36.1. Folate structure. The constituents are, from left to right, pteridine and p-aminobenzoic acid (PABA), which constitute the pteroyl moiety, and one or more glutamates that are attached by γ -carboxyl linkage (in this diagram, three glutamates are linked). Metabolic activity requires reduction to tetrahydrofolate at positions 5, 6, 7, and 8. Various one-carbon moieties are attached to the nitrogen at position 5 (N5-methyl, N5-formyl, or N5-formimino) or 10 (N10-formyl), or bridging 5 and 10 (N5,10-methylene or N5,10-methenyl). Each folate participates in specific reactions by transferring, accepting, or transforming its one-carbon moiety.

FIGURE 36.2. Folate metabolism and its linkage with cobalamin (reaction 4) to homocysteine and methionine metabolism (right). Vitamin co-factors are highlighted in boxes. Not all bidirectional reactions are noted as such, but the unidirectional nature of reaction 3 is the basis for the methyltetrahydrofolate trap hypothesis. The enzymes for the reactions include the following: (1) dihydrofolate (DHF) reductase; (2) thymidylate synthase; (3) methylene tetrahydrofolate (THF) reductase; (4) methionine synthase (maintained by a reductive system mediated by methionine synthase reductase); (5) serine hydroxymethyltransferase; (6) two sequential reactions mediated by two enzymatic activities of a single protein (methyleneTHF dehydrogenase and methenylTHF cyclohydrolase); (7) glutamate formiminotransferase; (8) formiminoTHF cyclodeaminase; (9) methenylTHF synthase; (10) glycinamide ribonucleotide (GAR) transformylase; (11) 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase; (12) methionine adenosyltransferase; (13) diverse S-adenosylmethionine (AdoMet)-dependent methyltransferases; (14) S-adenosylhomocysteine (AdoHcy) hydrolase (kinetics usually favor synthesis of AdoHcy); (15) betaine:homocysteine methyltransferase; (16) cystathionine β -synthase; (17) cystathionine γ -lyase. dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate; FAD, flavin adenine dinucleotide (riboflavin); FAICAR, formylAICAR; FGAR, formylGAR; FIGLU, formiminoglutamic acid; Glu, glutamic acid; MeCbl, methylcobalamin; PLP, pyridoxal 5'-phosphate.

Cobalamin

Cobalamin, a 1,355-Da member of the corrin family, is an organometallic co-factor. Four nitrogens of its planar tetrapyrrole anchor a central cobalt atom linked with a nucleotide (5,6-dimethylbenzimidazole) below and a variable prosthetic moiety above the pyrrole plane (Fig. 36.3). Specific cobalamins are named for their prosthetic moiety: methylcobalamin, which predominates in plasma and cytoplasm, and 5'-deoxyadenosylcobalamin, which predominates in mitochondria. Vitamin B₁₂, used popularly as a synonym for cobalamin, was the name given to cyanocobalamin,⁴ a stable pharmacologic preparation that must be converted to other forms for utilization. Noncobalamin corrinoids, often with major structural changes or deletions, are ubiquitous in microbial metabolism, but cannot be used by humans. Some noncobalamin analogs are nevertheless bound avidly by transcobalamin (TC) I (also called haptocorrin)^{20, 21} and are found in the gut, plasma, and, much less often, tissues.²²

To serve as an active co-enzyme, cobalamin requires reduction of its cobalt to the monovalent cob(I)alamin or divalent cob(II) alamin.²³ Reduced cobalamin has two known roles in humans. Attached to methionine synthase, it accepts the methyl group from methylTHF as methylcobalamin and transfers it to homocysteine (Fig. 36.2, reaction 4). Cobalamin activity for this reaction is maintained by methionine synthase reductase²⁴ and requires AdoMet. In cobalamin's other role, reduced mitochondrial cobalamin accepts 5'-deoxyadenosyl from adenosine triphosphate and binds to methylmalonyl coenzyme A (CoA) mutase. This mutase mediates an intramolecular rearrangement of L-methylmalonyl CoA to succinyl CoA in propionate metabolism.²⁵

Cobalamin deficiency has a major impact on folate, homocysteine, and methionine metabolism by impairing the methionine synthase reaction. Most evidence supports the concept that cobalamin deficiency thereby “traps” methylTHF, which has no alternative metabolic role or route.^{26, 27} Feedback mechanisms activate methyleneTHF reductase (Fig. 36.2, reaction 3) in an effort to mobilize more methylTHF but only end up diverting even more methyleneTHF from its other roles and into the trap. A paralysis of folate metabolism spreads as THF and other active folates decrease. An alternative to the trap hypothesis emphasizes that the failure of methionine synthesis ultimately leads to formate “starvation,”²⁸ with depletion of formylTHF, methenylTHF, and methyleneTHF.

Homocysteine and Methionine

Folate and cobalamin participate intimately in homocysteine and methionine metabolism. The eventual generation of AdoMet (Fig. 36.2, reaction 12) serves several major functions. AdoMet helps regulate the metabolism of folate and disposition of homocysteine

P.929

by inhibiting both methyleneTHF reductase (reaction 3) and betaine hydroxymethyltransferase (an alternate remethylator of homocysteine [reaction 15] confined to liver and perhaps kidney and lens), and by activating cystathionine β -synthase (reaction 16).²⁹

FIGURE 36.3. Cobalamin structure. Attached to the central cobalt atom of the corrin tetrapyrrole and to one of the pyrrole rings is the α -ligand, the 5,6-dimethylbenzimidazole nucleotide, extending below the corrin plane. The β -ligand (marked as X in the diagram) above the plane can be any one of several moieties, such as methyl, 5'-deoxyadenosyl, hydroxyl, or cyanide.

Even more importantly, AdoMet is the methyl donor for most cellular methylation reactions affecting proteins, nucleic acids, histones, phospholipids, and neurotransmitters, all mediated by various methyltransferases (Fig. 36.2, reaction 13).³⁰ DNA hypomethylation, which contributes to neoplasia, can result from AdoMet deficiency. In the methylation reactions, S-adenosylhomocysteine (AdoHcy) is formed. AdoHcy, which in excess inhibits AdoMet activity, can be hydrolyzed to homocysteine; under normal conditions, however, the direction of this reaction favors AdoHcy synthesis (reaction 14).

An alternate fate of homocysteine is its transsulfuration to cystathionine and then to cysteine; both of these steps require pyridoxal 5'-phosphate (reactions 16 and 17). This is the major catabolic pathway for homocysteine, which is cytotoxic in concentrations normal for other amino acids. The pathway also influences redox activity by generating glutathione, a major intracellular reducing agent.

Normal Folate Physiology

Nutritional Characteristics

Folate, named for green leafy vegetables, exists in nearly all classes of foods. Organ meats (e.g., liver and kidney) and yeast are particularly rich, although not frequently eaten, sources. More common sources are other meats, nuts, beans, orange juice, dairy products, grains, and cereals. However, food folate, mostly methylTHF and formylTHF, is labile. Large losses occur with storage and some cooking processes,³¹ especially when the water is discarded.⁹

Fortification of the American food supply in 1998 with 140 µg folic acid/100 g in grain and cereal products was mandated to lower the risk of neural tube defect births. Many food producers exceeded that amount, increasing the average folate intake by 190 µg/day.³² Folate levels have risen sharply, reducing the frequency of subnormal red cell folate from 37.6% to 4.5% in young women.³³ Supplement use has also grown in Western societies, especially among women and the aged.³⁴ However, overall folate intake remains poor in other countries.

Dietary recommendations³⁵ take into account folate bioavailability, which is highest for synthetic folic acid and lower for food folate, which tends to be polyglutamated and requires conversion to monoglutamate for optimal absorption. Recommended intake is therefore expressed in dietary folate equivalents, in which 0.5 µg of folic acid supplement or 0.85 µg folic-acid-fortified food delivers the dietary equivalent of 1 µg of food folate. The recommended dietary folate equivalent intake is 400 µg daily for adults, 600 µg for pregnant women, 500 µg for lactating women, and lesser amounts scaled for age in children. Women of reproductive age are advised to take 400 µg of folic acid as an additional supplement to prevent neural tube defect births.

Physiologic Cycle of Assimilation

Folate Absorption

The absorption combines specific saturable processes that tend to predominate in the upper small intestine and nonsaturable ones that predominate in the ileum.³⁶ Luminal binding proteins appear not to be involved. The saturable process allows absorption of all folates, usually after the polyglutamated forms are hydrolyzed to monoglutamated ones by glutamate carboxypeptidase II in the jejunal brush borders. Two transmembrane, high-affinity members of the solute carrier superfamily mediate the saturable absorption of reduced folates in the upper small intestine. The main one, the proton-coupled folate transporter, has optimal affinity for folate at the duodenal pH of 5.5.^{36, 37, 38} The reduced folate carrier has a higher affinity at pH 7.4 and thus has a lesser duodenal role.³⁶ Both these carriers exist in other tissues also. Conversion of absorbed folate to methylTHF appears to occur in the intestinal cell, which then exports the methylTHF into portal blood via carrier-mediated basolateral membrane transport, but some have proposed later hepatic conversion instead.³⁹ The liver either polyglutamates and stores the folate, secretes it for biliary enterohepatic recycling, or exports it for delivery elsewhere. Folate achieves peak levels in the blood 1 hour after ingestion.

Nonsaturable ileal absorption of folate assumes a dominant role whenever more than 200 µg of folate, which exceeds the capacity of the jejunal process, is ingested.³⁵ Such absorption of nearly unlimited amounts of unreduced monoglutamates may explain why oral folic acid is effective even when the more specific jejunal mechanisms fail in some malabsorptive disorders.

Folate Binders and Receptors

The various specific and nonspecific folate binders are incompletely understood and may not be mandatory for cellular uptake of folate. Specific binding proteins in the blood bind only a small fraction of circulating folate. Secretions, especially milk, also contain specific binding protein whose role is unclear but may withhold folate from bacteria.

The reduced folate carrier belongs to the SLC19 family of transporters, some members of which transport thiamine, and transports reduced folates (and methotrexate) into cells by a process linked to organic anions.³⁶ With its high activity at neutral

P.930

pH and operating at higher concentrations of folate, reduced folate carrier assumes major responsibility for folate uptake from the blood by the liver, kidney, leukocytes, placenta, and parts of the brain.

Folate receptor- α (FR- α or FR1) and FR- β (or FR2), are specific, partially homologous receptors in epithelial cells, placenta, hematopoietic cells, renal tubular cells, and malignant cells.^{36, 40} Their related genes lie on chromosome 11q13. FR- α and FR- β are covalently linked to glycosylphosphatidyl inositol anchors on cell membranes, bind and internalize methylTHF by endocytosis via clathrin-coated pits, and are recycled.⁴¹ FR- γ is confined to hematopoietic cells but lacks glycosylphosphatidyl inositol anchoring and is therefore readily secreted.⁴² The roles of these FR isoforms are not known, but FR α is active in renal tubular reabsorption of excreted folates. Some FR is found intracellularly, and some circulating folate-binding proteins appear to derive from FR. FRs are being explored as enhancers of drug delivery and cellular imaging because of their high expression in malignant and inflammatory cells. FR- α is also a co-factor for entry of Marburg and Ebola viruses into cells.⁴³

Folate Transport and Cellular Utilization

Dietary folate and reabsorbed biliary folate enter the bloodstream and are rapidly cleared to tissues.⁴⁴ The rapid flux probably explains why plasma folate declines within 3 weeks when intake is reduced. Plasma folate, which is mostly methylTHF, is bound nonspecifically and with low affinity to proteins such as albumin, but approximately one third circulates unbound and a tiny fraction is bound specifically by the previously discussed FR-derived binding proteins. None of the circulating proteins plays any obvious role in cell uptake of folates.

Cellular uptake of monoglutamated folate occurs via either membrane FR or reduced folate carrier, the details varying among cell types and conditions.^{18, 36} Passive diffusion also occurs. In the cell, folates are rapidly polyglutamated by folylpoly- γ -glutamate synthetase, which enhances cellular retention and promotes attachment to enzymes. The folate is transported by saturable mechanisms into organelles; 35% of intracellular folate is in mitochondria.

Folate Stores and Turnover

A classic depletion study in one volunteer suggests that body stores of folate can be depleted in a few months to levels that do not support normal hematopoiesis,⁹ but precise data are scarce. Old data estimate that normal liver folate content exceeds 7.5 mg.⁴⁵ The liver concentrates much of the body's folate and is a major site of one-carbon metabolism. Several folate pools exist, with different turnover rates ranging up to 100 days.⁴⁶ Enterohepatic recycling involves as much as 100 μ g of folate daily.⁴⁴

Approximately 200 μ g of folate is excreted fecally every day. However, that amount includes not only the endogenous losses via sloughed intestinal cells and nonreabsorbed biliary folate but also external folates, such as unabsorbed food folate and folate synthesized by intestinal bacteria.⁴⁶ Approximately 1 mg of folate is filtered daily in the glomerulus but is largely reabsorbed as its folate-binding protein attaches to megalin, the multiligand receptor in proximal tubules.⁴⁷ Oxidatively degraded folate is lost, primarily in urine. Daily losses thus approximate 1% to 2% of body stores, which is compatible with the folate depletion rate reported in a normal person after 2 to 3 months of dietary restriction.⁹

Normal Cobalamin Physiology

Nutritional Characteristics

Humans obtain their cobalamin secondhand from animals and fish, which ingested the bacteria that synthesize cobalamin, or from animal products, such as milk.^{45, 48} The more prodigious bacteria ingestors, such as ruminants and oysters, are rich sources. Plants do not contain cobalamin. Bioavailability varies with different foods^{45, 48, 49, 50} and is at least as important as content. Cereals, fortified with cobalamin, dairy products, and fish provide better cobalamin bioavailability than meat.^{49, 50} Cobalamin supplement use, often as part of a multivitamin, has grown.^{49, 51}

When absorption is normal, the recommended daily requirement of 2.4 μ g in adults⁵² provides more than 1 μ g cobalamin to compensate for the approximate daily loss. In children, recommended daily intake rises from 0.4 μ g in infancy to 1.8 μ g in preadolescence. A survey in 1995 indicated that typical daily intake of cobalamin in the United States is 4.0 to 6.2 μ g.⁵³ European surveys suggested that metabolic sufficiency plateaus at intakes of 4.2 μ g or higher, depending on the population surveyed.^{50, 54, 55}

Physiologic Cycle of Assimilation

Intestinal absorption and tissue uptake (Fig. 36.4) are designed to internalize and concentrate available cobalamin efficiently while excluding possibly harmful nonfunctional analogs. The process is tightly regulated by a system of binding proteins and receptors.^{56, 57, 58} Whether food-bound or as a free supplement, cobalamin that exceeds the capacity of IF-mediated uptake is poorly absorbed,⁵⁹ unlike the ready absorption of excess, free folic acid. IF mediates the absorption of more than 75% of the typically small cobalamin load in a meal but can accommodate little more than a total of 1 to 2 μg at a time.⁴⁵

Cobalamin-binding Proteins

Three proteins with nonoverlapping roles bind cobalamin with high affinity^{56, 57, 58, 60} (Table 36.1). IF and TC II (called TC by authors who eschew TC I and TC II terminology) share moderate structural homology but their genes are located on different chromosomes.^{61, 62} Crystallographic analysis of TC II has defined key functional regions⁶³ that may be shared by IF. Each protein binds cobalamin specifically and ferries it into cells by endocytosis via its specific receptor; neither protein binds nonfunctional corrinoid analogs avidly.²⁰ IF, which originates in parietal cells although chief cells may synthesize it ectopically in patients with gastritis,⁶⁴ is confined to the gastrointestinal tract. TC II is synthesized by endothelial and other cells and is found in plasma and other fluids (Table 36.1). Holo-TC II (TC II with bound cobalamin) is cleared quickly by cellular uptake; its half-life in plasma is 90 minutes.⁶⁵ Plasma levels of total TC II tend to rise in inflammatory and other disorders, suggesting an acute-phase reactant character unrelated to cobalamin status,^{56, 66, 67} but correlation with C-reactive protein levels is poor.⁶⁸ A common missense polymorphism of the TCN2 gene, C776G, displays no consistent phenotypic impact,^{69, 70, 71} but the less common A67G mutation was associated with lower holo-TC II without affecting metabolic cobalamin status.⁷¹

TC I (also called haptocorrin, R binder, or cobalophilin) is heavily glycosylated.⁵⁶ Its carbohydrate variability is prominent and affects major physicochemical characteristics.^{56, 72} Some carbohydrate variations led to ill-advised isoelectric point demarcation of a "TC III" subset of TC I, but others may substantively alter TC I clearance from plasma. TC I is synthesized in the specific granules of late myeloid precursors⁷³ and in exocrine gland epithelium.⁵⁶ TC I has only 33% to 36% homology to IF and TC II.^{62, 74} It also differs from them in two important ways: it binds nonfunctional corrinoid analogs as avidly as cobalamin, and it lacks specific receptors for cellular delivery. As a result, plasma TC I exists largely saturated with cobalamin (i.e., holo-TC I) and has a half-life of 9 to 10 days.⁶⁵ Thus, TC I carries more than 70% of cobalamin^{75, 76} and virtually 100% of analogs in plasma,^{20, 77} whose concentrations are nearly equal. Only 10% to 30% of plasma cobalamin is holo-TC II at any moment, which greatly underestimates the heavy but rapidly turning over holo-TC II traffic.

P.931

Holoprotein proportions can vary widely in some disorders, and the reason is not always known.^{76, 78} Desialylated TC I is cleared nonspecifically by hepatic receptors for asialoglycoproteins,⁷⁹ whereby some of its cobalamin is cleared in bile.

FIGURE 36.4. Assimilation and utilization of cobalamin. ado-cbl, 5'-deoxyadenosylcobalamin; IF, intrinsic factor; methyl-cbl, methylcobalamin; TC I (HC), transcobalamin I (haptocorrin); TC II, transcobalamin II. (Modified from Carmel R. Cobalamin deficiency. In Carmel R, Jacobsen DW, eds. Homocysteine in health and disease. Cambridge, MA: Cambridge University Press, 2001:289-305, with permission.)

TC I concentrations in all secretions exceed plasma levels manyfold.⁵⁶ TC I carries nearly all the cobalamin in breast milk, salivary TC I is the first protein to bind ingested cobalamin, and biliary TC I is involved in enterohepatic recycling of cobalamin. These facts suggest that much of the TC I role lies outside the bloodstream. It is plausible to suggest that TC I, whose role is considered unknown, is the primary “withholder” of excess cobalamin and, perhaps more important, all analogs that are used by

the vast human microbiome in the gut and elsewhere, as well as withholding unusable analogs from human cells.⁸⁰ The subject requires careful study. Several minor cobalamin-binding proteins and complexes have also been described in plasma, but their roles are unknown.^{56, 79, 81, 82, 83}

TABLE 36.1 COBALAMIN-BINDING PROTEINS

	Intrinsic Factor	TC II (TC)	TC I (Haptocorrin)
Gene	<i>GIF</i> (chr. 11q13)	<i>TCN2</i> (chr. 22q12.2)	<i>TCNI</i> (chr. 11q11-q12.3)
Cbl-related role	Promotes ileal uptake	Promotes uptake by all cells	Sequesters Cbl and nonfunctional corrinoids, withholding them from cellular uptake; carries all Cbl in milk and bile and most Cbl in blood; initial acceptor of Cbl in stomach
Cbl binding	High affinity and specificity for Cbl; low affinity for corrinoid analogs	High affinity and specificity for Cbl; low affinity for corrinoid analogs	High affinity for Cbl; high affinity for corrinoid analogs
Cells of origin	Gastric parietal cell ^a	Endothelial cell; fibroblast; ?ileal cell; ?hepatocyte	Neutrophil; exocrine gland epithelial and ductal cells
Distribution in fluids	Gastric juice	Plasma, CSF, semen, amniotic fluid	Plasma, all exocrine secretions, ^b CSF, semen
Protein structure	48-kDa glycoprotein (15% carbohydrate)	43-kDa polypeptide	66-kDa glycoprotein (33-40% carbohydrate)
Receptors	Cubilin-amnionless complex ("cubam")	TC II receptor; ^c Megalin ^d	None identified ^e
Consequence of Cbl binder deficiency	Cbl malabsorption	Severe cellular Cbl deficiency	Low serum Cbl level without Cbl deficiency

Cbl, cobalamin; chr., chromosome; CSF, cerebrospinal fluid; TC, transcobalamin.

^aEctopic production of intrinsic factor by chief cells occurs in patients with gastritis.

^bSecretions include saliva, breast milk, bronchial secretions, and tears.

^cThis specific receptor is ubiquitous and internalizes holo-TC II for cobalamin utilization. Its gene is *TCBIR/CD320*.

^dMultiligand receptor in proximal renal tubule, intestine, choroid plexus, type 2 pneumocyte, and yolk sac; renal role involves cobalamin salvage but roles elsewhere are uncertain. Its gene is *LRP2*.

^eDesialylated TC I may undergo nonspecific clearance by asialoglycoprotein receptors in the liver.

Cobalamin Absorption

Cobalamin is released from food by pepsin at an acid pH in the stomach and binds preferentially to salivary TC I rather than IF at this pH (Fig. 36.4, panel 1). Pancreatic secretions entering the duodenum neutralize the pH and provide proteases to degrade TC I.⁸⁴ The released cobalamin, including biliary cobalamin,²¹ thus becomes available to IF (Fig. 36.4, panel 2).

The IF-cobalamin complex eventually attaches to the cubilin receptor for IF in the ileum (Fig. 36.4, panel 3). Cubilin is a 460-kDa glycoprotein whose 27 CUB domains provide binding sites for many other ligands, such as vitamin-D-binding protein, transferrin, immunoglobulin light chain, albumin, and apolipoprotein A1;⁴⁷ it also exists in yolk sac, renal proximal tubules, and elsewhere. Cubilin lacks a transmembrane domain but is anchored by amnionless, a 45-kDa transmembrane protein that provides cell signaling for the “cubam” receptor complex.^{85, 86, 87} After endocytosis, the cubilin-IF-cobalamin complex is split, and cobalamin exits the ileal cell into the bloodstream several hours after its oral ingestion. Whether the exit is mediated by TC II or multidrug resistance protein-1⁸⁸ is unclear.

Plasma Transport and Cellular Utilization

Some of the portal blood holo-TC II is internalized by hepatocytes via TC II receptors.²¹ The remainder finds its way to other tissues for calcium-dependent, TC II receptor-mediated cellular endocytosis^{89, 90} (Fig. 36.4, panel 4). After lysosomal degradation of the TC II, its cobalamin is released for attachment to cytoplasmic methionine synthase and conversion to methylcobalamin and to mitochondria for conversion to adenosylcobalamin.

Specific uptake of holo-TC II also occurs in yolk sac, gut, and especially in the proximal renal tubule by a second receptor, megalin, a 600-kDa glycoprotein member of the low-density lipoprotein receptor family.⁴⁷ As is cubilin, with which it sometimes co-localizes, megalin is a multiligand receptor, but it has a considerably greater clientele of ligands; these include additional vitamin-binding proteins (such as folate-binding protein and retinol-binding protein), several lipoproteins, carrier proteins (such as albumin, lactoferrin, and transthyretin), hormones, enzymes, hemoglobin, and myoglobin. Most information on megalin derives from studies in the proximal renal tubule, which is rich in the protein, and in knockout mice. Megalin prevents the urinary loss of many filtered proteins, and virtually completely reabsorbs the 1.5- μ g cobalamin load in the holo-TC II that is filtered by the glomerulus daily.

Body Stores and Turnover

Cobalamin stores exceed daily requirement more than 1,000-fold. This contrast with the much smaller ratio for folate explains why cobalamin depletion takes years whereas folate depletion takes weeks to months. The total body content of cobalamin approximates 2.5 mg (2,500 μ g) in adults⁹¹ and only approximately 1 μ g is lost daily. Some of the loss occurs by biliary excretion of 1.4 μ g daily, but two thirds of that is reabsorbed via the IF mechanism.²¹ If the IF mechanism fails, as in pernicious anemia, biliary reabsorption ceases. Urinary loss of cobalamin is minor because of reabsorption by megalin (however, if plasma cobalamin exceeds TC II capacity, as happens after cobalamin injection, the free cobalamin escapes renal reabsorption).

It bears mention that corrinoid analogs outnumber cobalamin 98-fold in the colon,⁹² whereas they approximately equal cobalamin content in the plasma.⁷⁷ The extent of cobalamin conversion to analog in the body is unknown.

CLINICAL AND LABORATORY FEATURES

The hematologic consequences are identical in folate and cobalamin deficiency. So are many nonhematologic manifestations, with the notable exception of neurologic dysfunction. Some clinical variations reflect the ways in which the two deficiencies arise. Folate deficiency typically evolves rapidly, and it is often

P.933

associated with broad malnutrition and with alcohol abuse. In contrast, the evolution of cobalamin deficiency is usually measured in years, and it tends to be a purer deficiency state because malabsorption is often restricted to cobalamin alone.

Megaloblastic Anemia in Cobalamin and Folate Deficiency

Biochemistry

Deficiency of folate compromises the methylation of deoxyuridylate to deoxythymidylate (Fig. 36.2, reaction 2), and deficiency of cobalamin does so indirectly. However, impaired de novo thymidylate synthesis only partially explains megaloblastic anemia. Observations in nonanemic patients with cobalamin deficiency^{93, 94, 95, 96} and animal models⁹⁷ show that thymidylate synthase impairment alone need not lead to anemia. Other steps contribute.⁹⁸ The excess uracil from deoxyuridylate is misincorporated into DNA in place of thymine and active excision repair produces many single-strand breaks.⁹⁹ When excisions coincide at opposing DNA strand sites, double-stranded breaks result, which may explain the nuclear defects of megaloblastic anemia. The end result appears to be an arrest at various stages of interphase in hematopoietic precursors.¹⁰⁰ Even so, the details are incomplete and megaloblastic anemia is not restricted to cobalamin or folate deficiency.

Hematopathology

Megaloblastic anemia is a panmyelosis, even though its name suggests a disorder limited to red cells and erythroid hyperplasia is a prominent feature. Indeed, the immature appearance of megaloblastic nuclei and the occasionally intense myeloid proliferation in the marrow have led to a misdiagnosis of leukemia in rare cases. The morphologic hallmark is nuclear-cytoplasmic dissociation, which is best appreciated in precursor cells in the bone marrow aspirate (Fig. 36.5). Megaloblastic nuclei are larger than normoblastic nuclei, and their chromatin appears abnormally dispersed due to its retarded condensation. Random chromosomal abnormalities are seen, including centromere spreading,¹⁰¹ but nonrandom changes may also occur.^{102, 103} Cytoplasmic maturation appears unremarkable.

Giant band cells and metamyelocytes with large and often misshapen nuclei are typical. Neutrophils with characteristic hypersegmented nuclei (Fig. 36.6) appear in the blood early in the course,^{9, 104} but they do not arise directly from the giant metamyelocytes.⁹⁸ The mechanism of hypersegmentation and why it persists in the blood for more than a week after therapy¹⁰⁵ are unknown. As megaloblastic anemia worsens, neutropenia and thrombocytopenia develop. These can be severe in advanced cases but are uncommon when anemia is mild.⁴⁵ Platelets are often functionally impaired,¹⁰⁶ although megakaryocytes do not show definable morphologic changes. The same may apply to lymphocytes.¹⁰⁷

FIGURE 36.5. Normal and megaloblastic precursor cells in the bone marrow. A: Pronormoblast. B: Megaloblastic equivalent of cell in plate A. C: Late normoblast. D: Megaloblastic equivalent of cell in plate C. (From Lee RG, Foerster J, Lukens J, et al., eds. Wintrobe's clinical hematology, 10th ed. Philadelphia: Lippincott Williams & Wilkins, 1999:913, with permission.)

Erythroid macrocytosis (Fig. 36.6) is an early change. Individual macrocytes appear first, as detectable by hemoglobin and cell size measurements confined to reticulocytes,¹⁰⁸ followed by a gradual rise in overall mean corpuscular hemoglobin (MCH) and then mean corpuscular volume (MCV) that eventually crosses the line into abnormality (>97 fl) before the hemoglobin levels fall.⁹ In cobalamin deficiency, with its slow progression, macrocytosis precedes anemia by months.^{14, 15} Macro-ovalocytes are especially characteristic of megaloblastic anemia but are not specific.¹⁰⁹ Early megaloblastic changes in the bone marrow precede the macrocytosis but are easily missed. Eventually, poikilocytosis becomes more pronounced with teardrop cells. Nucleated red cells, Howell-Jolly bodies, and even Cabot rings appear in the blood in severe megaloblastosis.

As anemia progresses, iron and transferrin receptor levels, sideroblast counts, and the ferritin content of erythroid precursors and macrophages increase.^{45, 110, 111} Erythropoietin levels correlate with the severity of anemia but can vary widely.¹¹²

Megaloblastic anemia is the chief exemplar of ineffective hematopoiesis in all three hematopoietic cell lines; bone marrow hyperplasia is intense but reticulocytosis does not occur.^{45, 98, 100} Precursor cells are arrested at various stages in interphase but continue to mature. As megaloblastosis advances, most precursors die within the hypercellular bone marrow and are phagocytosed. Whether early cell death is primarily apoptotic or not is controversial and may depend on the model studied.^{100, 113, 114} Advanced megaloblastic anemia has a poorly understood component of intravascular hemolysis also; survival of normal red cells transfused into cobalamin-deficient patients is short.¹¹⁵ Serum glutathione, an antioxidant, appears to be the most significant metabolic predictor of anemia in cobalamin deficiency.¹¹⁶ Abnormalities of red cell membrane proteins, including spectrin, have also been described.¹¹⁷

The evolution of hematologic changes has been detailed elsewhere⁴⁵ and its laboratory characteristics are detailed further in the section "Hematologic Assessment." With progressive anemia also come fatigue, hypervolemia, and cardiovascular symptoms, as well as the pallor combined with hyperbilirubinemia that gives a classic lemon yellow skin color, and even retinal hemorrhages and, on occasion, pseudotumor cerebri.

Neurologic Dysfunction

Cobalamin Deficiency

Pathophysiology

Demyelination with subsequent axonal disruption and gliosis can affect all parts of the central nervous system. Peripheral nerves, however, tend to show axonal degeneration without

P.934

demyelination.^{118, 119} The classic myelopathic syndrome is subacute combined degeneration, in which posterior and lateral column damage predominates; dorsal, pyramidal, and spinocerebellar tracts are affected. The earliest changes appear in the cervical or thoracic spine and can be detected by magnetic resonance imaging (MRI) as hyperintensity on T2-weighted images (Fig. 36.7). Larger, more heavily myelinated fibers tend to be affected most often.¹²⁰

FIGURE 36.6. Blood smear from a patient with megaloblastic anemia due to cobalamin deficiency. Note characteristic large macro-ovalocytes (A) and hypersegmented neutrophils (B). (Courtesy of Irma Pereira MT [ASCP]SH.)

The biochemical mechanisms are unknown. Because myeloneuropathy is much more prominent in cobalamin deficiency than in folate deficiency, suspicion fell on the folate-unrelated role of adenosylcobalamin in propionate metabolism and its possible consequences to fatty acids in myelin. Most evidence now points to methionine synthase impairment and its effects on methionine metabolism and methylations instead.¹²¹ Animal data suggested that methionine ameliorates cobalamin deficiency-induced neurologic dysfunction, preliminary cerebrospinal fluid studies in humans described low AdoMet levels, and high AdoHcy-to-AdoMet ratios suggested inhibition of AdoMet's methylation activity by AdoHcy. Plasma homocysteine-related metabolite comparisons in neurologically impaired versus hematologically impaired patients with pernicious anemia suggest even greater complexity:¹¹⁶ cysteine levels were significantly higher in the neurologically affected patients and, surprisingly, AdoMet levels were actually higher in neurologically impaired patients. Neurologically impaired patients also had significantly higher serum folate levels than those without neurologic problems.^{116, 122, 123} It is unclear if these differences represent cause, concurrence, or consequence.

FIGURE 36.7. Magnetic resonance imaging (T2 weighted) of a sagittal section of the cervical spine of a man with pernicious anemia and severe myelopathy. Note the posterior localization of the high signal intensity lesion (arrow). (From Larner AJ,

Zeman AZ, Allen CMC, et al. MRI appearances in subacute combined degeneration of the spinal cord due to vitamin B₁₂ deficiency. *J Neurol Neurosurg Psychiatry* 1997;62:99-101, with permission.)

Clinical Features

The frequency of neurologic involvement in cobalamin deficiency is presumed lower than the frequency of anemia but is undefined (perhaps because it is not as explicit and quantifiable as anemia and because of patient selection biases). Often regarded as a late development, neurologic changes can precede anemia instead.^{124, 125, 126} Interestingly, the extents of neurologic and hematologic expressions of cobalamin deficiency tend to vary inversely in patients,^{116, 126} and the predilection tends to recur when deficiency relapses.^{126, 127, 128} Although genetic influences on clinical expression seem plausible, methyleneTHF reductase polymorphisms that increase folate availability for thymidylate synthase over methionine synthase did not predispose to neurologic manifestations in pernicious anemia.¹²⁹

Neuromyelopathy is the most common neurologic feature of cobalamin deficiency,^{120, 126, 130, 131} but it is not specific to it; copper deficiency, for example, produces similar findings,¹³² as well as macrocytosis.¹³³ Sensory changes in cobalamin deficiency include position sense disturbance and dysesthesia; pyramidal tract signs include spasticity and a Babinski reflex; neuropathy is exemplified by loss of tendon reflexes; and gait disturbances are common signs of advanced involvement. Manifestations tend to be symmetrical. Neuropathy, which is usually sensory but can be sensorimotor,¹³⁴ can be hard to differentiate clinically from posterior column involvement.^{126, 130, 135, 136}

The earliest manifestations are loss of vibratory sense in the feet and numbness, tingling, and loss of fine sensation. Others include loss of proprioception and, depending on the balance between myelopathy and neuropathy, hyperactive or diminished deep tendon reflexes. Involvement ascends up the legs, and, eventually, hands are affected as well. Muscle weakness and tenderness have been described sometimes. Ataxia, spasticity, gait disturbances, positive Babinski reflex, impotence, and bladder¹³⁷ and bowel dysfunction appear in advanced cases.

Cerebral symptoms, notably cognitive and emotional changes, can be severe in some cases^{124, 126} or so mild as to be recognized

P.935

only in retrospect after treatment. MRI reveals focal and diffuse changes in the brain¹³⁸ (Fig. 36.8). Tensor diffusion imaging also shows white matter changes in adjacent areas that seem normal on MRI.¹³⁹ Nevertheless, despite low cobalamin levels in 10% to 20% of patients with chronic dementias,^{95, 140} the low levels usually reflect only subclinical cobalamin deficiency (SCCD) and appear unrelated to chronic dementias, which rarely improve with cobalamin therapy.¹⁴¹ In very young children, however, some cobalamin deficiencies can cause developmental delay, lethargy, cerebral atrophy, and seizures.¹⁴²

FIGURE 36.8. Magnetic resonance imaging (T2 weighted) of the brain in a woman with pernicious anemia and cognitive dysfunction. Large confluent and focal areas of increased signal intensities are seen, predominating around the ventricles. The changes improved after therapy. (From Stojsavljevic N, Levic Z, Drulovic J, et al. A 44-month clinical-brain MRI follow-up in a patient with B₁₂ deficiency. *Neurology* 1997;49:878-881, with permission.)

Autonomic dysfunction is sometimes demonstrable with deficiency.^{118, 143, 144, 145} Other neurologic manifestations include visual changes, optic neuritis, which predominates in men, and disturbances of smell or taste.^{126, 146} Classic motor dysfunction is rare, other than that caused by spasticity and proprioceptive loss, but abnormal central motor conduction times have been described.¹³⁴ At early or late stages, MRI (Figs. 36.7 and 36.8) and functional electrophysiologic tests, such as electroencephalography, evoked potentials, and nerve conduction, show abnormalities.^{134, 138, 147, 148, 149, 150, 151}

Unlike anemia, neurologic dysfunction does not always reverse after cobalamin therapy. Residual deficits persist in 6% of patients;¹²⁶ they are not always predictable but tend to accompany more extensive involvement and longer duration before treatment begins.^{45, 130} Mistaken folate therapy has also been tied to the risk of neurologic irreversibility in patients with clinical cobalamin deficiency. The delayed cobalamin treatment when the anemia responds to folate presumably allows neurologic abnormalities to appear, progress, and, in occasional reports,¹⁵² perhaps even accelerate. The events are more ambiguous than assumed. Hematologic improvement after folate is usually neither complete nor long lived in pernicious anemia,^{152, 153} and transient neurologic responses to folate may occur too.¹⁵³ Nevertheless, the anecdotal reports of clinical acceleration cannot be completely dismissed and cannot be studied prospectively in

pernicious anemia. Folate should never be given alone to cobalamin-deficient patients, even those whose deficiency is subclinical and lacks convincing evidence for adverse effects.¹⁵⁴

Folate Deficiency

Neurologic defects occur in only occasional adults with folate deficiency^{155, 156, 157} and are rarely as severe as in cobalamin deficiency. Although myelopathy has been reported,¹⁵⁸ it is exceptional. Mild mental changes, such as forgetfulness and irritability,⁹ and mild neuropathy have been better accepted. A causative association with depression is controversial.^{159, 160} Attributions of any neurologic changes to folate deficiency, which often occurs in a setting of malnutrition, require high standards of proof, including consideration of alternative explanations such as alcohol abuse.

In sharp contrast, however, children with inborn errors of folate metabolism often have severe myelopathy and brain dysfunction, including seizures and mental retardation.^{142, 161, 162} The explanations for the neurologic differences between folate and cobalamin deficiency or between acquired and hereditary folate disorders are unknown.

Other Manifestations

Miscellaneous Clinical Findings

Atrophy of tongue papillae is common with cobalamin deficiency and sometimes gives rise to a beefy red tongue that may or may not cause symptoms.^{45, 163} Aphthous stomatitis and oral soreness can be prominent in some patients, including some without anemia. However, glossitis occurs with folate deficiency and other deficiencies also. The glossitis of cobalamin deficiency does not respond to folate.¹⁶⁴ Mucosal changes occur elsewhere too, including megaloblastic changes in buccal epithelium, cervical cells, and intestinal villi;^{45, 165, 166} the latter apparently caused temporary malabsorption of cobalamin and other nutrients.^{167, 168} Other reversible but unexplained clinical changes in pernicious anemia include: impaired osteoblastic activity,¹⁶⁹ although reports of bone density changes and risk of fractures have been inconsistent; darkening of nails and skin and change of hair color in severely deficient non-Caucasians;^{170, 171, 172} and sometimes marked weight loss.¹⁷³

Miscellaneous Laboratory Abnormalities

Platelet function is sometimes impaired,¹⁰⁶ but neutrophil dysfunction has been variable. Hemoglobin A₂ levels rise slightly.¹⁷⁴ Occasional patients with sickle cell trait have shown striking changes in hemoglobin S and F levels when folate-deficient.¹⁷⁵ Cobalamin deficiency also affects some nonhematologic serum analytes: bone alkaline phosphatase is often decreased¹⁶⁹ and immunoglobulin levels sometimes decline.¹⁷⁶ An adolescent with severe megaloblastic anemia had reduced ADAMTS13 activity.¹⁷⁷

Subclinical Deficiency and Indirect Consequences of Altered Vitamin Status

Automated metabolic tests have simplified identification of asymptomatic, nonanemic vitamin deficiency. The high frequency of these early subclinical states has opened them to scrutiny as possible public health issues, with varying outcomes. The uncertainties apply especially to cobalamin, because SCCD is widespread, dominates epidemiologic surveys, and is often confused with clinical deficiency, yet has unclear health implications and, therefore, unknown need for intervention.^{17, 178, 179}

Subclinical Cobalamin Deficiency

Many patients and healthy people—especially, but not exclusively, the elderly—have low cobalamin levels but are asymptomatic and have normal blood counts. These low serum levels were thought artifactual until sensitive deoxyuridine suppression tests

P.936

showed in 1985 that most of them reflected mild biochemical insufficiency that responded to cobalamin and, equally important, rarely involved IF-related malabsorption.^{94, 95, 96, 180} None of the subjects had cobalamin-related anemia although bone marrow cells displayed reversible metabolic defects. Similarly, none had clinical neurologic findings although some,^{96, 141, 181} but not all,¹⁸² displayed mild, reversible electrophysiologic changes.

Widespread methylmalonic acid (MMA) and homocysteine testing^{183, 184, 185} next showed that asymptomatic nonanemic SCCD was much more common than clinical deficiency.^{17, 186, 187, 188} Thus, a survey of community-dwelling elderly subjects found that 12% had biochemical insufficiency¹⁸⁸ but only 2% of them had IF antibody-positive pernicious anemia¹⁸⁹ and, by extrapolation, 1% to 2% more may have had undetected antibody-negative disease. Readers must be aware that epidemiologic data apply to SCCD alone because too few subjects have clinical deficiency.¹⁹⁰ Moreover, falsely low

cobalamin levels (i.e., with normal MMA and homocysteine) also outnumber clinical deficiency in surveys.¹⁹¹ Nevertheless, the mild metabolic abnormalities in some asymptomatic subjects with low-normal cobalamin levels led many laboratories to raise the cutpoint for “suspicious” cobalamin levels from 200 to 300 or 350 ng/L to capture more cases.¹⁸⁶ The change is open to criticism because nearly 70% of cases added thereby have normal MMA and homocysteine levels and are not cobalamin-deficient. The influx of suspected SCCD expanded the concept of cobalamin deficiency at the cost of overdiagnosis based on often nonspecific biochemical findings whose need for therapy was unclear.^{17, 179, 190, 192, 193}

Assumptions that SCCD, especially when unaccompanied by malabsorption, progresses inevitably to clinical deficiency are untested.^{179, 190} Asymptomatic persons without malabsorption have been free of symptoms and anemia for 10 years despite persistently low cobalamin levels,¹⁹⁴ and metabolic monitoring over 1 to 4 years showed infrequent progression of mildly elevated MMA levels.¹⁹² Only a small minority of people with SCCD have early pernicious anemia,¹⁸⁹ whose progression to clinical deficiency is very predictable. Most persons with SCCD have no identifiable cause for it,^{17, 178} and the likelihood of progression in the 30% to 40% who have food-cobalamin malabsorption appears limited.¹⁹⁵

TABLE 36.2 COMPARISON BETWEEN CLINICAL AND SUBCLINICAL COBALAMIN DEFICIENCY STATES

Characteristics	Clinical Deficiency	Subclinical Deficiency
Biochemical abnormalities	Often severe	Usually mild
Clinical abnormalities	Megaloblastic anemia is present in >75% of cases Neurologic or cognitive changes are present in >50% of cases Electrophysiologic (neurologic) abnormalities are usually present	Anemia is absent ^a Neurologic changes are absent ^a Mild electrophysiologic changes are sometimes present
Cobalamin absorption status	IF-related malabsorption causes >90% of cases ^b FBCM is uncommon Normal absorption is uncommon (e.g., veganism)	IF-related malabsorption is usually absent ^b FBCM is present in <50% of cases Most persons have normal absorption
Diagnostic criteria	Almost always one or more clinical abnormalities At least one abnormal biochemical finding	No clinical signs of cobalamin deficiency Ideally, at least two abnormal biochemical findings should be demonstrated
Likelihood of progression of deficiency	Very high because of the usual presence of IF-related malabsorption	Unknown, but probably small Any progression to symptoms (i.e., clinical deficiency) is likely to be very slow
Need for cobalamin therapy	Urgent in all cases	Unknown
Medical implications	Clinical deficiency indicates that medical management is needed	None known, but if SCCD is found during medical evaluation it must be evaluated medically
Public health implications	None known	Unclear at present ^c

FBCM, food-bound cobalamin malabsorption; IF, intrinsic factor; SCCD, subclinical cobalamin

deficiency.

^a Any anemia or neurologic findings found in a patient with suspected SCCD must have a cobalamin-unrelated cause (otherwise it is clinical deficiency and cannot be considered SCCD).

^b IF-related malabsorption refers to absence of IF (which defines pernicious anemia) or inability of IF to promote intestinal absorption (e.g., intestinal disease). If such malabsorption is present, SCCD is likely to progress to clinical expression.

^c Active research into potential public health issues requiring preventive interventions is ongoing but still inconclusive. High-dose cobalamin, folic acid, and pyridoxine may slow progression of cognitive decline in some elderly persons, but it is unknown whether SCCD is a factor.

SCCD is compared and contrasted with clinical cobalamin deficiency in Table 36.2.

Subclinical Folate Deficiency

Subclinical folate deficiency is less explicitly defined than SCCD for several reasons: folate status fluctuates more readily than cobalamin status because folate turnover is rapid;³⁵ folate deficiency tends to be accompanied by other deficiencies; and attention is often diverted from the deficiency to its hyperhomocysteinemia. The latter, and growing pharmacogenetic and gene-nutrient data, suggest that subclinical variations of folate status below the level of deficiency may subtly influence many health issues, which are discussed next.

Vitamins and Public Health Risks

Subclinical Cobalamin Deficiency and Cognition

Many epidemiologic associations with SCCD have been pursued but clinical trials have been infrequent. Cognitive decline in the elderly has undergone the most active study because neurologic manifestations are frequent in clinical deficiency. The most consistent associations for cognitive dysfunction have been with homocysteine status, with variable links to folate and, to often lesser extent, cobalamin status. As reviewed elsewhere,^{179, 196, 197} early clinical trials were inadequate or inconclusive.^{198, 199, 200, 201, 202} However, two long-term randomized clinical trials in Europe, where dietary fortification is not mandatory, reported reduced progression of brain atrophy and cognitive decline. One found that 0.8 mg of folic acid daily was effective.²⁰³ The second demonstrated that three vitamins (0.8 mg folic acid, 500 µg cobalamin,

P.937

and 25 mg pyridoxine) slowed brain atrophy by 30%²⁰⁴ and reduced cognitive decline.²⁰⁵ Its important features were that the subjects were mildly cognitively impaired at baseline (which predicts likely progression, but avoids the irreversibility of dementia), the responders were hyperhomocysteinemic, and it is not clear which of the three vitamins was the beneficial one.

Folate and Neural Tube Defect Prevention

Supplementation with folic acid has also been scrutinized for prevention of conditions not directly attributable to folate deficiency. Of the many studied targets and associations, such as cancer, vascular and thrombotic disease, osteoporosis, cognitive dysfunction, and birth defects, the only unambiguous effect has been on neural tube defect (NTD). Folate supplementation reduces a woman's risk of having a child with NTD,^{206, 207} but the benefit seems pharmacologic rather than amelioration of folate inadequacy. Genetic and other susceptibilities related to folate, cobalamin, or homocysteine probably underlie the NTD risk, more so than does maternal folate deficiency. For example, the MTHFR C677T polymorphism increases the risk of NTD.²⁰⁸ High rates of antibody to FR have also been reported in women with NTD pregnancies²⁰⁹ and deficiency of FR-α in mice is associated with neural tube and other birth defects.²¹⁰

Folate prophylaxis must begin at conception because the neural tube closes at approximately 3 weeks. Daily doses of 400 µg are effective, with 4 mg recommended for women who use anticonvulsants or have a history of previous NTD. All grain and cereal foods have been fortified with folic acid since 1998 in the United States, Canada, and a few other countries. NTD rates have fallen but not disappeared, leading some experts to urge additional fortification.²¹¹ The benefits must be weighed against the consequences of chronic use of high folic acid doses, as discussed in the section "Preventive and Other Uses of Supplements."

Considerable human and animal data associated lower folate status with increased risk of cancer, best demonstrated with colon cancer. However, the associations are complex, may include double-edged folate impact that depends on neoplastic status and details as much as on folate status, and are beyond the scope of this chapter. These issues are discussed in the section "Preventive and Other Uses of Supplements" at the end of the chapter.

Hyperhomocysteinemia

Extrapolation from inborn errors of homocysteine metabolism suggested that severe hyperhomocysteinemia may predispose to thrombotic manifestations.²¹² Extensive epidemiologic data associated even mild hyperhomocysteinemia with increased risks for coronary, cerebral, and peripheral vascular complications, although the associations were less firm in prospective, rigorously designed studies than in retrospective ones.^{213, 214} Genetic polymorphisms, primarily of methyleneTHF reductase, contribute to 9% of homocysteine level variation,²¹⁵ but even in the absence of vitamin deficiency folate, cobalamin, and vitamin B₆ often reverse the hyperhomocysteinemia. Indeed, folic acid fortification reduced the frequency of hyperhomocysteinemia from 20% to 32% to 5% to 14% in the elderly.²¹⁶ Nevertheless, the outcomes of large interventional vitamin trials on coronary and cerebrovascular disease prevention have been disappointing.²¹⁷ Indeed, some trials even suggested adverse effects.^{218, 219, 220, 221, 222}

Laboratory Evaluation

Laboratory evaluation must have two separate targets: documenting hematologic, metabolic, and clinical chemistry changes that identify cobalamin or folate deficiency, and documenting the underlying condition or disease that caused the deficiency.

Hematologic Assessment

The mechanisms of megaloblastosis were discussed in the section "Hematopathology." The classic blood count findings in cobalamin or folate deficiency are anemia, a high MCV and MCH, and, in more advanced cases, thrombocytopenia and neutropenia. Patients are often identifiable at an early stage in which they have MCV and MCH elevation alone, which precedes anemia by months in cobalamin deficiency¹⁵ but only by a few weeks in the more rapidly developing folate deficiency.⁹ At first, the MCV and MCH may simply be higher than the patient's baseline, without being explicitly abnormal (e.g., an MCV of 90 fl replacing one of 85 fl). An early anisocytosis as new macrocytes begin to emerge can be detected by measuring the MCV or hemoglobin content of reticulocytes¹⁰⁸ or by an elevated red cell distribution width, which, however, is not invariable in early deficiency.²²³ Red cell counts decline before hemoglobin and packed cell volume levels.

Megaloblastic anemia is not the only cause of macrocytic anemia, however, or even the most common (Table 36.3). A hospital survey found 64% of MCV values >100 fl to be due to chemotherapy, antiretroviral therapy, or alcohol abuse.¹⁰⁹ Cobalamin and folate deficiencies caused only 6% of the high MCV values but accounted for most MCV values above 110 fl.

Absolute reticulocyte counts typically fall slightly. The laboratory signs of ineffective erythropoiesis, serum lactate dehydrogenase and indirect bilirubin levels, are initially inapparent but rise as the hemoglobin approaches 10 g/dl.⁴⁵ As anemia worsens, lactate dehydrogenase levels may reach thousands of units per liter as intravascular hemolysis is added to ineffective erythropoiesis. Other markers include rising serum transferrin receptor, iron, ferritin, nontransferrin-bound iron, and methemalbumin levels, as well as low serum haptoglobin levels. Platelet and neutrophil counts usually decline only as the anemia progresses. The pancytopenia can ultimately mimic aplastic anemia, which too is usually macrocytic (but does not display the bilirubin and lactate dehydrogenase elevations).

Most of the hematologic variability is dictated by the stage at which the patient is discovered.⁴⁵ However, not every patient expresses the same degree of anemia for the degree of cobalamin deficiency. Many severely deficient patients have surprisingly mild anemia or even lack it.¹²⁵ The reasons are usually unknown but some may be linked to the unexplained tendency for inverse association between anemia and neurologic dysfunction.^{124, 125} Another influence on hematologic expression is coexisting iron deficiency or thalassemia that produces normal or low MCV in approximately 7% of patients with pernicious anemia;²²⁴ these MCVs are above baseline for the patients and fall after vitamin therapy.²²⁵ Iron deficiency sometimes also blunts the erythroid megaloblastic changes themselves, both morphologically and by deoxyuridine suppression testing.^{226, 227} Iron studies in untreated megaloblastic anemia often do not reveal the coexisting iron deficiency.⁴⁵ Because all marrow and blood indicators of iron status fall within 24 to 48 hours of vitamin therapy, sometimes transiently to low levels before rebounding, it is advisable to wait several days for the tests to stabilize and reveal the patient's true iron status.

Hypersegmentation of neutrophil nuclei is a constant feature but is variably defined⁴⁵ and may be unreliable in inexperienced hands. The most serviceable criteria are finding one or more neutrophils with six or more nuclear lobes or showing that at

least 4% to 5% of neutrophils have five lobes. Calculating lobe averages is considered the gold standard but comparison against published reference ranges is unreliable because interobserver variation is great. Hypersegmentation often precedes anemia,^{9, 104} but it is not found in subclinical deficiency.²²⁸ Hypersegmented neutrophils are not specific for cobalamin or folate deficiency; they are found in patients receiving chemotherapeutic drugs such as 5-fluorouracil or hydroxyurea, in some patients receiving steroid therapy for immune thrombocytopenic purpura,²²⁹ and in rare

P.938

patients with myelofibrosis or chronic myelogenous leukemia. It is unclear whether iron deficiency can cause hypersegmentation.²³⁰ Neutrophil segmentation is normally greater in blacks than in whites.²²⁸

TABLE 36.3 CAUSES OF MACROCYTOSIS, DEFINED AS MEAN CORPUSCULAR VOLUME (MCV) GREATER THAN 97 FL^a

Causes of Macrocytosis (MCV >97 fl)	Likelihood of Severe Macrocytosis (MCV >110 fl)
Megaloblastic anemia	
Cobalamin or folate deficiency	High
Some metabolic disorders (e.g., thiamine-responsive anemia)	High
Cytotoxic drugs (e.g., hydroxyurea, 5-fluorouracil)	High
Some immunosuppressive drugs (e.g., azathioprine)	High
Alcohol^b	
Without liver disease	Low
With liver disease	Moderate
Drugs^b	
Antiviral drugs	Moderate
Anticonvulsant drugs	Low
Disorders of red cell production^b	
Aplastic anemia; pure red cell aplasia	High
Myelodysplastic syndromes	Moderate
Myeloproliferative disease; leukemia	Low
Sideroblastic anemia (hereditary or acquired)	Low
Congenital dyserythropoietic anemia; ? Fanconi anemia; Blackfan-Diamond anemia	
Copper deficiency anemia	Moderate
Reticulocytosis^b	
Hemolytic anemia	Moderate
Nonhematologic disease^b	
Liver disease (alcohol unrelated)	Low

Physiologic^b	Hypothyroidism	Low
	Red cells are enlarged in the first 4 wk of life	Low
Idiopathic^b	Pregnancy	Low
	Chronic lung disease; smoking	Low
	Cancer	Low
	Multiple myeloma	Low
Artifact of electronic cell sizing^b	Cold agglutinins	High
	Severe hyperglycemia	High
	Hyponatremia	?
	Stored blood	?
	Warm antibody to red blood cells	?

^aMacrocytosis can be diagnosed when an MCV is not yet >97 fl, if the MCV is higher than in the past. The second column estimates the likelihood of finding severe macrocytosis (>110 fl in adults).

^bMacrocytosis is not accompanied by megaloblastic changes.

Laboratory Tests of Deficiency

Cobalamin and folate levels are measurable in serum and cells. The original microbiologic methods exploited the cobalamin or folate requirements of various micro-organisms, including differential sensitivities to specific forms of folate.^{45, 231, 232} Although rarely used today, microbiologic assays remain the gold standard. Radioisotope dilution competitive-binding assays for cobalamin and folate gave way to automated chemiluminescence-based competitive-binding assays a decade ago. Technical ease and demand have grown, but transparency, documentation, and validation of assay performance have diminished.^{233, 234} Long suspected of critical failures to identify low cobalamin levels, and sometimes producing results above 1,000 ng/L,^{234, 235} many automated assays have misidentified 22% to 35% of sera from untreated patients with pernicious anemia.²³⁶ The errors appear to involve failure to inactivate serum autoantibodies to IF, but at present the manufacturers' corrections are awaited.

No single biochemical test is diagnostically definitive for either cobalamin or folate deficiency.¹⁹⁰ In most clinical settings, the cobalamin test, when free of error, nevertheless suffices if the clinical picture is clear.¹⁹³ Several metabolic tests are available to clarify the vitamin levels (Table 36.4), and can be clinically decisive in difficult cases. However, a clinical "picture" is unavailable in SCCD, and all tests lack sufficient specificity.¹⁹⁰ Therefore, a panel evaluating cobalamin testing in epidemiologic research²³⁷ recommended that the diagnosis of SCCD should be based on finding at least two abnormalities, one metabolic (e.g., MMA or homocysteine) and one quantitating cobalamin content (e.g., serum cobalamin

P.939

or holo-TC II).¹⁹⁰ Metabolic tests are essential in the diagnosis of inborn errors of metabolism, in which vitamin levels are often normal. Metabolites are also ideal for monitoring response of deficiency to therapy because their levels do not change unless the therapy was effective, whereas vitamin levels (serum cobalamin, holo-TC II, or folate) rise upon vitamin entry into the bloodstream regardless of efficacy. Metabolite improvement is also delayed for several days, allowing a post-therapy window of time for diagnostic reassessment if needed.

TABLE 36.4 BIOCHEMICAL TESTS FOR THE DIAGNOSIS AND DIFFERENTIATION OF CLINICALLY RELEVANT COBALAMIN AND FOLATE DEFICIENCIES

Test	Test Finding in			
	Cobalamin Deficiency	Folate Deficiency	Sensitivity of Abnormal Test Result ^a	Specificity of Abnormal Test Result ^a
Serum cobalamin	Low	N or Low	Very good ^b	Poor
Serum folate	N or High	Low	Very good	Poor
Red cell folate	N or Low	Low	Good	Moderate
Serum methylmalonic acid	High	N	Very good	Poor
Serum 2-methylcitric acid ^c	High	N	Good	Nd
Plasma homocysteine	High	High	Very good	Poor
Plasma cystathionine ^c	High	High	Nd	Nd
Serum holo-transcobalamin II	Low	N	Presumably very good	Poor
Deoxyuridine suppression test ^{c, d}	Abnormal ^d	Abnormal ^d	Very good	Nd

N, normal result; Nd, not determined.

^a The sensitivity and specificity estimates (very good, >90%; good, 80% to 90%; poor <70%) apply only to clinically expressed cobalamin deficiency. They do not apply to subclinical cobalamin deficiency, in which sensitivity and specificity tend to be lower than in clinical deficiency, are usually determined only against other biochemical tests, or are unknown.

^b Automated chemiluminescence cobalamin assays, however, appear prone to falsely normal results when serum contains antibody to intrinsic factor.

^c The test is available only in research laboratories.

^d The discriminatory diagnostic power arises from including testing with vitamin additives in vitro.

Awareness of major pre-analytic influences on some tests, such as whether supplements must be interrupted during testing, whether plasma or serum must be used, and processing requirements, can be helpful. Interpretation is affected by common confounders, such as renal failure, which affects all cobalamin-related test values, and uncertainties, such as variations in reference intervals that can create or blur mildly abnormal results and compromise comparability between laboratories and methods.^{190, 238, 239, 240} Cutpoint variations are common among clinical laboratories,¹⁹³ and may also explain discrepancies and controversies in epidemiologic research.¹⁹⁰

Cobalamin Levels

In cobalamin deficiency, serum cobalamin levels fall below the generally accepted cutpoint of 200 to 250 ng/L (often expressed as 148 to 185 pmol/L; 1 ng = 0.738 pmol.) Despite a frequently cited study's unreproduced claim that serum cobalamin is insensitive to clinical deficiency,²⁴¹ diagnostic sensitivity has been 90% to 97% in clinical practice.^{183, 190, 242, 243} The lower the cobalamin level, the more likely is clinically noteworthy deficiency to exist,^{231, 232} but exceptions exist even at levels below 100 ng/L. Approximately 20% to 40% of low cobalamin levels are falsely low^{17, 190} (Table 36.4), which makes routine equation of low serum cobalamin with deficiency risky, especially when clinical findings are absent or equivocal. Although sensitivity and positive predictive value are poor in epidemiologic surveys involving SCCD,²⁴⁴ subnormal cobalamin levels in patients coming to medical attention require pursuit, as does any patient with a surprisingly normal level.¹⁹³

Many persons with SCCD have unexplained normal cobalamin levels,^{186, 242, 243} and homocysteine and MMA abnormalities compatible with deficiency outnumber low cobalamin levels in surveys of healthy elderly people.^{186, 188, 191} These observations led some authors to raise the cobalamin cutpoint for deficiency to 350 ng/L.¹⁸⁶ However, abnormal homocysteine and MMA have too many confounders to provide conclusive proof of deficiency, especially in asymptomatic patients with normal cobalamin levels (Table 36.4).

The causes of low cobalamin levels are listed in Table 36.5. Serum cobalamin frequently falls in folate deficiency, becoming subnormal in approximately 10% of cases, and recovers after folate therapy⁴⁵; such cases must be differentiated from combined deficiency of both vitamins. Cobalamin levels also decline during pregnancy, affecting 35% of women by the last trimester.^{45, 245} Levels can fall below 100 ng/L, but recover within days after delivery. The explanation is unknown, and metabolic studies do not find cobalamin deficiency.^{245, 246} Unexplained low cobalamin levels, most often without evidence of deficiency, also occur in patients with human immunodeficiency virus (HIV) infection,^{247, 248, 249} but the incidence has fallen from 27% to 8.7% because of high supplementation rates and more active retroviral therapy. Other conditions associated with unexplained low cobalamin levels include multiple myeloma^{250, 251} and multiple sclerosis.²⁵² An unexplained association with obesity²⁵³ may result from expanded plasma volume. Hereditary TC I deficiency is a frequent cause of low cobalamin levels^{80, 254} but acquired TC I deficiency, such as in severe neutropenic states²⁵⁵ and aplastic anemia, can also do so. Drugs, such as oral contraceptives and metformin, also cause mildly low cobalamin levels without inducing deficiency.^{256, 257, 258}

Elevated cobalamin levels are more frequent than low ones in clinical practice and are often unexplained.⁷⁸ The most common association of high levels was with renal failure,⁷⁸ although patients undergoing chronic high-flux hemodialysis have low levels.²⁵⁹ Other causes include liver disease²⁶⁰ and recent cobalamin therapy. A host of uncommon diseases with high plasma TC I levels, either because TC I is overproduced or because abnormally glycosylated TC I is cleared slowly, accumulate high cobalamin levels secondarily.^{72, 78, 79, 260} The diseases include chronic myelogenous and acute promyelocytic leukemias,⁵⁶ metastatic cancer,²⁶¹ fibrolamellar hepatoma,²⁶² and adult-onset Still's disease.²⁶³

P.940

In autoimmune lymphoproliferative syndrome, lymphocytes surprisingly contained TC I.²⁶⁴ When chronic myelogenous leukemia coexists with pernicious anemia, cobalamin levels are normal, not low.²⁶⁵ Spontaneous⁸² or therapy-acquired²⁶⁶ autoantibodies to TC II retain holo-TC II, leading to elevated cobalamin levels. Some blood-collection tubes containing separator gel produce higher cobalamin levels.²⁶⁷ Like TC I and TC II levels, cobalamin levels tend to be higher in blacks than in whites and Asians,²⁶⁸ which may have a genetic basis. Serum cobalamin is also mildly elevated in homozygotes for the common G461A nonsense mutation of the $\alpha^1, 2$ -fucosyltransferase gene FUT2, which regulates Lewis ABO(H) antigen expression,^{269, 270} but the mechanism whereby it affects the cobalamin level is unknown. *H. pylori* status was unrelated,²⁷⁰ making initial assumptions that FUT2 polymorphism affected cobalamin levels via *H. pylori*-related malabsorption unlikely.

TABLE 36.5 CAUSES OF LOW SERUM COBALAMIN LEVELS

Clinical cobalamin deficiency

Pernicious anemia (atrophic gastritis with loss of IF)

Hereditary IF deficiency

Post-gastrectomy state

Acquired intestinal disease with cobalamin malabsorption

Imerslund-Grösbeck syndrome

Small bowel bacterial overgrowth

Veganism

Infant exclusively breast-fed by mother with veganism or PA

Subclinical (biochemical) cobalamin deficiency

Food-cobalamin malabsorption (e.g., non-PA gastritis, gastric surgery)

Drugs

Vegetarianism

Idiopathic

Conditions associated with unexplained low cobalamin levels^a

Pregnancy

Folate deficiency

Cobalamin transport changes

Hereditary TC I deficiency

Acquired TC I deficiency (e.g., severe granulocyte disorders, ?metformin therapy)

Congenital specific-granule deficiency

Unexplained associations^a

Disorders with pancytopenia (e.g., aplastic anemia, myelodysplasia, PNH, hairy cell leukemia)

Other diseases (e.g., HIV infection, multiple myeloma, multiple sclerosis)

Drugs (e.g., oral contraceptives,^b anticonvulsants)

Pre-analytic influences^a

Inappropriately high cutpoint and reference range selection^c Hemodilution

IF, intrinsic factor; PA, pernicious anemia; PNH, paroxysmal nocturnal hemoglobinuria; TC I, transcobalamin I (haptocorrin).

^a Evidence of metabolically or clinically defined cobalamin deficiency or malabsorption has been found in only some cases in these categories.

^b Does not apply to post-menopausal hormone replacement.

^c Frequencies of “low levels” depend greatly on cutpoint selection, which is often arbitrary.

The impact can be great; for example, the frequency of “low levels” increases twofold or more following the shift of the cobalamin cutpoint from 200 ng/L to 300 ng/L.

Red cell cobalamin has little diagnostic value because levels are low in many other anemias; reticulocyte counts influence red cell cobalamin strongly.⁴⁵

Serum Folate

Folate deficiency, using megaloblastic anemia as a criterion, is traditionally defined by a serum folate level below 2.5 µg/L (also expressed as 5.7 nmol/L; 1 µg = 2.266 nmol.) However, using homocysteine elevation as the criterion implicates serum folate below 4.5 to 5.0 µg/L^{271, 272} or even 6.5 µg/L.²⁷³ These findings justify viewing serum folate levels between 2.5 and 5.0 µg/L with suspicion, especially in countries using folic acid fortification.

Pre-analytic influences abound. Ascorbate must be added to protect samples stored for a few days against oxidative damage. Spuriously high levels occur in hemolyzed blood samples, which release red cell folate into serum. Serum folate, which is mostly methylTHF, also tends to rise as cobalamin deficiency advances, and it becomes high in approximately 30% of cases^{45, 46} (Table 36.4). The new generation of automated nonisotopic assays is inadequately documented compared with older methods. Assay imprecision is frequently unexplained.²⁷⁴ Following dietary fortification and growing supplement use, subnormal results have become rare.

Red Blood Cell (Whole Blood) Folate

MethylTHF (60%) and formylTHF (26%) are the major folates in red cells.²⁷⁵ A red cell's folate content is constant and is viewed as a truer indicator of tissue folate than are serum levels, which fluctuate with changes in folate intake. Red cell levels below 160 µg/L are usually considered low,^{45, 276} but the reference intervals vary among laboratories and methods.

Red cell folate results cannot differentiate between folate and cobalamin deficiency (Table 36.4). Levels were low in 63% of cobalamin-deficient patients²⁷⁶ because the accumulating methyl-THF fraction is less easily polyglutamated and therefore poorly retained by cells. Because reticulocytes are rich in folate, red cell folate is high in states of intense reticulocytosis such as hemolytic anemia.²⁷⁶ Red cell folate, much of it bound to hemoglobin,²⁷⁷ is also slightly higher in deoxygenated than oxygenated cells. Transfusion, of course, invalidates red cell folate results. The greater variability and methodologic difficulties than with serum folate^{45, 238, 274} have led to divergent views about the usefulness of red cell folate assay.^{233, 278}

Plasma Total Homocysteine

Homocysteine rises with either folate or cobalamin deficiency (Table 36.4) and in many other conditions (Table 36.6). This nonspecificity limits its diagnostic value, but a normal result helps to exclude clinically relevant deficiency. The sensitivity exceeds 95% in clinically expressed cobalamin deficiency, with levels often above 50 µmol/L in pernicious anemia, but sensitivity is only 86% in clinical folate deficiency.²⁷⁹ Milder elevations and poorer sensitivity characterize its performance in subclinical deficiency of either vitamin.^{240, 280} Homocysteine falls several days after appropriate treatment of deficiency and becomes normal within a week.²⁴²

Plasma total homocysteine, which consists of reduced homocysteine and its oxidized forms, homocystine and mixed disulfides, can be measured by various chromatographic and automated immune or enzyme-based methods. Unfortunately, results vary among laboratories,²⁸¹ as do reference intervals. Major preanalytic influences include the requirement for plasma, as well as its immediate separation from blood cells, to minimize artificial cellular release of homocysteine, but many laboratories use serum for convenience and cost saving. Fasted samples are not necessary as long as a large meal is avoided. Age and sex affect normal levels.²⁸² Homocysteine values double between childhood and old age.²⁸¹ Levels above 12 to 14 µmol/L in women and 14 to 15 µmol/L in men are generally regarded as elevated. However, even normal levels can often be reduced by giving folate,²⁸³ which may reflect either unrecognized depletion or interaction with genetic and other influences.

As reviewed elsewhere,²⁸¹ homocysteine rises in many acquired and genetic conditions (Table 36.6). Folate intake and serum creatinine levels (even if still within the normal range) are major determinants of homocysteine status; creatinine measurement is advisable whenever the homocysteine level is high. Cobalamin levels assume greater influence in the elderly,^{282, 284} and the influence has increased in countries with folate fortification.

Levels of both cystathionine, a product of homocysteine transsulfuration, and AdoHcy, a product of remethylation, also rise in

P.941

folate and cobalamin deficiencies.²⁸⁴ Methionine levels, surprisingly, are usually unremarkable.^{116, 284}

TABLE 36.6 CAUSES OF ELEVATED HOMOCYSTEINE LEVELS

Causes	Degree of Homocysteine Elevation^a
Vitamin deficiency states	
Clinical cobalamin deficiency (acquired or hereditary ^b)	Mild to severe
Subclinical cobalamin deficiency	Mild or none
Folate deficiency (acquired or hereditary ^c)	Mild to severe
Vitamin B ₆ deficiency	Mild or none ^d
Riboflavin deficiency	Mild or none
Medical conditions	
Renal failure ^e	Mild to moderate
Post-transplantation	Mild to moderate
Hypothyroidism	Mild

Acute lymphocytic leukemia	Mild
Psoriasis	Mild
Drugs and toxins	
Alcohol abuse	Mild to severe
Methotrexate and other antifols	Mild to severe
Trimethoprim; anticonvulsants; fenofibrate; cyclosporine A	Mild
Drugs affecting vitamin B ₆ (e.g., niacin, azauridine)	Mild ^d
Levodopa	Mild
Nitrous oxide toxicity (causes cobalamin inactivation)	Mild to severe

Genetic disorders

Cystathionine β -synthase deficiency	Severe
Methylene tetrahydrofolate reductase polymorphisms (homozygous C677T or A1298C mutations)	Mild or none ^f

Physiologic and lifestyle factors^g

Male sex; older age	Mild
Coffee, smoking	Mild

Artifact

Use of serum sample instead of plasma; delay in centrifugation	Mild, but can be variable
Selection of inappropriately low cutpoint	Variable

^a Homocysteine elevations are categorized arbitrarily here as mild (15 to 25 $\mu\text{mol/L}$), moderate (25 to 50 $\mu\text{mol/L}$), and severe (>50 $\mu\text{mol/L}$).

^b Homocysteine elevation does not occur in genetic cobalamin disorders in which methylcobalamin function is spared.

^c Plasma homocysteine elevation does not occur in cerebral folate deficiency.

^d Often inapparent unless post-methionine-loading measurement is done.

^e Homocysteine elevation may occur even with serum creatinine changes within the reference interval.

^f Often inapparent unless folate status is also compromised.

^g It is not always known if other influences contribute to the differences attributed to these factors.

Methylmalonic Acid

MMA, a product of accumulated D-methylmalonyl CoA, increases in serum and urine in cobalamin deficiency but not in folate deficiency, making MMA a more specific test for cobalamin deficiency than homocysteine. MMA is also subject to fewer pre-analytic influences. Serum levels are elevated in 98.4% of patients with clinical deficiency, such as pernicious anemia.²⁷⁹ Most laboratories consider MMA elevated above 280 nmol/L (0.28 $\mu\text{mol/L}$), but published cutpoints have varied between 210 and 480 nmol/L,²⁸⁵ which predictably affects the diagnostic frequency of abnormality.^{190, 191} Levels often exceed 1,000 nmol/L in clinical deficiency but are usually only mildly elevated in SCCD. MMA becomes normal within a week after cobalamin therapy;²⁴² folate therapy has no effect.

Elevated MMA is often used as sole evidence of cobalamin deficiency in epidemiologic studies²⁸⁶ and in validating the performance of other biomarkers, such as holo-TC II.¹⁹⁰ However, despite a high sensitivity that allows a normal MMA level to exclude the possibility of cobalamin deficiency, MMA susceptibility to many cobalamin-unrelated influences (Table 36.7) disqualifies it as a diagnostic gold standard.^{190, 192} Independent influences on the MMA level include not only cobalamin status but also serum creatinine, age, and sex, but these account for only 16% of MMA variation.²⁸⁷ Some MMA elevations are unexplained, and mild, isolated, and often spontaneously fluctuating elevations are common in SCCD.^{192, 240} The observation that nonelevated MMA levels can fall after antibiotic therapy^{242, 288} suggests intestinal bacteria contribute to serum MMA, perhaps through bacterial propionate metabolism. High MMA levels are common during the first year of life but they are transient.²⁸⁹ Their explanation is unknown, but the MMA levels respond to cobalamin therapy also.²⁹⁰

Serum MMA assay is now automated and increasingly available in reference laboratories. Less information is available about urine MMA assay. An alternative product of propionyl CoA metabolism, 2-methylcitric acid, rises in cobalamin deficiency.²⁹¹

P.942

TABLE 36.7 CAUSES OF ELEVATED METHYLMALONIC ACID LEVELS

Cobalamin deficiency

High-normal serum creatinine

Renal failure

Old age

Unexplained transient elevation in normal babies in first year of life^a

Hereditary disorders of cobalamin metabolism in which methylmalonate metabolism is affected

Hereditary disorders of methylmalonate metabolism (e.g., methylmalonyl CoA mutase deficiency)

Methylmalonate metabolism polymorphisms

? Bacterial contamination of the small bowel^b

Idiopathic

^cApplication of a liberal cutpoint for methylmalonic acid assay

^aIt is unclear if subclinical cobalamin deficiency exists in some cases.

^bReduction of methylmalonic acid levels has been described after antibiotic therapy in patients with bacterial contamination of the small bowel. The phenomenon has been attributed to propionate metabolism by bacteria.

^cThe optimal cutpoint for methylmalonic acid has not been defined. Laboratories and studies that use lower cutpoints than usual (e.g., 210 nmol/L) identify greater numbers of subjects with “high” or “abnormal” levels.

Holo-transcobalamin II

Holo-TC II, which carries all cobalamin available to cells, is conceptually attractive as a substitute for measuring total cobalamin, most of which is carried by TC I and unavailable to cells.²⁹² It is presumed to be very sensitive to cobalamin depletion because it is more often abnormal than other markers of cobalamin status. Serum levels are thought to represent a balance between holo-TC II entering the bloodstream, from the gut and perhaps elsewhere, and its very rapid uptake by tissues. However, it is unclear whether serum holo-TC II, whose half-life is measured in minutes, is more sensitive to intermittent transport fluxes than to the long-term changes in cobalamin stores that lead to cobalamin deficiency;¹⁹⁰ for example, it is unknown if temporarily reduced (i.e., 1 or 2 weeks) inflow from the gut, due to transiently

reduced dietary intake or transient malabsorption caused by drugs, may reduce serum holo-TC II without there being any cobalamin depletion, which takes years. The contribution of holo-TC II reabsorbed in the renal tubule is also unknown.

Moreover, holo-TC II validation rests largely on comparisons against cobalamin assay, with MMA as the (unsatisfactory) arbiter of cobalamin status in surveys of subjects with SCCD.^{244, 293} As reviewed elsewhere,¹⁹⁰ these analyses showed marginal superiority of holo-TC II to total cobalamin in SCCD, but clinical assessment has been insufficient and some clinical studies identified shortcomings. Chief among the shortcomings has been poor holo-TC II specificity.^{190, 244, 294} Reported confounding causes of low holo-TC II include oral contraceptive use,²⁵⁶ a common TCN2 A67G polymorphism,⁷¹ alcoholism and various hematologic disorders such as myelodysplasia,²⁹⁵ and an effect of malabsorption independent of cobalamin adequacy.²⁹⁶ Much work remains to be done²⁹⁷ before recommendations that holo-TC II become the primary tool to determine cobalamin status²⁹⁸ can be accepted.

Other Tests

Loss of the normal ability of added deoxyuridine to suppress thymidine incorporation into DNA by bone marrow cells deficient in cobalamin or folate²⁹⁹ is as sensitive a test for cobalamin deficiency as homocysteine or MMA assay.³⁰⁰ The test served to first document and define SCCD.^{94, 95, 96, 180} Adding cobalamin or folates to the cells can usually differentiate between the two deficiencies.^{299, 301} This labor-intensive test has been replaced by metabolite testing.

Formal diagnostic trials of reticulocyte response to a dose of folic acid or cobalamin small enough to ensure the specificity of response to it³⁰² are no longer needed. Nevertheless, objective documentation of the clinical response to therapy often has diagnostic value and is an important part of management.

SPECIFIC DISORDERS CAUSING COBALAMIN OR FOLATE DEFICIENCY

Diagnostic evaluation must include identification of the specific condition responsible for the deficiency. Identification of the cause helps confirm the diagnosis of deficiency, ascertains the prognosis, and is invaluable for management. The underlying cause predicts the rate at which deficiency, especially of cobalamin, progresses or relapses. Often, the cause itself can also be treated directly.

Causes of Cobalamin Deficiency

The discussion of causes follows the order of the cobalamin assimilation and utilization steps illustrated in Figure 36.4. The overwhelming majority of clinically apparent cobalamin deficiencies are malabsorptive in origin, of which pernicious anemia is the most common.

Dietary Insufficiency

Adults

The circumscribed dietary source for cobalamin and the huge ratio of body stores to daily loss protect most adults from becoming severely deficient on a purely dietary basis. Malnutrition limited to a few weeks or months does not produce cobalamin deficiency. The adults at risk tend to be committed, long-term vegetarians, especially vegans, but even they seldom become sufficiently depleted to develop megaloblastic anemia or myelopathy. A study of vegetarian women showed that their cobalamin intake was 1.68 ± 1.60 $\mu\text{g}/\text{day}$, one half that of nonvegetarian controls.³⁰³ Surveys of vegetarians identify little or no change in MCV,^{304, 305} and macrocytic anemia is uncommon. Most often, vegetarians display SCCD, with mild biochemical abnormalities.^{306, 307, 308} The risks are greater in those with lifelong dietary inadequacy in developing countries, such as India, where public health measures may be warranted.³⁰⁹ Sometimes, metabolic abnormalities persist even after the diet has been liberalized.³⁰⁷ Coexisting disorders, such as malabsorption, should be explored in vegetarian adults who actually develop symptoms of deficiency.^{310, 311}

Children

Young children, who must negotiate normal neurologic development and normal expansion of cobalamin stores simultaneously often have more serious consequences of dietary restriction. Children in macrobiotic communities show persistent metabolic abnormalities³¹² and an often suspect cognitive performance,³¹³ even years after starting cobalamin supplementation. Phenylketonuric diets restricted in animal protein may predispose to mild biochemical cobalamin deficiency.^{314, 315}

The consequences can be much more catastrophic for babies born to and exclusively breast-fed by mothers who are strict vegetarians or have undiagnosed pernicious anemia.^{170, 315, 316, 317, 318} It is instructive of the cobalamin differences between adults and children that the mothers are asymptomatic and only mildly deficient, whereas the children have severe neurologic and developmental abnormalities, often including movement disorders, which may increase just after therapy is begun.³¹⁹ Long-term deficits may persist.³²⁰ Although the frequency of the syndrome in at-risk babies is

unknown, maternal deficiency is thought to be the most common cause of cobalamin deficiency in childhood.¹⁴² The impact on growth and developmental retardation is unclear but preventive efforts are warranted.

P.943

Malabsorption

Pernicious Anemia

The defect that defines pernicious anemia is not the anemia but the loss of IF that produces severe malabsorption of all forms of cobalamin. The atrophic gastritis that is universal in acquired pernicious anemia differs from the more common atrophic gastritis, which maintains IF secretion long after acid secretion ceases.^{321, 322}

With its loss of the parietal cells that synthesize IF, pernicious anemia is irreversible and many features suggest its autoimmune nature.^{45, 322, 323} At least one of two autoantibodies to gastric antigens is found in 85% of cases, one directed against IF and one against the parietal cell; the gastric histology suggests an inflammatory disorder, cell-mediated immune abnormalities have been reported, steroid therapy sometimes restores IF secretion, and other autoimmune disorders often coexist.

The gastritis has been subdivided into types A and B.³²⁴ Type A gastritis is found in 80% to 90% of patients with pernicious anemia, although it is the less common gastritis form in the general population; it is characterized by the presence of parietal cell antibody and is limited to the fundus while sparing the antrum, which is often hypertrophic. Type B pangastritis usually results from *Helicobacter pylori* infection and lacks such autoantibodies. Although it is the most common gastritis generally, only 10% to 20% of patients with pernicious anemia have it, suggesting that its role in pernicious anemia is infrequent.³²⁵

Pernicious anemia appears to have a familial predisposition, and relatives have increased frequencies of atrophic gastritis, antibodies to parietal cells, and thyroid disease.^{45, 326} Pernicious anemia is diagnosed most often after the age of 60 years,⁴⁵ although the gastritis begins many years earlier.³²⁷ A survey of the elderly in Los Angeles found that 1.9% had unrecognized, often pre-clinical pernicious anemia.¹⁸⁹ Earlier surveys in Scandinavia reported prevalences of 0.13% to 0.2% among all ages.⁴⁵ Women are affected almost 50% more often than men in most surveys.^{45, 328} Although northern Europeans have the highest rates, pernicious anemia is universal.^{45, 189, 268, 328, 329, 330, 331, 332} The frequency in blacks may approach that in whites.¹⁸⁹ The reason why black women develop the disease more often before 50 years of age than do whites and have antibody to IF more often is unknown;³²⁸ American Hispanics display a less significantly younger age trend for pernicious anemia.^{268, 331} Even in whites, approximately 10% of cases occur at a young age, sometimes in childhood or adolescence.⁴⁵ Called juvenile pernicious anemia in children, it is accompanied by especially high rates of gastric antibodies, immune endocrinopathy, and a positive family history.

In addition to causing relentless cobalamin deficiency, pernicious anemia carries many disease-specific associations and prognostic implications. The most serious is an increased risk for two gastric tumors, both predominating in the fundus.³²² A Swedish registry showed a 26.4-fold increased risk of gastric carcinoid and a 2.2-fold increased risk for gastric adenocarcinoma.³³³ The carcinoid tumors metastasize in only 20% of cases, however.^{322, 334} The increased risk for gastric carcinoma has been widely but not unanimously accepted.^{45, 322, 335, 336, 337, 338} Many authors recommend endoscopy at the time of diagnosis in every patient with pernicious anemia,³³⁹ but routine re-examinations are not advised. An increased risk of esophageal squamous cell carcinoma³³³ is controversial.

Iron deficiency affects 21% of patients at diagnosis of pernicious anemia and another 23% develop it later.³⁴⁰ An independent cause is not always found, suggesting that iron malabsorption due to gastritis and achlorhydria plays a role.³⁴¹ Bacterial contamination of the stomach and upper small bowel, presumably abetted by achlorhydria, has been described in pernicious anemia.³⁴² An increased frequency of gallstones has also been suggested.³⁴³

At some point, approximately 10% of patients develop clinical or latent thyroid disease, most often hypothyroidism.³⁴⁴ Related autoimmune disorders associated with pernicious anemia include vitiligo, hypoparathyroidism, hypoadrenalism, and myasthenia gravis.⁴⁵ An unusual coexistence is with agammaglobulinemia or common variable immunodeficiency;³⁴⁵ the patients are young, have type B gastritis, often have bacterial overgrowth, and are at very high risk for gastric cancer. Other immune associations of pernicious anemia may include immune thrombocytopenia, immune hemolytic anemia, transient red cell aplasia, diabetes mellitus, biliary cirrhosis, chronic lymphocytic leukemia, and renal tubular acidosis.^{45, 346, 347, 348, 349, 350, 351} Links have also been suggested with myelodysplasia, leukemia, and myeloproliferative diseases,^{265,}

^{338, 352, 353, 354} and perhaps with sickle cell anemia. ^{355, 356} An increased rate of tuberculosis was reported in Asian Indians and Chinese with pernicious anemia. ^{330, 332}

Hereditary Intrinsic Factor Deficiency

Also called congenital pernicious anemia, this autosomal recessive disorder is characterized by an absent, unstable, or nonfunctional gastric IF^{142, 357, 358, 359} (Table 36.8). Gastric status is otherwise normal, although unexplained basal hypochlorhydria sometimes occurs.³⁵⁷ Several mutations of the GIF gene have been found,^{360, 361} some in patients originally misdiagnosed to have Imerslund-Grösbeck syndrome because of spurious Schilling test results. Hereditary deficiencies of IF and TC I, whose genes lies near each other, coexisted in one family.³⁶² Patients with hereditary IF deficiency usually develop anemia, myelopathy, and, occasionally, developmental delay in the first few years of life as cobalamin stores from birth become depleted. Infrequently, diagnosis is delayed until adolescence or later.³⁵⁷

Food-cobalamin Malabsorption

Studies in 1973 demonstrated that absorption testing with free crystalline cyanocobalamin, such as in the Schilling test, failed to identify defective release of food-bound cobalamin.³⁶³ As reviewed elsewhere,¹⁹⁵ tests using food vehicles revealed that many patients could not absorb food-bound cobalamin while absorbing free cobalamin normally, the disparity that is diagnostic for food-cobalamin malabsorption (when free cobalamin absorption fails, as in pernicious anemia, of course, food-bound cobalamin cannot be absorbed either).

The crux in food-cobalamin malabsorption appears to be the loss of pepsin and the acid secretion needed for optimal pepsin activity, without losing IF secretion³⁶⁴ (Fig. 36.4, panel 1). Most prominent among patients with food-cobalamin malabsorption were those with partial gastrectomy, other gastric surgery, or gastritis, all of whom had intact IF secretion. However, the gastric disorders are heterogeneous. Some patients have severe autoimmune gastritis and achlorhydria but others have *H. pylori* induced gastritis.³⁶⁵ Although it may have therapeutic implications as a reversible cause of malabsorption,³⁶⁵ the association with *H. pylori* infection lacks sufficient diagnostic sensitivity and specificity to be equated with food-cobalamin malabsorption.^{240, 366, 367} Food-cobalamin malabsorption improves after antibiotic therapy sometimes, but whether this reflects the disappearance of *H. pylori*³⁶⁵ or anaerobic bacteria,³⁶⁸ or both, was not proven directly. Reported cures of cobalamin deficiency anemia solely by eradicating *H. pylori* require more documentation.²⁴⁰ Patients taking acid-suppressive drugs, such as omeprazole, also malabsorb food cobalamin;^{195, 369} cobalamin deficiency is infrequent in them, although low cobalamin levels were reported in a retrospective study of patients who may have had other predispositions to low levels.³⁷⁰

Food-cobalamin malabsorption need not cause cobalamin deficiency, perhaps because it is sometimes reversible and because it may not abrogate reabsorption of biliary cobalamin, but it affects 30% to 40% of people with SCCD.¹⁹⁵ Severe deficiency occurs much less often.^{96, 195, 311, 371, 372} Progression to pernicious anemia with loss of IF has been reported in a few cases.^{311, 371}

↑, increased levels; ↓, decreased levels; ado-cbl, adenosylcobalamin; Cbl, cobalamin; HC, haptocorrin; Hcys, homocysteine; IF, intrinsic factor; MMA, methylmalonic acid; MM-CoA, methylmalonyl coenzyme A; mod, moderate; N, normal levels; TC, transcobalamin.

Gastric Surgery

Subtotal gastrectomy eventuates in cobalamin deficiency in 15% to 30% of patients.^{45, 373, 374} Some of these patients develop clinical deficiency with megaloblastic anemia and neuropsychiatric problems. However, absorption of free cobalamin (Schilling test) most often remains normal,³⁷⁵ and most patients have only food-cobalamin malabsorption and SCCD.^{195, 363} Iron deficiency and folate malabsorption may also develop.^{376, 377} Food-cobalamin malabsorption and SCCD complicate other gastric procedures too, such as bariatric surgery.^{378, 379}

Pancreatic Insufficiency

Pancreatic proteases degrade TC I and release its cobalamin for transfer to IF.⁸⁴ One half of patients with chronic pancreatic insufficiency have abnormal Schilling test results, requiring exogenous pancreatic extract for correction. It is unclear why such apparently severe malabsorption rarely, if ever, eventuates in clinically apparent cobalamin deficiency.

Bacterial Overgrowth of the Small Bowel

Large enough numbers of bacteria may accumulate in the upper small bowel if anatomical abnormalities (e.g., fistulas, strictures, large diverticula) or motility disorders exist (e.g., autonomic dysfunction in diabetes). Bacteria take up cobalamin and, in that location, may compete with IF for it.³⁸⁰ Bacteria also generate nonfunctional corrinoid analogs,³⁸¹ whose contribution to the cobalamin deficiency is unclear. The deficiency can be clinically overt and is sometimes the only obvious manifestation of bacterial

P.945

overgrowth. Antibiotics reverse the malabsorption, but relapse occurs if the cause of bacterial overgrowth persists.

Parasitic Infestation

The classic parasitic cause of cobalamin deficiency is *Diphyllobothrium latum*, which infests freshwater fish.^{45, 382} The tapeworms in the upper small intestine compete avidly for cobalamin. Most patients are asymptomatic, but cobalamin levels are often low.³⁸³ It is uncertain whether the worm load or coexisting conditions, such as a frequent atrophic gastritis, determine the extent of deficiency. The infection is rare in the United States. *Giardia lamblia* has been associated with cobalamin malabsorption, particularly in children and immunocompromised patients, but it is unclear if the association is a causal one. Low cobalamin levels have been reported in heavy *Strongyloides stercoralis* infection.³⁸²

Gastrinoma

The Zollinger-Ellison syndrome can cause cobalamin malabsorption. The basis appears to be the low pH in the intestine.³⁸⁴ Ileal uptake of the IF-cobalamin complex requires a neutral pH.

Ileal Diseases

If they involve enough of the ileum, acquired diseases impair receptor-mediated absorption of IF-bound cobalamin (Fig. 36.4, panel 3). Schilling tests had successfully demonstrated malabsorption refractory to oral IF or antibiotics and led to a

diagnostic pursuit of the specific ileal disease. The tests' disappearance has made these malabsorptive diagnoses inaccessible.

Tropical sprue is endemic in the Caribbean, South Asia, and elsewhere. Manifestations can appear long after a person has emigrated. Cobalamin deficiency occurs in chronic cases and is sometimes the sole clinical finding.^{385, 386} Some patients have folate deficiency instead, especially early in the course, or have both deficiencies. The vitamin differences may vary regionally, as does the often impermanent response of tropical sprue to folate and antibiotics. As in all acquired ileal diseases, other nutrients are often at risk also. The disease's prevalence appears to be declining but a subclinical tropical enteropathy may exist.³⁸⁷

The frequency of cobalamin malabsorption and deficiency varies in celiac disease, inflammatory bowel disease, and dermatitis herpetiformis.^{388, 389} Deficiency often depends on the extent of ileal involvement, and resections that exceed 20 cm make deficiency more likely.³⁹⁰ Atrophic gastritis may sometimes contribute to the deficiency. Ileal malabsorption has been associated with acquired immunodeficiency syndrome but does not explain most of the low cobalamin levels (see the "Cobalamin Levels" section of "Laboratory Tests of Deficiency").

As noted, the risk of cobalamin malabsorption and deficiency after ileal surgery appears to be proportional to its extent. Long-term malabsorption occurs with jejunioileal bypass for obesity.^{391, 392} Deficiency has also been attributed to malabsorption with ileal reservoirs for the ureters in patients with bladder cancer^{393, 394} and for restorative proctocolectomy in ulcerative colitis.³⁹⁵ Puzzlingly, however, Schilling tests have been normal with ileal reservoirs.³⁹⁵

Imerslund-Gräsbeck Syndrome (Megaloblastic Anemia Type 1)

Selective malabsorption of cobalamin arises from genetic defects affecting the ileal IF receptor (Table 36.8). Two mutations of the cubilin gene have been identified in Finnish families;^{396, 397} some Norwegian families have mutations of the amnionless gene,³⁹⁸ and other mutations of these genes have been reported in the Mediterranean area and elsewhere.³⁹⁹ The malabsorption is limited to cobalamin and usually produces classical clinical signs of deficiency in the first few years of life.^{142, 400, 401} Diagnosis is occasionally delayed and, with disappearance of the Schilling test, differentiation from hereditary IF deficiency can be difficult. The disorder is often accompanied by mild and apparently benign proteinuria because cubilin, a multiligand receptor, also reabsorbs albumin in renal tubular cells.^{402, 403}

Drugs, Toxins, and Related Toxicities

Many drugs and toxins interfere with cobalamin absorption, usually by unknown mechanisms. Examples include alcohol, colchicine, neomycin, cholestyramine, paraaminosalicylic acid, and slow-release potassium, but the true list of offending drugs is probably longer. Cobalamin deficiency rarely occurs with any of them because exposure and malabsorption must be uninterrupted and last for several years in order to deplete cobalamin stores. Few drugs fulfill those criteria. The low cobalamin levels in metformin users have been widely equated with cobalamin deficiency, yet MMA levels are normal;²⁵⁷ the low cobalamin may represent acquired TC I deficiency instead.²⁵⁸

Transport and Cellular Defects

Most disorders of cobalamin transport to cells and cellular utilization are genetic in origin and usually affect children. In contrast with malabsorptive and dietary disorders, their effects usually develop rapidly and serum cobalamin levels are usually normal.

Transcobalamin II Deficiency and Transcobalamin II Receptor Defect

Deficiency of TC II impairs cobalamin delivery to cells, although some cobalamin enters cells by unknown, presumably nonspecific means (Table 36.8). TC I-bound cobalamin continues to circulate, so normal cobalamin levels are maintained, with rare exceptions.⁴⁰⁴ The children typically have megaloblastic anemia and failure to thrive in the first year of life.¹⁴² Neurologic dysfunction is less frequent⁴⁰⁵ and may appear chiefly when treatment is inadequate.⁴⁰⁶ Some children also have infections suggesting immune hypofunction.⁴⁰⁷ Schilling test results have often been abnormal, perhaps because TC II must take up the absorbed cobalamin. The diagnosis requires immunoassay of total TC II, but a nonfunctional TC II has also been described.⁴⁰⁸ Several TCN2 mutations have been identified.^{409, 410} Patients respond to frequent cobalamin injections. Oral therapy has been used after stabilization, but complications have also been attributed to undertreatment.⁴¹¹

The phenotype is very different in deficiency of TC II receptor caused by homozygous TCbIR/CD320 nonsense mutation:⁴¹² moderate methylmalonic aciduria is the lone finding and there are no symptoms. The explanation for this paradoxical presentation is unknown.

Transcobalamin I (Haptocorrin) Deficiency

This disorder, often mistaken for and treated as cobalamin deficiency, is typically uncovered in adults with unexplained low cobalamin levels (Table 36.8). Serum cobalamin is low because 70% or more of it is carried by TC I. Cellular and metabolic cobalamin status is normal.^{83, 254, 413, 414, 415} Corrinoid analogs, typically carried by TC I, appear to be absent in severely TC I-deficient plasma;⁸⁰ tissue analog content is unknown. A few patients have had atypical, probably unrelated neurologic dysfunction that was unaffected by cobalamin therapy,^{254, 415} and probably reflects coincidence or selection bias for cobalamin testing (which led to TC I testing). The diagnosis requires demonstration of TC I absence in plasma and secretions, such as saliva, which is typical of severe deficiency. Nine severely deficient patients, all non-Caucasians, have been identified, and the frequency in a prospective survey of samples with low cobalamin levels appears to be 0.6%.²⁵⁴ A combined deficiency of TC I and lactoferrin, which are synthesized together in specific granules of myeloid cells and in exocrine gland epithelium, was found in a family;⁴¹⁵ interestingly, the affected patients were not predisposed to infection. Another family had coexisting deficiencies of TC I and IF, whose genes are not far apart.³⁶²

P.946

TC I deficiency was thought rare until a mild deficiency identical to that seen in obligate heterozygous relatives of severely deficient patients,⁴¹⁵ was found in 15% of patients with low cobalamin levels.²⁵⁴ Such patients have low or low-normal levels of plasma TC I and saliva TC I. The diagnosis requires ruling out cobalamin deficiency and measuring plasma TC I (serum often provides spuriously normal TC I results). Four heterozygous TCN1 mutations,^{356, 416, 417} also seen in severely deficient patients with homozygous or compound heterozygous mutations, were found in 34 affected members in 24 families.⁸⁰

Nitrous Oxide Toxicity

Nitrous oxide oxidizes cob(I)alamin, irreversibly inactivating the methionine synthase to which the cobalamin is bound.⁴¹⁸ Because exposure during dental and surgical procedures is brief and enzyme is regenerated quickly, clinical expression does not occur despite mild metabolic abnormalities lasting a few days.^{419, 420} There are two exceptions to the benign consequences. One is repetitive exposure,^{421, 422} such as "recreational" abuse of the gas. The other is when a patient with unrecognized, clinical cobalamin deficiency is exposed to nitrous oxide during lengthy or repeated surgery.^{423, 424, 425, 426} Within days, megaloblastic anemia results but neuropsychiatric dysfunction is often especially severe.

Nitric oxide also reacts with cobalamin and inhibits methionine synthase,⁴²⁷ but no clinical impact is known.

Cbl Mutations

Inborn errors affecting intracellular cobalamin metabolism, designated cbl mutations (Table 36.8), are sorted by their metabolic changes, whether homocystinuria, methylmalonic aciduria, or both. The disorders are then differentiated by complementation studies in which the metabolic behaviors of patients' fibroblasts fused with known-disease fibroblasts are compared. Most genes are known but the proteins coded by some of them are unknown.¹⁴²

Homocystinuria without MMA elevation marks the cblE defect, caused by methionine synthase reductase deficiency; the cblG defect, caused by methionine synthase deficiency; and the cblD-variant 1. Megaloblastic anemia and prominent neurologic problems occur, usually in the first few years of life,⁴²⁸ but diagnosis can sometimes be delayed.⁴²⁹ Therapy is generally effective, although the neurologic problems are difficult to reverse unless treated early.

Isolated methylmalonic acidurias (cblA, cblB, cblD-variant 2, mutase, and epimerase defects) affect adenosylcobalamin, which is required in the methylmalonyl CoA mutase reaction, or other methylmalonyl enzymes. The cblB defect affects adenosyltransferase, whereas mitochondrial reduction of cobalamin appears to be defective in cblA and cblD-variant 2.¹⁴² These disorders cause lethargy, vomiting, dehydration, failure to thrive, hypotonia, and acidosis but do not produce megaloblastic anemia.⁴³⁰ Presentation is in the first months of life, but the course and response to cobalamin may vary. The clinical picture in cblD-variant 2 was complicated by an intracranial hemorrhage at birth. The two mutase defects affect the methylmalonyl CoA mutase enzyme itself: muto, characterized by enzyme deficiency, and mut-, with abnormal enzyme. Methylmalonyl CoA epimerase (racemase) deficiency was described in a patient with mild MMA elevation.⁴³¹ The mutase and epimerase defects do not involve cobalamin or respond to it, have either no clinical manifestations or just the mild ones seen in other methylmalonic acidurias, and are mentioned only for the differential diagnosis of methylmalonic aciduria.

The combined homocystinuria-methylmalonic acidurias include the cblC, cblD, cblF, and cblJ defects, which affect both methylcobalamin and adenosylcobalamin. Megaloblastic anemia is prominent in cblC, often with a microangiopathic and thrombocytopenic process resembling the hemolytic uremic syndrome,⁴³² but megaloblastic anemia is muted in cblD and

cbfF defects.⁹³ Many children with cblC, the most common of the cbl disorders, have severe courses marked by neurologic dysfunction, acidosis, perimacular degeneration, and thromboses.⁴³³ Prognosis is often poor. The cblD defect can vary in hematologic and neurologic severity and includes venous thromboses.^{93, 434} The defect involves the MMADHC gene, which has a cobalamin binding motif and a putative mitochondrial targeting sequence.⁴³⁴ CblD is puzzling because, despite complementation identity, different mutations of the gene can produce homocystinuria, methylmalonic aciduria, or both;^{434, 435} each is discussed within its metabolic group. Variable presentations are seen in the cblF and cblJ defects, in which lysosomal export appears defective.^{436, 437, 438}

Increased Requirements

High demand for cobalamin in hypermetabolic and increased cell turnover states has been proposed, but its documentation is incomplete. Patients with clinical consequences have yet to be identified satisfactorily.

Old Age

Normal aging does not cause cobalamin deficiency but common disorders of aging, such as gastritis and gastric atrophy, predispose to it.^{178, 322, 439} The elderly are at increased risk for both clinically expressed and subclinical deficiencies, including the most common causes of each form, pernicious anemia and food-cobalamin malabsorption, respectively. Although frequencies vary with the studied population and the test cutpoint selection, most studies estimate that 10% or more of the elderly are affected, with SCCD outnumbering clinical deficiency severalfold. The frequency of low cobalamin levels outnumbers low folate levels^{191, 440}.

Elevated cobalamin levels appear to be independent predictors of mortality in elderly patients with or without cancer.^{441, 442} The explanation is unknown.

Causes of Folate Deficiency

The origin of folate deficiency is often multifactorial. Limited intake may not be able to compensate for increased folate demand, or a drug or genetic polymorphism that mildly inhibits folate metabolism can convert borderline folate intake into frank deficiency. That being said, the landscape of folate deficiency has changed dramatically as a result of food fortification and folate supplement use. The incidence of deficiency has decreased sharply. Between 1988-1994 and 2001-2002, the frequency of serum folate levels below 3 µg/L declined from 18.4% to 0.2% of the American population and that of red cell folate below 160 µg/L declined from 45.8% to 7.1%, across all economic and demographic strata.⁴⁴³ Other studies reported even greater impact in those who also took folate supplements.⁴⁴⁴ The folate status of American elderly leapfrogged that of younger adults, largely because of higher rates of supplement use,⁴⁴³ whereas Europeans, with less exposure to fortification and supplements, showed metabolic signs of folate deficiency as they aged further.⁴⁴⁵

Dietary Insufficiency

The relatively small ratio of folate stores to daily requirement makes it possible to become folate-deficient after only a few months of poor intake, and the likelihood and speed of deficiency are enhanced when other causes coexist. The most common of these is abuse of alcohol,⁴⁴⁶ especially hard liquor, which also contains little folate.

Children

Delivery of maternal folate to the fetus is efficient,⁴⁵ so folate deficiency is rare at birth. Folate levels decline thereafter, and problems arise in some children in whom growth demands and limited diet combine. Premature infants have especially high requirements.⁴⁴⁷ The availability of folate from milk is limited.⁴⁵ Deficiency can appear in babies whose diet depends heavily on milk and who do not receive folate-fortified foods or supplements.

P.947

Folate deficiency can also occur with restricted diets, such as those given for phenylketonuria.

Malabsorption

Intestinal Malabsorption

Documented in only 2% of folate-deficient patients in one study,²⁷⁹ malabsorption is a distant second to malnutrition and alcoholism as a cause of folate deficiency. Deficiency appears early in tropical sprue, which can feature marked gastrointestinal symptoms and other absorptive defects.^{385, 386} The intestinal lesion itself can remit with folate therapy, although the remission can be limited. Celiac disease also causes folate malabsorption and deficiency in some patients, with or without cobalamin deficiency.^{389, 448} Inflammatory bowel disease, such as Crohn disease, which involves ileum most prominently, produces folate deficiency less often.⁴⁴⁹ Folate malabsorption has been described in patients with

dermatitis herpetiformis. The impact, if any, of food fortification on folate deficiency in patients with malabsorption requires study.

Other Malabsorptive Mechanisms

Folate absorption is reduced in atrophic gastritis and other gastric disorders or with drugs that cause achlorhydria.^{377, 450, 451, 452} It is not clear how often deficiency results.⁴⁵¹ Similarly, folate absorption diminishes when oral pancreatic replacement therapy, which buffers pH, is given for pancreatic insufficiency,⁴⁵³ whereas cobalamin absorption may improve.

Drugs and Toxins

Alcohol abuse is a major contributor to folate deficiency⁴⁴⁶ and should be suspected even when other causes of deficiency are found. The risk is highest in alcoholics who eat poorly, but alcohol also has direct effects on folate metabolism and transport. The latter include interruption of the enterohepatic recycling of hepatic methylTHF, direct toxicity to enterocytes, formation of aldehyde adducts, and increased degradation of folates.^{454, 455, 456, 457}

Sulfasalazine interferes with folate absorption and perhaps with folate-related enzymes.⁴⁵⁸ Hydantoin, and to a lesser extent other anticonvulsants, have been associated with macrocytosis and low folate levels, but megaloblastic anemia is uncommon.⁴⁵ The mechanisms are unclear. Valproic acid inhibits mitochondrial folate metabolism and affects fetal folate metabolism.⁴⁵⁹ Antifolates, such as methotrexate, inhibit folate binding to dihydrofolate reductase and thus limit the availability of THF (Fig. 36.2, reaction 1). Their effect can be bypassed by administering reduced folates such as 5-formylTHF (leucovorin; folinic acid). Trimethoprim-sulfamethoxazole and pyrimethamine are potent inhibitors of bacterial dihydrofolate reductase but weak inhibitors of the human enzyme. They cause megaloblastic anemia infrequently but appear to do so especially in patients with other limitations of folate status.⁴⁶⁰ Oral contraceptive use has been associated with diminished serum folate levels, but deficiency has not been well documented.

Inborn Errors of Folate Transport and Metabolism

Methylene Tetrahydrofolate Reductase Deficiency

Homozygous deficiency of this enzyme (Fig. 36.2, reaction 3), to be distinguished from the common polymorphism that causes no disease, produces severe neurologic dysfunction, including myelopathy, developmental delay, seizures, and microcephaly.¹⁴² Thrombosis may also occur. Symptoms usually arise in the first year, but mild cases may not be diagnosed until adulthood. Anemia does not develop because methyleneTHF remains available for thymidylate synthesis (reaction 2). Serum folate is low because methyleneTHF cannot be converted to methylTHF, the main circulating form of folate. The diagnosis is made by measuring enzyme activity in fibroblasts or leukocytes, which correlates with disease severity. Many mutations of the reductase gene have been identified.¹⁴² Early treatment, which includes betaine, is essential.⁴⁶¹

Hereditary Folate Malabsorption

This rare disorder is characterized by impaired transport of folate across both the intestinal mucosa and the choroid plexus because of mutations affecting the proton-coupled folate transporter, which is located at both those sites.^{36, 37} As a result, serum, red cell, and cerebrospinal fluid folate levels are very low. Megaloblastic anemia and severe neurologic dysfunction, including seizures, appear in the first few months of life.¹⁶¹ Diarrhea, mucositis, immunodeficiency, and failure to thrive also occur. Intensive parenteral and even intrathecal therapy have often been used, but some patients respond well to oral folinic acid.^{37, 161}

Cerebral Folate Deficiency

Cerebral folate deficiency is characterized by decreased cerebrospinal fluid methylTHF, whereas, unlike in hereditary folate malabsorption, folate absorption and systemic metabolism are normal.¹⁶² Thus, it features mental and neurologic manifestations similar to hereditary malabsorption but lacks low serum and red cell folate levels and megaloblastic anemia. Many affected children display mutations of the FOLR1 gene that codes for FR- α , which regulates methylTHF transport across the choroid plexus.^{462, 463} Others have autoantibody to FR- α instead,^{162, 464} including one middle-aged adult.⁴⁶⁵ Unrelated conditions can produce varying degrees of the same cerebral methylTHF deficiency without apparent mutations or FR- α abnormality.^{162, 466} These miscellaneous conditions await clarification. As illustrated in the next section, various hereditary disorders can produce similar pictures. The cerebral folate deficiency often responds to folinic acid;^{162, 467} folic acid is contraindicated.

Miscellaneous Folate Disorders

Five members from two families with megaloblastic anemia, seizures, microcephaly, and developmental delay had dihydrofolate reductase deficiency. They had normal serum folate and cobalamin levels but displayed a cerebral folate deficiency syndrome, with methylTHF deficiency and tetrahydrobiopterin deficiency limited to cerebrospinal fluid.^{467, 468} Hematologic improvement rapidly followed folinic acid therapy, but neurologic improvement was incomplete.

A mutation of the MTHFD1 gene, which encodes a single protein with three enzyme activities in folate metabolism (Fig. 36.2, reaction 6), was identified in a child with megaloblastic anemia, atypical hemolytic uremic syndrome, immunodeficiency, and homocystinuria.⁴⁶⁹

A single report of familial aplastic anemia with defective cellular uptake of folate⁴⁷⁰ remains a mystery.

Genetic Polymorphisms

No clinical consequences have been confirmed for many missense mutation polymorphisms affecting genes for folate-related enzymes and transport proteins.⁷⁰ The best-studied exception is the gene for methyleneTHF reductase, whose C677T and, to a lesser extent, A1298C mutations are common in most populations except blacks. These polymorphisms produce mildly diminished enzyme activity and no direct symptoms. However, mild hyperhomocysteinemia is seen if folate intake or levels are diminished in persons homozygous for the C677T mutation. Consequences such as increased risks for neural tube defect births and cardiovascular risks have been described and often appear tied to lower levels of folate intake.⁴⁷¹ It is interesting that reduced leukemia and colorectal cancer risks have been associated with this mutation.⁴⁷²

Increased Demand or Increased Losses

Fetal needs divert maternal folate via placental receptors. Other settings for increased demand for folate are lactation, chronic hemolytic anemia, and perhaps psoriasis and myeloproliferative

P.948

diseases. Evidence for stress on folate metabolism by increased requirements exists but lacks clear metabolic proof of depletion.^{35, 473, 474, 475, 476} Deficiency usually results when dietary intake cannot compensate adequately or disorders such as alcohol abuse or malabsorption supervene. Folic acid is often given routinely to pregnant women and patients with chronic hemolysis. However, a frequent mild elevation of homocysteine in sickle cell anemia appears unrelated to folate status or supplementation,⁴⁷⁷ and a randomized supplementation trial in sickle cell anemia failed to show clinical benefits.⁴⁷⁸ The increased detection of pernicious anemia in patients with sickle hemoglobinopathy suggests that monitoring is advisable by physicians who routinely prescribe folic acid.^{355, 356}

Folate is lost during dialysis, and supplements are often given. Alcohol abuse, anticonvulsants, and oral contraceptives have been proposed to cause increased folate catabolism and loss.⁴⁷⁹

Syndromes of Unknown Cause

A syndrome of acute deficiency, megaloblastic changes in bone marrow (but not peripheral blood), and pancytopenia was described in severely ill patients in intensive care units;⁴⁸⁰ serum folate levels have been normal. The entity is unclear because such patients have many illnesses and receive many drugs.

Causes of Megaloblastic Anemia Other than Cobalamin or Folate Deficiency

Thiamine-responsive Megaloblastic Anemia

A familial syndrome of megaloblastic anemia, diabetes mellitus, and sensorineural deafness can occur during childhood or adolescence.^{481, 482} Some patients may have additional features.⁴⁸³ The megaloblastic anemia and diabetes improve at least partially with thiamine therapy. Neither folate nor cobalamin has a known causative or therapeutic role. Several mutations of the thiamine transporter-1 gene have been found.^{483, 484, 485, 486} The patients have no evidence of thiamine deficiency.

Hereditary Orotic Aciduria

Megaloblastic anemia unrelated to folate or cobalamin accompanies developmental delay, orotic acid crystalluria, and ureteral problems in affected children.⁴⁸⁷ There is clinical heterogeneity. Some patients also have congenital malformations and immune deficiency. The defect usually involves the gene for both orotate phosphoribosyltransferase and orotidine 5'-monophosphate decarboxylase, which catalyze uridine-5-monophosphate synthesis. Oral uridine is effective.

Miscellaneous Causes

Chemotherapeutic agents that affect nucleoprotein synthesis, such as hydroxyurea and 5-fluorouracil, cause megaloblastic anemia. More easily distinguishable from megaloblastic anemia are the bizarre nuclear changes in arsenic toxicity.

Myelodysplastic syndromes occasionally feature nuclear characteristics that resemble megaloblastic change, but hyposegmentation of neutrophil nuclei ("pseudo-Pelger-Huet") is more common than hypersegmentation. Erythroleukemia and some cases of acute myelogenous leukemia also show megaloblastlike nuclear dysplasia in erythroid precursors.

Laboratory Diagnosis of the Causes of Deficiency

Cobalamin Deficiency

Malabsorption is the main suspect when evaluating causes because approximately 94% of cases of clinical cobalamin deficiency in adults have gastrointestinal origins.²⁷⁹ The situation has been modified by the increasing, often accidental identifications of patients with the usually clinically irrelevant SCCD, which is much less often associated with malabsorption.^{178, 179}

Although malabsorptive disorders in children, whether classically acquired as in adults or hereditary, are not unusual, the diagnostic approach in children differs and depends on age and other issues. Genetic metabolic disorders tend to present in early childhood but can be delayed; MMA and homocysteine must usually be measured because cobalamin levels may be normal. Maternal cobalamin status must also be part of the evaluation of very young children.

Direct Tests of Cobalamin Absorption

The classic absorption test, the Schilling test, assessed absorption of free crystalline cobalamin by measuring urinary excretion of an oral dose of ⁵⁷Co-labeled cyanocobalamin that approximated the amount in a meal.^{45, 488} If excreted radioactivity was subnormal, the test was repeated with an oral dose of IF. Correction of an abnormal result by IF diagnosed pernicious anemia; lack of correction suggested an intestinal problem. If results became normal upon re-testing after antibiotic treatment or with an oral pancreatic extract, intestinal bacterial overgrowth or pancreatic insufficiency, respectively, were likely. The Schilling test and all its variants have disappeared because of concerns about isotope use, limited and suspect sources of IF, and the tests' inconvenience and occasional unreliabilities.⁴⁸⁸

Probably contributing to the test's disappearance were misperceptions that diagnosing malabsorption was clinically irrelevant, which may have been reinforced by the large influx of new patients with SCCD, whose results were consistently normal.⁴⁸⁸ A new absorption test measuring serum holo-TC II response to oral cobalamin⁴⁸⁹ has not been convincingly validated.

Several food-cobalamin absorption tests have identified impaired release of ingested cobalamin from its binding to food proteins, using ⁵⁷Co-labeled cobalamin attached to egg, egg yolk, or chicken serum as vehicles in a procedure otherwise identical to the Schilling test which tested only absorption of free cobalamin.^{195, 363, 375} These tests have disappeared as well. Substitution of often mistaken, indirect criteria for direct foodcobalamin absorption testing has generated a series of unreliable reports by some authors, as noted elsewhere.⁴⁸⁸ Blood tests for gastritis/gastric atrophy or H. pylori status are also unreliable surrogate markers.^{240, 366}

Autoantibody to Intrinsic Factor

Testing serum for antibody to IF sometimes permits the diagnosis of pernicious anemia without having to resort to the Schilling test. Type I antibody, which blocks the cobalamin-binding site of IF, is slightly more frequent and more easily tested than type II antibody, which complexes with a nonbinding IF epitope. Antibody is found in 50% to 70% of patients with pernicious anemia, with the higher frequencies when more sensitive assays are used.^{490, 491, 492} Some groups of patients have higher rates; 96% of black women with pernicious anemia are positive.³²⁸ With the disappearance of Schilling tests, IF antibody, whose specificity exceeds 95%,^{45, 493} is the only practical option for diagnosing pernicious anemia, despite its poor sensitivity. However, serum containing excess free cobalamin often produces false-positive IF antibody results; blood samples obtained within days after a cobalamin injection must be avoided.⁴⁹⁴

Autoantibody to Gastric Parietal Cell

Parietal cell antibody is directed to the membrane H⁺,K⁺-adenosine triphosphatase pump subunits pre-existing in cytoplasmic tubulovesicles.^{323, 495} The antibody occurs in 80% to 90% of patients with pernicious anemia. However, it is specific for immune gastritis, not for pernicious anemia.⁴⁹⁶ Moreover, the

antibody tends to disappear with time,⁴⁹⁷ and it is not as sensitive as IF antibody in many types of patients, such as the young and some ethnic groups.^{332, 491}

Functional Blood Tests of Gastritis and Gastric Atrophy

Serum gastrin is elevated in 80% to 90% of patients with pernicious anemia,⁴⁹⁸ reflecting their gastric achlorhydria and frequent antral hypertrophy.^{322, 324} Levels tend to be very high, often in the thousands, particularly in women.^{491, 498} However, hypergastrinemia has many, more frequent causes, such as nonpernicious anemia atrophic gastritis or omeprazole use. Serum pepsinogens also reflect gastric status. Pepsinogen I, derived from fundic chief cells, is usually decreased in pernicious anemia, whereas pepsinogen II, which derives from fundus and antrum, is normal or elevated because of antral sparing in most patients with pernicious anemia.⁴⁹⁹ A low pepsinogen I-to-II ratio or low pepsinogen I level, or both, may be the most sensitive blood tests for pernicious anemia⁴⁹⁸ but have limited specificity. None of the tests mentioned in this section are diagnostically reliable in food-bound cobalamin malabsorption either.³⁶⁶

Direct Gastric Tests

Measuring IF content in stimulated gastric juice is the most reliable test for pernicious anemia but requires gastric intubation and is not generally available. Measuring gastric acid secretion has some diagnostic value because the presence of acid rules out Addisonian pernicious anemia.

Tests of Intestinal Function

Without the Schilling test, intestinal malabsorption of cobalamin is not identifiable. Today, intestinal malabsorption can only be suggested if other gastroenterologic tests, such as blood tests for celiac disease or ileal biopsy, identify a specific disease. Duodenal biopsy is more accessible than ileal biopsy but has much less diagnostic relevance to cobalamin.

Cobalamin-binding Proteins

Serum TC II assay identifies TC II deficiency in children with unexplained cobalamin deficiency (usually, but not always, accompanied by normal cobalamin levels) but is rarely needed when evaluating adults. TC I assay (testing plasma, and never serum) is useful in patients of all ages with unexplained low cobalamin levels who are asymptomatic or have equivocal symptoms.²⁵⁴ Measuring apoproteins with cobalamin-binding capacity assays is not as useful as immunoassays for total TC II or TC I, and becomes unreliable after cobalamin injection which saturates apoproteins, rendering them unmeasurable. TC I assays, and to a lesser extent TC II assays, can sometimes also help explain high cobalamin levels.^{56, 78, 260}

Folate Deficiency

Because dietary insufficiency, alcohol abuse, and drug effects often contribute to folate deficiency,²⁷⁹ a careful history is usually the most effective diagnostic test. Malabsorption must be considered when a dietary cause is not apparent. Tests of folate absorption are unavailable, and response to oral folic acid does not rule out malabsorption.

Acquired causes of deficiency predominate in children too. Dietary deficiency may occur in specific settings and can be aggravated by the demands of growth and development. Hereditary disorders are rare but can be severe.¹⁴² They may feature low folate levels, as in methyleneTHF reductase deficiency or hereditary malabsorption, or normal levels. Relevant enzymes can be measured and genetic mutations are increasingly identifiable. If neurologic symptoms exist, measuring cerebrospinal fluid folate, including methylTHF, can be diagnostically helpful whether serum levels are normal or not.

MANAGEMENT

Management of cobalamin and folate deficiencies extends beyond giving the right vitamin and can be complex.¹⁹³ It can be undermined by patient noncompliance¹²⁷ and by physician error, which most often involves underestimation of the disorder and its requirements, especially the value of precise diagnosis of underlying causes. Management goals are to reverse symptoms; select the appropriate dose, route, and duration of vitamin replacement; ensure that the vitamin deficiency was identified correctly and that the patient responded appropriately; identify the underlying disorder that caused the deficiency and treat it directly, if possible, define its prognosis, and manage its complications; and provide patient education. These goals do not apply easily to SCCD, whose need for therapy is undefined.¹⁹³

Reversal of Presenting Symptoms

Course

Megaloblastic anemia reverses quickly with the correct vitamin. The patient often begins to feel better within a day, before anemia improves. New reticulocytes appear in 2 to 3 days. Effective hematopoiesis replaces ineffective hematopoiesis, as lactate dehydrogenase and bilirubin decline and maturation of erythroid precursors becomes more normoblastic. Although neutrophil hypersegmentation persists for 2 weeks or more,¹⁰⁵ white blood cell and platelet counts rise in the first week if they had been decreased. Peak reticulocytosis occurs at 7 to 10 days. As new normocytic cells accumulate, which can be detected with reticulocyte-specific profiling,¹⁰⁸ the MCV declines. The blood count becomes fully normal before 8 weeks have elapsed. In most cases, neurologic improvement becomes noticeable in the first few weeks.

There are no signs or symptoms to reverse in patients with SCCD, but occasionally mild signs can be identified retroactively upon their improvement after cobalamin therapy.

Monitoring the Response

Homocysteine and MMA levels begin to fall within a few days of therapy and can be used to monitor response;^{183, 184} monitoring vitamin levels, whether cobalamin, holo-TC II, or serum folate, has little value because plasma levels rise passively regardless of therapeutic effectiveness. Reticulocyte response can be assessed best at the end of the first week, and it is always useful to determine completeness of hematologic response after 8 weeks. An incomplete response at either time usually indicates a coexisting anemia, perhaps one that was initially inapparent; most often, the cause is iron deficiency, which can be masked in megaloblastic anemia. A poor response can also indicate that the original diagnosis was incorrect.

The extent of neurologic improvement cannot always be predicted. In general, the likelihood of full reversal with cobalamin is inversely related to the duration of symptoms before therapy was started and the extent of the original dysfunction. Whatever reversal can be expected is usually completed by 6 months, but improvement occasionally continues until a year or more. Progression despite therapy throws doubt on cobalamin deficiency as its cause.

Blood Transfusion

Patients with megaloblastic anemia tend to compensate for even severe anemia surprisingly well⁵⁰⁰ and usually can be managed supportively until cobalamin therapy takes effect. The temptation

P.950

to transfuse should be resisted unless coexisting conditions or worrisome symptoms and signs (e.g., cardiopulmonary or cerebrovascular) require immediate intervention. If transfusion is given, care must be taken to avoid aggravating the pre-existing volume overload.

Vitamin Replacement

Unless folate and cobalamin deficiency coexist, using both vitamins together has uncertain benefits and, done reflexively, can muddy the specificity of the response and the patient's understanding of the medical condition.

Cobalamin Deficiency

Rapid reversal of anemia or neurologic dysfunction is achieved most reliably with intramuscular cobalamin. Cyanocobalamin use predominates in the United States and is the model here, although hydroxocobalamin is more physiologic and its better retention allows less frequent injection.⁵⁰¹ Methylcobalamin can also be used but its advantages are unclear. As little as 1 to 2 μg of cobalamin produces quick hematologic response, but a series of 1,000- μg injections is usually given during the first few weeks. Because nonspecific intestinal absorption of cobalamin is very limited, many details of subsequent therapy depend on whether the IF mechanism is intact. When absorption is normal, oral cyanocobalamin can usually be used, and doses of 2 to 5 μg do not substantially exceed IF capacity. Intranasal and sublingual preparations, which bypass IF, have no proven advantages, and may be ineffective if rhinitis or other mucosal conditions exist.

If free cobalamin cannot be absorbed, as in pernicious anemia, most maintenance regimens call for 100 to 1,000 μg cyanocobalamin given intramuscularly once a month. Most of the 1,000- μg dose is excreted rapidly in the urine, but the amount retained (100 to 150 μg) is greater than with 100- μg doses (55 μg retained). Very high oral doses, long known to be effective even in patients with pernicious anemia,⁵⁹ have been resurrected with daily oral doses of 1,000 μg (or even 2,000 μg) as a suitable alternative,⁵⁰² although clinical response has not been consistently optimal.⁵⁰³ The advantage of oral therapy is avoidance of injection, with its discomfort, costs, and inconvenience. This must be weighed against the need to take a large dose every day, often for life; the need to monitor periodically because daily compliance is surely

poorer in daily practice than it has been among research volunteers; and the incomplete documentation of equivalence of neurologic improvement after oral and parenteral cobalamin.¹⁹³ Because relapse occurs sooner when oral rather than parenteral therapy is discontinued,¹²⁸ repletion of stores by injection before embarking on oral maintenance is advisable.

Cobalamin replacement must continue for as long as the underlying cause persists. Occasional patients seem to require more frequent injections for unknown reasons^{59, 193} and should be allowed to do so or be given hydroxocobalamin. The only known side effects of cobalamin are rare allergic or even anaphylactic reactions, sometimes to the preservative. Some patients treated with depot preparations of hydroxocobalamin form anti-TC II antibodies, which seem to produce no effects other than very high serum cobalamin levels.²⁶⁶ Isolated British reports of high rates of sudden death during treatment of severe megaloblastic anemia, attributed to the transient hypokalemia in early hematologic response to therapy (in fact, similar hypokalemia accompanies treatment of iron deficiency anemia), have not been confirmed.⁵⁰⁴ Giving potassium preventively is unnecessary unless special circumstances dictate it.

The optimal treatment of elderly patients (or anyone) with SCCD is unclear. Oral 6- μ g doses, typical of most multivitamins, are not always effective.^{378, 379} Controlled trials of graded oral doses in elderly persons with SCCD reported persistent MMA abnormalities until daily doses exceeded 50 to 500 μ g^{505, 506, 507} but did not document absorption status or why the poor responses occurred.²⁴⁰ The assumption that food-cobalamin malabsorption allows normal absorption of free cobalamin when taken with meals is untested and may be mistaken.¹⁹³

Hereditary disorders require individually tailored therapy and close monitoring because expression, severity, and response vary even in the same disorder. Other sources can be consulted for relevant details.¹⁴²

Folate Deficiency

Oral synthetic folic acid is stable and efficiently absorbed.³⁵ Daily doses of 1 mg usually suffice, and it is better absorbed than food folate, even by patients with malabsorptive disorders. Monitoring the response can determine if higher doses or intramuscular injections are needed. Body stores can be repleted within a month or two. The need to continue longer is guided by the underlying disorder, its persistence or likelihood of recurrence, and the patient's dietary, medical, and social details.

Treatment of children with inborn errors of folate metabolism calls for larger doses, often given parenterally, and may require specialized regimens.¹⁴² Folinic acid is needed for disorders that require reduced folic acid, such as cerebral folate deficiency, and in patients using drugs that inhibit dihydrofolate reductase.

Direct toxicity of folic acid is minimal.⁵⁰⁸ Seizure disorders have worsened in some patients receiving large doses intravenously.⁵⁰⁹ Concern about folate administration to someone with unrecognized and untreated clinical cobalamin deficiency has engaged attention because of adverse experiences in patients with pernicious anemia. The anemia of cobalamin deficiency usually responds at least partially to folic acid, although relapse occurs eventually.^{152, 153} In the meantime, unchecked neurologic progression can occur. This issue with diverse ramifications is discussed further in the section, "Preventive and Other Uses of Supplements."

Assurance of Response

The diagnosis of deficiency is often made with varying degrees of certainty, especially in minimally symptomatic patients. The less clear the original evidence, the greater is the value of monitoring therapeutic response.

Managing Underlying Disorders Causing the Deficiency

Pernicious anemia is the most likely cause for clinically obvious cobalamin deficiency, but other malabsorptive causes account for at least 25% of cases.²⁷⁹ This sizeable minority includes independently treatable causes whose identification may be simple (e.g., the history of gastric surgery) or require greater effort (e.g., pursuing bacterial overgrowth). An important goal is to determine how long therapy must continue. As to pernicious anemia, conclusive diagnosis has tangible clinical value despite the disease's irreversibility. For example, it confers the confidence to recommend endoscopy to screen for cancer and to insist upon lifelong cobalamin therapy. Ironically, many patients (and some physicians) attribute cobalamin deficiency to dietary inadequacy, which accounts for only 1% of clinically expressed cases. The dietary inadequacy needed to create clinically overt deficiency is usually dramatic and obvious.

The diagnostic pursuit of causes of folate deficiency is diametrically different. Poor diet is by far the most common cause and malabsorption is among the least common.²⁷⁹ The post-fortification era has removed much of the folate deficiency attributable to inadequate intake alone.^{443, 510} The causes today need to be reexamined to determine if fortification has left behind mostly the

deficiencies requiring medical interventions, such as alcoholism, small bowel disease, and drugs affecting folate status.

Patient Education

Pernicious anemia is a prototype of the ideal medical encounter: a disease with potentially disastrous consequences that is easily and safely treated. Yet, therapy is frequently discontinued.¹²⁷ Patient education about cause, course, and prognosis is critical. Noncompliance occurs in many serious diseases throughout medical practice, especially those with toxic or inconvenient therapies. Just the opposite may be operative in pernicious anemia; its simple vitamin therapy may lull patients (and sometimes physicians) into complacency about its medical importance.^{511 512}

Preventive and Other Uses of Supplements

Nonmedical vitamin use is widespread, especially among the elderly, women, whites, and the affluent. Thirty-five percent of American adults report recent supplement use,⁵¹³ and 38% of the elderly have folate levels above 20 µg/L.⁵¹⁰ Both folate and cobalamin are generally viewed as beneficial and innocuous. However, experience with chronic supplementation using high daily doses in minimally deficient and nondeficient persons is limited.

Folic Acid

Folic acid fortification has successfully reduced NTD rates, leading to advocacy for raising fortification levels further to maximize the prevention²¹¹ and for raising cobalamin intake.⁵¹⁴ Self-supplementation is popular for purposes of varying validity, and the 1 mg folic acid intake limit advised by the Food and Drug Administration to reduce the likelihood of masking undiagnosed cobalamin deficiency³⁵ is often exceeded with supplements.

Three categories of adverse consequences are being investigated, with still tentative conclusions. First, epidemiologic studies have not provided consistent answers about folate-related neurologic and cognitive risks in persons with SCCD,^{154, 179, 515, 516, 517, 518, 519, 520, 521} Second, levels of unmetabolized folic acid appear to be high as serum folate levels several times normal have become common in the general population.^{520, 522, 523, 524} Whether folic acid poses adverse oxidative risks has been inconclusive.^{522, 525, 526} Third, folate deficiency is linked with higher cancer risk, especially well documented in colorectal cancer,⁵²⁷ and high folate intake has decreased that risk.^{528, 529} Yet, folate may also accelerate precancerous conditions, such as colonic adenomatous polyps.⁵²⁷ All this suggests a binary folate effect, reducing risk of new neoplasia and accelerating transformation of precancerous lesions. To this have been added unexpected data, including clinical trials, linking high folic acid intake, with or without cobalamin and pyridoxine, with risks of other cancers, such as breast cancer,^{530, 531, 532} but other studies disagree.^{533, 534}

A homocysteine-lowering trial in patients with diabetic nephropathy found that folic acid, cobalamin, and pyridoxine unexpectedly worsened renal function and vascular complications.⁵³⁵ It seems clear that safety issues of high folate intakes need careful study.^{527, 536}

Cobalamin

The public health debate about cobalamin supplementation programs for SCCD is in its early stages.¹⁷⁹ Most supplements contain 6 µg of cyanocobalamin, but many contain 25 µg or more. However, these usual doses may not suffice in the elderly or in persons with food-cobalamin malabsorption. Studies, including clinical trials, have reported many persons whose SCCD does not fully correct despite supplements of 100 µg or more.^{51, 240, 378, 379, 505, 506, 507} The absorptive or other limitations impairing responsiveness in the elderly need to be defined.

Evidence that high-dose cobalamin, folic acid, and pyridoxine supplementation may slow the progression of brain atrophy and cognitive decline^{204, 205} is of great interest. The mechanisms of these promising findings need elucidation, but so do concerns whether chronic intake of high daily doses of vitamins has any negative consequences.

The value of dietary fortification with cobalamin to circumvent the cobalamin deficiency-related risks of folate fortification is also unclear. Fortification with cobalamin must grapple with the paradox that bioavailability may be limited precisely in those who might benefit most, whereas those needing it the least absorb cobalamin efficiently (and may have been responsible for most of the seeming responsiveness to oral doses that studies of supplementation have reported). Studies must examine critical subsets, not just overall population-wide data. The efficacy and practicality of fortifying are not obvious currently, especially if high doses prove necessary.^{537, 538} The risks of chronic, daily intake of high doses are unknown, but accumulation of inactive cyanocobalamin in cells has been reported.⁵³⁹

Chapter 37

Inherited Aplastic Anemia Syndromes

Akiko Shimamura

Blanche P. Alter

The inherited bone marrow failure syndromes may primarily affect a single or multiple hematopoietic lineages. Four inherited bone marrow failure syndromes associated with aplastic anemia will be discussed in this chapter: Fanconi anemia (FA), dyskeratosis congenita (DC), Shwachman-Diamond syndrome (SDS), and congenital amegakaryocytic thrombocytopenia (CAMT). The congenital bone marrow failure disorders affecting primarily one cell line are discussed elsewhere in this text (Diamond Blackfan anemia, Chapter 39; Congenital Neutropenias, Chapter 57). While the inherited marrow failure disorders are rare, early diagnosis is important for optimal medical management, cancer surveillance, and family planning. Some of the disorders are associated with sensitivity to chemotherapy and radiation, and thus diagnosis of those underlying disorders prior to initiation of treatment of aplastic anemia or associated malignancies is crucial.

A careful medical and family history together with a thorough physical examination may provide important clues to distinguish acquired from inherited bone marrow failure.¹ A family history suggestive of cancer predisposition, such as malignancies at an unusually young age, may be obtained. A history of excessive toxicity following treatment with genotoxic agents may be present. A family history of congenital anomalies or stigmata characteristic of the inherited bone marrow failure syndromes may provide additional clues. Other potential etiologies for cytopenias should be ruled out. Once the diagnosis of an inherited bone marrow failure syndrome is made, it is important to test all family members at risk for the disease regardless of clinical symptoms since manifestations may vary widely among family members.

These disorders are increasingly being recognized in adults, who often manifest milder clinical phenotypes and whose first manifestation of an underlying inherited bone marrow failure syndrome may be aplastic anemia or malignancy.² With the advent of genetic and laboratory diagnostic testing, the diseases are also increasingly recognized in patients who lack the characteristic physical stigmata conventionally associated with the disease. Genetic test results must be interpreted critically and within the clinical context of the patient. Methodologic limitations of genetic testing and the distinction between functional mutations versus rare polymorphisms are important considerations.

FANCONI ANEMIA

FA is an inherited chromosomal instability syndrome with a variable clinical presentation that includes congenital anomalies, progressive pancytopenia, and cancer susceptibility. Guido Fanconi first reported a familial syndrome of pancytopenia and congenital physical abnormalities in 1927.^{3, 4} The diagnostic hallmark of FA is increased chromosomal breakage in response to DNA damaging agents such as mitomycin C (MMC) or diepoxybutane (DEB). Remarkable advances in the last few years have elucidated the molecular pathways disrupted in FA cells. Potential clinical implications of recent molecular studies will be discussed.

Clinical Features

FA should be considered in patients with congenital anomalies, aplastic anemia, or a family history of bone marrow failure or cancer susceptibility. The International Fanconi Anemia Registry (IFAR) analysis of 370 patients found that nearly 40% of patients had no reported physical findings.⁵ Aplastic anemia or malignancy may be the presenting sign of the underlying diagnosis of FA in the absence of physical anomalies or prior family history. The manifestations of FA can vary between affected members of the same family, suggesting that additional genetic, epigenetic, or environmental factors likely influence the disease course.

A wide range of congenital anomalies has been reported in FA patients (reviewed in Refs. 1, 6) (Table 37.1). Skin pigmentary changes, short stature, and radial bone and thumb abnormalities are the most common manifestations associated with FA, although these may be seen in some of the other inherited bone marrow failure syndromes as well. Abnormalities of the skeletal, ocular, renal, genital, aural, gastrointestinal (GI), cardiac, and central nervous systems have also been reported with high frequency.

The hematologic complications of FA typically present within the first decade of life. Early manifestations include moderate single or bilineage cytopenia with red cell macrocytosis. Elevated levels of fetal hemoglobin (Hb F) help to distinguish inherited from acquired aplastic anemia. Marrow failure may range in severity from mild asymptomatic cytopenias to severe aplastic anemia. This is in contrast to other chromosomal instability syndromes, such as ataxia telangiectasia, or Bloom syndrome, which are not typically associated with bone marrow failure.

Patients with FA are at increased risk of developing myelodysplasia (MDS) or acute myeloid leukemia (AML).^{7, 8} In a cohort study of 145 patients with FA, the cumulative incidence of AML reached 10% by age 24 years and plateaued thereafter.⁸ Patients with FA are also at increased risk of developing solid tumors, particularly squamous cell carcinomas of the head and neck, skin, GI tract, and genital tract.⁹ The cumulative incidence of solid tumors was low in younger patients but progressively increased with age starting at around 20 years of age, and reached 29% by age 48 years.⁸ FA patients, particularly those who have received

P.955

androgen treatment, are also at increased risk of liver tumors. Treatment of malignancies is limited by the low tolerance of FA patients to chemotherapy and radiation. Myeloid malignancies in FA patients have been successfully treated with hematopoietic stem cell transplantation (HSCT), though patient numbers are small and follow-up is limited. The role of pretransplant chemotherapy is unclear.¹⁰ For solid tumors, surgical resection is the mainstay of therapy. Regular and frequent surveillance for cancers is particularly important in this population and is discussed further in the section "Supportive Care." Patients with the FANCD1/BRCA2 subtype manifest an especially high rate of early onset AML and specific solid tumors (brain and Wilms) compared with other FA subtypes.^{11, 12, 13}

TABLE 37.1 PHYSICAL FINDINGS ASSOCIATED WITH FA

Skeletal

Short stature

Radial ray anomalies (thumbs, hands, radii)

Hip and spine anomalies

Skin

Hyperpigmentation (Café au lait spots)

Hypopigmentation

Genitourinary

Renal structural anomalies

Hypogonadism

Craniofacial

Microcephaly ophthalmic anomalies (microphthalmia, epicanthal folds)

Otic anomalies (external and middle ear anomalies, deafness)

Genitourinary

Hypogonadism

Renal anomalies

Gastrointestinal malformations

Esophageal atresia or tracheoesophageal fistula

Imperforate anus

Cardiac malformations

Growth hormone deficiency has been observed in rare FA patients,¹⁴ and treatment with growth hormone improved growth in a subset of these patients¹⁵; its use is controversial because of a hypothetical risk of cancer or leukemia.¹⁶ Additional endocrine disorders associated with FA include hypothyroidism with or without thyroid hormone binding globulin deficiency, abnormal glucose tolerance, and diabetes mellitus.^{14, 17} Although FA is associated with short stature, endocrine evaluation is important to rule out treatable endocrine causes that might further contribute to poor growth.

There are currently 15 known FA subtypes (A, B, C, D1 [BRCA2], D2, E, F, G, I, J [BRIP1, BACH1], L, M, N [PALB2], O [RAD51C], and P [SLX4]). With the exception of subtype B, which is X-linked recessive, all the other FA subtypes follow an autosomal recessive pattern of inheritance.^{18, 19} FA is found with similar frequencies in both genders and has no known ethnic restriction. The heterozygote carrier frequency has been recently reestimated at 1 in 181 in the United States and is higher in regions with founder effects such as Israel.²⁰ The mean age at diagnosis is generally reported to be between 7 and 9 years of age, with 75% of cases diagnosed between the ages of 4 and 14; however, FA has been diagnosed in neonates as well as in adults in their fifties.

Differential Diagnosis

Other inherited and acquired causes of bone marrow failure should be considered (see Chapter 41). FA may be considered in patients with characteristic congenital anomalies and may be the underlying diagnosis in patients with VACTERL-H (vertebral anomalies, anal atresia, cardiovascular malformations, tracheoesophageal fistula, renal and limb anomalies, plus hydrocephalus, MIM 276950).²¹ Cells derived from patients with other chromosomal breakage syndromes or syndromes with similar constitutional findings, such as Bloom syndrome or ataxia telangiectasia, may also exhibit high rates of spontaneous chromosomal breakage; however, they do not generally show increased chromosomal breakage in response to DNA crosslinkers such as MMC or DEB. Other chromosomal breakage syndromes are not typically associated with marrow failure. The exception is Nijmegen breakage syndrome, which may be associated with some increased chromosomal breakage with MMC and may be confused with FA.²² FA may also be considered in patients with a family history suggestive of cancer predisposition, patients presenting with cancers at an unusually young age, or patients who experience severe toxicity with chemotherapy or radiation.

FIGURE 37.1. Chromosomal breakage in FA. Peripheral blood lymphocytes from a FA patient were cultured without (left panel) or with (right panel) mitomycin C (MMC). The black arrows indicate chromosomal breaks. The red arrows indicate radial chromosomal fusions characteristic of FA. (Courtesy of Lisa Moreau, Dana Farber Cancer Institute, Boston, MA.)

Laboratory

Cell morphology on peripheral blood smear is typically unremarkable except for red cell macrocytosis and mild anisocytosis, though these are variably present. Thrombocytopenia or leukopenia typically precede anemia. Pancytopenia may be progressive over time. Erythrocyte macrocytosis and increased Hb F levels may be present even in the absence of cytopenias.

Bone marrow biopsy findings vary from normal cellularity to frank aplasia. Morphologic examination of the bone marrow aspirate may show dysplastic features, with nuclear-cytoplasmic maturation disynchrony. Dyserythropoiesis with multinucleate forms or nuclear fragmentation may be seen. Bone marrow aspirates should be sent for cytogenetic analysis, as FA patients are at high risk for malignant transformation. The appearance of cytogenetic clones of unclear clinical significance in the absence of morphologic evidence of MDS must be considered carefully, since cases of persistent or transient clonal abnormalities without apparent progression to leukemia have been reported.²³ At a minimum, patients with persistent unexplained changes in blood counts or new cytogenetic marrow abnormalities should be monitored closely with serial blood counts and a follow-up bone marrow examination to assess for possible malignant evolution. Amplification or gains of chromosome 3q26q29 were shown to correlate with increased risk of MDS and AML in one study.²⁴

The diagnosis of FA is based on the demonstration of increased chromosomal breakage in the presence of DNA cross-linking agents, such as MMC or DEB.^{25, 26} (Fig. 37.1) DEB is preferred in some centers since it is associated with less variability in chromosomal breakage among normal controls. The chromosomal breakage test is usually performed on metaphase spreads of peripheral blood lymphocytes cultured with MMC or DEB. A total of 50 metaphase cells are analyzed for chromosomal

P.956

breakage, including the formation of radial figures—a hallmark of this disease. Results are compared to a normal control and a positive control that have been run in parallel. Results are generally reported as aberrations per cell and the number of cells with breaks or radial forms. Increased spontaneous chromosomal breakage may be observed in some FA patients¹²; nonetheless, the rate of breakage is markedly enhanced by exposure to MMC or DEB regardless of patient

phenotype or severity of disease. Chromosomal breakage in response to MMC/DEB can also be assessed in fetal cells obtained for prenatal diagnosis by amniocentesis or chorionic villus sampling.^{27, 28} If the disease-causing mutation is known for a given family, these assays can be used for prenatal diagnosis or preimplantation genetic diagnosis.²⁹ FA patient cells also exhibit cell cycle abnormalities with G2 phase prolongation and arrest by flow cytometry.^{30, 31} Studies comparing results of DEB chromosomal breakage with cell cycle analyses of patients referred for FA testing showed close correlation between the results of these two tests.³² Constitutive elevation of serum alpha-fetoprotein (AFP) has been reported in FA patients,³³ although variations in AFP levels determined by different methodologies and the lack of specificity has limited the diagnostic utility of this test so far.³⁴ FA heterozygous carriers cannot be reliably detected by testing for chromosomal breakage. Genetic mutation testing is available for the FA genes.³⁵

Clonal somatic reversion to wild-type has been observed in a subset of cells from some FA patients. Increased chromosomal breakage may be limited to a subpopulation of lymphocytes in such patients. The reversion to normal cellular phenotype has been attributed to recombination or gene conversion events leading to selective growth advantage of the reverted cells^{36, 37}; somatic reversion has been reported in early hematopoietic lineages.³⁸ Patients with a high degree of wild-type mosaicism may be difficult to diagnose. In cases with a high degree of suspicion for FA and normal blood breakage analysis, the MMC/DEB test should be performed on skin fibroblasts, since somatic mosaicism has not been observed in fibroblasts.

Pathophysiology

Models of the FA biochemical pathway have emerged from molecular studies of the cloned FA gene products. The reader is referred to recent excellent reviews of this rapidly evolving field.^{39, 40, 41} At least 15 different FA complementation groups (A, B, C, D1 [BRCA2], D2, E, F, G, I, J [BRIP1, BACH1], L, M, N [PALB2], O [RAD51C], and P [SLX4]) have been identified, and the corresponding genes have also been identified⁴² (Table 37.2). The gene for Fanconi subtype D1 is the previously identified tumor suppressor gene, BRCA2.⁴³ Biallelic mutations in BRCA2 are associated with an increased risk of early onset leukemia¹¹ and solid tumors, particularly Wilms and midline brain tumors.^{12, 13} The FANCI/BACH1/BRIP1 gene encodes a DNA helicase, which is an enzyme that unwinds DNA. The FANCM (Hef) gene shares regions of homology with both helicases and endonucleases, though these functions have yet to be directly demonstrated. FANCM may function in DNA translocation. The FANCL/PHF9/POG gene shares homology with other E3 ubiquitin ligases. The most common FA subtype is FA-A (60%), followed by FA-C (14%) and FA-G (10%)⁴⁴; the other FA subtypes are rare. The types of mutations associated with FA are highly variable.

TABLE 37.2 FA GENES

Subtype	Gene	FA patients (Estimated) %	Inheritance Pattern	Chromosome Location	Ubiquitinated FANCD2
A	<i>FANCA</i>		60 Autosomal recessive	16q24.3	Absent
B	<i>FANCB</i>		2X-linked recessive	Xp22.31	Absent
C	<i>FANCC</i>		14 Autosomal recessive	9q22.3	Absent
D1	<i>FANCD1/BRCA2</i>		3 Autosomal recessive	13q12-13	Present
D2	<i>FANCD2</i>		3 Autosomal recessive	3p25.3	NA
E	<i>FANCE</i>		3 Autosomal recessive	6p21-22	Absent
F	<i>FANCF</i>		2 Autosomal recessive	11p15	Absent
G	<i>FANCG</i>		10 Autosomal recessive	9p13	Absent

I	<i>FANCI</i>	1 Autosomal recessive	15q25-q26	Absent
J	<i>FANCI/BACH1/BRIP1</i>	2 Autosomal recessive	17q22-q24	Present
L	<i>FANCL/PHF9/POG</i>	<1 Autosomal recessive	2p16.1	Absent
M	<i>FANCM/Hef</i>	<1 Autosomal recessive	14q21.3	Absent
N	<i>FANCN/PALB2</i>	<1 Autosomal recessive	16p12	Present
O	<i>FANCO/RAD51C</i>	<1 Autosomal recessive	17q22	Present
P	<i>FANCP/SLX4</i>	<1 Autosomal recessive	16p13 .3	Present

The FA genes function coordinately in a common molecular pathway to regulate DNA repair. Loss of function of any FA gene results in sensitivity to DNA interstrand crosslinks, which block the progression of DNA replication. The FA proteins FANCA, FANCB, FANCC, FANCE, FANCF, FANCG, FANCL, and FANCM associate into a nuclear complex ("FA complex") together with proteins FAAP24 and FAAP100 and the E2 ubiquitin conjugating enzyme UBE2T. A model (Fig. 37.2) has emerged whereby stimuli such as S phase entry, or DNA damage by agents such as MMC, or ionizing radiation leads to activation of the FA complex, which functions as an E3 ubiquitin ligase to covalently attach a ubiquitin protein (monoubiquitinate) to the FANCI and FANCD2 proteins. The monoubiquitinated FANCD2/FANCI dimer translocates to nuclear foci with BRCA1, a known cancer susceptibility gene product implicated in DNA repair, as well as FANCD1/BRCA2, FANCN/PALB2, RAD51, ATR, NBS1, and FANCI/BACH1/BRIP1. Monoubiquitination of FANCD2 and FANCI is required for MMC resistance and is dependent on the functional integrity of the upstream Fanconi proteins. FANCD2 monoubiquitination remains intact in bone marrow failure syndromes other than FA.⁴⁵ FANCD2 monoubiquitination can be assessed on a Western blot and serves as a useful biochemical diagnostic screen for FA.¹³ FANCM, in complex with FAAP24 and MHF, binds to stalled replication forks at sites of unresolved interstrand crosslinks. FANCM recruits the FA complex, which in turn monoubiquitinates the FANCD2/FANCI dimer. Ubiquitinated FANCD2/FANCI associates

P.957

with the nuclease FAN1 which can cleave and release the crosslink to allow DNA replication to proceed by translesion synthesis. RAD51 functions in homologous recombination. FANCI/BRIP1 is a DNA helicase that is important for homologous recombination repair. FANCP/SLX4 interacts with and stimulates the DNA repair endonucleases XPF-ERCC1, MUS81-EME1, and SLX1, and may be important for resolution of homologous recombination intermediates. Elucidation of the Fanconi biochemical pathway in turn led to the identification of interactions between the Fanconi proteins and other known tumor suppressor pathways. These findings provide biochemical support for a role of the Fanconi pathway in tumorigenesis. For example, FANCD2 was subsequently shown to be phosphorylated by ATM kinase at a serine residue at amino acid position 222.⁴⁶ This phosphorylation is required for the cell cycle S phase checkpoint in response to radiation.⁴⁶ ATM function is disrupted in the chromosomal instability syndrome ataxia telangiectasia. Thus, FANCD2 links two DNA repair pathways, the Fanconi pathway and the ataxia telangiectasia pathway. Dysfunction of the Fanconi pathway or the ATM pathway is associated with increased cancer susceptibility. The Fanconi biochemical pathway was further implicated in DNA repair by the identification of the gene for FANCD1 as the tumor suppressor gene, BRCA2.⁴³ The FA pathway also interacts with other DNA damage checkpoint proteins including ATR, CHK1, and γ -H2AX.

FIGURE 37.2. Schematic diagram of the Fanconi anemia (FA) pathway. FA proteins (A, B, C, D1, D2, E, F, G, I, J, L, M, N) are depicted with shaded circles. Additional DNA repair proteins interacting with the FA pathway are denoted in non-shaded circles. Following activation of the FA core complex by DNA damage or the cell cycle, the D2 and I proteins are monoubiquitinated. Monoubiquitinated D2/I are translocated to chromatin where they colocalize with additional DNA repair proteins to participate in interstrand DNA crosslink repair. Ub, ubiquitin; P, phosphorylation.

Given the compelling biochemical data linking the Fanconi pathway to other known DNA repair pathways functioning in tumor suppression, the question of whether asymptomatic FA heterozygotes carry an increased risk of developing malignancies is a subject of active investigation. Heterozygous BRCA2 mutations are associated with increased risks of breast and ovarian cancer.⁴⁷ The reason why breast and ovarian cancer is uncommon in the FA patient population is not known, but may be related to decreased estrogen levels in these patients. Currently, not all FANCD1/BRCA2 mutations reported in FA patients have been associated with increased cancer risk in heterozygous carriers in the general population, and it is currently unclear whether all the FANCD1/BRCA2 mutations leading to FA (when both alleles are mutated) will also confer cancer predisposition in family members in whom only one BRCA2 allele may be mutant.¹³ Counseling of family members of patients with the FA-D1 subtype must currently be tempered with caution. Cancers have been reported in some heterozygous carriers of different FA genes (FANCD1/BRCA2 FANDJ/BRIP and FANCN/PALB2) with loss of heterozygosity of the FA gene in the tumor consistent with a tumor suppressor gene model (reviewed in Ref. 48).

In addition to a nuclear role in DNA repair, numerous studies suggest additional potential functions for the FA proteins. FA cells are sensitive to many different extracellular apoptotic signals, such as interferon- γ , TNF- α , and double-stranded RNA.^{49, 50, 51, 52} Furthermore, Fanconi proteins such as FANCC may have additional roles in other signaling pathways.⁵³

Studies also suggest a role for the FA proteins in mediating oxidative stress.^{54, 55} DEB, a clastogen to which Fanconi cells are especially susceptible, can cause oxidative DNA damage. FA cells may exhibit increased susceptibility to oxidative damage, and reactive oxygen species can damage DNA and lead to DNA crosslinks and double-stranded breaks.

The molecular etiology of marrow failure in FA remains an area of active investigation. A recent study reports p53 hyperactivation in hematopoietic stem/progenitor cells deficient in FA gene expression resulting in cell cycle arrest.⁵⁶ This

finding is further supported by the demonstration that knockdown of p53 expression in a zebrafish model of FA rescues the developmental abnormalities.⁵⁷ Since p53 knockdown rescues the hematopoietic abnormalities in other marrow failure syndromes, p53 may represent a final common pathway for cellular stress or DNA damage in marrow failure syndromes. Abrogation of DNA damage checkpoints has been associated with a milder marrow failure phenotype; however, these FA patients remained at risk for malignant transformation to leukemia.⁵⁸ A potential role for environmental toxins in the severity of the FA phenotype has been demonstrated in murine models where disruption of the FA pathway results in increased sensitivity to reactive aldehydes associated with an increased risk of developmental anomalies and a propensity to develop leukemias.⁵⁹

Supportive Care

Cancer surveillance and education play an important role in the management of FA patients. Physicians should counsel patients regarding established behavioral and environmental risk factors associated with increased cancer risk. Since FA patients have a defect in DNA repair, imaging studies should minimize exposure to ionizing radiation. For example, when clinically feasible, it is reasonable to use MRI scans or ultrasound rather than CT scans for FA patients.

Because of the increased risk of MDS and leukemia in patients with bone marrow failure syndromes, frequent complete blood counts and annual bone marrow aspirates and biopsies with cytogenetic analysis are recommended, particularly since hematopoietic stem cell transplant outcomes are superior for patients transplanted prior to emergence of leukemia. FA patients are at risk for clonal cytogenetic abnormalities (reviewed in Ref. 60). Assessment of the clinical significance of a cytogenetic clonal abnormality requires consideration of the specific clone, the number of chromosomal abnormalities, the presence of significant marrow dysplasia (some baseline mild dysplasia is common in FA), and whether there are concomitant progressive peripheral cytopenias.^{23, 61} Chromosomal abnormalities common in AML, such as t(8:21), inv(16), or trisomy 8, have not been reported in FA.^{23, 62} Amplifications of 3q are common in FA but rarely seen in AML. FA AML also had a higher frequency of 1q amplification, loss of part or all of chromosome 7, and gain of 13q and del 20q.^{62, 63}

For patients on androgen therapy, regular physical examinations for liver size, liver ultrasound for masses or abnormalities every 6 to 12 months, and frequent liver enzyme tests are recommended. Annual examination by an otolaryngologist for leukoplakia or other signs of squamous cell carcinoma of the

P.958

oral cavity and oropharynx is important for patients with FA, DC, and those FA patients previously treated with bone marrow transplantation. Annual endoscopy can be considered in older FA and DC patients. Regular dental exams are important both for maintenance of oral hygiene and for detecting leukoplakia. Patients should be evaluated immediately for symptoms of pain in the mouth or throat, difficulty swallowing, changes in voice, anorexia, or weight loss. Suspicious lesions should be biopsied immediately, since early surgical excision is the mainstay of cancer therapy in FA patients. Annual gynecologic examinations, including Pap smears and HPV (human papilloma virus) exams, are recommended at puberty or after the age of 16. Counseling regarding sexual activity should be provided. Barrier methods of contraception may be particularly pertinent for the FA patients who are already at risk of cervical and vulvar malignancies. Regular breast exams are also recommended, although it is not clear what role mammography should play in cancer screening of these patients. HPV, which may be associated with an increased risk of squamous cell carcinoma of the head and neck, exhibits increased proliferation and epithelial cell expansion secondary to elevated levels of the viral E7 protein when the FA pathway has been disrupted.⁶⁴ Vaccination against HPV should be offered to all FA patients, males and females, in accordance with current guidelines.

Regular endocrinology evaluations are important, particularly in the pediatric population if the patient exhibits poor growth or delayed puberty. Hypothyroidism and diabetes are not infrequent in FA patients. A recent study reported one or more endocrine abnormalities in more than 70% of patients with FA.^{17, 65} GI symptoms may present in FA patients, necessitating prompt referral to a gastroenterologist.

Treatment

HSCT is the only curative therapy for the hematologic manifestations of FA. Patients with FA are exquisitely sensitive to the toxicity of the usual chemotherapy and radiation regimens used in preparation for BMT,⁶⁶ particularly organ toxicity and graft-versus-host disease (GVHD). In addition, these regimens confer an increased risk of subsequent malignancies, primarily squamous cell carcinomas of the head and neck.^{67, 68} Reduced dose conditioning regimens are used for FA patients (reviewed in Ref. 69). An appropriate conditioning regimen combined with use of a matched sibling donor has resulted in survivorship of up to 80%.^{70, 71, 72} Post-HSCT malignancies, especially squamous cell carcinomas of the head and neck, remain a long-term risk. Acute and chronic GVHD and radiation are risk factors for post-transplant squamous

cell carcinomas.^{67, 68, 73, 74} Regimens with the goal of reducing transplant-related toxicity and long-term cancer risk are under investigation.^{75, 76, 77} Clinical trials replacing radiation with fludarabine, a potent immunosuppressive agent with less cytotoxicity, have reported successful engraftment using either HLA-matched family member donors or alternative donors.^{78, 79, 80, 81, 82, 83, 84} Some families opt to pursue preimplantation genetic diagnosis to provide a donor for patients who lack an unaffected HLA-identical sibling donor.⁸⁵ Treatment of AML in FA patients is challenging,¹⁰ and HSCT is generally the treatment of choice for eligible candidates.

Medical therapies are available for patients who either lack a suitable HSCT donor or for whom the risk of HSCT is high. Androgens may improve the blood counts in approximately 50% of patients with FA. Experience is greatest with oxymetholone, but widespread use is limited by its associated virilizing side effects, which are particularly problematic for female patients or very young patients. In a recent study, improvement in anemia and thrombocytopenia were noted in 7 of 8 patients with FA treated with danazol with minimal side effects.⁸⁶ Suggested treatment guidelines have been proposed by a consensus committee of the FA Research Foundation, although these guidelines must be individualized for each patient and undergo continuous modification as new data emerge. The suggestion of the committee is to consider an allogeneic stem cell transplant or androgen therapy if the hemoglobin falls below 8g/dl, if anemia is symptomatic, if the platelet count falls below 30,000/mm³, or if the neutrophil count falls below 500/mm³.⁸⁷ The earliest and most frequent response to androgens is seen in red cells, with reticulocytosis and increase in hemoglobin generally occurring within the first 1 to 2 months of treatment. Responses in the white cell count and platelet count are variable and may not be seen until after 6 to 12 months of therapy. Resistance to therapy may develop over time (generally years). A common starting androgen regimen consists of oxymetholone 2 to 5 mg/kg/day given orally. Androgen doses may be slowly tapered to the minimal effective dose with careful monitoring of the blood counts. Side effects of androgen administration include liver toxicity, such as elevated liver enzymes, cholestasis, peliosis hepatis, and increased propensity to develop hepatic tumors (benign adenomas and malignant hepatomas). Other side effects of androgens include acne, oily skin, enlarged penis/clitoris, hoarseness/voice deepening, hair growth or hair loss, behavioral changes, hot flashes, breast enlargement or tenderness, amenorrhea, fluid retention, and secondary hypertension.

Hematopoietic growth factors such as G-CSF or GM-CSF have been shown to improve the neutrophil count in the majority of treated patients.^{88, 89} In a few patients, platelet or red cell counts also improved following treatment with G-CSF.⁸⁹ Growth factor treatment is generally not recommended for patients with MDS and is generally avoided for those with a clonal cytogenetic abnormality of the bone marrow, although there are no available data that directly address whether G-CSF increases leukemia risk. It is reasonable to perform a bone marrow aspirate and biopsy as well as cytogenetic studies prior to the initiation of growth factor therapy and monitor regularly throughout therapy.

Results of a gene therapy trial for FA-C patients were reported.⁹⁰ Three FA-C patients underwent 3 to 4 cycles of retroviral transduction of G-CSF-mobilized peripheral blood CD34⁺ mononuclear cells (MNC), while a fourth patient received a single infusion of transduced cells. The transduced wild-type FANCC gene was detected in peripheral blood and bone marrow MNC in association with increased hematopoietic colony growth in vitro. Transient improvement in bone marrow cellularity accompanied these findings and two patients experienced a transient improvement in blood counts. While the selective advantage of corrected cells makes FA an appealing candidate for gene therapy,⁹¹ potential limitations include low CD34⁺ cell numbers,⁹² poor ex vivo expansion of hematopoietic stem/progenitor cells,⁹³ and the residual risk of leukemia associated with the remaining noncorrected hematopoietic cells.³⁸ The development of leukemia in a few patients receiving gene therapy for X-linked SCIDS⁹⁴ raises concerns about the potential growth advantage theoretically conferred by gene correction of a preleukemic hematopoietic stem/progenitor cell in FA patients. In a *Fancc*^{-/-} mouse model, ex vivo cultured stem/progenitor cells exhibited a propensity to develop cytogenetic abnormalities and myeloid malignancies.⁹⁵ Additional studies to optimize ex vivo expansion of hematopoietic stem cells are ongoing.

Published data to guide management of leukemia in FA are scarce. Patients are susceptible to severe mucositis, end-organ toxicities, and prolonged or intractable cytopenias with chemotherapy. Outcomes with chemotherapy alone are poor, so the current treatment of choice for leukemia is a hematopoietic stem cell transplant. Successful treatment of solid tumors is typically best attained with surgical excision of localized tumors. Treatment of solid tumors with chemotherapy or radiation is limited by the high rates of toxic side effects such as mucositis or prolonged or intractable marrow suppression.

P.959

DYSKERATOSIS CONGENITA

DC is an inherited disorder classically characterized by lacey reticular skin pigmentation, nail dystrophy, and leukoplakia (the diagnostic triad). The advent of genetic testing and telomere length analysis revealed a broad spectrum of clinical phenotypes; indeed, the classical clinical triad is absent in a subset of patients.⁹⁶ X-linked recessive, autosomal dominant, and autosomal recessive inheritance patterns have been reported. Patients exhibit a predisposition to bone marrow failure, malignancy, and pulmonary dysfunction. See excellent recent reviews for additional details.^{97, 98}

Clinical Features

The DC registry established in 1995 undertook a comprehensive study of the clinical features associated with DC.⁹⁹ By 1999, the registry included 92 families from 20 countries. There were 148 DC patients, of whom 127 were male and 21 were female. Twentyfive families showed an X-linked recessive pattern of inheritance, while 51 families had sporadic affected males. Sixteen families included one or more affected females, representing both autosomal dominant and autosomal recessive forms of the disease.

The severity of the clinical phenotype can vary widely in affected members of the same family. The classic triad of skin, nail, and oral findings may be lacking. A variety of other clinical features have also been described in patients with DC (Table 37.3). The range of physical findings in female patients is similar to that reported in male patients.⁹⁹ Most of the somatic abnormalities are not present early in life but develop progressively with age. The skin pigmentation is typically reticular and mottled in appearance, and may be localized or widespread. The classical triad of abnormal skin pigmentation, nail dystrophy, and leukoplakia generally appears between the ages of 5 and 10 years, with a median age of onset between 6 and 8 years (range 0.5 to 26 years).⁹⁹ Both the tempo of symptom progression as well as symptom severity are highly variable between patients. For example, nail dystrophy can range from minimal nail irregularities to progressive atrophy and even complete nail loss.

Peripheral cytopenias of two or more peripheral lineages were affected in the majority of registry patients, though single lineage cytopenias were also reported.⁹⁹ The median age of onset of pancytopenia was 8 years, with 50% developing pancytopenia below the age of 10.⁹⁹ The bone marrow is typically hypocellular, though cellularity may be normal or even increased early in the disease. Bone marrow failure or its associated complications accounted for the majority of deaths (67%).

Approximately 20% of patients develop pulmonary disease with reduced diffusion capacity and/or restrictive pulmonary disease.^{99, 100, 101} Pulmonary complications account for nearly 10% of deaths.⁹⁹ Postmortem studies reveal pulmonary fibrosis and abnormalities in the pulmonary microvasculature. Similarly, a high incidence of early and late fatal bone marrow transplant-associated pulmonary complications has also been reported in DC patients.¹⁰²

Immunologic abnormalities, including low or high immunoglobulins, reduced numbers of B or T cells, and reduced stimulation by phytohemagglutinin, have been described in some DC patients.^{99, 103} Opportunistic infections such as *Pneumocystis carinii* pneumonia have been reported.^{104, 105}

Malignancies were noted in 13 out of 148 patients (8.8%) in the DC registry.⁹⁹ These developed in older patients, generally after the second decade of life. It is possible that a higher incidence of cancers might have been observed had not many patients succumbed to aplastic anemia at an earlier age. An increased incidence of MDS and AML has also been observed.⁹⁹ Eight cases of carcinomas were reported in patients aged 20 to 56 years.⁹⁹ A recent report from the National Cancer Institute cohort identified similar cancer risks in FA and DC, with cumulative incidences of solid tumors of 20% to 30% by age 50 years, and 10% AML for age 40 years. The majority of the tumors in DC are HNSCC.^{106, 107}

- Microcephaly
- Urethral stricture/Phimosis
- Osteoporosis/aseptic necrosis/scoliosis
- Deafness
- Bone marrow failure
- Malignancy
- Pathophysiology

Reduced hematopoietic progenitor cell colonies have been described for all three hematopoietic lineages compared with controls.^{108, 109, 110, 111} DC patients show a reduction in the proliferative capacity of myeloid progenitors as measured by secondary colony formation following replating.¹¹² Bone marrow cells from DC patients show poor growth in long-term bone marrow culture assays. The defect is intrinsic to the hematopoietic stem cells since DC stromal cells are able to support hematopoietic cells from normal controls, while DC hematopoietic cells grow poorly on normal control stroma.¹¹¹

The X-linked recessive form of DC was linked to Xq28 and the gene was identified by positional cloning and named DKC1¹¹³ (Table 37.4). DKC1 encodes a ubiquitously expressed protein, dyskerin. Dyskerin also interacts with TERC, which is the H/ACA RNA component of the human telomerase complex.¹¹⁴ Cells from DC patients manifest abnormally shortened telomeres and reduced telomerase activity.¹¹⁵ In further support of a telomerase defect in DC, the mutations responsible for some cases of the autosomal dominant form of DC were found to reside in the RNA template, TERC, itself,¹¹⁶ and in TERT, the telomerase reverse transcriptase^{117, 118} (Table 37.4). Telomerase is an enzyme that adds DNA sequences to the ends of chromosomes (the telomeres) to prevent loss of terminal repeats (TTAGG) during DNA replication (reviewed in Ref. 119). Telomeres are important for the prevention of chromosomal fusions and rearrangements. Spontaneous unbalanced chromosomal rearrangements have been described in fibroblasts and bone marrow cells from DC patients.¹²⁰ While telomerase activity is abundant early in development, it is later detectable only in a subset of tissues with dividing cells, including the progenitor cells of the hematopoietic system, the basal layer of the epidermis, intestinal cells, and hair follicles. These tissues

P.960

mirror those most severely affected in DC patients. Telomere loss has also been implicated in contributing to the process of aging, and DC may represent a form of premature aging of tissues with a high replicative requirement.^{121, 122} The gene(s) responsible for some of the sporadic or autosomal dominant as well as the autosomal recessive forms of DC have not yet been identified. Sequence alternations in TERT have also been described in some patients with aplastic anemia in the absence of the characteristic physical findings of DC.^{118, 123} Mutations in additional components of telomerase NOP10 (NOLA3)¹²⁴ and NHP2 (NOLA2)¹²⁵ as well as TERT and CTC1¹²⁶ are found in patients with autosomal recessive DC. In further support of DC as a telomere disorder, mutations in TIN2, a component of the shelterin complex that binds and protects telomeres, cause an autosomal dominant form of DC.¹²⁷ WRAP53, which encodes the TCAB1 protein, functions in the intracellular translocation of telomerase to the Cajal bodies for assembly.¹²⁸

TABLE 37.4 SUMMARY OF BONE MARROW FAILURE SYNDROMES

Clinical Features	Inheritance Pattern	Gene	Additional Laboratory	Associated Malignancies
--------------------------	----------------------------	-------------	------------------------------	--------------------------------

			Testing		
Fanconi anemia	Radial ray, skin, craniofacial, genitourinary, gastrointestinal, cardiac	Autosomal recessive	<i>FANCA</i> , <i>FANCC</i> , <i>FANCD1</i> , <i>FANCD2</i> , <i>FANCE</i> , <i>FANCF</i> , <i>FANCG</i> , <i>FANCI</i> , <i>FANCI</i> , <i>FANCI</i> , <i>FANCL</i> , <i>FANCM</i> , <i>FANCN</i> , <i>FANCO</i> , <i>FANCP</i> , <i>FANCB</i>	Chromosome breakage	AML, carcinomas (head and neck, gynecologic); brain and Wilms in <i>D1/BRCA2</i>
Dyskeratosis congenita	Abnormal nails, reticular rash, leukoplakia	X-linked recessive	<i>DKC1</i>	Telomere length	AML, carcinomas (head and neck, anogenital)
		Autosomal dominant	<i>TERC</i> <i>TERT</i> <i>TINF2</i>		
		Autosomal recessive	<i>NHP2</i> <i>NOP10</i> <i>TERT</i> <i>WRAP53</i> <i>CTCI</i>		
Shwachman-Diamond syndrome	Short stature, fat malabsorption, skeletal anomalies	Autosomal recessive	<i>SBDS</i>	Serum trypsinogen, pancreatic isoamylase	AML
Congenital amegakaryocytic thrombocytopenia		Autosomal recessive	<i>C-MPL</i>		AML

AML, acute myeloid leukemia

Dyskerin also exhibits strong homology to two previously characterized proteins: *Saccharomyces cerevisiae* Cbf5p^{129, 130} and rat NAP57.¹³¹ Like Cbf5p and NAP57, dyskerin is localized primarily in the nucleolus and shares some homology with RNA pseudouridine synthases. Pseudouridine synthases together with small nucleolar RNAs (snoRNAs) isomerize uridine bases in ribosomal RNAs (rRNAs) to pseudouridine. In the absence of Cbf5p, yeast rRNA processing is defective.¹³⁰ Impaired translation initiation from internal ribosome entry site sequences has been observed in *Dkc1^m* mice and in cells from DC patients.¹³²

It is increasingly apparent that the classical clinical syndrome of DC represents only the most severe form of the disease. Previously unrecognized milder forms exhibiting only isolated findings or marrow failure alone may now be identified through telomere length measurement and genetic testing.

Differential Diagnosis

DC must be distinguished from other inherited bone marrow failure syndromes that also present with aplastic anemia, congenital anomalies, and cancer predisposition, such as FA. In contrast to FA, cells from DC patients do not manifest increased chromosomal breakage in response to MMC or DEB.¹³³ Literature reports differ over whether cells from DC patient cells exhibit increased chromosomal breakage in response to DNA damaging agents.^{134, 135, 136, 137, 138} Since DC patients may develop aplastic anemia in the first decade of life prior to the manifestation of skin or nail abnormalities, their underlying diagnosis may be missed. DC may mimic graft-versus-host disease in patients previously transplanted for aplastic anemia. Patients with DC typically present with very short telomeres for age; this assay is a clinically approved test.⁹⁶

Laboratory Findings

In addition to peripheral cytopenias, red cell macrocytosis and elevated Hb F may be seen in patients with DC.¹³⁹ However, these signs of stress erythropoiesis are nonspecific, as they are seen in many patients with any of the inherited bone marrow failure syndromes. As noted above, immunologic abnormalities have also been described in some patients.^{99, 103}

Primary DC skin fibroblasts grow slowly in culture and exhibit abnormal morphology. X-chromosome inactivation patterns in female obligate carriers showed complete skewing, consistent with a growth or survival disadvantage for cells expressing only the defective X-chromosome allele.^{140, 141, 142} Spontaneous unbalanced chromosomal translocations have been observed.^{120, 143}

P.961

Telomere length analysis is a useful diagnostic screen for DC since patients with DC exhibit very short (<first percentile of age-matched controls) telomeres in multiple lymphocyte subsets by multicolor flow cytometric fluorescent in situ hybridization (Flow-FISH).^{96, 144} Since over half of patients diagnosed clinically with DC lack mutations in the DC genes known to date, telomere length provides a useful diagnostic screen. Experience with telomere length testing is still limited, and must be interpreted within the clinical context of the patient. Genetic testing is clinically available, but negative genetic testing does not rule out the diagnosis of DC.

Supportive Care

Supportive care for DC patients is similar to that outlined for aplastic anemia and FA patients. Annual pulmonary function testing is recommended, given the risk of developing pulmonary fibrosis. Exposure to pulmonary toxins, such as cigarettes, should be avoided. Regular endocrinology visits are particularly important, since DKC patients are at increased risk of osteoporosis, and their diet, vitamin D, and parathyroid hormone levels and calcium status should be monitored. Patients with significant immunologic dysfunction resulting in reduced immunoglobulin levels may benefit from IVIG therapy.

Treatment

The only curative treatment for bone marrow failure MDS or AML in DC remains allogeneic stem cell transplantation (SCT).^{102, 145, 146, 147, 148, 149, 150, 151, 152} Although long-term survivors have been reported, early and late fatal pulmonary and vascular complications after SCT remain a significant problem.^{102, 145, 148, 149, 153} In one case, a successful lung transplant followed several years after bone marrow transplantation for aplastic anemia due to DC that had not been diagnosed.¹⁵⁴ The avoidance of drugs associated with pulmonary toxicity and the use of radiation-sparing conditioning regimens may provide useful avenues for future study. DC may be mistaken for chronic GVHD in patients transplanted for aplastic anemia.^{155, 156} Treatment with ATG and cyclosporin is generally not effective in these patients.¹⁵⁷ Improvement in peripheral blood counts has been described in some patients following treatment with the androgen oxymetholone.¹⁵⁸ Improved neutrophil counts in response to GM-CSF^{159, 160} or G-CSF^{161, 162} have been reported. Combined treatment with G-CSF and erythropoietin led to improved neutrophil and red cell counts in one case report.¹⁶³

SHWACHMAN-DIAMOND SYNDROME

Clinical Features

SDS is characterized clinically by the combination of exocrine pancreatic insufficiency and bone marrow failure (see Refs. 164, 165, 166 for recent reviews). The differential diagnosis includes other inherited and acquired causes of marrow failure as well as other causes of exocrine pancreatic insufficiency, such as cystic fibrosis, Pearson syndrome, and cartilage hair hypoplasia.

Exocrine pancreatic insufficiency typically presents in infancy with failure to thrive and loose, foul-smelling stools consistent with steatorrhea. Fecal fat measurements may be helpful, but a normal test does not rule out the diagnosis of SDS, since exocrine pancreatic function may improve in a subset of patients. Exocrine pancreatic insufficiency may improve with age to become clinically asymptomatic in a subset of patients. The pancreas in patients with SDS shows fatty replacement of the pancreatic acini, with sparing of the ducts and islets. Fat-soluble vitamin deficiencies (vitamins A, D, E, and K) may be seen. Neutropenia is the most common feature of marrow failure in SDS. Neutropenia may be either intermittent or persistent.¹⁶⁷ Patients are predisposed to infections, particularly bacterial and fungal. Abnormalities of T or B cells have also been reported and may contribute to infectious complications.¹⁶⁸ Anemia and/or thrombocytopenia may also be seen and a subset of SDS patients develop aplastic anemia. The red blood cells may be macrocytic.

There is no pathognomonic feature of the bone marrow in SDS patients; nonetheless, a bone marrow examination with aspirate, biopsy, and cytogenetics is important to rule out other causes of cytopenias. Marrow cellularity may be normal, low, or high. As with other inherited bone marrow failure syndromes, mild dysplastic features may be seen in the erythroid, myeloid, and megakaryocytic lineages. There is a risk for progression to pancytopenia and aplastic anemia (20% to 25%) or myelodysplastic syndrome/AML (5% to 33%).^{6, 167, 169} Hb F is elevated at some stage in approximately 80% of patients.¹⁶⁷

Marrow cytogenetic abnormalities may be seen, such as abnormalities of chromosome 7 (monosomy 7, deletions/translocations of 7q, isochromosome 7) as well as 20q-, which are particularly common. In the absence of morphologic evidence for MDS, the clinical significance of most cytogenetic abnormalities is unclear. These cytogenetic clonal populations may wax and wane over time or even disappear.¹⁷⁰

Additional features that may be variably associated with SDS include: skeletal abnormalities, including metaphyseal dysostosis and osteopenia, failure to thrive despite early institution of pancreatic enzyme supplementation (see below), hepatic abnormalities, and abnormal dentition.¹⁶⁵

Laboratory Findings

SDS is the second most common cause of inherited pancreatic insufficiency, after cystic fibrosis.¹⁷¹ Sweat chloride is normal and serves to distinguish these patients from those with cystic fibrosis. Serum trypsinogen is generally depressed in SDS patients at any age, although it may improve with time.¹⁷² Isoamylase levels remain low after the age of 3 and are useful in this older age group.¹⁷² Other tests for exocrine pancreatic function include pancreatic stimulation or elevated fecal fat measurement, though the latter test is not specific for pancreatic dysfunction. Imaging studies may reveal a fatty, atretic pancreas. Fecal elastase may be decreased, but the sensitivity of this test as a screen for SDS remains to be ascertained. Fat-soluble vitamin levels (vitamins A, D, E, and K) may be low secondary to malabsorption. Skeletal imaging studies may reveal a wide variety of abnormalities, which are often asymptomatic, although metaphyseal dysostosis may require treatment.¹⁷³

Over 90% of patients who meet clinical criteria for SDS harbor autosomal recessive mutations in the SBDS gene. While the presence of biallelic pathogenic SBDS mutations is helpful in confirming the diagnosis, the absence of mutations does not rule out the diagnosis of SDS if the patient meets diagnostic criteria on clinical grounds.¹⁶⁶

Pathophysiology

SDS is an autosomal recessive disorder with an estimated incidence of 1 in 75,000.¹⁷⁴ In the majority (90%) of affected patients reported, mutations have been detected in the Shwachman-Bodian-Diamond syndrome (SBDS) gene located on chromosome 7q11.^{175, 176} SBDS is highly conserved throughout evolution and is expressed in all human tissues tested to date.¹⁷⁶ The human SBDS protein is found in both the nucleus and cytoplasm, and shuttles in and out of the nucleolus in a cell cycle-dependent fashion.¹⁷⁷

SBDS has been implicated in multiple cellular functions. Attention has focused on its role in ribosome biogenesis. Human SBDS associates with the 60S ribosomal precursor but not with the mature 80S ribosome.¹⁷⁸ Yeast failing to express the SBDS ortholog Sdo1 grows poorly. This slow growth is rescued by

mutations in Tif6, the yeast ortholog of eIF6 which functions in ribosome biogenesis and ribosomal subunit joining.¹⁷⁹ Deletion of murine Sbds results in early embryonic lethality.¹⁸⁰ Using conditional Sbds knockout murine models, Sbds was shown to function in coupling the GTPase Efl1 to the release of eIF6 from the nascent 60S ribosomal subunit.¹⁸¹ eIF6 sterically hinders the association of the 60S ribosomal subunit to the 40S subunit^{182, 183}; thus, eIF6 release is required for final assembly of a translationally active 80S ribosomal subunit. SBDS has also been implicated in additional molecular pathways including mitotic spindle stabilization,¹⁸⁴ cellular stress response,¹⁸⁵ actin dynamics,¹⁸⁶ and signaling downstream of RANK for osteoclast differentiation.¹⁸⁷

Supportive Care

Regular monitorings of the peripheral blood counts and periodic bone marrow examinations are recommended. Fevers in the setting of neutropenia warrant prompt medical evaluation for appropriate cultures and treatment with broad spectrum antibiotics. Hematopoietic growth factors (such as recombinant human granulocyte colony-stimulating factor [rhG-CSF]) may stabilize or improve the neutropenia. The main indication for G-CSF therapy is serious bacterial or fungal infection related to neutropenia, though some centers opt to initiate treatment based on the neutrophil counts. Patients with a history of recurrent or severe bacterial infections may benefit from prophylactic G-CSF. Although there is a theoretical risk that G-CSF might stimulate the growth or progression of leukemic clones, there is no direct evidence to address this.^{169, 188} Transfusion support with red cells or platelets should be provided as clinically indicated for severe or symptomatic anemia and thrombocytopenia. There are no published reports to support the use of erythropoietin therapy unless erythropoietin levels are low.

Endocrinology evaluation is useful in these patients to rule out treatable comorbid conditions that could further exacerbate short stature or osteopenia. Dietary counseling may be helpful to ensure adequate intake of calcium and vitamin D.

Treatment

Therapy in SDS is initiated based on clinical manifestations. Fat malabsorption is treated with the administration of oral pancreatic enzymes. Exocrine pancreatic functions may vary over time, and thus regular assessment by a gastroenterologist is recommended.^{189, 190, 191} Patients benefit from supplementation with water-soluble versions of vitamins A, D, E, and K. Fecal fat measurements, vitamin levels, and prothrombin time provide useful measures of exocrine pancreatic function.

Bone marrow transplantation can cure the hematologic aspects of SDS and has been evaluated as a potential therapy in SDS patients with marrow failure, MDS, or AML.^{192, 193, 194, 195, 196, 197} The results in the published literature, consisting largely of case reports, point to an increased risk of complications from end-organ dysfunction, particularly hepatic, cardiac, and pulmonary, as well as transplant-associated problems. Indications for transplant include severe or symptomatic cytopenias, high risk MDS, and leukemia. Outcomes for leukemia remain poor with standard chemotherapy regimens, and thus transplant is the treatment of choice. SDS patients receiving cytotoxic therapies are at risk for prolonged or intractable cytopenias, so appropriate preparations for stem cell support are warranted. As with the other inherited marrow failure syndromes, potential sibling donors regardless of clinical phenotype should be tested for pathogenic mutations identified in the proband. Reported survival rates are lower for patients transplanted for overt leukemia.^{194, 195} For this reason, regular surveillance of blood counts and bone marrow exams have been recommended to increase the likelihood of detecting early signs of malignant transformation.

CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA

Clinical Features

Patients with CAMT typically present in the neonatal period with petechiae, purpura, or bleeding typically involving the skin, mucous membranes, or GI tract.¹⁹⁸ Intracranial bleeding has also been reported. Bleeding may be life threatening. Thrombocytopenia at birth is usually severe with platelet counts typically less than 50,000 and often less than 20,000. A family history of miscarriages has been reported.¹⁹⁸ Patients are at risk for developing cytopenias in all three hematopoietic lineages and may progress to severe aplastic anemia, which develops later in childhood, with a median age of 3.7 years.¹⁹⁸ A recent retrospective study reported pancytopenia in 14 out of 20 patients at a median age of 38 months with a range between 6 and 53 months.¹⁹⁸ Two clinical forms of CAMT have been described.¹⁹⁹ Patients in CAMT group I are characterized by severe, persistent thrombocytopenia and early onset of pancytopenia. Patients in CAMT group II are characterized by transient increases in platelet counts to over 50,000/ μ l early in life and either a delayed onset of pancytopenia or lack of pancytopenia to date.¹⁹⁹ The development of AML or MDS has been reported in patients with CAMT.¹⁹⁸

Skeletal abnormalities are not typically seen in patients with CAMT. In a recent report, two patients with cardiac abnormalities and six with failure to thrive were reported.¹⁹⁸ Cerebral malformations have been detected, but the possibility that some of these may represent sequelae of prior intracranial hemorrhage could not be excluded. The presence of congenital anomalies together with thrombocytopenia should prompt diagnostic workup for other disorders such as FA, thrombocytopenia-absent-radii (TAR) syndrome, amegakaryocytic thrombocytopenia with radioulnar synostosis (ATRUS), Paris-Trousseau syndrome, or the Hoyeraal-Hreidarsson variant of DC. Mutations in MPL have been identified as one of many causes of familial aplastic anemia.

Differential Diagnosis

Complete blood counts and evaluation of the blood smear should be performed. In cases where primary marrow dysfunction appears likely, a bone marrow examination with cytogenetics is indicated. Thrombocytopenia in the neonate may be secondary to other causes such as infections (e.g., TORCH: toxoplasmosis, rubella, cytomegalovirus, herpes simplex, other viruses), sepsis, Kasabach-Merritt syndrome, thrombosis, or medications. Infants may exhibit transient thrombocytopenia in the setting of maternal HELLP syndrome. Immune-mediated thrombocytopenia from transplacentally acquired maternal alloantibodies or autoantibodies is also common in the neonatal period. Other rare causes of thrombocytopenia include the giant platelet syndromes: Bernard-Soulier syndrome, Glanzmann's thrombocythemia, and May-Hegglin disease. Additional inherited syndromes associated with thrombocytopenia, such as GATA-1 mutations²⁰⁰ or other inherited bone marrow failure syndromes, must also be considered. The absence of radial ray anomalies distinguishes CAMT from TAR. While patients with TAR exhibit thrombocytopenia at an early age, platelet counts generally improve with age, though counts may fluctuate. Aplastic anemia has not been reported in TAR patients, although AML or MDS has been reported.^{201, 202, 203}

Laboratory Findings¹⁹⁸

The platelets in CAMT are of normal size and morphology but low in number, typically in the 20,000/ μ l range, but higher platelet counts do not rule out the diagnosis. Laboratory tests for platelet

P.963

function are also normal. The red cells may be normocytic or macrocytic. Mean platelet volume is typically normal. The bone marrow initially shows normal cellularity but exhibits reduced or absent megakaryocytes. Thrombopoietin (TPO) levels are typically elevated (see below). Genetic testing for mutations in the c-Mpl gene is available.

Pathophysiology

CAMT is an autosomal recessively inherited disorder associated with mutations in the c-Mpl gene, which encode the receptor for TPO.^{204, 205} Mutations may be located throughout the gene and include nonsense, missense, and splicing mutations. A correlation between clinical severity and mutation classification has been observed.¹⁹⁹ Patients in the more severe CAMT group I carry mutations predicted to abrogate the production of a full length c-mpl protein. Patients in CAMT group II carry missense mutations that appear to represent hypomorphic alleles retaining some residual activity resulting in the milder clinical phenotype.¹⁹⁹

CAMT patients exhibit high TPO serum levels,²⁰⁶ and their endogenous serum TPO appears functional.²⁰⁷ TPO is important for megakaryocyte development but also for hematopoietic stem cell survival. Mice deficient in either TPO or c-Mpl exhibit both thrombocytopenia as well as reduced numbers of hematopoietic stem cells and progenitors.²⁰⁸ Stem cell dependency on TPO likely contributes to the development of aplastic anemia in CAMT patients.

Supportive Care

Indications for platelet transfusions vary, but generally they are reserved for patients who are experiencing bleeding symptoms. Prophylactic platelet transfusions may be considered for patients posing a high bleeding risk (e.g., prior to surgery). Antifibrinolytic medications such as aminocaproic acid or tranexamic acid may be helpful in stabilizing clots, particularly for mucous membrane bleeding such as oral or nasal bleeding. These agents inhibit plasminogen activation within the clot. Agents that inhibit platelet function, such as aspirin or nonsteroidal antiinflammatory agents should be avoided. Desmopressin acetate (DDAVP) has been used in some patients with thrombocytopenia, though side effects such as SIADH (syndrome of inappropriate antidiuretic hormone secretion) must be monitored.

Treatment

Currently, the only curative therapy for CAMT is a hematopoietic stem cell transplant.^{198, 209, 210, 211, 212, 213} Testing for biallelic c-mpl mutations is a consideration prior to choosing a sibling transplant donor. Whether c-mpl carrier status

affects transplant outcomes is unclear. Abnormal platelet production has been noted in a sibling who was heterozygous for c-mpl mutation and exhibited decreased megakaryocyte colony formation in vitro despite normal platelet counts,²¹⁴ but a good short-term outcome using one sibling carrier donor has been reported.²¹⁰ Considerations for timing of transplant include minimizing the risk of allosensitization from donor blood products or infectious complications secondary to neutropenia. The reader is referred to several recent comprehensive reviews for additional information.^{215, 216}

Chapter 38

Acquired Aplastic Anemia

Robert A. Brodsky

HISTORICAL BACKGROUND

The earliest case description of aplastic anemia was by Dr. Paul Ehrlich in 1888.¹ He described a young woman who died following an abrupt illness that manifested as severe anemia, bleeding, hyperpyrexia, and a markedly hypocellular bone marrow. The term aplastic anemia was first introduced in 1904 by Chauffard. In 1972, a patient with aplastic anemia became the first recipient of successful allogeneic bone marrow transplantation.² The development of bone marrow transplantation and potent immunosuppressive therapy in the 1970s greatly improved the prognosis of an illness that was almost uniformly fatal within a few years of diagnosis. Although aplastic anemia remains a potentially devastating illness, with prompt intervention most patients now survive the disease.

ACQUIRED VERSUS CONSTITUTIONAL APLASTIC ANEMIA

Acquired aplastic anemia can occur in any age group and is usually the consequence of an autoimmune attack against hematopoietic stem cells. Awareness of the less common inherited forms of bone marrow failure is critical in the assessment of any new patient with aplastic anemia (Chapter 37). These inherited disorders can masquerade as acquired aplastic anemia, but rarely respond to immunosuppressive therapies; management usually consists of supportive care or in severe cases bone marrow transplantation (BMT).^{3, 4} Inherited forms of bone marrow failure generally present in the first decade of life and are often associated with physical anomalies, (e.g., short stature, upper-limb anomalies, hypogonadism, café-au-lait spots); however, inherited forms of bone marrow failure may present well into adulthood. Some patients have a positive family history of cytopenias, highlighting the importance of taking a careful family history when evaluating aplastic anemia patients.

Fanconi anemia, the most common form of inherited bone marrow failure, is usually an autosomal recessive disorder that is characterized by defects in DNA repair and a predisposition to leukemia and solid tumors.⁵ Recently, a rare, X-linked form of Fanconi anemia has been described.⁶ Dyskeratosis congenita (DKC) is an inherited bone marrow failure syndrome that results from loss of function mutations of telomerase components and displays considerable clinical and genetic heterogeneity. Although DKC classically presents with the triad of abnormal skin pigmentation, nail dystrophy, and mucosal leukoplakia, these findings can be subtle.^{7, 8} X-linked recessive, autosomal dominant and autosomal recessive forms of DKC are recognized.^{9, 10} Telomerase reverse transcriptase (TERT) and the RNA component of telomerase (TERC) form the core of the active telomerase complex. Autosomal dominant DKC can result from mutations of TERC¹¹ or TERT.¹² The X-linked recessive DKC results from mutations in the gene *DKC1*, whose gene product, dyskerin, is important for stabilizing the telomerase RNA-protein complex.^{13, 14} Mutations of the *TINF2* gene can also lead to DKC. *TINF2* mutations result in dysfunction of the shelterin complex, interfering with its protection of telomeres and leading to reduced telomere length. Accelerated telomere shortening leads to bone marrow failure, genetic instability, and premature aging.

Inherited amegakaryocytic thrombocytopenia is characterized by severe thrombocytopenia and megakaryocyte absence at birth. Missense or nonsense mutations in the *c-mpl* gene are present in most patients. A high percentage of these patients subsequently develop multilineage bone marrow failure in the second decade of life.¹⁵ Shwachman-Diamond syndrome is an autosomal recessive disorder characterized by pancreatic exocrine dysfunction, metaphyseal dysostosis, and bone marrow failure.¹⁶ Similar to Fanconi anemia, there is an increased risk of developing myelodysplasia or leukemia at an early age. Hypomorphic mutations in the Shwachman-Bodian-Diamond Syndrome (SBDS) gene on chromosome 7 have been found in roughly 85% of cases.¹⁷ The SBDS gene is important for ribosome biogenesis, but how this leads to bone marrow failure is unclear. These inherited forms of aplastic anemia are described in more detail in Chapter 37. The remainder of this chapter focuses on acquired aplastic anemia, hereafter referred to as aplastic anemia.

EPIDEMIOLOGY

Incidence, Age, and Geographic Distribution

Precise estimates of the incidence of aplastic anemia are confounded by the imprecision in establishing the diagnosis. The International Aplastic Anemia and Agranulocytosis Study (IAAAS), conducted in Europe and Israel, is the largest and most comprehensive epidemiologic study of bone marrow failure.¹⁸ This prospective study (performed between 1980 and 1984) reported that the overall incidence of aplastic anemia was 2 cases per 1 million people; however, the incidence may be two to threefold higher in Southeast Asia.¹⁹

Aplastic anemia most commonly presents in children and young adults, but there is a second smaller peak in incidence after age 60.^{20, 21} Similar to other autoimmune diseases, certain histocompatibility locus specificities, especially HLA-DR2, are associated with an underlying predisposition to aplastic anemia.²² Although aplastic anemia has been causally associated with many agents, including drugs, benzene exposure, insecticides, and viruses, no etiologic agent can be

identified in most cases.^{23, 24} A population-based case-control study of aplastic anemia in Thailand found that drugs were the most commonly implicated cause, but they explained only 5% of newly diagnosed cases.²³

Benzene and Environmental Toxins

The medical literature is replete with case reports of aplastic anemia associated with environmental exposures, most notably benzene or radiation exposure. However, rigorous epidemiologic studies supporting an association between environmental toxins and aplastic anemia are lacking. A major confounder is that benzene and other toxins predispose people to myelodysplastic syndromes (MDS) and leukemia. Older literature was unlikely to have been able to distinguish different types of marrow failure, such as aplastic anemia, MDS, and hypoplastic leukemia, leading to an overestimation of the association between benzene and aplastic anemia. Although the magnitude of the risk remains uncertain, benzene is probably not a major risk factor for aplastic anemia in countries with modern standards of industrial hygiene. A large case-controlled study in Thailand employing modern diagnostic and epidemiologic methods found that individuals of lower economic status and younger age are at greater risk for developing aplastic anemia than their counterparts in other countries following exposure to solvents, glues, and hepatitis A. Grain farmers were also found to have a higher risk of developing aplastic

P.966

anemia (relative risk = 2.7) regardless of whether they used insecticides.¹⁹ These same investigators noted marked differences in incidence between northern and southern rural regions of Thailand and among Bangkok suburbs, implicating potential environmental factors in causing the disease.²⁵

Radiation

Ionizing radiation is directly toxic to bone marrow stem/progenitor cells, and high doses (>1.5 Gy to the whole body) can lead to severe pancytopenia within 2 to 4 weeks after exposure; the LD₅₀ has been estimated at about 4.5 Gy, and a dose of 10 Gy or greater is thought to have 100% mortality.^{26, 27} Although pancytopenia is common after a single high dose of radiation, an increased risk of aplastic anemia is not well documented as a delayed event from atomic bomb survivors.²⁸ Although the principles of managing pancytopenia following radiation exposure are similar to those of aplastic anemia, it is important to recognize that the mechanism of bone marrow failure is different. Bone marrow failure in most cases of community acquired aplastic anemia is due to autoimmune destruction of bone marrow stem/progenitor cells; however, radiation-induced bone marrow failure is dose dependent and is a consequence of direct toxicity to stem and progenitor cells. Supportive care with blood transfusions, granulocyte colony-stimulating factor, and antibiotics is the mainstay of therapy for radiation-induced bone marrow failure, inasmuch as autologous reconstitution will occur in most patients who survive the immediate consequences of radiation exposure.

Drugs and Chemicals

A plethora of case reports and small series have implicated drugs as the cause of bone marrow failure; however, proving a causal association in these rare idiosyncratic reactions is difficult. The more common classes of drugs implicated in causing aplastic anemia are listed in Table 38.1. Nevertheless, drugs were not found to be a common cause of aplastic anemia in two large, controlled, population-based studies.^{18, 29} An epidemiologic study in Thailand examined 541 patients and 2,261 controls. Exposures were determined by in-person interview. The investigators observed significantly elevated relative risk estimates for sulfonamides (5.6), thiazides (3.8), and mebendazole (3.0). Interestingly, no increased risk was associated with chloramphenicol, perhaps the most widely implicated drug in case reports; however, chloramphenicol use in this study was infrequent.²⁹

When drugs are implicated in causing aplastic anemia, it is important to recognize that unlike agranulocytosis and drug-induced thrombocytopenia, stopping the putative drug does not usually lead to hematopoietic recovery. Most cases of drug-induced aplastic anemia lead to an idiosyncratic immune response directed against hematopoietic stem cells and are managed similarly to those with idiopathic aplastic anemia. Notable exceptions include patients who receive high doses of cytotoxic chemotherapy drugs (e.g., alkylating agents, antimetabolites, antimetotics) or rare individuals who have thiopurine methyltransferase deficiency (TPMT). TPMT catalyzes the S-methylation of 6-mercaptopurine, 6-thioguanine, and azathioprine.³⁰ Most individuals have high or intermediate activity of TPMT; however, there are rare individuals (<0.1% of the population) with undetectable levels of TPMT. Exposure to even low dosages of 6-thioguanine, azathioprine, or 6-mercaptopurine, as used in inflammatory bowel disease and lupus, can result in severe bone marrow failure within weeks of starting the drug. Withdrawal of the drug usually leads to hematopoietic recovery in 2 to 4 weeks. Reliable polymerase chain reaction-based methods are now available for detecting the major inactivating mutations at the human TPMT locus.^{31, 32}

TABLE 38.1 CLASSIFICATION OF DRUGS MOST COMMONLY IMPLICATED IN CAUSING APLASTIC ANEMIA

Nonsteroidal Analgesics

Phenylbutazone, indomethacin, ibuprofen, sulindac, diclofenac, piroxicam

Anticonvulsants

Hydantoins, carbamazepine, phenacemide

Antibiotics

Sulfonamides, chloramphenicol

Antiprotozoals

Quinacrine, chloroquine

Antithyroid Drugs

Methimazole, propylthiouracil

Gold

Viruses

Viruses, similarly to drugs, are often implicated, but seldom proven to cause aplastic anemia. Viral infections, especially in chronically ill patients, often lead to transient cytopenias, but frank aplastic anemia is uncommon. These transient cytopenias can be due directly to infection and cytolysis of hematopoietic cells or indirectly through the elaboration of inhibitory cytokines. True aplastic anemia following viruses also appears to result usually from an idiosyncratic immune response directed against hematopoietic stem cells. Acute infection with Epstein-Barr virus (EBV) is often associated with peripheral blood cytopenias. Rarely, acute EBV infection can be complicated by the development of aplastic anemia.^{33, 34, 35} There is no convincing data that B19 parvovirus causes aplastic anemia, but this virus is often linked with aplastic anemia due to the unfortunate term "aplastic crisis," used to describe the transient red cell aplasia and severe anemia that occurs in sickle cell anemia patients who are acutely infected with B19 parvovirus. The only known natural host cell of parvovirus B19 is the human erythroid progenitor.³⁶ The receptor for the virus is a neutral glycolipid, globoside, also known as the erythrocyte P antigen.³⁷ Globoside is expressed on erythroid progenitors, erythrocytes, fetal myocardium, placenta, some megakaryocytes, and endothelial cells; it is not present on hematopoietic stem cells. Other viruses, including a variety of herpes viruses and the human immunodeficiency virus have been implicated in triggering aplastic anemia, but convincing causal data are lacking. Spontaneous recovery, response to immunosuppression, and response to antiviral therapy have all been described; however, for those with severe disease, conventional therapy (immunosuppression or bone marrow transplantation) should be initiated early.

Seronegative (non-A through non-G) hepatitis precedes the diagnosis of aplastic anemia in 3% to 5% of cases and is recognized as hepatitis-associated aplastic anemia.³⁸ After orthotopic liver transplantation for fulminant seronegative hepatitis, up to 30% of patients will develop aplastic anemia (HAA).^{39, 40} In most cases, the hepatitis resolves spontaneously; however, when severe aplastic anemia (SAA) follows, it is often fatal and presents within a few months after the onset of hepatitis.⁴¹ The pathophysiology of HAA is unknown, but is thought to be immune mediated because it responds to immunosuppressive therapy.⁴¹ Furthermore, patients with HAA have a skewed T-cell repertoire, and liver biopsies from these patients show lymphocytic infiltration.⁴²

Pregnancy

Pregnancy-associated aplastic anemia is a rare entity, and despite numerous case reports, the association is not well understood.^{1, 43, 44}

P.967

The onset of aplastic anemia can occur during pregnancy or shortly after delivery. Moreover, in women with a history of aplastic anemia who had been treated into remission with immunosuppressive therapy, there is an increased risk for relapse of aplastic anemia during pregnancy. The European Group for Blood and Marrow Transplantation performed a retrospective study on the outcome of pregnancy in 36 women who had received immunosuppressive therapy to treat aplastic anemia.⁴⁵ Seven of the pregnancies (19%) were complicated by relapse of aplastic anemia. In contrast to idiopathic aplastic anemia, pregnancy-associated aplastic anemia is often associated with spontaneous remissions.

However, in patients with severe disease, therapy should be initiated promptly, because maternal and fetal mortality are not uncommon.^{43, 44, 45}

PATHOPHYSIOLOGY

Autoimmunity

Aplastic anemia was originally thought to result from a direct toxic effect on hematopoietic stem cells. In the late 1960s, Mathé and colleagues were among the first to postulate an autoimmune basis for aplastic anemia.⁴⁶ After administering antilymphocyte globulin for conditioning, they performed bone marrow transplantation in aplastic anemia patients using partially mismatched donors. Although the transplanted marrow failed to engraft, some patients experienced autologous recovery of hematopoiesis, suggesting that growth and differentiation of the patient's hematopoietic stem cells were being suppressed by the immune system. An analysis by the International Bone Marrow Transplant Registry of identical twin bone marrow transplants in aplastic anemia patients also suggests an autoimmune etiology for the majority of patients. Attempts to treat aplastic anemia by simple transfusion of bone marrow from an identical twin fails to reconstitute hematopoiesis in about 70% of patients.⁴⁷ However, repeating the procedure following a high-dose cyclophosphamide conditioning regimen is successful in most patients.⁴⁸

The first laboratory evidence of autoimmunity in aplastic anemia was provided by experiments showing that lymphocytes from aplastic anemia patients inhibit allogeneic and autologous hematopoietic colony formation *in vitro*.⁴⁹ Subsequently, cytotoxic T lymphocytes were found to mediate the destruction of hematopoietic stem cells in aplastic anemia.^{50, 51} These cytotoxic T cells are more conspicuous in the bone marrow of aplastic anemia patients than in the peripheral blood,^{52, 53, 54} and they overproduce interferon- γ and tumor necrosis factor (TNF).⁵⁵ TNF and interferon- γ are direct inhibitors of hematopoiesis and appear to up-regulate Fas expression on CD34⁺ cells.⁵⁶ Immortalized CD4⁺ and CD8⁺ T-cell clones from aplastic anemia patients also secrete Th1 cytokines and are directly toxic to autologous CD34 cells.^{50, 51} There is also evidence for a humoral autoimmune response in aplastic anemia; autoantibodies against kinectin, a 1,300 amino acid molecule expressed on human hematopoietic cells, liver, ovary, testis, and brain cells have been found in approximately 40% of aplastic anemia patients.⁵⁷ Antidiazepam-binding related protein-1 is another putative autoantibody found in some patients with aplastic anemia;⁵⁸ however, the relevance of these autoantibodies to the pathophysiology of aplastic anemia is unclear. Studies in aplastic anemia patients examining T-cell diversity using complementarity-determining region (CDR3) spectratyping further implicate an autoimmune pathophysiology in aplastic anemia. T cells from aplastic anemia patients have limited T-cell receptor β -chain heterogeneity, suggesting oligoclonal T-cell expansion in response to a specific, but as yet unrecognized, antigen.^{51, 59}

Stem Cells

A reduction in the number of hematopoietic stem/progenitor cells is a universal laboratory finding in aplastic anemia. CD34⁺ cells, assayable hematopoietic progenitors, and long-term culture-initiating cells are strikingly reduced in aplastic anemia.^{60, 61} However, some healthy hematopoietic stem cells persist in most patients with aplastic anemia inasmuch as complete recovery of normal hematopoiesis can occur with effective immunosuppressive therapy.^{62, 63} T cells from aplastic anemia patients kill hematopoietic stem cells in an HLA-DR restricted manner^{50, 51} via Fas ligand.⁵⁶ Hematopoietic stem cells represent several classes of cells with varying capacity for long-term production of the different hematopoietic lineages and variable expression of Fas ligand and HLA-DR.⁶⁴ The most primitive hematopoietic stem cells express little or no HLA-DR^{64, 65} or Fas,^{66, 67} and the expression of both HLA-DR and Fas increases as the stem cells mature. Thus, the primitive hematopoietic stem cells, which normally represent less than 10% of the total CD34⁺ cells, may be relatively invisible to the autoreactive T cells; conversely, the more mature hematopoietic stem cells may be the principal targets of the immune attack in aplastic anemia.⁶⁸ The primitive hematopoietic stem cells eluding the autoimmune attack may be responsible for the slow hematopoietic recovery that occurs in aplastic anemia patients following immunosuppressive therapy.

Clonality and Aplastic Anemia

Clonal hematopoietic stem cell disorders such as paroxysmal nocturnal hemoglobinuria (PNH) and MDS frequently arise from aplastic anemia. Even before the widespread use of immunosuppressive therapy, 5% of patients with aplastic anemia progressed to clonal hematopoiesis. This suggests that the increase in MDS and PNH following immunosuppressive therapy is not a direct consequence of treatment. Rather, the increased survival following immunosuppressive therapy allows time for these underlying clones to develop and expand.^{69, 70}

MDS is a clonal hematopoietic stem cell disorder that produces multilineage hematologic cytopenias (Chapter 79). It is associated with heterogeneous karyotypic abnormalities, often involving chromosomes 5, 7, or 8. Up to 15% of children and adults with aplastic anemia will develop MDS following immunosuppressive therapy, with monosomy 7 being the

most common chromosomal abnormality to emerge.^{71, 72} PNH results from the expansion of an abnormal hematopoietic stem cell that harbors a somatic mutation of the X-linked gene, PIGA.^{73, 74} The PIGA gene product is required for glycosylphosphatidylinositol (GPI) anchor biosynthesis; consequently, PNH cells are deficient in all GPI-anchored proteins (GPI-AP). The GPI-APs (CD59 and CD55) protect cells from complement-mediated destruction; their absence explains the complement-mediated intravascular hemolysis associated with PNH.

Small to moderate PNH clones are found in up to 70% of patients with aplastic anemia.^{69, 75} Typically, less than 20% GPI-AP-deficient granulocytes are detected in aplastic anemia patients at diagnosis, but occasional patients may have larger clones. DNA sequencing of the GPI-AP-deficient cells from aplastic anemia patients reveals clonal PIGA gene mutations.⁷⁶ Moreover, many of these patients exhibit expansion of the PIGA mutant clone and progress to clinical PNH. Although it was once thought that PNH evolving from aplastic anemia is more benign than classical PNH, this observation may be a consequence of lead time bias, inasmuch as many of these patients eventually develop classical PNH symptoms after the PIGA mutant clone expands. Interestingly, the PNH clone can regress, remain stable, or expand in aplastic anemia patients treated with immunosuppressive therapy; however, expansion of the PNH clone is commonly associated with relapse.^{77, 78}

The mechanism whereby PNH clones expand is not entirely clear; however, a preponderance of data suggests that the PNH stem cell has a conditional growth advantage in the setting of aplastic anemia. Specifically, it has been suggested that PNH cells

P.968

may be relatively resistant to an autoimmune attack on the bone marrow, possibly because they are deficient in GPI-anchored UL binding proteins (ULBP) that serve as receptors for NKG2D, a ligand that is important for natural killer cells and T cells.^{79, 80} Alternatively, it has been proposed that “second hit” mutations may also give the PNH clone a growth advantage.⁸¹ These hypotheses are not mutually exclusive.

CLINICAL FEATURES AND DIAGNOSIS

Aplastic anemia can present abruptly over days, or insidiously over weeks to months. Clinical manifestations are proportional to the peripheral blood cytopenias and may include dyspnea on exertion, fatigue, easy bruising, petechia, epistaxis, gingival bleeding, heavy menses, headache, and fever. A complete blood count, leukocyte differential, reticulocyte count, and a bone marrow aspirate and biopsy can establish the diagnosis. Peripheral blood flow cytometry to rule out PNH^{82, 83} and bone marrow karyotyping to help exclude hypoplastic myelodysplastic syndromes (hMDS) should be performed on all patients. Flow cytometric assays to detect PNH cells can be performed with either monoclonal antibodies⁸³ or a fluorescein-conjugated proaerolysin variant known as FLAER.⁸⁴ Unlike monoclonal antibodies that bind the protein portion of a GPI-anchored protein, FLAER binds to the glycan portion of the GPI anchor and is highly sensitive and specific for detecting PNH cells.^{69, 82} Patients less than 40 years of age should be screened for Fanconi anemia using the clastogenic agents diepoxybutane or mitomycin C that test for increased chromosomal breakage.⁵ Up to 10% of patients with Fanconi anemia will have a false negative chromosomal breakage analysis due to mosaicism. In these patients, fibroblasts from a skin biopsy or buccal smear can be used to establish the diagnosis. A family history of cytopenias or pulmonary fibrosis should raise suspicion for an inherited disorder, even when physical abnormalities are not present.

A hypocellular bone marrow is required for the diagnosis of aplastic anemia (Table 38.2). Spicules from an aspirate may be surprisingly cellular in some patients despite overall marrow hypocellularity as most patients will have residual pockets of ongoing hematopoiesis. Thus, a 1- to 2-cm core biopsy is essential for assessing cellularity. Mild dyserythropoiesis is not uncommon in aplastic anemia, especially in cases with simultaneous small-to moderate-sized PNH populations; however, the presence of a small percentage of myeloid blasts or dysplastic features in the myeloid or megakaryocyte lineages favors a diagnosis of hMDS (Table 38.3). Distinguishing between aplastic anemia and hMDS is often challenging, especially in older patients where hMDS is more common. The percentage of CD34⁺ cells in the bone marrow is often helpful.^{85, 86} CD34 is expressed on hematopoietic progenitors and is fundamental to the pathophysiology of both diseases; in MDS clonal expansion emanates from a CD34⁺ stem cell, and in aplastic anemia the CD34⁺ stem cells are the target of an autoimmune attack (Fig. 38.1). Accordingly, the percentage of CD34⁺ cells is usually ≤0.3% in aplastic anemia, whereas the CD34 percentage is either normal (0.5% to 1.0%) or elevated in hMDS.⁸⁵

TABLE 38.2 DIFFERENTIAL DIAGNOSIS OF PANCYTOPENIA WITH A HYPOCELLULAR BONE MARROW

Acquired aplastic anemia

Inherited aplastic anemia
 Fanconi anemia
 Dyskeratosis congenita
 Shwachman-Diamond syndrome
 Amegakaryocytic thrombocytopenia
 Reticular dysgenesis
 Hypoplastic myelodysplastic syndromes
 Large granular lymphocytic leukemia (rare)
 Hypoplastic PNH (PNH/aplastic anemia)
 PNH, paroxysmal nocturnal hemoglobinuria.

TABLE 38.3 BONE MARROW FINDINGS THAT HELP TO DISCRIMINATE APLASTIC ANEMIA FROM MYELODYSPLASIA

Characteristic	Myelodysplastic Syndromes	Aplastic Anemia
Cellularity	Usually increased or normal ^a	Decreased
CD34 count	Normal to increased	Decreased
Erythropoiesis		
Megaloblastosis	Common	Common
Dyserythropoiesis	Common	Sometimes
Ringed sideroblasts	Common	Never
Myelopoiesis		
Increased blasts	Common	Never
Megakaryocytes		
Dysplastic	Common	Never

^a A hypocellular bone marrow is found in up to 15% of cases of myelodysplastic syndromes.

Classification

As do most autoimmune diseases, aplastic anemia encompasses a wide spectrum of disease activity ranging from mild to severe. The risk of morbidity and mortality from aplastic anemia correlates best with the severity of the cytopenias rather than bone marrow cellularity. Thus, acquired aplastic anemia is classified as nonsevere (NSAA), severe (SAA), or very severe (VSAA) based on the degree of peripheral blood pancytopenia (Table 38.4). A bone marrow cellularity of less than 25% and markedly decreased values of at least two of three hematopoietic lineages (neutrophil count <500/μl, platelet count <20,000/μl, and absolute reticulocyte count of <60,000/μl) define SAA. VSAA satisfies the above criteria except the neutrophil count is <200/μl, whereas NSAA is characterized by a hypocellular bone marrow, but with cytopenias that do not meet the criteria for severe disease. The 2-year mortality rate with supportive care alone for patients with SAA or VSAA approaches 80%,⁸⁷ with invasive fungal infections and overwhelming bacterial sepsis being the most frequent causes of death. NSAA is seldom life-threatening and in many instances requires no therapy.

SUPPORTIVE CARE

Transfusions

Patients with symptomatic anemia and/or thrombocytopenia associated with wet purpura or bleeding require immediate blood transfusions. All transfusions in patients with suspected aplastic anemia should be irradiated to prevent transfusion-associated GVHD. If the patient is a potential BMT candidate and is cytomegalovirus (CMV)-negative or the CMV status is unknown, CMV transmission should be avoided by either leukoreduction or the use of CMV-negative products. Blood donation from family

members should be avoided to prevent alloimmunization that could also complicate future BMT. After stabilization of the patient, blood products should be used judiciously to prevent cardiopulmonary compromise and to reduce the risk of hemorrhage; a platelet goal of 10,000/ μL will suffice for most patients, although some patients will tolerate even lower platelet goals without bleeding or petechiae.

FIGURE 38.1. Aplastic anemia versus hypoplastic myelodysplastic syndrome (hMDS). A: Bone marrow biopsy from patient with aplastic anemia. B: Higher power of biopsy from A showing cluster of nucleated red cells. C: Low-power view of biopsy from a patient with hMDS. D: High-power view of bone marrow from patient in C showing small blast population. Brown pigment represents iron. E: CD34 immunoperoxidase stain (brown) of marrow from patient with hMDS.

TABLE 38.4 CLASSIFICATION OF APLASTIC ANEMIA BASED ON SEVERITY OF PANCYTOPENIA

Severe aplastic anemia (SAA)

Bone marrow cellularity <25%

Two of three peripheral blood criteria:

Absolute neutrophil count <500/ mm^3

Platelet count <20,000/ mm^3

Reticulocyte count <60,000/ mm^3 or <1% corrected reticulocyte count

Very severe aplastic anemia (vSAA)

Same as SAA with absolute neutrophil count $<200/\text{mm}^3$

Nonsevere (moderate aplastic anemia)

Bone marrow cellularity $<25\%$

Peripheral blood cytopenias do not fulfill criteria for SAA

Antibiotics

Overwhelming sepsis caused by bacteria or fungus (especially aspergillus) is the most frequent cause of death from aplastic anemia. In most circumstances, prophylactic antibiotics are unnecessary. However, for patients with absolute neutrophil counts that are consistently $<200/\mu\text{L}$, prophylaxis with oral antibiotics, such as a quinolone and a triazole antifungal, is reasonable. Patients with febrile neutropenia should be treated promptly with broad-spectrum antibiotics; in patients with persistent fever after the initiation of antibacterial antibiotics, aspergillus coverage should be added. Prophylaxis for *Pneumocystis carinii* pneumonia should be given to

P.970

all patients for at least 6 months after immunosuppressive therapy, BMT, or high-dose cyclophosphamide therapy.

Growth Factors

Hematopoietic growth factor deficiency (such as erythropoietin, granulocyte colony-stimulating factor, thrombopoietin, or granulocyte-monocyte colony-stimulating factor) is not responsible for the bone marrow failure in aplastic anemia; levels of measurable hematopoietic growth factors are markedly elevated in aplastic anemia patients in a compensatory attempt to increase blood production. Hence, these factors should not be used in lieu of definitive therapy. Hematopoietic growth factors are often used after immunosuppressive therapy or high-dose cyclophosphamide therapy to accelerate hematopoietic recovery, but their use has not been shown to improve survival.

DEFINITIVE TREATMENT

Nonsevere (Moderate) Aplastic Anemia

There are limited data on the long-term prognosis of patients with moderate aplastic anemia. Although moderate aplastic anemia can progress, many patients will remain stable for years, and some may spontaneously improve, even in the absence of specific treatment.⁸⁸ Treatment should be based on the degree of cytopenia, not bone marrow cellularity. Patients with asymptomatic cytopenias probably require no therapy. Patients with more significant cytopenias, such as symptomatic anemia, may benefit from a trial of immunosuppressive therapy with antithymocyte globulin and cyclosporine (ATG/CSA)⁸⁹ or CSA alone.⁹⁰ Daclizumab, a humanized monoclonal antibody to the interleukin-2 receptor, improved blood counts in 6 of 16 patients with moderate aplastic anemia.⁹¹ However, it is not clear that treatment of moderate aplastic anemia will effect survival.

Definitive Therapy for Severe Aplastic Anemia

Bone Marrow Transplantation

Allogeneic BMT from an HLA-matched sibling donor is the treatment of choice at most centers for young patients with SAA (Table 38.5). A major advantage of BMT over standard immunosuppressive therapy is a marked reduction in the risk of relapse and the outgrowth of late clonal disorders such as MDS and PNH.⁹² Cyclophosphamide (50 mg/kg/day \times 4 days) with or without ATG, is commonly used for conditioning before stem cell transplantation. Although this regimen is nonmyeloablative, the immunosuppression is sufficient to allow engraftment in most cases.^{93, 94, 95} Avoidance of total body irradiation and busulfan reduces transplant-related complications such as mucositis, graft-versus-host disease (GVHD), second malignancies, and infertility. Alternative regimens using fludarabine, cyclophosphamide and antithymocyte globulin are increasingly being used.⁹⁶ Survival rates following matched sibling allogeneic BMT have steadily improved since the 1970s largely because of improved supportive care, improved typing, and better GVHD prophylaxis.⁹⁷ Late BMT-related complications such as chronic GVHD occur in up to one third of patients, with many of these patients requiring long-term therapy for their GVHD.⁹⁸ Patient age and the type of allograft (HLA-matched sibling, unrelated, or mismatched donors) are the most important factors influencing outcome. In patients under 30 years of age, the cure rate after HLA-matched sibling BMT ranges from 70% to 90%.^{98, 99, 100} However, the risk of GVHD steadily increases with age, leading to reduced survival.

Alternative Donor Bone Marrow Transplantation

Unrelated donors and mismatched transplants have almost twice the transplant-related mortality and risk of GVHD as matched sibling donor transplants (Table 38.6).²⁴ Less than 30% of patients will have an HLA-matched sibling donor. Thus, bone marrow transplantation from unrelated or mismatched donors is usually reserved for patients who fail to respond to one or more courses of immunosuppressive therapy. The best results with unrelated and mismatched transplants are seen in patients under 21 with disease duration of less than 1 year.^{101, 102, 103} The International Bone Marrow Transplant Registry reported on the results of 318 alternative donor transplants between 1988 and 1998.¹⁰⁴ Most patients in this series were young, heavily transfused, and of poor performance status. The probability of graft failure was 20% and the survival probability at 5 years was less than 40%. The Fred Hutchinson Cancer Research Center reported on the results of unrelated allogeneic bone marrow transplantation in aplastic anemia after conditioning with low-dose total body irradiation, high-dose cyclophosphamide, and ATG.¹⁰³ The median age was 19 years, and with a median follow-up of 7 years, 61% of HLA-identical and 40% of HLA nonidentical transplant recipients survived the procedure; however, more than 70% of patients acquired acute GVHD, and over 50% developed chronic GVHD. However, improved typing, newer conditioning regimens, and better GVHD prophylaxis are leading to better survival, higher engraftment rates, and less GVHD. EBMT data using fludarabine, cyclophosphamide, and ATG conditioning ± total body irradiation (TBI) demonstrated survival rates as high as 75%.¹⁰⁵ Survival is best

P.971

in children and in patients who undergo BMT within 2 years of diagnosis. Another promising approach to facilitate engraftment and to mitigate the risk of GVHD is the use of post-transplant cyclophosphamide for GVHD prophylaxis.^{106, 107}

Immunosuppressive Therapy

Immunosuppressive therapy with ATG/CSA is used in patients who are not candidates for bone marrow transplantation because of older age or lack of a matched sibling donor. ATG is produced by immunizing animals (horse or rabbit) against human thymocytes and kills human T cells through its cytolytic activity. The largest experience is with horse ATG, although rabbit ATG has recently been approved for use in the United States. CSA suppresses T-cell function by inhibiting the expression of nuclear regulatory proteins. Both single-agent ATG and single-agent CSA⁹⁰ can induce remissions in acquired aplastic anemia; however, the combination ATG/CSA leads to a higher response rate and a greater likelihood of achieving transfusion independence.^{89, 108} A randomized controlled trial demonstrated that horse ATG/CSA is superior to rabbit ATG/CSA. However, difficulties in maintaining quality control have led to the withdrawal of horse ATG in Europe since June of 2007.

The response rates to ATG/CSA range between 60% and 80% (Table 38.7), with 5-year survival rates comparable to BMT.¹⁰⁹ However, in contrast to BMT, most patients are not cured of their disease. Most patients respond within 6 to 12 weeks after receiving ATG/CSA. ATG is usually given over 4 days but CSA must be continued for at least 6 to 12 months before tapering the drug. Persistent cytopenia is common and many patients relapse, become dependent on cyclosporine, or develop secondary clonal disease such as PNH or MDS.^{71, 89, 110, 111} The European Group for Blood and Marrow Transplantation (EBMT) SAA working party performed a retrospective analysis of 468 patients treated with immunosuppressive therapy between 1975 and 1986.¹¹² Patients who survived more than 2 years (n = 223) were classified as long-term survivors. The actuarial mortality rate for long-term survivors was 22% at 8 years, and the actuarial risks of developing PNH and MDS were 13% and 15%, respectively, at 7 years. Bacigalupo and colleagues reported a response rate and overall survival of 77% and 87%, respectively, in 100 patients (median age, 16 years) treated with ATG/CSA, prednisolone, and granulocyte colony-stimulating factor.⁶² The risk of relapse was 9% and cytogenetic abnormalities developed in 11%, but the actuarial probability of discontinuing cyclosporine therapy was only 38% at 5 years. The National Institutes of Health (NIH) treated 122 patients (median age, 35 years) with the combination of ATG/CSA and methylprednisolone and followed them over a period of 8 years.⁷¹ The response rate was 58% and actuarial survival at 7 years was 55%; 13% of patients died within 3 months of treatment,

P.972

mostly from fungal infections. The relapse rate for responders was 40% and 13 patients developed MDS. In an attempt to improve response rate and survival, and to decrease the relapse rate and secondary MDS that occurs after ATG/CSA, the NIH added mycophenolate (1 gram twice daily for 18 months) to the standard ATG/CSA regimen. This three-drug regimen resulted in a 62% response rate, but 37% of the responders relapsed (most while taking mycophenolate) and 9% progressed to either MDS or leukemia; thus, the addition of mycophenolate did not improve response or survival.¹¹³ Sirolimus and Tacrolimus have also been used as alternatives to cyclosporine but no clear advantage in terms of response, relapse, or secondary clonal disease has been demonstrated. Alemtuzumab is another active immunosuppressive therapy for SAA but response rates in untreated patients are less than 30%.

TABLE 38.7 REPRESENTATIVE RESULTS TRIALS OF IMMUNOSUPPRESSIVE THERAPY FOR SEVERE APLASTIC ANEMIA

High-dose Cyclophosphamide

High-dose cyclophosphamide remains (often in conjunction with ATG) the most commonly used BMT conditioning regimen for aplastic anemia.^{93, 114} Interestingly, complete reconstitution of autologous hematopoiesis occurs in 10% to 15% of patients undergoing allogeneic BMT for aplastic anemia.^{115, 116, 117} Most of these patients have maintained long-term remissions despite autologous reconstitution. The EMBT reported that 10% of SAA patients experience autologous reconstitution following BMT using a cyclophosphamide + ATG conditioning regimen. Interestingly, 10-year survival (84%) in patients with autologous recovery was equivalent or better than in patients who engrafted (74%).¹¹⁸

Cyclophosphamide is a prodrug and is converted to 4-hydroxycyclophosphamide and its tautomer, aldophosphamide, by the hepatic cytochrome P-450 system.¹¹⁹ These compounds diffuse into cells and are converted into the active alkylating compound, phosphoramidate mustard, through simple intracellular decomposition. The major mechanism of cyclophosphamide detoxification appears to be inactivation of aldophosphamide by cellular aldehyde dehydrogenase to form the inert compound, carboxyphosphamide. ALDH1A1, previously called class I ALDH or cytosolic ALDH, ALDH1, or retinaldehyde dehydrogenase 1, appears to be the aldehyde dehydrogenase most responsible for cyclophosphamide detoxification.¹²⁰ ALDH1A1 also plays an important role in ethanol metabolism, but its major function appears to be the biosynthesis of retinoic acid from vitamin A (retinol).¹²⁰ After alcohol dehydrogenase oxidizes retinol to retinaldehyde, ALDH1A1 oxidizes retinaldehyde to retinoic acid. Retinoic acid is essential for cellular growth and differentiation. Cells with high proliferative potential, such as hematopoietic stem cells, express high levels of ALDH1A1 because of their requirement for retinoic acid and are thus resistant to cyclophosphamide.^{121, 122} Conversely, lymphocytes have low levels of aldehyde dehydrogenase and are rapidly killed by high doses of cyclophosphamide. High-dose cyclophosphamide is therefore highly immunosuppressive, but not myeloablative, allowing endogenous hematopoietic stem cells to reconstitute hematopoiesis.

High-dose cyclophosphamide without BMT has been used to treat aplastic anemia patients who lack a suitable donor.^{63, 123, 124, 125, 126, 127, 128} In a pilot study, 7 of 10 patients achieved durable complete remissions. No relapse or clonal evolution was observed with a median follow-up of 10.8 (range, 7.3 to 17.8) years. Investigators at the National Institutes of Health initiated a randomized trial of high-dose cyclophosphamide plus CSA versus ATG/CSA.¹²⁶ This trial closed after enrolling 31 patients (17% of the planned accrual) because early toxicity appeared to be higher in the cyclophosphamide plus CSA arm. However, no stopping rules were met, and there were no statistical differences in response rate, survival, or secondary clonal disorders.

Subsequently, a large mature study has confirmed the efficacy of high-dose cyclophosphamide for treating SAA.¹²⁸ Investigators from Johns Hopkins treated 67 SAA patients with high-dose cyclophosphamide; 44 patients were treatment naïve and 23 were refractory to one or more previous immunosuppressive regimens. At 10 years, the overall actuarial survival, response rate, and event-free survival was 88%, 71%, and 58%, respectively, for the 44 treatment-naïve patients. Patients with refractory SAA fared less well: at 10 years, overall actuarial survival, response, and event-free survival rates were 62%, 48%, and 27%, respectively. For treatment-naïve patients, the median time to a neutrophil count of $0.5 \times 10^9/L$ was 60 (range, 28 to 104) days, the median time to last platelet and red cell transfusion was 117 and 186 days, respectively. Relapse occurred in just 2 of the treatment-naïve patients, one of whom was retreated with high-dose cyclophosphamide into a second complete remission. Despite the high response rate and low risk of relapse and secondary clonal disease, many investigators are unwilling to accept the relatively long period of aplasia associated with this therapy. Additional large series and/or future randomized trials will be necessary to fully define the role of this promising therapy.

Relapsed and Refractory Severe Aplastic Anemia

There is no standard algorithm for managing patients with SAA who fail to respond, or relapse, after treatment with ATG/CSA; however, inasmuch as 30% to 40% of patients do not respond to initial therapy and another 20% to 40% of responding patients relapse, these patients pose a common treatment dilemma. Therapeutic options include allogeneic bone marrow transplant (usually from an unrelated or mismatched donor), re-treatment with ATG/CSA, alemtuzumab, or high-dose cyclophosphamide. Alternative donor allogeneic BMT probably offers the best chance for cure in children and young adults, but is associated with substantial morbidity and mortality in older patients. Patients with relapsed aplastic anemia are more likely to respond to a second course of ATG/CSA or to high-dose cyclophosphamide than patients with primary refractory disease. Response rates to a second course of horse or rabbit ATG/CSA ranges from 20% to 70% with the weighted average closer to 30%.^{129, 130, 131, 132, 133} High-dose cyclophosphamide or alemtuzumab may also salvage up to 30% of patients with refractory SAA.^{134, 135, 136} All of these potential options should be discussed with patients; however, patient age, performance status, timing and availability of a bone marrow donor, insurance coverage, and institutional expertise are factors in the decision process.

Treatment of Hepatitis-associated Severe Aplastic Anemia

There are no large prospective series to determine the best treatment for HAA, in part due to the rarity of the disease. Most reports consist of registry data, case series, or single case reports. Because HAA predominantly occurs in children, allogeneic BMT from an HLA-identical sibling is usually considered as first-line therapy. In patients without an HLA-identical sibling, ATG/CSA and high-dose cyclophosphamide have produced durable remissions.^{41, 137} The EBMT performed a retrospective cohort study from 257 centers to assess the epidemiology and treatment of HAA.¹³⁸ They identified 214 patients managed between 1990 and 2007. The incidence of HAA was 5% and the response rate and outcome did not appear to differ from idiopathic SAA. Similar results were reported by the Japan Childhood Aplastic Anemia Study Group who analyzed the outcome of 44 children with HAA. They reported a 70% response rate with immunosuppressive therapy and an 88% overall survival at 10 years.¹³⁹

Other Therapies

Numerous reports suggest that anabolic steroids are effective in treating aplastic anemia;^{140, 141, 142} however, for SAA, controlled

P.973

clinical trials have shown no benefit in terms of hematopoietic improvement¹⁴³ or survival.⁸⁷ Although it is clear that androgens should not be used as first-line therapy in SAA, a 3- to 6-month trial is not unreasonable in patients with refractory disease. Danazol, oxymetholone, and decanoate are often tried in such cases. Careful monitoring of liver function tests and vigilance for other hepatic complications (adenomas, tumors, etc.) are required. Eculizumab is a humanized monoclonal antibody that blocks terminal complement activity and prevents intravascular hemolysis in PNH.⁷⁴ The drug is FDA approved for the treatment of PNH but it does not improve bone marrow function; thus it should not be used to treat aplastic anemia.

Chapter 39

Red Cell Aplasia: Acquired and Congenital Disorders

Jeffrey M. Lipton

Bertil Glader

Robert T. Means, Jr.

ACQUIRED RED CELL APLASIA

Pure red cell aplasia (PRCA) is an acquired syndrome characterized by normochromic normocytic anemia, severe reticulocytopenia (reticulocyte count <1%), and an almost complete absence of erythroblasts from the bone marrow

(erythroblasts <0.5%).^{1, 2} In contrast to aplastic anemia, in which the aplasia involves all three cell lines, in PRCA the aplasia is selective for the erythroid cell line so that patients have normal leukocyte and platelet counts.³ PRCA is a rare disorder that affects any age group and both males and females equally.

This disorder was first described by Kaznelson in 1922⁴ and has appeared in the literature under a variety of different names, including pure aplastic anemia, erythrophthisis, chronic hypoplastic anemia, aplastic crisis, erythroblastopenia, erythropoiesis imperfecta, Blackfan-Diamond syndrome, pure red cell agenesis, and primary red cell anemia.¹ Today the term PRCA is used primarily to describe this disorder in adults, although some of the causes of RBC aplasia in adults also are seen in children. Diamond-Blackfan anemia (DBA) refers to a pathophysiologically different congenital syndrome of children. Transient erythroblastopenia of childhood (TEC) describes a typically self-limited PRCA variant that occurs most commonly in infants and children and is discussed below. It must be noted, however, that DBA can present in adulthood and should be considered in the differential diagnosis of PRCA at any age.

PRCA may be primary or may be secondary to a variety of neoplastic, autoimmune, or infectious diseases (Table 39.1). Primary acquired PRCA affects individuals of any age in the absence of any underlying disorder. It may run an acute and usually self-limited course or may persist chronically as a form of refractory anemia. In adults the acute form of primary PRCA is very rare and the chronic form of this disorder predominates. Acute PRCA in adults escapes diagnosis because acute arrest of erythropoiesis of short duration does not lead to symptoms of anemia, as a result of the long lifespan of the red cells.

Etiology and Pathogenesis

PRCA may occur as a primary disorder or may develop as a hematologic complication in the course of a variety of diseases (Table 39.1). In the section that follows, differing etiologies of PRCA and their associated pathogenetic mechanisms are described. Secondary etiologies are arranged in approximate order of clinical significance or frequency.

Primary Acquired (Autoimmune) Pure Red Cell Aplasia

In primary acquired PRCA and TEC, multiple studies have indicated that the arrest of erythropoiesis is caused by the presence in the patient's plasma of an erythropoietic inhibitor. Early studies in mice have shown that injection of patients' plasma leads to a significant suppression of *in vivo* erythropoiesis as measured by ⁵⁹Fe incorporation into newly formed red cells.^{101, 102} Evaluation of the response of patients' marrow cells to erythropoietin by measuring heme synthesis *in vitro* showed that, in the presence of normal plasma, PRCA marrow responds normally to erythropoietin, but in the presence of a patient's autologous plasma, a significant decline in heme synthesis is observed, suggesting the presence in the patient's plasma of an inhibitor acting on erythroid cells.^{103, 104} In about 60% of cases, patients' marrow cells respond to erythropoietin in a normal way by increasing the rate of heme synthesis by 2- to 9-fold and in about 40% an inhibitor of erythropoiesis can be detected in their plasma. This inhibitor has been localized to the IgG fraction, and it disappears from the plasma after remission of PRCA.^{103, 104, 105}

The stage of erythropoiesis at which the arrest occurs has been studied by assaying PRCA marrow cells in semisolid media for erythroid progenitors. Despite a conspicuous absence of erythroblasts from the PRCA marrow, in at least 60% of patients, normal numbers of early burst-forming unit erythroid (BFU-E) and late colony-forming unit erythroid (CFU-E) erythroid progenitors can be detected, indicating that the arrest occurs at any level between CFU-E and basophilic erythroblasts. In the remainder of patients the erythroid cell compartment is affected at a stage earlier than the CFU-E, so that the CFU-E and/or BFU-E marrow pools are significantly reduced.^{1, 106, 107, 108} The presence of normal numbers of erythroid progenitors has been associated with a favorable outcome of immunosuppressive therapy.^{106, 108} The patient's serum IgG inhibits maturation and differentiation of erythroid progenitors into erythroblasts *in vitro*. The inhibition is dose-dependent and is no longer present in the IgG fraction of the patient's plasma collected after remission.¹⁰⁵ The inhibitory effect of the IgG is specific for erythroid cells, because no effect on myeloid progenitor cell growth is detected.^{107, 108, 109}

The target antigen and mode of action of the IgG inhibitor of erythropoiesis has been investigated in a number of cases of primary autoimmune PRCA, but appears to be variable. As discussed above, it may target erythroid CFU-E and/or BFU-E progenitors or it may be directed against morphologically recognizable erythroblasts.^{110, 111} The molecule(s) on the erythroid cell membrane with which the PRCA IgG inhibitor interacts has not yet been defined. In rare cases, endogenous erythropoietin itself appears to be the target antigen.^{112, 113} In some cases of autoimmune hemolytic anemia, concurrent with PRCA, the antibody causing hemolysis can also suppress erythroid progenitor colony formation,⁷⁵ while in other cases the two processes result from two different antibodies.^{76, 77}

In addition to antibody-mediated PRCA, cases of PRCA have been reported in which the immunologic mechanism is T cell mediated. These cases appear to be particularly associated with thymomas.^{114, 115, 116, 117, 118, 119, 120, 121} There are also

cases of PRCA in which no immune pathogenic mechanism or other known mechanism can be established by in vitro assays. These cases are classified as idiopathic PRCA. However, failure to demonstrate an immune mechanism does not necessarily exclude an immune pathogenesis, since the outcome of treatment seems to be the same among autoimmune and idiopathic cases.¹

Transient Erythroblastopenia of Childhood

This is a common cause of acquired red cell aplasia in young children^{122, 123} due to a transient antibody-mediated suppression of normal erythropoiesis.^{124, 125} The disorder is characterized by the gradual (over weeks) development of anemia (hemoglobin level of 2 to 8 g/dl), reticulocytopenia, and a pronounced reduction of bone marrow erythroblasts. The platelet count is normal to increased. The leukocyte count is usually normal, although 20% of children

P.976

may have significant neutropenia (less than 1,000 neutrophils per dl). The disorder uniquely occurs in previously healthy young children from 6 months to 4 years of age and is seen with equal frequency in boys and girls. Occasionally cases of the disorder occur in clusters, suggesting it may be a consequence of some seasonal environmental toxin or virus. To date, however, serologic studies have failed to reveal exposure to a common virus. The natural history of TEC is that all patients recover spontaneously in a few weeks and there are no long-term hematologic sequelae. In many children with the disorder, particularly if there is evidence of recovery at the time of diagnosis, no specific therapy other than careful observation is necessary. Erythrocyte transfusions are indicated only if a child is symptomatic from the anemia, and rarely is more than one transfusion needed. Neither iron nor steroid therapy have any role in the management of this disorder. The diagnosis often is confused with that of iron deficiency anemia, although the erythrocytes in patients with TEC are normocytic (mean corpuscular volume [MCV] 70 to 85 fl, which is normal for children), whereas iron deficiency anemia is characterized by microcytosis (MCV, 50 to 70 fl). TEC also may be confused with DBA, although the latter generally presents before 6 months of age, often is associated with congenital abnormalities, and usually is characterized by macrocytic erythrocytes with many fetal-like features. (See section "Diamond-Blackfan Anemia.")

TABLE 39.1 CLASSIFICATION OF PURE RED CELL APLASIA

Congenital

Inherited

Diamond-Blackfan anemia

Anti-Epo antibodies after treatment with Epo^{99, 100}

Epo, erythropoietin; PRCA, pure red cell aplasia; TEC, transient erythroblastopenia of childhood.

Myelodysplastic Primary Pure Red Cell Aplasia

A small percentage of cases of idiopathic PRCA, usually refractory to treatment, may evolve into acute leukemia, and these cases are classified as preleukemic or myelodysplastic.^{1, 126} In a sense, such cases should be regarded not as part of a PRCA syndrome but rather as myelodysplastic morphologically resembling PRCA.

Parvovirus-induced Pure Red Cell Aplasia

It has been known for many years that human B19 parvovirus is responsible for the aplastic crisis seen in patients with chronic hemolytic anemia.^{127, 128, 129, 130, 131} It was subsequently demonstrated that B19 parvovirus can produce chronic PRCA in immunocompromised patients, such as those with HIV, posttransplantation, or on immunosuppressive drugs.^{45, 46, 47, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141}

B19 parvovirus directly infects human erythroid progenitors by a process requiring the red cell surface P antigen (globoside).^{142, 143} Individuals who do not express P antigen are not susceptible to parvovirus infection.¹⁴⁴ B19 parvovirus induces apoptosis in erythroid progenitors.¹⁴⁵ The precise mechanism by which this occurs is unclear, but appears to involve viral nonstructural protein 1.^{146, 147} Hypoxia-inducible factor-1 appears to upregulate expression of viral messages in infected cells.¹⁴⁸

Recombinant Erythropoietin-induced Immune Pure Red Cell Aplasia

As noted earlier, autoimmune PRCA caused by antibodies against endogenous Epo has been described infrequently.^{112, 113, 149} Beginning in the mid- to late 1990s, cases of PRCA associated with antibodies against recombinant human (rh) Epo began to appear.

These cases occurred in patients with end-stage renal disease receiving rhEpo for anemia management.^{99, 150, 151, 152, 153, 154, 155, 156} These cases were unusual in that more than 90% of cases involved a particular rhEpo product, it was primarily associated with subcutaneous treatment, the vast majority of cases occurred outside the United States, and there was wide nation-to-nation variation, even allowing for use of specific rhEpo products.^{99, 157, 158, 159, 160, 161, 162, 163, 164, 165}

Eventually the process was attributed to packaging features of the rhEpo product (such as adjuvant effects of the material used in syringes).^{157, 166, 167, 168, 169, 170} In response to changed packaging, the problem has largely resolved.

P.977

It has been suggested that the low level immunogenicity of rhEpo might be enhanced in specific patients by the presence of Epospecific CD4⁺ T cells, or by HLA-DRB1*09.^{92, 171, 172, 173, 174}

Thymoma

The association between thymic neoplasms and PRCA has been known for many years.^{5, 6, 7, 40, 175, 176, 177, 178} PRCA may precede the development of thymoma, coexist with thymoma, or develop even years after the surgical removal of a thymoma. The incidence of PRCA among patients with thymoma was earlier estimated to be as high as 15%; however, in more recent reports the incidence was found to be close to 4%.^{1, 179} Approaching it from the other perspective, the presence of a thymoma among patients presenting with PRCA was initially reported to be as high as 50%, but in more recent series it was estimated to be close to 9%.^{1, 61, 118, 175, 180} The pathogenetic mechanism involved is uncertain but presumably related to T cell-mediated processes.^{118, 120, 181, 182}

Lymphoproliferative Disorders

Various lymphoproliferative syndromes have been associated with severe erythroid aplasia (see Table 39.2), with chronic lymphocytic leukemia (CLL) of B cell, T cell type, or with the large granular lymphocyte (LGL) type, the last being the most frequent.^{8, 183} The incidence of severe erythroid aplasia among patients with CLL may be as high as 6%, with many cases missed because severe normochromic anemia and reticulocytopenia is a frequent manifestation of advanced-stage CLL and is usually attributed to the primary disease process. The development of erythroid aplasia does not affect the prognosis of CLL and in the majority of cases does not seem to be related to previous cytotoxic chemotherapy.^{1, 8} PRCA has been also described in association with Hodgkin¹² and non-Hodgkin lymphomas,¹³ multiple myeloma,²¹ Waldenström's macroglobulinemia,²³ angioimmunoblastic lymphadenopathy,¹⁶ and Castleman's disease.⁹⁷

TABLE 39.2 DRUGS AND CHEMICALS ASSOCIATED WITH PURE RED CELL APLASIA

Allopurinol	Isoniazid
α-Methyldopa	Lamivudine
Aminopyrine	Leuprolide
Anagryne	Linezolid
Arsphenamine	Maloprim (dapsone and pyrimethamine)
Azathioprine	Mepacrine
Benzene hexachloride	Methazolamide
	Micafungin
Bromsulphalein	Mycophenolate mofetil
Calomel	Penicillin
Campath-1H	
Carbamazepine	D-Penicillamine
Cephalothin	Pentachlorophenol
Chenopodium	Phenobarbital
Cladribine	Phenylbutazone
Chloramphenicol	Procainamide
Chlormadinone	Salicylazosulfapyridine
Chlorpropamide	Santonin
Co-trimoxazole	Sodium dipropylacetate
Diphenylhydantoin Erythropoietin (recombinant)	Sodium valproate
Estrogens	Sulfasalazine
Fenbufen	Sulfathiazole
Fenoprofen	Sulindac

FK506	Tacrolimus
Fludarabine	Thiamphenicol
Gold	Tolbutamide
Halothane	Rifampicin
Interferon- α	Zidovudine

Most pathophysiologic studies have been performed in CLL-associated PRCA. PRCA appears to derive from immune suppression, but not typically through inhibitory antibodies.¹⁴ Various studies have demonstrated that in T cell CLL (including LGL type), the T lymphocytes are responsible for the suppression of erythropoiesis.^{11, 184, 185} The suppression is mediated by direct cell-to-cell interaction, mainly between a subset of T cells expressing receptors for the γ chain of IgG (T γ cells) and erythroid progenitors, and it is HLA-DR restricted.¹⁸⁴ The suppression is selective for the erythroid cells and is not detectable after remission of the PRCA.^{184, 185} Similar findings have been reported in B cell CLL, in which there seems to be a progressive increase in the marrow of T γ cells, which, when they reach a critical concentration, suppress erythropoiesis and cause red cell aplasia.^{116, 117, 121} In LGL lymphocytosis, clonal expansion of LGLs of the γ/δ type expressing killer-cell inhibitory receptors for Class I HLA antigens has been shown to be responsible for lysis of erythroblasts, most likely related to the declining density, with eventual disappearance of HLA-I antigens in late marrow erythroid cells. However, the role of killer-cell inhibitory receptors in the pathogenesis of PRCA in large granular lymphocytosis remains unclear, since such receptors are also detectable in large granular lymphocytosis patients without PRCA.^{186, 187} Expansion of the marrow population of CD8⁺/perforin⁺ memory T cells has also been noted in thymoma-associated PRCA patients.¹⁸⁸

Other Hematologic Malignancies

PRCA has been reported in association with chronic myelogenous leukemia,^{24, 25} chronic myelomonocytic leukemia,⁹ chronic eosinophilic leukemia,³³ primary myelofibrosis,^{26, 27} essential thrombocythemia,²⁸ and acute lymphoblastic leukemia.^{30, 31} Few cases have been studied in detail, but in general the course of PRCA appears to run independently of the associated disease and may reflect a coincident autoimmune disorder.²⁴

Nonthymic Solid Tumors

There have been a number of reports of PRCA observed in patients with nonthymic, nonhematologic malignancies (see Table 39.1).

Given that these reports are rare and that the primary malignancy and PRCA typically run independent courses,¹ it is likely that the association is coincidental.

Autoimmune Disorders/Collagen Vascular Disease

It should not be surprising that PRCA is a hematologic complication of various autoimmune diseases, including collagen vascular diseases, such as systemic lupus erythematosus,^{67, 68} rheumatoid arthritis,⁷² mixed connective tissue disease,⁷³ Sjögren syndrome,^{6, 189} autoimmune hemolytic anemia,^{75, 76, 77} multiple endocrine gland insufficiency,⁷⁴ autoimmune hypothyroidism,^{190, 191} inflammatory bowel disease,⁷⁸ autoimmune liver disease,^{79, 80} pyoderma gangrenosum,¹⁹² and pernicious anemia.⁸⁹ PRCA may occur prior to, during, or after the onset of these disorders. When investigated in detail, cases of PRCA associated with autoimmune or collagen vascular diseases are typically found to be mediated by antibodies which inhibit erythropoiesis.^{193, 194}

P.978

ABO-incompatible Stem Cell Transplantation

PRCA may occur as a consequence of ABO-incompatible bone marrow or stem cell transplantation.^{93, 94, 195, 196, 197} In one series, this complication occurred in 26% of ABO-incompatible transplants and was most common in circumstances where a blood group O recipient was transplanted from a blood group A donor.¹⁹⁷ Erythroid precursors express surface blood group antibodies, and anti-A or anti-B isoagglutinins from recipient plasma cells are the etiologic agents.⁹⁴ There is a 60% to 70% frequency of spontaneous recovery, but the remainder may develop sustained PRCA requiring treatment.¹⁹⁷

Pure Red Cell Aplasia with Infections Other Than Parvovirus

Acute, self-limited PRCA may develop in the course of various infections.^{1, 51, 53, 55, 60, 62, 64, 199, 200} Viral hepatitis and infectious mononucleosis in particular have been reported many times in association with PRCA. In general, PRCA remits with treatment or the resolution of the underlying infection. Studies on the pathogenesis of PRCA in the course of viral hepatitis, infectious mononucleosis, and HTLV-1 infection have suggested that the suppression of erythropoiesis is mediated by cytotoxic T lymphocytes.

Drugs and Chemicals

Many drugs and chemicals have been reported as causes of PRCA^{38, 92, 139, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226} (Table 39.2). Drug-induced PRCA is usually an acute disorder that remits soon after discontinuation of the drug or cessation of exposure to the chemical. It may appear after the first exposure to the drug or a significant time after its initiation. In most instances, the association of a drug with PRCA is circumstantial and is based on the evidence that PRCA remits after discontinuation of the drug.^{1, 227} Diphenylhydantoin, azathioprine, chlorpropamide, and isoniazid have been repeatedly implicated as causes of PRCA, and in certain instances their association with PRCA has been proven by recurrence of anemia upon reinstatement of therapy.¹

Different drugs cause erythroid aplasia through different mechanisms. Studies on direct drug effects on erythroid cell growth in vitro may be confusing because many drugs may have nonspecific effects on hematopoietic colony formation in vitro. IgG inhibitors of erythropoiesis have been shown for diphenylhydantoin and rifampin.^{206, 228} Isoniazid and procainamide appear to use a different mechanism.^{229, 230}

Pregnancy

Pregnancy also has been associated with PRCA that usually but not always, remits after delivery.^{81, 82, 83, 84, 85, 86} Development of PRCA during one pregnancy does not necessarily predict recurrence of the disease in subsequent pregnancies. This syndrome is also discussed in Chapter 42.

Miscellaneous Disorders

In rare cases, PRCA has been associated with renal failure,⁸⁷ severe malnutrition producing marasmus and/or kwashiorkor,^{61, 88} and riboflavin,^{88, 90} vitamin B₁₂,^{89, 91} and folic acid deficiencies.⁹¹

Clinical Presentation

There are no clinical features or physical findings characteristic of PRCA other than the signs and symptoms of anemia. Since a complete arrest of erythropoiesis would cause a decline of red cell mass of roughly 1% a day, so the development of anemia in PRCA is gradual, allowing for physiologic compensation which would mitigate symptomatology for any given degree of anemia. In secondary cases, physical findings related to the underlying disease may be present. Patients with chronic PRCA requiring transfusion support may have findings suggesting iron overload.

Laboratory Evaluation

Peripheral Blood Counts

In acquired PRCA the erythrocytes are normochromic and normocytic. There is a complete absence of polychromatophilic red cells on the smear, and the reticulocyte count is between 0% and 1%. A reticulocyte count >1% should raise serious doubt about the correctness of the diagnosis. The white cell count and the differential count are usually normal. Occasionally, mild leukopenia, lymphocytosis, and/or eosinophilia may be present. The platelet count is usually normal. Mild thrombocytopenia of 100,000 to 150,000 platelets/ μ l is occasionally seen, and some patients may have a mild reactive thrombocytosis. When present, these abnormalities typically reflect a state of immune activation.

Bone Marrow

The hallmark of PRCA is the absence of erythroblasts from an otherwise normal marrow. The cellularity of the marrow is normal or slightly increased. Markedly increased cellularity with elimination of fat spaces should lead away from the diagnosis of PRCA. In typical cases the erythroblasts are either totally absent, or they constitute <1% on the marrow differential count (Fig. 39.1A). In a small number of cases, a few proerythroblasts and/or basophilic erythroblasts may be seen, not exceeding 5% of the differential count.^{1, 231} The presence of large proerythroblasts ("giant pronormoblasts") with vacuolated cytoplasm and pseudopodia formation may raise the suspicion of an active B19 parvovirus infection but are not diagnostic.^{232, 233, 234}

In some cases a phase of ineffective erythropoiesis characterized by erythroid hyperplasia with maturation arrest at the stage of proerythroblasts or basophilic erythroblasts in the marrow and reticulocytopenia in the blood may precede the development of PRCA, develop during the course of PRCA, or appear after partial response to treatment and before the

return of erythropoiesis to normal.^{235, 236} While this morphologic picture in the absence of dysplastic changes in other lineages or cytogenetic abnormalities should raise suspicion of PRCA, bone marrow examination would need to be repeated at a later time to confirm the diagnosis.

The myeloid cells and the megakaryocytes in the marrow are normal and exhibit full maturation. An increased number of lymphocytes on marrow smear, or an increased number of lymphoid aggregates in marrow biopsy, or a mild increase in plasma cells, eosinophils, or mast cells may be seen. These findings are presumed to reflect inflammatory/immune activation. Iron stores are increased and normally distributed, but during recovery or the phase of ineffective erythropoiesis, a few ring sideroblasts may be seen.¹

Cytogenetics

Cytogenetic studies on marrow cells in PRCA are normal. An abnormal karyotype indicates a preleukemic/myelodysplastic disorder with the morphologic appearance of erythroid hypoplasia.^{126, 237, 238} Such patients do not respond well to immunosuppression.^{126, 239}

Ferrokinetics

Ferrokinetic studies show a prolonged clearance of ⁵⁹Fe, no accumulation of iron in the sacral bone, and almost undetectable incorporation into red cells, findings consistent with an almost

P.979

complete arrest of erythropoiesis. Ferrokinetic parameters return to normal after full hematologic recovery except in adult patients in partial remission, in whom ineffective erythropoiesis may be present.²³⁵ Bone marrow imaging by the use of ⁵⁹Fe or ^{98m}Tc shows little or no uptake, but returns to normal upon remission. In both children and adults with PRCA, ⁵¹Cr red cell survival is mildly shortened to a degree inadequate to explain the severity of the anemia.^{235, 236, 240} Patients who are refractory to treatment and who are supported by regular red cell transfusions may develop a significant hemolytic component after alloimmunization or development of hypersplenism.¹

FIGURE 39.1. A: Characteristic bone marrow biopsy from a Pure red cell aplasia (PRCA) patient. B: Bone marrow biopsy from same patient after successful response to immunosuppression. Note easily identifiable erythroblasts.

Other Laboratory Abnormalities

Vitamin B₁₂, folic acid, ferritin, serum iron, and saturation of transferrin are normal or elevated. Serum erythropoietin levels are increased in proportion to the severity of the anemia.³ A number of different immunologic abnormalities have been reported in patients with chronic PRCA, including hypogammaglobulinemia, monoclonal gammopathies, pyroproteins, decreased complement, antinuclear antibodies, decreased or increased B cells, and impaired PHA-induced lymphocyte cytotoxicity.^{1, 3, 120, 241} More recently, in a number of patients the presence of lymphocytes with γ or δ T cell receptor gene rearrangement has been described.^{114, 116, 119, 121, 182, 242, 243} Some of these cases certainly represent PRCA secondary to a T cell lymphoproliferative disorder and not primary PRCA.

Evaluation and Treatment

PRCA, myelodysplastic syndromes (MDSs), and other primary marrow failure disorders are suspected in similar clinical circumstances, and the initial diagnostic approach is bone marrow examination. Specimens should be sent for cytogenetics and flow cytometry as well as routine pathology. In PRCA, a normocellular marrow in which there is almost a complete absence of erythroblasts but with normal myeloid cells and megakaryocytes is expected. A hypocellular marrow

with trilineage hypoplasia suggests aplastic anemia; dyspoietic marrow morphology, or ringed sideroblasts, suggests an MDS.

In all patients with PRCA, polymerase chain reaction (PCR) testing for parvovirus DNA should be performed.^{244, 245} Parvovirus serology may be of value in immunocompetent patients, but is misleading in the immunocompromised.²⁴⁵ For that reason, PCR on peripheral blood is the test of choice. If parvovirus testing is negative, computerized tomography should be performed on all adult patients to rule out thymoma. Flow cytometry studies performed on the diagnostic bone marrow will identify a lymphoproliferative disorder as the possible etiology of PRCA. Abnormal cytogenetics would indicate an MDS. Patients with renal failure who develop PRCA while being treated with rhEpo should be evaluated for anti-Epo antibodies. Testing for underlying autoimmune disorders can be performed if otherwise clinically indicated, but typically would not alter therapy.

Immunosuppressive/Immunomodulatory Therapy

Drugs should be reviewed as possible contributors to PRCA, and any active infection should be treated. Underlying malignancies should be treated. MDSs appearing as PRCA should be managed as MDSs (Chapter 79). Otherwise, in the absence of documented parvovirus infection or thymoma, the initial approach to PRCA is immunosuppression or immunomodulation (Table 39.3). Figures 39.1A and 39.1B display bone marrow biopsy results from a patient before and after immunosuppression. Approximately two-thirds of PRCA patients will respond to an immunosuppression approach.^{1, 108, 239, 246, 247, 248}

Corticosteroids

Corticosteroids are the traditional first line drugs. Prednisone is given orally at a dose of 1 mg/kg/day until a remission is induced. As indicated in Table 39.3, approximately 40% of patients will have a remission on steroids. Corticosteroid-induced remission usually occurs within 4 weeks and continuation of a trial with prednisone longer than 12 weeks is not recommended.²⁴⁶ The effect of treatment can be assessed by weekly reticulocyte counts and measurements of hemoglobin concentration. A rising reticulocyte count and/or stabilization of the hematocrit are the first laboratory findings indicating response to treatment. Once the hematocrit reaches a level of 35%, the dose of prednisone can be tapered very slowly and the drug can be eventually discontinued, preferably after 3 to 4 months. Rapid tapering of prednisone may lead to recurrence of anemia. A number of responders may be prednisone-dependent, requiring small doses of the drug to maintain a normal hematocrit.^{246, 249, 250} The dependence of the response on low-dose prednisone can be assessed during the period of slow tapering, and the minimum dose required can be easily determined.

For patients who do not respond to prednisone within 2 to 3 months, the dose should be rapidly tapered to approximately 20 to 30 mg daily, and the use of a second agent considered.

Cyclosporine

Cyclosporine appears to be the single most effective immunosuppressive used for PRCA (Table 39.3), and it has been P.980

suggested that it should be considered the immunosuppressive drug of choice for this disorder.²⁴⁷ Figure 39.2 shows the response of a patient refractory to several other agents prior to cyclosporine therapy.¹⁰⁵ Cyclosporine is substantially more expensive than prednisone, and requires monitoring of drug levels and of renal function.

TABLE 39.3 RESPONSE OF PURE RED CELL APLASIA (PRCA) TO VARIOUS IMMUNOSUPPRESSIVE THERAPIES

• Study	• Dessypris ¹	• Lacy et al. ²³⁹	• Charles et al. ¹⁰⁸	• Sawada et al. ²⁴⁷	• Total
• Number of patients	• 49	• 47	• 37	• 62	• 195
• Primary PRCA	• 32	• 25	• 18	• 62	• 137
• Secondary PRCA	• 17	• 22	• 19	• 0	• 58
• Corticosteroids	• 18/41 ^a	• 9/29	• 9/36	• 14/22	• 50/128 (39%)
• Cytotoxic agents ^b	• 24/54	• 14/29	• 8/27	• 0/3	• 46/113 (41%)

• Antithymocyte γ -globulin	• 2/6	• 0/1	• 8/12	• —	• 10/19 (53%)
• Cyclosporine	• 3/4	• 4/5	• 2/3	• 28/36	• 37/48 (77%)
• Intravenous immunoglobulin G	• —	• 1/2	• 2/8	• —	• 3/10 (30%)
• Plasmapheresis	• —	• —	• 0/2	• —	• 0/2 (0%)
• Splenectomy	• 4/23	• 0/1	• 0/1	• —	• 4/25 (16%)
• Multiple treatments	• 35/49	• 28/47	• 28/37	• —	• 91/133 (68%)

Note: Many patients did not respond to treatment or suffered relapses, so one patient may be included in more than one treatment modality.

^a Number of responders/number of patients treated.

^b Including cyclophosphamide, azathioprine, or methotrexate, each given either alone or in combination with prednisone.

Cyclosporine may be used as a single agent or concurrently with low-dose prednisone (usually 30 mg prednisone/day or less). The usual starting dose of cyclosporine is 6 mg/kg/day, although initial doses as much as 12 mg/kg/day have been used.^{105, 248, 251, 252} Target trough levels are 150 to 2,500 ng/ml.²⁴⁸ When the hematocrit approaches target levels (usually 35% to 36%), a slow taper is begun. Some patients may require maintenance therapy. If a patient has not responded in 3 to 4 months, cyclosporine should be tapered off and another agent started.

Although cyclosporine is not leukemogenic as are some of the cytotoxic drugs used for PRCA, there are reports of lymphoma development in PRCA patients treated with cyclosporine.¹⁰⁵ Whether these cases represented treatment-induced lymphomas or were cases of lymphoma-associated PRCA is not clear.

FIGURE 39.2. Time course of response of patient 9 to Cyclosporine A (CsA). Hematocrit (closed circles) and uncorrected reticulocyte count (open circles) are shown. Treatments administered in the 8 months prior to CsA (equine antithymocyte globulin [ATG] and rabbit antilymphocyte serum [ALS]), and the duration of CsA therapy, are indicated on the figure. Prior to beginning CsA (time 0), the patient had required biweekly transfusion to maintain his hematocrit at the levels indicated. No transfusions have been required subsequently. Reproduced with permission from Means et al. *Br J Haematol* 1991;78:114-119. RBC, Red blood cells.

Cytotoxic Agents

In patients not responding to prednisone, cyclosporine, or both, cyclophosphamide or azathioprine can be given alone, or with small doses of prednisone, which seems to increase the effectiveness of treatment. The overall response rate to cytotoxic agent-based therapy is approximately 40% (Table 39.3). The initial dose of either agent is 50 mg po daily. If the white blood and platelet counts allow it, it is increased by 50 mg weekly or biweekly to a maximum of 150 mg daily until remission occurs or bone marrow suppression develops. The mean time to response is about 11 to 12 weeks, with a broad range of 2 to 26 weeks.^{1, 108, 239, 246} If response occurs, prednisone is tapered and then the dose of cytotoxic agent is progressively decreased and eventually discontinued. If bone marrow toxicity develops, the drug is discontinued and the marrow is allowed to recover. If, after 3 months of treatment, no response and no marrow toxicity is seen, the dose can be increased progressively (by 50 mg biweekly) to a maximum tolerable or 250 mg daily under close monitoring of the blood counts. If reticulocytosis or stabilization of the hematocrit is noticed, the dose is gradually reduced. If the absolute neutrophil count decreases to <1,000/ μ l or the platelet count drops to <100,000/ μ l, the cytotoxic drug is discontinued. In a number of patients, with the return of granulocytes and platelets to normal, a reticulocytosis is seen, followed by a return of erythropoiesis to normal. If no response occurs, another type of immunosuppressive treatment should be initiated.

Other Immunosuppressive/Immunomodulatory Modalities

Rituximab, a humanized monoclonal antibody against CD20, has been reported to be effective in PRCA whether primary/autoimmune or associated with lymphoproliferative disorders.^{10, 15, 68, 137, 163, 253, 254, 255, 256} It has also been used effectively in PRCA following ABO-incompatible stem cell transplantation.^{15, 95, 96, 257, 258, 259, 260} In isolated case reports, successful treatment of PRCA by Campath-1H²⁶¹ or alemtuzamab^{262, 263, 264} have been reported.

P.981

High-dose intravenous γ -globulin is primarily used for the treatment of parvovirus-induced PRCA (below). It has also been shown to be effective in patients with immune-mediated PRCA, whether primary or secondary.^{265, 266, 267, 268} Donor lymphocyte infusion has been reported to be effective in PRCA following ABOincompatible stem cell transplantation.^{95, 269, 270}

There are a number of immunomodulatory modalities used primarily in PRCA patients who are refractory to other approaches. Plasmapheresis may be considered in patients who have failed other immunosuppressive approaches. Since the IgG inhibitor of erythropoiesis removed by plasmapheresis is distributed in both intravascular and extravascular spaces, an aggressive approach to plasmapheresis is required, often in concert with immunosuppression.^{271, 272, 273, 274} Antithymocyte globulin (ATG), formerly the routine therapy after corticosteroids and cytotoxic agents, is used uncommonly in refractory patients. The overall response rate to ATG is approximately 50% (Table 39.3). ATG is given on the same treatment schedule as is used for aplastic anemia (Chapter 38).^{108, 239, 246, 275}

Splenectomy has also been used as a final therapeutic maneuver in patients who are refractory to all other forms of treatment. Responses to splenectomy have been reported in ~17% of such recalcitrant-to-treatment cases within the first 2 to 3 postoperative months.^{1, 240, 276, 277, 278, 279} After splenectomy, patients may become responsive to agents against which they were previously resistant.

There are a small number of case reports of PRCA treated by bone marrow or stem cell transplantation.^{280, 281}

Parvovirus-associated Pure Red Cell Aplasia

As was discussed earlier, in immunocompetent individuals B19 parvovirus infection produces transient and self-limited erythroid suppression that is generally unnoticed except in patients with chronic hemolytic disorders. In immunocompromised patients, parvovirus infection can lead to chronic PRCA. Patient with PRCA and documented parvovirus infection (best demonstrated by PCR on peripheral blood) should be treated with high-dose intravenous

γglobulin, which confers passive immunity.^{45, 245, 268, 282, 283} If the immunocompromised state persists, periodic retreatment may be necessary. In HIV patients, relapses of parvovirus-induced PRCA are rare in patients with CD4 lymphocyte count greater than 300/μl.²⁸³

Thymoma-associated Pure Red Cell Aplasia

In the presence of a thymoma, thymectomy should be performed before the initiation of any immunosuppressive treatment. In 30% to 40% of patients with thymoma, erythropoiesis returns to normal within 4 to 8 weeks after thymectomy.^{5, 175, 284, 285, 286, 287, 288} In patients who either do not respond to thymectomy or recur after thymectomy, immunosuppressive therapy is frequently effective. Thymectomy in the absence of thymoma is not recommended.¹ Responses to octreotide and tacrolimus have been reported in thymoma-associated PRCA.^{289, 290}

Anti-Epo Antibody-associated Pure Red Cell Aplasia

As noted earlier, many cases of anti-Epo antibody-mediated PRCA induced by rhEpo therapy in renal failure patients have been reported. Such patients should be managed with immunosuppression, like other immune-mediated PRCA patients.^{92, 156, 158, 161, 267, 274, 291, 292, 293, 294, 295, 296} The overall response rate to immunosuppression has been reported to be 78%, with cyclosporine being the most effective agents, and steroids the least effective.^{156, 294} Patients who undergo renal transplantation appear to have remission of PRCA.^{155, 156} In one series, no patient who did not receive immunosuppression (with or without renal transplantation) developed a remission,¹⁵⁶ while there are case reports of eventual recovery with no therapy apart from cessation of rhEpo therapy and transfusion support.^{150, 297}

The issue of whether or not a patient who has experienced anti-Epo antibody-induced PRCA can ever be retreated with rhEpo or a different rhEpo product remains an open one. The reported antibodies appear to cross react with all available rhEpo agents.⁹⁹ While there are several case reports of successful rechallenge with epoetin or darbepoetin, and even of recovery while continuing rhEpo therapy,^{92, 298, 299, 300, 301, 302} the practice is not recommended.^{303, 304}

Continuous Epo receptor agonist (CERA) is a peptide which is not immunologically similar to rhEpo but activates the Epo receptor. CERA has been proposed as a treatment for rhEpo-induced PRCA.³⁰⁵ In a study of 14 patients, 13 became transfusion-independent, and anti-Epo antibodies became undetectable in 6. However, half the patients studied developed grade 3 or 4 toxicity.³⁰⁵

Refractory Pure Red Cell Aplasia

For patients who respond and relapse, retreatment is often effective. Despite the variety of therapeutic modalities available, there will be some PRCA patients who do not respond to therapy. These individuals will require transfusion support, with chelation management to minimize complications of iron overload.

The survival of patients with primary PRCA is estimated to be 14 years.²⁴⁶ A poorer prognosis is associated with myelodysplastic PRCA variants. The 3% to 5% of PRCA patients who develop acute myeloid leukemia (AML) typically fall into this latter category.^{126, 246, 306} Development of subsequent aplastic anemia in PRCA patients has been reported but is rare.³⁰⁷

DIAMOND-BLACKFAN ANEMIA

DBA (Online Mendelian Inheritance in Man, OMIM, #105,650), first recognized as a discrete clinical entity in 1938,³⁰⁸ is one of a rare group of genetic disorders known as the inherited bone marrow failure syndromes (IBMFS).³⁰⁹ These disorders share a predilection to bone marrow failure, birth defects, and cancer and are characterized by proapoptotic and/or prosenescent hematopoiesis. Furthermore, almost in defiance of their rarity, the IBMFS have provided extraordinary insights into DNA repair, telomerase function, the misfolded protein response, signal transduction and, in the case of Shwachman-Diamond syndrome and DBA, ribosome biogenesis and function (see Chapter 37).

With the discovery of a number of "DBA genes" and the availability of highly annotated patient databases, the diagnostic criteria for DBA have evolved considerably. The classical diagnostic criteria, established 75 years ago³⁰⁸ and refined decades later,³¹⁰ are (a) normochromic, usually macrocytic, and occasionally normocytic anemia developing in early childhood; (b) reticulocytopenia; (c) normocellular bone marrow with selective deficiency of erythroid precursors; (d) normal or only slightly decreased granulocyte count; and (e) normal or slightly increased platelet count. However, with the identification of the first gene known to be mutated in DBA it has become evident that there exist many not as strictly defined cases. Ongoing gene discovery will no doubt classify patients that today are only considered to have probable or even possible DBA.³¹¹ DBA is frequently associated with a variety of somatic malformations and rarely with developmental delay, usually in the setting of a large genetic deletion. Approximately 80% of patients respond to corticosteroids with an

improvement in, or complete remission of, their anemia.^{311, 312} However, prolonged corticosteroid treatment has been problematic for many patients.³¹²

P.982

Since the first description of this syndrome 75 years ago, a number of theories have been put forth regarding its etiology. The myriad discarded explanations have included humoral³¹³ or cellular^{314, 315} suppression of erythropoiesis, a microenvironmental defect,³¹⁶ and accessory cell failure.³¹⁷ In the late 1970s the concept of erythroid failure as a consequence of a block in the erythroid maturation pathway was introduced,^{2, 318} and it rapidly became evident that the erythroid failure in DBA results from an intrinsic erythroid progenitor/precursor-cell defect,^{2, 318, 319, 320} rather than an extrinsic immune or microenvironmental abnormality. Convincing data show that there is a defective pathway from the multipotent bone marrow progenitor to the mature CFU-E, and most prominently through terminal differentiation to the proerythroblast and beyond,^{319, 320} in which an intrinsic defect in erythroid progenitors and precursors render them highly sensitive to death by apoptosis.^{321, 322} It is now clear that in at least 60% to 70% of cases, proapoptotic or prosenescent erythropoiesis and many of the other manifestations of DBA are consequences of faulty ribosome assembly or function.³²³ Exactly how ribosome dysfunction leads to tissue specific red cell failure, poor growth, birth defects and cancer remains a topic of intense inquiry. However, only approximately 70% of patients with DBA can be explained by either sequence changes or deletions in either small or large subunit-associated ribosomal protein (RP) genes.³²⁴ David Nathan suggested decades ago that DBA should result from faulty transcription regulation of erythropoiesis. Virtually unpredictably, however, DBA is in the majority of instances a ribosomopathy. However, the recent discovery of a mutation in the erythroid transcription regulator GATA1 in a family with clinical DBA³²⁵ suggests that DBA is not only a ribosomopathy but also, as predicted by Nathan, a "transcriptionopathy."

Etiology and Pathogenesis

Normal erythropoiesis is dependent upon interactions between erythroid progenitors and accessory cells, the bone marrow stroma, and their locally acting cytokines.³²⁶ Thus, the erythroid failure in DBA could have arisen from an absence of, or failure in,³²⁷ any one of these elements to act or to respond appropriately. Some early investigators described a marrow microenvironmental defect³¹⁶ or implicated accessory cell dysfunction.³¹⁷ Others seemingly found evidence that the red cell failure in DBA was due to the presence of cytotoxic or autoreactive T cells,^{314, 315} or humoral inhibitors of erythropoiesis.³¹³ These findings were never substantiated,^{2, 318, 319, 327, 328, 329} and it is now accepted that DBA results from an intrinsic progenitor defect.^{2, 318, 319, 320, 321, 322, 329, 330, 331} Freedman et al.² first suggested that some patients had decreased numbers of CFU-E; whereas studies by Nathan et al.,³¹⁸ using chronically affected either multiply-transfused or steroid-dependent patients, suggested a block in maturation between the earliest committed multipotent myeloid progenitor and the immature BFU-E. In addition, these investigators found that the progenitors expressed in culture were relatively insensitive to erythropoietin,^{330, 331} reiterated the concept of progenitor hyporesponsiveness to erythropoietin, and suggested that this abnormality could be corrected in part by the addition of glucocorticoids in vitro, implying a relationship between clinical response to corticosteroids and in vitro progenitor response. A series of studies by Lipton and colleagues confirmed these observations. In these studies, some patients expressed normal, or nearly normal, numbers of BFU-E-derived colonies but had decreased numbers of CFU-E-derived colonies in the presence of exogenous cytokines and erythropoietin; while other patients demonstrated normal numbers of (albeit small and poorly differentiated) colonies derived from both BFU-E and CFU-E.³¹⁹ These data suggested that DBA is a heterogeneous disorder in which erythropoiesis may be blocked at different stages of erythroid differentiation. This observation was later confirmed in studies by McGuckin and colleagues.³³²

Further investigations confirm that DBA is due to an intrinsic disorder of the erythroid progenitor that involves its inability to respond normally to inducer(s) of erythroid proliferation and differentiation,³²⁰ resulting in accelerated apoptosis,³²¹ and that the effect could be ameliorated by corticosteroids.³²² The mechanism of steroid action in DBA is not clear but it is likely that the steroid response is not related to the DBA-specific defect. Recent studies by Varricchio and colleagues³³³ suggest that variations in alternatively spliced species of the glucocorticoid receptor (GR) may explain how GR polymorphisms are an important modifier of disease severity and response to corticosteroids. It needs to be explored whether specific GR polymorphisms are predictive of steroid response in DBA. Clearly, the variable expression of both the hematologic and nonhematologic manifestations of DBA, particularly within multiplex families, strongly suggests robust interactions with modifying genes.

The intrinsic defect in the erythron has not been found to be associated with any abnormalities in erythropoietin or its receptor.^{334, 335} A mildly decreased leukocyte count and the development of pancytopenia, bone marrow hypoplasia, and reduced clonogenic cell output in lymphocyte assays,³³⁶ as well as hypogammaglobulinemia and T cell abnormalities,^{317, 337} support this contention in many but not all cases. Furthermore, other studies show that, in addition to erythroid progenitors, a defect in CFU-GM can be found in a subset of patients.³³² These in vitro studies are consistent with the observation that neutropenia and even aplastic anemia occur in some DBA patients. The response of erythroid cell growth and differentiation to a variety of cytokines in addition to erythropoietin, such as SCF and IL-3, has been evaluated, with no abnormalities of the cytokines or their receptors being identified.^{338, 339, 340, 341, 342} Moreover, somatic malformations, growth failure, and cancer predisposition cannot be easily explained by an abnormality in erythropoietin or cytokine receptors. However, for approximately 30% of patients there is not yet an identified gene. Furthermore, there are sufficient numbers of patients, in addition to those described by Gazda and colleagues as harboring a GATA1 mutation,³²⁵ lacking described nonhematologic manifestations of DBA to imply that rare cases may indeed involve erythroid-restricted pathways. Additionally, the discovery by Ebert and colleagues that an acquired RPS14 mutation can explain the erythroid failure in 5q- MDS³⁴³ suggests that some cases of DBA may be the consequence of acquired somatic, rather than germ line, mutations.³⁴⁴

With the identification of the first DBA gene, RPS19, a gene that encodes an RP located at chromosome 19q13.2,^{345, 346} and a second gene coding for RPS24,³⁴⁷ it became obvious that other RP genes would be implicated in the molecular pathogenesis of DBA. Based upon the original technique used to describe RPS19 (cloning of a cytogenetic abnormality from an informative patient), linkage analysis, resequencing of the known ribosome-associated protein genes, or most recently, a variety of techniques for the detection of copy number variants in the genome,^{324, 348} a number of additional RP gene mutations/deletions have been identified, accounting for approximately 70% of all cases of DBA. Currently, the RP genes confirmed to be mutated in DBA are RPL5, RPL11, RPL35A, RPS7, RPS10, RPS17, RPS19, RPS24, and RPS26.^{324, 345, 346, 347, 348, 349, 350, 351} Rarer abnormalities of less certain significance have been identified in isolated patients or families. These likely DBA genes include RPL3, RPL7, RPL9, RPL14, RPL19, RPL23A, RPL26, RPL25, RPL36, RPS8, RPS15, and RPS27A.^{351, 352, 353, 354} The nature of the mutations studied thus far suggests that there is either complete loss of function or nonexpression of the mutated allele. Thus, current evidence strongly supports that in patients with RPS19 (the most studied) and other small or large ribosomal subunit-associated protein gene mutations, DBA results from RP protein haploinsufficiency.³⁵⁵ When the gene is knocked down in cellular models,^{356, 357} there is resulting failure of erythropoiesis. In the in vitro models this defect can also be corrected

P.983

when the normal gene is overexpressed, resulting in increased RPS19 protein expression and restoration of erythropoiesis.³⁵⁸ Furthermore, a number of mouse and fish models have been developed confirming the role of RP haploinsufficiency in erythroid failure.^{359, 360, 361, 362} But despite the discovery of at least 9, and likely more, small and large subunit-associated RP gene mutations, the mechanism of erythroid failure and the other clinical manifestations of DBA are only partially explained. Much work needs to be done in order to connect faulty ribosome function with red cell failure, the congenital anomalies associated with DBA, as well as the clear recognition of DBA as a cancer-predisposition syndrome.^{363, 364} A number of theories have been proposed to account for the pathophysiology of DBA. Time will allow for the elucidation of the perhaps myriad explanations necessary to explain the pathophysiology of the DBA non-ribosomopathies. With regard to the DBA ribosomopathies, it is likely that at least one explanation provides the fundamental explanation for DBA-associated proapoptotic erythropoiesis, congenital anomalies, and cancer predisposition. While it appears that RP haploinsufficiency leads to aberrant ribosomal RNA (rRNA) processing of uncertain significance, the fundamental lesion appears to be a faulty translational apparatus created by RP haploinsufficiency leading to nucleolar stress signaling. This results from RPL5, RPL11, and 5S rRNA binding to MDM2 (murine double minute) and its human ortholog HDM2, leading to a decrease in its ubiquitin ligase activity essential for p53 degradation, thereby stabilizing p53 and resulting in accelerated apoptosis.^{360, 361, 365} The regulatory pathway utilizing RPL5 and RPL11 to bind to HDM2, reducing its ubiquitin ligase activity, seems central to this stress signaling; so much so that even when small ribosome-associated proteins are deficient, offering no excess of RPL5 and RPL11, as is the case for large subunit-associated haploinsufficiency resulting in degraded large subunits, the RPL5 and RPL11 TOP (terminal oligopyrimidine tract) mRNAs are translationally upregulated. The fact that both RPL5 and RPL11 are known as "DBA" genes and that they represent a severe congenital anomaly phenotype³⁵¹ tells us that there is much more to be learned about how HDM2 is regulated when their encoding genes are haploinsufficient. Furthermore, the tissue specificity of defects manifested by a germ line mutation in a ribosome-associated protein, as opposed to a relatively more erythroid-restricted transcription regulator such as GATA1, particularly in the erythron, begs for explanation. One explanation suggests that certain proteins

that are canonically translated are favored over others and that those proteins may be overrepresented in the erythron.³⁶⁶ The other supports the notion that the makeup of ribosomes is tissue specific (i.e., not all 80 RPs are required in every tissue), favoring translation in some tissues and not others as a consequence of any particular RP haploinsufficiency.³⁶⁷ Likely there are multiple explanations related to the complexity of tissue specific translation. Regardless, the knockdown of p53 in DBA animal models ameliorates the erythroid failure,^{361, 368, 369} making the therapeutic targeting of p53 in DBA an intriguing although potentially risky approach. Elucidating all the downstream events leading to accelerated cell death and understanding the interdicting mutations that lead to cancer in DBA are important subjects of inquiry.

Clinical Presentation

DBA usually presents in infancy. Severe anemia is recognized at birth in 25% of patients, with 65% diagnosed by 6 months of age and 90% within the first year of life.^{311, 312} DBA presenting as hydrops fetalis has been reported.³⁷⁰ The disease may also present in older children and adults.^{311, 371} Although rare instances of X-linked inheritance have been reported, the incidence in males equals that in females. The majority of cases are reported in whites, but the disorder has been reported in virtually all ethnic groups.³¹¹

Josephs in 1936,³⁷² and Diamond and Blackfan in 1938,³⁰⁸ were the first to describe red cell failure in infants. The variety of descriptive names for what is now preferably called DBA include “congenital pure red cell hypoplastic anemia,” “congenital red cell aregenerative anemia,” “erythrogenesis imperfecta,” “chronic erythroblastopenia,” “primary red cell aplasia,” and “Josephs-Diamond-Blackfan anemia.”^{310, 311} The classical diagnostic criteria for DBA reflect the careful clinical analysis performed by Diamond and colleagues³¹⁰ and, more recently, by Alter.^{309, 373} Recently, however, a consensus conference took place during which, as a consequence of robust gene discovery, the diagnostic criteria for DBA were expanded to account for nonclassical presentations.³¹¹ For a still valuable compilation of the clinical syndrome of DBA that is beyond the scope of this chapter, interested readers are referred to Young and Alter's classic monograph.³⁰⁹

The Diamond Blackfan Anemia Registry of North America (DBAR), a database of >600 patients, was established in 1991 and has been described in detail.^{311, 312, 374} The DBAR has provided important information regarding the epidemiology and biology of DBA.^{312, 364, 375} The male-to-female ratio of cases is approximately 1:1. The median age at presentation is 8 weeks, with a median age at diagnosis of 12 weeks. More than 90% of the reported cases present clinically by 1 year of age. The mainstays of therapy, as described below, remain red cell transfusions and corticosteroids. Physical anomalies, not including short stature, are found in nearly 50% of patients. Short stature is clearly a constitutional feature of DBA, but may also be due to chronic anemia, iron overload, corticosteroid administration, or a combination of all these. Thus it is difficult to always ascribe growth failure directly to the disorder. The constellation of physical anomalies found in the 47% of affected patients with typical hematologic manifestations includes a high percentage of craniofacial anomalies (50% of patients with anomalies) as well as upper limb and hand, in particular thumb (38%), as well as genitourinary (39%) and cardiac (30%) abnormalities. Table 39.4 enumerates the congenital anomalies collected in a series by Alter.³⁷⁵ Of interest, there appears to be no genotype-phenotype correlation with regard to steroid responsiveness, remission, or cancer predisposition. However, mutations in RPL5 and RPL11 are disproportionally associated with orofacial and thumb anomalies.^{351, 376} Figure 39.3 illustrates typical thumb abnormalities in a patient with DBA as the consequence of an RPL11 gene mutation.

Laboratory Evaluation

With the discovery of genetic mutations there are numerous “patients” recognized with minimal or no hematologic manifestations. With that in mind, classical DBA is characterized by severe anemia, with hemoglobin levels at presentation as low as 2 to 3g/dl. There is a marked reticulocytopenia, frequently as low as zero. There are usually no significant abnormalities in other cell lines. Occasionally, there is mild to moderate neutropenia and infrequently severe neutropenia requiring G-CSF support^{311, 375, 377, 378} or thrombocytopenia.³⁷⁹ However, thrombocytosis in the range of 400,000 to 700,000 is more common.³⁷⁹ Although originally described as a normochromic, normocytic anemia, macrocytosis was noted at presentation in ~30% of cases reviewed by Alter³⁷⁸ in patients for whom data were available. The percentage of patients with macrocytosis increases with the age of the patient, as the disease becomes chronic when the normal red cell MCV would decrease during the first year of life. Indeed, the persistence of “fetal-like” red cells, with macrocytosis, “i” antigen, increased fetal hemoglobin (HbF), and red cell glycolytic and hexose-monophosphate (HMP) shunt enzyme activities characteristic of fetal cells are a consistent finding. The HbF is typical of fetal cells,^{377, 378} with an elevated glycine-to-alanine ratio at position 136 of the γ chain. Of note is that the fetal-like characteristics

P.984

are not concordant; cells with high HbF are not necessarily those with the “i” antigen. Although red cells contain

significant HbF, as determined by hemoglobin electrophoresis, the distribution is uneven as evaluated by the Kleihauer-Betke method. Alter points out that red cells contain both fetal and adult hemoglobin and that the "re-expression of fetal erythropoiesis is thus incomplete, and not clonal."³⁷⁸ Although glycolytic and HMP shunt enzymes have a fetal pattern, erythrocyte adenosine deaminase (eADA), a purine salvage pathway enzyme, is increased in activity in DBA patients but not in normal fetal or cord blood erythrocytes.³⁸⁰ When compared to controls with normal eADA activity obtained from patients with hemolytic anemia, Fanconi anemia, and those with steroid-dependent nephrosis, as well as virtually all patients with TEC, approximately 85% of the patients with typical DBA have elevated eADA activity.^{380, 381, 382} In some DBA patients with normal eADA activity there is markedly elevated orotidine decarboxylase activity.^{380, 383} Although abnormalities in purine or pyrimidine biosynthesis are consistent findings in most DBA patients and in some animal models and serve as a valuable screening tool, this observation has not yet been helpful in understanding the pathophysiology of DBA. Red cells of some patients with acute leukemia, adult-type chronic myelogenous leukemia, myeloproliferative disorder with Down syndrome, dyskeratosis congenita with pancytopenia, and megaloblastic anemia were also found occasionally to have increased eADA activity.³⁸¹ This may suggest an association of elevated eADA activity with abnormal progenitor function. Also of interest is the observation that W/W^v and S1/S1^d mice, with genetically determined red cell failure, have elevated erythrocyte nucleoside deaminase activity.³⁸⁴ Further advances in this area must await a detailed understanding of the biochemistry of hematopoiesis. However, from a practical prospective, eADA activity determinations provide a reasonably useful means for distinguishing ~85% of DBA from TEC (see section "Differential Diagnosis"). To date none of the described hematologic abnormalities have been linked to a specific pathophysiology, and they have no predictive value in distinguishing steroid responding from nonresponding patients.

TABLE 39.4 PHYSICAL ABNORMALITIES IN PATIENTS WITH DIAMOND-BLACKFAN ANEMIA

Low birth weight
 Short stature, no steroids
 Head and face:
 "Cathie" facies
 Other facies
 Small head
 Large head

FIGURE 39.3. Typical displaced and “trigger” thumbs in a patient with Diamond-Blackfan anemia.

Vitamin B₁₂, folate, serum iron, and transferrin saturation are elevated or normal in patients with DBA.^{310, 380} Erythropoietin levels seem to reflect the degree of anemia, or may be elevated for the degree of anemia and remain elevated even in steroidresponsive patients.^{310, 378} Approximately one-third of patients evaluated by Alter had hypogammaglobulinemia, consistent with the finding of in vitro immunologic abnormalities in some DBA patients.^{317, 378, 385} Recently an association of hypogammaglobulinemia with RP haploinsufficiency³⁸⁶ has been described, perhaps explaining this observation.

Examination of the bone marrow biopsy and aspirate at diagnosis in childhood usually reveals normal cellularity with a paucity of erythroid precursors. Myeloid and megakaryocyte lineages appear normal. Myeloid-to-erythroid (M:E) ratios at diagnosis are usually around 10:1 and with time may become as high as 100:1.³¹⁰ This progression of erythroid failure

(with time) seems to parallel the more severe abnormalities in in vitro progenitor differentiation observed in older chronically affected patients as compared to those newly diagnosed.³¹⁹ The heterogeneity of the disorder is reflected in the marrow. In one series of 9 patients, all had marked erythroid hypoplasia; 4 had virtually no erythroid precursors, 2 had erythroid maturation up to the polychromatophilic or orthochromatic normoblast stage, and 3 had a maturation arrest at the proerythroblast stage, with 2% to 7% of the total nucleated cells being proerythroblasts.³¹⁹ In Alter's review, 28 of 29 DBA patients had erythroid hypoplasia. One had erythroid hyperplasia with a maturation arrest. Several of Alter's patients had normal numbers of proerythroblasts but no differentiation beyond that stage. In a series of patients studied by Bernard et al., 90% had erythroid hypoplasia, 5% had normal erythroid precursors, and 5% had erythroid hyperplasia.³⁸⁷ Although all patients have a profound reticulocytopenia, the erythroid arrest in DBA has been demonstrated by progenitor assays, or morphologically, to occur at all stages of maturation from the multipotent myeloid progenitor to the late normoblast. These and other observations³³⁶ suggest that the defect may become more profound with age and that the arrest in erythropoiesis moves to an earlier stage of differentiation

P.985

as patients get older. This is, however, somewhat confounding in light of the presence of remissions.³¹²

Imaging studies are useful to help delineate congenital abnormalities that may be present in patients with DBA. Skeletal surveys and, in particular, CT scans are not usually warranted in light of the increased risk of cancer in DBA, but selected radiographs may define suspected bony anomalies. Renal and cardiac ultrasonography is warranted and may detect suspected and perhaps significant anomalies.

Genetics

Prior to the identification of causative mutations Alter estimated that there is more than one affected family member in ~10% of cases.³⁷⁵ Early data from the DBAR provided a comparable or even slightly higher rate when robust clinical and hematologic data were available. Early case reports are representative of the now known genetics of DBA. In these families there were reports of affected same- and opposite-sex siblings,^{376, 388, 389, 390} including identical twins,³⁹¹ and maternal or paternal half-siblings.^{392, 393, 394, 395} There were also instances of parental transmission.^{395, 396, 397, 398} Striking evidence of autosomal dominant inheritance is illustrated in one case report of DBA in a male infant who had an affected mother and maternal grandfather.³⁹⁹ Thus, the clinical evidence is consistent with the known majority of cases of autosomal dominant inheritance resulting from RP haploinsufficiency and the rare X-linked inheritance caused by a mutation in GATA1.

The genetics of the majority of cases of DBA have become firmly established since 1997, when after studying a patient with a 19:X translocation, Gustavsson and colleagues^{345, 346, 400} used linkage analysis to show that DBA mapped to chromosome 19q13.2. That observation led to the cloning of a gene that encodes a ribosomal protein, RPS 19. Studies have shown that the RPS19 mutation accounts for only ~20% to 25% of familial as well as sporadic cases. With the description of a second "DBA gene," RPS 24, also a component of the 40S ribosomal subunit,³⁴⁷ and the subsequent identification of mutations or deletions in both small and large subunit-associated RP genes in approximately 70% of patients,^{349, 350, 351, 352, 353, 354} as well as a rare causative mutation in the transcription regulator GATA1,³²⁵ about 30% of patients remain genetically unclassified at this time. Thus the majority of familial cases are of dominant inheritance, with sporadic cases representing new dominant mutations. Within the identified pedigrees there is marked heterogeneity in the expression of the DBA phenotype. This heterogeneity exists for both the hematologic and nonhematologic manifestations of DBA. Thus the DBA phenotype appears to be the result of complex interactions between DBA and non-DBA genes. A family with discordant hematologic manifestations including a nonhematologically affected phenotype as well as discordance of craniofacial anomalies in affected family members has been reported.⁴⁰¹ The incidence of genetically determined cases is no doubt underestimated because of the apparent variable penetrance of the autosomal dominant cases in which an elevated HbF, MCV, or erythrocyte ADA activity may be the only abnormality in a parent or sibling of a child with typical DBA.^{311, 312} Indeed, in the case described, the mothers of affected cousins had none of these hematologic or nonhematologic abnormalities.⁴⁰¹ By tracing RPS19 mutations in families, the UK group has shown that nearly half of all patients have autosomal dominantly inherited DBA.⁴⁰² Therefore, in the absence of a molecular diagnosis for all DBA genotypes, families of affected individuals should be evaluated to determine HbF levels, MCV, and eADA activity. A number of cases currently felt to be sporadic or autosomal recessive in nature will no doubt be recategorized, but recessive inheritance as a mode of transmission is far from ruled out. The appearance of DBA in the male and female children of unaffected parents has also been observed. Reported gonadal mosaicism in DBA is rare.⁴⁰³ Furthermore, parental consanguinity has been observed,^{404, 405} supporting an, as of yet unconfirmed, autosomal recessive mode of

inheritance. That approximately 30% of DBA cases have not been assigned a genetic cause supports the possibility that additional cases consistent with novel recessive modes of inheritance will be described in the future.

The absence of a phenotype is a particularly distressing finding, as the use of such potential hematopoietic stem cell transplantation (HSCT) donors with such a “silent phenotype” may result in transplant failure.⁴⁰⁶ Furthermore, genetic counseling in these instances is inherently imprecise.⁴⁰⁷

The vast majority of DBA patients have a normal karyotype, but the few reported abnormal cases, in particular leading to the discovery of the first⁴⁰⁰ and other genes,³⁵⁰ have been of great importance; thus, karyotypic analysis is suggested as part of the initial evaluation.

Differential Diagnosis

The differential diagnosis of classical DBA includes the normochromic, normocytic (or macrocytic) anemias that present from birth through the first year of life. These anemias are pathophysiologically distinct from the majority of causes of PRCA seen in adults that are frequently associated with an underlying disorder (Table 39.1). However, it is clear that DBA does present in adulthood and these cases are often undiagnosed as such. Conversely, a patient presenting with red cell failure at age 5 and diagnosed with atypical DBA was confirmed to have 5q- MDS some 20 years later.³⁴⁴ And the association of PRCA with thymoma, as described in adults, has not been described in infancy, although it has been observed in a 5-year-old girl.⁴⁰⁸ Thus an index of suspicion for DBA should be maintained with regard to all cases of PRCA presenting at any age. In classical cases the differential almost always consists of DBA versus TEC (Table 39.5). Of note, patients with Pearson syndrome, resulting from large deletions of the mitochondrial genome, may present with pure red cell failure. Clinical suspicion or the presence of vacuolated erythroid precursors in the marrow should prompt a stain for ringed sideroblasts and the evaluation for a mitochondrial DNA deletion. A careful history, physical examination, and examination of the peripheral blood smear can usually rule out hemorrhage, myelosuppression resulting from infection, renal failure, infiltrative disease, severe

P.986

protein malnutrition, or drug-related red cell failure, as well as the aplastic crisis of a chronic hemolytic anemia (such as sickle cell anemia or hereditary spherocytosis). Because folate deficiency as a cause of the hypoplastic crises associated with chronic hemolytic anemia is prevented by prophylactic administration of the vitamin, acquired hypoplastic anemia in these patients is now most frequently a consequence of human parvovirus B19 infection. Evidence of human parvovirus B19 infection (see Parvovirus-induced pure red cell aplasia) has been found in patients with all congenital hemolytic disorders.^{127, 128, 129, 130, 142, 409, 410, 411} Red cell aplasia in otherwise normal neonates resulting in fetal hydrops, and in a patient on treatment for acute lymphoblastic leukemia, has also been described, apparently due to parvovirus infection.⁴¹² Chronic red cell aplasia due to parvovirus B19 after 10 years of transfusion-dependent anemia has been eradicated by the use of intravenous immunoglobulin.⁴⁵ Thus, parvovirus infection should be ruled out in all atypical instances of red cell failure in children. This can be best accomplished by PCR analysis, as IgM and IgG antibody evidence will be lacking in the presence of significant immunodeficiency.

TABLE 39.5 DIFFERENTIAL DIAGNOSIS OF DIAMOND-BLACKFAN ANEMIA (DBA) VERSUS TRANSIENT ERYTHROBLASTOPENIA OF CHILDHOOD (TEC)

	DBA	TEC
Pure red cell aplasia	Present	Present
Age	<1 y	>1 y
Inheritance	Sporadic and dominant or possibly but unlikely recessive inheritance Mutation analysis available for known DBA genes	Not inherited
Congenital anomalies	Present	Absent
Mean corpuscular volume	Elevated	Normal
Fetal hemoglobin	Elevated	Normal

i RBC antigen	Present	Absent
Erythrocyte ADA activity	Elevated	Normal

ADA, adenosine deaminase; RBC, red blood cell.

All RBC characteristics except ADA activity are helpful only when tested in a reticulocytopenic child. During recovery from TEC, a transient wave of fetal-like erythropoiesis may be detected.

A bone marrow examination revealing red cell aplasia or severe hypoplasia with no abnormalities in myeloid or megakaryocyte lineages, as well as no evidence of infiltrative disease, congenital dyserythropoietic anemia, vacuolated precursors, or ringed sideroblasts in an infant or young child, suggests either DBA or TEC. Table 39.4 outlines the important features that distinguish TEC, a temporary immune-mediated suppression of erythropoiesis that frequently follows a viral infection, from DBA. There is a moderate to severe anemia with reticulocytopenia. The disease is not familial, and there are no associated anomalies. The age of onset is usually a bit older than for congenital PRCA. One key point in differentiating between DBA and TEC is the presence of fetal characteristics in the erythrocytes of many patients with DBA (see section "Laboratory Evaluation"). As previously described, these characteristics include an elevated MCV for age, elevated levels of HbF and "i" antigen, and a fetal erythrocyte glycolytic and HMP shunt enzyme pattern.⁴¹³ The presence of "fetal-like" cells is much less reliable in differentiating DBA from TEC in very young infants, in whom red cells normally possess fetal characteristics. However, this is a situation where measuring eADA may be useful, because the activity of this enzyme is the same in neonates and older children. Even in typical DBA, only 30% of patients have "fetal-like" erythrocytes at diagnosis. Recovery from TEC is characterized by "stress erythropoiesis," giving rise to erythrocytes with fetal characteristics."⁴¹⁴ Making a diagnosis of TEC retrospectively after a long course of corticosteroids subjects the child to needless toxicity. As previously described, studies by Glader and coworkers^{380, 381, 382} have demonstrated that elevated eADA activity can be used to distinguish DBA from TEC. Unfortunately, many patients are transfused prior to consideration of the diagnosis, making an accurate eADA activity determination impossible. A molecular diagnosis can be made about 70% of patients and these assays are now commercially available. Based on the differences listed in Table 39.4, a high index of suspicion of TEC should prompt avoidance of steroids, minimal red cell transfusions, and alleviation of parental concern. Cases that are atypical or those who do not recover spontaneously deserve a genetic evaluation.

Treatment

If the diagnosis of DBA versus TEC is in doubt and the child has symptomatic anemia, the patient should be modestly transfused to a hemoglobin level of 7 to 8 g/dl so that erythropoiesis will not be suppressed, delaying recovery in those patients who have TEC. The use of corticosteroids in TEC is ineffective and should be assiduously avoided. In 1951, corticosteroid treatment in the form of ACTH was first shown to be effective in DBA^{415, 416}; however, the transfusion of packed red blood cells is the initial treatment. Transfusions should continue until 1 year of age if possible. The ability to defer corticosteroid treatment is dependent upon the availability of a safe blood supply and the ability to maintain appropriate venous access. The current approach is to start all patients on prednisone, 2 mg/kg/day orally in 3 to 4 divided doses, sometime as close to 1 year of age as can be accomplished. By delaying the start of corticosteroids, it is anticipated that many of the significant side effects associated with early steroid administration (growth retardation, developmental delay, osteopenia, hyperglycemia, hypertension, etc.) can be avoided.³¹¹ A reticulocyte response usually occurs within 1 to 2 weeks. The clinical response to prednisone therapy is variable. Data from the DBAR reveal that 79% of patients were initially responsive to corticosteroids, 17% were nonresponsive, and 4% were never treated with steroids.³⁷⁴ At the time of the analysis only 37% of patients were using corticosteroids. Steroid-related side effects were observed in most patients, at least transiently, with 48%, 22%, and 12% manifesting cushingoid features, pathologic fractures, and cataracts, respectively. Thirty-one percent of the patients were receiving red cell transfusions. Some patients respond rapidly and can be tapered off prednisone, remaining in remission for extended periods of time; others respond but require continued therapy, with erythropoiesis ceasing rapidly if steroids are discontinued. Thus the ability of responders to achieve an effective every-otherday dose schedule is variable. Of the transfused patients enrolled in the DBAR, 35% were never steroid-responsive, 22% became steroid-refractory, 33% could not be weaned to an acceptable dose, and 5% were never on steroids. A small number were transfused for unspecified reasons. Some patients may be tapered off steroids even after many years. Indeed, the actuarial likelihood of remission is 20% by age 25 years, with 72% entering remission during the first decade of life. Patients appear to remit equally from steroid and transfusion therapy. Almost 75% of these patients have what appears to be a sustained remission. Although high-dose corticosteroid pulses may evoke an erythroid response in some patients,^{417, 418} the potential side effects and the need for repeat pulses and the failure of this modality in subsequent studies⁴¹⁹ have limited its utility. Likewise, trials of cyclosporine (CsA), erythropoietin,

interleukin-3, metoclopramide, etc., despite anecdotal reports in DBA, have not been particularly encouraging (reviewed in Ref. 311). Furthermore, the potential toxicity of this agent makes it less preferable to red cell transfusions for those patients who cannot be weaned to an acceptable corticosteroid dose. In some patients who fail to respond to prednisone there may be a response when oxymetholone (2.0 to 5.0 mg/kg/day) is added. However, experienced clinicians do not advocate the use of androgens in infants and young children because of their limited effectiveness and considerable side effects. If there is no response within a month, prednisone is discontinued in favor of transfusion and iron chelation. These patients may receive periodic prednisone trials, because they may respond at a later date.

For patients in whom there is a response, the hemoglobin is followed until a level of 10 g/dl is achieved. The steroid dose is then tapered until the patient is on the smallest possible alternateday dose. A Monday-Wednesday-Friday dose schedule is usually effective and easier to comply with than a strict every-other-day regimen. The dosage in a Monday-Wednesday-Friday schedule may range from a few milligrams even in adolescents to as much as 40 to 50 mg. The target dose is 0.5 mg/kg/day or 1 mg/kg every other day. Arbitrary discontinuation of therapy should be discouraged, because reestablishment of erythropoiesis after discontinuation of an effective every-other-day course of prednisone requires reinstitution of the original daily dose. For patients who are steroid-refractory or in whom the dose cannot be tapered to an alternate-day regimen and thus require high daily doses that cause toxicity, chronic transfusion is instituted. Data from the DBAR and accumulated international experience demonstrate

P.987

that more patients than originally anticipated have significant steroid-related side effects even on a low-dose, every-other-day schedule. These are in addition to pathologic fractures and cataracts, and include poor growth, osteoporosis, and osteonecrosis, and may require the discontinuation of corticosteroids in favor of chronic transfusion therapy. Patients must be carefully monitored and steroid therapy discontinued when morbid side effects ensue, even if the dose is within the "accepted" range.

In recent years, HSCT has been used in DBA patients with good results. The first successful transplant for DBA was performed by August and colleagues in 1976.⁴²⁰ In a 1998 review of stem cell transplantation in DBA by Alter that analyzed 35 of the 37 cases reported to that date in the literature, the actuarial survival for predominantly allogeneic HLA-matched donor transplants was 66%.⁴²¹ Two more recent studies suggest that the actuarial survival is in the range of 90% for matched related HSCT in young, otherwise healthy patients.^{422, 423} The historical substantial risks associated with alternative-donor bone marrow transplantation favor transfusion and chelation in those patients unable to achieve an every-other-day steroid schedule; however, the hesitancy to use unrelated donors is changing as recent results from patients transplanted since 2000 are dramatically better, likely as the result of more precise high-resolution HLA-typing, an expanded donor pool, and better pretransplant management of iron overload.⁴²² Modern chelation regimens seem to be very effective in reducing the consequences of iron overload in chronically transfused patients, but the long-term results of these programs are currently not known. The recent availability of an oral chelating agent promises to improve compliance with better-tolerated chelation regimens than the traditional nightly continuous subcutaneous infusions. This uncertainty and the other risks of transfusion (i.e., sensitization and infection) make the decision regarding bone marrow transplantation (when a suitable alternative donor exists) versus chelation therapy for DBA patients who are steroidrefractory or steroid-intolerant, one that must be individualized and constantly reevaluated. In particular, poor compliance with chelation regimens has resulted in significant morbidity and mortality in young adult patients with transfusion-dependent DBA.³¹¹ A recent "How I Treat" article by Vlachos and Muir⁴²⁴ provides a highly annotated approach to the treatment of DBA.

Prognosis

The DBAR describes an overall actuarial survival rate at ~40 years of age as $75.1\% \pm 4.8\%$, with $86.7\% \pm 7.0\%$ for corticosteroid-maintainable patients, and $57.2\% \pm 8.9\%$ for transfusion-dependent patients. There is a statistically significant survival advantage for steroid-maintainable versus transfusion-dependent patients.^{311, 312} Deaths due to infection in splenectomized patients with DBA are now dramatically reduced through the use of pneumococcal and Hemophilus influenzae vaccines, prophylactic penicillin, and careful follow-up and management. In addition, splenectomy is performed only for hypersplenism and an increased transfusion requirement, not as specific therapy for DBA. However, despite modern chelation schemes, transfusion-related hemosiderosis is a significant cause of death in DBA. Deaths from infection (Pneumocystis jiroveci pneumonia, varicella pneumonia, Pseudomonas pneumonia, sepsis, and one unknown infection), vascular access device complications, hematopoietic stem cell transplant complications, aplastic anemia, and malignancy^{311, 312} are described. Seventy percent of deaths were treatment-related, with alternative-donor HSCT the leading cause of death in DBA. Only one HLA-matched related and one alternative-donor HSCT recorded by the DBAR

were done for the indication of severe aplastic anemia. The major indication was either steroid nonresponsiveness or intolerance. Since that publication, the results for unrelated HSCT have improved significantly, and this modality is under constant evaluation on a case-by-case basis. The most recent analysis from the DBAR reports an overall HLA-matched related-donor transplant survival of $76.9\% \pm 8.4\%$, with a $93.8\% \pm 6.1\%$ survival for patients equal to or less than 9 years of age. For unrelated donor transplants the overall survival has improved from $32.1\% \pm 11.7\%$ (1994 to 1999) to $85.7\% \pm 13.2\%$ (2000 to present).

For several years, it has been recognized that DBA is a syndrome predisposing to cancer, both hematopoietic and nonhematopoietic malignancies. A recent analysis of the prospective cohort of 608 patients enrolled in the DBAR since 1991 was performed to provide the first quantitative assessment of cancer incidence in DBA patients.³⁶⁴ Among the 608 patients, there were 9,458 person-years of follow-up. There were 15 solid tumors, 2 cases of AML, and 2 cases of MDS diagnosed at a median age of 41 years. The cancer incidence in DBA is significantly elevated, with an observed-to-expected (O/E) ratio of 5.4 for all cancers and 287 for MDS, 28 for AML, 36 for colon cancer, 33 for osteogenic sarcoma, and 12 for female genital cancers, respectively. Clearly, in addition to understanding the mechanism of cancer predisposition in DBA, surveillance strategies must be considered for this at-risk population.

Future Directions

Advances in cellular and molecular biology have dramatically increased our understanding of the pathophysiology of DBA. DBA has been shown to be the consequence of an intrinsic progenitor cell defect and in the majority of cases the consequence of abnormal ribosome assembly/function. At least nine and likely more RP genes as well as the transcription regulator GATA1 have been implicated. Careful clinical investigation has defined the syndrome, and the study of the cellular biology of the disorder has borrowed from and contributed to the understanding of the mechanism of hematopoietic progenitor cell differentiation. Using the DBAR and other international databases, important epidemiologic, clinical, and laboratory observations have been made with regard to the clinical presentation and inheritance of DBA. These databases have yielded other important observations on the genetics of congenital malformations in DBA, the therapeutic outcomes including the efficacy of HSCT, and the recognition of DBA as a cancer-predisposing syndrome. In particular, they have provided the essential substrate of well-characterized patients and multiplex families necessary for gene discovery. Robust gene discovery will no doubt permit the molecular classification of all cases of DBA.

Dr. Louis Diamond, whose career spanned over 60 years and who had been a teacher to many and an inspiration to the rest,⁴²⁵ would be pleased to know that from his description of an esoteric little disease has arisen fundamental new knowledge that has allowed extraordinary insights into the regulation of hematopoiesis and morphogenesis and the mechanisms of oncogenesis.

Acknowledgments

The authors acknowledge the contributions of Dr. Emmanuel Dessypris, whose excellent work on previous editions of this chapter served as the template for the current version.

Chapter 40

Congenital Dyserythropoietic Anemias

Gary Kupfer

Linette Bosques

Bertil Glader

The congenital dyserythropoietic anemias (CDAs) are a heterogeneous group of inherited blood disorders characterized by anemia and morphologic abnormalities of erythroid precursors in the bone marrow, a consequence of dyserythropoiesis and ineffective erythropoiesis.^{1, 2} These disorders principally affect the erythroid lineage, whereas other nonerythroid hematopoietic lineages seem to be unaffected. On the basis of morphologic abnormalities of the bone marrow, CDAs were classified into three different types: type I, type II, and type III. However, additional variants requiring further characterization have also been identified.³ Approximately 600 cases of CDA have been reported worldwide, CDA II being the most common.³ CDA I and II are inherited in an autosomal recessive pattern, and CDA III exhibits autosomal dominant inheritance and a sporadic form.⁴ The disease-related genes for CDA I, II, and III have been localized by linkage analysis, and the disease-causing genes have been identified for CDA I and II.

CDA patients display marked ineffective erythropoiesis and dyserythropoiesis.^{5, 6} Ineffective erythropoiesis may lead to intermittent jaundice, splenomegaly, hepatomegaly, and iron overload.^{2, 7} Iron overload is also a result of blood transfusion therapy, although even transfusion-independent patients may develop iron overload due to increased iron absorption.⁸ Dyserythropoiesis results in a variety of dysplastic features of erythroblasts in the bone marrow: internuclear chromatin bridges, karyorrhectic nuclei, binuclearity, multinuclearity, vacuolation of the cytoplasm, and duplication of the plasma membrane.⁹ Diagnosis of CDA relies on light and electron microscopy analyses to identify the characteristic morphologic abnormalities of the erythroblasts in the bone marrow.¹⁰ Mutation analysis is becoming available for some CDAs.

CDA should be suspected in any individual with a chronic anemia that is largely due to ineffective erythropoiesis, as well as in individuals with unexplained iron overload. The presence of ineffective erythropoiesis is characterized by a low absolute reticulocyte count for the degree of anemia despite erythroid hyperplasia in the marrow. Further suggestive laboratory data include a low serum haptoglobin level and increased serum lactic dehydrogenase (LDH) activity. Generally, the anemia is mildly or moderately macrocytic in CDA I, normocytic in CDA II, and mildly macrocytic in CDA III.

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE I (CDA I)

CDA I is inherited in an autosomal recessive pattern and it represents the second most common form of CDA.⁶ It is most prevalent among Western Europeans, Middle Easterners (Israeli Bedouins, Lebanese, Kuwaitis, Saudi Arabians), Indians, and Japanese, with more than 150 reported cases.²

Clinical Features

Observations on CDA I have been enhanced by studies on a large cluster of cases in Israeli Bedouin families^{11, 12, 13} and on cases in the German CDA registry.¹⁴ The anemia varies from mild to severe, with the most severe cases presenting in infancy and the milder cases presenting in adolescence or later in life. Some degree of anemia is present in about two thirds of neonates, often requiring transfusion, but less than 10% of cases remain transfusion dependent later in life.^{14, 15} Occasionally, severe anemia in the fetus causes hydrops fetalis with pericardial and pleural effusions and edema.^{16, 17} Jaundice and splenomegaly are common findings at all ages. Gallstones may develop and require cholecystectomy. In addition, distal limb malformations, such as syndactyly, absence of phalanges and nails, an additional phalanx, and duplication or hypoplasia of the metatarsals, have been reported in several cases of CDA I.¹⁸ Other congenital abnormalities found include café au lait spots, short stature, flattened vertebral bodies, hypoplastic rib, Madelung deformity, and deafness.² Deterioration of vision with retinal angioid streaks and macular degeneration has been described in two cases.^{19, 20}

Laboratory Features

CDA I patients usually have a macrocytic anemia with MCV values up to 115; normocytic CDA I patients still display macrocytes and thus an increased RDW. Anisocytosis, poikilocytosis (including teardrop-shaped poikilocytes), and basophilic stippling are other features of the peripheral blood smear (Fig. 40.1). Increased hemoglobin A₂ levels and unbalanced globin chain synthesis are found in some cases in the absence of β -thalassemia mutations.¹³ Bone marrow examination reveals marked erythroid hyperplasia with megaloblastic erythroblasts. One of the defining features of CDA I is the presence of thin internuclear chromatin bridges between nearly completely separated erythroblasts in 0.6% to 2.8% of cells^{6, 10} (Fig. 40.2). In only one well-documented case were such bridges not seen.¹⁹ A small proportion of erythroblasts are binucleate and occasional cells have three or four nuclei. Other abnormalities include RBC basophilic stippling, irregular nuclear outlines, and karyorrhexis.

A second defining structural feature of CDA I is multiple rounded electron-lucent areas within the electron-dense heterochromatin seen in up to 60% of erythroblasts, giving the nucleus a spongy or "Swiss cheese" appearance^{10, 21} (Fig. 40.3B,C). In some erythroblasts, there are also marked invaginations or evaginations of the nuclear envelope, and the

invaginations carry cytoplasm and cytoplasmic organelles such as mitochondria into the nucleus (Fig. 40.3C).²² Bone marrow macrophages contain phagocytosed morphologically abnormal erythroblasts (Fig. 40.4).

P.991

FIGURE 40.2. Bone marrow smear of a patient with congenital dyserythropoietic anemia type I showing an internuclear chromatin bridge. (From Wickramasinghe SN. Congenital dyserythropoietic anemias. In: Wickramasinghe SN, McCullough J, eds. Blood and bone marrow pathology. Edinburgh: Churchill Livingstone, 2003:273-282, with permission.)

Management

CDA I often follows an indolent course, although patients may require red cell transfusions in infancy, with infections, and during pregnancy. Only some patients benefit from splenectomy and this is in contrast to CDA II.^{2, 11, 14} Erythropoietin administration has no effect on the anemia of CDA I.²² Following the fortuitous observation that treatment of hepatitis C in a CDA I patient with interferon- α 2a led to a substantial hematologic improvement, several additional patients, including a severely affected infant, have been treated with interferon- α 2a, interferon- α 2b, or peg-interferon- α 2b, and these patients also have also experienced hematologic improvement.^{16, 24, 25, 26, 27, 28, 29} Interferon- α should be considered in the management of CDA I with severe anemia. In one case, long-term therapy was reported to reduce iron overload.²⁹ Careful monitoring for secondary hemochromatosis is important, at times requiring iron chelation therapy.

FIGURE 40.3. Ultrastructure of erythroblasts from a normal individual (A) and a patient with congenital dyserythropoietic anemia type i. B and C demonstrate the abnormal “Swiss cheese” appearance of the heterochromatin (compare with A), and C shows invagination of the nuclear membrane and nuclear membrane-bound areas of cytoplasm (containing iron-laden mitochondria) within the nucleus. (From Wickramasinghe SN. Congenital dyserythropoietic anaemias: clinical features, haematologic morphology and new biochemical data. *Blood Rev* 1998;12:178-200, with permission.)

Molecular Biology of CDA I

In 1998 the gene for CDA I was localized to chromosome 15q15.1-15.3.³⁰ and it is now recognized that CDA I is caused by mutations in the CDAN1 gene.³¹ CDAN1 has 28 exons spanning 15 kb of genomic DNA and encodes a highly conserved protein of unknown function called codanin-1. Mutations in the CDAN1

P.992

gene are mainly located in the 3' half of the gene and no homozygote for null type mutations has been identified, suggesting that the complete absence of codanin-1 may be lethal.³² One founder missense mutation is observed mainly in Israeli Bedouins with CDA I which converts arginine to tryptophan at codon 1,040 and generates an NcoI restriction site.³¹ This same missense mutation was found in 11 individuals with CDA I of two unrelated Lebanese families. A single mutation in CDAN1 has been found in several sporadic cases and in one case, no mutations in CDAN1 were found.³¹

Analysis of codanin-1 orthologs revealed the *Drosophila* homolog, *dlt*, is required for cell survival and cell cycle progression through the S phase.³³ Interestingly, codanin-1 increases during the S phase and is phosphorylated and excluded from condensed chromosomes during mitosis.³⁴ This study demonstrated that codanin-1 localizes to the nucleus, specifically to heterochromatin, during interphase and it is regulated by E2F1 transcription factors.³⁴ Another study confirmed codanin-1 localization to the nucleus, but it revealed that it is more abundant in the cytoplasm.³⁵ Codanin-1 mutations lead to the abnormal accumulation of heterochromatin protein HP1 α in the Golgi apparatus of CDA I erythroblasts but not normal erythroblasts.³⁵ However, overall chromatin structure as indicated by genomewide epigenetic marks of several histone modifications is normal in CDA I erythroblasts.

Recently, codanin-1 was shown to interact with histone chaperone Asf1, which regulates the import of histones during DNA replication.³⁶ Codanin-1 knockdown increases the amount of chromatin-bound Asf1, enhancing DNA synthesis.

Conversely, forced expression of codanin-1 interferes with Asf1 function due to Asf1 sequestration in the cytoplasm. Thus codanin-1 acts as a negative regulator of replication.

This close association with heterochromatin suggests that codanin-1 may be involved in mechanisms controlling gene transcription and chromatin structure remodeling. Thus, a clear understanding of the biochemical behavior of codanin-1 may provide us insight into how this interaction is established.

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE II (CDA II)

Type II CDA was first categorized as such by Heimpel and Wendt in 1968. It is the most common type of CDA, and several hundred patients have been described.³ The mode of inheritance is autosomal recessive.

Clinical Features

CDA II is usually a normocytic anemia with evidence of ineffective erythropoiesis and premature peripheral red cell destruction, causing jaundice and hepatosplenomegaly. In very mild cases, the anemia may be so slight as to remain undiscovered until late in adult life, although a majority of patients have a hemoglobin less than 11 g/dl. Overall, a third of affected children require transfusion in the first year of life, but transfusion requirements decrease in subsequent years, and only 5% of patients need regular transfusions in adulthood.³⁷ As in other congenital disorders in which ineffective erythropoiesis is a prominent feature, such as β thalassemia major, complications of extramedullary hematopoiesis may occur, such as dysmorphic facies, particularly in severely affected individuals. Cholelithiasis and secondary hemochromatosis are frequent complications, with iron overload the presenting manifestation in some cases.³⁸ Occasionally, transient red cell aplasia secondary to parvovirus B19 infection may develop.³⁹ Mental retardation,³ hemihypertrophy,³ and piebaldism and vaginal atresia have all been reported.⁴¹

Laboratory Features

Peripheral blood smear features include anisocytosis, poikilocytosis, basophilic stippling, and some irregularly contracted cells (Fig. 40.5). Bone marrow examination reveals marked erythroid hyperplasia without megaloblastosis. The defining erythroblast abnormality is prominent binuclearity. Proerythroblasts are morphologically normal, but basophilic and early and late polychromatic erythroblasts are binucleated, with up to 10% to 35% of late erythroblasts being so (Fig. 40.6). Some of these nuclei have irregular outlines or show karyorrhexis. In many binucleate late polychromatic erythroblasts, the nuclei are equal in size, and each of the two nuclei has a diploid DNA content suggesting the possibility that the cells resulted from a failure of cytokinesis following normal mitosis. The phagocytosis of red cells and erythroblasts by bone marrow macrophages leads to the formation of Gaucher-like macrophages (pseudo-Gaucher cells) in some individuals.

Electron microscopy reveals the characteristic presence of peripheral cisternae in erythroid cells.⁴⁰ These are discontinuous double membranes running parallel to and 40 to 60 nm away from the cell membrane (Fig. 40.7).⁴²

Peripheral cisternae are found in some red cells, a substantial proportion of mononucleate

P.993

and binucleate late polychromatic erythroblasts, and a smaller proportion of early polychromatic erythroblasts. They appear to represent endoplasmic reticulum (ER) as they contain disulfide isomerase that is known to be present in ER.⁴³

FIGURE 40.6. Bone marrow smear from a patient with congenital dyserythropoietic anemia type II, showing binucleate late polychromatic erythroblasts and karyorrhexis.

FIGURE 40.7. Electron micrograph of a mononucleate late polychromatic erythroblast (A) and part of a binucleate late polychromatic erythroblast (B) from a case of congenital dyserythropoietic anemia type II showing peripheral cisternae. (Part B from Wickramasinghe SN. Congenital dyserythropoietic anemias. In: Wickramasinghe SN, McCullough J, eds. Blood and bone marrow pathology. Edinburgh: Churchill Livingstone, 2003:273-282, with permission.)

When tested against a panel of ABO-compatible acidified sera (pH 6.8) from normal individuals, about 30% of the sera lyses CDA II red cells (acidified serum lysis test or Ham test). Unlike paroxysmal nocturnal hemoglobinuria (PNH), there is rarely lysis of the patient's red cells by his or her own serum. In addition, CDA II cells do not lyse in isotonic sucrose as PNH cells do. The lysis in acidified heterologous sera is due to a naturally occurring complement-binding immunoglobulin (Ig) M antibody against an unidentified antigen on CDA II cells. The combination of the characteristic morphologic abnormalities and the serologic finding led Crookston et al.⁴⁴ to propose the acronym HEMPAS (hereditary erythroblastic multinuclearity with positive acidified serum test) for CDA II. The acidified serum lysis test previously was most informative and useful to diagnose PNH; however, this test now has been replaced by quantitation of CD55 and CD59 by flow cytometry (see Chapter 35). As a consequence there is decreased availability of the Ham test in clinical laboratories and this test is rarely used to help identify CDA II.

The principal biochemical feature of CDA II is defective N-glycosylation of the erythrocyte membrane proteins, band 3 (anion exchange protein 1) and band 4.5 (glucose transporter 1).^{45, 46, 47} This causes band 3 and band 4.5 to migrate at lower molecular weights on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). During normal maturation of erythroid cells, the erythrocyte membrane proteins are glycosylated with polylactosaminoglycans. Band 3 and band 4.5 proteins normally contain long polylactosamine chains attached to complex N-linked oligosaccharides.⁴⁸ However, in CDA II, erythrocyte membrane proteins carry altered N-glycans with truncated polylactosamine structures.⁴⁸ Instead, glycosylation is shifted to lipid acceptors resulting in the accumulation of polylactosamines as glycolipids. Immunogold electron microscopy analysis using antiband 3 antibodies reveals irregular clustering of underglycosylated band 3 protein in CDA II erythrocyte membranes when compared to normal erythrocytes.⁴⁹ SDS-PAGE of red cell membrane proteins can be used as a diagnostic criterion in lieu of a positive acidified serum lysis test.

Management

Some cases of CDA II follow an indolent course, whereas transfusion-dependent individuals often benefit from splenectomy, usually with a moderate increase in hemoglobin concentration.^{3, 37} Most important, patients should be monitored closely for secondary hemochromatosis, which can occur even in the absence of regular transfusion as a result of ineffective erythropoiesis with increased iron absorption.⁵⁰ The extent of iron overload increases progressively with age,^{3, 37} and about 20% of cases develop cirrhosis.³ Iron chelation therapy may be indicated, or alternatively, phlebotomy may be considered in patients with mild anemia. In one case of CDA II with co-inherited β -thalassemia trait⁵¹ and one of a variant CDA II with a negative Ham test,⁵² allogeneic bone marrow transplantation has been curative.

Molecular Biology of CDA II

Abnormalities in two Golgi enzymes previously were implicated in the pathogenesis of CDA II: N-acetylglucosaminyltransferase II and α -mannosidase II.⁵³ In fact, an α -mannosidase II knockout mouse reproduces a phenotype similar to CDA II.⁵⁴ However, further familial studies have excluded linkage of CDA II to the N-acetylglucosaminotransferase and α -mannosidase II genes.⁵⁵ In addition, it has been found that abnormalities of glycosylation of red cell membrane proteins are not confined to CDA II, being present, albeit to a lesser degree, in both CDA I and III.^{56, 57}

From studying several families, the CDA I1 gene (CDAN2) has been localized to chromosome 20q11.2.^{58, 59} The disease-causing gene in CDA II is SEC23B, which spans approximately 54 kb on chromosome 20p11.23.^{60, 61} It encodes an essential component of the coat protein complex II (COPII)-coated vesicles that transport secretory proteins from the endoplasmic reticulum to the Golgi apparatus. The majority of CDA II patients harbor mutations in the SEC23B gene, although 10% of CDA II patients have no detectable mutations in this gene.^{37, 60, 61} The most frequent SEC23B mutations are the coding region missense mutations, R14W and E109K, and nonsense mutations, R497C and I318T.^{61, 62, 63, 64} Splice-site mutations and frameshift mutations have also been reported.^{63, 64} Compound heterozygosity for a frameshift or nonsense mutation and a missense mutation result in a more severe CDA II phenotype than homozygosity for two missense mutations,

P.994

establishing a genotype-phenotype relationship. However, CDA II patients homozygous for nonsense mutations have never been reported, suggesting that some SEC23B expression is necessary for embryonic viability.^{60, 61} In light of the identification of SEC23B, earlier described abnormalities in two Golgi enzymes implicated in the pathogenesis of CDA II: N-acetylglucosaminyltransferase II and α -mannosidase II are even more compelling.⁵³

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE III (CDA III)

This disorder was first described in 1951 in an American family by Wolfe and von Hofe under the name familial erythroid multinuclearity, and in 1962 in a Swedish family by Bergström and Jacobsson as hereditary benign erythroreticulosis.^{65, 66} CDA III represents the rarest CDA variant with a familial and a sporadic form.⁶⁷ The familial form is inherited in an autosomal dominant pattern, and the sporadic form is inherited in an autosomal recessive pattern or may arise de novo as a dominant mutation.^{6, 67} The disease gene has been localized in the Swedish family with CDA III to a 4.5 cM interval on chromosome 15q21-q25.⁶⁸ The possibility of an individual having CDA III is considered in the face of a mild macrocytic anemia not due to other common conditions.

Clinical Features

Individuals may experience fatigue, weakness, and episodes of abdominal pain and jaundice resulting from gallstones. Splenomegaly is absent in the dominantly inherited cases but is present in most sporadic cases. Intravascular hemolysis and consequent hemosiderinuria may be present and occasionally lead to iron deficiency. Iron overload does not develop in the Swedish cases probably because of iron loss from hemosiderinuria.⁶⁹ In the Swedish family, the prevalence of monoclonal gammopathy of unknown significance and myeloma is increased,⁶⁹ and visual disturbances due to macular degeneration and angioid streaks may be seen in older patients.⁷⁰ Single sporadic cases have been reported to develop Hodgkin disease and malignant T-cell lymphoma.^{71, 72}

Laboratory Features

The macrocytic anemia is generally of mild to moderate severity. The peripheral blood smear displays basophilic stippling, irregularly contracted erythrocytes, anisocytosis, and poikilocytosis (Fig. 40.8).² A distinguishing feature of CDA III is markedly abnormal erythroblast proliferation resulting in giant binucleated and multinucleated erythroblasts with up to 12 nuclei (Fig. 40.9A-D) and total DNA content up to 48 N.^{65, 73} Electron microscopy shows multinucleated erythroblasts with multiple nuclear clefts in the heterochromatin, which may lead to nuclear lobulation and karyorhexis (Fig. 40.10).⁷⁴ Individual nuclei within the same multinucleated cells (with up to 12 nuclei) can display different shapes and sizes and abnormal heterochromatin appearance.⁷⁴ The cytoplasm of many erythroblasts contains large autophagic vacuoles, inclusions containing β globin chains, iron-loaded mitochondria, and myelin figures.

CONGENITAL DYSERYTHROPOIETIC ANEMIA VARIANTS

A category, designated CDA type IV, was proposed to describe cases with bone marrow appearances typical of CDA II, but a negative Ham test with heterologous sera. Some of these cases may simply represent CDA II in which an insufficient number of heterologous sera were used in the test. Examples exist of cases that have been reclassified as CDA II when retested with more sera. The availability of SEC23B gene testing should help define if these are truly CDA II variants.

FIGURE 40.8. Blood smear from a patient with congenital dyserythropoietic anemia type III.

Several cases have been reported with features other than those of CDA I, II, or III that seem to represent distinct forms of CDA rather than variants of the three classic types. Most of these have been tentatively assigned to four phenotype-based groups designated CDA group IV, V, VI, and VII and their essential features are shown in Table 40.1;^{2, 6} the majority belong to group IV.^{75, 76} They have been designated as groups rather than types as there is evidence of phenotypic and/or genetic heterogeneity within each group. In addition to these groups, each of which includes three or more families, there are cases with unique features reported in only one or two families.

A father and daughter had a disorder with probable autosomal dominant inheritance characterized by normal hemoglobin values, macrocytes in the blood film, and dyserythropoiesis including internuclear chromatin bridges, but unlike in CDA I, the erythroblast heterochromatin was ultrastructurally normal.⁷⁷ Other single cases have shown large cytoplasmic vacuoles, macrocytosis without anemia, and marked irregularities of nuclear outline in a high proportion of erythroblasts⁷⁸ or transfusion-dependent anemia with gross nonspecific dyserythropoietic changes in many erythroblasts including marked irregularities of nuclear outline.⁷⁹ In two consanguineous Arab families, CDA was associated with microcytosis, many binucleate late erythroblasts, a negative Ham test, and chronic recurrent multifocal osteomyelitis; the inheritance was autosomal recessive and homozygous mutations in the LPIN2 gene on chromosome 18p were present.^{80, 81} A third Arabic patient with this syndrome also had a homozygous mutation in LPIN2.⁸²

A missense mutation of erythroid transcription factor KLF1 has been reported to cause CDA with erythroid hyperplasia and unique ultrastructural abnormalities in the bone marrow.⁸³ A characteristic feature of this CDA variant is the high number of orthochromatic erythroblasts in the peripheral blood that fail to undergo terminal erythroid differentiation and thus retain their nuclei. Furthermore, patient-derived CD34⁺ cells induced down the erythroid lineage in vitro show impaired enucleation. Electron microscopy reveals erythroblasts with endoreplication of nuclear membrane with abnormally large nuclear pores, severe anisopoikilocytosis, and cytoplasmic inclusions. Clinically, the patient described with this mutation required frequent blood transfusions due to hemolytic anemia. Treatment with erythropoietin or interferon- α was ineffective. Following splenectomy, the patient became transfusion-independent and hemoglobin

P.995

levels stabilized. The patient had no mutations in the CDAN1 and SEC23B genes. The disease-causing mutation was discovered to affect exon 3 of the KLF1 gene, converting glutamate 325 to lysine (E325K). The patient displayed

dysregulation of globin gene expression, resulting in the persistence of embryonic and fetal hemoglobins. Additionally, the patient's circulating erythroblasts and mature erythrocytes were deficient in the adhesion molecule CD44 and water channel AQP1. Of interest, a well-studied patient with very similar clinical features had been reported in the 1990s.

This previous patient had a moderate normochromic normocytic anemia, dyserythropoiesis, circulating erythroblasts, ineffective erythropoiesis, and the following features: deficiency of erythroid but not leukocyte CD44, a unique Colton blood group, 50% hemoglobin F, small amounts of ζ - and ϵ -globin chains in some red cells, reduced expression of aquaporin 1 (CHIP), and rounded intraerythroblastic inclusions composed of tightly packed double

P.996

membranes.^{84, 85, 86} More recently, when this earlier patient was reevaluated, she also was found to have the same KLF1 mutation.⁸³

FIGURE 40.10. Erythroblast from a case of congenital dyserythropoietic anemia type III showing stellate intracytoplasmic inclusions. (From Wickramasinghe SN, Wahlin A, Anstee D, et al. Observations on two members of the Swedish family with congenital dyserythropoietic anaemia, type III. *Eur J Haematol* 1993;50:213-221, with permission.)

TABLE 40.1 FEATURES OF CONGENITAL DYSERYTHROPOIETIC ANEMIA (CDA) GROUPS IV-VII^a

Group Defining Features

IV	Severe transfusion-dependent anemia Marked erythroid hyperplasia, usually normoblastic Markedly ineffective erythropoiesis Slight/moderate increase in nonspecific dyserythropoietic changes including markedly irregular or karyorrhectic nuclei Absence of the marrow abnormalities characteristic of CDA I-III Absence of precipitated protein within erythroblasts by electron microscopy (which excludes α -thalassemia syndromes and CDA group VII)
V	Normal or near-normal Hb with normal or slightly increased MCV Predominantly unconjugated hyperbilirubinemia Marked normoblastic/mildly or moderately megaloblastic erythroid hyperplasia Grossly ineffective erythropoiesis Little or no erythroid dysplasia
VI	Normal or near-normal Hb with marked macrocytosis (MCV 119-125 fl) Erythroid hyperplasia with cobalamin and folate-independent florid megaloblastic erythropoiesis and nonspecific dyserythropoiesis

Ineffective erythropoiesis

VII Severe transfusion-dependent anemia

Marked normoblastic erythroid hyperplasia with nonspecific dyserythropoietic changes, especially irregular nuclear shapes, in many polychromatic erythroblasts

Markedly ineffective erythropoiesis

Intraerythroblastic inclusions resembling precipitated globin that do not react with antibodies to α - or β -globin chains (electron microscope studies)

Hb, hemoglobin; MCV, mean corpuscular volume.

^aCDA group IV is distinct from CDA type IV, which is a term that has been used to describe a variant of CDA type II.

FIGURE 40.11. Bone marrow appearances resembling those of congenital dyserythropoietic anemia. A: Myelodysplastic syndrome with frequent binucleate late polychromatic erythroblasts. B: Thiamine-responsive anemia with multinucleate megaloblasts. (Part B from Wickramasinghe SN. Macrocytic anemia. In: Wickramasinghe SN, McCullough J, eds. Blood and bone marrow pathology. Edinburgh: Churchill Livingstone, 2003:229-247, with permission.)

Congenital dyserythropoiesis is associated with thrombocytopenia in patients with mutations in the gene for the transcription factor GATA1.^{2, 87} However, the presence of thrombocytopenia would generally be considered to exclude such cases from the category of CDAs.

In addition to the congenital dyserythropoietic disorders discussed in this chapter, acquired conditions occasionally can be associated with ineffective erythropoiesis and dyserythropoiesis.^{2, 6, 9} These include vitamin B₁₂ or folate deficiency, severe iron deficiency, thalassemia syndromes, some unstable hemoglobins, sideroblastic anemias, myelodysplastic syndromes, acute myeloid leukemia, aplastic anemia, malaria, Kala azar, alcohol abuse, and liver disease. It is noteworthy that morphologic features characteristic of CDA I, II, and III may be seen in some acquired dyserythropoietic states. For example, internuclear chromatin bridges such as those seen in CDA I may be found occasionally in myelodysplastic syndromes (MDSs), in *Plasmodium falciparum* malaria, and during marrow regeneration following transplantation. A high proportion of binucleate late erythroblasts such as is seen in CDA II may be encountered in MDS (Fig. 40.11A) and marked multinuclearity of erythroblasts as found in CDA III is seen in some cases of erythroleukemia and thiamine-responsive anemia (Fig. 40.11B).

Chapter 41

Anemias Secondary to Chronic Disease and Systemic Disorders

Robert T. Means, Jr.

ANEMIA OF CHRONIC DISEASE

The anemia that is often observed in patients with infectious, inflammatory, or neoplastic diseases that persist for more than 1 or 2 months is called anemia of chronic disease (ACD). The characteristic feature of this syndrome is the occurrence of hypoferrremia in the presence of ample reticuloendothelial iron stores. ACD is defined by the presence of this unique combination of findings.^{1, 2, 3} As so defined, the syndrome does not include anemias caused by marrow replacement, blood loss, hemolysis, renal insufficiency, hepatic disease, or endocrinopathy, even when those disorders are chronic. These other syndromes are discussed in the sections "Anemia of Chronic Renal Insufficiency," "Anemia in Cirrhosis and Other Liver Diseases," and "Anemias Associated with Endocrine Disorders" in this chapter. To further complicate

nomenclature, the acute anemia observed in critically ill patients and that component of postsurgical anemia not attributable to blood loss appear to be pathophysiologically identical to ACD.

As the discussion above suggests, the designation ACD is far from perfect.⁴ The alternate term, anemia of inflammation has become more widely used in recent years,^{4, 5} but also has significant etymologic deficiencies, and the more pathophysiologically correct term cytokine-mediated anemia⁶ is not commonly used. Highly specific descriptive designations, such as anemia of defective iron reutilization,⁷ hypoferrmic anemia with reticuloendothelial siderosis, and thesauric hypoferrmic anemia,⁸ are also rarely used and have the limitation of focusing solely on the iron-related aspects of the syndrome.

Associated Syndromes

ACD is extremely common and, overall, is probably more common than any anemia syndrome other than blood loss with consequent iron deficiency. Cash and Sears evaluated all the anemic individuals admitted to the medical service of a busy municipal hospital during two 2-month periods in 1985 and 1986.⁹ After patients with active bleeding, hemolysis, or known hematologic malignancy were excluded, 52% of anemic patients met laboratory criteria for ACD.⁹ The syndrome is also observed in 27% of outpatients with rheumatoid arthritis¹⁰ and in 58% of new admissions to inpatient rheumatology units.¹¹ However, it should be remembered that 40% of patients in the series reported by Cash and Sears lacked one of the traditional "ACD-associated disorders."⁹ Approximately one-third of this latter group had renal insufficiency, in which pathophysiologic mechanisms implicated in ACD are active.¹² Clinical disorders commonly associated with ACD are listed in Table 41.1.

Clinical and Laboratory Description

Because this type of anemia occurs in association with so many diseases, the clinical manifestations necessarily vary widely. Usually, the signs and symptoms of the underlying disorder overshadow those of the anemia, but on rare occasions, developing anemia provides the first evidence of the primary condition. This situation may be observed particularly in difficult-to-diagnose clinical syndromes, such as temporal arteritis.¹³

Anemia

Development and Severity

Typically, anemia develops during the first 1 to 2 months of illness and thereafter does not progress.² The hematocrit usually is maintained between 0.25 and 0.40,^{2, 14, 15} but significantly lower values are observed in 20% to 30% of patients.^{9, 10} The hemoglobin concentration and hematocrit generally provide an accurate reflection of the extent to which the circulating red cell mass is reduced, although in certain cases, expansion of the total blood volume would mean that the reduction in red cell mass is less than the hemoglobin or hematocrit indicates.^{16, 17}

A general correlation exists between the degree of anemia and the severity of the underlying disease.² For example, infections accompanied by pronounced fever, chills, and suppuration are associated with more severe anemia than those with fewer systemic manifestations.¹⁸ In infected wounds, the degree of anemia

P.999

is related to the number of organisms present.¹⁸ Correlation has also been observed between the severity of the anemia and the activity of rheumatoid arthritis as judged by fever, severity of joint swelling and inflammation, and the erythrocyte sedimentation rate.^{19, 20} In patients with malignant disease, anemia is more severe when metastases are widespread than when the disease is localized; however, the development of anemia does not require or imply neoplastic involvement of the bone marrow.^{21, 22}

TABLE 41.1 CONDITIONS ASSOCIATED WITH ANEMIA OF CHRONIC DISEASE

Chronic Infections^{9, 16}

Pulmonary infections: abscesses, emphysema, tuberculosis, pneumonia

Subacute bacterial endocarditis

Pelvic inflammatory disease

Osteomyelitis

Chronic urinary tract infections

Chronic fungal disease

Meningitis

Human immunodeficiency virus

Chronic, Noninfectious Inflammations

Hodgkin disease

Non-Hodgkin lymphoma

Leukemia

Multiple myeloma

Miscellaneous

Alcoholic liver disease

Congestive heart failure^{165, 167}

Thrombophlebitis

Ischemic heart disease

Idiopathic

Typically, the percentage of reticulocytes is normal or reduced,² although on rare occasions it may be slightly increased.¹⁸ The reticulocyte production index is decreased, although not to the same degree seen in primary marrow failure states like aplastic anemia or pure red cell aplasia.

Morphologic Features

The erythrocytes usually are normocytic and normochromic; however, hypochromia and microcytosis may be observed. In older series, microcytosis (mean corpuscular volume [MCV] <80 fl) was observed in 2% to 8% of patients with ACD^{19, 23, 24}; however, other, more recent studies report a frequency of 20% to 40%.^{9, 15} Hypochromia (mean corpuscular hemoglobin concentration, 26 to 32 g/dl) is more common than microcytosis. In various series, hypochromia was observed in 23% to 50% of patients with chronic infection, 50% to 100% of patients with rheumatoid arthritis, and 44% to 64% of patients with cancer.^{2, 15} Overall, it is observed in 40% to 70% of patients with ACD.^{9, 10, 19, 23, 24} Hypochromia may be observed even though the hematocrit remains within normal limits.²⁵ Microcytosis in ACD is usually not as striking as that commonly associated with iron deficiency anemia; values for MCV <72 fl are rare.^{2, 15} Another distinction from iron deficiency is that hypochromia typically precedes microcytosis in ACD but typically follows the development of microcytosis in iron deficiency.² Slight anisocytosis and poikilocytosis may be detected, but such changes tend to be less prominent than in iron-deficient subjects. Routine examination of the blood smear rarely reveals specific morphologic abnormalities. The width of the erythrocyte size distribution curve (red cell distribution width) is typically elevated to a moderate degree, and generally does not help in distinguishing iron deficiency and ACD. Newer parameters calculated by automated hematologic analyzers, such as reticulocyte hemoglobin content (Chr), may assist in distinguishing ACD from iron deficiency.^{26, 27}

Laboratory Markers of Iron Status

Characteristically, serum iron concentration is decreased, total iron-binding capacity (or serum transferrin concentration) is reduced, and transferrin saturation may be below normal, though not to the same degree as in iron deficiency.^{2, 24} In patients with infection, hypoferrremia develops early in the course of the illness, often within 24 hours, and is observed even in acute, self-limited febrile diseases or after experimentally induced fever in humans or animals.^{8, 14, 28, 29} When the infection is of short duration, the serum iron returns to normal and anemia does not develop; in prolonged illnesses, the serum iron level remains low as long as the disease is active. When the disorder subsides, anemia often is relieved before the serum iron level returns to normal. The degree of hypoferrremia is related to the severity of the underlying illness.^{19, 24, 30}

In bone marrow aspirates stained for iron, the number of sideroblasts is reduced to 5% to 20% of the total quantity of normoblasts (normal, 30% to 50%). In contrast, the amount of hemosiderin within macrophages usually is increased; exceptions to this probably represent cases complicated by iron deficiency.²

Serum ferritin level is a useful indicator of iron status in patients without underlying inflammatory disorders. In patients with ACD, however, the serum ferritin level indicative of adequate reticuloendothelial iron stores requires upward adjustment. Serum ferritin values usually increase in patients with inflammatory diseases,³¹ and extreme elevations of serum ferritin may be a nonspecific indicator of significant underlying disease.³²

When iron deficiency coexists, the serum ferritin level falls but may not reach values as low as those found in uncomplicated iron deficiency. Values of 60 to 100 $\mu\text{g/L}$, previously suggested as the appropriate lower limit of normal for serum ferritin in chronic inflammation, may be too low, depending upon the parameters of the ferritin assay used.^{33, 34, 35, 36} At one institution, all patients with serum ferritin levels $<30 \mu\text{g/L}$ were iron-deficient by marrow examination, as were the majority of hospitalized patients with serum ferritin levels of 30 to 100 $\mu\text{g/L}$ and approximately one-third of hospitalized patients with serum ferritin levels between 100 and 200 $\mu\text{g/L}$ (Fig. 41.1).³⁷ Combining the serum ferritin level with other parameters, such as erythrocyte sedimentation rate and C-reactive protein, did not improve its predictive value,³⁸ although it has been suggested that the combination of serum ferritin with red cell ferritin may be more predictive.³⁹ The recognition of iron deficiency in patients with chronic inflammatory states is not a trivial issue: Iron deficiency contributes to anemia in up to 27% of anemic rheumatoid arthritis patients¹⁰ and probably accounts for periodic reports of successful treatment of "the anemia of chronic disease" with iron preparations.⁴⁰ A patient with chronic inflammatory disease and a serum ferritin $<30 \mu\text{g/L}$ is certainly iron-deficient, and a patient with a serum ferritin $>200 \mu\text{g/L}$ is certainly not iron-deficient; in other circumstances, certainty can be provided only by examination of a Prussian blue-stained marrow specimen. Elevated concentration of soluble transferrin receptors (sTfRs) in serum is another way to identify iron-deficient individuals with normal serum ferritin concentrations.⁴¹

Serum or plasma sTfR concentration is elevated in iron deficiency but is not elevated in uncomplicated ACD. It will be elevated in ACD cases complicated by iron deficiency.^{42, 43, 44, 45} sTfR concentration is most accurately interpreted in the context of the serum ferritin concentration,^{41, 46} and is often expressed as a ratio to the log of the serum or plasma ferritin concentration (called the transferrin receptor index or transferrin/ferritin index).⁴⁶

As will be discussed later in this chapter, the iron regulatory peptide hepcidin appears to be a significant driver of the pathogenesis of ACD. Circulating hepcidin concentration is expected to be elevated in ACD.^{5, 47} Well-studied and reproducible assays for hepcidin have been developed,^{48, 49, 50, 51, 52, 53} and while none are available for routine clinical use at present it is reasonable to assume that they will be available in the near future. It has been suggested that serum hepcidin concentration can be plotted against CHr and that the combination of elevated hepcidin and normal CHr will distinguish ACD from both iron deficiency (normal hepcidin, high CHr) and the combined state of ACD and iron deficiency (low CHr, high hepcidin).⁵⁴

FIGURE 41.1. Comparison of serum ferritin levels from iron-deficient and non-irondeficient patients as identified by bone marrow examination during 1994 to 1995 at the University of Cincinnati Medical Center. Dashed lines indicate the range of normal for the laboratory.

P.1000

Other Biochemical Findings

The concentration of free protoporphyrin in the erythrocytes (FEP) tends to be elevated in patients with ACD.^{14, 55, 56} However, FEP increases more slowly in ACD than it does in iron deficiency, and it does not become clearly abnormal until significant anemia has developed.

A variety of other biochemical changes often are detected in patients with chronic diseases. Many of these changes reflect alteration of levels of particular plasma proteins, often called acute-phase reactants.^{57, 58, 59, 60, 61} The concentrations of certain plasma proteins, such as fibrinogen, ceruloplasmin, haptoglobin, C-reactive protein, orosomucoid, C3, and amyloid A protein, increase^{62, 63, 64}, whereas the concentrations of albumin and transferrin characteristically decrease.⁶⁵ The increase in ceruloplasmin accounts for the increase in serum copper levels often noted in association with chronic diseases.^{2, 14} An elevated fibrinogen level is probably the most important factor in the increased sedimentation rate.

Patients with chronic illness develop accelerated protein catabolism and negative nitrogen balance associated with muscle proteolysis.^{64, 65} Over time, this phenomenon can result in muscle wasting, increased urea excretion, weight loss, and growth impairment in children. However, protein catabolism generates amino acids that can be used by the patient as alternative energy sources or to supply substrates for biosynthetic processes related to host response. In this context, it is perhaps relevant that elevated serum levels of tumor necrosis factor (TNF), a cytokine implicated in the pathogenesis of ACD, are noted in patients with significant malnutrition.^{66, 67}

Kinetic Characteristics

Erythrocyte survival is modestly but significantly reduced in patients with ACD. In two studies comparing red cell survival in anemic patients with rheumatoid arthritis to red cell survival in normal individuals, the mean red cell survivals noted were 81 days versus 98 days, and 90 days versus 114 days, respectively.^{68, 69} In a similar study comparing red cell survivals in 10 anemic patients with a variety of chronic inflammatory states to 10 normal individuals, the mean values observed were 80 days versus 88 days, respectively.⁶⁸ The usual manifestations of increased blood destruction, such as increases in serum bilirubin values and urobilinogen excretion, are not typically observed.^{2, 70}

There is little evidence of a compensatory erythropoietic response to this reduction in red cell survival. The reticulocyte count usually is normal or decreased, and little or no erythroid hyperplasia of the marrow is observed. The pathogenetic significance of these findings is discussed in the following section. Kinetic data indicate that anemia develops because the

bone marrow fails to increase red cell production sufficiently to compensate for a mild decrease in the lifespan of the red cells.^{2, 8, 68} Ferrokinetic studies involving patients with chronic infections,^{71, 72} rheumatoid arthritis,⁷³ and various malignant diseases^{21, 22, 74} reveal that the rate of disappearance of iron from the plasma is rapid, the plasma iron transport rate is normal or slightly increased, the uptake of iron into erythrocytes and the amount of iron turning over through red cells daily are normal or increased, and the fraction of red cells renewed daily is increased.² When techniques that allow the division of marrow iron turnover (a measure of total erythropoiesis) into red cell iron turnover and ineffective iron turnover were used, marrow iron turnover was normal in patients with ACD.^{68, 69, 75, 76} Ineffective iron turnover was also normal, or even less than normal, indicating a lack of ineffective erythropoiesis as traditionally defined.⁶⁸ In iron-deficient subjects, ineffective iron turnover is increased, perhaps because of greater stimulation of the marrow.

Pathogenesis

Efforts to clarify the pathogenesis of ACD have focused on three principal abnormalities: shortened erythrocyte survival, impaired marrow response, and disturbance in iron metabolism. The modest shortening of the erythrocyte survival creates an increased demand for red cell production on the marrow. Normally, the marrow could easily accommodate this demand, but in the setting of ACD, the marrow is unable to respond fully because of a combination of a blunted erythropoietin (Epo) response, an inadequate progenitor response to Epo, and limited iron availability (Fig. 41.2).

Cytokines

ACD is one manifestation of the systemic response to immunologic or inflammatory stress, which results in the production of various cytokines.^{3, 77} The ability to trigger this cytokine response appears to be the common pathogenetic factor shared by the various conditions associated with this anemia syndrome.⁷⁸ The central role of these molecules suggests that ACD may be best understood as a cytokine-mediated process.⁶ The cytokines most often implicated in the pathogenesis of ACD are TNF,^{79, 80, 81} IL-1,^{82, 83} IL-6,⁸⁴ and the interferons,^{85, 86, 87} concentrations of which have been reported to be increased in the serum or plasma of patients with disorders associated with ACD.^{85, 87, 88, 89, 90, 91} Therapeutic administration of TNF or interferon may induce anemia.^{92, 93} The role of IL-6 is complex. IL-6 administration itself does not suppress erythropoiesis but rather is associated with increased plasma volume; therefore there is a dilutional component to any observed anemia.¹⁷ The association of IL-6 with hepatocyte activation may thus explain the dilutional component of the anemia observed in liver disease.^{94, 95, 96} However, IL-6 is also a potent inducer of hepcidin, proposed as a major mediator of the iron abnormalities of ACD.⁵

The Role of Hepcidin

While inflammation-induced cytokine activation is clearly the initial event in the pathogenesis of ACD, the liver-produced antimicrobial peptide hepcidin appears to be the most important mediator through which cytokines exert their effects on the pathogenetic mechanisms of ACD.^{5, 97, 98} Hepcidin is an acute-phase-reacting peptide, largely regulated by IL-6 but also by cytokine pathways not linked to IL-6.^{5, 99, 100} Patients with hepatic adenomas secreting hepcidin exhibit a hypoferremic anemia that resolves with resection of the adenoma.⁹⁷ Urinary hepcidin excretion is strongly correlated with serum ferritin concentration and is markedly elevated in patients with anemia of inflammation (defined as anemia

P.1001

with a characteristic clinical setting and an elevated serum ferritin) compared to iron-deficient patients.⁵ Hepcidin promotes macrophage iron retention by causing internalization of the iron export protein ferroportin.¹⁰¹

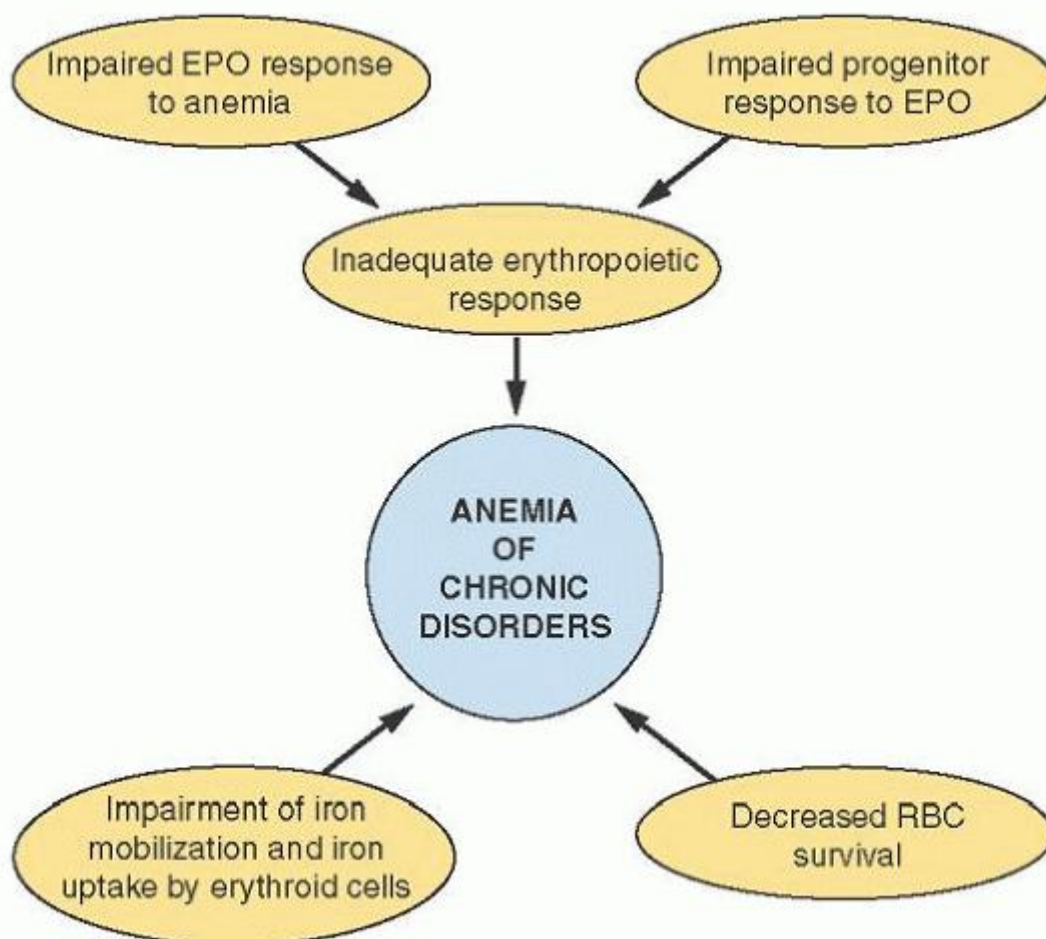

FIGURE 41.2. Schematic diagram representing contributing mechanisms in the pathogenesis of anemia of chronic disease. EPO, erythropoietin; RBC, red blood cell.

Of the pathogenetic mechanisms shown in Figure 41.2, hepcidin clearly drives the abnormalities in iron metabolism. However, it may be linked to other elements as well. Under conditions of limited Epo availability, hepcidin is associated with impaired erythroid colony formation *in vitro*.¹⁰² Increased circulating hepcidin appears to be linked to the degree of resistance to recombinant (rh) Epo therapy in dialysis patients.¹⁰³ Hepcidin and Epo production appear to be regulated in an inverse relationship by hypoxiainducible factor,¹⁰⁴ which may potentially provide some linkage between hepcidin and the relative Epo deficiency of ACD. This latter connection remains to be demonstrated.

Shortened Erythrocyte Survival

The rate of survival of cells from patients with arthritis, when transfused into normal subjects, is normal, and the survival of red cells from normal individuals in the circulation of patients with arthritis is less than the normal rate.^{2, 23} Therefore, shortened red cell survival in patients with chronic inflammatory disorders is attributed to an extracorporeal mechanism.³⁰ IL-1 levels and shortened red cell survival are correlated in anemic patients with rheumatoid arthritis,¹⁰⁵ and mice that become anemic after exposure to TNF *in vivo* also exhibit a shortened red cell survival.¹⁰⁶ Neocytolysis, a selective hemolysis of newly formed erythrocytes associated with Epo deficiency,^{107, 108} has been proposed as a mechanism for shortened red blood cell survival in ACD. Peroxynitrite, derived from the reaction of the cytokine second messenger nitric oxide and superoxide, may contribute to red cell rigidity and thus to decreased survival.¹⁰⁹

Impaired Marrow Response

Normal bone marrow, capable of a six- to eightfold increase in the red cell production rate, should easily compensate for such a modest reduction in erythrocyte survival. Its failure to do so in ACD suggests that impaired production capacity is of fundamental importance in the pathogenesis of this condition. The possible defects in erythropoiesis fall into three categories: inappropriately low Epo secretion, diminished marrow response to Epo, and iron-limited erythropoiesis.

An inverse relationship between serum or plasma Epo levels and hemoglobin normally exists: As the hemoglobin decreases, the Epo level rises.¹¹⁰ A similar inverse relationship between hemoglobin and Epo level exists in anemic individuals with rheumatoid arthritis, cancer, and human immunodeficiency virus infection^{111, 112, 113, 114}; however, for any given anemic patient in these disease categories, the Epo level was lower than that found in equally anemic individuals with iron deficiency, indicating that the Epo response to anemia was blunted. This impaired Epo response is cytokine-mediated. IL-1, TNF- α , and transforming growth factor β inhibit production of Epo by various hepatoma cell lines and by isolated perfused rat kidneys in vitro.^{115, 116} This effect occurs at the messenger RNA level.¹¹⁵ It has been proposed that this inadequate Epo secretion is adaptive; that is, it reflects reduced tissue oxygen use so that normal oxygenation is maintained despite reduced hemoglobin levels. One colorful description of this process is that the "hematologic thermostat has been turned down a bit",⁸ perhaps to allow diversion of substrates normally used in erythropoiesis to more immediately critical activities. Changes that ordinarily signify erythrocyte adaptation to tissue hypoxia, such as increased erythrocyte 2,3-diphosphoglycerate (2,3-DPG) levels, are observed in ACD.¹¹⁷ Hemoglobin oxygen affinity is also slightly decreased in these patients but overlaps the range observed in normal subjects.¹¹⁷

Although the Epo levels of patients with ACD are lower than those observed in equally anemic iron-deficient individuals, they are still higher than are observed in normal individuals who are not anemic. This implies that inhibition of Epo production cannot entirely account for the impaired erythropoiesis associated with ACD, and that the erythroid progenitors themselves exhibit an abnormal response to Epo. Studies of anemic cancer patients support this concept.^{118, 119}

TNF, IL-1, and interferon have all been reported to inhibit erythropoiesis in vivo and in vitro.^{90, 92, 120, 121, 122, 123, 124, 125, 126, 127, 128} TNF inhibits in vitro colony formation by human erythroid colony-forming units (CFU-E) indirectly, through interferon- β and possibly other soluble factors released from marrow accessory cells in response to TNF.^{129, 130} The inhibitory effect of rhIL-1 on human CFU-E colony formation was also indirect and dependent on marrow accessory cells; however, the responsible accessory cells in this case were T lymphocytes, and the mediator was interferon- γ , which also exhibits a direct inhibitory effect on human CFU-E.¹³¹ Although interferon- α and interferon- β share a common receptor, interferon- α does not exert a direct inhibitory effect on human CFU-E colony formation. Instead, its effect is mediated through an unidentified soluble factor released by T lymphocytes.¹³² The inhibitory effects of interferon- α and interferon- β exhibit synergy with interferon- γ .¹³² An important point to consider in reviewing the various models for cytokine effects on erythropoiesis is that none of the systems described operates in isolation in vivo. Thus, TNF induces IL-1 production by macrophages, IL-1 induces interferon- γ production by T lymphocytes, and interferon- γ can exhibit positive or negative feedback on production of IL-1 and TNF.

Treatment with recombinant human Epo (rhEpo) can correct ACD in many cases. Inhibition of in vitro erythroid colony formation by interferon- γ , but not interferon- α and interferon- β , can be corrected by exposure to high concentrations of Epo.^{132, 133} Epo also suppresses hepcidin production.^{134, 135}

Abnormal Iron Metabolism

It has been proposed that lack of iron for erythropoiesis contributes to the inadequate marrow response in ACD. Evidence of a functional iron deficiency in this syndrome includes erythrocyte microcytosis, increased FEP,^{14, 56} reduced transferrin saturation,²⁴ and decreased marrow sideroblasts.²⁴

Ferroketic studies have proved confusing. It has been reported that erythroid iron turnover correlated with serum iron levels, permitting a conclusion that marrow proliferation was limited by availability of iron in ACD.¹¹⁸ Other studies found no correlation between marrow iron turnover and serum iron concentration.^{68, 69, 76, 136}

The major contributor to hypoferrremia in patients with ACD is probably a shift of iron from a transferrin-bound, available circulating state to an intracellular storage state. Iron absorption appears to be normal, but iron tends to remain in the mucosal cell and in hepatocytes.^{137, 138} Macrophages, the major site from which iron is obtained for erythropoiesis, also exhibit increased iron storage. This process is mediated by hepcidin, which downregulates the iron egress regulatory ferroportin, thus trapping iron intracellularly.¹⁰¹

The dominant factor in the iron abnormalities of ACD is clearly hepcidin, discussed above and at greater length in Chapter 23. A number of other processes of less overarching significance may contribute under particular circumstances to the iron anomalies observed. Apoferritin is normally synthesized in response to increased intracellular iron concentration.¹³⁹ It has been suggested that excess apoferritin is made in inflammatory and malignant conditions, and the surplus binds a larger-than-usual amount of iron entering the cell.^{140, 141, 142} In effect, such a mechanism would divert iron from the rapid to the slow pathway of iron release. Rodents injected with recombinant TNF developed

a hypoferrmic anemia associated with impaired storage iron release and incorporation into erythrocytes.^{106, 143} It has also been reported that IL-1 increases translation of ferritin messenger RNA and that this additional ferritin could act as a trap for iron that might otherwise be available for erythropoiesis.¹⁰⁵ Nitric oxide, which is a common mediator of cytokine effects, has similar effects on ferritin expression.^{144, 145} Lactoferrin is a transferrinlike protein found in neutrophil-specific granules.^{146, 147} It is released from the neutrophil during phagocytosis or stimulation by IL-1.¹⁴⁸ At low pH, lactoferrin binds iron more avidly than does transferrin.¹⁴⁹ Lactoferrin-bound iron is not immediately available for erythropoiesis¹⁵⁰; rather, it binds to specific receptors on macrophages (particularly in the liver and spleen) and is endocytosed and subsequently incorporated into ferritin.^{151, 152} Thus, lactoferrin transfers iron from its transferrin-bound, circulating state to a storage state, from which it cannot be rapidly mobilized.¹⁵³ One group of investigators found that reducing the available lactoferrin by inducing neutropenia in rats blunted the hypoferrmic response to IL-1,¹⁵⁴ but another group found that administration of recombinant IL-1-induced hypoferrmia in mice, even in the face of severe neutropenia.¹⁵⁵

In addition to decreased availability of iron, erythroid progenitors may also be unable to fully use the iron available to them. Erythroblasts from anemic patients with rheumatoid arthritis express fewer surface TfR than do erythroblasts from normal individuals. These TfR also exhibit lower binding affinity for transferrin.¹⁵⁶ Furthermore, acute-phase reactants, such as α_1 -antitrypsin, impair transferrin binding to erythroblasts and also inhibit transferrin internalization.¹⁵⁷ rhEpo appears to induce a greater level of TfR expression on erythroid cells.¹⁵⁸

Anemia in Patients with Cancer

Much of the anemia commonly observed in patients with cancer can be attributed to the mechanisms involved in ACD; however, certain processes unique to malignancy may also contribute. Erythroid precursors may be displaced from marrow by metastatic tumor,¹⁵⁹ tumor-induced fibrosis,¹⁶⁰ or tumor-associated marrow necrosis.¹⁶¹ The treatment of cancer can also produce or exacerbate anemia by a variety of mechanisms, including impaired Epo production¹⁶² and cytotoxic effects of therapy on erythroid progenitors.¹⁶³

Diagnosis

Studies suggest that diagnosis of anemia of moderate degree, as is commonly observed in ACD, is often missed.¹⁶⁴ ACD should be considered in anemic patients with associated inflammatory, infectious, or neoplastic states. As described in Table 41.1,⁹ not all cases are associated with a classic chronic disease, but virtually all cases are associated with states of cytokine or immune activation. This is likely the mechanism associated with the increasing number of reports of ACD in congestive heart failure.^{103, 165, 166, 167} The diagnosis is confirmed by demonstrating hypoferrmia with adequate reticuloendothelial iron stores in a patient with an appropriate clinical syndrome. Typically, the serum transferrin is either low or low normal, and sTfR concentration is normal in ACD. The major differential diagnosis is iron deficiency anemia. This is not a trivial distinction. The diagnosis of iron deficiency mandates identification of a source of blood loss. Incorrectly labeling a patient with ACD as iron-deficient exposes that patient to intrusive and expensive (although fairly safe) diagnostic procedures and to ineffective therapy. Mislabeling an iron-deficient patient as having ACD may result in failure to diagnose an underlying gastrointestinal malignancy at a curable stage and in failure to offer inexpensive and effective therapy. The diagnosis of iron deficiency is discussed in detail in Chapter 23 and in the section "Abnormal Iron Metabolism." It has been suggested that a marker of inflammation or cytokine activation, such as C-reactive protein or IL-6 should be an element of the diagnosis of ACD.^{168, 169} This may not be necessary in cases of ACD associated with "classic" ACD-related disease, like rheumatoid arthritis, but may be helpful in ACD which are less typical, or perhaps complicated by iron deficiency.

In principle, absence of an elevated serum or plasma hepcidin concentration could rule out ACD. When hepcidin assays become available for routine use in a clinical context, it will be important to carry out well-designed studies to determine whether they will contribute more to diagnosis than currently available clinical markers of iron status.¹⁷⁰

Treatment

The focus of therapy should be on the underlying disorder. The anemia itself is rarely an important clinical problem. Thus, direct approaches to correction of the anemia are rarely necessary. Fewer than 30% of patients have anemia sufficiently severe to necessitate transfusion, and assessment of the symptomatic state should always be considered before administration of blood products.

rhEpo and the rhEpo analog darbepoetin, are effective in ACD but expensive,^{171, 172, 173} and many if not most third-party payers will not reimburse for its use in ACD. It is not currently approved for this purpose in the United States. Limitations on the use of rhEpo in anemic cancer patients for safety reasons (discussed below) limit the use of rhEpo in ACD at present. Because most patients were not symptomatic from their anemia, symptomatic benefit was rarely reported in the

initial studies.^{171, 172} Subsequent studies using more sophisticated evaluation instruments have reported increased quality of life in anemic patients with rheumatoid arthritis¹⁷⁴ or cancer¹⁷⁵ treated with Epo. It can also be used for ACD patients who wish to donate blood for autologous transfusion at elective surgery but are too anemic to do so¹⁷⁶ or to permit autologous blood donation by a patient with ACD and multiple alloantibodies.¹⁷⁷ It has been proposed that rhEpo administration may be of benefit in anemic patients with congestive heart failure.^{178, 179, 180, 181, 182}

It is debated whether or not to administer iron routinely to patients receiving therapy with Epo products. It is this author's practice to do so in the absence of elevated serum ferritin levels. In one study of anemic patients with rheumatoid arthritis, the concurrent use of iron supplementation was a powerful predictor of response to Epo¹⁸³; however, many of the patients in this study may have been iron-deficient. Although there are reports of correction of ACD by intravenous iron without Epo,^{40, 184} normalization of hemoglobin was largely seen in patients who were also iron-deficient.⁴⁰ Iron therapy by itself is likely to be useful only in patients who have concurrent iron deficiency,¹⁰ and then only for the component of anemia caused by iron deficiency. There is no convincing evidence that iron alone corrects ACD per se. Anemic cancer patients treated with concurrent intravenous iron and rhEpo appear to have a better response than those treated with no iron supplementation or with iron supplementation alone.¹⁸⁵

Studies of the use of rhEpo in cancer patients have been associated with increased adverse outcomes in certain cases,^{186, 187, 188, 189, 190} leading to restrictions on circumstances in which rhEpo can be used in cancer therapy. While there is debate in the literature as to whether the observed outcomes reflected unique features of particular rhEpo regimens or of specific patient populations,^{191, 192, 193} the clinician is encouraged to review current guidelines prior to initiating therapy.

As noted earlier, Epo downregulates hepcidin production. Given the significant role of hepcidin in the pathogenesis of ACD, therapy directed against hepcidin would be attractive in principle. Antisense hepcidin has been reported to decrease anemia in an animal inflammation model.¹⁹⁴ At present, however, there are no specific antihepcidin agents available for clinical use.

P.1003

ANEMIA OF CHRONIC RENAL INSUFFICIENCY

Anemia is an almost invariable manifestation of chronic renal failure, often contributing substantially to the morbidity of the condition. It may be considered as typical of the disease as azotemia.¹⁹⁵ In the era before the availability of rhEpo, 98% of patients on hemodialysis were anemic¹⁹⁶; even now, 48% of renal failure patients before dialysis and 28% of hemodialysis patients have hematocrit values <0.30.^{197, 198} The term anemia of chronic renal insufficiency refers to that anemia resulting directly from failure of the endocrine and filtering functions of the kidney. The kidney is the major source of Epo, and the ability to secrete this hormone is lost as the kidney fails. In addition, renal failure is associated with other pathologic processes, including some that may inhibit erythropoiesis and others that may shorten erythrocyte survival. Lack of sufficient Epo is by far the most important of these anemia-causing factors; consequently, the hypoproliferative features of the anemia tend to predominate.¹⁹⁹

In clinical settings associated with chronic renal failure, additional factors may also contribute to the development of anemia, but these should be considered complications rather than fundamental components of the anemia of renal insufficiency itself. In the presence of infection or inflammation, ACD is likely to be observed. Iron deficiency anemia (see Chapter 23) may develop because of blood loss from the gastrointestinal tract or (less frequently) hematuria or from retention of blood in the hemodialysis apparatus tubing.^{199, 200} The megaloblastic anemia of folate deficiency also may occur in patients on dialysis^{201, 202} but is otherwise uncommon.²⁰³ Certain types of renal disease, including the hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura, are associated with microangiopathic hemolytic anemia (see Chapter 48). Finally, aluminum intoxication can cause microcytic anemia in dialysis patients, although this has become rare in modern dialysis practice.²⁰⁴

Clinical Description

Chronic renal failure occurs during the final stages of several renal diseases. As a rule, the nature of the underlying disease bears little relation to the degree of anemia, although anemia may be less severe in patients with hypertensive renal disease²⁰⁵ and is considerably less severe in patients with polycystic disease.^{206, 207} In one series, the mean hematocrit in 12 subjects with polycystic disease was 0.297, compared with 0.212 in 24 subjects with other types of chronic renal failure.²⁰⁷ Apparently, the Epo-secreting function of the kidney is preserved in polycystic disease—even when the filtering

function is lost.^{207, 208} Erythropoietic activity can be found in the cystic fluid and may arise from single interstitial cells juxtaposed to proximal tubular cysts.²⁰⁷

In most instances, the patient seeks medical attention because of symptoms related to the underlying renal disease, and anemia is an incidental finding. Occasionally, however, the renal symptoms are so subtle and so slowly progressive that the patient cites only symptoms of pallor, exertional dyspnea, or other signs of the cardiovascular adjustment to anemia. The severity of the anemia bears a rough relationship to the degree of renal insufficiency. Anemia is not routinely observed until the creatinine clearance falls to <45 ml/minute/ 1.73 m² body surface area, which corresponds roughly to a serum creatinine of 2.0 to 2.5 mg/ml in an average-sized adult.²⁰⁹ At creatinine clearance rates below that, a statistically significant correlation between creatinine clearance and hematocrit has been reported.^{210, 211} However, the variation in the results of these studies is so great that one cannot reliably predict the hemoglobin level in an individual patient on the basis of renal function.

Laboratory Findings

Anemia tends to become more severe as renal failure worsens, but in most patients the hematocrit ultimately stabilizes between 0.15 and 0.30.² Because regulation of body water and electrolyte balance is impaired in renal disease, the apparent degree of anemia may be exaggerated or minimized by alterations in plasma volume.

The erythrocytes usually are normocytic and normochromic, but slight macrocytosis is occasionally observed.²¹² The majority of red cells appear normal on blood smears. Occasionally, however, "burr" cells (Fig. 41.3) are observed along with some triangular, helmet-shaped, or fragmented cells. The reticulocyte count often is within normal limits,²¹³ but it may be moderately increased.^{212, 214} In one study, the numbers of reticulocytes were normal when the blood urea nitrogen (BUN) value was <130 mg/dl; at higher BUN levels, however, their number often was increased.²¹⁵ The highest values (average, 6%) were observed with extreme azotemia (BUN, 300 to 350 mg/dl).

The leukocyte count typically is normal, but slight neutrophilic leukocytosis may be observed. In one series, the leukocyte count averaged 10.7×10^9 /L.²¹³ The platelet count is either normal or slightly increased,²¹³ but platelet function may be severely impaired, resulting in defective hemostasis (see Chapter 52).

The bone marrow tends to be moderately hypercellular, and slight erythroid hyperplasia may be observed. The myeloid-to-erythroid ratio averaged 2.5:1.0 in one study.²¹³ Erythroid maturation appears morphologically normal. In some instances, especially when renal failure is relatively acute, hypoplasia of erythroid elements is noted.^{216, 217} In a study of 100 predialysis renal failure patients with hemoglobin concentrations less than 11 g/dl and not treated with rhEpo, 48% of patients had no detectable bone marrow iron.²¹⁸

The serum bilirubin level was within normal limits in all of the 26 patients in one series.²⁰⁸ The hemolytic index, a measure of urobilinogen excretion in relation to total circulating hemoglobin, was increased in ~40% of patients evaluated.^{212, 219}

Values for serum iron vary considerably in renal disease.^{212, 219} As a rule, the value is normal when renal impairment is mild. With more severe disease, some investigators observe a decrease in serum iron levels,²²⁰ whereas others note hyperferremia.^{220, 221} Whether a characteristic disturbance of serum iron concentration is associated with "uncomplicated" renal failure remains to be determined. One group of investigators has reported that the gastrointestinal absorption of iron is reduced in patients with chronic renal failure.²²² Other researchers, using a different method, found that iron absorption was related to disturbances in iron balance and was unrelated to the degree of anemia, the rate of erythropoiesis, or the degree of azotemia.²²³ FEP may be normal or moderately increased,²¹² but the increased values seem to occur only in patients with hypoferremia.²²⁴ The erythrocyte lactate dehydrogenase level is within normal limits.²²⁵ Serum hepcidin levels in dialysis patients appear to track with iron status, and to be low in the iron-deficient.²²⁶ At any given level of iron stores, higher hepcidin levels appear to predict anemia progression.²²⁷

P.1004

The glycosylated fraction (A_1) of hemoglobin (the best-known component of which is hemoglobin A_{1c}) tends to increase in chronic renal failure. In uremic patients who have not undergone dialysis, the hemoglobin A_1 value averaged 10.8% of the total hemoglobin, compared with 7.1% in nonuremic individuals.²²⁸ In uremic patients treated with dialysis, the value averaged 8.8%. The increase is thought to result from carbamylation of the hemoglobin molecule by urea-derived cyanate; it can be detected by using column chromatography but not by using certain chemical methods designed for hemoglobin A_{1c} . The magnitude of the increase usually correlates with the average value for BUN over the preceding 2 to 3 months. The increase in the A_1 fraction may continue after successful renal transplantation has brought the azotemia under control; in this case, the increase might reflect disturbed carbohydrate metabolism²²⁹ and probably reflects hemoglobin A_{1c} .

Pathogenesis

It has been known for many years that three factors are involved in the pathogenesis of anemia of chronic renal failure. These factors are Epo deficiency, suppression of marrow erythropoiesis, and shortened red cell survival.^{230, 231, 232} When anemia is severe, ferrokinetic studies typically demonstrate that the plasma iron transport rate is normal, but red cell iron utilization and erythrocyte iron turnover are decreased.^{199, 212} With milder degrees of anemia, ferrokinetic measurements tend to be near normal. In anemic patients, however, such "normal" values indicate an insufficient marrow response to the stimulus of anemia. The success of recombinant Epo in the treatment of anemia of renal failure has caused the other two factors to receive short shrift in recent years.

As renal function deteriorates, renal Epo secretion decreases.^{232, 233} Measured Epo values may be lower than normal, higher than normal, or normal.^{210, 232, 233, 234} However, it is important to remember that even the "increased" Epo concentrations observed in this syndrome are still strikingly low for the degree of anemia.²³⁵ Overall, the usual relationship between Epo and hemoglobin concentrations is lost, indicating a loss of customary feedback mechanisms.²¹¹ Some capacity to induce Epo secretion is preserved, however, because even the very low levels of Epo secretion in renal disease change in response to hemorrhage or transfusion.²³¹ Certain extrarenal sources of erythropoietic hormone account for some of the activity found in serum, especially that found in anephric subjects.^{235, 236} This extrarenal Epo secretion does not, however, appear to increase sufficiently in response to anemia to compensate for deficiencies at the renal source.²³⁷ Elegant studies in sheep²³⁸ and subsequent confirmatory studies in human patients^{239, 240} have established the primacy of Epo deficiency in the pathogenesis of anemia of chronic renal failure.

There is also a significant body of data suggesting that the inadequate marrow response to anemia is not due solely to Epo deficiency. The observation that the rate of erythropoiesis improved in patients treated with dialysis even though Epo levels were unchanged^{214, 241} suggested that retained uremic toxins depress erythropoiesis directly. This field of research has been quite confusing, because not all investigators have been able to confirm the presence of inhibitors or to demonstrate their specificity. Several groups of investigators have shown that plasma from uremic patients can depress heme synthesis,²⁴² or inhibit growth of erythroid colonies in vitro, or both.^{243, 244, 245, 246} The polyamine spermine and

other molecules that accumulate in renal failure have been proposed as candidates.^{244, 245, 247, 248, 249} Inhibitors of multipotential stem cell (colony-forming unit granulocyteerythroid-macrophage-megakaryocyte) growth have also been detected in uremic plasma,²⁵⁰ but they are of uncertain pathophysiologic importance.²⁴⁴ Parathyroid hormone, associated with secondary hyperparathyroidism in renal failure patients, may also contribute to marrow suppression.²⁵¹ The hematocrit increases in approximately one half of the patients with renal failure who undergo parathyroidectomy, although only to a modest degree.^{252, 253, 254} Some, but not all, investigators suggest that levels of parathyroid hormone similar to those found in the serum of uremic patients depress the growth of erythroid colonies in vitro.^{251, 255, 256, 257} Hyperparathyroidism may also exert its effects by causing marrow fibrosis.^{252, 254}

Allen and colleagues have demonstrated that inhibition of erythroid colony formation by uremic serum can be abrogated by neutralizing antibodies to TNF and interferon- γ .¹² These data suggest that cytokine-mediated anemia mechanisms typically associated with ACD may be active in renal failure.²⁵⁸ It is also possible that the excellent response of anemia of renal failure to Epo does not indicate a lack of contributing inhibitors but rather reflects the ability of Epo to overcome an inhibitor, as has been reported for interferon- γ .¹³³

A third pathogenetic factor is hemolysis. Erythrocyte survival, although often within normal limits, may be slightly to moderately reduced.²⁵⁹ Depending on the evaluation technique used, 20% to 70% of uremic patients show shortened red cell survival.^{195, 212, 214, 220} The extent to which red cell survival is decreased is somewhat related to the degree of azotemia.¹⁹⁹ Cross-transfusion studies suggest that the hemolytic factor, when present, is extracorporeal. Survival of normal cells transfused into patients is shortened, whereas patients' cells survive normally in normal recipients.^{195, 212, 220} Less commonly, shortened survival of uremic patients' cells is observed even in normal subjects.²²⁰ In some patients, splenic sequestration of red cells may be a contributory factor.²⁶⁰

The hemolytic factor(s) is presumed to be a toxic substance (or substances) normally excreted or metabolized by the kidney. Guanidine and its derivatives appear to be a subset of the many retained metabolites that adversely affect erythrocyte survival.^{12, 261} The hypothetical factor(s) is apparently not dialyzable.²³⁰ Peroxidation of membrane lipids by free radicals may also contribute to the shortened survival observed.²⁶²

In ~20% of uremic patients not treated with dialysis, the red cell pentose phosphate pathway is impaired as a result of a poorly defined substance in the plasma.^{263, 264} This defect is best detected by using the ascorbate-cyanide test; other tests of pentose phosphate pathway function may yield normal results.²⁶⁵ Administration of glutathione returns the ascorbate-cyanide test to normal.²⁶² Oxidant drugs, such as primaquine or sulfonamides, produce a Heinz body hemolytic anemia in patients with the pentose phosphate pathway defect. Even in the absence of drug exposure, Heinz bodies may be observed in the red cells of uremic patients if they have undergone splenectomy.²⁶⁶ Contamination of dialysate water by chloramines, which inhibit phosphoglyceromutase and thus cause accumulation of glycolytic intermediates, may worsen this defect.^{267, 268} Decreased oxidative stress may also contribute to the observed lower frequency of anemia in patients undergoing peritoneal dialysis compared to those on hemodialysis.²⁶⁹ In one study, use of the antioxidant N-acetylcysteine was associated with improved hematocrit.²⁷⁰

Cation transport may be impaired in uremic red cells: The defect reverts toward normal after dialysis.^{271, 272} When sensitive measures are used, nearly all patients can be shown to have such an abnormality²⁷²; in those most severely affected, the erythrocyte sodium concentration is increased.²⁷¹ Considerable disagreement surrounds the nature of the defect, with various investigators reporting abnormalities in cation pump site number or function^{271, 272} and others reporting the presence (or absence) of soluble, dialyzable inhibitors of pump function.^{273, 274, 275}

Evidence of impaired erythrocyte glycolysis has been found in uremic patients²⁷⁶; however, in most studies, the overall glycolytic rate is increased,^{277, 278} probably because of the elevation in plasma levels of inorganic phosphorus.²⁷⁷ The increase in the glycolytic rate probably accounts for the observed increase in red cell

P.1005

adenosine triphosphate levels.^{277, 279} Hemoglobin oxygen affinity is reduced,²⁸⁰ presumably because of increased erythrocyte adenosine triphosphate and 2,3-DPG levels. Such abnormalities would not be expected to cause reduced red cell survival.

Neocytolysis, the selective hemolysis of newly formed red cells, has been reported after Epo withdrawal in dialysis patients and may contribute to shortened red cell survival in dialysis patients.²⁸¹

Management and Course

Recombinant Human Erythropoietin

rhEpo has been available for treatment of anemia of renal disease since the mid 1980s^{240, 282} and has revolutionized the approach to this disorder. Therapy with this agent or rhEpo analogs such as darbepoetin,²⁸³ is safe and effective, and has been reported to improve quality of life and cognitive function.^{284, 285} It is the treatment of choice for anemia in renal insufficiency, being effective in patients receiving peritoneal or hemodialysis.²⁸⁶ It is equally efficacious in anemia due to renal insufficiency that is not sufficiently advanced to require dialysis, but in which the creatinine clearance is <45 ml/minute/1.73 m² body surface area or the serum creatinine is >2.5 mg/ml.^{210, 232, 287, 288}

Epo can be administered intravenously or subcutaneously. Although Epo was originally given three times weekly (to coincide with dialysis schedules), single weekly or less frequent dosing schedules are similarly efficacious if the dose is increased appropriately.²⁸⁹ A standard starting dose would be 100 to 150 U/kg/week or its equivalent. Higher doses generally result in faster correction of anemia; target hemoglobin is typically attained within 6 to 8 weeks.^{287, 290} Iron supplementation is generally necessary, particularly in patients on hemodialysis. The target hemoglobin range is to be no higher than 11 to 12 g/dl; some reports suggest that higher levels may have an adverse clinical impact.²⁹¹ The long-acting Epo analog darbepoetin (novel erythropoiesis-stimulating protein) appears to be safe and effective in the anemia of renal failure.^{290, 291, 292, 293} The recommended starting dose is 0.45 µg/kg/week for patients on dialysis, and 0.45 µg/kg/ 4 weeks for patients before dialysis.

Continuous Epo receptor activator is a new peptide agent which is not an Epo analog but which activates the Epo receptor. Its role in the management of the anemia of renal failure is under study.²⁹⁴

Side Effects/Adverse Reactions

As noted earlier, rhEpo products are generally safe but complications may occur. When used for anemia in renal disease, increased blood pressure is an important complication, experienced by up to 35% of patients.^{295, 296} Rarely, the hypertension is abrupt and severe with encephalopathy and seizures.²⁹⁷

The occurrence of hypertension appears to be more closely related to the rate of increase in the blood hemoglobin level than the dose of rhEpo.²⁹⁸ It tends to be a transient phenomenon confined to the first 3 to 6 months of treatment. The pathogenesis is incompletely understood and probably multifactorial.²⁹⁸ Because heart rate, stroke volume, and cardiac output decrease as anemia is corrected, an increase in peripheral vascular resistance may be responsible. Daytime vasoconstriction may be a consequence of reduced plasma volume.²⁹⁵ Left ventricular hypertrophy, an important predictor of cardiac morbidity and mortality in renal patients, tends to decrease by ~18% within a year of correction of anemia; this beneficial effect may be diminished by hypertension.²⁹⁶ However, Epo can also contribute to hypertension through vasopressor effects, often mediated by nitric oxide, which appear most active in renal insufficiency.^{299, 300, 301}

In early studies, prolonged or less effective dialysis^{302, 303} and increased thrombotic events were thought to be problems associated with Epo treatment, but these concerns were not borne out in a large study.²⁸⁶ Anaphylaxis in response to Epo has been described but is extremely rare³⁰⁴.

Erythropoietin Resistance

As mentioned earlier, more than one-fourth of hemodialysis patients have a hematocrit <0.30. The failure of patients to respond optimally to Epo therapy or a requirement for unusually high doses is referred to as Epo resistance. The possible causes of Epo resistance are listed in Table 41.2.

Iron deficiency is the most common cause.^{305, 306} Loss of blood in the dialysis apparatus is an important source of iron depletion.³⁰⁷ Most patients require iron supplementation at some time during their course.³⁰⁸ In general, those with serum ferritin levels <100 to 200 µg/L or with transferrin saturation values <20% to 25%^{309, 310, 311} require iron supplementation, but such values may not appear until resistance to rhEpo becomes apparent. In another study, patients with serum ferritin values between 100 and 400 ng/ml were as likely to respond to iron replacement as those with serum ferritin <100 ng/ml.³¹² Other investigators found that a low MCV, but not a low serum ferritin, predicted response to iron replacement.³¹³ The best early predictors of Epo response are serum sTfR concentration and serum fibrinogen.³¹⁴

Response rate approaches 100% when both are low and 29% when both are high, reflecting both the patient's iron status and the presence or absence of inflammation. Some authors recommend routine oral iron supplementation for all patients. However, oral iron administration can be limited by intolerance, so that compliance is relatively poor.³⁰⁸ Efficacy may also be limited. Consequently, intravenous iron replacement is recommended for dialysis patients.^{315, 316, 317} Studies comparing oral versus intravenous iron supplementation generally find that the intravenous replacement group achieves higher hemoglobin levels with lower Epo use.^{313, 318} In order to avoid iron overload, intravenous iron replacement is discontinued or decreased when the ferritin exceeds 500 ng/ml.³¹⁹

Inadequate hemodialysis is associated with Epo resistance.³²⁰ As a general rule, the intensity of dialysis must be sufficient to reduce the BUN by 65% or more to ensure optimal Epo response. Such factors as the frequency and duration of dialysis and characteristics of the dialyzer may need to be adjusted to achieve this goal.^{321, 322} Mortality is also reduced by attention to dialysis

P.1006

intensity. Rates of reimbursement for dialysis in the United States have discouraged optimal intensity, with the result that mortality is higher there than in Western Europe and Japan.

TABLE 41.2 CAUSES OF ERYTHROPOIETIN RESISTANCE

Iron deficiency

Blood loss (in dialysis apparatus, gastrointestinal, genitourinary)

Insufficient iron supplementation

Concurrent cytokine activation

Infection

Inflammation

Neoplasm

Insufficient dialysis intensity

Aluminum toxicity

Secondary hyperparathyroidism

Folate deficiency

Angiotensin-converting enzyme inhibitors

Renal allograft failure

Antierythropoietin antibody-mediated resistance

Pure red cell aplasia

Other

Splenomegaly

As discussed earlier, secondary hyperparathyroidism often accompanies renal failure, and the associated marrow fibrosis may contribute to the anemia^{251, 252, 254} and to Epo resistance. Treatment with vitamin D₃ can decrease rhEpo requirements and improve hemoglobin values.³²³ Aluminum toxicity is an uncommon cause of anemia and responds to chelation therapy.³²⁴

If Epo resistance is associated with an increased MCV, folate supplementation is warranted.²⁰¹ Serum folate levels may not be helpful in this situation. In some cases, iron replacement may unmask folate deficiency in dialysis patients.³¹³

Associated infections or inflammatory states, as in ACD, may provoke cytokine-mediated anemia mechanisms. In addition, there are a number of minor etiologies of Epo resistance. The use of angiotensin-converting enzyme inhibitors in renal failure patients (particularly those undergoing transplantation) may exacerbate Epo resistance.^{325, 326} Splenomegaly may create a requirement for higher Epo dosing: This is resolved by splenectomy.²⁶⁰ Infrequent cases of Epo resistance due to anti-Epo antibodies, including production of pure red cell aplasia, have been reported.^{327, 328, 329} It appears to be a result of packaging and delivery characteristics of particular Epo products (especially in Western Europe and Canada), rather than a reaction to Epo itself. This topic is discussed at length in Chapter 39.

Renal Replacement Therapy

Renal replacement approaches (transplantation and dialysis) aim to restore or substitute for lost renal function. As such, they may have some effects on anemia associated with renal failure.

Renal Transplantation

In many ways, renal transplantation is the most complete and satisfactory treatment for renal insufficiency. With a successful graft, the hematologic response is often striking. Anemia is usually corrected over an 8- to 10-week period.^{330, 331, 332} For the most part, the improvement results from Epo secretion by the grafted kidney. Two peaks of Epo secretion have been documented: an early peak, in which serum Epo levels increase approximately ninefold and then return to normal after ~7 days; and a second, smaller, more sustained increase in Epo levels, which begins on approximately day 8 and is accompanied by reticulocytosis and a gradual increase in hemoglobin levels. Epo values return to normal when the hematocrit reaches 0.32. The early peak is seen only in patients with delayed graft function and is not associated with hematologic improvement.^{330, 332} The second peak is associated with recovery of the graft excretory function and is presumed to be the important factor in the hematologic response.

Approximately 80% of patients experience an increase in blood hemoglobin concentration after renal allograft.³³¹ Failure to respond usually can be explained on the basis of hemorrhage, vigorous immunosuppression, or graft rejection. The rejection phenomenon often is accompanied transiently by increased Epo levels,^{333, 334} but this is followed by a profound reduction in Epo levels and reticulocyte counts.³³⁵ Improvement in erythropoiesis occurs earlier when cyclosporine is used for immunosuppression rather than with antilymphocyte globulin. With the latter, the reticulocyte peak is delayed ~2 days. Cyclosporine immunosuppression, however, may be associated with slower correction of the anemia.³³⁵ In ~20% of transplant patients, erythrocytosis follows correction of the anemia.³³⁰ This complication is discussed in Chapter 48 and can sometimes be avoided by pretransplant use of Epo.³³⁵

Dialysis

Most patients with end-stage renal disease are maintained on dialysis. As a modality for managing anemia, dialysis has been essentially eclipsed by the availability of Epo and is primarily of interest because the mild increment observed in hemoglobin concentration provides circumstantial evidence for the role of circulating inhibitors. Red cell production increases slightly in patients on hemodialysis, with attendant small increases in hematocrit and decreases in transfusion requirement.³³⁶

As a general rule, anemia is less severe in patients receiving peritoneal dialysis, with consequently lower Epo and transfusion requirements.^{337, 338, 339, 340, 341, 342} Increments in hemoglobin in the absence of Epo are gradual and of modest extent: They are accompanied by an increase in red cell mass and a reduction in plasma volume.³⁴⁰ The reasons for the beneficial effects of peritoneal dialysis on erythropoiesis are not firmly established. An increase in Epo production has been reported,³³⁹ whereas other data suggest that removal of inhibitors in the "middle molecule" range (500 to 1,500 daltons) is the important mechanism.³⁴³ Induction of a lower degree of red cell oxidative stress by peritoneal dialysis compared to hemodialysis has been suggested as an alternative explanation.²⁶⁹

In the Epo era, the importance of other treatments for anemia of renal disease, such as androgens, has become of primarily historical interest. Blood transfusion support may still be required for patients who fail to respond to rEpo products. The risks of bloodborne infections and of iron overload are significantly increased by the use of transfusion.³³⁶

ANEMIA IN CIRRHOSIS AND OTHER LIVER DISEASES

Some degree of anemia is commonly observed in patients with liver disease. Although it has been studied most extensively in patients with alcohol-induced cirrhosis (Laennec cirrhosis), changes in red cell morphology and other contributors to anemia have been observed in various other liver diseases, including biliary cirrhosis,³⁴⁴ hemochromatosis,⁹⁶ postnecrotic cirrhosis, and acute hepatitis.³⁴⁵ When the term anemia of liver disease is used, it refers to the mild to moderate anemia associated with liver disease in the absence of any complicating factors such as blood loss, marrow suppression by exogenous agents, or nutritional deficiency. This syndrome apparently results from a combination of intravascular dilution due to volume overload, shortened red cell survival, and impaired ability of the marrow to respond optimally to the anemia. In addition, some patients develop a severe hemolytic anemia associated with morphologically abnormal erythrocytes (spur cells). Hemolytic anemia associated with Wilson disease is discussed in Chapter 32.

The anemia actually observed in patients with liver disease reflects both the "uncomplicated" anemia discussed above and the consequences of factors extrinsic to the liver itself. Alcohol abusers can develop a characteristic sideroblastic anemia, often accompanied by impaired folate metabolism or overt folate deficiency (see Chapter 36), or may have direct suppression of hematopoiesis by alcohol.³⁴⁶ Individuals with cirrhosis of any etiology are at increased risk for hemorrhage. Blood loss occurs in 24% to 70% of patients with alcoholic cirrhosis.⁹⁶ The upper gastrointestinal tract is the major site of bleeding, but loss of blood from the nose, hemorrhoids, and uterus often occurs in association with coagulopathy of hepatic origins.

Prevalence and Clinical Manifestations

Approximately 75% of patients with chronic liver disease develop anemia as defined by a reduction in the hematocrit or hemoglobin level.^{95, 96, 347} The whole blood volume in liver disease (especially cirrhosis) averages 10% to 15% greater than normal but may be as much as 30% to 35% increased; thus, hemodilution tends to exaggerate the prevalence and degree of anemia.^{95, 96, 347, 348}

P.1007

For the same reason, the hematocrit may be decreased despite a normal red cell mass. The majority of cirrhotic patients are described as anemic, but in only 30% to 40% is the red cell mass reduced.^{95, 348} Patients with more severe liver disease and bleeding tend to have reduced red cell mass.⁹⁶ The magnitude of the hypervolemia in cirrhosis appears to be related to the degree of portal hypertension, but not to the presence or absence of ascites (Table 41.3).

The anemia is usually mild to moderate. In cirrhotic patients, the hemoglobin level averages ~12 g/dl or the hematocrit ~0.36.^{96, 348} The hemoglobin level rarely falls below 10 g/dl in the absence of bleeding or severe hemolysis. Approximately 5% of liver disease patients, all of whom have relatively severe hepatocellular disease, develop spur cell hemolytic anemia and hemoglobin concentrations <10 g/dl.³⁴⁹ Spur cell anemia may be seen chronically with cirrhosis, or it may develop rapidly in association with fulminant hepatic failure. Morphologic and hemolytic abnormalities may resolve or diminish if liver function improves. Spur cell anemia can also occur in infants with cholestatic liver disease.³⁵⁰

Episodic hemolysis can occur in association with alcoholic liver disease even before cirrhosis.^{351, 352} These episodes are typically related to binge drinking, are usually mild to moderate in severity, and tend to resolve in 2 to 4 weeks if the patient abstains. Splenomegaly is not a major finding in these patients. When accompanied by jaundice and hyperlipidemia, the condition is known as Zieve syndrome.^{353, 354, 355} It is unclear whether this transient form of hemolysis in liver disease is a syndrome of discrete and characteristic pathogenesis or simply a coincident constellation of abnormalities to which patients with liver disease are prone independently. The clinical diagnosis of hemolysis in alcoholic liver disease is problematic in any event, because interruption of alcohol intake is frequently accompanied by reticulocytosis, and liver disease of any etiology may be associated with jaundice.

Hematologic Findings

More often than not, anemia of liver disease is mildly macrocytic: The MCV rarely exceeds 115 fl in the absence of megaloblastic changes in the bone marrow.^{95, 96} When macrocytosis (particularly with very elevated MCVs) is found in patients with liver disease, complicating folate deficiency or stimulated erythropoiesis must be suspected, but such findings may not explain the macrocytosis observed in patients with milder forms of the disease.³⁵⁶ The reported proportion of patients with liver disease who have increased MCV varies from 33% to 65%.^{96, 347, 357, 358, 359} Even more common is “thin” macrocytosis—an increase in mean cell diameter with a normal mean cell volume. In one study of 222 patients with various kinds of liver disease, the mean cell diameter was increased in 137 (62%).³⁵⁸ The patients were classified into three groups: thin macrocytosis (81 patients), target macrocytosis (39 patients), and thick macrocytosis (17 patients). The MCV was increased only in the last group. In a sense, thin macrocytes and target macrocytes are the mirror image of the microspherocytes observed in autoimmune hemolysis. The latter result from a decreased membrane pulled more tightly over a constant volume; the former result from a membrane that is more abundant.

TABLE 41.3 CHANGES IN BLOOD VOLUME IN PATIENTS WITH CIRRHOSIS

Measurement	Normal Subjects	Patients with Cirrhosis	
		Without Ascites	With Ascites
Hematocrit	0.42	0.35 (-17%)	0.34 (-19%)
Red cell mass (ml/kg)	23	20 (-13%)	19 (-17%)
Plasma volume (ml/kg)	42	57 (+35%)	55 (+31%)
Whole blood volume (ml/kg)	65	74 (+14%)	74 (+14%)

Values are means of 24 normal subjects, 63 patients with cirrhosis and no ascites, and 34 patients with cirrhosis and ascites. All groups included approximately twice as many men as women.

Data modified from Lieberman FL, Reynolds TB. Plasma volume in cirrhosis of the liver. *J Clin Invest* 1967;46:1297-1308.

The reticulocyte count often is increased, but this depends on the point in the natural history of disease at which it is measured. In one series, the mean reticulocyte percent of all anemic cirrhotic patients was only 2.8%.⁹⁵ However, erythropoiesis can be transiently suppressed by alcohol, and after acute alcohol withdrawal, reticulocyte percentages in the 8% to 10% range are not uncommon.^{346, 357, 360} Sustained reticulocytosis of 15% or more is unusual in the absence of hemorrhage, spur cell anemia, or other complicating conditions.

Target cells and cells with increased diameters are evident on blood smear (Fig. 41.4). The cells appear hypochromic, but the appearance is related to the thinness of the cell rather than to reduced hemoglobin concentration. These morphologic changes are accompanied by increased resistance to hemolysis in osmotic fragility tests.³⁵⁸ When spur cell hemolytic anemia supervenes, characteristic acanthocytes—erythrocytes covered with five to ten spike-like projections—are evident. The acanthocytes are morphologically indistinguishable from the distorted erythrocytes found in patients with abetalipoproteinemia. Stomatocytes are sometimes observed in association with the transient hemolytic episodes associated with acute fatty liver disease,³⁶¹ but they are also noted in alcoholics who display no evidence of hemolysis.³⁶²

Approximately 50% of patients with cirrhosis have mild thrombocytopenia, but values $<50 \times 10^9/L$ are uncommon.^{95, 347} A variety of leukocyte abnormalities may be observed; in a study of 25 patients, 16 had lymphopenia, 4 had neutropenia, and 12 had neutrophilia.³⁴⁷

Bone marrow cellularity is normal or increased.^{96, 347, 359} Often, erythroid hyperplasia is observed. Red cell precursors at times have been described as macronormoblasts, a term that implies their size is increased, but their nuclear chromatin appears normal.^{347, 359, 363} Frank megaloblastosis is seen in $<20\%$ of patients.

Pathogenesis

Shortened Erythrocyte Survival

Red cell survival is decreased in approximately two-thirds of patients with alcoholic liver disease. The precise extent to which this occurs varies depending on the technique used to measure survival, but it is usually of only moderate degree.^{95, 96, 345} Shorter survival tends to be observed in more anemic patients.

P.1008

When indirect bilirubinemia is observed in a liver disease patient (elevated total bilirubin with $>70\%$ indirect), erythrocyte survival is particularly likely to be reduced.³⁶⁴ Erythrocyte survival also was significantly shortened in patients with biliary cirrhosis,³⁴⁴ obstructive jaundice, and infectious hepatitis,^{345, 364} even in the absence of anemia.

FIGURE 41.4. Macrocytes and target cells in liver disease ($\times 1,500$).

The mechanism for the observed decrease in red cell lifespan is not fully understood; it is most probably multifactorial. Results of cross-transfusion studies demonstrate improved survival when patients' cells are transfused to normal recipients, suggesting that the hemolytic mechanism is extracorporeal (i.e., not intrinsic to the erythrocyte).³⁶⁵ Congestive splenomegaly and splenic sequestration are major suspects in this category,^{96, 351, 357, 366, 367} although they cannot always be demonstrated.⁹⁶ In some cases, correction of the hemolytic process may occur after splenectomy.

Abnormal erythrocyte metabolism is a possible intracorporeal factor leading to reduced erythrocyte survival in liver disease. Activity of the methylene blue-stimulated pentose phosphate shunt is decreased, with consequent glutathione instability and a tendency to form Heinz bodies.^{368, 369} This metabolic abnormality renders the cell sensitive to oxidant hemolysis, but whether this form of hemolysis is an important mechanism of shortened erythrocyte survival in liver disease is uncertain, because a comparable shunt defect in most patients with glucose 6-phosphate dehydrogenase deficiency does not lead to hemolysis unless oxidant drugs are encountered. However, oxidant drugs can produce hemolysis in liver disease, as when patients with hepatitis C are treated with ribavirin.³⁷⁰ Another metabolic abnormality encountered occasionally in liver disease is hypophosphatemia, with reduced erythrocyte adenosine triphosphate levels and consequent hemolysis.³⁷¹

Characteristic alterations in red cell membrane lipids are found in patients with hepatitis, cirrhosis, and obstructive jaundice and may also be another contributor to shortened red cell survival.^{351, 372, 373, 374, 375, 376, 377} In the usual uncomplicated case, a 25% to 50% increase in both cholesterol and lecithin is noted in the membrane. These changes result in an increased cell surface area associated with the target cells or thin macrocytes that are so characteristic of liver disease. The loss of sialic acid from the red cell surface may contribute to impaired viability of the cell.³⁷⁸ Bile duct obstruction leads to an increase in the activity of neuraminidases, enzymes that remove sialic acid. However, it is not proven that such abnormalities shorten red cell survival.³⁵¹

In spur cell hemolytic anemia, the erythrocyte membrane accumulates excess cholesterol without a corresponding increase in lecithin, resulting in the characteristic morphologic abnormality. This change is accompanied by pronounced reduction in erythrocyte survival, probably because the distorted cells are less deformable than normal and thus become trapped by splenic macrophages. Passage through the spleen causes loss of cell surface with transformation of echinocytes to acanthocytes,^{366, 375} but in fact, the spleen is not required for development of spur cells.^{379, 380} Splenectomy may ameliorate severe hemolysis.³⁶⁶ The mechanism whereby the red cell lipid pattern becomes altered is not well understood. One possible factor is an alteration in the cholesterol-to-phospholipid ratio in high-density plasma

lipoproteins, because mature erythrocytes are unable to synthesize lipids and depend largely on plasma lipids for replenishment.³⁸¹ In addition, the process of red cell phospholipid repair appears to be defective in spur cell anemia.^{382, 383} Phospholipid biosynthesis is inhibited and therefore cannot compensate for the increased membrane cholesterol characteristic of liver disease. Other potential contributors to altered erythrocyte membrane lipids in liver disease are changes in plasma lecithin-cholesterol acyltransferase activity, retention of lytic bile acids,³⁸² and an increase in the intrinsic proteolytic activity of the membrane.³⁸⁴

Zieve syndrome has been mentioned earlier. It has been proposed that the transient hemolytic anemia in this syndrome is caused by the lytic action of certain plasma lipids.³⁵⁴ However, hypertriglyceridemia by itself does not cause hemolysis^{353, 376, 377}; erythrocyte lipids in these patients are similar to those described in patients with only a modest hemolytic component³⁷⁷; and hemolytic anemia may occur in patients with acute fatty liver disease even if plasma triglyceride levels are not increased.³⁵² Alcohol-induced vitamin E deficiency with decreased polyunsaturated fatty acids in membrane lipids may play a role in some patients³⁵³; similar findings have been reported in vitamin E-deficient children.³⁸⁵

Erythropoiesis

In addition to the shortened erythrocyte survival, the marrow response to the anemia in patients with liver disease may be inadequate. Plasma iron turnover, red cell iron utilization, and erythrocyte iron turnover were normal or reduced in the majority of patients in one series, whereas these parameters were increased two- to threefold in another.^{96, 386} The presence or absence of complications may explain such discrepancies. Alcohol, in particular, depresses erythropoiesis, and if the patient is studied before the effects of alcohol ingestion subside, marrow function appears depressed.³⁶⁰

Serum from cirrhotic patients can suppress hematopoietic colony formation in vitro,³⁸⁷ and cytokines implicated in inhibition of erythropoiesis have been found to be increased in patients with liver disease.³⁸⁸ Dyserythropoiesis with morphologic abnormalities and intramedullary hemolysis has also been reported in severe liver disease.³⁸⁹ It has been suggested that extrarenal Epo by the liver is abnormal in patients with liver disease, but in fact, the expected inverse relationship between hemoglobin and Epo production has been found to be preserved in liver disease and to result in levels appropriate for the degree of anemia.^{66, 390}

ANEMIAS ASSOCIATED WITH ENDOCRINE DISORDERS

A mild to moderate anemia commonly accompanies disorders affecting the thyroid, adrenals, parathyroids, gonads, or pituitary. It is usually not associated with symptomatology (other than that associated with the underlying endocrinopathy) and in fact may reflect a physiologically appropriate hemoglobin concentration because the hormone deficiency often results in reduced oxygen requirements. The anemia is therefore "adaptive."³⁹¹ In consultative hematology practice, these individuals present as referrals for evaluation of moderate anemia with normal iron, B₁₂, and folate studies, generally with a question from the referring doctor of whether marrow examination is required. The endocrine disorder is typically undiagnosed at time of referral.

Hypothyroidism

Anemia is observed in 21% to 60% of hypothyroid patients and is more common in hypothyroid men than in hypothyroid women.³⁹² The frequency of anemia was 39% in patients with subclinical hypothyroidism, and 43% in patients with overt hypothyroidism in one series.³⁹³ The anemia observed may be normocytic and normochromic, hypochromic and microcytic, or macrocytic. The last category comprises roughly one-third of anemic patients in most reported series; the frequency of the other two morphologic types varies considerably in different reports (Table 41.4).^{391, 394, 395, 396, 397}

The uncomplicated anemia of hypothyroidism is either normocytic or slightly macrocytic, as is suggested by the predominance of these findings in most series.^{392, 395, 396} Hypochromic microcytic anemia found in association with hypothyroidism should

P.1009

be considered iron deficiency until proven otherwise.^{391, 392, 396} Biochemical markers of iron deficiency are present: The microcytic anemia responds (at least in part) to iron therapy, even if thyroid hormone is not administered, but does not typically respond to thyroid hormone without iron.³⁹² Iron deficiency in hypothyroidism may be normocytic, so an important step is to determine the serum iron, transferrin, and ferritin concentrations. Hypothyroid individuals are more likely to become iron-deficient because of predisposition to menorrhagia³⁹⁷ and achlorhydria³⁹⁶ and because thyroid hormone itself may be essential for normal iron absorption.³⁹¹ Severely macrocytic anemia usually results from complicating deficiency of vitamin B₁₂³⁹⁶ or folate.³⁹⁵

TABLE 41.4 INCIDENCE OF VARIOUS TYPES OF ANEMIA MORPHOLOGIES IN PATIENTS WITH MYXEDEMA

Type of Anemia	Reference 396 (%)	Reference 391 (%)
Normocytic, normochromic	4	13.5
Hypochromic, microcytic	14	4.5
Macrocytic	13	8
All anemias	31	26

When patients with iron, folate, or vitamin B₁₂ deficiency are excluded, the remaining individuals should be considered to have “uncomplicated anemia of hypothyroidism,” which is a manifestation of the hormone deficiency itself.^{395, 396} All or nearly all children with anemia and hypothyroidism have the uncomplicated form of the syndrome.³⁹⁸ Anemia usually affects children whose height is below the third-percentile. The anemia usually is mild, with the hematocrit rarely falling below 0.35. The plasma volume often is decreased, which tends to make the reduction in hematocrit less than might be expected for a given decrease in red cell mass.^{396, 399} The degree of anemia is related to both the severity and the duration of the hypothyroidism.⁴⁰⁰ The hematocrit declines for as long as 6 months after thyroidectomy in previously euthyroid subjects, even though the basal metabolic rate remains at a stable reduced level.

The MCV may be increased in hypothyroid patients, even in the absence of anemia (350). Anisocytosis, poikilocytosis, and other red cell morphologic abnormalities are uncommon, but acanthocytes are apparent in ~20% of patients.³⁹¹ Usually, the leukocyte and platelet counts are within the normal range, although both may be slightly reduced.⁴⁰⁰ The bone marrow may be mildly hypoplastic, but the myeloid-to-erythroid ratio is not significantly altered.^{401, 402} Hemoglobin A₂ levels are reduced slightly.⁴⁰³

Pathogenesis

The anemia of hypothyroidism results from decreased red cell production. Erythrocyte survival is normal or even slightly prolonged in humans,^{396, 404} but plasma iron transport and erythrocyte iron turnover rates are reduced, indicating subnormal red cell production.^{221, 404} As noted earlier, the anemia of hypothyroidism is considered “adaptive”—that is, a physiologic adjustment to the reduced needs of the organism for oxygen.³⁹¹ Epo secretion is reduced in hypothyroid patients,⁴⁰⁵ and 2,3-DPG levels are not increased⁴⁰⁶ as occurs in most anemic and hypoxic states. Thyroid hormones can enhance erythropoiesis in vitro and presumably in vivo as well.⁴⁰⁷ The observation that the noncalorigenic D-isomer of triiodothyronine can stimulate erythropoiesis without altering oxygen consumption has been cited as evidence of a hormonal effect that is not oxygen-dependent.⁴⁰⁸

The response of anemia of hypothyroidism to thyroid hormone is gradual. No striking reticulocytosis occurs, and the hematocrit returns to a normal value only gradually over approximately a 6-month period (range, 3 to 12 months).^{392, 396} The MCV almost always decreases, regardless of its initial value or the presence or degree of anemia, and stabilizes after 4 to 6 months or more.⁴⁰⁹

Hyperthyroidism

A mild anemia with no other apparent etiology occurs in 10% to 25% of patients with hyperthyroidism.^{410, 411} Anemia is primarily observed in individuals with severe or prolonged hyperthyroidism.⁴¹⁰ More typically, the hemoglobin value falls somewhat but remains within normal limits.⁴¹⁰ The anemia of hyperthyroidism is in many ways the mirror image of that observed in hypothyroidism. MCV is either normal or modestly decreased and, consistent with the comparison to hypothyroidism, may be decreased even in the absence of anemia.⁴¹⁰ Hemoglobin A₂ levels are slightly increased but not as much as in thalassemia.⁴⁰³ Both the anemia and the microcytosis are corrected when the hyperthyroidism is successfully treated; on average, the hemoglobin increases 0.5 g/dl, and the MCV increases 6 fl.

The pathogenesis of anemia and microcytosis of hyperthyroidism is not well understood. Plasma volume may be increased, suggesting dilution.³⁹⁹ Erythropoiesis usually is accelerated but ineffective.^{411, 412} Some (but not all) investigators report increased levels of erythrocyte 2,3-DPG.^{406, 413, 414, 415} Such a change would reduce oxygen affinity and improve oxygen delivery, thereby compensating for the reduced hemoglobin level. Increased plasma Epo levels have been reported⁴¹⁶—the opposite of what has been described for hypothyroidism.

Adrenal Insufficiency

Although anemia (in the sense of a decreased red cell mass) is common and probably nearly universal in adrenal insufficiency, it may be masked by the dehydration characteristic of this syndrome.^{417, 418} In a series of patients with

untreated Addison disease, the average blood hemoglobin level was 13.2 g/dl (range, 9.4 to 18.0 g/dl).⁴¹⁹ The red cells were normocytic and normochromic. After institution of hormone replacement, the average hemoglobin fell to 10.7 g/dl and the hematocrit from 0.42 to 0.33, presumably reflecting the expansion of plasma volume associated with clinical improvement. Later in the course of the disease, reticulocytosis and a return to normal hemoglobin levels occurred.⁴¹⁹ Pernicious anemia is observed in 3% to 16% of cases of nontuberculous adrenal insufficiency and may complicate 13% of adrenal insufficiency cases associated with the polyglandular autoimmune syndrome type I.^{420, 421}

Androgen Deficiency

After puberty, values for the hematocrit, blood hemoglobin concentration, and red cell count average ~10% to 13% higher in men than in women.⁴²² In castrated men, these values fall to within the normal female range.^{423, 424} This is almost certainly due to a difference in Epo production,⁴²⁵ although the relationship between hemoglobin and Epo concentration does not differ between the sexes. After the sixth decade, male hemoglobin values fall back toward those observed in women.^{422, 426} The anemia in these patients is corrected by androgen replacement.

The differences in red cell parameters between the sexes are accounted for chiefly by the stimulating effect of androgens on erythropoiesis. In addition, some observers suggest that estrogens exert a suppressive effect. Thus, castration of male rats precipitates a decrease in hemoglobin, whereas castration of female rats brings about an increase.^{427, 428} The administration of androgens to castrated males restores male values for hemoglobin concentration. Androgens can also stimulate erythropoiesis in normal subjects (see Chapter 44). In normal men, testosterone enanthate

P.1010

induced an average red cell mass increase of 1.7 to 2.3.⁴²⁹ The increase in hematocrit was of smaller magnitude (from 0.456 to 0.494), probably because the plasma volume also increased. Androgens act by increasing renal synthesis of Epo.^{430, 431} Estrogens produce anemia when given in large amounts to rats.^{432, 433} It has been suggested that this effect results from suppression of hepatic synthesis of Epo, but it may also simply represent opposition to androgen effects in general.

Hypopituitarism

Moderately severe anemia is a well-recognized feature of pituitary insufficiency, regardless of cause. In an extensive review of cases of Simmonds disease in the first half of the 20th century, the average blood hemoglobin concentration was ~10 g/dl, with similar values reported in patients with hypopituitarism that arose from neoplasms.^{434, 435, 436} Anemia is also evident in prepubertal pituitary dwarfs but tends to be underappreciated because of contracted plasma volume.^{437, 438} The anemia usually is normocytic and normochromic, and the red cells appear normal morphologically. In some patients, slight hypochromia or macrocytosis has been observed^{435, 439}; however, complicating deficiencies of iron or folate were not excluded. Results of kinetic studies demonstrate reduced red cell production.⁴³⁷

The anemia of hypopituitarism results chiefly from deficiencies of the hormones of target glands controlled by the pituitary, especially the thyroid and adrenal hormones, but also from a deficiency of androgens. In addition, lack of other pituitary factors, such as growth hormone,^{437, 440} prolactin,⁴⁴¹ or factors characterized less clearly,⁴⁴² may be of importance. The interrelations of these various hormones have been studied experimentally in animals, especially the rat. In this species, hypophysectomy results in a moderately severe, slightly hypochromic and microcytic anemia^{440, 443} associated with a pronounced decrease in erythroid elements in the bone marrow.⁴⁴⁴ No hemolysis has been reported. Combined adrenalectomy and thyroidectomy results in an anemia that is similar, but not identical, to that noted after hypophysectomy.^{440, 445}

As suggested for the anemia of hypothyroidism, panhypopituitarism probably produces its effects on erythropoiesis chiefly by reducing tissue oxygen consumption.⁴⁴⁰ The organism reacts to this decreased need for oxygen by secreting less Epo, and the red cell mass diminishes until a new equilibrium between oxygen supply and demand is established. This hypothesis is supported by the observations that (a) tissue oxygen consumption is low in the hypophysectomized rat, even if the red cell mass is restored to normal levels⁴⁴⁰; (b) once equilibrium is established, the marrow of the hypophysectomized animal responds to hypoxia, bleeding, or cobalt administration^{440, 446}; (c) correlation between oxygen consumption and rate of erythropoiesis is apparent in hypophysectomized animals given thyroxine or 2,4-dinitrophenol⁴⁴¹; and (d) erythrocyte 2,3-DPG levels, which increase when tissue oxygen delivery is compromised, are normal in patients with panhypopituitarism.⁴⁴⁷

Treatment with a combination of thyroxine, cortisone, and growth hormone corrects both the anemia and the marrow hypoplasia⁴⁴⁰ and is more effective than any single hormone by itself. In one reported case of panhypopituitarism

secondary to craniopharyngioma, anemia persisted and progressed despite replacement hormone therapy. Administration of rhEpo (6,000 IU/day) was followed by correction of the anemia, with the blood hemoglobin level rising from 6 g/dl to normal over a 3-month period.⁴⁴⁸

Hyperparathyroidism

Secondary hyperparathyroidism as a contributor to anemia of renal failure has been discussed earlier. Anemia is a rare complication of primary hyperparathyroidism.^{449, 450} At one institution, 17 of 332 patients (5.1%) with primary hyperparathyroidism were anemic, with hematocrit values ranging from 0.23 to 0.37.⁴⁵¹ None had leukopenia or thrombocytopenia. The anemia was normocytic and normochromic, and no reticulocytosis was evident. Five patients had bone marrow examinations. Four of these patients had 25% or more of their marrow replaced by fibrosis. Anemic patients appeared to have relatively severe hyperparathyroidism as judged by the presence of bone cysts, subperiosteal bone resorption, and particularly high values for serum calcium, alkaline phosphatase, and parathyroid hormone. The hematocrit increased in all seven patients who underwent parathyroidectomy; in six patients, it became normal.⁴⁵¹

The cause of the anemia in these patients remains obscure. Although renal failure and gastrointestinal bleeding occur in association with hyperparathyroidism, they could not be implicated as an etiologic factor in this group of anemic patients, nor was incidental iron deficiency evident. Some authors conclude that parathyroid hormone decreases proliferation of erythroid precursors in culture.²⁵¹ Marrow fibrosis may also be a result of excess hormone levels.^{252, 253} Myelofibrosis is a common finding in bone marrow biopsy specimens, but the usual morphologic signs of myelophthisis are lacking.⁴⁵⁰

When hyperparathyroidism is secondary to renal disease, it is difficult to ascertain the relative importance of the hormone excess versus the Epo deficit characteristic of renal failure as a contributor to the observed anemia. Of note, however, is that medical treatment of hyperparathyroidism with vitamin D₃ can bring about improvement in anemia and decreased requirement for Epo in some patients.³²³

Anorexia Nervosa

Anemia is observed in as many as 84% of patients with anorexia nervosa admitted to the hospital.^{452, 453, 454} A moderate degree of leukopenia or thrombocytopenia may also be observed. The peripheral blood smear shows a striking composite process, and bone marrow examination shows gelatinous transformation with necrosis, as well as decreased cellularity in most cases.^{453, 454, 455} These are essentially the findings observed in starvation, and they return to normal with improved nutrition.^{453, 454, 455} Hemolytic anemia has also been reported in anorexia nervosa.⁴⁵⁶ This was presumed to be a complication of hypophosphatemia (see Chapter 32).

Chapter 42

Anemias During Pregnancy and The Postpartum Period

Robert T. Means, Jr.

OVERVIEW/EPIDEMIOLOGY

By the second trimester of pregnancy, at least a mild degree of maternal anemia (defined as a hemoglobin concentration or hematocrit below the lower limit of normal for healthy adult females) is almost universal.¹ Significant anemia (defined as a hemoglobin concentration <10 g/dl) occurs with a prevalence ranging between 2% and 26%, depending upon the population studied.^{2, 3, 4} In all populations, but particularly in the less-developed countries of the world, anemia is a major contributor to maternal and fetal morbidity and mortality.^{2, 3, 4, 5, 6}

Anemia in pregnancy represents a combination of various potential etiologies. The common underlying mechanism, encountered routinely, is a consequence of the physiology of pregnancy itself (physiologic anemia of pregnancy). Superimposed on this can be deficiency of nutrients (typically in the context of a preexisting deficiency exacerbated by childbearing), hemolysis, or marrow failure syndromes. It should also be remembered that pregnant women remain susceptible to etiologies of anemia unrelated to their pregnancy.⁷ In some cases, such as sickle cell anemia, the underlying condition has major implications for the management of pregnancy.

MATERNAL ERYTHROPOIESIS

There is an increase in maternal erythropoiesis during the third trimester preceded by an increase in serum erythropoietin concentrations, presumably on the basis of reduced oxygen delivery to maternal renal tissues during the late second and early third trimesters.⁸ Similarly, serum erythropoietin concentrations are elevated in fetuses with anemia, and correlate with hypoxemia.⁹

The biology of erythropoietin and erythropoiesis in the fetus is discussed in Chapter 43. Erythropoietin is also present in human breast milk in concentrations of 10 to 20 mU/ml, essentially the same as in amniotic fluid.¹⁰ Erythropoietin concentrations in the mother's milk do not correlate with erythropoietin concentrations in her blood. In fact, over the first weeks of lactation, maternal serum erythropoietin concentrations fall, whereas milk erythropoietin concentrations increase, reaching the highest concentrations in women breast-feeding for a year or more. The source of erythropoietin in breast milk appears to be mammary gland epithelium. Erythropoietin in human breast milk, like that in amniotic fluid and colostrum, is relatively protected from proteolytic digestion in the fetal and neonatal gastrointestinal tract.¹⁰

PHYSIOLOGIC ANEMIA OF PREGNANCY

Expansion of the plasma volume is the cause of the physiologic anemia of pregnancy (Table 42.1). Expanding the plasma volume reduces the volume-dependent indicators of anemia (the hematocrit, the blood hemoglobin concentration, and the circulating erythrocyte count) but does not reduce the absolute amounts of hemoglobin or of erythrocytes in the circulation as a whole. The mechanisms underlying these changes are uncertain. It has been speculated that the physiologic anemia of pregnancy serves the purpose of reducing maternal blood viscosity, thereby enhancing placental perfusion and facilitating oxygen and nutrient delivery to the fetus. Beginning in approximately the sixth week of pregnancy, the plasma volume increases disproportionately to the red cell mass. Plasma volume generally reaches a maximum value at approximately 24 weeks' gestation¹¹ but may continue increasing as late as the 37th week.¹² At its peak, the plasma volume is about 40% higher among pregnant women than among nonpregnant women.^{13, 14} The reduction in the hematocrit, hemoglobin concentration, and circulating erythrocyte count generally occurs by the seventh to eighth week of pregnancy,^{11, 14} and continues until a new equilibrium is reached at the 16th to 22nd week.^{13, 15} As a result of this new physiologic equilibrium, it has been suggested that a hemoglobin concentration <11 g/dl in the late first trimester and <10 g/dl in the second and third trimesters are the lower limits below which a cause other than the physiologic anemia of pregnancy should be sought.¹⁶ In patients with β -thalassemia trait who have only modest anemia at baseline, hemoglobin concentration may drop significantly after the first trimester of pregnancy.¹⁷

During pregnancy, a 15% to 25% increase in the red cell mass generally occurs but is concealed by the dilutional effect of the increase in plasma volume.^{12, 13} A greater increase in red cell mass occurs if the mother takes iron supplements.¹ Ferrokinetic studies demonstrate accelerated erythropoiesis during pregnancy, supporting the concept of an increase in red cell mass.^{18, 19} Choi and Pai investigated erythropoiesis during pregnancy among 342 women by examining reticulocyte subpopulations using flow cytometry and also by measuring serum transferrin receptor concentrations. They found no differences between prepregnancy and those during the first and second trimesters. However, during the third trimester of pregnancy, reticulocyte maturity index and serum transferrin receptor concentrations increased twofold. After delivery these values decreased, falling to nonpregnant values about 5 weeks after delivery. They concluded that maternal erythropoiesis increases late in gestation and returns to normal by about 1 month after delivery.²⁰

Maternal plasma volume generally decreases during the final weeks of pregnancy, and consequently the hematocrit, hemoglobin, and circulating erythrocyte count increase.^{21, 22} However, studies of maternal blood volume in late pregnancy yield conflicting results depending on whether the patient is supine or in the decubitus position, and the effects of the gravid uterus

P.1013

compressing blood vessels are an additional source of variation. As a result, the results observed may represent only variations within the error of measurement or random occurrences.^{13, 21, 23} The maternal blood volume generally returns to prepregnancy levels within 1 to 3 weeks after delivery, in part reflecting blood loss at delivery.^{19, 24, 25}

TABLE 42.1 FEATURES OF THE PHYSIOLOGIC ANEMIA OF PREGNANCY

Plasma volume begins to increase during the sixth week of pregnancy.

There is no significant increase in erythrocyte production during the first trimester.

Dilutional anemia is first apparent by the seventh to eighth week.

Increase in erythrocyte production is apparent during the second trimester.

Lowest hemoglobin explainable by dilutional effect (the physiologic anemia of pregnancy) is 11 g/dl in the first trimester and 10 g/dl in the second and third trimesters.

Physiologic anemia of pregnancy is normochromic, is normocytic, does not worsen during the third

trimester, and does not require additional evaluation or specific treatment.

IRON DEFICIENCY DURING PREGNANCY

The physiologic anemia of pregnancy is normochromic and normocytic. Therefore, if a pregnant woman has a microcytic hypochromic anemia, nonphysiologic causes must be considered. Iron deficiency is common in women of childbearing age and is certainly the most common cause of nonphysiologic anemia during pregnancy.¹ It is particularly common in economically and socially disadvantaged populations.^{26, 27} The prevalence of iron deficiency ranges from 16% to 55% in pregnant women during the third trimester. This partially reflects utilization of iron by the fetus, and partially reflects pre-existing iron deficiency.^{1, 26, 28} In a Cochrane review, Milman et al. observed that among fertile women, 20% have presumed iron reserves of >500 mg (defined as a serum ferritin concentration >70 µg/L), which is stated as the required minimum during pregnancy; 40% have iron stores of 100 to 500 mg (defined by a serum ferritin concentration 30 to 70 µg/L), and 40% have undetectable iron stores (serum ferritin <30 µg/L).²⁹ The fetus is a privileged recipient of the nutrients required for hemoglobin synthesis. Thus, the hemoglobin concentration of infants born to mothers who have severe iron deficiency anemia is normal, and the serum iron, transferrin saturation, and serum ferritin levels are unrelated to maternal iron status.^{30, 31, 32}

In a study by De Leeuw et al., 84% of women not supplemented with oral iron lacked stainable iron in bone marrow aspirates after delivery at term, whereas 81.5% of women treated with iron had stainable iron present at term.¹ The demand for absorbed iron increases from 0.8 mg/day in early pregnancy to 7.5 mg/day in late pregnancy. An iron supplement of 65 mg/day beginning at or before 20 weeks' gestation generally is adequate to prevent iron deficiency during pregnancy.²⁹

There is evidence that the risks of premature delivery, low birth weight, and infant death are increased by severe iron deficiency. However, it is difficult to distinguish the effects of the iron deficiency itself from the conditions that produced the deficiency. A large case-control study from Venezuela indicated that maternal iron deficiency was associated with increased risk of premature delivery (risk ratio, 1.70; 95% confidence interval, 1.18 to 2.57).³³ However, when Mahomed reviewed 20 trials evaluating the issue of iron supplementation in pregnancy for the Cochrane database, he concluded that iron supplementation during pregnancy resulted in a substantial reduction in women with anemia (a hemoglobin below 10 g/dl late in pregnancy) but had no detectable effect on maternal or fetal outcome.³⁴ Thus, whether maternal iron deficiency adversely influences pregnancy is controversial. In fact, it is not entirely clear whether maternal iron deficiency reduces the fetal iron supply. Harthoorn-Lasthuizen et al. found no significant differences in iron status of neonates born to iron-deficient versus iron-replete women and concluded that the fetal iron supply is not negatively influenced by iron deficiency in the mother.³⁵ In contrast, Turgeon O'Brien et al. reviewed medical records of 202 pregnant women to examine the association of low- and high-ferritin levels and anemia with pregnancy outcome.³⁶ They observed an inverse relationship between firsttrimester anemia and birth weight, but they observed no relationship in the second and third trimesters. They suggested that maternal iron deficiency in early pregnancy was associated with poor fetal weight gain but that maternal iron deficiency later in pregnancy was not. During iron deficiency, the placenta becomes hypertrophied, a possible cause of maternal hypertension. A specific variant of pica, namely (ingestion of baking powder) can lead to symptoms suggesting preeclampsia.³⁷

Recombinant erythropoietin administration, combined with iron replacement, has been reported to be an effective treatment for moderate and severe iron deficiency anemia during pregnancy,^{38, 39} although a meta-analysis of this topic suggests that the benefits from erythropoietin are relatively modest.⁴⁰

The usual criteria for diagnosing iron deficiency are valid during pregnancy (see Chapter 23), including a reduced mean corpuscular volume (MCV), a reduced serum transferrin saturation to ≤15%, and a reduced serum ferritin concentration. Measurement of serum transferrin receptors may be useful in complicated situations in which inflammatory disease makes the serum ferritin value less reliable.⁴¹ Interpretation of serum iron values can be complicated during pregnancy: Even in apparently iron-replete women, serum iron levels progressively decline, and values for serum total iron-binding capacity and free erythrocyte protoporphyrin increase,^{1, 42} findings that usually indicate iron deficiency. Expression of the iron-regulatory peptide hepcidin appears to be suppressed during pregnancy, consistent with an increased iron demand.⁴³

Dietary supplementation with 78 mg of elemental ferrous iron daily during pregnancy increased the hematocrit, hemoglobin concentration, and red cell mass, with the red cell mass rising to nearly twice that found in similar, apparently healthy women not supplemented.¹ At term, the mean hemoglobin concentration averaged 12.4 g/dl in those who received the supplement and 10.9 g/dl in those who did not. In Bantu women, whose diet is habitually high in iron, a significant change in serum iron does not occur, and iron deficiency anemia does not develop during pregnancy.⁴⁴ Some

have recommended that all pregnant women receive iron supplements beginning at 18 to 20 weeks' gestation in doses ranging from 30 to 60 mg/day,²⁶ whereas others recommend that iron supplementation be provided selectively. A typical regimen in this second circumstance is as follows: No iron supplementation if the serum ferritin concentration is $>70 \mu\text{g/L}$; low-level iron supplementation (40 mg elemental iron/day) if serum ferritin is between 30 and 70 $\mu\text{g/L}$; and 80 to 100 mg elemental iron/day in women with lower serum ferritin concentrations.⁴⁵

Actual iron deficiency anemia should be treated as in individuals who are not pregnant (see Chapter 23). Constipation may be an especially problematic side effect in pregnant women; therefore, gradual increases in dose until fully therapeutic levels are achieved and an emphasis on taking medication with meals are particularly important precautions. Rarely, parenteral treatment may be necessary.

DEFICIENCY OF FOLATE AND OTHER NUTRIENTS DURING PREGNANCY

Macrocytic anemia of pregnancy is typically megaloblastic and in most cases results from deficiency of folic acid.^{46, 47, 48, 49, 50} In a study from India, macrocytic anemia in pregnancy carried a more negative prognosis for both mother and child than did iron deficiency.⁵¹ Megaloblastic anemia during pregnancy begins most often in either the third trimester or shortly after delivery.⁵² Folate requirements increase during pregnancy, and the diets of many pregnant patients are insufficient to meet the increased need.^{53, 54} Although folate deficiency occurs most often in economically deprived patients, this consequence of inadequate eating habits is not confined to the poor.^{52, 53, 54, 55} Particularly in pregnant adolescents, the diet may provide an inadequate source of folate, regardless of economic status.⁵⁴ In uncomplicated pregnancies, the gastrointestinal absorption of dietary folate (polyglutamate) and of folic

P.1014

acid (monoglutamate) is normal.^{56, 57} Folate deficiency during pregnancy is relatively common, although its frequency depends on the population studied. The prevalence varies from 1% to 50% of pregnant patients.^{48, 52, 55, 58} In North America, the prevalence is 1% to 4%.⁵⁰ Not all patients in whom the serum concentration of folate is low develop megaloblastic anemia. In those who do, often the serum folate concentration was low earlier in pregnancy.⁵²

Pregnant women often have no symptoms with folate deficiency anemia and may be found to have blood hemoglobin levels of 6 to 9 g/dl in the third trimester or postpartum. Folate deficiency is clearly associated with fetal neural tube defects and cleft palate, but these defects are established very early in fetal development, long before maternal megaloblastic anemia is detected.⁵⁰ The association between low serum folate during the first trimester of pregnancy and fetal neural tube defects has been known for over 25 years.⁵⁰ Lumley et al. reviewed this issue for the Cochrane database, examining four trials involving 6,425 women treated with folate or placebo.⁵⁹ Preconceptional folate supplementation reduced the incidence of neural tube defects to a relative risk of 0.28 (95% confidence interval, 0.13 to 0.58). Folate did not increase miscarriage, ectopic pregnancy, or stillbirth. Multivitamins without folate did not prevent neural tube defects, and adding multivitamins to folate supplementation did not produce additional preventive effects. Thompson et al. reported an unexpected but significant reduction in childhood acute lymphoblastic leukemia among offspring of women supplemented with folate during pregnancy.⁶⁰

An association between bacteriuria and folate deficiency was noted in pregnant patients. In experimental systems, infection may induce folate-deficient megaloblastic anemia. Malabsorption (see Chapter 36) may be associated with megaloblastic anemia of pregnancy, even in nontropical areas.⁵⁰

In rare cases, folate-deficient pregnant patients develop erythroblastopenia and bone marrow changes morphologically simulating acute leukemia.⁶¹ Application of current molecular, immunologic, and cytochemical tools for diagnosing leukemia will avoid a mistaken diagnosis.

Megaloblastic anemia during pregnancy, as in the nonpregnant patient, is suggested by an increased MCV with oval macrocytes and hypersegmented granulocytes on blood smear, but a bone marrow examination can be done if doubt exists. Folate deficiency must be distinguished from vitamin B₁₂ deficiency. The latter is rare in pregnancy, and the distinction can often be made on clinical grounds, especially on the basis of a careful nutritional history.

Folate is transported across the placenta against a concentration gradient. Infants born to mothers with the megaloblastic anemia of pregnancy have no anemia and no biochemical evidence of folate deficiency.⁶² The concentration of vitamin B₁₂ also is two to three times higher in cord blood than in maternal blood.⁶³ Nevertheless, this nutritional advantage is insufficient to protect the infant if the mother is vitamin B₁₂ deficient and if the sole source of nutrition is the mother's milk. Megaloblastic anemia accompanied by irreversible neurologic damage has been documented in breast-fed infants of vegan mothers^{64, 65} and in breastfed infants of mothers with subclinical pernicious anemia.^{66, 67}

Dietary supplementation with approximately 0.3 mg of folic acid daily during pregnancy reduces the occurrence of megaloblastic anemia to approximately 0.7% of all pregnant women,^{49, 68, 69} whereas a supplement of only 0.1 to 0.2 mg/day is not adequate to maintain serum folic acid concentration at normal levels.^{70, 71} A supplement of 0.45 mg/day results in supranormal values for serum folate,^{69, 71} but, even with this amount of supplementation, megaloblastic anemia may occur in a pregnant patient in whom the course is complicated by urinary tract infection, hemolysis, or hemorrhage.⁷¹ Nevertheless, because true pernicious anemia caused by a lack of intrinsic factor and vitamin B₁₂ does occur in pregnant patients,⁷² the considerations regarding masking of pernicious anemia with folate doses of 0.40 mg/day or more apply (Chapter 36). Both the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists recommend daily supplements of 0.4 mg of folic acid for pregnant women at low risk for neural tube defects; for pregnant women with a history of previous pregnancies associated with neural tube defects or at otherwise high risk, 4 mg of folic acid daily is recommended.^{73, 74, 75} For patients not at high risk for neural tube defects but at increased risk for folate deficiency, such as those with chronic hemolytic anemia, the supplement may be increased to 1 mg/day.⁵⁰

For established deficiencies, the regimen described in Chapter 36 should be followed. If the possibility of vitamin B₁₂ deficiency cannot be excluded, vitamin B₁₂ injections should be added to the regimen.

Anemia due to zinc deficiency has been associated in some studies with fetal growth restriction, congenital abnormalities, and neurodevelopmental delay. Iodine deficiency during pregnancy is very uncommon in developed countries but can result in fetal wastage, preterm delivery, and neonatal hypothyroidism. Deficiency of magnesium, selenium, copper, and calcium has also been associated with complications of pregnancy and fetal development.^{76, 77} In a study in Nepal, vitamin A supplementation reduced maternal mortality, and suggested that vitamin A influences the synthesis of erythropoietin and thus might decrease maternal anemia, although other studies carried out in pregnant women in Africa have not confirmed this.^{78, 79, 80}

MATERNAL ANEMIA ASSOCIATED WITH PRENATAL INFECTIONS

Most clinically significant infections of the fetus are viral or protozoal, but generally these conditions result in minimal evidence of infection in the mother. Specifically, women carrying a fetus infected with cytomegalovirus, toxoplasmosis, rubella, herpes simplex, or parvovirus B19 generally have no anemia related to the infection. However, certain infectious diseases during pregnancy do result in maternal anemia. For example, intestinal helminth infections, common in certain parts of the world, produce or exacerbate iron deficiency during pregnancy, resulting in anemia. Nurdia et al. reported that 70% of 442 pregnant women from Central Java, Indonesia, had either *Trichuris trichiura*, *Necator americanus*, or *Ascaris lumbricoides* detected during pregnancy.⁸¹ They observed a significant negative association between hookworm infection and serum ferritin in the first trimester and suggested that anthelmintic therapy should be given to infected women before conception as a means of improving their iron status. Similarly, Torlesse and Hodges reported that anthelmintics were useful in Sierra Leone, reducing the decline in hemoglobin concentration during pregnancy by more than 6.5 g/L.⁸²

Syphilis generally does not lead to anemia in pregnancy. Mavrov and Goubenko, from Ukraine, reported on 155 pregnant women with syphilis. They observed that 78% of the women remained asymptomatic throughout pregnancy, although placental and fetal/neonatal pathology were found in about half of cases.⁸³

Malaria can cause maternal and fetal anemia.⁸⁴ This is a significant issue in the less-developed countries of the world. Standard methods of diagnosing malaria are often ineffective during pregnancy.⁸⁴ The anemia is mild in most neonates with malaria, but with a marked placental accumulation of parasites, intrauterine growth retardation can be significant.⁸⁵ Steketee et al. reviewed studies between 1985 and 2000 and summarized the risk of neonatal anemia, low birth weight, and infant mortality associated with maternal malaria. Indeed, maternal malaria was associated with substantial risks for anemia (population attributable risk, 3% to 15% increased), low birth weight (8% to 14% increased risk), and infant mortality (3% to 8% increased risk).

P.1015

They estimated that each year 75,000 to 200,000 infant deaths are associated with maternal malaria.⁸⁶ More recent studies from Nigeria, Benin, and India have shown similar results.^{87, 88, 89}

HEMOLYTIC ANEMIA IN PREGNANCY

Pregnancy-induced Hemolytic Anemia

A variety of hemolytic anemia syndromes can occur in pregnant women just as in nonpregnant women. In fact, pregnancy can exacerbate underlying autoimmune hemolytic anemia.⁹⁰ Thus, hemolytic anemia is not particularly uncommon in

obstetric practice. However, a rare entity has been described in which an idiopathic hemolytic anemia occurs during pregnancy, resolves completely after pregnancy, and recurs during subsequent pregnancy (Table 42.2). The pathogenesis of this anemia is not known. Terms for the condition include idiopathic autoimmune hemolytic anemia of pregnancy, unexplained hemolytic anemia associated with pregnancy, and pregnancy-induced hemolytic anemia. The condition is not homogeneous. In the cases reported by Ng et al. from Kuala Lumpur and Benraad et al. from The Netherlands,^{91, 92} women had immunoglobulin G warm antibodies and were successfully treated with glucocorticoids. In some cases, a positive direct antiglobulin (Coombs) test is not found.^{93, 94, 95} The majority of cases have no identifiable immune mechanisms and have a variable response to glucocorticoids.^{96, 97, 98}

This pregnancy-induced hemolytic anemia becomes apparent in the third trimester of pregnancy and in most cases remits completely within 2 months of delivery, sometimes taking as long as 4 or 5 months. The anemia is usually very severe, even life threatening to mother and fetus. Corticosteroids and intravenous immunoglobulin (IVIG) have been reported to be successful in some cases, but many of the women have been treated with repeated erythrocyte transfusions. Generally, the transfused donor cells have a shortened survival. Neonates born to women with pregnancy-induced hemolytic anemia generally have transient hemolysis, lasting 1 to 2 months; severe jaundice requiring neonatal exchange transfusion has not been reported.

Autoimmune Hemolytic Anemia during Pregnancy

In cases of autoimmune hemolytic anemia during pregnancy, whether idiopathic or of an identified variety, the degree of hemolysis is generally more severe in the mother than that in the fetus.⁹⁹ However, therapy that ameliorates the maternal disease (such as corticosteroids or IVIG) often does not protect the fetus. This is in contrast to autoimmune thrombocytopenia during pregnancy, in which maternal and fetal platelet counts are likely to be concordant.

TABLE 42.2 FEATURES OF IDIOPATHIC PREGNANCY-INDUCED HEMOLYTIC ANEMIA

There is no identifiable mechanism.

Anemia becomes apparent in the third trimester.

Anemia remits completely within 2 mo of delivery.

Anemia generally recurs in subsequent pregnancies.

Anemia is usually severe, even life threatening.

Corticosteroids and intravenous immunoglobulin are sometimes helpful.

Erythrocyte transfusions are the mainstay of treatment for severe anemia.

Donor cells have a shortened survival.

Neonates generally have transient nonsevere hemolysis.

HELLP Syndrome

Preeclampsia is characterized by gestational hypertension and proteinuria or pathologic edema; eclampsia is complicated by the additional occurrence of seizures.^{100, 101} Preeclampsia and eclampsia are systemic diseases involving the kidney, liver, heart, and central nervous system. Hematologic complications have been recognized for some time and include microangiopathic hemolytic anemia with characteristic fragmented red blood cells (RBCs) in the peripheral blood, thrombocytopenia, and well-defined abnormalities of the coagulation system.^{102, 103} This subset of patients with severe preeclampsia/eclampsia is considered to have HELLP syndrome, characterized by hemolysis (H), elevated liver (EL) enzymes, and low platelet (LP) counts (Table 42.3).^{104, 105}

It is thought that RBC fragmentation and thrombocytopenia associated with HELLP are a result of a number of interrelated, largely mechanical factors, including endothelial damage, vasoconstriction coupled with hypertension, and the deposition of fibrin in injured vessels. Women with preeclampsia have abnormalities in coagulation, including signs of chronic intravascular coagulation,¹⁰⁶ shortened platelet lifespan,^{103, 107} decreased plasma antithrombin III activity,^{108, 109} abnormalities in circulating fibrinogen multimers¹¹⁰ and increased fibrin deposition within the kidney and the liver.^{111, 112} Increased rates of factor VIII consumption have been reported by some although not all investigators.^{113, 114, 115} Patients with preeclampsia have decreased hemopexin relative to healthy pregnant mothers.¹¹⁶ Women with preeclampsia also have higher circulating levels of the endogenous vasoconstrictor endothelin and other abnormalities of endothelial function.^{117, 118, 119, 120} Patients with preeclampsia have an imbalance of placental prostacyclin and thromboxane production that favors vasoconstriction.¹²¹

TABLE 42.3 MAJOR CLINICAL CHARACTERISTICS OF HELLP SYNDROME, TTP, AND HUS

Clinical Features	HELLP Syndrome	TTP	HUS
Target organ/system involved	Liver	Neurologic	Renal
Gestational age	Second to third trimester	Second trimester	Postpartum
Platelets	Decreased	Decreased	Decreased
PT/PTT	Normal	Normal	Normal
Hemolysis	Present	Present	Present
Fibrinogen	Normal	Normal	Normal
Creatinine	Normal/increased	Increased	Increased
Liver enzymes	Increased	Normal	Normal
ADAMTS-13	Mild-moderate	Severely	Variable; typically severely
	Decreased	Decreased/absent	Decreased

HELLP, hemolysis (H), elevated liver (EL) enzymes, and low platelet (LP) counts; HUS, hemolytic-uremic syndrome; PT, prothrombin time; PTT, partial thromboplastin time; TTP, thrombotic thrombocytopenic purpura.

Modified from Saphier CJ, Repke JT. Hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome: A review of diagnosis and management. *Semin Perinatol* 1998; 22(2):118-133.

P.1016

HELLP syndrome reportedly occurs in 20% of women with severe preeclampsia and 10% of women with eclampsia.¹²² The median gestational age at presentation is 32 to 34 weeks, with a range of 24 to 39 weeks.¹²³ Clinical findings at presentation include malaise, right upper quadrant tenderness, hypertension, and edema. Most women with HELLP syndrome are not anemic at presentation, although they may drop their hemoglobin out of proportion to the volume of blood lost at delivery.¹²³

Laboratory features include elevated liver enzymes (i.e., alanine aminotransferase [ALT] and aspartate aminotransferase [AST]), thrombocytopenia with $<100,000/\mu\text{l}$ in most patients, and evidence of compensated hemolysis. The latter is probably the most specific abnormality associated with HELLP syndrome, but sometimes difficult to detect. The peripheral blood smear usually reveals schistocytes and there also may be burr cells and polychromatophilia.¹²³ In one study, however, schistocytes were seen in only a small fraction of patients and it was proposed that the fragmented cells may have been removed by the spleen.¹²⁴ Hemoglobinemia and hemoglobinuria occur in $<10\%$ of cases. The one consistent abnormality noted in women with HELLP syndrome is a decreased serum haptoglobin in virtually all patients, and this may be considered to be a highly sensitive test to detect this RBC abnormality when only a few schistocytes are present on smear.¹²⁴ Patients with HELLP syndrome have been reported to have mild to moderate reduction in the von Willebrand factor cleaving protease ADAMTS-13 compared to nonpregnant women or women experiencing an uncomplicated pregnancy. These reduced levels were not due to inactivating antibodies.¹²⁵ Severely reduced ADAMTS-13 levels would suggest a diagnosis of thrombotic thrombocytopenic purpura (TTP) rather than HELLP.¹²⁶ TTP is also distinguished from HELLP by an increased lactate dehydrogenase (LDH)/AST ratio.¹²⁷

The management of pre-eclampsia with HELLP syndrome is a matter of some obstetric debate, and is beyond the scope of this chapter. In general, the issues relate to immediate delivery or close observation, and these in turn are governed by maternal clinical status and fetal gestational age.^{123, 128} The most common approach is to deliver the fetus as soon as possible or, if it is likely that there is fetal lung immaturity because of gestational age, steroids are administered to the mother for 2 to 3 days, and then the infant is delivered. It is intriguing that a small but significant fraction of women (30%

in one study) spontaneously improves without more aggressive intervention.¹²⁹ In contrast to TTP, there currently are no data indicating a role for plasmapheresis.

One of the most serious complications is hepatic rupture, with 50% maternal and 60% to 70% fetal mortality. Other complications include disseminated intravascular coagulation, renal failure, pulmonary edema, and placental abruption.¹⁰⁵ Overall, maternal mortality ranges from 0% to 4% in different series.¹²³ Hematologic and chemical abnormalities resolve within a few days of delivery. Neonatal mortality is 5% to 20%,^{105, 123} and this is more a reflection of fetal age rather than any specific complication of maternal HELLP issues.

Pregnancy-associated Thrombotic Thrombocytopenic Purpura and Hemolytic-uremic Syndrome

In most reported studies of thrombotic microangiopathy with pregnancy, TTP and hemolytic-uremic syndrome (HUS) have been distinguished on the basis of the predominant symptomatology, neurologic or renal. TTP most commonly occurs antepartum, with a significant majority of cases presenting before 24 weeks' gestation. Postpartum TTP is uncommon.¹³⁰ HUS, on the other hand, typically occurs after a normal delivery and a symptomfree interval, and is characterized by acute-onset renal failure and microangiopathic hemolytic anemia.^{106, 128} Hypertension is almost always found. A small fraction (10% to 15%) of HUS and TTP patients have signs of preeclampsia. Sometimes TTP/HUS is not correctly diagnosed until the patient, thought to have preeclampsia, has an atypical prolonged recovery in the postpartum period.¹³¹

Laboratory results show the expected hemolytic anemia with many RBC fragments. Severe thrombocytopenia usually is present. Fibrin breakdown products are often increased, but the findings of other coagulation studies usually are normal.¹⁰⁶ In postpartum HUS azotemia is the rule, but is rare in TTP.

In an extensive case review, the overall maternal mortality was 44%. The mortality rate was reduced to 0% with plasma therapy, but was 68% if plasma therapy was not instituted.^{106, 131, 132, 133, 134} The pregnancy should not be terminated because this does not cure the disease, and the fetus may survive with successful therapy. The presence of severely reduced ADAMTS-13 activity at the outset of pregnancy in any woman with a history of TTP should suggest a need for plasma exchange during pregnancy.¹²⁶

BONE MARROW FAILURE SYNDROMES ASSOCIATED WITH PREGNANCY

Aplastic Anemia/Pure Red Cell Aplasia

Pregnancy may occur in patients with existing bone marrow failure syndromes,^{135, 136, 137} although this is uncommon and requires cooperation between a high-risk obstetrics expert and a hematologist experienced with bone marrow failure syndromes. Predictors of a poor outcome include thrombocytopenia and aplastic anemia associated with paroxysmal nocturnal hemoglobinuria.¹³⁶ Even more uncommon is aplastic anemia that develops during pregnancy. Whether this is a coincident association in most cases is unclear: The observation that approximately up to 25% of these individuals experience a spontaneous remission after delivery suggests that it is not coincidence.^{138, 139} Patients are generally managed with supportive care during pregnancy, and receive specific immunosuppressive therapy subsequently if necessary.

Pure red cell aplasia may also have its initial onset in pregnancy. These patients should be managed with supportive care also, and the majority will experience a remission after delivery. In some cases, subsequent pregnancies are associated with recurrence.^{140, 141, 142}

Sideroblastic Anemia

There have been a number of case reports and small series of sideroblastic anemia with onset during pregnancy. Some cases appear to represent a coincident association with idiopathic sideroblastic anemia,¹⁴³ whereas others appear to be pregnancy induced, and may recur with subsequent pregnancies.^{144, 145} A pregnancy-associated syndrome with morphologic features of both sideroblastic anemia and amegakaryocytic thrombocytopenia has been described, which responds to immunosuppression, but may also undergo spontaneous remission after delivery.¹⁴⁶

POSTPARTUM ANEMIA

Postpartum anemia is common, particularly among low-income women. Studying nearly 60,000 women who were enrolled in the Special Supplemental Nutrition Program for Women, Infants, and Children, Bodnar et al. reported an overall incidence of postpartum anemia of 27%. However, rates reached 48% among non-Hispanic black women. Prenatal anemia was the best predictor

P.1017

of postpartum anemia. Maternal obesity, multiple births, and formula feeding also predicted postpartum anemia.²⁷

Peripartum hemorrhage is an obvious and common cause of postpartum anemia. An estimated blood loss at delivery in excess of 500 ml is claimed to be a good predictor of postpartum anemia.¹⁴⁷ Unsuccessful vacuum extraction can cause peripartum hemorrhage and subsequent postpartum maternal anemia. Sheiner et al. evaluated over 2,100 cases of delivery by vacuum extraction in Israel between 1990 and 1998¹⁴⁸ and reported that 5.4% of all deliveries were complicated by unsuccessful extraction, with a subsequent cesarean section. Postpartum anemia was much more common in the women following unsuccessful vacuum extraction than in those in whom cesarean sections were not preceded by attempts at vacuum extraction. Maternal blood loss during and after the unsuccessful vacuum extraction procedures was suggested as the cause.

Hemorrhage occurring a week or more after delivery, so-called secondary postpartum hemorrhage, has a high morbidity rate. Hoveyda and MacKenzie analyzed 132 consecutive women presenting with secondary postpartum hemorrhage over a 3-year period at Barrett Maternity Hospital, Northampton, United Kingdom.¹⁴⁹ They observed this complication in just under 1% of women and found that most presented in the second week after delivery. Histories of either primary postpartum hemorrhage or manual removal of the placenta were the only significant risk factors identified. Eighty-four percent of these women were rehospitalized, 63% required surgery, and 17% received blood transfusions.

Peripartum hemolysis is another cause of postpartum anemia. Hemolytic reactions have been described in women receiving second- and third-generation cephalosporins, such as cefotetan, administered prophylactically for cesarean section.^{150, 151}

Recombinant erythropoietin has been used to treat postpartum anemia. Meta-analysis suggests that although erythropoietin treatment is safe and tends to be associated with a more rapid rise in hematocrit, it may not reduce the need for transfusion.¹⁵² Similarly, intravenous iron administration for postpartum anemia is associated with a more rapid hemoglobin increment than oral iron.¹⁵³ However, the relative safety compared to oral iron is not established.¹⁵⁴

Chapter 43

Anemias Unique to the Fetus and Neonate

Robert D. Christensen

Robin K. Ohls

INTRODUCTION

The reference ranges used to define normal hematocrit, hemoglobin, erythrocyte count, and the erythrocyte indices, change considerably during fetal life as well as in the weeks after birth.^{1, 2} Consequently, the laboratory findings that define anemia in a fetus or neonate are highly dependent on the gestational and postnatal age. Once anemia is recognized in a fetus or neonate, the differential diagnosis used to seek for the cause is unique from that at all other ages. In this chapter we display the pertinent reference ranges and review the underlying differences in erythropoiesis, erythrocyte structure, function, and metabolism that make anemias in the fetus and neonate so unique.

ERYTHROPOIETIN BIOLOGY IN THE FETUS AND NEONATE

Erythropoietin has both erythropoietic effects and nonerythropoietic effects during human fetal and neonatal development (Table 43.1).^{3, 4} Although initially described by, and principally known for, its actions on erythroid progenitors, erythropoietin is also an important physiologic growth factor for fetal small intestinal villous enterocytes and neurons.^{4, 5, 6, 7}

Erythropoietin is a constituent of amniotic fluid, in concentrations of 25 to 40 mU/ml. A normal human fetus swallows 200 to 300 ml of amniotic fluid per kilogram body weight per day, and thus swallows 10 to 15 U of erythropoietin/kg/day.⁸ In humans, erythropoietin does not cross the placenta from maternal to fetal circulations, and it appears that the source of the erythropoietin in amniotic fluid is not the maternal circulation. In the second and third trimesters, amniotic fluid is largely derived from fetal urine, with minor constituents from fetal tracheal effluent and the placenta and fetal membranes. However, erythropoietin in amniotic fluid does not appear to come from fetal urine. The fetal kidney makes little erythropoietin before delivery, and the first-voided urine of neonates generally has no detectable erythropoietin.⁸ Studies using *in situ* hybridization and immunohistochemistry indicate that the source of erythropoietin in amniotic fluid is largely maternal: from mesenchymal and endothelial cells in the deciduae and from the amnion.⁸

Erythropoietin is present in human colostrum and breast milk in concentrations of 10 to 20 mU/ml.^{4, 5, 6, 7, 8, 9} Erythropoietin concentrations in mother's milk do not correlate with erythropoietin concentrations in her blood. In fact, over the first weeks of lactation, maternal serum erythropoietin concentrations fall, whereas milk erythropoietin concentrations increase, reaching the highest concentrations in women breast-feeding for a year or more. The source of erythropoietin in breast milk appears to be mammary gland epithelium.^{7, 8}

TABLE 43.1 ACTIONS OF ERYTHROPOIETIN IN THE HUMAN FETUS

Site of Erythropoietin Production	Mechanism of Erythropoietin Delivery to Target Cells	Actions at Target Cells
Hepatocyte/hepatic macrophages	Paracrine	Erythropoiesis/angiogenesis
Glia	Paracrine	Neural migration
Glia	Paracrine	Neural protection from hypoxia
Decidua and amniotic membranes (amniotic fluid)	Swallowed by fetus	Small bowel villous development
Mammary epithelia (breast milk)	Swallowed by neonate	Small bowel villous development

Erythropoietin in human amniotic fluid, colostrum, and breast milk is relatively protected from proteolytic digestion in the fetal and neonatal gastrointestinal tract.⁸ Rather than being absorbed from the gastrointestinal track into the blood, the erythropoietin swallowed by the fetus and neonate binds to erythropoietin receptors on the luminal surface of villous enterocytes, where it serves topically as a growth and development factor. Indeed, experimental animals artificially fed formulas devoid of erythropoietin have retarded villous development, a condition that can be remedied by enteral recombinant erythropoietin and blocked by antierythropoietin antibody.^{4, 5, 6, 7, 8, 9}

Erythropoietin is produced by cells in the developing central nervous system and is present in relatively high concentrations in fetal cerebrospinal fluid (CSF).^{10, 11, 12, 13, 14, 15} Among newborn infants, the highest concentrations of erythropoietin in the CSF are seen in the most premature neonates, and by several years of age CSF erythropoietin concentrations are generally below 1 mU/ml.⁵ Erythropoietin receptors are expressed on human fetal neurons,^{10, 11, 12, 13, 14, 15} and at least small quantities of recombinant erythropoietin, administered intravenously, cross the blood-brain barrier and appear in the CSF fluid.¹⁶ Erythropoietin in the central nervous system is a neuroprotectant from hypoxia. Erythropoietin production increases rapidly in the brain during hypoxia, and when erythropoietin binds to receptors on

neurons, antiapoptotic activity is induced. Cell culture systems and whole animal models illustrate a marked neuroprotective effect of erythropoietin.¹⁷ The clinical utility of recombinant erythropoietin as a neuroprotectant is a topic of recent and ongoing studies.^{18, 19, 20, 21, 22}

The liver is the primary site of erythropoietin production in the fetus. The kidney does not become the primary site until several months after birth. In the human fetus, the kidney produces about 5% of the total erythropoietin during mid-gestation. The developmental mechanisms regulating the switch in erythropoietin production from the liver to the kidney are not completely known but may involve developmental expression of transcription activators such as hypoxia inducible factor and hepatic nuclear factor 4, or developmental methylation of promoter and enhancer regions. Alternatively, the switch might involve the GATA transcription factors, particularly GATA-2 and GATA-3, which are negative regulators of erythropoietin gene transcription.

Erythropoietin ameliorates experimental damage to the placenta and fetal liver induced by lipopolysaccharide.²³ Elevated concentrations of erythropoietin in fetal blood and/or amniotic fluid may indicate fetal hypoxia, and although erythropoietin may have a protective role for some fetal cells, such as neurons, placental, hepatic, and intestinal villous cells, it might also be a marker for poor neurodevelopmental outcome on the basis of severe or chronic hypoxia.^{23, 24, 25, 26}

NORMAL ERYTHROCYTE VALUES DURING HUMAN FETAL DEVELOPMENT

Normal ranges for erythrocyte values of the human fetus and neonate are generally not available. This is because blood is not drawn on healthy neonates to establish such ranges. Instead, reference ranges are used, consisting of the 5th to the 95th

P.1019

percentile values compiled from laboratory tests performed on neonates who were thought to have minimal pathology relevant to the laboratory test, or pathology unlikely to affect the test results significantly. The premise on which the reference range concept is based is that these values approximate normal ranges, although they were admittedly obtained for a clinical reason and not from healthy volunteers.^{1, 2}

Circulating erythrocytes in the mid- and third trimester fetus have features reminiscent of what is called "stress erythropoiesis in adults. These features include marked anisocytosis, poikilocytosis, macrocytosis, and a relatively high percentage of nucleated erythrocytes. Marrow cellularity in the fetus is relatively high, and because the available marrow space is fully cellular, the fetus and newborn infant have little marrow reserve on which to call. Erythroid precursors account for 30% to 65% and myeloid cells 45% to 75% of nucleated marrow cells at birth.²⁷ The myeloid to erythroid ratio at birth is approximately 1.5:1. Marrow cellularity decreases after birth, attaining a density that is normal for adults by 1 to 3 months.²⁸ Initially, this decrease in cellularity results from a rapid decline in red cell precursors. At 1 week of age, erythroid elements account for only 8% to 12% of nucleated cells, and the myeloid to erythroid ratio exceeds 6:1. The normal adult proportion of myeloid to erythroid precursors is not established until the third month. Both the percentage and absolute number of lymphocytes increase during the first 2 months, so that by 3 months of age, they constitute nearly 50% of marrow nucleated cells. Differential counts of bone marrow aspirates from preterm infants are the same as those for term infants.²⁹

Normal reference ranges for the hemoglobin concentration on the day of birth, at gestational ages ranging from 22 to 42 weeks, are shown in Figure 43.1. The reference ranges gradually increase during this period in utero, and there are no differences between genders.³⁰ After birth, the anatomic site of blood sampling to measure the hemoglobin and hematocrit influences the test result.^{1, 2, 31} Perfusion of small vessels in the extremities can be relatively poor, particularly during hypotension or skin cooling, resulting in increased transudation of fluid and hemoconcentration. Consequently, the hemoglobin concentration and packed cell volume of capillary blood are 5% to 10% higher than those of venous blood.² The difference between capillary and venous values is greatest at birth but disappears by 3 months of age. The discrepancy is greatest in preterm infants and in those with hypotension, hypovolemia, and acidosis.³² Differences can be minimized, but not fully resolved, by warming the extremity before sampling, obtaining freely flowing blood, and discarding the first few drops. The interpretation of serial observations necessitates the consistent use of one site of blood sampling.

FIGURE 43.1. Reference ranges for blood hemoglobin concentration at birth. Values are shown from 24,416 subjects after 22 to 42 weeks gestation. The solid line shows the mean value and the dashed lines show the 5% and the 95% reference range. (From Jopling et al. Reference ranges for hematocrit and blood hemoglobin concentration during the neonatal period; data from a multihospital healthcare system. *Pediatrics* 2009;123:e333-e337.)

Hemoglobin concentrations increase during the first hours after birth attributable in part to a shift of fluid from the intravascular compartment but also to the transfusion of fetal red cells from the placenta at the time of birth.² After the first day, the reference ranges for hemoglobin and hematocrit gradually decrease, as shown in Figure 43.2 (term and late preterm neonate) and Figure 43.3 (preterm neonates).

The mean corpuscular volume (MCV) at birth is highly dependent on gestational age, as shown in Figure 43.4.³³ Values below the 5th percentile are seen in neonates with α -thalassemia trait or hereditary spherocytosis.^{34, 35, 36} A low MCV at birth due to fetal iron deficiency is less common, but this can occur with chronic fetomaternal hemorrhage or twin-to-twin transfusion syndrome. The mean corpuscular hemoglobin (MCH), like the MCV, is high at birth, by adult standards, and is highly dependent on gestational age. In contrast, the mean corpuscular hemoglobin concentration (MCHC) does not change with gestational age and should be in the range 33 to 35 g/dl in all neonates whether born prematurely or at term. An MCHC value >36 to 36.5 g/dl can suggest hereditary spherocytosis, particularly if accompanied by an MCV below the reference range for gestational age.^{35, 36}

Reticulocytosis and normoblastosis reflect the accelerated nature of fetal erythropoiesis. Reticulocyte counts at birth are approximately 5%, with a range of 4% to 7%.² Counts in preterm infants are slightly higher, averaging 6% to 10%. Reticulocytes remain elevated for the first 1 to 2 days of life, then drop abruptly to 0% to 1%.

Nucleated red blood cells (NRBC) are seen regularly on blood smears during the first day of life. The reference ranges for NRBC, according to gestational age at birth, are shown in Figure 43.5.³⁷ Elevations in NRBC in preterm infants correlate with adverse outcomes of intraventricular hemorrhage (IVH) and periventricular leukomalacia.^{37, 38} Elevations in NRBC in term infants correlate with hypoxic ischemic encephalopathy and with adverse neurodevelopmental outcomes.^{37, 38}

FIGURE 43.2. Reference ranges for blood hemoglobin concentration of term and late preterm neonates during the first month after birth. The solid line shows the mean value and the dashed lines show the 5% and the 95% reference range. (From Jopling et al. Reference ranges for hematocrit and blood hemoglobin concentration during the neonatal period; data from a multihospital healthcare system. *Pediatrics* 2009;123:e333-e337.)

FIGURE 43.3. Reference ranges for blood hemoglobin concentration of neonates 29 to 34 weeks gestation during the first

month after birth. The solid line shows the mean value and the dashed lines show the 5% and the 95% reference range. (From Jopling et al. Reference ranges for hematocrit and blood hemoglobin concentration during the neonatal period; data from a multihospital healthcare system. *Pediatrics* 2009;123:e333-e337.)

Red cell morphology in the newly born preterm or term neonate is characterized by macrocytosis and poikilocytosis. Target cells and irregularly shaped cells are particularly prominent. A high proportion of stomatocytes is noted when viewed by phase contrast microscopy.³⁹ Similarly a high proportion of siderocytes (3.16% vs. normal male adult mean of 0.09%) are seen.⁴⁰ Differential staining of red cells for fetal hemoglobin (HbF) provides a demonstration of the switch in hemoglobin synthesis that precedes birth: the younger macrocytes contain a minimal amount of HbF, whereas the smaller older cells are rich in HbF.⁴¹

Variations in red cell size and shape are somewhat greater than those observed in term infants, and cytoplasmic vacuoles are evident in nearly one-half of all cells when viewed by using interference-contrast microscopy. Red cell survival is shorter in preterm than in term infants. For infants who undergo exchange transfusion or multiple transfusions, both erythropoietin concentrations and reticulocyte counts are lower at any given hemoglobin concentration.⁴² It had been assumed that oxygen delivery is decreased in newborns because of the presence of a high-affinity hemoglobin, but a leftward shift in the hemoglobin-oxygen dissociation curve due to high levels of HbF might actually better maintain oxygen delivery during episodes of severe hypoxemia.⁴³

The capacity of a fetus or neonate to deliver oxygen to tissues is better estimated by the circulating red blood cell volume than by the hematocrit or hemoglobin concentration. However, measuring the circulating red blood cell volume in a fetus or neonate is particularly difficult. Therefore, either the hematocrit or the hemoglobin is often used in making transfusion decisions. Mock

P.1021

et al. used a nonradioactive method, based on in vivo dilution of biotinylated RBC enumerated by flow cytometry, to estimate the correlation between hematocrit and circulating RBC volume in infants below 1,300 grams, between 7 and 79 days of life. They found that venous hematocrit values correlated highly with the circulating erythrocyte volume ($r = 0.907$; $p < 0.0001$).⁴⁴

FIGURE 43.4. Reference ranges for mean corpuscular volume (MCV) upper panel, and mean corpuscular hemoglobin (MCH) on the day of birth. Values are shown from subjects after 22 to 42 weeks gestation. The solid line shows the mean value and the dashed lines show the 5% and the 95% reference range. (From Christensen et al. The erythrocyte indices of neonates, defined using data from over 12,000 patients in a multihospital healthcare system. *J Perinatol* 2008;28:24-28.)

Neonates have a shorter red cell survival than do children and adults.⁴⁵ The life span of red cells from term infants is estimated to be 60 to 80 days with use of the ⁵¹Cr method and 45 to 70 days using methods involving ⁵⁹Fe.⁴⁵ Fetal studies using [¹⁴C] cyanatelabeled red cells in sheep revealed an average red cell life span of 63.6 ± 5.8 days.⁴⁶ The mean red cell life span increased linearly from 35 to 107 days as the fetal age increased from 97 days (midgestation) to 136 days (term).

Neonatal red cells transfused into adults have a similarly short survival,⁴⁷ indicating that factors intrinsic to the newborn red cell are responsible. Also, adult red cells survive normally in newborn recipients.⁴⁸ The life span is not parametrically distributed, in that most cells are destroyed before the mean survival is reached. Shortened red cell survival as well as demands imposed by an expanding red cell mass account for erythropoietic rates at birth that are three to five times higher than those of normal adults.

The abrupt transition from the uterus to an oxygen-rich environment triggers responses that have a profound effect on erythropoiesis. During the first 2 months of life, the infant experiences both the highest and lowest hemoglobin concentrations occurring at any time in development. Although quite variable, erythropoietin levels at birth usually are well above the normal adult range. Erythropoietin levels fall in the immediate postnatal period, with a half-life of 2.6 ± 0.5 hours in infants with polycythemia and 3.7 ± 0.9 hours in infants born to mothers with preeclampsia.⁴⁹ By 24 hours, the erythropoietin value is below the normal adult range, where it remains throughout the first month. The decrease in erythropoietin is followed by a decline in the number of bone marrow precursors⁵⁰ and a fall in the reticulocyte count.

The combination of shortened cell survival, decreased production, and growth-related expansion of the blood volume is responsible for a progressive fall of the hemoglobin concentration

P.1022

to a mean of approximately 11 g/dl at 2 months of age.⁵¹ The lower range of normal for infants of this age is approximately 9 g/dl. This nadir is called physiologic anemia, because it is not associated with apparent distress and is not prevented with nutritional supplements. Stabilization of the hemoglobin concentration is heralded by an increase in reticulocytes at 4 to 8 weeks.⁵⁰ Thereafter, the hemoglobin concentration rises to a mean level of 12.5 g/dl, where it remains throughout infancy and early childhood.

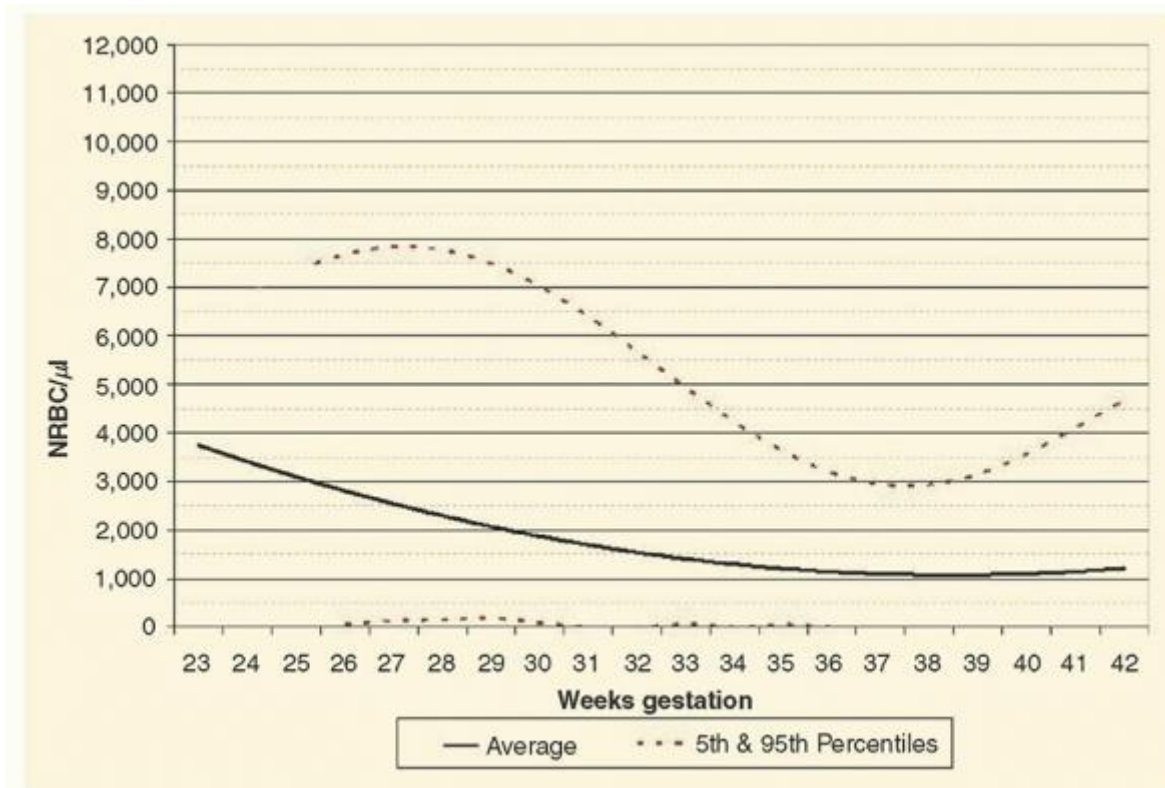

FIGURE 43.5. Reference ranges for blood concentrations of nucleated erythrocytes on the day of birth. Values are shown from subjects after 23 to 42 weeks gestation. The solid line shows the mean value and the dashed lines show the 5% and the 95% referenc range. (From Christensen et al. Neonatal reference ranges for blood concentrations of nucleated red blood cells. *Neonatology* 2010;99:289-294.)

At term, the placenta and umbilical cord contain 75 to 125 ml of blood, or approximately one fourth to one third of the fetal blood volume. The umbilical arteries constrict shortly after birth but the umbilical vein remains dilated, and blood flows in the direction of gravity. Infants held below the level of the placenta can receive half of the placental blood volume

(30 to 50 ml) in 1 minute. Conversely, infants held above the placenta can lose 20 to 30 ml of blood back into the placenta per minute.⁵² The blood volume of infants with early cord clamping averages 72 ml/kg, whereas the volume of infants with delayed cord clamping averages 93 ml/kg. Linderkamp et al. compared postnatal alterations in blood viscosity, hematocrit, plasma viscosity, red cell aggregation, and red cell deformability in the first 5 days in full-term neonates with early (less than 10 seconds) and late (3 minutes) cord clamping.⁵³ The residual placental blood volume decreased from 52 ± 8 ml/kg of neonatal body weight after early cord clamping to 15 ± 4 ml/kg after late cord clamping. The neonatal blood volume was 50% higher in the late cord-clamped infants than in the early cord-clamped infants.

It is possible to promote placental transfer of blood to preterm infants by delaying the clamping of the umbilical cord for 30 seconds. In fact transfer of about 10 ml/kg body wt can be expected using this method.⁵⁴ In a randomized trial by Mercer et al., this maneuver of delayed cord clamping among infants <1,500 grams birth weight resulted in less IVH and less late-onset sepsis.⁵⁵ An alternative approach involves "milking" or "stripping" of the umbilical cord after delivery, while the placenta is still attached to the uterus. This maneuver moves fetal blood toward the fetus before the umbilical cord is clamped. Delayed clamping and cord stripping are roughly equivalent means of providing a small transfusion before birth of a very low birth weight (VLBW) infant, thereby reducing the odds that a donor blood transfusion will be needed during the first days after birth when phlebotomies for laboratory tests commonly result in transfusions to replace the rapidly depleted red cell mass.^{56, 57, 58}

FETAL AND NEONATAL ERYTHROCYTE MEMBRANE AND METABOLISM

The erythrocyte membranes of neonates differ slightly from those of adults.⁵⁹ The percentage of spectrin dimers and the spectrin tryptic peptide patterns are the same as in adult cells⁶⁰ but neonatal cells have more immunoreactive myosin.⁶¹ The quantity and distribution of lipids differ in several respects from adult red cells. Total lipid, phospholipid, and cholesterol are increased out of proportion to the surface area of newborn red cells.^{62, 63} Neonatal cells also exhibit increased endocytosis in response to membraneactive agents, suggesting that the membranes of neonatal cells are less stable and are capable of greater reorganization.⁵⁹

Antigen expression differs from that of adult cells. The A, B, S, and Lutheran antigens are present in decreased amounts. Replacement of the i antigen with its adult counterpart I requires its conversion from a linear poly lactosamine to a branched poly lactosamine.⁵⁹ Reduced A and B antigenicity may result in part from decreased branching and increased stimulation of glycoproteins on neonatal red cells.⁶⁴

At term, red cell deformability and viscoelastic properties are normal.⁶⁵ Similarly, osmotic fragility of erythrocyte from preterm neonates is similar to or even slightly less fragile than erythrocytes of term neonates. However, preterm neonates may have a small subpopulation of cells that are more susceptible to hemolysis, giving preterm infants a greater tendency to develop hemolytic jaundice.⁶⁶

Increased concentrations of certain erythrocyte enzymes in neonates can be explained by the young mean age of red cells. The increase in glycolytic enzymes is comparable in magnitude to that observed in high-reticulocyte adult blood.^{67, 68} Increased glycolytic enzyme activity, in turn, is responsible for increased consumption of glucose and galactose and increased levels of adenosine triphosphate (ATP).⁶⁹ Unique metabolic characteristics of neonatal erythrocytes are summarized in Table 43.2.

P.1023

TABLE 43.2 METABOLIC CHARACTERISTICS OF FETAL/NEONATAL RED BLOOD CELLS

Metabolic characteristics explained by young mean cell age

Increased enzyme activity

Hexokinase

Aldolase

Triosephosphate isomerase

Phosphoglycerate mutase

Pyruvate kinase

Lactate dehydrogenase
Glucose-6-phosphate dehydrogenase
6-Phosphogluconate dehydrogenase
Glutathione reductase
Glyoxalase I and II
Galactokinase
Galactose-1-phosphate uridyl transferase
Increased glucose and galactose consumption
Increased levels of ATP
Metabolic characteristics distinctive for neonatal red cells
Embden-Meyerhof pathway
Increased activity of phosphoglycerate kinase, enolase, glucose phosphate isomerase, and glyceraldehyde-3-phosphate dehydrogenase
Decreased activity of phosphofructokinase
2,3-Diphosphoglycerate instability
Pentose phosphate pathway and glutathione metabolism
Decreased glutathione peroxidase and glutathione synthetase
Glutathione instability
ATP and phosphate metabolism
ATP instability
Decreased phosphate uptake, slower incorporation of phosphate into ATP and 2,3-diphosphoglycerate
Nonglycolytic enzymes
Decreased enzyme activity
Carbonic anhydrase
Catalase
Cholinesterase
Adenylate kinase
Phosphoribosyl transferase
Cytochrome *b*₅ reductase
ATP, adenosine triphosphate.

The activities of four enzymes in the Embden-Meyerhof pathway—phosphoglycerate kinase, enolase, glucose phosphate isomerase, and glyceraldehyde-3-phosphate dehydrogenase—are increased out of proportion to cell age.^{70, 71} The activity of phosphofructokinase, a rate-controlling enzyme in glycolysis, is only 40% to 70% of that in adult red cells of comparable age.^{68, 69, 71} Low levels of phosphofructokinase may produce a block in glycolysis, resulting in the accumulation of glucose-6-phosphate and fructose-6-phosphate and a decrease in the amounts of 2,3-diphosphoglycerate (2,3-DPG) and phosphoenolpyruvate.⁷¹ Decreased activity of phosphofructokinase is probably explained by accelerated decay of a less stable fetal isoenzyme.⁷² Neonatal red cells contain a homotetramer of liver-type phosphofructokinase subunits rather than the heterotetramer of liver and muscle subunits present in adult cells.⁷³ Differences in the relative proportions of isoenzymes have also been described for hexokinase and enolase.⁷⁴ The concentration of 2,3-DPG falls rapidly during short periods of incubation,⁶⁹ apparently because of accelerated breakdown. Preterm infants have lower 2,3-DPG

concentrations than term infants. These concentrations gradually increase with gestation.^{75, 76} Concentrations can be increased with the use of erythropoietin, thereby shifting the oxygen dissociation curve to the right.⁷⁷

The activities of two key enzymes of the pentose phosphate pathway, glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase, are increased by virtue of a young mean red cell age.^{68, 69} The response of the pentose phosphate pathway to oxidant stimuli is normal, and the level of reduced glutathione is equal to or greater than that found in adults.⁷⁰ Despite this, newborn cells exhibit glutathione instability, increased Heinz body formation, and a propensity to increased methemoglobin generation, all indicative of greater susceptibility to oxidant-induced injury.⁶⁷ The basis for this oxidant vulnerability is not known. Although red cells of the newborn infant have low levels of activities of both glutathione peroxidase⁷⁸ and glutathione synthetase,⁷⁹ no apparent relationship exists between these deficiencies and oxidant vulnerability.⁸⁰ Other factors that have been implicated in attempts to explain metabolic differences include deficient catalase activity, decreased numbers of membrane sulfhydryl groups,⁸¹ greater residual membrane hemoglobin,⁸² and other plasma factors.^{83, 84} Studies evaluating the antioxidant capacity of preterm red cells and plasma from infants with respiratory distress syndrome reported no difference in activity between sick and well preterm infants, and antioxidant activity appeared intact. The study did not provide convincing evidence of oxidative damage and diminished antioxidant defenses in preterm infants with neonatal respiratory distress syndrome.⁸⁵

Although elevated at birth, the red cell ATP level falls rapidly during short periods of incubation. The uptake of labeled orthophosphate by cord blood cells is slower than that by adult cells, resulting in delayed incorporation of phosphate into ATP and 2,3-DPG.⁸⁶ This disturbance in energy metabolism has been held responsible for accelerated potassium loss during incubation. Neonatal erythrocytes have increased rates of endocytosis compared to adult erythrocytes; these rates gradually decrease to adult levels with prolonged incubation.⁸⁷ In septic neonates, ATP concentration in red blood cells was significantly lower than in neonates with respiratory distress syndrome and controls, whereas the 2,3-DPG concentration was increased.⁸⁸

The activity of a number of nonglycolytic enzymes differs in neonatal red cells compared to adult red cells. Carbonic anhydrase,⁸⁶ catalase,⁸⁹ acetylcholinesterase,⁹⁰ adenylate kinase,⁹⁰ hypoxanthine-guanine-phosphoribosyl transferase,⁹¹ and cytochrome b₅ reductase⁹² are all less active than in adult red cells. Differences in carbonic anhydrase activity have been exploited by using this enzyme to lyse selectively any contaminating maternal cells from samples of mixed fetal and maternal cells obtained for the prenatal diagnosis of hemoglobinopathies.⁹³ Reduced activity of cytochrome b₅ reductase, the enzyme responsible for methemoglobin reduction, contributes to the infant's vulnerability to methemoglobinemia. This enzyme exists in both soluble and membrane-bound forms. The membrane-bound form is the precursor enzyme that is posttranslationally processed to a smaller soluble form, probably by a calmodulin-dependent endogenous protease.⁹⁴ Neonatal red cells have membrane-bound cytochrome b₅ reductase activity comparable to that of adult cells but are limited in their ability to convert membrane-bound enzyme to the soluble form.

Cord blood contains HbF (α_2, γ_2), HbA (α_2, β_2), and HbA2 (α_2, δ_2), with HbF constituting the major fraction (50% to 85%) at term. Because of this, hemoglobinopathies involving β -chain synthesis, such as sickle cell disease and β -thalassemia, do not present in the neonatal period. The G- γ to A- γ ratio at birth is approximately 3:1, in contrast to a ratio of 2:3 in adults.⁹⁵

P.1024

HbA accounts for 15% to 40% of the hemoglobin at term and HbA2 is present in only trace amounts (mean, 0.3%), but increases slowly after birth, reaching the normal adult level (2% to 3%) by 5 months. The level of HbF at birth is influenced by a number of variables, the most significant of which is gestational age. Premature infants have more HbF and postmature infants less (Fig. 43.6).⁹⁵ Neonates who have survived chronic intrauterine hypoxia, such as occurs with maternal heart and lung disease, have higher levels of HbF. The switch from γ -chain synthesis to β -chain synthesis appears to be developmentally programmed. Neither intrauterine transfusion nor neonatal exchange transfusion affects the synthetic rates of β - and δ -chains.⁹⁶

HbF has an affinity for oxygen that is greater than that of HbA.⁹⁷ The oxygen tension at which the hemoglobin of cord blood is 50% saturated is 19 to 21 mm Hg, 6 to 8 mm Hg lower than that of the hemoglobin of normal adult blood. This shift to the left of the hemoglobin-oxygen dissociation curve results from poor binding of 2,3-DPG by HbF.⁹⁸ The position of the oxygen dissociation curve is determined by both the percentage of HbA and the red cell content of 2,3-DPG.⁹⁹ As the relative proportion of HbA increases, the oxygen dissociation curve shifts by approximately 4 to 6 months of age to a position that is normal for the adult (Fig. 43.7). The increased oxygen affinity of HbF confers a physiologic advantage to the fetus in facilitating the transfer of oxygen from mother to fetus.

HbF is resistant to alkali denaturation, and unlike HbA is not eluted from fixed blood smears immersed in an acid buffer.¹⁰⁰ This property permits the differential staining of HbF and HbA, a technique used to detect fetal cells in the maternal circulation.

FETAL AND NEONATAL ANEMIA DUE TO HEMOLYSIS

Bilirubin is effectively cleared from fetal blood by the placenta and is metabolized by the maternal liver.¹⁰¹ As a result, fetal hemolytic disease does not present with significant jaundice immediately at birth. However, after birth the products of heme catabolism must be processed by the neonate's liver, which is limited in its ability to metabolize bilirubin efficiently, in part because of a relative deficiency of the cytoplasmic acceptor protein ligandin, and in part because of decreased activity of uridine diphosphoglucuronyl transferase.¹⁰²

Causes of hemolytic disease in the newborn are noted in Table 43.3. Worldwide, isoimmunization caused by maternal-fetal blood group incompatibility is the most common cause of hemolytic anemia. Antigens in the ABO, MN, Rh, Kell, Duffy, and Vel systems are well developed on fetal red cells during early intrauterine life.¹⁰³ They are present in the fifth to seventh gestational week and remain constant through the remainder of intrauterine development. Other antigens, such as the Lutheran and XgA systems, develop more slowly but are present at birth, unlike Lewis antigens, which develop after birth. By 2 years of age, red cell and plasma antigens have developed a pattern that is seen throughout the remainder of life.¹⁰⁴

FIGURE 43.6. Decline in fetal hemoglobin synthesis as a function of gestational age. Solid dots represent cord blood samples from preterm infants, open circles are samples from term infants. (From Bard H. The postnatal decline of hemoglobin F synthesis in normal fullterm infants. *J Clin Invest* 1975;55:395-398, with permission.)

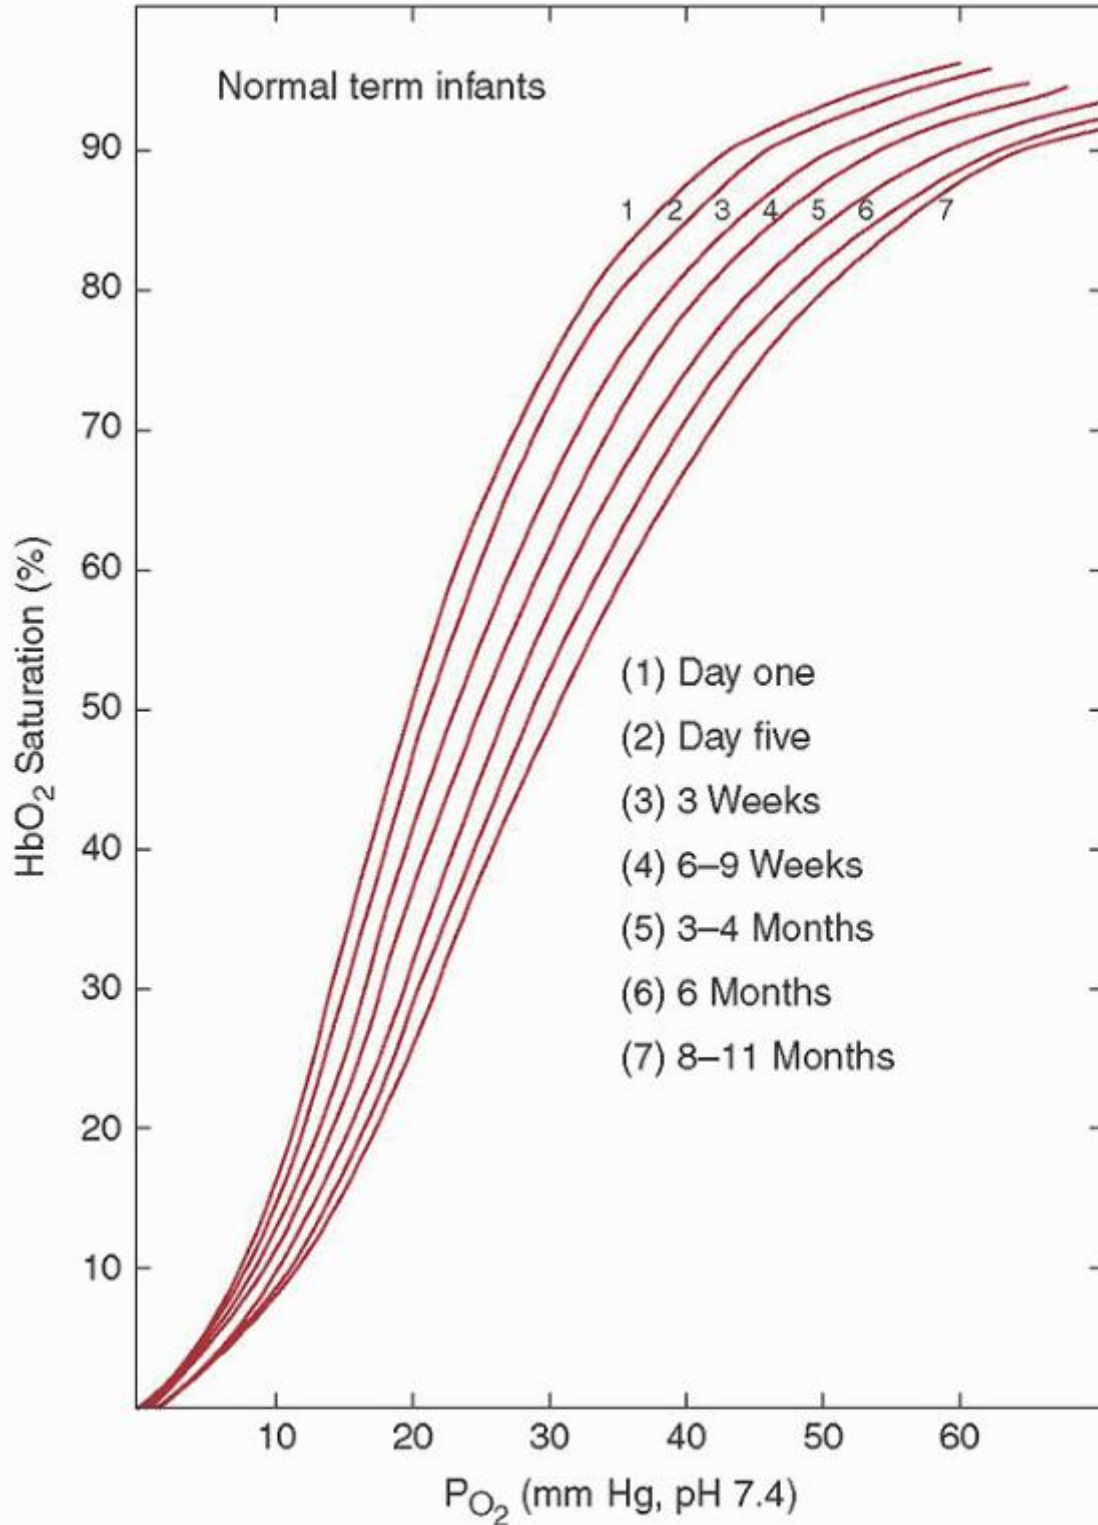

FIGURE 43.7. Oxygen dissociation curves of blood from term infants at different postnatal ages. (From Oski FA, Delivoria-Papadopoulos M. The red cell 2,3-diphosphoglycerate, and tissue oxygen release. *J Pediatr* 1970;77:941-956, with permission.)

Although A and B antigens are present early in utero, A and B isoagglutinin production occurs later during the second and third trimesters.¹⁰⁴ By 30 to 34 weeks gestation, about one half of all fetuses have some measurable anti-A or anti-B

antibodies. The fetal production of such antibodies is not related to maternal blood type, rather, intrauterine exposure to gram-negative organisms whose antigens are chemically related to those of blood groups A and B act as a potent stimulus for antibody development. Isoimmunization due to Rh or ABO incompatibility is the most common cause of hemolytic disease in the newborn period. ABO incompatibility represents a spectrum of hemolytic disease in newborns.

Fetuses with hemolytic anemia due to anti-Kell antibody have lower reticulocyte counts and total serum bilirubin levels than comparable anti-D anemic fetuses.¹⁰⁵ The level of hemolysis caused by anti-Kell antibodies is less than that caused by anti-D antibodies, but fetal erythropoiesis is blunted because Kell sensitization results in both suppression of fetal erythropoiesis and hemolysis. Anti-Kell antibodies cause fetal anemia by suppressing erythropoiesis at the level of erythroid progenitors.

P.1025

TABLE 43.3 CAUSES OF HEMOLYTIC DISEASE IN NEWBORNS

Immune-mediated

- Rh incompatibility (anti-D antibody)
- ABO, c, C, e, E, G incompatibility
- Minor blood group incompatibility:
 - Fya (Duffy), Kell group, Jka, MNS, Vw
- Drug-induced (penicillin, α -methyldopa, cephalosporins)
- Maternal autoimmune hemolytic anemia

Non-Immune mediated

Congenital erythrocyte enzyme defects

- Glucose-6-phosphate dehydrogenase deficiency
- Pyruvate kinase deficiency
- Hexokinase deficiency
- Glucose phosphate isomerase deficiency
- Pyrimidine 5' nucleotidase deficiency

Hereditary erythrocyte membrane disorders

- Spherocytosis
- Elliptocytosis
- Stomatocytosis
- Pyropoikilocytosis
- Other membrane disorders

Infection

- Bacterial sepsis (*Escherichia coli*, group B streptococcus)
- Parvovirus B19 (can present with hydrops fetalis)
- Congenital syphilis
- Congenital malaria
- Congenital TORCH infections (toxoplasmosis, rubella, cytomegalovirus,

disseminated herpes)

Other congenital viral infections

Hemoglobin defects

α -Thalassemia syndromes

γ -Thalassemia syndromes

α - and γ -Chain structural anomalies

Macro- and microangiopathic hemolysis

Cavernous hemangiomas

Arteriovenous malformations

Renal artery stenosis or thrombosis

Other large vessel thrombi

Severe coarctation of the aorta

Severe valvular stenoses

Other causes

Disseminated intravascular coagulation

Hypothyroidism

Galactosemia

Lysosomal storage diseases

Prolonged metabolic acidosis from metabolic disease (amino acid and organic acid disorders)

High titers of anti-C antibody have been associated with neonatal hemolytic disease.¹⁰⁶ However, routine screening of anti-C titers during pregnancy is not warranted, because antibody titers do not accurately reflect the severity of hemolytic disease.¹⁰⁷ C(w) is a low-frequency antigen in the Rh blood group system with a prevalence of about 2% among Caucasian populations. Anti-C(w) is not too uncommon in pregnancy (0.1% incidence), but clinically significant hemolytic disease of the newborn is very unusual.¹⁰⁸

FETAL AND NEONATAL ANEMIA DUE TO HEMORRHAGE

Hemorrhage can occur at any time during the prenatal, perinatal, and postnatal periods (Table 43.4).

Prenatal Hemorrhage

Small numbers of maternal and fetal erythrocytes cross the placental barrier during pregnancy. The volume of fetal blood identified in the maternal circulation, at delivery, is generally on the order of 0.01 to 0.1 ml. However, approximately 1 in 400 pregnancies is associated with a fetal to maternal hemorrhage of 30 ml or more, and approximately 1 in 2,000 pregnancies are associated with a potential fetal transplacental hemorrhage of 100 ml or more.¹⁰⁹ To detect and quantify fetal-maternal hemorrhage, flow cytometric-based methods, quantifying erythrocytes with HbF in the maternal circulation, are more sensitive than the Kleihauer-Betke.¹⁰⁹ Significant fetal-maternal hemorrhage has been described following maternal trauma,¹¹⁰ but most cases have no identified antecedent.

Term neonates born after a large fetomaternal hemorrhage present with pallor and tachypnea but they generally have minimal to no requirement for supplemental oxygen. Hemoglobin concentrations can be extremely low at birth, between 4 and 6 g/dl, and a significant metabolic acidosis is often present as a result of poor perfusion.

Twin-twin transfusion occurs in 5% to 30% of monochorionic twin gestations and involves placental anastomoses that allow net transfer of blood from one twin to the other.¹¹¹ The perinatal mortality rate can be as high as 70% to 100%, depending on severity

and timing of presentation. Approximately 70% of monozygous twin pregnancies have monochorionic placentas.¹¹² Although vascular anastomoses are present in almost all such cases, not all of those develop twin-twin transfusion.

TABLE 43.4 CAUSES OF HEMORRHAGE IN THE FETUS/NEONATE

Prenatal

Chronic and/or acute twin-to-twin transfusion syndrome

Chronic and/or acute fetal-maternal hemorrhage

Hemorrhage into amniotic fluid after periumbilical blood sampling

Traumatic amniocentesis

Maternal trauma

Trauma after external cephalic version

Perinatal

Placental abruption

Placenta previa

Vasa previa

Trauma or incision of placenta during cesarean section

Ruptured normal or abnormal (varices, aneurysms, hematoma) umbilical cord

Placental hematoma

Velamentous insertion of the cord

Nuchal cord

Postnatal

Subgaleal hemorrhage

Cephalohematoma

Hemorrhage associated with disseminated intravascular coagulation/sepsis

Intraventricular/intracranial hemorrhage (prematurity, trauma, isoimmune thrombocytopenia)

Organ trauma (liver, spleen, adrenal, renal, gonadal)

Pulmonary hemorrhage

Iatrogenic blood loss (phlebotomy, central line accidents)

Acute twin-twin transfusion generally results in twins of similar size but with hemoglobin concentrations that vary by more than 5 g/dl. In chronic twin-twin transfusion, the donor twin becomes progressively anemic and growth retarded, whereas the recipient becomes polycythemic, macrosomic, and sometimes hypertensive. Both can develop hydrops fetalis; the donor twin becomes hydropic from profound anemia, and the recipient from congestive heart failure and hypervolemia. The donor twin often has low amniotic fluid volumes, whereas the recipient twin has increased amniotic fluid.

Chronic twin-twin transfusion can be diagnosed by serial prenatal ultrasounds measuring cardiomegaly, discordant amniotic fluid production, and fetal growth discrepancy of >20%. Percutaneous umbilical blood sampling can determine if hemoglobin concentration differences of greater than 5 gm/dl exist between the two fetuses.¹¹³ After birth, the donor twin may require transfusions and can also experience neutropenia, hydrops from severe anemia, growth retardation, congestive heart failure, and hypoglycemia. The recipient twin is often the sicker of the two. Problems include hypertrophic cardiomyopathy, congestive heart failure, polycythemia, hyperviscosity, respiratory difficulties,

hypocalcemia, and hypoglycemia. Neurologic evaluation and imaging are helpful because of the risk of neurologic cerebral lesions in 20% to 30% of both twins.¹¹⁴

Prenatal treatment for twin-twin transfusion consists of close monitoring and reduction amniocenteses to decrease uterine stretch and prolong the pregnancy. Treatment in utero using laser surgery to ablate bridging vessels has become more common in the past decade. Most recent reports conclude an improvement in fetal survival using selective laser ablation.^{115, 116, 117}

Perinatal Hemorrhage

Obstetric complications, such as placenta previa, abruption, incision or tearing of the placenta during cesarean section, and cord evulsion, can result in significant neonatal blood loss. Placental abruption involves premature separation of the placenta from the uterus and occurs in 3 to 6 per 1,000 live births.¹¹⁸ Risk factors for abruption include cigarette smoking, prolonged rupture of the membranes, chorioamnionitis, hypertension (before pregnancy and pregnancy-induced), and advanced maternal age.^{119, 120, 121} The incidence of abruption increases with lower gestational age, and abruption can be a cause of preterm delivery.¹²⁰ Mortality ranges from 0.8 to 2.0 per thousand births, or 15% to 20% of the deliveries in which significant abruption occurs.

Placenta previa involves part or all of the placenta overlying the cervical os. Maternal risk factors for developing a placenta previa are essentially the same as those for abruption.^{122, 123} Vasa previa (anomalous vessels overlying the internal cervix os) can be made with transvaginal color Doppler, and should be suspected in any case of antepartum or intrapartum hemorrhage. Although vasa previa is uncommon (1 in 3,000 deliveries), the perinatal death rate is high, ranging from 33% to 100% when undetected before delivery.¹²⁴

Infants born after placental abruption or previa can be hypovolemic due to prenatal hemorrhage. Although the majority of the blood loss is maternal, loss of fetal blood can also occur, thus in neonates born after abruption or previa it is important to monitor blood pressure, hemoglobin/hematocrit, and tissue perfusion.

Cord rupture can occur during delivery due to traction on a shortened, weakened, or otherwise abnormal umbilical cord. Cord aneurysms, varices, and cysts can all lead to a weakened cord. Cord infections (funisitis) can also weaken the cord and increase the risk of rupture. Hematomas of the cord occur infrequently (1 in 5,000 to 6,000 deliveries) and can be a cause of fetal blood loss and fetal death. Hematomas of the cord can be diagnosed in utero by ultrasound and differentiated from other lesions of the placenta and cord.¹²⁵

Velamentous insertion of the umbilical cord occurs when the cord enters the membranes distant from the placenta, and is present in approximately 0.5% to 2.0% of pregnancies. These vessels are more likely to tear, even in the absence of traction or trauma. The fetal mortality is high in this condition, because rapid detection is difficult.¹²⁶

Postnatal Hemorrhage

Loss of fetal blood during delivery can occur into the placenta. The fetal-placental-umbilical cord unit contains about 120 ml/kg of blood, at term. After delivery, but before the umbilical cord is severed, blood in this unit can flow predominantly toward or away from the neonate. A fetoplacental hemorrhage can occur when the neonate is held significantly higher than the placenta after birth, for instance, on the mother's abdomen. It has been suggested that neonates can lose 10% to 20% of their blood volume when born with a tight nuchal cord, which allows blood to be pumped through umbilical arteries toward the placenta, while constricting flow back from the placenta to the baby, through the umbilical vein, which is more easily constricted due to its thin wall structure. However, in a study of over 200,000 deliveries, those with a tight nuchal cord (6.7%) did not have outcomes different from those with loose nuchal cords or with no nuchal cords.¹²⁷ On that basis, it is not clear that tight nuchal cords typically cause clinical problems.

Hemorrhage into the subgaleal space can be a life-threatening neonatal complication.¹²⁸ However, the spectrum of severity ranges widely, from a small asymptomatic hemorrhage to a massive one causing hypovolemic shock. Associations are well known between vacuum or forceps-assisted delivery and subgaleal hemorrhage, but some cases occur when neither vacuum nor forceps were applied. In 38 neonates recently reported with a subgaleal hemorrhage, 21 occurred after vacuum, two after forceps, four after vacuum followed by forceps, and 11 when neither vacuum nor forceps were used. Thirty-five were admitted to an intensive care unit. Transfusions were given to 13, but no transfusions were given in the group where neither vacuum nor forceps was used, suggesting their hemorrhages were less severe.¹²⁸

Anemia appearing after the first 24 hours of life in a nonjaundiced infant can be a sign of hemorrhage. Visible hemorrhages, such as a cephalohematoma, as well as internal occult hemorrhages, can occur. Breech deliveries may be associated with renal, adrenal, or splenic hemorrhage into the retroperitoneal space. Delivery of macrosomic infants, such

as infants born to diabetic mothers, can result in hemorrhage. Infants with overwhelming sepsis can bleed into soft tissue and organs, such as liver, adrenal glands, and lungs.

The liver in a neonate is prone to iatrogenic rupture, resulting in a high morbidity and mortality.¹²⁹ Infants may appear asymptomatic until the liver ruptures and hemoperitoneum occurs. This can occur in term and preterm infants¹³⁰ and has been associated with chest compressions during cardiopulmonary resuscitation. Surgical intervention involving vascular tamponade has been reported to save some infants; however, the mortality remains high.¹³¹

Splenic rupture can result from birth trauma or as a result of distention caused by extramedullary hematopoiesis. Abdominal distension and discoloration, scrotal swelling, and pallor are clinical signs of splenic rupture; these signs may also be seen with adrenal hemorrhage or hepatic rupture.¹³² Other rare causes of postnatal hemorrhage include hemangiomas of the gastrointestinal tract,¹³³ vascular malformations of the skin, and hemorrhage into soft tumors, such as giant sacrococcygeal teratomas or ovarian cysts.

P.1027

FETAL AND NEONATAL ANEMIA DUE TO CONGENITAL INFECTION

Neonatal bacterial sepsis can cause anemia on the basis of hemolysis, DIC, and/or hemorrhage. Neonates with sepsis are generally jaundiced and have hepatosplenomegaly. Some bacterial organisms responsible for neonatal sepsis produce hemolytic endotoxins that result in accelerated erythrocyte destruction.¹³⁴

Congenital infections due to cytomegalovirus, toxoplasmosis, rubella, syphilis, and herpes simplex can also cause hemolytic anemia. Fetal and neonatal infection with parvovirus B19 can cause severe anemia, hydrops, and fetal demise.¹³⁵ The fetus or neonate generally presents with a hypoplastic anemia, but hemolysis can occur as well. The virus replicates in erythroid progenitor cells and results in red cell aplasia. In utero transfusions for hydropic fetuses can be successful. Intrauterine fetal infusion of B19 IgG-rich high titer gammaglobulin has been reported to be successful.¹³⁶

Other fetal infections associated with neonatal anemia include malaria and HIV. Congenital malaria is seen rarely in the United States, generally in large cities where imported cases of malaria are increasing. In certain African countries, congenital malaria has been reported in up to 20% of neonates.¹³⁷ Congenital HIV infection in a neonate is generally asymptomatic. However, infants born to mothers on zidovudine can have a hypoplastic anemia due to suppressive effects of the drug on fetal erythropoiesis.¹³⁸

ANEMIA OF PREMATURITY AND OTHER HYPOPROLIFERATIVE DISORDERS

Impaired erythrocyte production can occur in a fetus or neonate for a variety of reasons. Lack of an appropriate or sufficient marrow environment (as seen in osteopetrosis), lack of specific substrates or their carriers (e.g., iron, folate, vitamin B₁₂, or transcobalamin II deficiency), and lack of specific growth factors (e.g., decreased erythropoietin production or abnormalities in Epo receptors) can be causative.

Anemia of Prematurity

Infants delivered before 32 completed weeks gestation typically develop a transient and unique anemia known as the anemia of prematurity.¹³⁹ During the first week or two after birth, while in an intensive care unit, anemia secondary to phlebotomy loss is common.¹⁴⁰ However after this period has passed, a second anemia is sometimes seen; it is characterized as a normocytic, normochromic, hyporegenerative anemia, with serum erythropoietin concentrations significantly below those found in adults with similar degrees of anemia.¹⁴¹ This anemia is not responsive to the administration of iron, folate, or vitamin E. Some infants with the anemia of prematurity are asymptomatic, whereas others have clear signs of anemia that are alleviated by erythrocyte transfusion. These signs include tachycardia, rapid tiring with nipple feedings, poor weight gain, increased requirements for supplemental oxygen, episodes of apnea and bradycardia, and elevated serum lactate concentrations.^{139, 140, 141}

The reason preterm infants do not significantly increase serum erythropoietin concentration during this anemia is not known.¹⁴² Indeed, it is unclear whether production of erythropoietin does in fact increase, yet the serum concentration does not. Certainly their erythroid progenitors are sensitive to erythropoietin,^{143, 144} and concentrations of other erythropoietic growth factors appear to be normal.¹⁴⁵

The molecular and cellular mechanisms responsible for the anemia of prematurity are multifactorial, and include the transition from fetal to adult hemoglobin, shortened erythrocyte survival, and hemodilution associated with a rapidly increasing body mass.^{139, 140} It is unknown whether preterm infants rely on erythropoietin produced by the liver (the

source of erythropoietin in utero), or that produced by the kidney, or a combination of the two. Regardless of the mechanism responsible for the anemia of prematurity, exogenous erythropoietin administered to preterm infants accelerates effective erythropoiesis.^{146, 147} A meta-analysis of studies evaluating the use of “late erythropoietin administration to prevent and treat the anemia of prematurity reveals a positive effect on decreasing transfusion requirements in preterm infants.¹⁴⁸ In addition, beneficial neurodevelopmental effects of recombinant erythropoietin administration have been reported in preterm infants.^{17, 18, 19, 20, 149, 150}

Pharmacokinetic studies of darbepoetin, the long-acting erythropoietic stimulator, have been conducted among neonates with the anemia of prematurity, with the speculation that less frequent dosing and cost savings might render darbepoetin a more attractive alternative than recombinant erythropoietin for treating the anemia of prematurity.^{151, 152, 153, 154} Following subcutaneous and intravenous dosing, darbepoetin has a considerably shorter terminal half-life in neonates than in adults (Table 43.5). Intravenous dosing appears to be as effective as subcutaneous dosing.¹⁵³ Newer, long-acting Epo mimetics, such as CERA (continuous erythropoiesis receptor agonist), have yet to be studied in neonates, but may hold promise as potential agents to decrease transfusions and provide neuroprotection. Although a minimal number of clinical studies evaluating darbepoetin administration to preterm infants have been published, numerous RCTs evaluating Epo administration to preterm infants have consistently shown evidence of increased erythropoiesis and a decrease in transfusions.¹⁴¹

A consistent finding in the largest RCTs has been an elevation in hematocrit among Epo-treated infants compared with placebo/controls, despite the implementation of strict transfusion guidelines aimed at maintaining hematocrits in a similar range. For those neonatal practitioners electing to maintain hematocrits at higher levels, the use of Epo can gain a “buffer” of 4% to 6% hematocrit points, decreasing the number of transfusions given. This may benefit preterm infants in a number of ways, given recent studies that have reported associations between RBC transfusions and necrotizing enterocolitis (NEC)¹⁵⁵ and between RBC transfusions and IVH.^{156, 157}

Other Hypoproliferative Anemias

During the neonatal period, hypoproliferative anemias are rare, with the exception of the anemia of prematurity, which is common (Table 43.6). The hypoproliferative anemia Diamond-Blackfan syndrome can be diagnosed at birth, but characteristically is not recognized until after 2 to 3 months of age. In fact, 10% to 25% of infants with Diamond-Blackfan syndrome have at least a mild anemia at birth.¹⁵⁸ Severe anemia with hydrops has been

P.1028

reported in conjunction with this syndrome. Aase syndrome, another congenital hypoplastic anemia syndrome involving marrow and skeletal anomalies,¹⁵⁹ is sometimes classified as a variant of Diamond-Blackfan syndrome. Congenital dyserythropoietic anemia is a rare disorder marked by ineffective erythropoiesis, megaloblastic anemia, and characteristic abnormalities of the nuclear membrane and cytoplasm seen on electron microscopy. Fanconi pancytopenia rarely is manifested during the neonatal period. This autosomal-recessive disorder is characterized by marrow failure and congenital anomalies, including abnormalities in skin pigmentation, gastrointestinal anomalies, renal anomalies, and upper limb anomalies.¹⁶⁰ Approximately one third of patients have no obvious congenital anomalies, and anemia is less common than thrombocytopenia and leukopenia. Five genetic phenotypes of Fanconi pancytopenia have been reported, and two of the genes have been cloned.¹⁶¹ Cells are hypersensitive to DNA cross-linking agents such as diepoxybutane and mitomycin C. The diepoxybutane test represents a sensitive and specific diagnostic test. When Fanconi anemia is recognized in a neonate, it is generally on the basis of the congenital anomalies and not the hematologic abnormalities. However, congenital thrombocytopenia, manifested during the immediate newborn period, progressing to pancytopenia has rarely been reported.¹⁶² Erythropoietin concentrations are usually elevated, and HbF production is increased. A significant percentage of patients develop myelodysplastic syndrome or acute myelogenous leukemia later in life. Treatment of Fanconi pancytopenia includes androgen therapy, and, in many cases, bone marrow transplantation has been successful.

TABLE 43.5 TERMINAL T ½ OF DARBEPOETIN AMONG ADULTS, CHILDREN, AND NEONATES AFTER SUBCUTANEOUS OR INTRAVENOUS DOSING

	After Subcutaneous Dosing (hours)	After Intravenous Dosing (hours)

TABLE 43.6 SYNDROMES ASSOCIATED WITH FETAL/NEONATAL ANEMIA

Genetic Syndrome	Phenotypic Features	Genotypic Features
Adenosine deaminase deficiency	Autoimmune hemolytic anemia, reduced erythrocyte adenosine deaminase activity	AR, 20q13.11
Congenital dyserythropoietic anemias	Type I (rare): megaloblastoid erythroid hyperplasia and nuclear chromatin bridges between nuclei; type II (most common): "hereditary erythroblastic multinuclearity, positive acidified serum (HEMPAS) test, increased lysis to anti-i; type III: erythroblastic multinuclearity ("gigantoblasts), macrocytosis	Type I: 15q15.1-q15.3; type II: 20q11.2; type III: 15q21
Diamond-Blackfan syndrome	Steroid-responsive hypoplastic anemia, often macrocytic after 5 mo of age	AR; sporadic mutations and AD inheritance described; 19q13.2, 8p23.3-p22
Dyskeratosis congenita	Hypoproliferative anemia usually presenting between 5 and 15 yr of age	X-linked recessive, locus on Xq28; some cases with AD inheritance
Fanconi pancytopenia	Steroid-responsive hypoplastic anemia, reticulocytopenia, some macrocytic RBCs, shortened RBC lifespan. Cells are hypersensitive to DNA cross-linking agents	AR, multiple genes: complementation; group A: 16q24.3; B:: C: 9q22.3; D2: 3p25.3; E: 6p22-p21; F: 11p15; G: 9p13
Osler hemorrhagic telangiectasia syndrome	Hemorrhagic anemia	AD, 9q34.1
Osteopetrosis	Hypoplastic anemia from marrow compression; extramedullary erythropoiesis	AR: 16p13, 11q13.4-q13.5; AD: 1p21; lethal: reduced osteoclasts
Pearson syndrome	Hypoplastic sideroblastic anemia, marrow cell vacuolization	Pleioplasmatic rearrangement of mitochondrial DNA; X-linked or AR
Peutz-Jeghers syndrome	Iron-deficiency anemia from chronic blood loss	AD, 19p13.3
X-linked α -thalassemia/mental retardation (ATR-X and ATR-16) syndromes	ATR-X: hypochromic, microcytic anemia; mild form of hemoglobin H disease ATR-16: more significant hemoglobin H disease and anemia are present	ATR-X: X-linked recessive, Xq13.3; ATR-16: 16p13.3, deletions of α -globin locus

AD, autosomal dominant; AR, autosomal recessive; RBC, red blood cell.

Autosomal-recessive osteopetrosis is a rare disorder characterized by osteoclast dysfunction, resulting in a decreased bone marrow space.¹⁶³ Developmental delay, ocular involvement, and neurodegenerative findings occur in association with hypoplastic anemia. Patients are generally treated with hematopoietic stem cell transplantation, but they are particularly susceptible to posttransplantation complications after myeloablation, and reduced-intensity conditioning programs may be helpful.¹⁶⁴

Pearson syndrome is a congenital hypogenerative anemia that can progress to pancytopenia, and additionally affects the exocrine pancreas, liver, and kidneys.¹⁶⁵ Patients with this syndrome can present during the neonatal period, but typically do so later in infancy, often in the first year of life. Presenting features include failure to thrive, with anemia, neutropenia, and/or thrombocytopenia. The marrow examination typically shows characteristic vacuoles within erythroid and myeloid precursors, hemosiderosis, and ringed sideroblasts. The syndrome is caused by a loss of large segments of mitochondrial DNA.^{166, 167}

CONSIDERATIONS REGARDING ERYTHROCYTE TRANSFUSION IN THE NEONATAL PERIOD

Transfusion of banked donor erythrocytes can be life saving for small and ill neonates with severe anemia or hemorrhage. However, risks of transfusions exist and must be weighed against potential benefits each time a transfusion is considered. Two transfusion risks are highly unique to VLBW (<1,500 g) infants. The first is an association between RBC transfusions administered in the first few days after birth and the subsequent occurrence of a grade 3 or 4 IVH.^{156, 157, 167} The second is an association between RBC transfusions administered during the third to fourth week and the subsequent occurrence of NEC.^{155, 167, 168, 169, 170, 171, 172} Much remains to be discovered about the pathogenic links between transfusions and these adverse outcomes, and more work is needed to establish whether transfusions are causatively associated with these adverse outcomes or are co-variables.¹⁶⁸

P.1029

Means of avoiding transfusion among VLBW infants are listed in Table 43.7 and include: (1) Delay clamping of the umbilical cord, (2) strip or milk the cord, (3) draw all initial laboratory tests from fetal blood in the placenta and thereby draw no blood from the neonate, (4) reduce phlebotomy losses in the first days and weeks, (5) adopt written transfusion guidelines, (6) remove unnecessary indwelling catheters, (7) use an early dose(s) of erythropoietin or darbepoetin, and (8) optimize nutrition.

The idea of sterilely salvaging anticoagulated fetal blood from the umbilical cord and placenta at the time of birth, for a subsequent autologous transfusion for small or sick neonates has had limited study.^{173, 174, 175, 176, 177} Harvesting cord blood from term pregnancies for stem cell transplantation is successful and popular.¹⁷⁶ However, harvesting from extremely preterm deliveries has practical limitations that have prevented this from becoming routine practice.¹⁷⁷ A few reports have used a modification of this practice for transfusion immediately after birth, aimed at immediate volume expansion of ill and small neonates.^{178, 179, 180, 181} Most such reports describe processing and storing the fetal blood in case a transfusion is needed in the subsequent days or weeks. Reports from Japan¹⁸² and Germany¹⁸³ describe successful cord/placental blood transfusion for neonates with surgical problems. Earlier studies by Golden et al. demonstrated bacteriologic safety of this practice when the blood is used within 4 hours of delivery.^{174, 175} As better means are developed for harvesting, storing, and administering autologous fetal blood from extremely preterm deliveries, the benefits of using this blood, rather than donor blood, for early transfusions might outweigh the risks.^{184, 185, 186}

The recent use of bi- or multiprobe near infrared spectroscopic (NIRS) monitoring in the NICU has provided new evidence of a benefit of RBC transfusions in selected patients.¹⁸⁷ Tissue oxygenation is estimated by NIRS on the basis of different near infrared light absorbance by oxyhemoglobin versus deoxyhemoglobin. Unlike pulse oximetry, NIRS evaluates hemoglobin oxygen saturations deeper in the tissue, about 2 cm below the skin surface, thus reflecting values from mixed arteriolar, venous, and capillary sources. When oxygen delivery to tissues becomes limited by anemia, oxygen extraction increases and venous oxygen saturation falls.¹⁸⁷

Van Hoften et al. used NIRS monitoring to evaluate 33 preterm neonates before, during, and after a clinically ordered transfusion of 15 ml/kg RBC infused over a period of 3 hours.¹⁸⁸ They found that regional cerebral tissue oxygen saturation and the fractional tissue oxygen extraction correlated with the pretransfusion hemoglobin level, with lower hemoglobin levels predicting a lower cerebral oxygen tension. Their data supported the conclusion that a blood hemoglobin concentration <9.7 g/dl in a preterm infant corresponds with diminished cerebral oxygenation, and that erythrocyte transfusion improves this parameter. Dani et al. from Florence, Italy reported on 15 preterm infants using similar methodology, and came to a similar conclusion, that in neonates with a hemoglobin below about 6 g/dl, transfusion can often increase cerebral, splanchnic, and renal oxygenation.¹⁸⁹ Bailey et al. applied biprobe NIRS monitoring during a 20-minute period just before a clinically ordered RBC transfusion; 40 such measurements (each integrated over 30 seconds) were made.^{190, 191} One probe on the forehead was intended to assess cerebral and one on the abdomen to assess splanchnic changes. The measurements from each site were averaged into a ratio of oxygen saturations measured from the cerebral and splanchnic sites. The ratios were expressed as a SCOR (splanchnic-cerebral oxygenation ratio). Ratios

were correlated with independent means of judging whether the transfusion actually provided a benefit. A SCOR at or below 73% (meaning the average oxygenation in the splanchnic circulation was $\leq 73\%$ of the cerebral circulation) performed well in identifying the neonates who were likely to benefit from a transfusion.

TABLE 43.7 STRATEGIES FOR REDUCING ERYTHROCYTE TRANSFUSIONS AMONG VERY LOW BIRTH WEIGHT NEONATES

- Delay clamping of the umbilical cord by 45 to 60 sec after birth, with the neonate in a position lower than the placenta.
- Strip or milk the umbilical cord at birth, moving additional blood from the placenta and umbilical cord into the neonate, before the umbilical cord is clamped.
- Draw all initial laboratory blood tests (blood culture, CBC, etc.) using fetal blood in the umbilical cord/placenta, thereby initially drawing no blood from the neonate.
- Develop a consistent approach to minimizing phlebotomy losses in the first days and weeks.
- Adopt written transfusion guidelines.
- Remove indwelling catheters once they are not critically needed.
- Early dose(s) of recombinant erythropoietin or darbepoetin.
- Optimize nutrition.

With recent technological and other creative advances, it is becoming clear that NICU transfusions should not be ordered simply on the basis of the hemoglobin/hematocrit values. Better practice guidelines will likely consider NIRS and other measures of oxygen delivery to determine transfusion need.

Chapter 44

Erythrocytosis

Robert T. Means, Jr.

DEFINITIONS AND TERMINOLOGY

The terms polycythemia and erythrocytosis are often used as if they are interchangeable; in fact, they describe related but distinct findings that usually, but not always, coexist. Polycythemia (“many cells”) describes an increase in the total quantity or volume (mass) of red blood cells in the body without any implication regarding leukocytes or platelets. An increase in the concentration of erythrocytes, however, whether measured as number of cells, hemoglobin (Hb), or packed cell volume (PCV, hematocrit), is more correctly designated erythrocytosis. Erythrocytosis may be the result of an increase in the red cell volume or mass (polycythemia; also called absolute erythrocytosis) or the result of a reduced plasma volume (called relative or spurious polycythemia or erythrocytosis), which produces an increase in red cell concentration that does not reflect an increase in the quantity of red cells in the body.

Despite the precision with which these terms are defined, opportunities for confusion abound. Polycythemia vera (also called polycythemia rubra vera) is a myeloproliferative disorder associated with trilineage marrow hyperplasia and characterized by an increased red cell mass, usually in association with leukocytosis and thrombocytosis. The outdated term erythremia refers to this disease (see Chapter 82). Some patients who do not have this myeloproliferative disease are described as having polycythemia vera simply because they have an elevated red cell mass (i.e., their polycythemia is “true” [“vera”]). Confusion on this point is frequently encountered in consultative hematology practice.

PATHOLOGIC PHYSIOLOGY

Red cell survival in polycythemic states is typically normal, implying that increased red cell mass reflects increased erythropoiesis. As the red cell mass rises, the total blood volume typically increases: the variability of changes in plasma volume means that the degree of increase is unpredictable.¹

The clinical manifestations of erythrocytosis are related in part to the disorder responsible for erythrocytosis (e.g., thrombosis in patients with polycythemia vera,² hypertension in relative polycythemia,³ etc.). In addition, the increased blood volume and increased blood viscosity that occur in association with polycythemia themselves produce certain symptoms and signs; these are related to the degree of the increase and the resulting effects on blood flow and oxygen transport.⁴ Thus, the “ruddy cyanosis” seen in patients with polycythemia vera is a consequence of dilatation of cutaneous vessels by expanded blood volume and sluggish local circulation caused by increased blood viscosity.^{5, 6, 7} Headache, dizziness, tinnitus, a full feeling in the head, and a bleeding tendency may develop in patients with erythrocytosis and expanded blood volume regardless of the basic cause.^{8, 9, 10, 11} These symptoms usually are relieved by normalization of the hematocrit.

Blood Viscosity and Oxygen Transport

Viscosity is an intrinsic characteristic of a liquid and represents the tendency of that liquid to resist changes in shape. The viscosity of blood is a result of the interaction of several factors, including the red cell concentration by volume, the physical characteristics (deformability, aggregability, and size) of red cells, the plasma volume, plasma proteins, platelet count, and leukocyte number and character.¹² In this chapter, the red cell concentration by volume is referred to as the hematocrit, reflecting common usage. Other authors, particularly those studying rheology and oxygen transport, refer to this parameter as the volume of packed red blood cells or PCV. As discussed below, the blood viscosity affects the oxygen content and delivery. This section focuses primarily on the contribution of red cell concentration to viscosity and oxygen transport; more complete discussions are available elsewhere.¹²

The rate of flow of a liquid through a tube of fixed length is directly related to the pressure gradient across that length of tube and to the radius raised to the fourth power (r^4) and inversely related to the viscosity of that liquid (Poiseuille's law).^{9, 10, 13, 14} Determinations of the effects of erythrocytosis on blood viscosity were largely made by determining the flow rate of venous blood through an 18-gauge needle under known pressure and thus calculating viscosity.¹⁴ The values thus determined are only an approximation of the in vivo situation. Poiseuille's law is strictly applicable only to fluids that maintain constant viscosity under differing flow rates; this is not the case with blood (Fig. 44.1).^{13, 14} As the velocity of flow (indicated by the shear rate) increases, the viscosity at any given hematocrit decreases.¹⁴ Other factors that interact with the hematocrit to contribute to viscosity are the mean erythrocyte corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH).^{15, 16, 17} At any given hematocrit, decreased MCV or MCH (or both) is associated with increased viscosity, especially at low flow rates.^{16, 17} This is a clinically significant observation, because iron deficiency (low MCV) with a normal Hb

P.1033

or hematocrit is a common endpoint of the treatment of polycythemia by phlebotomy.

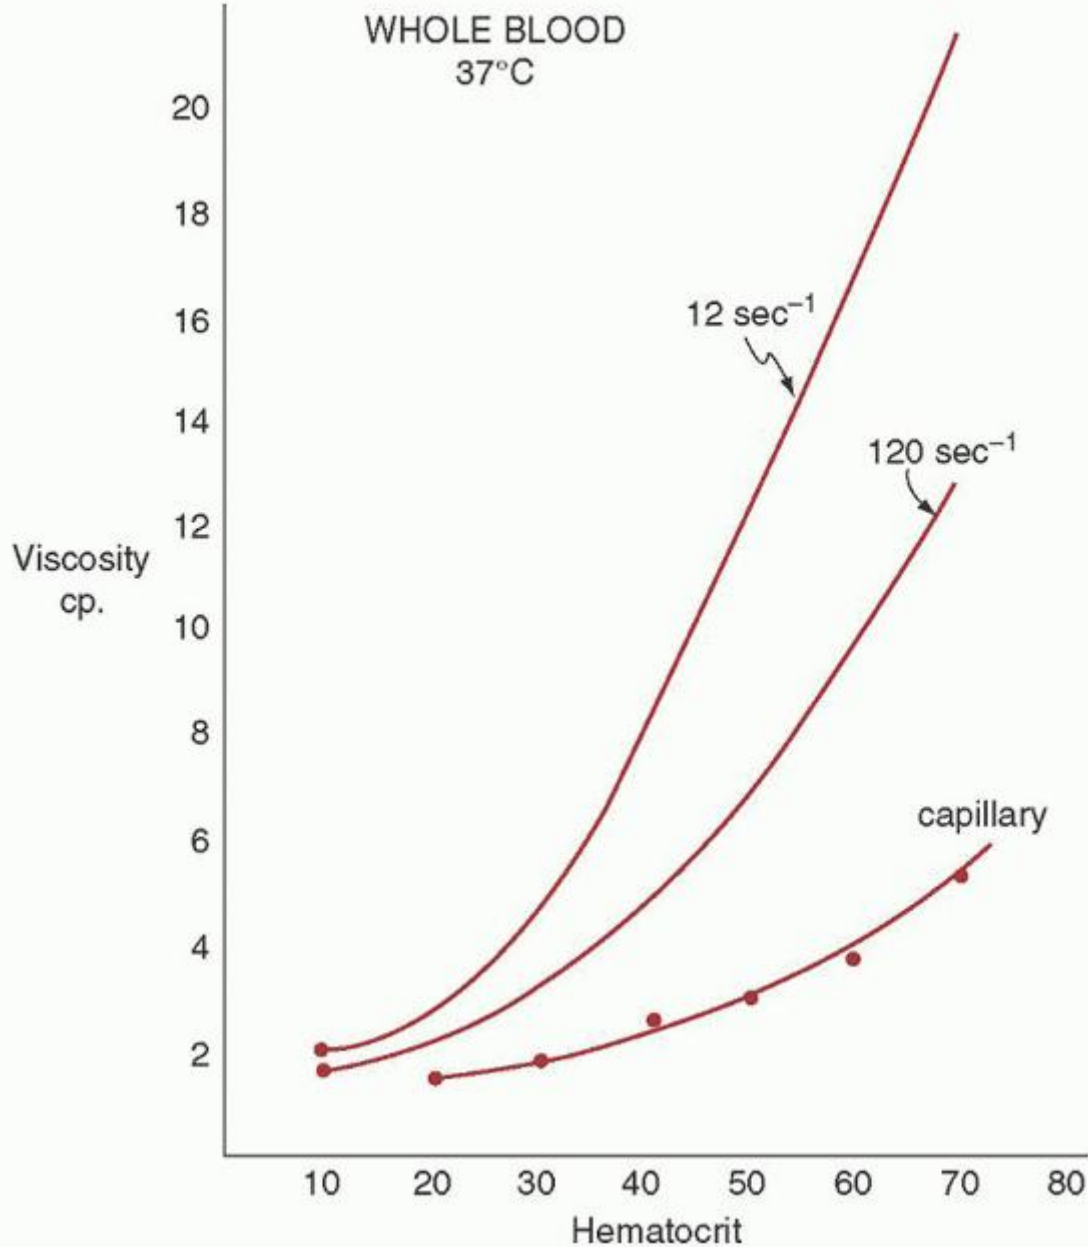

FIGURE 44.1. Relation of volume of packed red cells (hematocrit) to blood viscosity in centipoise (cp) as measured in a capillary viscosimeter compared with that calculated for shear rates of 120 sec^{-1} (ascending aorta) and 12 sec^{-1} (medium arteriole). (From Wells RE Jr, Merrill EW. The variability of blood viscosity. *Am J Med* 1961;31:505, with permission.)

It is noted above that the model for determining blood viscosity represents a somewhat artificial system: calculated values probably exceed those existing in vivo.¹³ However, studies of cerebral blood flow in patients with erythrocytosis of various etiologies have demonstrated the clinical effects of an elevated hematocrit on in vivo blood flow.^{18, 19, 20, 21} Cerebral blood flow in patients with erythrocytosis was significantly reduced compared to controls whether it was due to an elevated red cell mass,¹⁹ due to reduced plasma volume,^{20, 21} or of unknown etiology¹⁸ (Table 44.1). Hematocrit reduction, either by venesection^{18, 19, 20, 21} or by volume expansion,²¹ improved cerebral blood flow.

The determination of blood viscosity values at different hematocrits allows the estimation of blood flow rates under different conditions. As Poiseuille's law predicts (and the data in Table 44.1 imply), blood flow decreases linearly with increasing viscosity.²² The rate of oxygen transport can then be calculated from the blood flow rate and oxygen content. At a given vessel size and pressure gradient, the predicted relation of oxygen transport to hematocrit is expressed by an arch-shaped curve (Fig. 44.2A).^{14, 22, 23} At low hematocrits, the reduced Hb content of blood translates into reduced

oxygen content. At elevated hematocrits (>0.5 to 0.6), increased viscosity reduces oxygen transport despite increased blood oxygen content. Optimal oxygen transport would be predicted to occur in the normal hematocrit range.^{22, 23, 24, 25, 26} Experiments in normovolemic dogs (Fig. 44.2B, dashed line) support this prediction.²³

The differences in oxygen transport observed between normovolemic and hypervolemic dogs at different hematocrits (Fig. 44.2B) reflect the probable situation occurring in patients with erythrocytosis due to an expanded red cell mass (polycythemia). In polycythemia, the associated hypervolemia permits an oxygen transport curve that is similar to that of normovolemic patients but which is elevated and shifted to the right.^{23, 26} Therefore, in patients with tissue hypoxia, polycythemia is beneficial because it leads to hypervolemia and increases oxygen transport (compare oxygen transport at hematocrit 0.6 on the hypervolemic and normovolemic curves in Fig. 44.2B). In contrast, in patients who have a normal or decreased total blood volume (as in relative or spurious polycythemia), erythrocytosis has an adverse effect on oxygen transport.

Relation to Treatment of Polycythemia

The considerations noted above are of interest in understanding not only the pathophysiology of the different etiologies of erythrocytosis, but also their treatment. Patients with polycythemia vera have no need for increased tissue oxygen transport. In some areas where fixed vessel diameter (from arteriosclerosis) limits increased blood flow, however, the additional impeding effect of increased blood viscosity may limit oxygen transport and result in local tissue ischemia. Phlebotomy can bring about a significant clinical benefit (see Chapter 82). When treating by phlebotomy, however, blood volume should not be reduced too greatly at any one episode, especially in patients with known symptoms of cardiovascular disease (angina pectoris, transient ischemic attacks). This is particularly true early in the course of therapy, when hematocrit (and consequently viscosity) is highest.²⁷ Rather, time should be allowed for hemodilution to occur between phlebotomies; in emergencies, the blood volume should be maintained by infusing saline or some other plasma expander.⁶ A concern is that the patient not suddenly be shifted from the hypervolemic, erythrocytosis-beneficial curve to the normovolemic, erythrocytosis-adverse curve. Another concern is that a sudden fall in blood volume from any cause, such as dehydration or acute hemorrhage, may result in local ischemia because increased cardiac output cannot compensate immediately for the effects of high viscosity. In patients with congestive heart failure, the need for reduction of blood viscosity may be urgent, because the ability to increase cardiac output to compensate for the increased blood viscosity has been compromised. The oxygen-Hb dissociation curve is shifted to the right in such patients.²⁸

TABLE 44.1 EFFECT OF ERYTHROCYTOSIS ON CEREBRAL BLOOD FLOW

Etiology of Erythrocytosis (No. of Patients)	Reference	CBF (ml/100 g/min)	Percent Normal CBF
Polycythemia ¹⁶	19	37.9 ± 11.2	54.8 ± 16.2
Mixed ³⁹	18	41.4 ± 10.5	63.6 ± 16.2
Relative polycythemia	20		
High-normal red blood cell mass ²¹		45.8 ± 10.9	66.8 ± 15.9
Low plasma volume ¹⁸		48.8 ± 12.9	71.1 ± 18.8
Relative polycythemia ⁵	21	40.7 ± 5.4	59.9 ± 7.8

Note: Values expressed as mean ± standard deviation.

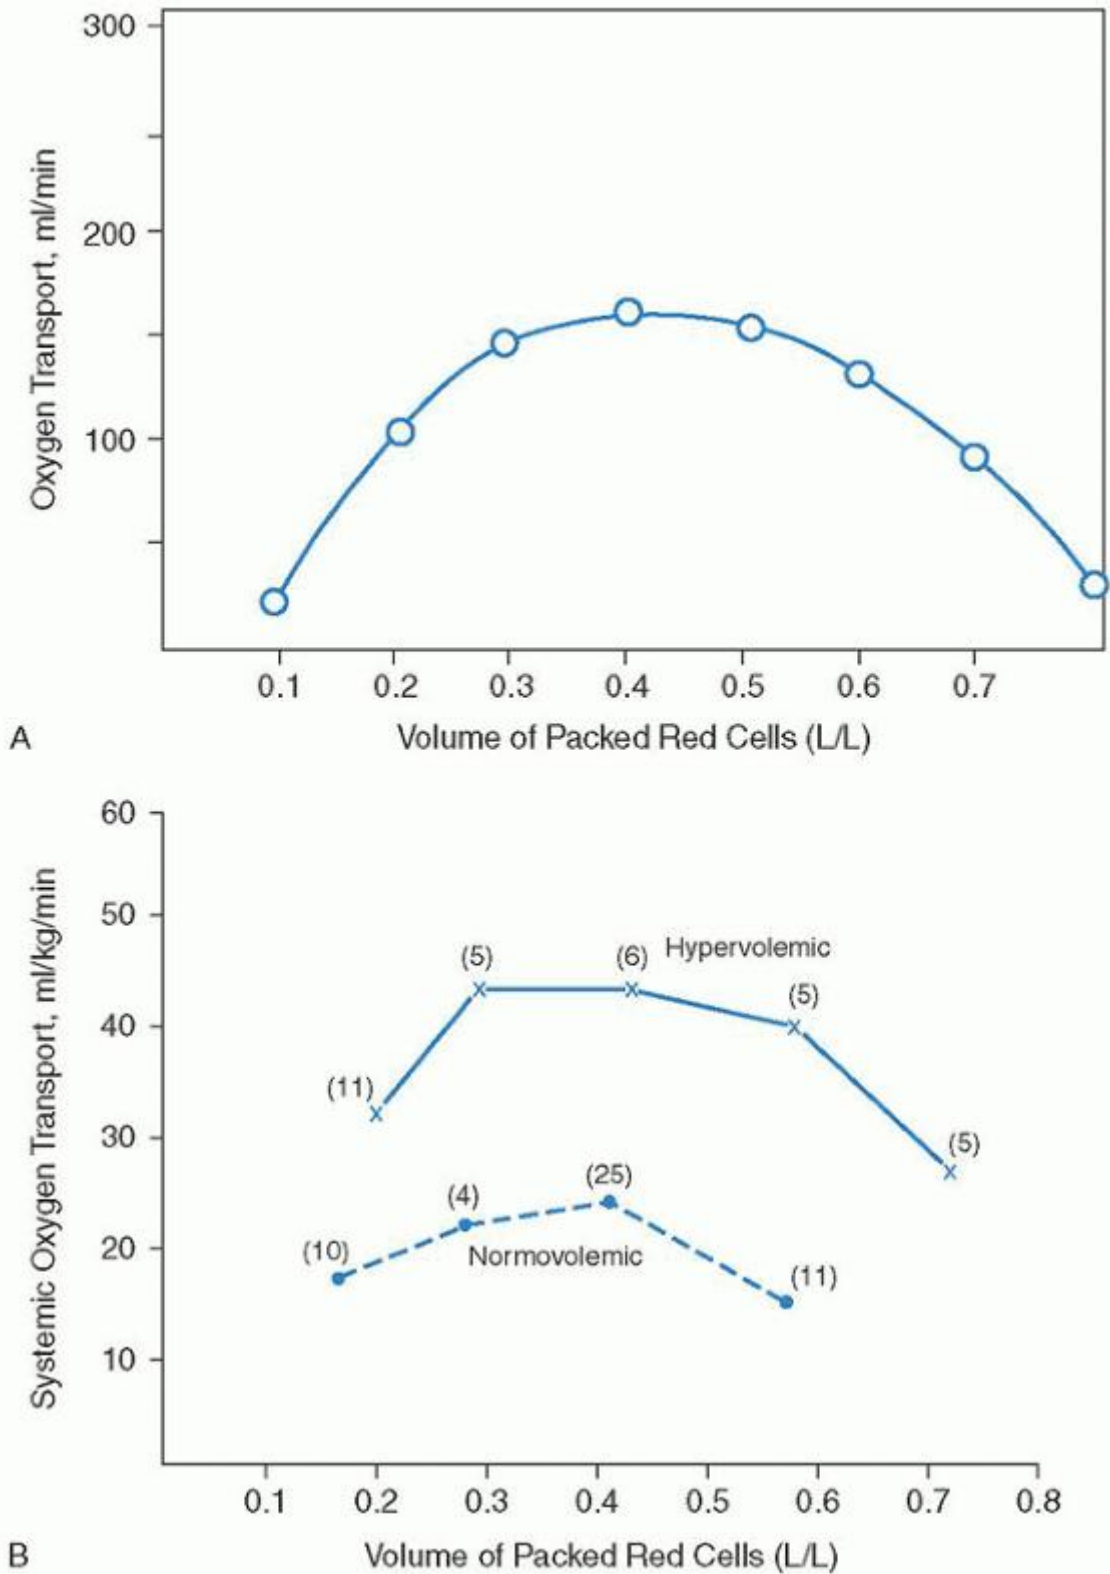

FIGURE 44.2. Arterial oxygen transport at different volumes of packed red cells and thus different viscosity values. A: Values in curve were calculated from blood viscosity values as measured by Pirofsky.⁹ B: Systemic oxygen transport as calculated from cardiac output measured in normovolemic and hypervolemic dogs. (From Murray JF, Gold P, Johnson BL Jr. The circulatory effects of hematocrit variations in normovolemic and hypovolemic dogs. *J Clin Invest* 1963;42:1150-1159, with permission.)

In contrast to polycythemia vera, patients with polycythemia due to tissue hypoxia may benefit from an increased hematocrit.

P.1034

Reduced arterial oxygen saturation means that blood oxygen transport is less efficient at particular Hb or hematocrit levels. Therefore, the curves for oxygen transport would be shifted closer to the origin than those noted in situations in which Hb oxygenation is normal (Fig. 44.2B). In the presence of decreased arterial oxygen saturation, tissue hypoxia may persist even when erythrocytosis is marked. The main advantage to decreasing blood viscosity and blood volume in hypoxic (secondary) polycythemia is to decrease the cardiac workload. One would predict that in such situations an increase in tissue oxygen transport and clinical improvement should result from phlebotomy; results show that this is the case.²⁹ Again, especially early in the course, phlebotomy with preservation of an expanded blood volume may be beneficial.^{6, 27} To achieve the best balance between increased cardiac work and decreased tissue hypoxia in patients with hypoxemic erythrocytosis, some authors suggest that the hematocrit be maintained between 0.50 and 0.55;^{6, 29} however, the subjective symptomatology of the patient is usually the best guide.²²

CLASSIFICATION AND APPROACH TO THE PATIENT WITH ERYTHROCYTOSIS

An increase in hematocrit (erythrocytosis) may result from decreased plasma volume or from polycythemia, which is an increase in the absolute quantity of red cells or red cell mass. The various forms of erythrocytosis are listed in Table 44.2. They are classified according to red cell mass (relative erythrocytosis or polycythemia vs. actual polycythemia). Polycythemia, in turn, is divided into primary polycythemia (polycythemia vera and familial primary polycythemia/primary proliferative polycythemia) and polycythemia driven by erythropoietin production (secondary polycythemia). The secondary polycythemic syndromes are divided into those that represent a response to tissue hypoxia (physiologically appropriate) and those driven by erythropoietin not produced in response to tissue hypoxia (physiologically inappropriate).

TABLE 44.2 CLASSIFICATION OF ERYTHROCYTOSIS

Relative Erythrocytosis or Polycythemia (Spurious Polycythemia)

Hemoconcentration

Spurious polycythemia (Gaisböck syndrome)

Polycythemia (Absolute Erythrocytosis)

Primary polycythemia

Polycythemia vera

Primary familial polycythemia

Secondary polycythemia

Secondary to decreased tissue oxygenation (physiologically appropriate polycythemia or hypoxic erythrocytosis)

High-altitude erythrocytosis (Monge disease)

Pulmonary disease

Chronic cor pulmonale

Ayerza syndrome

Cyanotic congenital heart disease

Hypoventilation syndromes

Primary alveolar hypoventilation

Pickwickian syndrome, Ondine curse

Positional desaturation

Sleep apnea

Abnormal hemoglobins

Inherited

Acquired: Drugs and chemicals, carboxyhemoglobin

Familial polycythemia

Secondary to aberrant erythropoietin production or response (physiologically inappropriate polycythemia)

Tumors, cysts, hemangiomas, and so forth

Androgen abuse

Erythropoietin abuse

Familial polycythemia

Idiopathic polycythemia

An approach to the evaluation of the patient with erythrocytosis is outlined in Figures 44.3 and 44.4. Although actual polycythemia can usually be differentiated from relative polycythemia on clinical grounds (as described below), an assessment of the red cell mass is the initial step in evaluation. Traditionally, this has been done by measurement of red cell mass and blood volume by isotope labeling. Normal values are presented in Table 44.3, but considerable variation exists from one subject to another in red cell, plasma, and total blood volume, even when expressed as milliliters per kilogram (ml/kg) body weight. This variation results, in part, from differences in body fat content^{31, 32, 33, 34}; blood volume is more closely related to lean body mass³³ than to weight or surface area. It has been proposed that a red cell mass of at least 125% of that predicted should be considered as indicating polycythemia.³⁵ It has been a common practice at many to measure either plasma volume or red cell volume and, from one of these determinations, to calculate total blood volume on the basis of the relative amounts as indicated by a hematocrit determination. In the view of most,^{36, 37, 38} but not all,¹⁵ investigators, this practice is associated with an increased chance of error; measuring red cell mass and plasma volume separately is preferable. It must be emphasized that blood volume measurements do not differentiate between secondary polycythemia and polycythemia vera; they are useful only in distinguishing absolute from relative erythrocytosis.

However, availability of actual red cell volume measurement has become limited to a small number of large medical centers with special expertise. Surrogate measures based on Hb or hematocrit are now the routine basis for distinguishing relative and actual polycythemia. In men with a hematocrit > 0.60 or women with a hematocrit > 0.55, there is reported to be >99% likelihood that the red cell mass is elevated.³⁹ In its 2007 criteria for the diagnosis of polycythemia vera, the World Health Organization (WHO) uses an Hb concentration of >18.5 g/dl in men or 16.5 g/dl in women to define an elevated red cell mass.⁴⁰ In a comparative study, the hematocrit 0.60/0.55 standard was reported to identify elevated red cell mass more accurately than the Hb concentration 18.5/16.5 g/dl standard.⁴¹ It should be noted that in certain circumstances of severe hemoconcentration (e.g., in the systemic capillary leak syndrome⁴²), Hb concentrations or hematocrits in this range may be observed in patients with a normal red cell mass. Such patients typically exhibit anasarca and other physical findings suggestive of severe intravascular volume depletion and redistribution of intravascular volume.

The goal of the approach outlined in Figures 44.3 and 44.4 is initially to distinguish spurious (relative) polycythemia from actual polycythemia, then to distinguish polycythemia vera from secondary polycythemia and primary proliferative polycythemia, to rule out other primary polycythemia, and finally to identify the etiology of secondary polycythemia. The characteristics of polycythemia vera are outlined in Chapter 82; the other polycythemic syndromes are discussed below. A certain number of patients are not readily classified as having either polycythemia vera or secondary polycythemia. These patients fall into a category called (for want of a more physiologic term) idiopathic polycythemia or idiopathic erythrocytosis and appear to represent a heterogeneous group of disorders (see below).

The diagnostic approach to polycythemia has been substantially altered by the observation that more than 95% of patients with polycythemia vera express a mutation in the JAK2 gene in which phenylalanine is substituted for valine at position 617.^{43, 44, 45} JAK2 V617F mutation-negative polycythemia vera patients have been reported to have mutations in other exons of JAK2.⁴⁶

P.1035

P.1036

It is tempting to regard the JAK2 mutation in polycythemia vera as conceptually analogous to the bcr/abl mutation in chronic myelogenous leukemia; however, the JAK2 V617F mutation is also found in other myeloproliferative disorders.⁴⁴ Its implications are discussed in more detail in Chapter 82, but in terms of differential diagnosis, it should be regarded as a marker of a myeloproliferative state. Polymerase chain reaction-based assays for JAK2 V617F versions of this test are widely available through reference laboratories in the United States and Europe at costs in the \$300 to \$500 range. As the role of JAK2 assessment in the approach to myeloproliferative disorders continues to expand, increasing numbers of medical centers are developing in-house tests for JAK2 V617F.

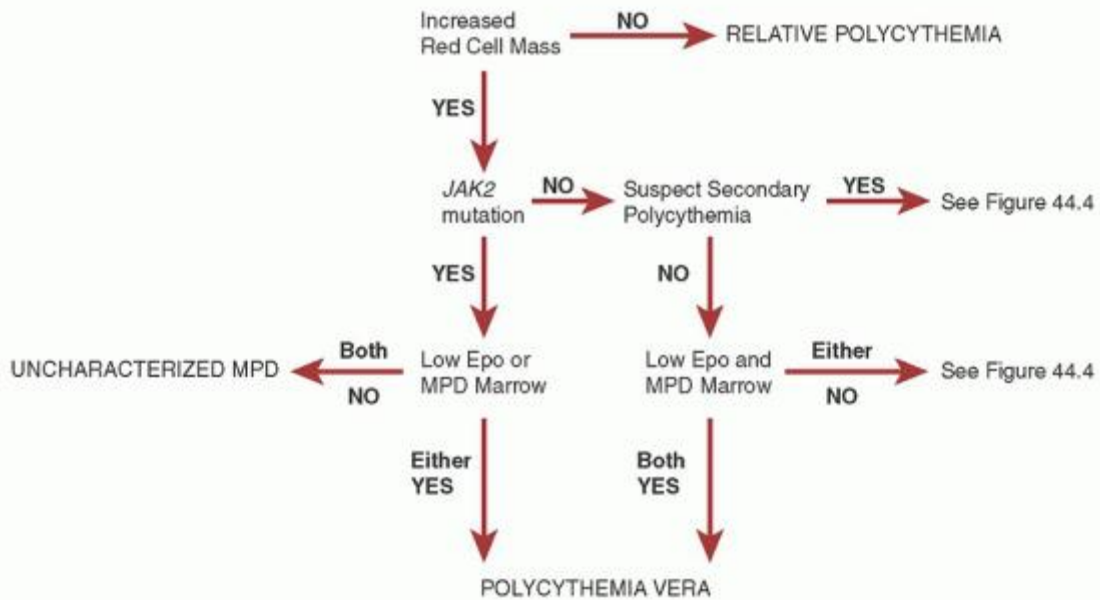

FIGURE 44.3. Approach to patients with erythrocytosis. EEC, endogenous erythroid colonies; EpoR, erythropoietin receptor; JAK2 mutation, testing for JAK2 V617F or other mutations associated with polycythemia vera; low Epo, serum or plasma erythropoietin concentration less than the lower limit of normal; MPD, myeloproliferative disorder; MPD marrow, bone marrow findings suggestive of a myeloproliferative disorder (see text); MPD, myeloproliferative disorder; VHL, von Hippel-Lindau protein.

	No.	Red Blood Cells	Plasma	Total Blood Volume
Women				
Sea level				
Wennesland et al. ³⁴	97	25.4 ± 2.6	36.8 ± 3.7	—
Huff and Feller ³¹	20	24.4 ± 2.6	34.8 ± 3.2	58.9 ± 4.9
Men				
Sea level				

Wennesland et al. ³⁴	199	28.3 ± 2.8	34.4 ± 4.0	—
Huff and Feller ³¹	42	28.3 ± 4.1	33.5 ± 5.2	61.5 ± 8.6
Weil et al. ³⁰ 1,600 m ^b	16	27.1 ± 3.7	33.0 ± 5.3	60.0 ± 8.6
Weil et al. ³⁰ 3,100 m ^b	19	26.8 ± 3.2	31.9 ± 3.6	58.7 ± 5.8
Weil et al. ³⁰	39	31.8 ± 6.7	35.2 ± 5.3	66.8 ± 8.5

^aRed blood cell volume measured by ⁵¹Cr method. Other values calculated without correction for trapped plasma.

^b Only values of which we are aware at altitudes significantly above sea level. They may be somewhat low for unknown reasons; the packed cell volumes at 1,600 m were the same as at sea level, a finding that contradicts an earlier author's own large experience.

The WHO criteria for the diagnosis of polycythemia vera requires evidence of an increased red cell mass, and a JAK2 or other functionally similar mutation and one minor criterion; or evidence of an increased red cell mass and all three minor criteria.⁴⁰ The minor criteria are a serum or plasma erythropoietin concentration below the range of normal for the laboratory; a bone marrow examination exhibiting the characteristic features of a myeloproliferative disorder (hypercellularity with trilineage hyperplasia, clustered pleomorphic megakaryocytes, and no features of inflammation) and the formation of erythroid colonies in vitro in the absence of added erythropoietin ("endogenous erythroid colonies"[EECs]).⁴⁰ Although these tests can be evaluated in any order desired, ease of test access would suggest that erythropoietin concentration be ordered first, followed by marrow evaluation if necessary. In a JAK2 mutation-positive patient, either a characteristic erythropoietin concentration or a characteristic marrow would permit the diagnosis of polycythemia vera. In a JAK2 mutation-negative patient, absence of both a characteristic erythropoietin concentration and a characteristic marrow would rule out the diagnosis. EEC assays, a hallmark of myeloproliferative disorders in general,^{47, 48} are not readily available outside of research laboratories, which limits their diagnostic practicality.

The roles of erythropoietin levels and EEC assays in the differential diagnosis of erythrocytosis are most strongly supported by their association with the WHO diagnostic criteria; as stand-alone tests in individual cases, utility is less clear.^{49, 50, 51} Although mean serum erythropoietin concentration in the subset of patients with polycythemia vera is significantly lower than that observed in secondary polycythemia, there is considerable overlap, making it less useful for individual cases. This would be expected physiologically. A patient with secondary polycythemia due to tissue hypoxia would have an elevated serum erythropoietin level until the hematocrit was sufficiently high to oxygenate tissue adequately; then the erythropoietin concentration would be expected to decrease. The intermittent nature of detection of an elevated serum erythropoietin concentration in secondary polycythemia has been described,⁵² as has the failure of serum erythropoietin concentrations to predict clinical course in idiopathic erythrocytosis.⁵³ Studies have been reported demonstrating that polycythemia vera and secondary polycythemia can be distinguished based on the serum erythropoietin response to phlebotomy: after phlebotomy, serum erythropoietin levels increase in secondary polycythemia but remain stable in polycythemia vera.⁴⁹ EECs corresponding to erythroid burst-forming units were observed in 12 of 17 polycythemia vera patients, 3 of 11 secondary polycythemics, 1 of 6 relative polycythemics, and 1 of 11 normal individuals in one series.⁵⁴

Soluble transferrin receptors are typically elevated in all forms of polycythemia and thus do not distinguish polycythemia vera and secondary polycythemia.⁵⁵

As a general approach to the evaluation of erythrocytosis, all patients with presumed polycythemia should undergo JAK2 V617F testing. If the clinical features are suggestive of a secondary etiology of polycythemia, patients who do not show a JAK2 mutation should follow the process outlined in Figure 44.4. Individuals without a documented JAK2 mutation but in whom suspicion of a myeloproliferative disorder is high, should be investigated for minor WHO criteria (Fig. 44.3).

RELATIVE POLYCYTHEMIA

Lowered fluid intake, marked loss of body fluids, or a combination of both causes a decrease in plasma volume and may produce a relative erythrocytosis. The decrease in plasma volume may result from any cause of intravascular fluid loss, insensible fluid loss, persistent vomiting, severe diarrhea, copious sweating, postoperative complications, or shift of fluid into the extravascular space ("third spacing")^{3, 37, 42, 56} or may be an effect of high altitude.⁵³ In severe burns, plasma loss leads to hemoconcentration.

Chronic relative polycythemia or erythrocytosis has been variously referred to as Gaisböck syndrome,⁵⁷ “stress” erythrocytosis,³ benign polycythemia,^{52, 56} benign erythrocytosis,⁵⁸ spurious polycythemia,^{59, 60} pseudopolycythemia,⁶¹ and apparent polycythemia.⁶² The last three terms are the most accurate: in the absence of an elevated red cell mass, there is no polycythemia. In one series of 215 patients referred with a diagnosis of polycythemia vera,⁶³ 18 (8.3%) were believed to have chronic relative erythrocytosis, possibly caused by “stress.”³ Patients with relative polycythemia or erythrocytosis are typically male; the mean age at diagnosis is less than is seen in patients with polycythemia vera.⁶² Obesity is typically described as an associated feature,³ although not all studies support this association.⁶⁴ Other features reported to be strongly associated with relative polycythemia are hypertension and smoking;^{62, 64, 65} associations with alcohol abuse and renal disease are occasionally reported.^{62, 63} It is probable that this syndrome is not a true clinical entity.⁶⁰ The red cell mass values generally accepted as normal at sea level, or at any given altitude, represent the mean ± 2 standard deviations. Thus, on the basis of the normal frequency distribution curve for this physiologic parameter, the values in 2.5% of the population are above this range. The individuals in this group should not be regarded as necessarily abnormal.⁶⁶

The optimal management of relative polycythemia is unknown. As noted previously, phlebotomy increases cerebral blood flow even in patients with relative polycythemia; whether it is of

P.1037

symptomatic benefit is less clear.^{20, 21} It should probably be avoided. Theoretic arguments can be made that contracting the blood volume further in these patients who already are normovolemic or slightly hypovolemic may impair tissue perfusion. Satisfactory control of hematocrit can be obtained in at least two thirds of patients by reduction of excess weight, improved hypertension control, avoidance of diuretics, and reduction if not cessation of smoking.⁶⁴ Potentially leukemogenic cytoreductive therapy, such as radioactive phosphorus or oral chemotherapeutic agents, is probably never indicated.

Some types of high-affinity Hbs (Heathrow,⁶⁷ Pierre-Benite,⁶⁸ Rahere⁶⁹) may show relative polycythemia.

POLYCYTHEMIA (ABSOLUTE ERYTHROCYTOSIS)

Primary Polycythemia

Polycythemia Vera

Polycythemia vera is discussed in Chapter 82.

Primary Familial Polycythemia (“Chuvash Polycythemia”)/Primary Proliferative

Polycythemia familial erythrocytosis or polycythemia is a term used to describe instances in which two or more members of a family have polycythemia, do not have polycythemia vera, and have no identifiable “secondary” causes.⁷⁰ This finding can result from a constellation of pathophysiologic mechanisms, including abnormalities of oxygen-Hb interaction, or idiopathic constitutive erythropoietin secretion. These syndromes are discussed under etiologies of secondary polycythemia, below.

Primary familial polycythemia is a term used to describe a syndrome observed in families with abnormalities of the erythropoietin receptor, resulting in hypersensitivity to erythropoietin and consequent erythrocytosis.^{71, 72, 73} This particular autosomal dominant trait does not necessarily confer an adverse prognosis early in life: the propositus of the first such family described was an Olympic gold medalist in cross-country skiing.⁷¹ However, these individuals are at increased risk for thrombotic and vascular mortality later on. A variant of this syndrome occurs with high frequency among the people of the Chuvashia region of the former Soviet Union.⁷⁴ These individuals appear to have a mutation in the oxygen-sensing pathway regulating erythropoietin production, typically involving von Hippel-Lindau protein, and also in the response of erythroid progenitors to erythropoietin.^{75, 76, 77, 78} This effect on erythropoietin signaling appears to be mediated by loss of JAK2 regulation of erythropoiesis.⁷⁹ As in other patients with familial erythrocytosis due to aberrant erythropoietin signaling, Chuvash polycythemia patients have increased risk for vascular disease.⁸⁰ Isolated cases with similar mechanisms are referred to as primary proliferative polycythemia.

Secondary Polycythemia (Physiologically Appropriate [Hypoxic])

Insufficient oxygen supply to the tissues may result from any of the following, alone or in combination: (a) decreased ambient oxygen pressure (e.g., high altitude); (b) pulmonary diffusion or mixing abnormalities; (c) right-to-left cardiopulmonary shunts, as in cyanotic congenital heart disease; (d) hypoventilation; or (e) altered oxygen-carrying

affinity of Hb. In all of these disorders, insufficient tissue oxygenation leads to increased erythropoietin production and a consequent increase in red cell mass (see Chapter 6).

High-altitude Erythrocytosis

In 1890, Viault showed that erythrocytosis develops during sojourn at high altitude.⁸¹ He found erythrocyte counts of 7.5 to 8.0×10^{12} cells/L not only in natives of the Peruvian Andes working in a mine at an altitude of 4,392 m above sea level, but also in himself and in a traveling companion, although his blood count in Lima (160 m above sea level) had been normal. On a Mt. Everest expedition, researchers demonstrated that red cell volume and values of total Hb rose progressively as higher altitudes were attained; at 19,000 feet (5,800 m), mean values were 49% above those at sea level. The increase in total blood volume was partially masked by reductions in plasma volume.^{82, 83} A sharp increase in erythropoietin production occurs within the first week of high-altitude exposure and is associated with mobilization of iron stores and evidence of iron-deficient erythropoiesis.⁸⁴ Mechanisms of adaptation to living at high altitude apparently are multiple and differ between ethnic groups.^{85, 86}

The rapid ascent to high altitude is accompanied by symptoms of fatigue, dizziness, pulsating headache, anorexia, nausea, vomiting, insomnia, and irritability, a syndrome well known to mountain climbers and residents of high altitudes and referred to as acute mountain sickness or acute altitude disease.^{87, 88, 89, 90} The symptoms first appear some 4 to 6 hours after reaching a high altitude but may be delayed for as many as 96 hours, suggesting that the pathogenesis represents more than simple hypoxia. The incidence is greatest in younger persons, in those flying to high altitude, or in those who climb fast and spend few nights acclimatizing. Gender, the weight of the load carried, and recent respiratory infection do not appear to affect the incidence.⁸⁸ Severity is greatest in the young and in less-experienced climbers and correlates with the speed of ascent and the altitude reached.⁹¹ Thus, all persons develop symptoms if they are suddenly transported from sea level to 15,000 feet (4,570 m) or higher, whereas a few develop symptoms at 8,000 to 10,000 feet (2,400 to 3,000 m).⁸³ After 4 to 8 days, acclimatization usually occurs, and symptoms remit spontaneously.^{88, 92} In some individuals, however, symptoms may progress to cerebral confusion, coma, and even death related to pulmonary edema unless the subject is returned to low altitude.^{87, 93}

The pathogenesis of acute mountain sickness may involve hypoxia and subsequent excessive secretion of antidiuretic hormone and adrenal steroids with resulting fluid retention, increased blood volume, and finally cerebral edema, pulmonary congestion, or both.^{94, 95, 96, 97, 98} The incidence and severity of symptoms can be considerably reduced or prevented by appropriate treatment.⁹⁹

The events associated with acclimatization after arrival at high altitude are not understood completely but probably include the following:

- An increase in erythrocyte 2,3-biphosphoglycerate (BPG) levels and a shift to the right in the oxygen-Hb dissociation curve, thus allowing better tissue delivery of oxygen despite decreased arterial oxygen saturation.^{86, 100, 101, 102} The increase in 2,3-BPG appears to compensate for the left shift in the curve that results from the initial hypocapnia and increase in arterial pH.^{100, 103}
- Increased erythropoietin production with subsequent increase in iron mobilization, reticulocytosis, and increase in red cell mass and blood volume.¹⁰⁴
- Correction of the initial excessive antidiuretic hormone and adrenal steroid secretion and return to the normal diurnal variation of plasma steroid levels.⁹⁸

The final result is a new equilibrium at decreased oxygen saturation and carbon dioxide tension with increases in alveolar ventilation, respiratory frequency, and red cell mass.⁹² These manifestations of acclimatization are quickly lost on descent to sea level, even after many years of residence at high altitude.

In some individuals, however, after a few or many years of good adaptation, excessive erythrocytosis develops, and arterial oxygen saturation may fall to as low as 60% (normal, 81%).

P.1038

An incapacitating illness characterized by alveolar hypoventilation develops. This entity is known as chronic mountain or altitude sickness or Monge disease.¹⁰⁵ Diminished mental acuity, headaches, dyspnea, fatigue, reduced physical fitness, nausea, vomiting, diminution of visual acuity, dizziness, tinnitus, vague or even excruciating pains in the extremities, paresthesias, and cough are characteristic symptoms. If the condition advances, symptoms include incessant dyspnea, aphonia, profound lethargy, and even coma. The face is bluish violet or almost black, the eyelids are edematous and

bluish, the sclerae are intensely colored by distended capillaries, the tongue is thick, the hands are enlarged and turgid, the fingers are clubbed, and dependent edema may be observed. The thorax is more barrel-shaped than in healthy inhabitants of the same region and altitude. Hypotension is often present. The spleen and the liver are infrequently enlarged, unless cardiac failure ensues.

Erythrocytosis is more marked than in normal residents of high altitudes, with hematocrits up to 0.84 L/L and Hb values as high as 28.0 g/dl. MCV is normal or slightly increased, and the mean corpuscular hemoglobin concentration (MCHC) is normal. Normal reticulocyte and leukocyte counts are usually observed. Hyperbilirubinemia owing to unconjugated bilirubin may be pronounced. Red cell turnover is greater in these individuals than in normal residents of high altitudes. Platelet counts usually are normal or high, yet epistaxis is common, and hemoptysis, bleeding of the gums, and purpura may occur. Red cell volume is greatly increased (88 to 95 ml/kg body weight). The results do not appear to be completely explainable by differences in erythropoietin production.^{105, 106, 107, 108, 109, 110}

Affected individuals usually are in the fourth to sixth decade of life. Remissions and relapses are described. Ascent to still higher altitudes aggravates symptoms, whereas descent to sea level relieves them. Cardiac impairment does not appear until late in the disease course, and death occurs more often from hemorrhage, pulmonary tuberculosis, or bronchopneumonia than from cardiac insufficiency.

At first, the disease was considered a distinct entity. It has been suggested that the disease is an exaggeration of the process of acclimatization and aging, because patients with chronic mountain sickness had Hb concentrations within the normally distributed values for large groups of native residents. Support for this suggestion comes from the observation that chronic lung disease increases the likelihood of chronic mountain sickness.¹¹¹ Chronic mountain sickness has not been reported to occur in natives of the Himalayas.¹¹² This may reflect in part occupational differences, namely mining, and a consequently high incidence of chronic lung disease in the Andes as compared with the pastoral occupation of the Sherpas. Investigation of selective gene expression in populations in whom chronic mountain sickness is prevalent, may further enhance understanding of this syndrome.^{113, 114, 115}

Differentiation of chronic mountain sickness from other causes of hypoxic polycythemia should not be difficult. Cases of congenital or acquired cyanotic heart disease can be distinguished by the cardiac findings. Polycythemia vera is not altered by increased ambient oxygen tension, whereas in Monge disease, descent to sea level produces complete relief of symptoms, together with a pronounced reduction in the blood volume and restoration of normal blood counts.¹¹⁶

Pulmonary Disease

A variety of diseases, such as chronic obstructive pulmonary disease, diffuse pulmonary infiltrates (fibrous or granulomatous), kyphoscoliosis, and multiple pulmonary emboli, leads to erythrocytosis as the result of inadequate oxygenation of the blood circulating through the lungs. Not all patients with lung disease and decreased arterial oxygen saturation, however, have elevated Hb or hematocrit levels,^{117, 118} and only in approximately 50% is an increase in red cell mass noted.¹¹⁹ The reason for this suboptimal response to hypoxia is not clear, but it does not appear to result from a decrease in erythropoietin production or the presence of chronic infection.^{117, 118, 120} When polycythemia occurs, it usually is associated with increased MCV, reduced MCHC,¹¹⁹ and normal MCH¹²⁰ values. The red cell morphology changes have been attributed to increased water uptake by the cell, which in turn may result from carbon dioxide retention.¹¹⁷ If polycythemia is present, it is corrected by chronic oxygen administration.¹²¹

Vascular malformations in the lung may also be associated with erythrocytosis.^{122, 123} Pulmonary arteriovenous fistulae should be suspected when a murmur is heard in a lung field in association with erythrocytosis.

Chronic Cor Pulmonale

The clinical picture of chronic cor pulmonale varies, but oxygen deficiency with arterial desaturation and elevated pulmonary artery pressure is of central importance.^{124, 125} Polycythemia with its associated increase in blood viscosity and volume appears to be the physiologic price of a compensatory mechanism progressively extended to the point at which it is more injurious than beneficial.¹²⁶ As in less severe pulmonary disease, the MCV of the red cells tends to be elevated, whereas the MCHC generally is decreased.¹²⁷

Cyanotic Heart Disease

Marked degrees of polycythemia may be seen in patients with a partial shunt of the blood from the pulmonary circuit. Hematocrit levels greater than 0.60 are not uncommon. The most frequent defects producing such polycythemia are pulmonary stenosis (usually with defective ventricular or atrial septum, patent foramen ovale, or patent ductus arteriosus), persistent truncus arteriosus, complete transposition of the great vessels, and the tetralogy of Fallot (pulmonary stenosis, defective ventricular septum, dextroposition of the aorta, right ventricular hypertrophy). Individuals

with such defects exhibit evidence of disturbed cardiorespiratory function, marked cyanosis, clubbing of the fingers and toes, and sometimes stunted growth.

The total plasma volume may be reduced to below normal levels, but the increase in the size of the red cell mass is so great that the total blood volume usually is higher than normal.¹²⁸ Erythroid hyperplasia is observed in the marrow.^{129, 130}

The general consensus is that low oxygen tension resulting from shunting of unoxygenated blood through or around the lungs with consequent desaturation of the arterial blood stimulates erythropoietin production. With successful operative intervention, this value may be significantly corrected, with resolution of polycythemia.

Acquired Heart Disease

In 1901, Abel Ayerza described a syndrome characterized clinically by slowly developing asthma, bronchitis, dyspnea, right-sided heart failure, and severe cyanosis with associated polycythemia.¹³¹ The striking degree of cyanosis led Ayerza to describe these patients as "black cardiacs." It was subsequently demonstrated that the unifying feature of these patients was not pulmonary disease but rather pulmonary arterial hyperplasia, leading to pulmonary hypertension and consequent right-sided heart failure.¹³² In all forms of acquired heart disease, any erythrocytosis that may develop is correlated to some extent with the degree of cardiopulmonary decompensation. It is typically minimal. Polycythemia is reportedly accompanied by evidence of intensified erythropoiesis in the bone marrow, an increase in red cell mass, and some macrocytosis.¹³¹

P.1039

Hypoventilation Syndromes

Polycythemia is found occasionally in patients who exhibit no evidence of pulmonary disease or cardiovascular shunts. The primary defect in at least some of these patients appears to be an inadequate ventilatory drive from the respiratory center in the brain.^{126, 133} A similar defect has been reported in patients with the Pickwickian syndrome, so called because of the description of Joe, the hypersomnolent fat boy, in Dickens's *The Pickwick Papers*.¹³⁴ In the setting of extreme obesity, these patients exhibit somnolence, cyanosis, and hypercapnia and may develop periodic respiration, ultimately with right ventricular failure. Voluntary hyperventilation alleviates the hypercapnia, and in many patients, loss of weight restores normal alveolar ventilation and reverses the syndrome.^{135, 136} Alveolar hypoventilation and erythrocytosis, however, do not develop in all obese individuals; it appears that only in the presence of an insensitive respiratory center does a massive panniculus limit respiratory function and result in alveolar hypoventilation, hypoxemia, and hypercapnia.¹³⁷ In some patients, the decreased ventilatory drive is of unknown cause or is a result of idiopathic disease of the medullary respiratory center (Ondine curse)^{133, 138}; other etiologies include bulbar poliomyelitis, vascular thrombosis, or previous encephalitis.^{126, 137} In any case, the consequent hypoxemia results in elevated levels of erythropoietin and erythrocytosis, with hematocrits reported as high as 0.75⁸.

Patients with polycythemia and positional arterial oxygen desaturation have also been reported.¹³⁹ Whether this results from alveolar hypoventilation while supine or from shunting through an arteriovenous malformation while upright is unclear.¹⁴⁰ Obstructive sleep apnea has been associated with polycythemia (presumably due to episodic erythropoietin secretion during apneic episodes) in some¹⁴¹ but not all¹⁴² reports.

Abnormal Hemoglobins

Inherited Abnormalities of Hemoglobin

Certain mutant Hbs are characterized by increased oxygen, and patients who carry such Hbs tend to develop erythrocytosis.^{143, 144, 145, 146} More than 200 high-affinity Hbs have been characterized, of which roughly half produce significant erythrocytosis.¹⁴⁷ Oxygen-Hb dissociation curves are shifted dramatically to the left in individuals carrying these abnormal Hbs. The degree of left shift can be quantified by determining the P₅₀ (i.e., the oxygen pressure at which Hb is half-saturated). The normal value in whole blood is 23 to 29 mm Hg at standard pH, temperature, CO₂ content, and barometric pressure. The whole-blood P₅₀ is almost invariably decreased in patients with a high-affinity Hb; most values fall between 9 and 21 mm Hg. In a few instances, the P₅₀ has been normal, or nearly so, in whole blood (e.g., HbG Norfolk¹⁴⁸), necessitating the measurement of the oxygen dissociation curve of the purified Hb to demonstrate the defect. The approach to the diagnosis of high-affinity Hb variants, the characteristics of patients with representative mutations, and the molecular pathology are discussed in Chapter 35.

The most important physiologic consequence of increased oxygen affinity is that release of oxygen is impaired at partial pressure of oxygen values normally found in tissues. Uptake of oxygen in the lungs is enhanced, but this effect is relatively unimportant, because normal Hb is nearly completely saturated in the lungs under the usual physiologic circumstances. As previously noted, however, the increased affinity may confer some advantages when environmental oxygen is low, such as at high altitudes.

Individuals with high-affinity Hbs are not at a disadvantage under hypoxic conditions. They tolerate ascent to high altitudes as well as or better than normal subjects and thus appear to be preadapted to hypoxic stresses. Under such conditions, the enhanced oxygen loading seems more important than the impaired delivery. Similarly, exercise tolerance appears unimpaired.¹⁴⁹ There is no evidence that oxygen delivery to the heart is defective in patients with high-affinity Hbs. Although myocardial infarctions and other findings of atherosclerotic cardiovascular disease are reported in these patients, it is unclear whether this is an actual association or simply reflects the high frequency of atherosclerosis in the general population.^{150, 151, 152}

High-affinity Hbs appear to exert no adverse effects on fetal development in utero. Theoretically, oxygen delivery to a developing noncarrier fetus might be impaired when the mother is a carrier, because the normal differential in oxygen affinity between fetal and adult Hb (which is in favor of the developing fetus) would be narrowed. However, only in the family with Hb Yakima was there a suggestion that spontaneous abortions occurred at an increased rate.^{153, 154} In contrast, normal pregnancy outcomes were recorded for mothers carrying the severe high-affinity variants Hb Bethesda, Hb Osler, and Hb Little Rock.¹⁵⁴ Evidently, maternal and fetal polycythemia and increased uterine and fetal blood flow compensate for the theoretic deficit in placental oxygen transport. There are no data addressing whether carrier fetuses have a developmental advantage over noncarriers born to these mothers; however, in dizygotic twins born to a mother with Hb Osler, the carrier twin developed more fully than the noncarrier as measured by the ponderal index (weight/length³).¹⁵⁴

It has been suggested that the homozygous state for high-affinity Hbs would be incompatible with life because of insufficient oxygen release to tissue. This may be true; however, at least four patients with abnormal Hb levels approximating those that would be observed in homozygotes have been described with no apparent ill effects (Hb Abruzzo,¹⁵⁵ Hb Crete,¹⁵⁶ and Hb Headlington¹⁵⁷). The unusually high proportion of abnormal Hb was clearly due to concurrent β -thalassemia in two cases¹⁵⁷ and probably in the others as well.

No treatment is indicated for most patients with high-affinity Hbs. Their erythrocytosis is a compensation for a physiologic state and should be regarded as "normal for them." In the rare patient with erythrocytosis and associated symptoms, phlebotomy may be used, but caution must be used to avoid lowering the hematocrit to a point at which oxygen delivery is impaired.¹⁵⁸ A reasonable approach is probably to phlebotomize the individual patient to the highest hematocrit at which he or she is no longer symptomatic rather than to a specific number.^{149, 158, 159} Certainly, reducing blood Hb concentrations to normal levels would be undesirable. Cyto-reductive agents should not be used for treatment.

Acquired Abnormalities of Hemoglobin

Moderate elevations of carboxyhemoglobin in erythrocytes shift the oxygen dissociation curve. In heavy smokers, carboxyhemoglobin concentration may reach sufficiently high levels (4.0% to 6.8%) to produce polycythemia.^{160, 161} In the older literature, polycythemia in association with phosphorus poisoning has been described, although it may have been merely relative erythrocytosis resulting from acute liver damage. Although certain drugs and chemicals (e.g., nitrites, nitrates, aniline dyes, sulfonamides, and nitrobenzene) produce toxic levels of methemoglobin, sulfhemoglobin, or both in the blood of even normal persons,^{162, 163, 164, 165, 166, 167} erythrocytosis apparently has not been described in patients with toxic methemoglobinemia.

Familial Polycythemia (Physiologically Appropriate)

Familial defects in 2,3-BPG metabolism (e.g., BPG mutase deficiency¹⁶⁸ or elevated erythrocyte adenosine triphosphate¹⁶⁹), which would have the effect of shifting the oxygen dissociation curve to the left, provide other physiologically appropriate (tissue hypoxia) reasons for polycythemia. A specific pyruvate kinase

P.1040

mutation resulting in higher than normal enzyme activity and decreased 2,3-BPG causing erythrocytosis has been described as well in association with erythrocytosis.¹⁷⁰

Secondary Polycythemia (Physiologically Inappropriate [Normoxic])

Unlike patients with physiologically appropriate secondary polycythemia, individuals with inappropriate polycythemia receive no benefit from the higher red cell concentrations. Treatment should be aimed at correcting the underlying disease; phlebotomy can be considered in the symptomatic.

Aberrant Erythropoietin Secretion

Erythrocytosis has been described in association with a variety of neoplasms, cysts, vascular abnormalities, and endocrinologic disorders. In the syndromes discussed in the preceding section, erythrocytosis was secondary (i.e., driven by increased erythropoietin); however, this erythropoietin secretion and the consequent erythrocytosis were physiologic responses to tissue hypoxia. In this section, disorders in which erythropoietin-driven erythrocytosis bears no relation to physiologic requirements are reviewed (Table 44.4).

Renal Disorders

Renal cell carcinoma (hypernephroma) is one of the disorders most frequently associated with erythrocytosis. Erythrocytosis is observed in 0.9% to 1.6% of patients with renal cell carcinoma (approximately one fourth as frequent a finding as anemia).¹⁷¹ Elevated serum erythropoietin levels, however, are observed in more than 60% of patients.¹⁷² Erythrocytosis also has been reported in patients with renal sarcoma, hemangioma, adenoma,¹⁷³ Wilms tumor,^{153, 174} renal cysts, hydronephrosis,^{175, 176, 177} horseshoe kidney,¹⁷⁵ and polycystic kidneys.¹⁷³ Renal artery stenosis has also been reported in association with erythrocytosis.¹⁷⁸

Erythrocytosis in renal cell carcinoma is attributed to constitutive erythropoietin production by the tumor. Erythropoietin messenger RNA can be demonstrated in renal carcinoma cells.¹⁷⁹ It is assumed that this is also the mechanism by which other parenchymal renal diseases produce erythrocytosis. Hydronephrosis and anatomic abnormalities probably produce erythrocytosis by increasing pressure on erythropoietin-producing cells in the renal parenchyma.¹⁸⁰ Significant and measurable concentrations of erythropoietin (sometimes >100 mU/ml) can be detected in fluid aspirated from renal cysts associated with polycythemia. Production of erythropoietin in renal cell carcinoma is said to predict a good response to therapy.¹⁸¹ Management of erythrocytosis in these patients should be directed at treatment of the responsible renal lesion with phlebotomy as an adjunct, when necessary.

Erythrocytosis is also observed in patients after renal transplantation.¹⁸² This phenomenon is associated with elevated serum erythropoietin; the source of erythropoietin is presumed to be the transplant recipient's native kidneys.^{183, 184} Effective therapeutic modalities include phlebotomy, angiotensin-converting enzyme inhibitors, and theophylline.^{185, 186, 187}

Liver Diseases

During fetal development, the liver contributes to erythropoietin production (Chapter 6); hepatic disease, like renal disease, may be associated with erythropoietin production and polycythemia. Erythrocytosis has been identified in persons with hepatocellular carcinoma with incidence 2.5% to 10.0%.^{188, 189} When measured, red cell mass has been shown to be increased,¹⁹⁰ and elevated serum erythropoietin levels have also been described.¹⁹¹ As with renal cell carcinoma, erythropoietin production by the tumor has been demonstrated.^{192, 193, 194} Remission of erythrocytosis may be observed after successful tumor treatment.^{193, 194}

Other

Human immunodeficiency virus infection^a

^a Polycythemia infrequently reported.

Erythrocytosis has also been reported with hepatic hamartomas and tumors metastatic to liver,¹⁷³ as well as hepatic angiomas¹⁹⁵ and hemangiosarcomas.¹⁹⁶ Polycythemia has been reported in the early stages of viral hepatitis.^{197, 198} Cirrhosis is occasionally listed in texts as associated with erythrocytosis, but this apparently does not occur except in the setting of another disease, such as cirrhosis with hepatocellular carcinoma.

Cerebellar Vascular Tumors

The association of erythrocytosis with vascular tumors of the cerebellum is well established.^{173, 199} Elevated serum erythropoietin

P.1041

levels and tumor production of erythropoietin have been demonstrated,^{200, 201, 202} but abnormalities in Von Hippel-Lindau

protein are observed as well.^{203, 204, 205} Correction of erythrocytosis may be observed after effective therapy and erythrocytosis may return with recurrence of the tumor.¹⁷³

Leiomyoma and Fibroid Tumors of the Uterus

Several cases in which large leiomyomas and fibroid tumors of the uterus were associated with erythrocytosis have been reported.^{206, 207} Erythrocytosis tends to subside after effective therapy and is also associated with production of erythropoietin by tumor.^{207, 208} Cutaneous leiomyomata have also been associated with erythrocytosis.²⁰⁹

Other Neoplasms

Rare instances of erythrocytosis in association with a variety of other tumors have been reported, but some of these associations may be coincidental.¹⁷³ However, erythropoietin synthesis by tumor cells has been clearly demonstrated in a patient with meningioma.²¹⁰ Erythrocytosis has also been reported in rare patients with chronic lymphocytic leukemia,²¹¹ systemic amyloidosis,²¹² placental trophoblastic tumors,²¹³ and atrial myxomas.²¹⁴

Endocrinologic and Other Disorders

Erythrocytosis has been reported in association with a number of endocrinologic disorders, including Cushing syndrome, primary aldosteronism,²¹⁵ virilizing ovarian tumors,²¹⁶ Bartter syndrome,²¹⁷ and pheochromocytoma.^{218, 219} In the latter disorder, tumor erythropoietin production has been reported.²²⁰

There have been a number of reports describing small numbers of patients with human immunodeficiency virus infection and polycythemia.^{221, 222, 223, 224, 225, 226} It is unclear if there is an actual pathophysiologic association or if this is coincidental.

Drug-induced Erythrocytosis

Anabolic and androgenic steroids may be abused by both recreational and professional athletes for purposes of improving performance.²²⁷ A consequence of androgen administration, either medicinal or extralegal, may be erythrocytosis.^{228, 229, 230} In some cases, the degree of erythrocytosis may be severe.

Recombinant human erythropoietin has also been abused by athletes (particularly those in endurance sports) to increase the red cell mass and thus oxygen-carrying capacity.^{231, 232, 233} As indicated earlier in Figure 44.2, this may backfire if the athlete becomes hypovolemic as a result of exertion. Cases of surreptitious erythropoietin self-administration resulting in accelerated hypertension and unstable angina have been reported.²³⁴ A perceived advantage of erythropoietin over androgens for this purpose is the inability to distinguish endogenous from exogenous erythropoietin as well as the lack of hepatic toxicity. Newer approaches that allow discrimination between exogenous recombinant erythropoietin and endogenous erythropoietin may make this practice less frequent.^{235, 236, 237, 238}

Familial Polycythemia (Physiologically Inappropriate)

Kindreds that exhibit an autosomal recessive erythrocytosis associated with increased erythropoietin production have been described.²³⁹

Idiopathic Polycythemia

The term idiopathic polycythemia (or erythrocytosis) refers to patients who have an elevated red cell mass of unknown etiology after appropriate investigation. It would include most of the patients formerly categorized as "benign erythrocytosis." The existence of this group, which is estimated to contain 20% to 30% of patients evaluated for polycythemia,¹⁴¹ essentially represents a failure to categorize all polycythemic patients correctly.

Of 25 patients reported in one series, 12 were found to have elevated erythropoietin levels and were therefore assumed to represent patients with secondary polycythemia; these patients tended to be younger than the patients with normal erythropoietin levels.¹³⁹ Progenitor culture studies were not helpful in subcategorizing the group in this particular study.¹³⁹ Some studies have reported endogenous colony-formation studies to be useful and serum erythropoietin levels not helpful,⁵⁰ whereas others have reported the opposite.²⁴⁰

Kiladjian et al. treated 39 patients with idiopathic erythrocytosis with pipobroman and compared their clinical course to 140 concurrently treated polycythemia vera patients.²⁴¹ The risk of leukemia, thrombosis, and myelofibrosis was the same in the two groups. This study confirms that the idiopathic erythrocytosis group contains a certain number of polycythemia vera patients; however, it does not provide a way to identify individuals who do not have a myeloproliferative disorder and therefore should not be exposed to leukemogenic agents.²⁴¹

Because this category probably represents a mixed bag, including early polycythemia vera, mild secondary polycythemia, and normal individuals at the higher end of the bell-shaped curve for red cell mass,⁶⁴ a cautious approach is warranted. Observation may be the most reasonable intervention; this may be the patient subset in which otherwise low-yield studies, such as erythroid progenitor studies, are likely to be useful. Periodic retesting for the JAK2 V617F mutation or other JAK2 mutations may also be useful, although a study that addressed this question found that less than 2% of idiopathic erythrocytosis patients studied exhibited the mutation.²⁴²

Chapter 45

Diagnostic Approach to the Bleeding Disorders

George M. Rodgers

Christopher M. Lehman

Except for that which occurs during menstruation, spontaneous bleeding is abnormal. Surprisingly, little blood is lost, even after large injuries, because of the efficiency with which vascular integrity is normally maintained and the rapidity with which it is restored after injury. In general, these phenomena reflect the functional effectiveness of normal hemostasis (see Chapters 17, 18, and 19). It must be recognized, however, that the adequacy of hemostasis is only relative, and despite the presence of normal vessels, platelets, and coagulation factors, bleeding can occur as the result of localized pathologic processes.

The 11 chapters in Part V deal with disorders that result from abnormalities of the hemostatic process. This chapter is a summary of the diagnostic approach to these disorders and includes a brief discussion of laboratory methods for their study. In subsequent chapters, individual disorders are considered in six categories: thrombocytopenia (Chapters 46, 47, 48, and 49), bleeding disorders caused by vascular abnormalities (Chapter 50), thrombocytosis (Chapter 51), disorders of

platelet function (Chapter 52), inherited coagulation disorders (Chapter 53), and acquired coagulation disorders (Chapter 54). The pathophysiology of thrombosis and the principles of antithrombotic therapy are summarized in Chapter 55.

CLINICAL EVALUATION OF THE BLEEDING PATIENT

A careful evaluation of the patient presenting with a bleeding disorder can often provide valuable clues as to whether the abnormality resides in the vessels, platelets, or the process of blood coagulation; a carefully obtained history can usually establish whether the disorder is inherited or acquired; and the physical examination may reveal findings such as the characteristic skin lesions of hereditary hemorrhagic telangiectasia, which alone may provide the diagnosis of a previously perplexing bleeding problem. Results of the clinical evaluation should lead to a rational and efficient laboratory investigation.

It is important to ask specific questions about bleeding because people with normal hemostasis may believe they bleed excessively.¹ Certain questions may discriminate between those with normal and abnormal hemostasis, including whether excessive bleeding occurs after tooth extraction or small cuts, whether spontaneous bruising or muscle bleeding occurs, or whether the patient has ever been transfused or treated with blood products.¹

MANIFESTATIONS OF DISORDERED HEMOSTASIS

Certain signs and symptoms are virtually diagnostic of disordered hemostasis. They can be divided arbitrarily into two groups: those seen more often in disorders of blood coagulation and those most commonly noted in disorders of the vessels and platelets. The latter group is often called purpuric disorders because cutaneous and mucosal bleeding usually are prominent. The clinical findings that are most valuable in distinguishing between these two broad categories are summarized in Table 45.1. Although these criteria are relative, they provide valuable clues to the probable diagnosis if they are applied to the predominant clinical features in a given patient.

TABLE 45.1 CLINICAL DISTINCTION BETWEEN DISORDERS OF VESSELS OR PLATELETS AND DISORDERS OF BLOOD COAGULATION

Finding	Disorders of Coagulation	Disorders of Platelets or Vessels
Petechiae	Rare	Characteristic
Deep dissecting hematomas	Characteristic	Rare
Superficial ecchymoses	Common; usually large and solitary	Characteristic; usually small and multiple
Hemarthrosis	Characteristic	Rare
Delayed bleeding	Common	Rare
Bleeding from superficial cuts and scratches	Minimal	Persistent; often profuse
Sex of patient	80%-90% of inherited forms occur only in male patients	Relatively more common in females
Positive family history	Common	Rare (except von Willebrand disease and hereditary hemorrhagic telangiectasia)

P.1044

Bleeding into Skin and Soft Tissues

Petechiae are characteristic of an abnormality of the vessels or the platelets, such as thrombocytopenia, and are exceedingly rare in the coagulation disorders. These lesions are small capillary hemorrhages ranging from the size of a pinhead to much larger (Fig. 45.1). They characteristically develop and regress in crops and are most conspicuous in areas of increased venous pressure, such as the dependent parts of the body and areas subjected to pressure or constriction from girdles or stockings. In patients with scurvy, petechiae may be distributed around hair follicles in the “saddle area” of

the thighs and buttocks (see Fig. 50.5). Petechiae must be distinguished from small telangiectasias and angiomas. Vascular structures such as telangiectasias or angiomas blanch with pressure, whereas petechiae do not.

In the purpuric disorders, petechiae commonly are associated with multiple superficial ecchymoses, which usually develop without perceptible trauma but seldom spread into deeper tissues. Small isolated ecchymoses are commonly noted in apparently normal women, especially on the legs, and in small children.

Although large superficial ecchymoses may be seen in association with the coagulation disorders, the most characteristic lesion is the large spreading hematoma (Fig. 45.2). Such hematomas may arise spontaneously or after trivial trauma and often spread to involve an entire limb by dissecting within muscles and deep fascial spaces, often with minimal discoloration of the overlying skin.

Hemarthrosis

Hemorrhage into synovial joints is virtually diagnostic of a severe inherited coagulation disorder, most commonly hemophilia A or hemophilia B, and is rare in disorders of the vessels and platelets or in acquired coagulation disorders. This disabling problem often develops with pain and swelling as chief symptoms but without discoloration or other external evidence of bleeding (see Fig. 53.3). Subperiosteal hemorrhages in children with scurvy and swollen painful joints that may develop in some patients with allergic purpura occasionally may be confused with hemarthrosis.

FIGURE 45.1. Diffuse petechial rash induced by a tourniquet in a patient with chronic idiopathic thrombocytopenic purpura (platelet count = $40 \times 10^9/L$).

FIGURE 45.2. Large dissecting hematoma of thigh in a patient with hemophilia. A. The lesion resulted from a slight bump to the inguinal area and spread to involve the entire thigh. (Courtesy of Dr. John Lukens.)

Traumatic Bleeding

The unavoidable traumas of daily life and even minor surgical procedures are a greater challenge to hemostasis than any test yet developed in the laboratory. In contrast to “spontaneous” bleeding manifestations, bleeding after trauma in a person with a hemorrhagic diathesis differs in a quantitative way from that which would normally be expected in terms of the amount, duration, and magnitude of the inciting trauma. Such variables are extremely difficult to assess accurately by taking the patient's history. The amount of blood lost may be exaggerated by the patient. The need for transfusions and the number administered may serve as a rough guide. The patient's statement concerning the duration of bleeding is

more reliable. Detailed inquiry as to past injuries and operations must be made because the patient is likely to forget procedures or injuries that were uncomplicated and to dwell on those in which bleeding was a problem. Whether reoperation was required for prolonged bleeding after tooth extraction or other minor surgical procedures may be helpful in identifying a patient with abnormal hemostasis.

In individuals with a coagulation disorder, the onset of bleeding after trauma often is delayed. For example, bleeding after a tooth extraction may stop completely, only to recur in a matter of hours and to persist despite the use of styptics, vasoconstrictors, and packing. The temporary hemostatic adequacy of the platelet plug despite defective blood coagulation may explain this phenomenon of delayed bleeding, as well as the fact that patients with coagulation disorders seldom bleed abnormally from small superficial cuts such as razor nicks. In contrast, posttraumatic or postoperative surgical bleeding in thrombocytopenic patients usually is immediate in onset, as a rule responds to local measures, and rarely is as rapid or voluminous as that encountered

P.1045

in patients with coagulation disorders. However, it may persist for hours or days after surprisingly small injuries.

Valuable information often is obtained from a careful review of dental procedures, because most patients have had one or more teeth extracted at some time during their lives. The amount of bleeding normally encountered varies greatly, but as a rough guide, uncomplicated extraction of a single molar tooth may result in brisk bleeding for up to 1 hour and slight oozing for up to 2 days in normal persons.² Typically, bleeding is more profuse from upper than from lower sockets and is more extensive after extraction of molar teeth, particularly impacted third molars, than after removal of other teeth. In patients with inherited coagulation disorders, the shedding of deciduous teeth often is uncomplicated.

The response to trauma is an excellent screening test for the presence of an inherited hemorrhagic disorder, and a history of surgical procedures or significant injury without abnormal bleeding is equally good evidence against the presence of such a disorder. The removal of molar teeth is a major challenge to hemostasis, as is a tonsillectomy, and it is a rare hemophiliac, however mildly affected, who can withstand these procedures without excessive bleeding.

Miscellaneous Bleeding Manifestations

Despite the fact that structural causes for bleeding (such as polyps, varices, and tumors) are commonly seen in patients with hematuria, hematemesis, and melena, bleeding from these sites may also be associated with both purpuric and coagulation disorders. Severe menorrhagia may be the sole symptom of women with von Willebrand disease (vWD), mild thrombocytopenia, or autosomally inherited coagulation disorders. Recurrent gastrointestinal bleeding or epistaxis in the absence of other bleeding manifestations is common in hereditary hemorrhagic telangiectasia. A coagulation disorder or a disorder of platelet function should be considered if protracted hematuria is the only symptom.

Bleeding into serous cavities and internal fascial spaces often occurs in patients with inherited coagulation disorders and may create serious diagnostic problems. In hemophilia, retroperitoneal hemorrhage or bleeding into the psoas sheath may mimic appendicitis, and hemorrhage into the bowel wall may be confused with intestinal obstruction. Signs and symptoms simulating a variety of acute intra-abdominal disorders also may be seen in association with allergic purpura. Bleeding into the central nervous system may complicate thrombocytopenia and may occur after minor trauma in patients with coagulation disorders. Multiple small retinal hemorrhages are common in patients with thrombocytopenia and other purpuric disorders but are uncommon in those with inherited coagulation disorders; large hematomas of the orbit may be seen in the latter group. The coexistence of bleeding and thromboembolic phenomena or bleeding from previously intact venipuncture sites is suggestive of diffuse intravascular coagulation (DIC). Protracted wound healing, wound dehiscence, and abnormal scar formation have been described in inherited afibrinogenemia, the dysfibrinogenemias, and in factor XIII deficiency.³ Hemoptysis rarely is associated with hemorrhagic disorders.

CLINICAL FEATURES OF INHERITED BLEEDING DISORDERS

An inherited bleeding disorder is suggested by the onset of bleeding symptoms in infancy and childhood, a positive family history (particularly if it reveals a consistent genetic pattern), and laboratory evidence of a single or isolated abnormality, most commonly the deficiency of a single coagulation factor.

Age at Onset: Bleeding in the Neonate

Birth and the neonatal period provide unique challenges to the hemostatic mechanism,⁴ and bleeding during the first month of life often is the first evidence of an inherited disorder of hemostasis. Small cephalohematomas and petechiae are common in the newborn as a result of the trauma of delivery. Large cephalohematomas that progressively increase in

size may result from hemophilia but are more common in association with acquired bleeding disorders such as hemorrhagic disease of the newborn (see Chapter 54). Bleeding from the umbilical stump and after circumcision is common in the acquired coagulation disorders, and it also occurs in the inherited coagulation disorders,⁵ with the exception of hypofibrinogenemia, dysfibrinogenemia, and factor XIII deficiency. The onset of bleeding from the umbilical cord may be delayed in these latter disorders. In the evaluation of bleeding in the neonate, the clinician should remember that hematochezia and hematemesis may originate from swallowed blood of maternal origin. Simple tests to distinguish such maternal blood from fetal blood have been described.⁵

Many infants with inherited coagulation disorders do not bleed significantly in the neonatal period. Less than one-third of patients with hemophilia A and B and only 10% of those with other inherited coagulation disorders have hemorrhagic symptoms during the first week of life. In such patients, the disorder may become clinically silent for a time. Hematomas may first be seen only when the child becomes active. Hemarthrosis commonly does not develop until a child is 3 or 4 years of age.

A mild inherited hemorrhagic disorder may be difficult to distinguish from the insidious onset of an acquired defect. Patients with mild inherited coagulation disorders may enter adult life before characteristic bleeding manifestations occur. These patients and those with some forms of inherited thrombocytopenia and disordered platelet function often describe a history of posttraumatic bruising and hematoma formation that they have come to accept as normal. In hereditary hemorrhagic telangiectasia, the lesions become more prominent with advancing age and may not be symptomatic until middle age. Similarly, in patients with Ehlers-Danlos syndrome, bleeding may not be a problem until adult life.

Family History

The family history is of great importance in the evaluation of bleeding disorders. In disorders inherited as autosomal dominant traits with characteristic symptoms and high penetrance, such as hereditary hemorrhagic telangiectasia, an accurate pedigree spanning several generations can often be obtained. The presence of typical bleeding manifestations in male siblings and maternal uncles is virtually diagnostic of X-linked recessive inheritance, which characterizes hemophilia A and hemophilia B. In such X-linked traits, the family history also may be helpful in a negative sense—that is, it may clearly exclude the disorder in certain offspring, such as the sons of a known hemophiliac. Details of the various genetic patterns that may be encountered are discussed in the chapters that deal with these conditions.

The limitations of the family history, however, are greater than is commonly realized. Hearsay history is difficult to evaluate, and it is often impossible to assess the significance of easy bruising or to differentiate between manifestations of a generalized bleeding disorder and more common localized lesions, such as peptic ulcer and uterine leiomyomas. A negative family history is of no value in excluding an inherited coagulation disorder in an individual patient. As many as 30% to 40% of patients with hemophilia A have a negative family history.⁶ The family history usually is negative in the autosomal recessive traits, and consanguinity, which is commonly present in these kindreds, is notoriously difficult to document or exclude.

P.1046

CLINICAL FEATURES OF ACQUIRED BLEEDING DISORDERS

Generalized bleeding may be a prominent feature of a wide variety of acquired disorders that encompass virtually the entire field of medicine. Bleeding manifestations usually are less severe than in the inherited forms, and the clinical picture often is dominated by evidence of the underlying disorder rather than by bleeding alone. In the neonate, for example, DIC usually is associated with significant complications such as sepsis, hypoxia, acidosis, or problems related to prematurity. The physician should suspect sepsis or occult thrombosis in any sick neonate with unexplained thrombocytopenia.⁵ Multiple hemostatic defects commonly are present in patients with acquired hemorrhagic diseases, which often include thrombocytopenia and significant coagulation abnormalities. In contrast, a single abnormality usually is found in patients with inherited hemorrhagic disorders.

In general, the emphasis of the study of the acquired bleeding disorders should be on the patient, not on the laboratory. A thorough history and the physical examination often reveal the cause of thrombocytopenia, such as a drug or acute leukemia. In most vascular disorders, including senile purpura, allergic purpura, scurvy, and amyloidosis, the history and physical examination are of primary diagnostic importance, and the laboratory has little to offer.

Drug History

The importance of exhaustive interrogation regarding drug use and chemical exposure cannot be overemphasized. The list of drugs associated with thrombocytopenia (see Table 47.6) or vascular purpura grows longer each year. Less common but more serious is drug-induced aplastic anemia, which may present initially with bleeding. Many commonly used drugs, notably aspirin, impair platelet function and produce abnormal findings on laboratory tests that often lead to expensive and unnecessary additional laboratory studies. The same drugs may provoke bleeding when administered to patients with pre-existing hemostatic defects such as hemophilia A. Drug ingestion also may produce coagulation abnormalities, and drugs that potentiate or antagonize the anticoagulant effects of coumarin derivatives may lead to bleeding or erratic laboratory control. The surreptitious ingestion of such agents is not uncommon.

TABLE 45.2 INTERPRETATION OF COMMON TESTS OF HEMOSTASIS AND BLOOD COAGULATION

Test	Normal Range^a (± 2 SD)	Common Causes of Abnormalities
Platelet count		
Phase microscopy	140,000-440,000/ μ l	Thrombocytopenia, thrombocytosis
Automated	177,000-406,000/ μ l	
Partial thromboplastin time (activated) ^b	26-36 sec ^{55, c}	Deficiencies or inhibitors of prekallikrein; high-molecular-weight kininogen; factors XII, XI, IX, VIII, X, and V; prothrombin or fibrinogen; lupus inhibitors; heparin; warfarin
Prothrombin time ^b	12.0-15.5 sec ^{66, c}	Deficiencies or inhibitors of factors VII, X, and V; prothrombin or fibrinogen; dysfibrinogenemia; lupus inhibitors; heparin; warfarin
Thrombin time ^b	14.7-19.5 sec	Afibrinogenemia, dysfibrinogenemia, hypofibrinogenemia, and hyperfibrinogenemia; inhibitors of thrombin (heparin) or fibrin polymerization (fibrin degradation products, paraproteins)
Fibrinogen assay ^b	150-430 mg/dl ⁷⁰	Afibrinogenemia, dysfibrinogenemia, and hypofibrinogenemia; inhibitors of thrombin or fibrin polymerization
Factor VIII assay ^b	50-150 U/dl	Hemophilia A and von Willebrand disease; acquired antibodies to factor VIII
Fibrin degradation product assay	0-5 μ g/ml ⁸⁰	Disseminated intravascular coagulation; fibrinolysis; thrombolytic drugs, liver disease; dysfibrinogenemia
D-dimer assay	0-0.4 μ g/ml	Disseminated intravascular coagulation; recent surgery; pregnancy; thromboembolism

^a Normal range in the University of Utah coagulation laboratory.

^b Tests affected by heparin.

^c Significant variations depending on reagents and technique.

Results of various coagulation tests may be abnormal in a surprisingly large percentage of hospitalized patients because of heparin that is administered therapeutically or is used in small amounts to maintain the patency of indwelling venous catheters, venous pressure lines, arteriovenous shunts, and various pumps and infusion machines. The partial thromboplastin time (PTT), in particular, may be greatly prolonged in patients who have received even a minute amount of this anticoagulant. Such coagulation abnormalities often are confused with DIC, inhibitors of factor VIII, and other serious coagulation disorders, and they commonly lead to repeated, and usually useless, coagulation studies. A thorough bedside inventory often is required to find out that heparin is indeed responsible. Prolongation of the thrombin time associated with a normal reptilase time or direct assay of heparin provides laboratory evidence of heparin contamination.

LABORATORY METHODS FOR STUDY OF HEMOSTASIS AND BLOOD COAGULATION

No single test is suitable for the laboratory evaluation of the overall process of hemostasis and blood coagulation, but methods of varying complexity and use are available for assessing various components and functions individually. The emphasis of the following discussion is on methods that are simple and widely available in most laboratories. The interpretation of the most commonly used tests and the range of values obtained in normal subjects with representative techniques are summarized in Table 45.2. Definitive coagulation methods usually require a specially equipped laboratory and trained personnel, and are discussed here from a general standpoint only. Additional comments concerning the use and limitations of the various methods are included in chapters dealing with individual disorders.

P.1047

Tests of Vascular and Platelet Phases

Bleeding Time

Hemostasis in a small superficial wound, such as that produced when measuring the bleeding time, depends on the rate at which a stable platelet plug is formed and, thus, provides a measure of the efficiency of the vascular and platelet phases. However, it does not discriminate between vascular defects, thrombocytopenia, and platelet dysfunction. The bleeding time leaves much to be desired in terms of reproducibility, because no two skin areas are exactly the same and it is impossible to produce a truly standard wound.⁷

Older studies using the bleeding time test supported the view that this test might be helpful in predicting bleeding in individual patients.⁸ More recent studies suggest that a bleeding time result is determined not only by platelet number and function, but also by hematocrit,⁹ certain components of the coagulation mechanism,^{10, 11} skin quality,¹² and technique.¹³ A careful analysis of this literature indicates that there is no correlation between a skin template bleeding time and certain visceral bleeding times,^{13, 14} and that no correlation exists between preoperative bleeding time results and surgical blood loss or transfusion requirements.¹⁵

A clinical outcomes study reported that discontinuation of the bleeding time in a major academic medical center had no detectable adverse clinical impact.¹⁶ A position paper of the College of American Pathologists and the American Society of Clinical Pathologists concluded that the bleeding time was not effective as a screening test, and that a normal bleeding time does not exclude a bleeding disorder.¹⁷ Patients thought to have a platelet-type bleeding disorder based on their personal or family history (or both) should be evaluated for vWD and the inherited qualitative platelet disorders, using assays discussed in the section Platelet Function Assays. Newer assays that may be useful in screening patients for platelet dysfunction are also discussed in the section New Assays of Platelet Function.

Platelet Enumeration

Platelets are considerably more difficult to count than erythrocytes or leukocytes. This difficulty is to be expected in view of the small size of these cells and their tendency to adhere to foreign surfaces and to aggregate when activated.

In general, techniques for platelet counting may be classified into two groups: hemacytometer or direct methods, in which whole blood is diluted and the platelets are counted in much the same way as leukocytes or erythrocytes, and fully automated electronic methods. Virtually identical values for the normal range of the platelet count have been obtained with modern methods, as summarized in Table 45.2.

An estimate of platelet numbers in a well-prepared blood smear by an experienced observer is a valuable check on the platelet count as determined by any method. In general, when a blood smear is examined at 100 × power, each platelet

counted/field represents approximately $10,000 \text{ platelets} \times 10^9/\text{L}$. Consequently, a normal blood smear should demonstrate, on average, at least 14 platelets/high-power field.

Instruments for totally automated platelet counting are widely used. Details of automated cell counters are discussed in Chapter 1. When automated methods are used, various nontechnical factors may produce falsely low platelet counts.¹⁸ These factors include platelet agglutinins,¹⁹ abnormal amounts of plasma proteins in various paraproteinemias, previous contact of platelets with foreign surfaces such as dialysis membranes,²⁰ large or giant platelets, platelet satellitism,²¹ lipemia,²² and ethylenediaminetetra-acetic acid (EDTA)-induced platelet clumping,²³ a phenomenon that may produce platelet clumps of sufficient size to artifactually increase the leukocyte count.²⁴ Spuriously high platelet counts may result from the presence of microspherocytes,²⁵ fragments of leukemic or red blood cells,²⁶ and Pappenheimer bodies.²⁷ Special technical modifications and the use of careful manual counting methods may be required to eliminate these artifacts and to obtain accurate platelet counts.

Platelet Volume Measurements

The widespread availability of particle counters in the clinical laboratory permits the accurate measurement of platelet volume on a routine basis. Mean platelet volume (MPV) is increased in disorders associated with accelerated platelet turnover as the result of large numbers of megathrombocytes²⁸ or in patients with Bernard-Soulier syndrome. Normal or decreased values for MPV usually are obtained in patients with disorders associated with deficient platelet production, in some patients with sepsis,²⁹ and in people with certain big-spleen syndromes.³⁰

Some authors suggest that increased MPV provides evidence of accelerated platelet production and may be interpreted in the same way as the reticulocyte count. The method is difficult to standardize, however, and when determined on routinely collected specimens by automated counters, it is affected by numerous variables pertaining to specimen collection, anticoagulant, temperature, and duration of storage.³¹ In view of these problems and the difficulty in interpreting platelet size heterogeneity under normal and abnormal conditions,³² these measurements should be interpreted with caution.

The presence of microcytic platelets in patients with some inherited thrombocytopenias such as Wiskott-Aldrich syndrome is reliably reflected by MPV measurements. On the other hand, giant platelets associated with Bernard-Soulier syndrome may be counted as leukocytes or erythrocytes and may not be reflected in the MPV.

Platelet Function Assays

Since the 1960s, platelet aggregation using platelet-rich plasma has been the standard method to assess platelet function. This method uses aggregometers, which are modified nephelometers that permit measurement of changes in optical density of a platelet suspension under conditions of constant temperature and continuous agitation (Fig. 45.3). Most instruments measure

P.1048

a combination of light scatter and absorption. Instruments have been developed that permit both nephelometric and photometric measurements and the simultaneous measurement of aggregation and nucleotide release.³³

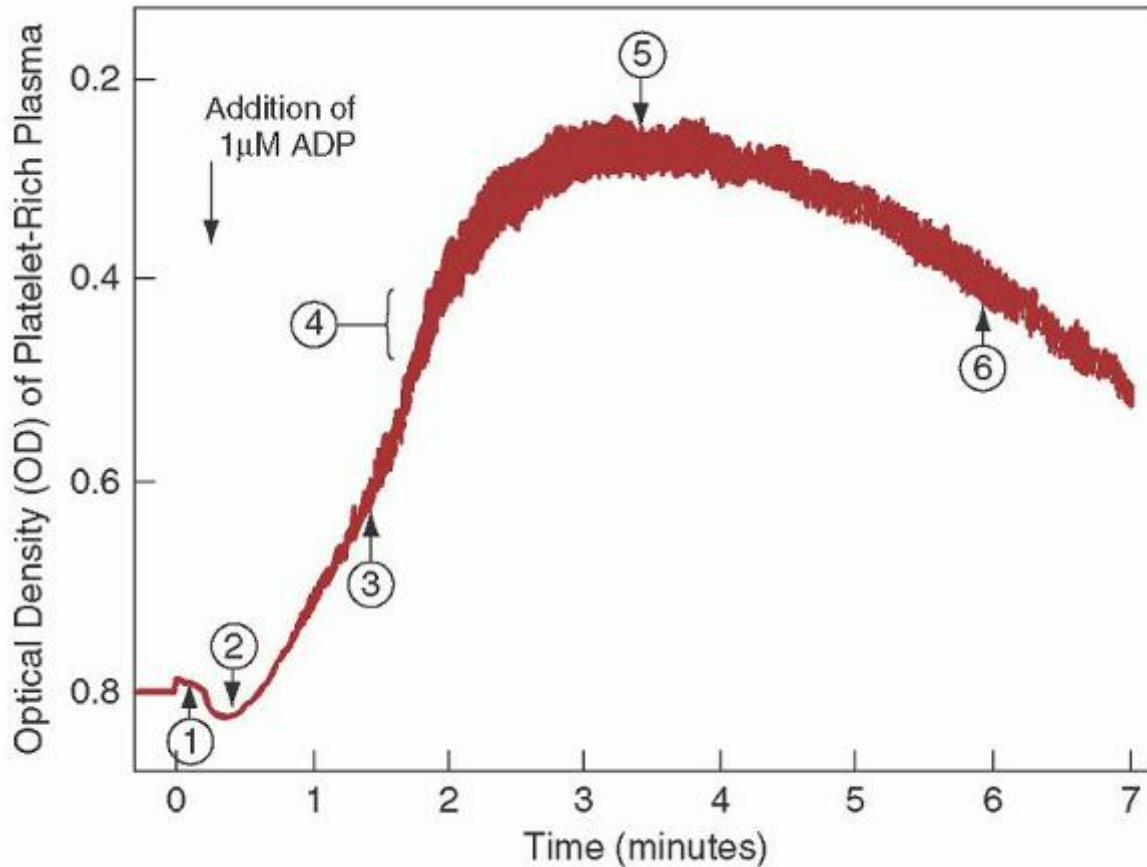

FIGURE 45.3. The interpretation of aggregometer tracings. Tracing of platelet aggregation produced by a low concentration of adenosine diphosphate (ADP), illustrating normal changes in optical density (OD)—that is, (1) a slight decrease caused by dilution with aggregating agent; (2) a transient increase caused by initial platelet swelling or shape change; (3) a rapid progressive decrease as platelet aggregates form, the size of which is roughly proportional to the amplitude of the oscillations in the tracing (4). The OD then reaches a nadir (5) from which maximal aggregation as a percentage of the initial OD may be calculated as follows: maximal aggregation (%) = $\text{OD at T}_0 - \text{minimum OD} / \text{OD at T}_0$. After this (6), a slow increase in OD caused by disaggregation occurs under some conditions.

Platelet aggregation usually is studied in suspensions of citrated platelet-rich plasma, in which the size and dimensions of the stirring bar, variations in plasma citrate concentration attributable to variations in hematocrit, the pH, and the nature of the buffers are important variables. Platelet suspensions usually are prepared by differential centrifugation, but methods that use albumin density gradient centrifugation and gel filtration have also been described.³⁴ Although harvesting platelets from the blood of thrombocytopenic patients is difficult, testing such platelets in the aggregometer is reproducible in suspensions containing as few as 50,000 platelets/ μL . Methods for the study of platelet aggregation in whole blood^{35, 36} also have been described. Interfaced computer systems have been developed for calculating and expressing platelet function data.³⁷

Adenosine diphosphate (ADP) in concentrations of 5 $\mu\text{mol/L}$ or higher produces platelet aggregation directly that is independent of the release of platelet-contained ADP.³⁸ Various other aggregating agents act mainly by inducing the release reaction, such as a suspension of connective tissue particles (collagen), epinephrine and norepinephrine, and thrombin. With epinephrine (5 $\mu\text{mol/L}$), a weak primary aggregating effect usually can be clearly distinguished from the subsequent release reaction, which produces a secondary wave of aggregation. Such primary and secondary waves of aggregation also may be seen with carefully titrated amounts of ADP (0.2 to 1.5 $\mu\text{mol/L}$).³⁸

Ristocetin is an antibiotic that induces platelet agglutination (platelet metabolic activity not required) in the presence of von Willebrand factor (vWF). Patients deficient in vWF (vWD) or in the receptor for vWF (Bernard-Soulier syndrome) have an abnormal ristocetin response. Ristocetin is tested in concentrations of 0.6 to 1.2 mg/ml; the lower concentrations are helpful in identifying specific variants of vWD, type 2B and platelet-type vWD (see Chapters 52 and 53).

The release reaction is measured only indirectly by routine aggregometry—that is, the aggregation associated with the release of ADP from the platelets (release-induced aggregation or secondary aggregation). Methods for the quantitation of various substances released from platelets have been described. For example, the amounts of ADP or serotonin released/unit of time serve as indices of dense body release³⁹; the amount of various hydrolytic enzymes or platelet factor 4 released is a measure of the extent of α -granule release.⁴⁰ Suggested guidelines for standardization of platelet aggregation methods have been proposed.^{41, 42}

Sensitive methods have been developed for the determination of platelet-derived substances in plasma that may serve as markers of intravascular platelet activation,⁴³ including platelet factor 4, β -thromboglobulin, stable prostaglandins (6-keto prostaglandin F₁ α and thromboxane A₂), and leukotrienes.⁴³ These measurements may have diagnostic value in thromboembolic disorders and syndromes characterized by intravascular platelet aggregation.

New Assays of Platelet Function

An appreciation of the limitations of the bleeding time test has led to the development of newer assays to evaluate platelet function.⁴⁴ Some of these are point-of-care tests. The clinical use and predictive value of these tests to identify patients with hemostatic disorders remain to be established. One assay, the platelet function analyzer (PFA-100), has been investigated for several years, and many published reports using this assay are available. In this method, citrated blood samples are exposed to high shear rates in a capillary flowing through an aperture within a membrane coated with collagen and either ADP or epinephrine.⁴⁵ The closure time to hemostatic plug formation within the aperture is the endpoint of the test. A large study using the PFA-100 found that prolonged closure times could be attributed to specific quantitative or qualitative abnormalities in platelet function or vWF (or both) in 93% of patients tested.⁴⁶ However, the International Society on Thrombosis and Haemostasis has taken the position that the PFA-100 is insufficiently sensitive and specific to be used as a screening device for platelet disorders.⁴⁷ It has been suggested that optimal use of the PFA-100 in evaluation of hemostasis would use an algorithmic approach, evaluating not only PFA-100 closure times, but also a complete blood count, blood smear, and assays for vWD and platelet aggregation to further evaluate abnormal closure times. A recent addition to the PFA repertoire is the INNOVANCE PFA P2Y test designed to assess P2Y₁₂-receptor blockade.

Several additional platelet function analyzers are available on the market, though they are not as well studied as the PFA-100.⁴⁸ The ICHOR II-Plateletworks system (Helena Laboratories, Beaumont, TX) compares impedance-derived platelet counts in samples with and without added platelet agonists to assess platelet function. This system has historically been used to evaluate cardiopulmonary bypass patients, but more recently has been applied to patients undergoing coronary stent placement. The Impact-R (Matis Medical, Beersel, Belgium) is an automated cone-and-plate research analyzer that assesses platelet adhesion and aggregation on a polystyrene surface under laminar flow conditions. The VerifyNow system analyzes platelet agonist-induced aggregation of fibrinogen-coated microparticles to assess platelet function. Agonist cartridges are designed to evaluate the effects of aspirin, clopidogrel, and GPIIb/IIIa platelet receptor inhibitor administration on platelet function. Platelet mapping, a modification of thromboelastography, measures the platelet contribution to clot strength in the presence of specific agonists.⁴⁹ To date, no platelet function analyzer assay has been sufficiently studied or validated to warrant routine clinical use.^{48, 50, 51}

Tests of Coagulation Phase

In general, meticulous performance of coagulation tests is more important than the exact technique chosen. Blood samples obtained by traumatic venipunctures or from indwelling catheters often are inadequate for coagulation studies.⁵² A poorly collected blood sample is a far more common cause of inaccurate results than is technical error.

With the exception of one assay for fibrin degradation products (FDPs), all coagulation tests are performed on citrated plasma, most commonly obtained using blue-top vacuum blood collection tubes that pull in nine parts of blood to one part citrate. The International Society for Thrombosis and Haemostasis recommends the routine use of 3.2% sodium citrate. A pool of freshly frozen citrated plasma from several normal donors is a suitable control for screening procedures in most laboratories. Lyophilized control plasma and borderline abnormal control plasmas are available commercially to standardize coagulation assays and to provide reference standards.

The citrate ion does not enter the erythrocyte. Consequently, the plasma citrate concentration is abnormally high when blood with a high hematocrit (>55%) is collected in usual concentrations of this anticoagulant. This may produce artifactual prolongation of one-stage screening tests of coagulation, such as the PTT.⁵³ To obtain interpretable data on such samples, tubes containing citrate concentrations appropriate for the hematocrit must be prepared by removing an aliquot of the citrate anticoagulant contained in standard blue-top tubes.

Activated Partial Thromboplastin Time

The activated partial thromboplastin time (PTT) is a simple test of the intrinsic and common pathways of coagulation. When a mixture of plasma and a phospholipid platelet substitute is recalcified,

P.1049

fibrin forms at a normal rate only if the factors involved in the intrinsic pathway (prekallikrein, high-molecular-weight kininogen, and factors XII, XI, IX, and VIII) and in the common pathway (factors X and V, prothrombin, and fibrinogen) are present in normal amounts (Fig. 45.4). Platelet substitutes of various kinds may be used, such as chloroform extract of brain⁵⁴ and other crude cephalin fractions as well as soybean phosphatides (inosithin). In the PTT, such platelet substitutes are provided in excess, and the test is unaffected by the number of platelets remaining in the plasma (unless the sample contains antiphospholipid antibodies). Platelet substitutes are only partial thromboplastins, however, and they are incapable of activating the extrinsic pathway, which requires complete tissue thromboplastin (tissue factor). Thus, the PTT bypasses the extrinsic pathway and is unaffected by a deficiency of factor VII. The PTT assay is used to detect factor deficiency, screen for the lupus anticoagulant, and monitor heparin anticoagulation.

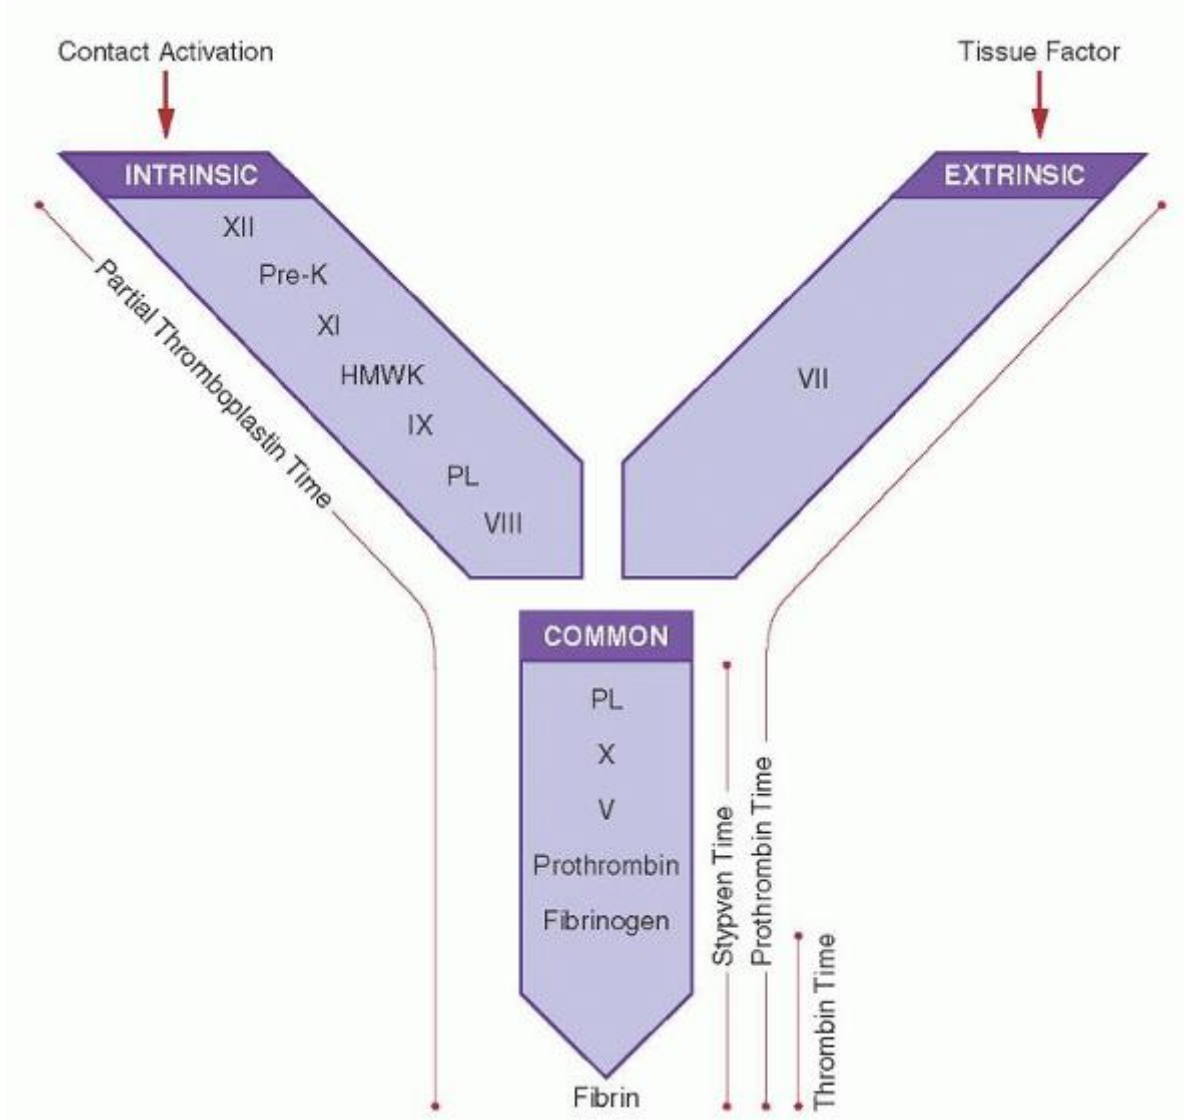

FIGURE 45.4. The interpretation of common screening tests of blood coagulation. Coagulation factors are indicated within arrow-shaped blocks, which represent the major pathways of coagulation. Screening tests are indicated at the side of these blocks in relation to pathways and coagulation factors measured by each. HMWK, high-molecular-weight kininogen; PL, phospholipid; Pre-K, prekallikrein.

The PTT is somewhat more sensitive to deficiencies of factors VIII and IX than to deficiencies of factors XI and XII or factors involved in the common pathway,^{55, 56} but with most techniques, the test usually yields abnormal results if the plasma level of any of the essential factors is <15% to 30% of the normal value. The PTT thus detects some mild coagulation disorders. However, the ability to detect mild factor deficiency is reagent-dependent, and certain PTT reagents may not detect factor deficiency as low as 5% to 10%.⁵⁷ As is the case with all one-stage tests, the PTT may be shortened by high levels of a single factor, most commonly factor VIII. Thus, a short PTT may signify any of the various hypercoagulable states (see Chapter 55),⁵⁸ and high levels of any of the factors involved in the intrinsic or common pathways of coagulation may mask deficiencies of other factors.⁵⁹

In the original method, contact activation was provided by the glass tube, but the addition of activators, such as ellagic acid, or particulate silicates, such as Celite or kaolin, provides more optimal and standardized contact activation and represents a significant improvement over the original nonactivated test.^{60, 61} The PTT is the routine assay currently used to evaluate intrinsic coagulation. The PTT of plasma deficient in prekallikrein (Fletcher factor) is abnormal when it is determined by standard methods using particulate activators such as Celite or kaolin.⁶² This abnormality is minimized or abolished by protracted contact activation (15 minutes⁶³), as compared with 2 to 3 minutes used in the standard technique. The PTT may yield normal results in prekallikrein deficiency when soluble activators such as ellagic acid are used.⁶³ A large recent pediatric reference interval study found no significant differences between adult PTT values and those of children ages 7 to 17 years.⁶⁴

Whereas increased PTT values may suggest a bleeding disorder, shortened PTT values have been found to be independent predictors of an increased risk of death, thrombosis, bleeding, and morbidity.^{58, 65} The use of the PTT in the control of heparin therapy and in detection of the lupus anticoagulant is discussed in Chapters 55 and 54, respectively.

Prothrombin Time

The production of fibrin by means of the extrinsic and common pathways (Fig. 45.4) requires tissue factor and factor VII, in addition to factors X and V, prothrombin, and fibrinogen. These pathways are measured by the prothrombin time (PT),⁶⁶ in which plasma is recalcified in the presence of excess tissue factor. This test does not require contact activation and bypasses the intrinsic pathway and the factors involved therein. Because tissue thrombo-plastins contain phospholipids that act as platelet substitutes, the test is unaffected by platelet numbers. Of the five coagulation factors measured by the PT (factors V, VII, and X, prothrombin, and fibrinogen), three (prothrombin and factors VII and X) are vitamin K-dependent and are decreased by coumarin-like drugs. As a result, the PT is the test used most widely for controlling oral anti-coagulant therapy. The PT usually is prolonged if the plasma levels of any of the requisite factors are <10% of normal, and it is more sensitive to deficiencies of factors VII and X than to deficiencies of fibrinogen and prothrombin. The PT also is prolonged by inhibitors of any of the essential factors and by heparin (unless heparin neutralizers are present in the PT reagent), but it is less sensitive to the anticoagulant action of heparin than is the PTT. A large pediatric reference interval study found that children ages 7 to 17 years have PT values ~1 second longer than normal adults.⁶⁴

Various modified techniques and thromboplastins,⁶⁷ including recombinant human thromboplastins,⁶⁸ have been developed to improve the use of the PT in the control of coumarin anticoagulant therapy (see Chapter 55). Use of the international normalized ratio in monitoring oral anticoagulation therapy is the recommended format (discussed in Chapter 55). The PT performed with bovine brain thromboplastin is abnormal in patients with certain genetic variants of factor IX deficiency but is normal in patients with the more common form of this disorder. The venom of the Russell viper contains an enzyme that initiates coagulation by the direct activation of factor X and does not require factor VII. The one-stage "prothrombin time" performed with this venom (the Stypven time) thus distinguishes between deficiency of factor VII and deficiency of factor X (Fig. 45.4).

Assay of Plasma Fibrinogen

Several accurate methods are available for the quantitative assay of plasma fibrinogen, a measurement of great clinical importance that should be available in all laboratories. Fibrinogen may be converted into fibrin, which is quantitated by gravimetric, nephelometric,⁶⁹ or chemical⁷⁰ methods. An immunologic⁷¹ method has also been described. Kinetic techniques based on the thrombin time, however, are simple to perform, and they have been widely adopted.⁷² Both gravimetric methods and those based on the thrombin time underestimate fibrinogen in the presence of high concentrations of FDPs; technical modifications designed to avoid these problems have been proposed.⁷³ Some nephelometric

P.1050

methods appear to be minimally affected by FDP. Modified methods that eliminate interference by heparin,⁷⁴ as well as

automated techniques, have been described. Marked differences in fibrinogen levels obtained by gravimetric and immunologic methods and those obtained by functional techniques are found in patients with the inherited dysfibrinogenemias. Reference values to identify patients with dysfibrinogenemia have been reported.⁷⁵

Thrombin Time and Related Techniques

When thrombin is added to plasma, the time required for clot formation is a measure of the rate at which fibrin forms (Fig. 45.4). This test (thrombin time) yields abnormal results when the fibrinogen level is <70 to 100 mg/dl, but it is unaffected by the levels of any of the other coagulation factors⁷⁶; it is greatly prolonged by heparin. The thrombin time may also be prolonged by a qualitatively abnormal fibrinogen (dysfibrinogen), elevated levels of fibrin (fibrinogen)-degradation products, certain paraproteins, and hyperfibrinogenemia. The thrombin time and modifications thereof are technically simple, can be performed quickly, and are valuable, particularly in the diagnosis of DIC. The reptilase clotting time is similar to the thrombin time in principle, but coagulation induced by this enzyme, which is prepared from snake venom, is unaffected by the presence of heparin.

Tests for Fibrin (Fibrinogen)-degradation Products and D-Dimer

Fibrin (fibrinogen)-degradation products (FDPs) are protein fragments of varying sizes that result from the proteolytic action of plasmin on fibrin or fibrinogen (see Chapter 18).⁷⁷ Plasma levels of these fragments are commonly increased in association with DIC and fibrinogenolysis, disorders in which their presence is of considerable diagnostic significance. Quantitative assays for FDP are based on several principles, such as the agglutination of latex particles coated with antifibrinogen antibody,⁷⁸ immunodiffusion,⁷⁹ and red cell hemagglutination inhibition.⁸⁰ Serum containing rheumatoid factor⁷⁸ or residual fibrinogen may yield false-positive results in some assays.⁸¹

None of the aforementioned methods distinguishes between fibrin degradation products and fibrinogen degradation products; to make this distinction, measurement of the DD-dimer or even more sophisticated methods are required.⁸² Extremely sensitive methods for the measurement of fibrinopeptides and specific FDP, such as the DD-dimer,⁸³ DDE-trimer, or B- β 15-42-related peptide, are useful as indices of DIC and as markers of subtle activation of coagulation in vivo (see Chapter 54).

Unpolymerized fibrin monomer is commonly present in the blood of patients with DIC. Various techniques (paracoagulation techniques) for demonstrating such monomers have been described; these range from the ethanol gelation test,⁸⁴ which is insensitive, to various protamine gelation techniques,⁸⁵ which are highly sensitive but nonspecific. Cryofibrinogen, which may be demonstrated in some cases of DIC, also may signify the presence of fibrin monomers. All of these assays to diagnose DIC have been supplanted by the D-dimer test.⁸³ The use of D-dimer tests to exclude venous thromboembolism is discussed in Chapter 55.

Tests for Factor XIII Activity

The principle of the factor XIII screening test is that clots crosslinked by factor XIII resist denaturation by high concentrations of urea or acid. Deficiency of factor XIII results in premature clot lysis.³ Patient plasma is recalcified to induce a clot; the clot is then suspended in 5 mol/L urea (or 1% monochloroacetic acid) for 24 hours. Clot stability is examined visually after 24 hours of incubation. Because this assay is a screening test, abnormal results should be repeated and confirmed using a quantitative factor XIII method, such as measuring factor XIII-dependent incorporation of labeled amines into substances such as fibrinogen or casein.⁸⁶

Tests for Fibrinolysis

The plasma euglobulin fraction contains plasminogen activators and fibrinogen. Most of the major antiplasmins are removed in the pseudoglobulin supernatant fluid. The rate of lysis of a fibrin clot prepared from the euglobulin fraction (the euglobulin clot lysis time) thus provides a measure of fibrinolysis in the absence of major inhibitors and is a measure of the activity of plasminogen activators.⁸⁷

Tests for fibrinogenolysis and assays for individual components of the fibrinolytic enzyme system, including plasminogen,⁸⁸ free plasmin,⁸⁹ and antiplasmins, are available. Routine coagulation assays for plasminogen activators and plasminogen activator inhibitors typically involve enzyme-linked immunosorbent assay (ELISA) methods.^{90, 91} Blood collection methods, timing, processing, and determination of assay-specific reference ranges are critically important in accurate evaluation of fibrinolysis parameters.^{90, 91}

Moderate concentrations of ϵ -aminocaproic acid (4×10^{-4} mol/L) inhibit plasminogen activators but not free plasmin. Thus, a shortened euglobulin lysis time in the presence of such concentrations of ϵ -aminocaproic acid indicates the

presence of free plasmin, as in association with fibrinolysis (see Chapter 54). Fibrinolysis in heated fibrin plates also measures free plasmin⁹² because plasminogen activators are thermolabile.

Bioassays for Coagulation Factors

Bioassays for coagulation factors are usually based on the familiar screening tests, such as the PT and PTT. In principle, the extent to which an unknown sample corrects the abnormality in plasma with a known deficiency is assumed to be proportional to the content of the deficient factor in the sample. The results of coagulation assays may be expressed in terms of units, which equal the amount of a given factor that is present in 1 ml of normal pooled or reference plasma. Alternatively, plasma levels of various factors may be expressed as a percentage of normal. Thus, plasma levels of various coagulation factors typically range from 50 to 150 U/dl, or 50% to 150% of normal.

One-stage methods for factors VIII and IX, which are based on the PTT and use substrate plasma from patients with severe inherited deficiencies (<1% of normal) of these factors, are somewhat simpler to perform than comparable two-stage methods. However, two-stage methods are more specific than one-stage methods, particularly in patients with intravascular coagulation and liver disease,⁹³ presumably because the two-stage methods are less affected by the presence of activated coagulation factors or traces of thrombin that increase the activity of factors V and VIII. One study found that for detecting low factor VIII levels, the clot-based assay was better than the chromogenic assay, while for elevated factor VIII levels, the chromogenic assay was preferred.⁹⁴ Plasmas deficient in specific factors are available commercially. Modifications that do not depend on natural substrates have been developed, including techniques for the assay of prothrombin⁹⁵; factors V,⁹⁶ VII, and X combined; and factors VIII,⁹⁷ IX,⁹⁸ X,⁹⁹ and XI.¹⁰⁰ Details of coagulation assay methodology have been summarized.¹⁰¹

Tests for Inhibitors of Coagulation

Abnormalities in any test of coagulation, if caused by deficiency of an essential factor, are corrected by the addition of small amounts of normal plasma. If the abnormality is caused by the presence of one of the various inhibitors of coagulation rather than a deficiency of an essential factor, the opposite is true: Small amounts of

P.1051

the patient's plasma impair coagulation in normal samples. These tests are called mixing studies or inhibitor screens. This phenomenon is the essence of all screening tests for inhibitors, most of which are based on one-stage coagulation techniques, such as the PT and PTT.¹⁰² The presence of heparin may be confirmed in various ways, including use of thrombin time and reptilase time assays, correction by protamine sulfate, or direct assays for activity of heparin or low-molecular-weight heparin.¹⁰¹

Tests for Physiologic Inhibitors of Coagulation

Several methods have been described for the assay of physiologic inhibitors of coagulation,¹⁰³ such as antithrombin,¹⁰⁴ heparin cofactor II, protein C,¹⁰³ ¹⁰⁵ and protein S.¹⁰⁶ ¹⁰⁷ Both immunologic and functional assays are available for many of these components.¹⁰³ Quantitative assays of such physiologic inhibitors may yield valuable information in patients with certain thromboembolic disorders (see Chapter 55).

Automated Coagulation Methods

Numerous instruments are available to detect automatically the endpoint of blood coagulation. These devices operate on a variety of principles: mechanical detection of the onset of fibrin formation, photometric recording of clot opacity, or the rate of fibrin polymerization. Such instruments are helpful in the performance of one-stage screening tests, such as the PT and PTT, especially if a large number of tests must be done daily.

Totally automated methods for performing coagulation tests are widely used. Automated instrument platforms have been developed to perform a large variety of coagulation methods with significant cost savings, permitting more laboratories to do comprehensive coagulation testing.¹⁰⁸ A College of American Pathologists Web site has summarized coagulation instrumentation (www.cap.org; see vendor surveys at the CAP Today link).

The thromboelastograph, an instrument that demonstrates changes occurring during blood coagulation and fibrinolysis, has been used by some investigators. Different coagulograms are described in association with various bleeding disorders and hypercoagulable states.¹⁰⁹ However, this is not a commonly used method to diagnose coagulation abnormalities in most laboratories. Its primary use is as a point-of-care instrument in the surgical setting.⁴⁴

The activated clotting time (ACT) is a whole blood clotting assay now used primarily as a point-of-care test. The ACT measures the clotting time for a whole blood sample after addition of particulate (contact) activators such as kaolin or

Celite; thus, this assay measures the intrinsic pathway of coagulation. The ACT is used mostly to monitor anticoagulation in the setting of cardiopulmonary bypass, cardiac catheterization, or dialysis. The ACT is preferable to the PTT in certain settings that require high-dose heparin, such as cardiopulmonary bypass.¹¹⁰

Other point-of-care coagulation instruments are being used in the setting of outpatient or home-based oral anticoagulation monitoring. Numerous studies have found that these instruments are at least as effective in providing safe and efficacious anticoagulation as is provided by physicians with standard laboratory anticoagulation testing.¹¹¹

Chromogenic and Fluorometric Techniques

Artificial peptides release chromogenic substances or fluorophores when they are enzymatically cleaved.^{112, 113} The hydrolysis of such peptides by activated coagulation factors provides a novel means for assessing various coagulation reactions.¹¹⁴ Such chromogenic and fluorometric techniques have been developed for the assay of prothrombin and factors VII, IX, and X¹¹⁵; antithrombin¹¹⁶; α_2 -antiplasmin; heparin; urokinase¹¹⁷; kallikrein¹¹⁸; plasmin; and other components of the fibrinolytic enzyme system.¹¹⁹ Assays also have been developed for coagulants that do not have enzymatic activity, such as cellulose sandwich fluoroimmunoassays for vWF antigen¹²⁰ and solid-phase front-surface fluorescence detection methods for factors VIIIc and IX.¹²¹ These methods appear to be intrinsically more precise and may be less time-consuming than traditional coagulation methods, and instruments designed specifically for their performance are available. Chromogenic and fluorometric assays are expensive, however, and at present are used mainly in research and in large reference coagulation laboratories.

INITIAL LABORATORY EVALUATION

Primary Screening Tests

The initial laboratory study of the bleeding patient should be guided by the information obtained from the clinical evaluation. In many cases, however, the routine use of a small battery of screening tests has merit because it usually saves time, and the results direct the course of further study. It is generally agreed that the most essential information usually can be obtained from the three tests summarized in Table 45.3, which, in view of their availability, simplicity, and low cost, are well suited to serve as primary screening tests. The platelet count provides the most reliable and reproducible test of primary hemostasis. The PTT measures all of the coagulation factors involved in the intrinsic and common pathways (Fig. 45.4) and generally is accepted as the best single screening test for disorders of blood coagulation. When supplemented with the PT, which assesses the extrinsic as well as the common pathway, the abnormality usually can be localized to one of the three pathways and the factors involved therein (Fig. 45.4 and Table 45.3). The results of these three tests thus provide a presumptive diagnosis, which can then be clarified further by the confirmatory methods summarized in the next section. The bleeding time test has been omitted from this evaluation because of its nonspecificity in the general clinical setting.^{13, 16} The definitive laboratory diagnosis of individual bleeding disorders is discussed in Chapters 46, 47, 48, 49, 50, 51, 52, 53 and 54.

It is important to realize that patients with mild bleeding disorders (factor VIII, IX, or XI deficiency) may have normal PTT values, because most PTT reagents do not detect mild deficiency states (factor levels of 20% to 30%).⁵⁷ Consequently, if the clinical suspicion is high, specific factor assays for these disorders should be performed, even if the initial evaluation suggested in Table 45.3 is not productive.

CONFIRMATORY TESTS

Thrombocytopenia

Thrombocytopenia, like anemia, is a symptom, not a diagnosis. It is the most common of the acquired bleeding disorders. Additional laboratory tests usually are not indicated merely to confirm the presence of thrombocytopenia (Table 45.3), but are helpful in establishing the mechanism for thrombocytopenia. It is useful, however, to examine the thrombocytopenic patient's blood smear to exclude pseudothrombocytopenia that may be seen in a small number of patients.^{18, 19} The differential diagnosis of thrombocytopenia is discussed at length in Chapters 46, 47, 48, and 49. One approach to evaluating thrombocytopenia is shown in Figure 45.5.

von Willebrand Disease

von Willebrand disease is the result of an abnormality in primary hemostasis combined with mild to moderate deficiency of

P.1052

factor VIIIc (see Chapter 53). In the classic case, the results of screening tests reveal a normal platelet count and a

prolonged PTT (Table 45.3). In many patients, however, the PTT will be normal. Furthermore, the results of all of the laboratory tests tend to fluctuate from time to time.¹²² If the clinical suspicion is high, initial laboratory studies directed at excluding vWD should be performed, because vWD is more common than the inherited disorders of platelet function (Fig. 45.6). Useful tests include bioassay of factor VIII (VIIIc), immunoassay of vWF antigen, and measurement of ristocetin cofactor activity. In many cases, the diagnosis of vWD requires repeated testing.

TABLE 45.3 PROFILES OF HEMOSTASIS SCREENING TESTS IN PATIENTS WITH BLEEDING DISORDERS

Prothrombin Time	Activated Partial Thromboplastin Time	Platelet Count	Differential Diagnosis
↑	—	—	Common Acquired factor VII deficiency (early liver disease; early vitamin K deficiency; early warfarin therapy) Rare Factor VII inhibitor; dysfibrinogenemia; some cases of DIC; inherited factor VII deficiency; certain factor X variants
—	↑	—	Common Deficiency or inhibitor of factors VIII, IX, or XI; vWD; heparin Rare Lupus inhibitor with qualitative platelet defect; certain factor X variants
↑	↑	—	Common Vitamin K deficiency; liver disease; warfarin; heparin; superwarfarin Rare Deficiency or inhibitor of factors X or V, prothrombin, or fibrinogen; lupus inhibitor with hypoprothrombinemia; DIC; dysfibrinogenemia; primary fibrinolysis
↑	↑	↓	Common DIC; liver disease Rare Heparin therapy with associated thrombocytopenia
—	—	↓	Common Increased platelet destruction; decreased platelet production; hypersplenism; hemodilution Rare Certain inherited platelet disorders (Wiskott-Aldrich syndrome, Bernard-Soulier syndrome)
—	—	↑	Myeloproliferative disorders

Common

Mild vWD; acquired qualitative platelet disorders (uremia, antiplatelet medications)

Rare

Inherited qualitative platelet disorders; vascular disorders; fibrinolytic disorders; factor XIII deficiency; autoerythrocyte sensitization; dysfibrinogenemia; mild factor deficiency (VIII, IX, XI); disorders of platelet procoagulant activity

↑, increased; ↓, decreased; —, normal; DIC, disseminated

intravascular coagulation; vWD, von Willebrand disease. *Note:* The differential diagnosis of bleeding disorders suggested by results of the prothrombin time, partial thromboplastin time, and platelet count is listed for each profile. This table includes the differential diagnosis of hemostasis screening test results in patients with a history of bleeding. Consideration of patients with abnormal coagulation tests and negative bleeding histories is not included in this table.

Modified from Rodgers GM. Common clinical bleeding disorders. In: Boldt DH, ed. Update on hemostasis. New York: Churchill Livingstone, 1990:75-120.

Another available test to evaluate patients for vWD is multimeric analysis of vWF. Patient plasma is separated by agarose electrophoresis, and vWF is identified by immunologic methods. The patient's multimeric pattern is compared to that of normal plasma. A more detailed description of this test is given in Chapter 53.

Qualitative Platelet Disorders

Symptoms of mucocutaneous bleeding in the presence of a normal number of platelets and normal results of coagulation tests (Table 45.3) are presumptive evidence of a disorder of platelet function (see Chapter 52). Inherited forms are uncommon, but bleeding caused by platelet dysfunction may be an important complication in patients with various acquired disorders, such as uremia. Commonly available confirmatory tests occasionally provide useful information regarding platelet dysfunction. Various morphologic abnormalities of the platelets may be seen on the blood smear. Strikingly large platelets are characteristic of certain inherited disorders, such as Bernard-Soulier syndrome. A markedly elevated platelet count is present in the myeloproliferative disorder, essential thrombocytosis.

Definitive methods for the study of platelet dysfunction are time-consuming and technically difficult. The absence of platelet aggregation by ADP, collagen, and epinephrine is characteristic of Glanzmann thrombasthenia. Deficient secondary wave aggregation is associated with various disorders of the release reaction, such as inherited deficiency of storage nucleotides, uremia, and aspirin ingestion. Abnormal responses to ristocetin indicate vWD or Bernard-Soulier syndrome.

P.1053

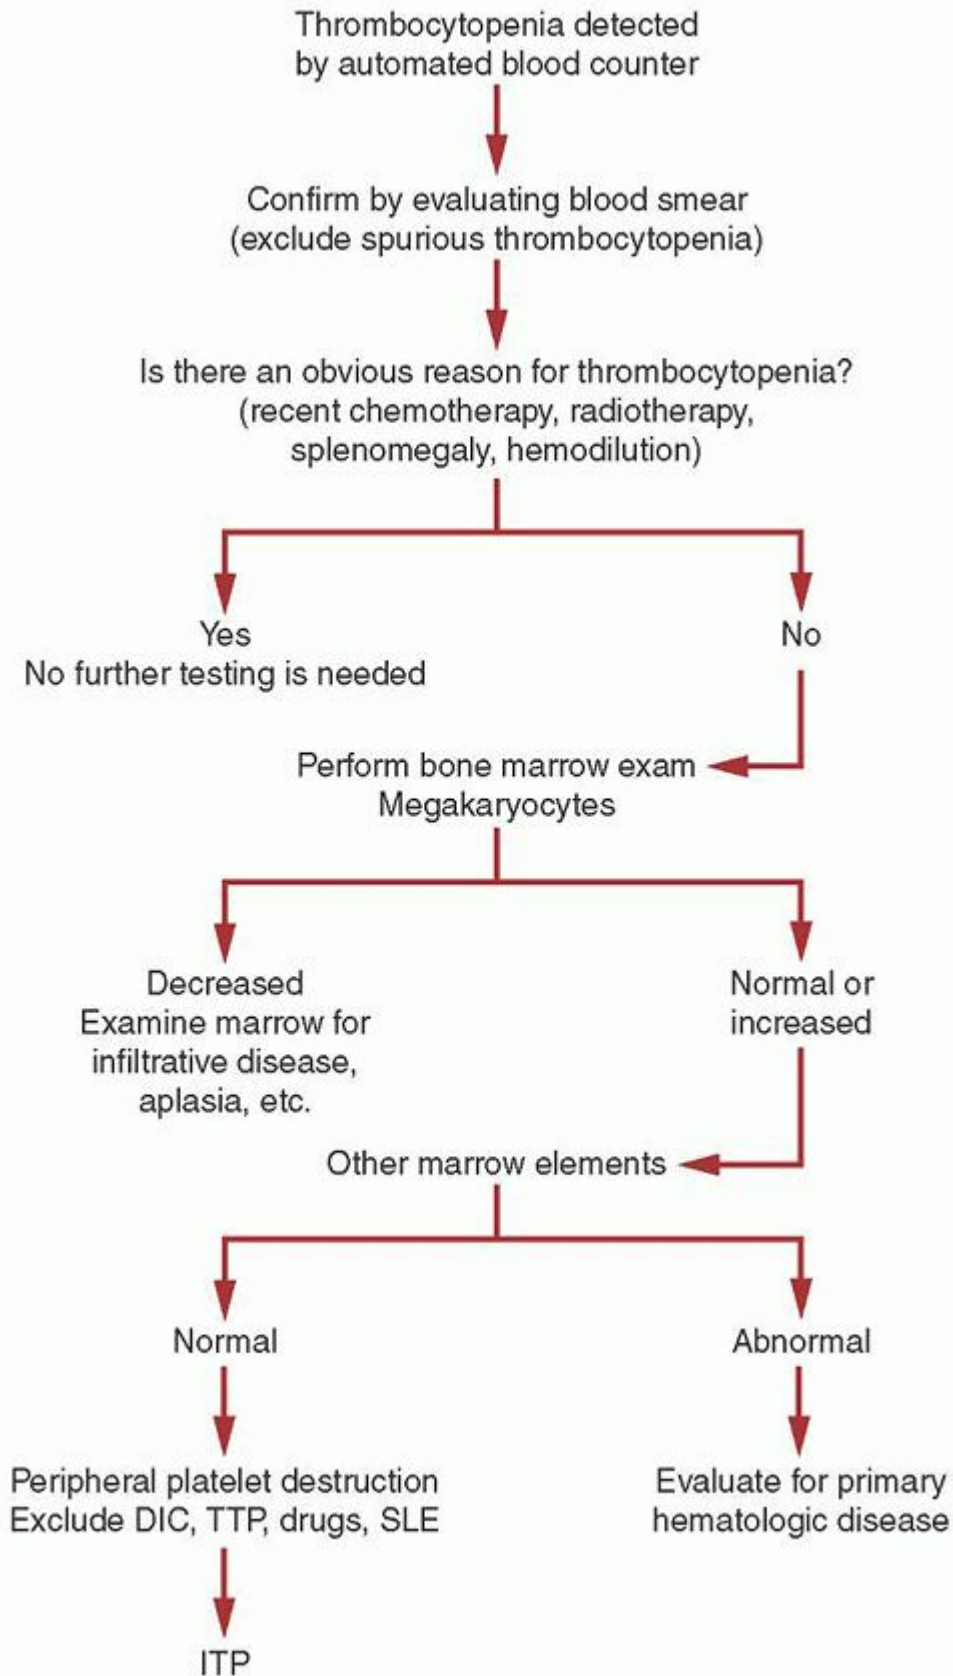

FIGURE 45.5. An approach for evaluation of thrombocytopenia. The necessity to do a bone marrow examination in the evaluation of idiopathic thrombocytopenic purpura (ITP) is controversial. ITP is a diagnosis of exclusion. DIC, disseminated

intravascular coagulation; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura. (Redrawn from Kjeldsberg C, ed. Practical diagnosis of hematologic disorders, 4th ed. Chicago: ASCP Press, 2006:319.)

Disorders of the Intrinsic Pathway of Coagulation

Disorders of the intrinsic pathway of coagulation are characterized by a prolonged PTT and a normal PT (Table 45.3). Inherited forms include deficiencies of factor VIII or IX (hemophilia A and B), prekallikrein, high-molecular-weight kininogen, factor XI, or factor XII (Fig. 45.7). Factor XII (Hageman factor) deficiency and deficiencies of prekallikrein or high-molecular-weight kininogen can be excluded readily, because they are not associated with excessive clinical bleeding. Distinguishing between deficiencies of factors VIII, IX, and XI is done by performing specific assays for these factors. Screens (mixing studies) should also be performed to exclude antibodies to the intrinsic factor under study. If a factor VIII inhibitor is identified, the titer should be quantitated (see Chapter 54). An algorithm approach for evaluating bleeding patients with an isolated, prolonged PTT is shown in Figure 45.8.

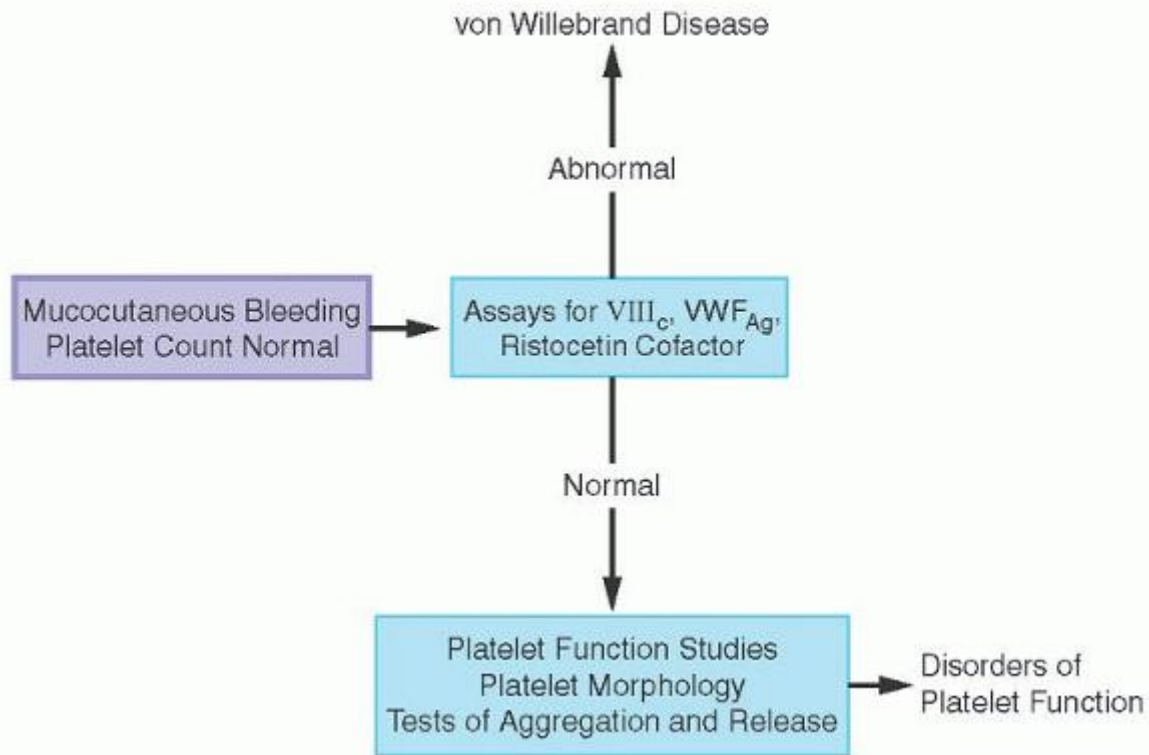

FIGURE 45.6. Laboratory diagnosis of von Willebrand disease (vWD) and platelet dysfunction. The initial evaluation reveals mucocutaneous bleeding symptoms in a patient with a normal platelet count (block on left). In vWD, the partial thromboplastin time also may be prolonged because of deficiency of factor VIIIc. Additional tests (blocks) and a suggested sequence for their performance are indicated as a flow diagram. Some patients with vWD may have normal assays for factor VIIIc, von Willebrand factor Ag (vWF_{Ag}), and ristocetin cofactor activity. These patients may be diagnosed by abnormal ristocetin-induced platelet agglutination when aggregation studies are performed or by multimeric analysis of vWF. For patients with normal studies for vWD and platelet dysfunction who are strongly suspected of having an inherited disorder, von Willebrand studies should be repeated.

Acquired coagulation disorders associated with a prolonged PTT and a normal PT include the lupus inhibitor and antibodies to factor VIII. Prolongation of the PTT is commonly the result of heparin administration or poorly collected blood samples.

Disorders of the Common Pathway of Coagulation

Prolongation of the PTT and PT in a patient with an inherited bleeding disorder indicates a deficiency of one of the factors in the common pathway—factor X, factor V, prothrombin, or fibrinogen, or a dysfibrinogen (Table 45.3 and Fig. 45.7). Such isolated deficiencies are exceedingly rare. On the other hand, deficiency of one or more of these factors is associated with additional abnormalities in the intrinsic and extrinsic pathways in many of the common acquired coagulation disorders, such as vitamin K deficiency, liver disease, and DIC. A prolonged PT usually suggests an acquired disorder

(excluding the rare cases of inherited factor VII deficiency) and usually is associated with a complex abnormality involving multiple pathways, such as DIC.

When confronted with this combination of findings, the first step should be to exclude or to identify an abnormality of fibrinogen. This may be accomplished by determination of the plasma fibrinogen level and tests for increased amounts of D-dimer or FDP. The most helpful ancillary procedures are the platelet count and examination of the blood smear for schistocytes. The laboratory findings characteristic of DIC are summarized in Chapter 54.

Inherited disorders associated with a low fibrinogen level include afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia (see Chapter 53). In certain dysfibrinogenemias, large amounts of unclotted fibrinogen remain in the serum and are detected by tests for FDP.

Inherited deficiencies of factor V, factor X, and prothrombin can be diagnosed by specific factor assays.

Disorders of the Extrinsic Pathway of Coagulation

A prolonged PT and a normal PTT (Table 45.3) suggest an isolated deficiency of factor VII, which is rare and may be the P.1054

result of an inherited or an acquired abnormality (Figs. 45.7 and 45.9). Less commonly, inhibitors of factor VII have been reported (see Chapter 54). Additionally, certain cases of DIC or dysfibrinogenemia may present with isolated prolonged PT values.¹²³ Because factor VII is essential only in the tissue factor-activated extrinsic pathway of coagulation, the Stypven time is normal in patients with factor VII deficiency.

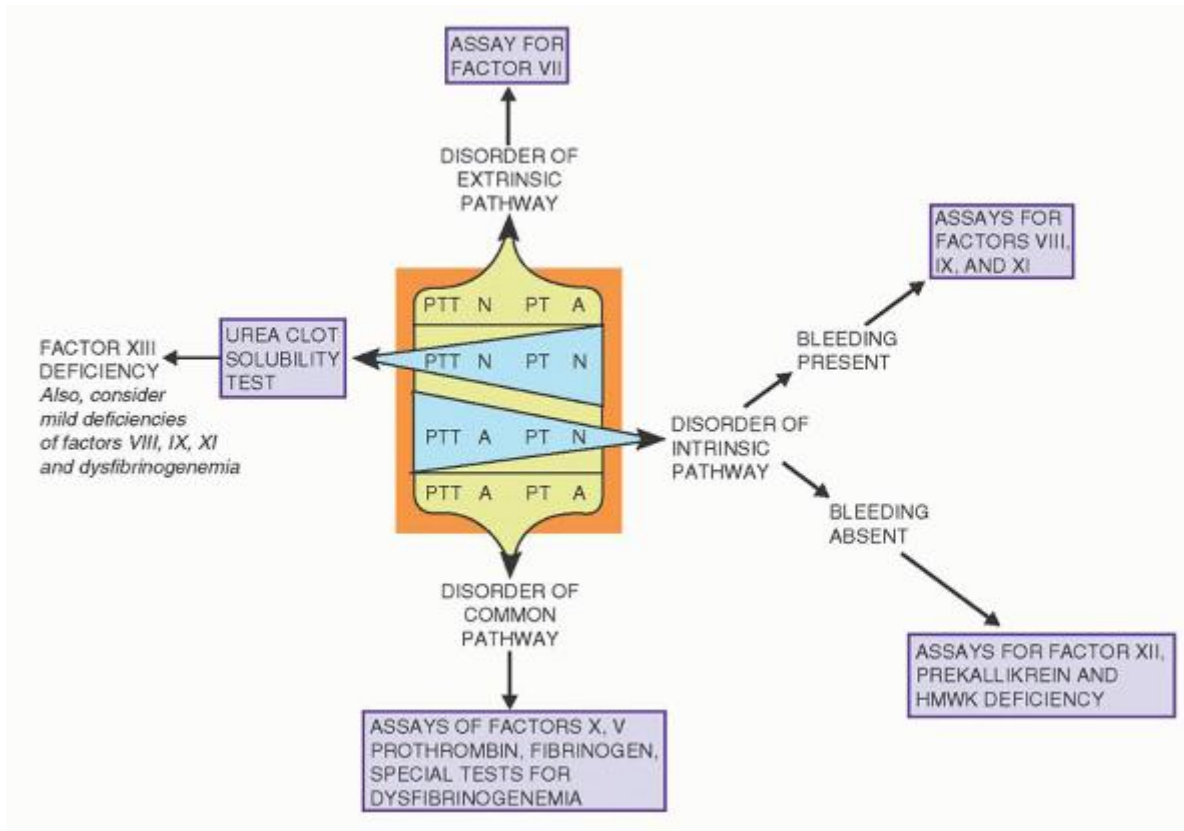

FIGURE 45.7. Laboratory diagnosis of inherited coagulation disorders. Results of primary screening tests of coagulation (activated partial thromboplastin time [PTT], prothrombin time [PT]) are summarized in the center block. Additional tests (blocks) and a suggested sequence for their performance are presented as a flow diagram. A more complete list of the differential diagnosis of bleeding disorders is presented in Table 45.3. A, abnormal; HMWK, high-molecular-weight kinogen; N, normal; PTT, partial thromboplastin time.

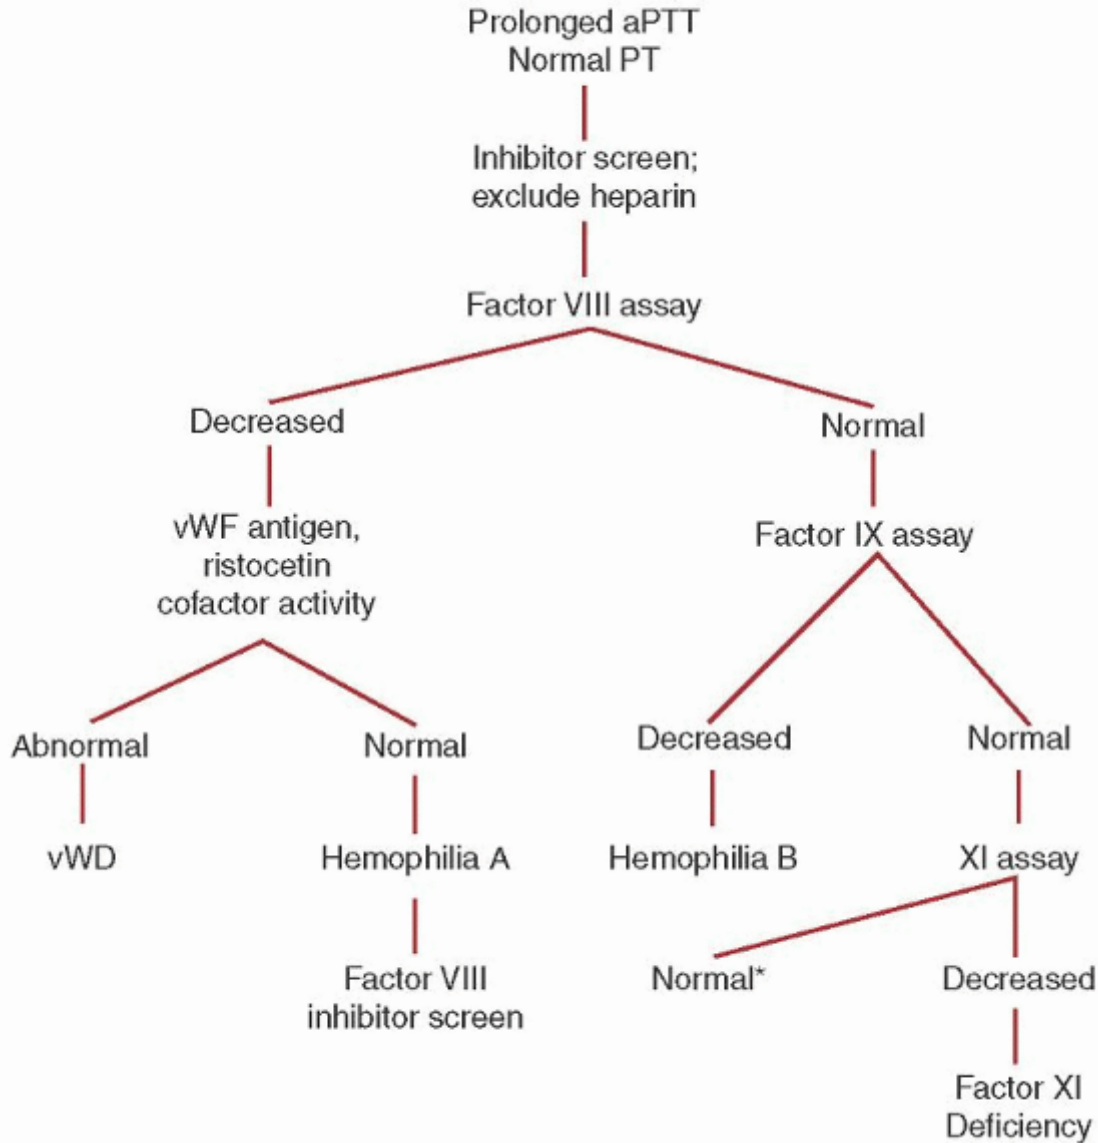

FIGURE 45.8. Evaluation of a patient with bleeding and an isolated, prolonged partial thromboplastin time (PTT). Asterisk indicates that patients with clinical bleeding but normal studies should be evaluated further for lupus anticoagulants associated with either platelet dysfunction or thrombocytopenia. PT, prothrombin time; PTT, activated partial thromboplastin time; vWD, von Willebrand disease; vWF, von Willebrand factor. (Redrawn from Kjeldsberg CR, Perkins SL, eds. Practical diagnosis of hematologic disorders, 5th ed. Chicago: ASCP Press, 2010:349.)

Disorders in Which Results of Primary Screening Tests Are Normal

Screening tests usually yield normal results in patients with bleeding disorders related to vascular abnormalities (Tables 45.3 and 45.4). The diagnosis is usually made from the associated clinical findings that are often characteristic, such as the skin lesions of

P.1055

hereditary hemorrhagic telangiectasia, allergic purpura, scurvy, and senile purpura. The results of screening tests also are normal in factor XIII (fibrin-stabilizing factor) deficiency, a disorder in which the diagnosis is made by the demonstration of characteristic clot solubility in urea or monochloroacetic acid.

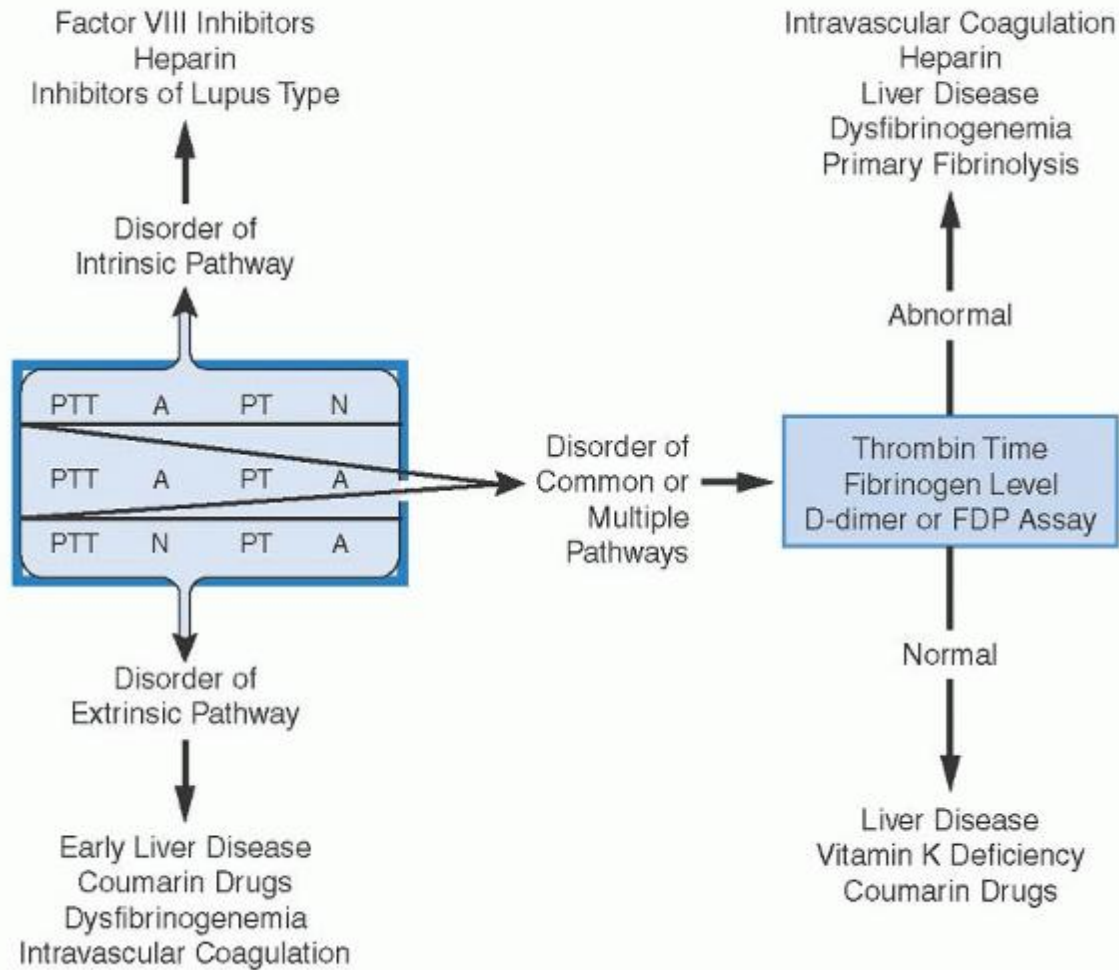

FIGURE 45.9. Laboratory diagnosis of acquired coagulation disorders. Results of primary screening tests of coagulation (partial thromboplastin time [PTT], prothrombin time [PT]) are summarized in the left-side block. Additional tests (right-side block) and a suggested sequence for their performance are presented as a flow diagram. Because of the complexity of acquired coagulation disorders and great variations in the results of laboratory tests that may be encountered in the various disorders and in individual patients, this diagram should be regarded as a general guide only. A more complete list of the differential diagnosis of bleeding disorders is presented in Table 45.3. A, abnormal; FDP, fibrin degradation products; N, normal.

TABLE 45.4 BLEEDING DISORDERS IN WHICH THE RESULTS OF PRIMARY SCREENING TESTS MAY BE NORMAL

- von Willebrand disease
- Mild inherited coagulation disorders, particularly factor XI deficiency
- Heterozygous carriers of inherited coagulation disorders
- Factor XIII (fibrin-stabilizing factor) deficiency
- Some forms of dysfibrinogenemia
- Disordered platelet function, particularly deficient release reaction; Scott syndrome
- Hereditary hemorrhagic telangiectasia
- Allergic and other vascular purpuras

α_2 -Plasmin inhibitor deficiency

Elevated levels of plasminogen activator

Although abnormal in the typical case, the results of screening tests may be normal or equivocal in patients with mild coagulation disorders (including heterozygous carriers), certain disorders of platelet function, mild forms of vWD, and dysfibrinogenemia or abnormal fibrinolysis.^{101, 124} More definitive tests are required to establish the diagnosis in these patients (Table 45.4). An increasing number of reports have indicated that many bleeding patients with normal screening studies have disorders of platelet procoagulant activity, such as Scott syndrome.¹²⁵

There are patients with a significant bleeding history in whom the results of detailed studies of hemostasis and blood coagulation are normal. Some have disorders of hemostasis that cannot be detected by methods currently available. The clinical management of these cases requires great care, and the fact that a clear-cut history of bleeding is always more significant than negative laboratory data cannot be overemphasized. Trauma may be denied in physically abused patients and may be self-inflicted in psychotic or neurotic patients.

PREOPERATIVE HEMOSTASIS EVALUATION

The value of obtaining routine screening tests before surgical procedures has been debated for years.¹²⁶ The screening tests for hemostasis are not totally satisfactory in detecting all mild hemostatic defects. Nevertheless, routine preoperative laboratory screening is of great value in certain high-risk patients who have disorders that predispose them to unexpected postsurgical bleeding, even from limited biopsy procedures. Important in this category are patients with liver disease, biliary obstruction, renal disease (particularly if complicated by azotemia), myelofibrosis, polycythemia vera, and other myeloproliferative disorders, particularly those associated with thrombocytosis and those with paraproteinemias. Included in this list should be all patients scheduled to undergo procedures involving the use of extracorporeal circulatory devices.

One approach to the question of preoperative hemostasis screening tests is to balance the financial costs of laboratory testing with the extent of surgery to be performed and with the amount of bleeding that can be safely tolerated. This approach makes the patient's hemostasis history particularly important. Patients scheduled for minor surgical procedures (dental, skin biopsy) do not need routine hemostasis screening tests if they have a negative history. In contrast, patients undergoing neurosurgery or other procedures that may induce a hemostatic defect (use of a bypass pump) or patients with a positive bleeding history need a hemostasis evaluation by the laboratory. Table 45.5 summarizes the recommendations of Rapaport in evaluating preoperative patients.¹²⁶

TABLE 45.5 GUIDELINES FOR PREOPERATIVE HEMOSTASIS EVALUATION

Bleeding Level	Bleeding History	Surgical Procedure	Recommended Hemostasis Evaluation
I	Negative	Minor	None
II	Negative	Major	Platelet count, PTT
III	Equivocal	Major, involving hemostatic impairment	PT, PTT, platelet count, factor XIII assay, euglobulin clot lysis time
IV	Positive	Major or minor	Level III tests; if negative, then factors VIII, IX, and XI assays, thrombin time, α_2 -antiplasmin assay; consider von Willebrand disease and platelet aggregation testing; consider specific tests for uncommon disorders listed in Table 45.3

PT, prothrombin time; PTT, activated partial thromboplastin time.

Note: Information in this table is a revision based on the suggested preoperative guidelines for hemostasis testing by Rapaport.¹²⁶ The bleeding time is omitted as a hemostasis test because of more recent appreciation of its weakness as a useful test. Comprehensive testing should be performed on level IV patients.

Modified from Rodgers GM. Preoperative hemostasis screening. In: Kjeldsberg CR, Perkins SL, eds.

Practical diagnosis of hematologic disorders, 5th ed. Chicago: ASCP Press, 2010:373.

EVALUATION OF THE NEONATE

Laboratory investigation of hemostasis and blood coagulation in the neonate and infant differs from that just outlined in several respects.¹²⁷ First, the quantity of blood that can be obtained is limited, and often, the venipuncture is difficult. Various microtechniques and modifications of standard coagulation techniques that involve the use of capillary blood have been developed to circumvent this problem.¹²⁸ Second, in terms of adult norms, the results of some tests are abnormal, even in healthy full-term infants (Table 45.6). Such physiologic abnormalities presumably are the result of deficiencies of the vitamin K-dependent factors and of additional abnormalities in the contact phase of coagulation and in the thrombin-fibrinogen reaction.^{4, 129}

The PT may be prolonged but often is normal if vitamin K is administered to the infant or mother.¹²⁹ Abnormalities of the thrombin time and the PTT are present in many normal neonates. These findings usually disappear within 2 to 6 months.⁴ These abnormalities and moderate deficiencies of the vitamin K-dependent factors (prothrombin; factors VII, IX, and X; and proteins C and S) are more pronounced in the premature than in the full-term infant, and they are inversely proportional to gestational age and birth weight. Levels of factors VIII and V as well as antithrombin may be low in extremely premature infants.¹³⁰ Factor VIII levels and the ratio of vWF_{Ag} to VIIIc are higher in term infants than in adults or older children.

Levels of factor V are normal in both neonates and thriving premature infants.^{129, 131} Levels of antithrombin and other physiologic inhibitors of coagulation and of factor XIII are below adult norms in term neonates.¹³² Significant abnormalities of platelet

P.1056

aggregation and of the results of other platelet function tests may be seen in normal neonates.¹³³ The newborn also is abnormally susceptible to drugs that impair platelet function, including those transferred placentally from the mother. The platelet count in term infants, as well as in thriving premature infants, is within the range found in adults and older children. Table 45.6 summarizes coagulation reference ranges in newborns, children, and adults.

TABLE 45.6 AGE-RELATED COAGULATION REFERENCE VALUES IN NEWBORNS, CHILDREN, AND ADULTS

Chapter 46

Thrombocytopenia: Pathophysiology and Classification

George M. Rodgers

PATHOPHYSIOLOGY

Thrombocytopenia may be defined as a subnormal number of platelets in the circulating blood. It is the most common cause of abnormal bleeding. Despite the number and diversity of disorders that may be associated etiologically, thrombocytopenia results from only four processes: artifactual thrombocytopenia, deficient platelet production, accelerated platelet destruction, and abnormal distribution or pooling of the platelets within the body (Fig. 46.1). The changes in the basic parameters of thrombopoiesis that are characteristic of each of these processes are summarized in Table 46.1.

Artifactual Thrombocytopenia

Artifactual thrombocytopenia, or falsely low platelet counts, occurs *ex vivo* when platelets are not counted accurately. This mechanism should be considered in patients who have thrombocytopenia but no petechiae or ecchymoses. Although inaccurate counting may occur in the presence of giant platelets¹ or with platelet satellitism,² the most common cause of artifactual thrombocytopenia is platelet clumping (pseudothrombocytopenia).³ Platelet clumping in pseudothrombocytopenia appears to be caused by anticoagulant-dependent platelet agglutinins that are immunoglobulins (Igs) of IgG, IgA, or IgM subtypes. Although clumping is most commonly seen when blood is collected into ethylenediaminetetraacetic acid anticoagulant, other anticoagulants may cause clumping, even hirudin or Phe-Pro-Arg chloromethyl ketone.⁴ Platelet clumping is also time-dependent and varies with the type of instrumentation used for automatic counting.⁴ There is evidence that the autoantibodies bind to glycoprotein IIb/IIIa,⁵ and in one study, there was over 80% concordance between the presence of anticardiolipin antibody and platelet agglutinins in individual patient plasmas.⁶ These autoantibodies have no known associations with disease or drugs and have been noted in some patients for over 10 years.⁷

Accelerated Platelet Destruction

Accelerated platelet destruction is the most common cause of thrombocytopenia. It leads to stimulation of thrombopoiesis and, consequently, to an increase in the number, size, and rate of maturation of the precursor megakaryocytes (Fig. 46.1).⁸ When the rate of platelet destruction exceeds this compensatory increase in platelet production, thrombocytopenia develops. "Compensated" platelet destruction without thrombocytopenia also may occur in patients with prosthetic heart valves and in patients with idiopathic thrombocytopenic purpura after splenectomy.^{9, 10, 11}

Platelet destruction may result from both intracorporeal defects and extracorporeal abnormalities. Intracorporeal defects are rare but have been demonstrated in certain forms of hereditary thrombocytopenia, such as Wiskott-Aldrich syndrome (see Chapter 49).¹² In such disorders, the survival of affected platelets is shortened in the circulation of both the patient and normal recipients. Platelets injured by either intracorporeal or extracorporeal processes usually are removed from the circulation by the spleen, liver, and reticuloendothelial system. Platelet destruction most often is the result of extracorporeal factors; various immunologic phenomena are the most common. Immunologic platelet destruction is discussed in Chapter 47.

Platelet consumption in intravascular thrombi or on damaged endothelial surfaces is another cause of thrombocytopenia. This occurs in disseminated intravascular coagulation (see Chapter 54) and in thrombotic thrombocytopenic purpura (see

Chapter 48) and other microangiopathic processes. Thrombocytopenia caused by other nonimmunologic platelet destruction is discussed in Chapter 49.

Deficient Platelet Production

Deficient platelet production may result from any of a number of processes. Those that depopulate the stem cell or megakaryocyte

P.1059

compartments are the most common, such as marrow injury by myelosuppressive drugs or irradiation and aplastic anemia. Deficient platelet production also may be the consequence of disordered proliferation within a precursor compartment of normal or even increased size. For example, in disorders characterized by megaloblastic hematopoiesis, hypertrophy of the precursor compartment occurs in response to thrombopoietic stimuli, but thrombopoiesis is ineffective and platelet production is insufficient. Rarely, abnormalities of the processes that normally regulate thrombopoiesis appear to underlie deficient platelet production, such as deficiency of thrombopoietin and cyclic thrombocytopenia.

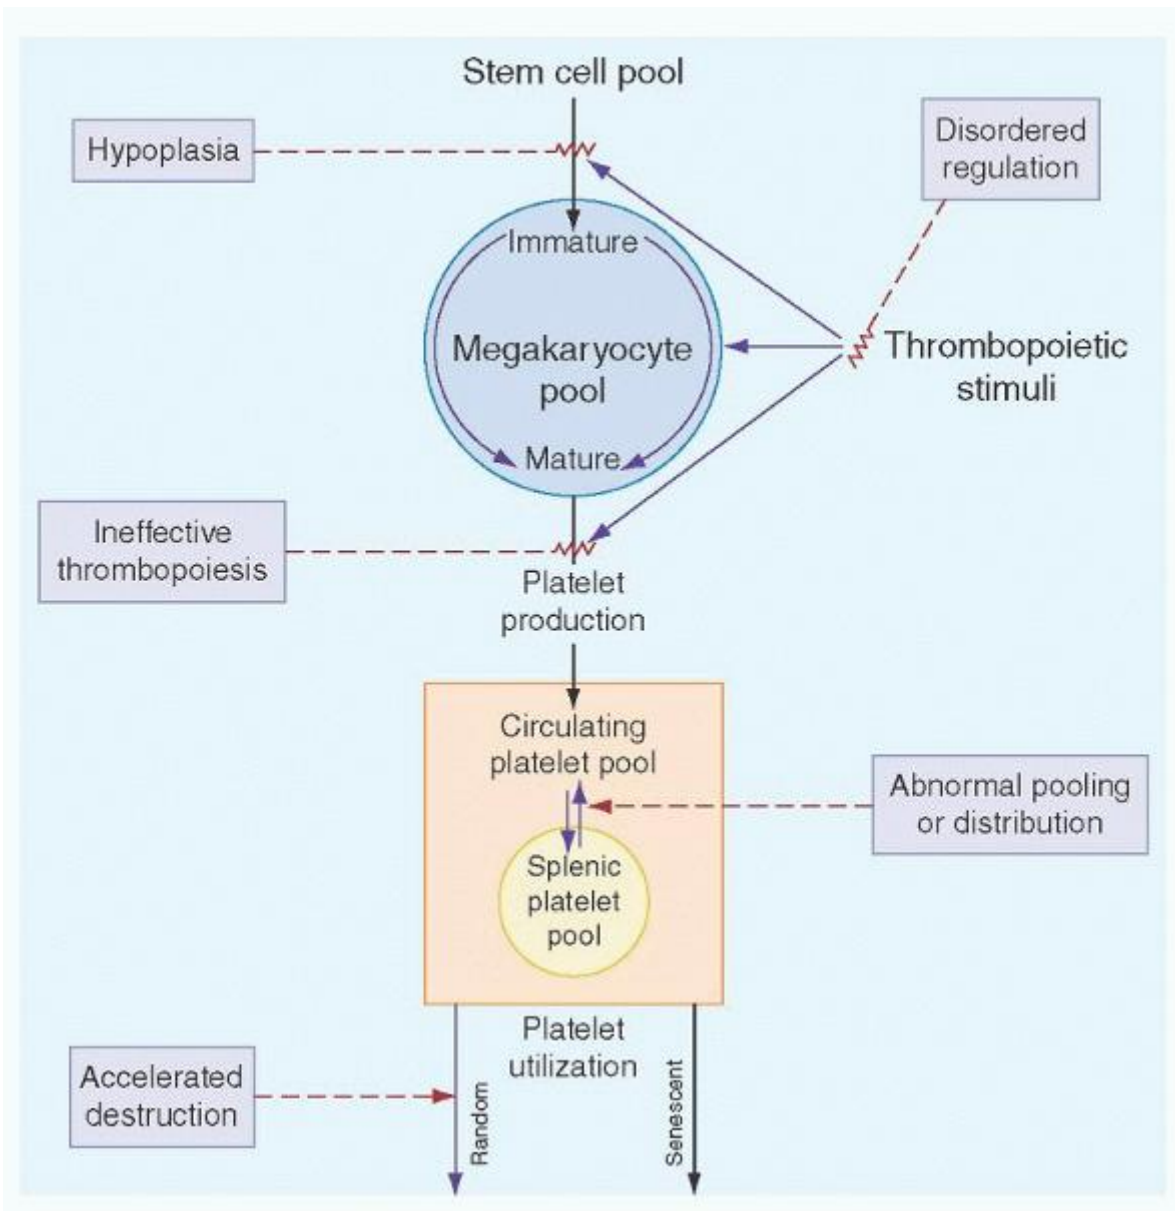

FIGURE 46.1. The pathophysiology of thrombocytopenia. A simplified diagram of the biodynamics of the megakaryocyte-platelet system (solid lines) and the mechanisms (dashed lines) by which pathologic processes (shaded blocks) produce

thrombocytopenia.

TABLE 46.1 THROMBOKINETIC PATTERNS IN VARIOUS FORMS OF THROMBOCYTOPENIA

Measurement	Decreased Production			
	Hypoproliferation or Hypoplasia ^a	Ineffective Thrombopoiesis ^b	Accelerated Destruction ^c	Abnormal Pooling
Total megakaryocyte mass ^d	Decreased	Increased	M increased	V increased
Megakaryocyte number	Decreased	M increased	Increased	V increased
Megakaryocyte volume	Increased	Normal or V decreased	Increased	V increased
Platelet turnover rate or production rate ^e	Decreased	Decreased	Increased	V increased
Total platelet mass	Decreased	Decreased	Decreased	? Normal
Splenic platelet pool	Decreased	Decreased	Decreased ^f	Increased
Platelet survival	Normal	V shortened	Shortened	V shortened

M, markedly; V, variably.

^a Includes myelophthistic processes.

^b Mainly in megaloblastic hematopoiesis; component of accelerated destruction present in some cases.

^c Minor component of ineffective thrombopoiesis present in some cases.

^d Equated to total thrombopoiesis.

^e Equated to effective thrombopoiesis.

Abnormal Pooling

Abnormal pooling or abnormal in vivo distribution of an essentially normal total platelet mass may produce thrombocytopenia. This type of thrombocytopenia is seen in the various disorders associated with splenomegaly (see Chapter 49), in which platelet production is normal or even increased, but most of the platelets are sequestered in the vastly enlarged extravascular splenic pool. Thrombocytopenia may also be caused by dilution of platelets when patients are massively transfused during blood loss. A discussion of various forms of thrombocytopenia attributable to deficient or ineffective thrombopoiesis or abnormal platelet pooling is included in Chapter 49.

CLASSIFICATION

A classification of thrombocytopenia based on pathophysiologic criteria is presented in Table 46.2. It should be recognized that multiple pathogenetic factors may simultaneously or sequentially play a role in the production of thrombocytopenia.

Methods for the measurement of serum thrombopoietin concentrations or reticulated platelets have been reported.

These techniques may both elucidate the pathophysiology of thrombocytopenia in various disease states and determine

the mechanism of thrombocytopenia in individual patients. Reticulated platelets can be identified with fluorescent dyes that bind to nucleic acids,

P.1060

especially RNA. Measurement of the percentage of reticulated platelets identifies platelets that have recently been released from the bone marrow. There is an increased percentage of reticulated platelets in patients with thrombocytopenia caused by increased destruction and a normal to reduced percentage of reticulated platelets in patients with deficient production.^{13, 14} The sensitivity and specificity of this method of distinguishing between these categories are reported to be more than 95%.¹⁵

TABLE 46.2 PATHOPHYSIOLOGIC CLASSIFICATION OF THROMBOCYTOPENIA

Artifactual thrombocytopenia

Platelet clumping caused by anticoagulant-dependent immunoglobulin (pseudothrombocytopenia)

Platelet satellitism

Giant platelets

Decreased platelet production (see Chapter 49)

Hypoplasia of megakaryocytes

Ineffective thrombopoiesis

Disorders of thrombopoietic control

Hereditary thrombocytopenias

Increased platelet destruction

Caused by immunologic processes (see Chapter 47)

Autoimmune

Idiopathic

Secondary: Infections, pregnancy, collagen vascular disorders, lymphoproliferative disorders, drugs, miscellaneous

Alloimmune

Neonatal thrombocytopenia

Posttransfusion purpura

Caused by nonimmunologic processes

Thrombotic microangiopathies

Disseminated intravascular coagulation (see Chapter 54)

Thrombotic thrombocytopenic purpura (see Chapter 48)

Hemolytic-uremic syndrome (see Chapter 48)

Platelet damage by abnormal vascular surfaces (see Chapter 49)

Miscellaneous (see Chapter 49)

Infection

Massive blood transfusions

Abnormal platelet distribution or pooling (see Chapter 49)

Disorders of the spleen (neoplastic, congestive, infiltrative, infectious, of unknown cause)

Hypothermia

Dilution of platelets with massive transfusions

Chapter 47

Thrombocytopenia Caused by Immunologic Platelet Destruction

Meghan S. Liel

Michael Recht

David C. Calverley

Immune thrombocytopenia (ITP) occurs when platelets undergo premature destruction as a result of autoantibody or immune complex deposition on their membranes. Although this disorder was previously known as idiopathic thrombocytopenic purpura, it is now correctly termed ITP because this nomenclature more clearly reflects the immune-

mediated mechanism of the disease.¹ In this chapter, both primary and secondary types of ITP are discussed (Table 47.1). Human immunodeficiencyvirus-related autoimmune thrombocytopenia, which is also in major part a result of the deposition of autoantibody or immune complexes, or both, on the platelet surface, is discussed in Chapter 64.

The diagnosis of ITP is primarily a diagnosis of exclusion, because currently available clinical assays for platelet-associated antibodies or serum antiplatelet antibodies/immune complexes are neither specific nor sensitive enough for routine clinical use. These disorders are characterized by peripheral thrombocytopenia (confirmed by examination of the peripheral smear), with a normal or increased number of megakaryocytes present on bone marrow examination, and absence of splenomegaly. Those patients who have no identifiable underlying cause, which might include infections, collagen vascular diseases, lymphoproliferative disorders (chronic lymphocytic leukemia or lymphoma), or drugs, are diagnosed as primary ITP. In some instances, ITP may be the presenting manifestation of an underlying disease, and additional manifestations appear weeks to months later.

PRIMARY IMMUNE THROMBOCYTOPENIA

Primary ITP refers to thrombocytopenia in which apparent exogenous etiologic factors are lacking and in which diseases known to be associated with secondary thrombocytopenia have been excluded. This syndrome has been recently reviewed.^{2, 3, 4, 5, 6}

Acute ITP and chronic ITP differ in incidence, prognosis, and therapy (Table 47.2). These differences illustrate the wide spectrum of disorders that by definition are included in the syndrome, but many clinicians have long believed that acute ITP and chronic ITP are fundamentally different disorders.

Miscellaneous

Incidence

The annual incidence of ITP in the United States is estimated to be 1.6/10,000.⁷ Acute ITP, defined as thrombocytopenia occurring for <6 months and usually resolving spontaneously, most often affects children and young adults. The incidence peaks in the winter and spring, following the incidence of viral infections.^{8, 9} Acute ITP is most common between 2 and 6 years of age. Approximately 7% to 28% of children with acute ITP develop the chronic variety.^{9, 10, 11} Chronic ITP, lasting >6 months and requiring therapy to improve the thrombocytopenia, occurs most commonly in adults. In chronic ITP in adults, the median age is usually 40 to 45 years,^{12, 13} although in one large series of patients, 74% of 934 cases were younger than age 40 (range, 16 to 87 years of age).¹⁴ The ratio of females to males is nearly 1:1 in acute ITP^{9, 10, 11, 15} and 2 to 3:1 in chronic ITP.^{13, 14}

Pathophysiology

The syndrome of ITP is caused by platelet-specific autoantibodies that bind to autologous platelets, which are then rapidly cleared from the circulation by the mononuclear phagocyte system via macrophage Fcγ receptors predominantly in the spleen and liver¹⁶ (Fig. 47.1). The ITP antibody does not fix complement in vitro when tested by the usual techniques, but activation of components of complement on the platelet surface may be demonstrated.^{17, 18}

A compensatory increase in platelet production takes place in most patients in response to the autoantibody-mediated platelet destruction described above. In others, however, platelet production appears to be impaired as a result of either intramedullary destruction of antibody-coated platelets by marrow macrophages or the inhibition of megakaryopoiesis. Autoantibodies from ITP patients have been shown to inhibit production of megakaryocytes in vitro, and megakaryocyte apoptosis has also been observed in this setting.^{19, 20, 21} Turnover studies have shown platelet production to be reduced or inappropriately normal in around two thirds of ITP patients.^{22, 23, 24} In one study, megakaryocytes were small in patients

with anti-gpIb/VI autoantibodies and increased in size and cytoplasmic area in patients with anti-gpIIb/IIIa autoantibodies,

P.1062

suggesting that the anti-gpIIb/IIIa autoantibody impairs platelet production.²⁵ Megakaryocyte colony formation (colony-forming unit megakaryocyte) is increased in acute ITP.^{26, 27} In chronic ITP, decreased megakaryocyte colony formation has been reported.²⁸

TABLE 47.2 FEATURES OF ACUTE AND CHRONIC IMMUNE THROMBOCYTOPENIA

Feature	Acute ITP	Chronic ITP
Peak age of incidence	Children, 2-6 y	Adults, 20-40 y
Sex predilection	None	3:1 female to male
Antecedent infection	Common 1-3 wk before	Unusual
Onset of bleeding	Abrupt	Insidious
Hemorrhagic bullae in mouth	Present in severe cases	Usually absent
Platelet count	<20,000/ μ l	30,000-80,000/ μ l
Eosinophilia and lymphocytosis	Common	Rare
Duration	2-6 wk; rarely longer	Months or years
Spontaneous remissions	Occur in 80% of cases	Uncommon

FIGURE 47.1. Antiplatelet antibody-induced destruction of platelets (P) in chronic immune thrombocytopenia. Immunoglobulin binds to platelet-associated antigen, resulting in phagocytosis by macrophages (M). Antiplatelet antibody-coated platelets bind to macrophages through macrophage Fc receptors (FcR). •, platelet membrane antigen; γ , platelet autoantibody.

Consistent with findings of inappropriately low platelet production in ITP, plasma levels of endogenous thrombopoietin have not been found to be elevated in ITP.^{29, 30} This differs from impaired platelet production settings such as following chemotherapy.^{29, 30, 31} This may be a result of clearance of thrombopoietin by the megakaryocyte and platelet mass.³²

Platelet Antibodies

In 1951, Harrington and colleagues first reported that the infusion of plasma from patients with ITP predictably induced thrombocytopenia in normal recipients.³³ Shulman and colleagues then demonstrated that the responsible factor was an immunoglobulin (Ig) of the IgG class that was species-specific and could be removed from serum by absorption to and elution from normal human platelets.³⁴ In addition, the platelet-depressing factor produced effects in vivo that were quantitatively and qualitatively similar to those produced by known platelet antibodies. In 1982, van Leeuwen first identified platelet membrane glycoprotein IIb/IIIa as a dominant antigen by demonstrating that the autoantibodies eluted from ITP platelets bound to normal platelets but not to platelets from patients with Glanzmann thrombasthenia.³⁵ Increased quantities of IgG have been demonstrated on the platelet surface in ITP, and the rate of platelet destruction is proportional to levels of such platelet-associated Ig.^{36, 37} Autoantibodies are readily found in plasma or platelet eluate in patients with active disease, but are infrequently found in patients in remission.^{38, 39} Disappearance of the antibodies correlates with the appearance of normal platelet counts.³⁸

The antiplatelet antibodies and platelet antigens involved in ITP have been extensively studied (Table 47.3). Antiplatelet autoantibodies bind to many of the major platelet membrane glycoproteins through the Fab portion of the molecule^{40, 41} (Fig. 47.2). Platelet gpIIb/IIIa was the first platelet antigen detected, and microtiter assays using platelet monoclonal antibodies to gpIb and gpIIb/IIIa later demonstrated that platelet autoantibodies bind to both major platelet membrane glycoproteins.^{42, 43, 44} Serum autoantibodies can react with IIb or IIIa or the intact IIb/IIIa complex.^{44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55} Platelet autoantibody binding to gpIb α has been reported, but data indicate that the majority of Ib/V/IX autoantibodies are directed to the complex.^{56, 57} Some autoantibodies react with gpIV and $\alpha_2\beta_1$, although the plasma from these patients usually also contains autoantibodies reacting with one of the other two major platelet membrane antigens.⁵⁷ Serum antibodies to P-selectin (CD62P) and $\alpha_v\beta_3$ have been detected as well, but their clinical significance is unknown.^{58, 59}

TABLE 47.3 CHARACTERISTICS OF PLATELET AUTOANTIBODIES IN PRIMARY IMMUNE THROMBOCYTOPENIA

		Comments
Ig subtype	IgG, IgA, IgM ^a	IgG and IgA have equal frequency
Antigen specificity	gpIIb/IIIa, Ib/V/IX	Most common antigens
	gpIa/IIa, IV	Never only antigen if positive
	Granule membrane protein-140	One patient reported
	Glycosphingolipid	Rare; unclear pathogenetic importance
	Cardiolipin	Common; ?pathogenetic importance
Presence of antibody		
Plasma	85% of patients	
Platelet eluate	75% of patients	
Complement fixation by antibody	Rare	Unresolved importance
Circulating immune complexes	Rare	Unresolved importance

gp, glycoprotein; Ig, immunoglobulin.

^a IgM is never present as the only antiplatelet Ig in an individual patient.

Antibodies in ITP sera have also been demonstrated to bind to glycosphingolipids^{60, 61} and cardiolipin.^{62, 63, 64, 65} Although two studies identified antiphospholipid antibodies (lupus anticoagulant activity or anticardiolipin antibodies) in 46% and 38%, respectively, of ITP patients at diagnosis, there was little clinical evidence that they played a role in the pathogenesis of the disease or affected outcome.^{66, 67}

The presence of antibodies against multiple antigens is seen in most patients.⁶⁸ Once destruction of platelets within antigenpresenting cells occurs, this generates a series of neoantigens that in turn results in sufficient antibody to cause thrombocytopenia. This phenomenon is termed epitope spread.⁶⁹ Plasma autoantibodies and autoantibodies eluted from

platelets in the same patient may have slight differences in antigen specificities within a membrane glycoprotein complex.⁴⁹ There is evidence from two studies that the specific β_3 antigen epitope in any given patient to which anti-gpIIIa autoantibodies are directed may influence the clinical presentation and course of the disease.^{49, 70} Whether these findings can be generalized to other ITP autoantibody epitopes is unknown.

Autoantibodies bind to platelets and cause thrombocytopenia primarily by shortening platelet survival. However, rare autoantibodies have also been reported that bind to glycoproteins and activate platelets.^{71, 72, 73, 74, 75} Additionally, one patient with an anti-gpIIIa antibody was reported to have developed an antibody-related defect in aggregation and adhesion.⁷⁶

The incidence of serum autoantibodies to platelet gpIIb/IIIa is the same in the acute and chronic forms of childhood ITP (68% vs. 62%, respectively).⁷⁷ The presence of anti-gpIIb/IIIa, therefore, does not predict which children will develop the chronic form of the disease, and, in fact, these data provide evidence that the mechanism may be the same in both acute and chronic forms of ITP.

The role of cell-mediated immunity in ITP remains uncertain, although data from patients with ITP suggest that T lymphocytes

P.1063

demonstrate phenotypic and functional abnormalities. Platelet reactive T-cell clones can be identified from the peripheral blood of adults and peripheral blood and spleens of children with chronic ITP, suggesting that autoreactive peripheral T lymphocytes may mediate or participate in disease pathophysiology.^{53, 78, 79} Adults with ITP often have increased numbers of HLA-DR⁺ T cells, increased numbers of soluble interleukin-2 receptors, and a cytokine profile suggesting the activation of precursor and mature helper T-cells.⁷⁹ CD3⁺ T cells from ITP patients in one DNA microarray study had increased expression of genes involved in cell-mediated cytotoxicity and, in addition, cytotoxic cell-mediated lysis of autologous platelets was shown in active ITP.⁸⁰

AUTOANTIBODIES

DRUG DEPENDENT ANTIBODIES

ALLOANTIBODIES

FIGURE 47.2. Types of antibody-mediated platelet destruction. A: Platelet autoantibodies bind to variable external and internal platelet epitopes. B: Quinine/quinidine-dependent antibodies. The antibody target is a complex of drug and glycoprotein (GP) (usually gPb/V/IX or gPIIb/IIIa). C: Heparin-dependent antibodies. The antigen-antibody complex

(target: platelet factor 4 [PF4]/heparin) activates platelets by the binding of immunoglobulin G (IgG) to Fc γ RIIA on platelets. D: Platelet alloantibodies bind to platelet tertiary conformational epitopes on the platelet membrane. (Modified from Kelton, reference 40.)

Platelet Survival

Platelet survival, measured using ⁵¹chromium- or ¹¹¹indium-labeled platelets, is shortened in ITP, and the survival time can range from 2 to 3 days to a matter of minutes.^{22, 23, 24, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89} Using ¹¹¹indium-labeled autologous platelets, some investigators found an inverse correlation between venous platelet count and platelet survival,⁸⁶ whereas others have not.⁸⁷ These study differences may relate to the types of patients included, as patients with mild to moderate thrombocytopenia have a longer measured platelet survival than patients with severe thrombocytopenia.

P.1064

Splenic sequestration and destruction account for the shortened survival in most patients,^{90, 91} but the liver and the reticuloendothelial cells of the bone marrow can play a major role in the sequestration of antibody-coated platelets, especially in patients with very low platelet counts or continued thrombocytopenia after splenectomy.^{22, 23, 86} Patients with severe thrombocytopenia have been found to have elevated levels of macrophage colony-stimulating factor⁹² and increased in vitro monocyte-platelet rosette formation.⁹³ The spleen has also been implicated as a site of antibody formation.^{94, 95} In a pathologic study of 83 spleens that had been removed after patients did not respond to steroid therapy, investigators found splenic weights of <300 g, prominent secondary lymphoid follicles (28%), foamy macrophages (67%), and megakaryocytic extramedullary hematopoiesis (60%).⁹⁶ These pathologic changes reflect the two major pathogenic roles of the spleen: Antiplatelet antibody production and macrophage-mediated platelet destruction.

Clinical Picture

Immune Thrombocytopenia in Children

In children with acute ITP, the onset of the disorder usually is sudden (Table 47.2). A history of infection preceding the onset of bleeding has been documented repeatedly.^{97, 98} In one series, such infections were noted within 3 weeks of the onset of ITP in 84% of cases.^{8, 9} Varicella zoster virus and Epstein-Barr virus are the most frequently identifiable viruses, although nonspecific unidentified viral infections predominate.⁹⁹ Acute ITP may also occur after vaccination.¹⁰⁰ Although it is most common between 2 and 5 years of age, ITP occurs in all pediatric age groups.¹⁰¹ The severity of ITP in infants is similar to that in older children, but compared to older children, a relatively small percentage of infants develop chronic ITP. A male preponderance was observed in the infant population in two studies.^{101, 102} Even though thrombocytopenia is likely to be severe, the bleeding manifestations of acute ITP in children usually are mild,¹⁰³ and intracranial hemorrhage occurs in <1% of patients. The rare adult with the acute form of the disorder, however, may suffer hemorrhage and a more fulminant course. Acute ITP in children usually is self-limited; spontaneous remissions occur in as many as 90% of patients.^{8, 9} The duration of the disease ranges from a few days to a few months, with an average of 4 to 6 weeks.¹⁰⁴ The favorable prognosis of ITP in children reflects the preponderance of the acute form of the disease in this age group. Children with thrombocytopenia of >6 months duration are classified as chronic ITP, although spontaneous remissions may still occur in an occasional child after 6 months.^{105, 106} Fever of mild degree has been reported, and the spleen tip may be palpable in up to 10% of patients, but this is believed to be the same incidence as is seen in normal children.¹⁰⁷ The spleen is usually of normal weight in those patients who proceed to splenectomy.⁹⁷

Immune Thrombocytopenia in Adults

In adults, the onset of the chronic form of the disorder usually is insidious (Table 47.2). A long history of hemorrhagic symptoms of mild to moderate severity is often described by the patient, but antecedent infections or fever are uncommon. Patients with chronic ITP usually have a fluctuating clinical course. Episodes of bleeding may last days or weeks and may be intermittent or even cyclic. Spontaneous remissions are very uncommon in adults, with an estimated occurrence of <5%.^{13, 14, 108, 109, 110} Most spontaneous remissions occur early; however, remissions have been described after 6 months in a small number of patients.¹³ Relapses in some cases are associated with vaccination.¹¹¹ Often the clinical course is surprisingly benign.

Bleeding Manifestations

The hemorrhagic manifestations of ITP are of the purpuric type. Patients with only ecchymoses and petechiae have "dry" purpura; those with mucous membrane bleeding in addition to skin manifestations have "wet" purpura.¹¹² Platelet counts

are usually lower and the complication rates higher in those with wet purpura. In a series of 712 patients reported by the Israeli ITP study group, 82% of all patients had bleeding limited to the skin, although 43% of adult women reported menometrorrhagia.⁹⁸

In general, the severity and frequency of hemorrhagic manifestations correlate with the platelet count (Fig. 47.3).¹¹³ Bleeding after trauma without spontaneous hemorrhage is usual in mildly affected patients with platelet counts $>50,000/\mu\text{l}$. Thrombocytopenia associated with counts between $10,000$ and $50,000/\mu\text{l}$ results in spontaneous hemorrhagic manifestations of varying severity, such as ecchymoses and petechiae. Patients with platelet counts $<10,000/\mu\text{l}$ are at risk for serious morbidity and mortality from bleeding, although the mortality rate is actually quite low.¹¹⁴ Patients who have an increased risk of bleeding include those with a history of bleeding, those with additional bleeding diatheses, and patients >60 years of age.^{12, 114} Older patients have also been reported to have an increased incidence of major, life-threatening bleeding.^{12, 115, 116}

Skin and Mucous Membranes

Spontaneous bleeding into the skin in the form of petechiae is characteristic. These lesions are minute, red to purple hemorrhages that range in size from that of a pinpoint to that of a pinhead (Fig. 47.4). They are flat, do not blanch with pressure, and appear and regress, often in crops, over a period of days. They are most conspicuous in areas of vascular stasis, such as the areas below tourniquet sites, the dependent portions of the body (especially around the ankles), and areas subjected to constriction from belts or stockings, as well as on skin surfaces over bony prominences. The presence of petechiae on the face and neck is unusual, except as the result of coughing.

Ecchymoses may develop on any skin surface. In ITP, they are seldom associated with subcutaneous hematomas and infrequently spread or dissect into deeper or adjacent structures. Large, purple, superficial ecchymoses may be seen, particularly on the back and thighs. Circular ecchymoses often surround even atraumatic venipuncture sites, but external bleeding from such sites is uncommon. Hemorrhagic vesicles or bullae may be seen inside the mouth and on other mucous surfaces. The bullae probably are the result of severe acute thrombocytopenia rather than a specific feature of any particular pathogenetic form.

FIGURE 47.3. Bleeding manifestations in relation to platelet count in patients with primary immune thrombocytopenia. Bleeding manifestations (or duration) are graded from 0 to 4, as follows: 0, no bleeding; 1, minimal, resulting from trauma; 2, spontaneous, but self-limited; 3, spontaneous, requiring special attention (e.g., nasal packs); and 4, massive uncontrolled or poorly controlled. (From Lacey and Penner, reference 113.)

FIGURE 47.4. Petechiae. Pinpoint, nonblanching erythematous capillary bleeding sites are most common in dependent body areas or pressure points.

Gingival bleeding and epistaxis are common. The latter usually responds for a time to conservative measures, such as nasal packing or tamponade, often to recur intermittently. Epistaxis may originate from lesions resembling petechiae in the nasal mucosa. Such lesions also may be found in the mucous membranes of the throat and mouth, sometimes in the absence of cutaneous hemorrhage. In many patients, discrete bleeding points cannot be identified.

The genitourinary tract is a frequent site of bleeding. Menorrhagia may be the only symptom of ITP and may appear for the first time at puberty. Hematuria also is a common symptom, the blood coming from the kidneys, the bladder, or the urethra, although bleeding into the kidney parenchyma is rare. Gastrointestinal bleeding is usually manifested by melena or, less often, by hematemesis.

Central Nervous System

Intracranial hemorrhage is the most serious complication of ITP. Fortunately, it is rare, affecting 1% to 2% or less of patients with severe thrombocytopenia.^{9, 117} The hemorrhages usually are subarachnoid, often are multiple, and vary in size from petechiae to large extravasations of blood. Numerous small hemorrhages often are seen in the retina; subconjunctival hemorrhage may also occur.

Bleeding after Trauma

Excessive bleeding often follows tooth extractions, tonsillectomy, or other operations or injuries and may first suggest the diagnosis of ITP. In contrast to the hereditary coagulation disorders, such traumatic bleeding is seldom voluminous or rapid. Slow persistent oozing may occur after trivial cuts, razor nicks, and scratches. Delayed bleeding and spontaneous hemarthrosis, which are characteristic of the hereditary coagulation disorders, are extremely rare in ITP.

Laboratory Findings

Blood

The mean platelet count of patients at the time of diagnosis of ITP is 25 to 30,000 and severe thrombocytopenia (<10,000) is frequently seen.^{117, 118} Abnormalities in platelet size and morphologic appearance are common. The platelets often are

abnormally large (3 to 4 μm in diameter) and reveal more than normal variation in size and shape. Abnormally small platelets and platelet fragments ("microparticles") also are evident and may represent the equivalent of microspherocytes and schistocytes.^{119, 120, 121, 122} Although megakaryocyte fragments may be apparent in routine blood smears, quantitative studies reveal subnormal numbers of these fragments.¹²³

Estimates of mean platelet volume (MPV) and the extent of platelet size heterogeneity (platelet distribution width) by means of automated particle counters may, if present, provide useful information in the evaluation of patients with ITP.¹²⁴ The presence of numerous megathrombocytes results in high MPV values.¹²⁵ Platelet distribution width also is increased, presumably reflecting an abnormal degree of platelet anisocytosis.¹²⁶ The exact mechanism underlying such megathrombocytosis is still uncertain, but it may be the result of accelerated platelet production in response to platelet destruction. When MPV is increased in patients with ITP, it is typically inversely correlated in a nonlinear manner with the platelet count. In contrast, low MPV values have been reported in association with big spleen syndromes¹²⁶ and some myeloproliferative disorders, after chemotherapy with cytotoxic drugs, and in patients with septic thrombocytopenia.¹²⁷

Significant abnormalities in the other blood counts should prompt a thorough evaluation for other causes of thrombocytopenia as these findings are unusual in ITP. Anemia, if present, is proportional to the extent of blood loss and is usually normocytic. If bleeding has been severe and long-standing, iron deficiency anemia may occur. Occasionally, recent severe hemorrhage may produce reticulocytosis and moderate macrocytosis. Antiplatelet antibodies in patients with ITP do not usually cross-react with erythrocytes, although erythrocyte fragmentation, presumably the result of weak complement activation, may occur.¹²¹ Patients may also have a positive direct Coombs test and autoimmune hemolytic anemia; the combination is known as Evans syndrome.^{128, 129}

The total leukocyte count and the differential count usually are normal. Eosinophilia has been noted, particularly in children, but this finding is by no means consistent. Lymphocytosis with abnormal cells resembling those characteristic of infectious mononucleosis also has been reported.^{130, 131}

Tests of hemostasis and blood coagulation reveal only changes attributable to thrombocytopenia, such as a prolonged bleeding time. The results of tests of blood coagulation, including prothrombin time, partial thromboplastin time, and fibrinogen, are normal in patients with uncomplicated thrombocytopenia. Slight increases in the levels of fibrinogen degradation products have been demonstrated in the plasma of some patients with ITP.¹³² Plasma levels of glyocalicin, a portion of platelet membrane gplb, may be high in patients with ITP and other forms of platelet destruction. As noted previously, concentrations of thrombopoietin are not significantly increased in ITP.

Bone Marrow

ITP causes no characteristic bone marrow changes; therefore, bone marrow examination should not be routine. The American Society of Hematology (ASH) guidelines for management of ITP recommend against bone marrow biopsy in both children and adults with history, physical exam, CBC, and peripheral smear typical of ITP.⁵ However, bone marrow aspiration may be helpful in the differential diagnosis of ITP in patients who have atypical findings that may suggest some of these other etiologies.

In patients with ITP, alterations in the bone marrow are usually limited to the megakaryocytes, although normoblastic hyperplasia may develop as a result of blood loss. The leukocytes are essentially normal with the exception of occasional eosinophilia.¹³³

Megakaryocytes usually are increased in size¹³⁴ and are increased or normal in number,^{135, 136} the numbers correlating roughly with the MPV. Morphologic abnormalities of these giant cells are present in most patients with ITP. "Smooth" forms with single nuclei, scanty cytoplasm, and relatively few granules are common. Presumably, they represent the results of markedly

P.1066

accelerated platelet production and the presence of many young forms.^{137, 138} The changes just summarized are similar to those found in most forms of thrombocytopenia caused by accelerated platelet destruction and are not characteristic or diagnostic of ITP.

Antiplatelet Antibodies

Primary ITP is a diagnosis of exclusion and relies on clinical impression. A number of different types of antiplatelet antibody tests have been developed and reported through the years.^{36, 139, 140, 141, 142, 143, 144, 145, 146} Most of these tests were quite cumbersome and therefore never became available for routine testing. These tests measured different types

of Ig, including serum antiplatelet antibodies, platelet-associated surface Ig, or total platelet Ig and are now generally regarded as unreliable.¹⁴⁷ The platelet Ig is released, along with other α -granule proteins, such as platelet factor 4 and β -thromboglobulin, during platelet activation and secretion. It is presumed that some of these released proteins bind to the platelet surface. These observations make it difficult to use either the platelet-associated IgG assays or the total platelet Ig assays for the diagnosis of ITP.¹⁴⁸

In a more recent generation of antiplatelet antibody assays, monoclonal antibodies for the specific platelet membrane glycoproteins that are implicated in ITP are used in antigen-capture-type assays (also called glycoprotein immobilization assays).¹⁴⁹ Studies have identified a specificity of 78% to 93%.^{150, 151} However, the sensitivity (49% to 66%) is not high enough to exclude the presence of ITP if the test is negative.^{68, 151, 152} None of these tests is in routine clinical use, and experts disagree on their role in the diagnosis of ITP. Future direction might include the use of flow cytometry in the diagnosis and follow-up of autoimmune thrombocytopenia.¹⁵³

Differential Diagnosis

The initial step in the evaluation of a thrombocytopenic patient is inspection of the peripheral blood smear to confirm the decreased platelet count.¹⁵⁴ Thrombocytopenia may be produced artifactually by clumping of the platelets in the blood sample caused by ethylenediaminetetra-acetic acid-associated platelet agglutinins (pseudothrombocytopenia),^{155, 156} or the platelets may be unavailable for counting because they are bound in rosette formation to the surface of white blood cells in the venous blood sample ("platelet satellitism").^{157, 158}

The diagnosis of ITP is usually a diagnosis of exclusion based on a demonstration of peripheral thrombocytopenia, with a history, physical examination, and complete blood count that do not suggest another cause for the thrombocytopenia. Splenomegaly suggests that the thrombocytopenia may be a result of hypersplenism related to the presence of a separate underlying disease associated with splenic enlargement.

The initial manifestations of acute leukemia, myelodysplastic syndrome,^{159, 160} myelophthisic processes, and aplastic anemia may mimic ITP. These other types of underlying hematologic disorders are suggested by anemia out of proportion to blood loss and by changes in the leukocytes not attributable to either hemorrhage or complicating infection. Although not routinely recommended for the diagnosis of ITP, bone marrow aspiration may be helpful in the differential diagnosis of ITP in patients who have atypical findings that may suggest some of these other etiologies.

The presence of schistocytes in the blood smear suggests that thrombocytopenia may be associated with a microangiopathic process (see Chapter 48). In thrombotic thrombocytopenic purpura (TTP) or hemolytic-uremic syndrome (HUS), thrombocytopenia is associated with laboratory manifestations of hemolysis, including elevated levels of lactate dehydrogenase and indirect bilirubin.¹⁶¹ Patients may also have transient, multifocal neurologic signs or symptoms, renal insufficiency, and/or fever in TTP, or renal insufficiency alone in HUS. After a diagnosis of ITP, the next essential step is to distinguish between primary ITP purpura and secondary forms of ITP purpura, such as human immunodeficiency virus, hepatitis C, or *Helicobacter pylori* infections; collagen vascular diseases such as systemic lupus erythematosus (SLE); lymphoproliferative disorders such as chronic lymphocytic leukemia; and drug ingestion. The ASH guidelines recommend considering testing all adults with a new diagnosis of ITP for hepatitis C and HIV as treatment plans differ in these settings.⁵ The importance of careful inquiry regarding drug ingestion or exposure to toxic substances cannot be overemphasized, because thrombocytopenia attributable to drugs or toxins often is indistinguishable from ITP.¹⁶² The development of thrombocytopenia in an adult, in particular, should arouse suspicion of a pharmacologic etiology, because many of the drugs associated with thrombocytopenia are used more often by adults than by children. It is also essential to eliminate the possibility that the thrombocytopenia is secondary to heparin administration. ITP may be produced by heparin administered in any dose and by any route of administration, including heparin-bonded catheters.¹⁶³ Finally, the antiphospholipid antibody syndrome is a disorder that may be associated with thrombocytopenia. In the usual case, this presentation may be associated with thromboembolic manifestations, anticardiolipin antibodies, and coagulation inhibitors of the lupus type (see Chapter 54).

Treatment of Primary Immune Thrombocytopenia

Many of the treatment recommendations for ITP are based on expert opinion rather than high-level evidence from randomized controlled trials. The ASH has published a practice guideline on ITP.^{5, 164, 165} The reader is referred to this practice guideline for specific questions regarding the treatment of patients with ITP.

Children

Childhood ITP is usually benign and self-limited. Therefore, treatment is not required for most patients. Treatment is reserved for patients with severe thrombocytopenia ($<20,000/\mu\text{l}$) and bleeding, or patients who remain thrombocytopenic

for >6 months, that is, those with chronic ITP (Table 47.4).¹⁶⁶ Treatment guidelines recommend observation for all children with no or mild bleeding, regardless of platelet count.⁵ Although the greatest

P.1067

fear in the acute form is intracranial hemorrhage, several large studies show that even with low platelet counts (<30,000/ μ l) life-threatening bleeding and intracranial hemorrhage are rare (<0.5%).^{166, 167}

TABLE 47.4 RECOMMENDATIONS FOR INITIAL TREATMENT OF IMMUNE THROMBOCYTOPENIA (IVIG) PATIENTS WITH PLATELET COUNTS <20,000-30,000/ μ l^a

	Children	Adults
Asymptomatic	None	Steroids (preferred) or IVIG
Minor purpura	None	Steroids (preferred) or IVIG)
Mucosal membrane bleeding that may require clinical intervention	IVIG or steroids	IVIG and/or steroids
Severe, life-threatening bleeding	Steroids and IVIG Hospitalization Consider platelet transfusion and other measures	Steroids and IVIG Hospitalization Consider platelet transfusion and other measures

^aThe current ASH guidelines recommend treatment for adults with platelet counts of <30,000/ μ l.

Treatment guidelines for pediatric ITP recommend first-line treatment with either a single dose of intravenous immunoglobulin (IVIG) (0.8 to 1 g/kg) or a short course of steroids.⁵ Several multicenter randomized trials have been performed in high-risk patients with acute ITP to define whether treatment is associated with a prompt increase in platelet counts. These clinical trials demonstrated that treatment with either oral prednisone or IVIG was associated with a more rapid rise in platelet count to >20,000/ μ l than either no therapy or treatment with anti-D.^{168, 169} Only IVIG shortened the time to reach a platelet count >50,000/ μ l. More recently, children with platelet counts <10,000/ μ l or counts of 10,000 to 29,000/ μ l and mucosal bleeding were studied in a prospective randomized clinical trial, and IVIG raised platelet counts faster than three corticosteroid regimens.¹⁷⁰ Therefore, IVIG should be preferentially used if a rapid rise in platelet count is desired.

Treatment of children who develop persistent ITP or are unresponsive to initial treatment is evolving. Splenectomy remains a standard given high response rates; however, many experts recommend delaying splenectomy for at least 12 months given the frequency of spontaneous remission.⁵ Rituximab treatment has been used in children and adolescents in a small study comprised of 36 patients with chronic ITP.¹⁷¹ In contrast to observations in adults, the median time to response was 1 week (range 1 to 7 weeks), and the overall response rate was 31%. Outcome was not associated with age, prior pharmacologic response, prior splenectomy, duration of disease, screening platelet count, refractoriness, or IgM reduction. Therefore, rituximab may be considered as an alternative to splenectomy in children with chronic ITP or in patients with persistent bleeding despite first-line treatments.⁵ High-dose dexamethasone (0.6 mg/kg/day) may also be considered in patients who are unresponsive to initial therapy based on small studies showing a 25% response rate in refractory patients.¹⁷²

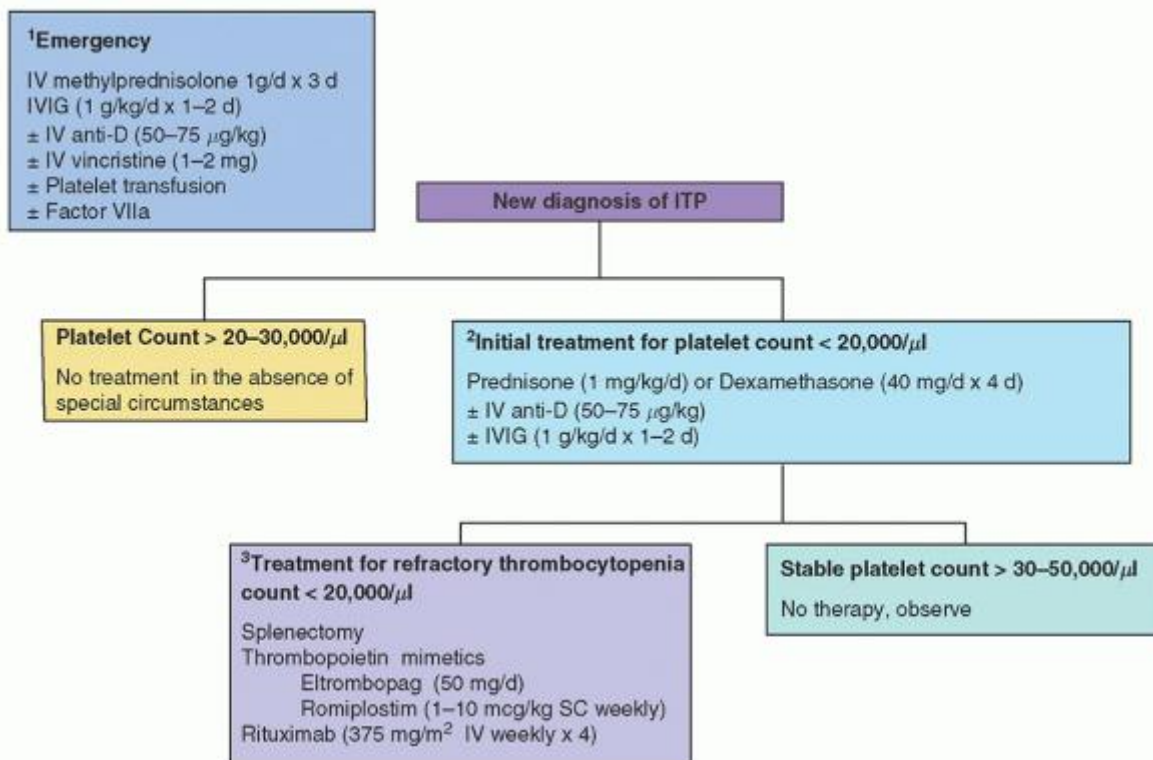

FIGURE 47.5. Therapy of adult immune thrombocytopenia (ITP). (1) Minimal emergency therapy includes intravenous (IV) methylprednisolone and intravenous immunoglobulin (IVIG). Intravenous anti-D and platelet transfusions may be given as needed. All three modalities given prior to transfusions may help preserve platelet longevity in the circulation and repeated or continuous platelet transfusions may be required in urgent situations. (2) Initial treatment of ITP typically consists of steroids (prednisone or dexamethasone) with the goal of attaining a platelet count of $>30,000/\mu\text{l}$ and cessation of bleeding. IVIG or anti-D may be used if steroids are contraindicated or the patient has persistent thrombocytopenia despite steroids. (3) Thrombocytopenia recurs in most adults as corticosteroids are tapered. Treatment options for refractory ITP include splenectomy, thrombopoietin mimetics, and rituximab. (Modified from Cines and Bussel, reference 459.)

Adults

Patients with chronic ITP may have mild thrombocytopenia that can be followed without treatment. The incidence of bleeding is correlated with the platelet count; therefore, patients with platelet counts $>50,000/\mu\text{l}$ rarely have spontaneous bleeding and may require treatment only if extensive operative procedures are planned. Patients with platelet counts $<20,000$ to $30,000/\mu\text{l}$ or significant mucosal membrane bleeding with platelet counts $<50,000/\mu\text{l}$ are usually treated⁵ (Table 47.4 and Fig. 47.5).

No prospective studies on long-term prognosis of ITP after treatment are reported. However, it has been reported that most adult patients have a good response to treatment (without necessarily returning to normal platelet counts) and have no excess mortality when compared to the general population.¹⁷³ A small group of patients who had severe thrombocytopenia after 2 years of primary and secondary therapies had a mortality risk of 4.2 (95% confidence interval, 1.7 to 10.0) resulting from both bleeding and infectious complications related to therapy.

ITP is uncommon in elderly patients; only 30% of patients in reported series are >45 years of age.^{133, 174} However, these patients may be more refractory to therapy¹¹⁵ and appear to have a higher incidence of hemorrhagic complications than younger patients.¹² Guthrie and colleagues reported a 52% incidence of life-threatening or fatal bleeding in their series of 40 patients

P.1068

older than age 45 years.¹¹⁵ This risk of fatal bleeding in patients with platelet counts that are chronically $<30,000/\mu\text{l}$ is estimated at 0.4% per year for patients <40 years of age and 13.0% per year for patients >60 years of age.¹⁷⁵

First-line Treatment

Initial treatment for adult patients with newly diagnosed ITP is typically steroids. Other options that increase the platelet count rapidly include IVIG and anti-D. The most recent ASH guideline recommends use of these alternative first-line therapies in patients with contraindications to steroids.⁵ Patients with life-threatening bleeding may require parenteral glucocorticoids and IVIG followed by platelet transfusions,¹⁷⁶ plasmapheresis,¹⁷⁷ or even emergency splenectomy as first-line treatment. Standard ITP treatments and their dosing schedules are shown in Table 47.5.

Steroids

Steroids are the conventional first-line therapy for adult ITP. Dameshek first reported his experience with prednisone therapy in 1958,¹⁷⁸ when 30 consecutive patients with acute (N = 11) or chronic (N = 19) ITP were treated with 20 to 150 mg/day of prednisone. Twenty-two of the patients demonstrated an increase in platelet count to normal after an average interval of 22 days and then were maintained on 2.5 to 15.0 mg/day of prednisone. In eight patients, prednisone was discontinued without relapse.

Numerous retrospective studies of steroid treatment in both children and adults with ITP have been reported.^{13, 14, 97, 98, 104, 108, 109, 110, 133, 174, 179, 180, 181, 182} The criteria for inclusion of patients in the individual studies and the criteria for response to treatment vary significantly among the reports; therefore, it is difficult to combine the data accurately. However, some useful observations can be made. Complete (CR) and partial (>50,000/ μ l) responses (PR) in patients treated with prednisone (usually, 1 mg/kg/day as starting dose) average 65% to 85%, but sustained responses after discontinuation of the drug occur in only 25% or less of patients.^{183, 184} Platelet counts usually increase within 1 week in responding patients and have usually reached peak values by 2 to 4 weeks. Patients who have not had any response by 4 weeks are unlikely to respond to prednisone and therefore should be considered for other forms of treatment. No pretreatment patient characteristics have predicted a patient's response to steroids.

TABLE 47.5 THERAPEUTIC AGENTS AND THEIR DOSING SCHEDULES

Agent	Dose and Schedule
Anti-D immunoglobulin	50-75 μ g/kg IV, repeated at 3-week intervals as indicated
Cyclophosphamide	150 mg daily for up to 8 wk
Colchicine	200 mg daily for up to 4 wk
Dexamethasone	40 mg daily for 4 d, repeated every 14 d for 4 cycles
Danazol	400 mg twice daily for 1 mo or longer
Eltrombopag	50 mg daily. Must be continued indefinitely.
IVIG	1 g/kg IV for 1-2 d, repeated every 2 to 4 wk as indicated
Prednisone	1 mg/kg daily for up to 28 d, then taper to lowest dose possible
Rituximab	375 mg/m ² IV weekly for 4 doses
Romiplostim	1-10 mcg/kg subcutaneous injection weekly. Start at 1 mcg/kg and titrate based on platelet count. Must be continued indefinitely.
Vincristine	2 mg at 5- to 7-day intervals for 2 or more doses
Vinblastin	7.5 mg at 5- to 7-day intervals for 3 or more doses

Modified from Narang et al.⁴⁶⁰

Several prospective randomized steroid treatment trials in patients with ITP have been reported. Bellucci and colleagues randomized patients between low (0.25 mg/kg/day) or high (1.0 mg/kg/day) prednisone for 3 weeks, with taper and discontinuation by the end of the fourth week.¹⁸⁵ If bleeding continued, patients could be increased from low dose to high dose, or a second 4-week course could be given. CR, defined as a platelet count >100,000/ μ l for at least 6 months, was seen in 74% of children and 41% of adults. CRs or PRs occurred in 83% of children and 59% of adults. No significant differences were seen between low- and high-dose regimens in either age group. Mazzucconi and colleagues randomized

patients between prednisone 0.5 mg/kg/day and 1.5 mg/kg/day.¹⁸⁶ The response rates in adults were not significantly different between patients treated with low- versus high-dose steroids: 30% and 34% CR, respectively. In children, however, the rates were 64% for low-dose versus 81% for high-dose prednisone. Therefore, there is evidence to support the use of lower doses of steroids in adults than have conventionally been used at the beginning of treatment. However, based on the opinion of an expert panel convened by the ASH, high-dose prednisone (1 mg/kg/day) is recommended as appropriate initial treatment in ITP patients with platelets <30,000/ μ l, including asymptomatic patients.^{5, 164, 165}

Another prospective randomized, controlled trial compared prednisone (1 mg/kg/day) to IVIG (400 mg/kg/day for 4 days), or to both in a small number of patients.¹⁸⁷ A platelet count >50,000/ μ l was achieved in 82%, 54%, and 92% of patients, respectively. The median times to peak platelet counts were 8.5, 7.0, and 7.0 days. These authors concluded that there was no advantage for IVIG over conventional corticosteroid treatment. In another recent randomized control trial, platelet counts >50,000/ μ l were achieved more quickly in patients receiving IVIG than in those receiving intravenous methylprednisolone, but long-term outcomes were the same.¹⁸⁸

There are also several studies that have evaluated the role of high-dose dexamethasone in the initial treatment of ITP. This protocol was initially developed because of concern regarding long-term side effects of daily prednisone use. Initial trials showed that using 40 mg of dexamethasone daily for 4 consecutive days results in an initial response in 85% of patients.^{189, 190} Additional work has shown that repeating dexamethasone bursts may provide long-term disease control in some patients. Mazzucconi and colleagues treated newly diagnosed patients with ITP with dexamethasone 40 mg daily for 4 days, repeating these cycles every 14 days for 4 cycles.¹⁹¹ A total of 85% of patients responded with 65% achieving a CR. Relapse-free survival at 15 months was 81% indicating that many of these patients may be long-term responders.

There are conflicting opinions regarding the choice of prednisone versus dexamethasone for first-line treatment of ITP. The writers of the 2011 ASH guidelines favor longer-term prednisone over dexamethasone⁵ but other experts in the field think that either is reasonable.¹⁹²

The mechanism of action of steroids in ITP involves both direct and indirect effects on thrombocytopenia. Steroids ameliorate thrombocytopenia directly by several mechanisms. Steroids may (a) decrease consumption of antibody-coated platelets by the spleen^{193, 194, 195} or bone marrow, (b) reduce antibody production by the spleen,^{94, 196} (c) decrease antibody production by the bone marrow,¹⁹⁷ and/or (d) increase marrow platelet production by undetermined mechanisms.¹⁹⁸

There is little doubt that corticosteroids in high doses ameliorate splenic sequestration of antibody-coated platelets. Corticosteroids decrease antibody-coated red blood cell sequestration in guinea

P.1069

pig spleens by decreasing Fc γ receptor proteins on macrophages,¹⁹⁹ and in vivo and in vitro data support a similar action of steroids in humans.^{90, 91, 194, 200, 201} Corticosteroids also decrease monocyte Fc receptors in autoimmune hemolytic anemia.²⁰² This down-regulation of monocyte/macrophage Fc receptors may account for the early effects of steroid treatment on platelet counts. Chronic corticosteroid treatment is associated with a decrease in antibody production, but this usually occurs after several weeks of high-dose steroids. Steroid treatment also results in increased platelet production in some ITP patients,¹⁹⁸ an effect that may be secondary to reduction of the antiplatelet Ig effect on thrombopoiesis, reduction in intramedullary destruction of antibody-coated platelets before their release into the circulation, or decreased antibody synthesis by bone marrow lymphocytes.

In addition to these direct effects on thrombocytopenia, steroids also act on endothelial cells to reduce bleeding. Experimental evidence indicates that thinning of the endothelium with development of endothelial fenestrations occurs in both animal models and humans with ITP, suggesting that platelets play a role in normal endothelial homeostasis.^{203, 204} Clinically, steroids are known to ameliorate the purpuric bleeding in ITP patients before the platelet count actually increases. Experimentally, investigators have demonstrated that 3 days after steroid therapy in rabbits and 4 days after steroid therapy in patients, the endothelial thinning reverts toward normal, providing a scientific explanation for this clinical observation.^{204, 205} This endothelial effect may in part be explained by the observation that when endothelial cells are cultured with steroids, cell morphology is altered, with greater confluence and increased protein synthesis and content.²⁰⁶

Intravenous Immunoglobulin

The intravenous administration of polyvalent Ig (IVIG), first used in 1981,²⁰⁷ may induce remissions in patients with life-threatening bleeding or in patients with refractory ITP. IVIG therapy has proved most effective in infants and small

children,^{208, 209} an age group in which the response is difficult to evaluate because of the frequency of spontaneous remissions. In adults this regimen has produced relatively less impressive long-term results,^{210, 211, 212, 213} although an occasional patient enters complete remission after the initial treatment and a series of booster doses.^{214, 215, 216, 217} In a review of 28 published reports of IVIG in 282 adults, 64% of patients had a peak platelet count $>100,000/\mu\text{l}$, and 83% had peak platelet counts $>50,000/\mu\text{l}$ ²¹⁸ after the initial infusion. Platelets may begin to rise after 2 days and usually reach peak levels by 1 week after treatment.

Regimens of 400 mg/kg/day for 5 days versus 1,000 mg/kg/day for either 1 or 2 days,^{219, 220} have been equally effective in randomized trials, and doses of 0.5 g/kg are as effective as 1.0 g/kg for maintenance therapy.²²¹ These doses produce significant increases in serum and platelet levels of IgG.^{209, 214, 216} In a randomized controlled trial, one dose of 1,000 mg/kg was superior to 500 mg/kg in raising platelet counts to $>80,000/\mu\text{l}$ by day 4.²²⁰ Most of these patients were being prepared for splenectomy or delivery.

Several mechanisms are thought to be involved in the beneficial effects of IVIG. They include Fc receptor blockade of reticuloendothelial cells,^{214, 216, 222, 223, 224, 225} effects on B cells and antibodies^{226, 227, 228, 229, 230, 231} and anti-inflammatory effects.^{232, 233} No evidence exists that reduction of antiplatelet antibodies accounts for the acute effects of therapy.²³²

Therapy with IVIG remains expensive. The rapid nature of the response to treatment makes it an ideal agent for treatment of patients for life-threatening bleeding or before surgery^{234, 235}; however, the role of IVIG in long-term therapy remains uncertain. The major side effect of treatment is headache, although some patients also develop fever, myalgias, and skin rashes.²³⁴ There are also reports of acute renal failure occurring in up to 7% of patients, especially older patients and those with diabetes, or baseline increases in creatinine (or both).^{236, 237} The patients may be oliguric, and most demonstrate peak creatinine levels by day 5 after the IVIG infusion. Hemodialysis may be required acutely, and several patients required chronic dialysis. The volume of fluid required for IVIG administration can also be a major problem in some older patients with co-morbidities such as congestive heart failure.

Anti-D

Intravenous Rho (D) immune globulin (anti-D) has been studied in children and adult ITP as an alternative to IVIG.^{238, 239, 240} The mechanism of action is unknown; however, it is believed that the antibody coats the red blood cells of Rh-positive patients and either blocks the reticuloendothelial clearance of platelets or modulates the immune system, resulting in an increase in the platelet count.^{240, 241} Although infusion of both IVIG and anti-D slow the Fc γ -receptor-mediated destruction of antibody-coated platelets, responses to anti-D appear to uniquely correlate with polymorphisms specific to the Fc γ RIIIa and Fc γ RIIIb receptors.²⁴² This is characterized by increases in the plasma levels of IL-6, tumor necrosis factor- α , monocyte-chemoattractant protein-1, and IL-10 that are specific to IV anti-D infusions compared with IVIG.

Children respond better than adults, and nonsplenectomized patients respond better than splenectomized patients to anti-D.^{241, 243} The platelet count does not begin to increase for 48 to 72 hours, so it may not be as effective for the treatment of life-threatening bleeding compared with IVIG. The effect lasts for several weeks to a month, and patients respond well to retreatment. They may respond to intramuscular injections given weekly as maintenance.²⁴⁴ Occasionally, patients have a sustained remission.²⁴⁵ Most patients exhibit a modest decrease in hemoglobin, and most have subclinical signs of mild hemolysis,²⁴³ with decreased haptoglobin, increased lactate dehydrogenase, and increased indirect bilirubin. Red cell survival is only modestly reduced.²⁴⁶ No correlation has been found between the amount of hemolysis and the platelet response, leading some investigators to question the proposed effect on reticuloendothelial blockade.²⁴⁷

Reinfusion of autologous red blood cells that have been opsonized with anti-D has produced both complete and partial remissions in a small number of patients, even after splenectomy.²⁴⁸ With respect to anti-D dosing, early studies in adults receiving 25 to 50 $\mu\text{g}/\text{kg}/\text{day}$ showed an increase in platelet count of $>20,000/\mu\text{l}$ in 79% of patients. However, the platelet count did not increase for >72 hours, which made this treatment approach less efficient for bleeding patients.²⁴⁹ More recent studies have shown a more rapid increase of the platelet count within 24 hours and a longer duration of the increase when using a higher dose of 75 $\mu\text{g}/\text{kg}$ compared with 50 $\mu\text{g}/\text{kg}$.²⁵⁰ Anti-D therapy now carries a black box warning that requires observation of the patient for 8 hours after administration due to the risk of intravascular hemolysis and disseminated intravascular coagulation.²⁵¹

Treatment of Chronic Primary Immune Thrombocytopenia

Many adult patients with ITP, even if they initially respond to steroids, will develop chronic ITP. Chronic ITP is defined as ITP lasting longer than 12 months.¹ Patients who are asymptomatic and have platelet counts between 30,000 and 50,000/ μl may be managed with careful observation.^{164, 184} Symptomatic patients with platelet counts $<30,000/\mu\text{l}$ who had an initial response to steroids can be retreated with prednisone and then tapered to find the minimum dose that can

maintain the patient hemorrhage-free, even if the platelet count is not $>30,000/\mu\text{l}$. If patients can be maintained on 10 mg every other day, additional treatment may not be

P.1070

indicated. Some patients observed for years with platelet counts of $10,000/\mu\text{l}$ have had no significant bleeding other than ecchymoses or petechiae, even without steroid therapy.²⁵² Splenectomy has been the traditional therapy for refractory cases of ITP. There are more options now with accumulating evidence regarding the role of rituximab and thrombopoiesis-stimulating agents.

Splenectomy

Patients with severe thrombocytopenia ($<10,000/\mu\text{l}$) who do not respond to steroids (administered for up to 4 weeks) or who relapse during steroid tapering, and patients with platelet counts of $<30,000/\mu\text{l}$ for periods up to 3 months, should be considered for splenectomy.⁵ Most patients demonstrate a response to steroids within 2 to 4 weeks, but a late response is rarely seen. Therefore, the best time for splenectomy in a patient who does not respond to steroid therapy must be determined individually.

Sustained CRs to splenectomy (variously defined as platelet counts of $100,000$ to $150,000/\mu\text{l}$) have been reported in ~50% to 80% of patients, depending on the series.^{252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265} After the operation, the platelet count may increase rapidly, often within 24 to 48 hours, and may reach levels as high as 1 million/ μl or even higher in approximately 10 days.⁹⁷ Operative mortality is $<1\%$, and perioperative bleeding is rare.^{13, 14, 98, 108, 109} Platelet transfusions are usually given only if the patient has bleeding after the spleen has been removed. Postsplenectomy infections are also rare, especially if patients have received immunization to encapsulated organisms (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*) before splenectomy. Laparoscopic splenectomies in ITP patients are as successful as conventional splenectomies, although patients occasionally may require conversion to an open procedure.^{266, 267} Therapeutic responses are reported also when splenic ultrasound,²⁶⁷ splenic radiation,^{268, 269} or partial splenic embolization²⁷⁰ was used instead of splenectomy.

Patients who do not respond to splenectomy or who relapse after an initial response to splenectomy should be studied for the presence of accessory spleens.^{262, 271, 272, 273, 274, 275} The incidence of accessory spleens found at the time of the original splenectomy ranges from 15% to 20%.^{257, 262} The incidence of accessory spleens in patients who relapse after splenectomy may be as high as 50%,^{133, 263, 264} and surprisingly, the majority of these patients demonstrate postsplenectomy changes (i.e., Howell-Jolly bodies) on their peripheral blood smears. Relapse secondary to an accessory spleen may occur weeks to years after the initial splenectomy. Scanning methods have varying sensitivities; conventional^{99m}Tc scans,^{99m}Tc scans using heatdenatured red blood cells, or computed tomography scans can be used. Accessory spleens as small as 0.5 cm have been found when¹¹¹In scans were performed preoperatively and isotope detector probes were used intraoperatively to detect all accessory splenic tissue.²⁵⁷ A review of 56 published cases demonstrated a 73% excellent therapeutic response and a 27% moderate response to accessory splenectomy.²⁵⁷

The effectiveness of splenectomy in the therapy for ITP is attributed to removal of the organ that is primarily responsible for the destruction of antibody-sensitized platelets. The increase in platelet count correlates with an increase in platelet survival, whereas platelet production remains unchanged.¹⁹⁸ The removal of the spleen may also result in a reduction of antibody production, but this effect is probably of minimal significance in view of the immediate favorable responses to splenectomy. No factors have consistently predicted a response to splenectomy; age, concentration of platelet-associated IgG, the time between diagnosis and splenectomy, the patient's response to steroids, IVIG or intravenous anti-D, and the peak postoperative platelet count have all been studied.^{256, 276, 277, 278, 279, 280} The site of platelet sequestration, based on preoperative⁵¹Cr- and¹¹¹In-labeled platelet survival studies, may be predictive of response,^{260, 281} but these techniques are seldom used.

Rituximab

Rituximab, an anti-CD20 monoclonal antibody, has produced CRs or PRs in approximately 60% of patients.^{282, 283, 284, 285, 286} Rituximab causes selective B-cell lysis in vitro and B-cell depletion in vivo.²⁸⁷ Involved mechanisms of action include apoptosis, antibody-dependent cell-mediated cytotoxicity, and/or complement-dependent cytotoxicity. Recovery of B-cell counts usually occurs by 6 to 12 months after completion of treatment.

Most of the patients in the studies of rituximab in ITP had relapsed or refractory disease, and some had undergone splenectomy. The majority of studies have used the standard treatment dose of $375\text{ mg}/\text{m}^2$ weekly for four weekly doses;²⁸⁶ however, published reports have shown that lower doses are effective as well.²⁸⁸ The side effects were mild and

seen most commonly after the first infusion. The long-term safety profile of rituximab is felt to be favorable. Only one case of progressive multifocal leukoencephalopathy, a rare but fatal consequence of rituximab administration, has been reported in a patient with ITP.²⁸⁹ There are two different response patterns, early versus late.²⁹⁰ Patients with an early response to four weekly infusions had an increasing platelet count after the first or second infusion and peaked between weeks 6 and 10. Late responders had no rise of their platelet count during treatment but increased their platelet count between weeks 6 and 8, with the peak occurring shortly thereafter. In one study, the B-cell count in patients who responded was lower than in patients who did not have a response.²⁸⁵

A recent meta-analysis of studies employing rituximab in the treatment of refractory/relapsed patients consisted of 299 patients described in 15 reports.²⁹¹ The overall response rate was 55%, of which 38% of patients achieved a CR, which was defined as a platelet count of at least 100,000 to 150,000/ μ l. In addition, 17% of the patients achieved a PR, which was defined as a platelet count of >50,000 and <100,000/ μ l. The median duration of response was 74 weeks (24 to 120 weeks) and in PR patients was 55 weeks (12 to 160 weeks). CR in splenectomized patients (62%) was higher than in nonsplenectomized patients (available from five studies, n = 126).²⁷² Another recent meta-analysis showed similar results with 43.6% of patients achieving a CR (>150,000/ μ l) and 62.5% of patients achieving a PR (>50,000/ μ l).²⁸⁶

Longer-term studies have shown that prolonged disease responses are less common. Patel et al. reported that with 2.5 years of follow-up 1 in 6 patients remained in remission.²⁹² Most patients with relapse can be retreated with rituximab with success.²⁹³ The role of rituximab as part of first-line therapy for ITP is currently under investigation²⁹⁴ but is not considered a standard of care.

Thrombopoiesis-stimulating Agents

Thrombopoiesis-stimulating agents (thrombopoietin mimetics) are another, recently approved treatment option for management of refractory ITP. There are two currently available thrombopoiesis-stimulating agents, eltrombopag and romiplostim. They have both been the subject of randomized controlled trials in refractory ITP.

Eltrombopag, an oral agent, is a peptide that interacts with the transmembrane domain of the thrombopoietin receptor thereby stimulating differentiation and proliferation of megakaryocytes in the bone marrow. The most common side effects are mild elevation in liver enzymes and nausea/vomiting.²⁹⁵ In a study published in 2009, 114 patients with refractory ITP were randomized to eltrombopag versus placebo in a 2:1 randomization.²⁹⁵ After 6 weeks of follow-up, 59% of patients in the eltrombopag arm versus 16% in the placebo arm had achieved a platelet count >50,000 and less bleeding was observed in the eltrombopag arm.

P.1071

Platelet counts dropped again within 2 weeks of discontinuing therapy. A phase III study (RAISE) in patients with chronic ITP published in 2011 showed similar results.²⁹⁶ After two weeks of therapy, median platelet counts in the eltrombopag group were 53,000 to 73,500 versus 17,500 to 23,000 in the placebo arm. Patients in the eltrombopag arm had less bleeding and were more successfully tapered off their other ITP treatments.

Similar results have been seen with romiplostim. Romiplostim is an injectable thrombopoietin mimetic that is given once per week. It is a thrombopoietin mimetic peptide (peptibody) which binds to the thrombopoietin receptor. In a randomized study published in 2008, patients with ITP were randomized in a 2:1 fashion to romiplostim versus placebo.²⁹⁷ In splenectomized and nonsplenectomized patients, 79% and 88% of patients receiving romiplostim achieved a platelet count >50,000. Only a very low number of patients in the placebo arm achieved this threshold (14% of nonsplenectomized patients, 0% of splenectomized patients). This correlated with decreased use of other ITP therapies. The most common side effects are arthralgias, fatigue, and nausea.²⁹⁸ Serious adverse events are rare. Additional trials have shown that romiplostim is safe and effective for prolonged use²⁹⁹ and that decreased bleeding is observed in patients receiving romiplostim due to higher platelet counts.³⁰⁰ With prolonged use patients do still require regular platelet monitoring as the dose required may vary over time.²⁹⁹ As with eltrombopag, indefinite treatment is required as platelet counts fall quickly when treatment is discontinued.

There has been some concern regarding increased marrow fibrosis in patients receiving eltrombopag or romiplostim. Preclinical data showed increased fibrosis in the marrow of rats treated with romiplostim.³⁰¹ This appeared to be dose dependent and decreased after the treatment was discontinued. In the same paper, a retrospective review of clinical trials using romiplostim was performed.³⁰¹ Reticulin deposition was noted in 10 of 271 patients; however, most patients did not have bone marrow biopsies performed. In 5 patients who had pretreatment bone marrow biopsies, reticulin deposition increased in 4 patients. In all patients, reticulin staining decreased when romiplostim was discontinued. In 10 patients

followed prospectively with serial bone marrow biopsies, only 1 of 10 patients treated developed new reticulin fibrosis on treatment. Similar findings are seen with eltrombopag. The clinical significance of this finding is unclear.

Although the thrombopoietin mimetics are effective in both splenectomized and nonsplenectomized patients, expert panels recommend that they be reserved for patients with refractory ITP after splenectomy and patients with contraindications to splenectomy.⁵ This recommendation is based on concerns regarding the requirement for indefinite treatment which is accompanied by significant cost and risk of long-term toxicities that have not yet been identified.

Immunosuppressive Drugs

Immunosuppressive therapy for ITP has yet to be evaluated thoroughly; the overall effectiveness of these potent drugs is variable, and remissions achieved have been short-lived. Poor results were reported in children.³⁰² Favorable results are nevertheless noteworthy, because they were obtained in refractory patients who had not responded to splenectomy or steroids.³⁰³

Preliminary reports of successful treatment in refractory patients have been published using high-dose methylprednisolone^{234, 304} and cyclophosphamide-based combination chemotherapy.³⁰⁵ Cyclophosphamide alone, either daily oral or pulse intravenous therapy, induced remissions in 16% to 55% of patients.^{14, 303, 306, 307, 308} However, this drug must be administered for several weeks before the platelet count rises and often must be continued for an indefinite period to maintain the remission, and side effects such as leukopenia and alopecia often are significant. Azathioprine, cyclosporin A, mycophenolate mofetil, actinomycin, and other immunosuppressive agents, either alone or in combination with corticosteroids, have variable success.^{309, 310, 311, 312, 313, 314, 315} Vincristine and vinblastine, administered intravenously at weekly intervals, may be as effective as cyclophosphamide but act more rapidly, often increasing the platelet count within 7 days.^{316, 317, 318, 319, 320} In addition to their suppressive effects on cellular and humoral immune responses, these agents increase platelet production in both animals and normal human subjects.^{321, 322} In ITP, their mechanism of action has been postulated to be inhibition of microtubule-dependent events required for monocyte-macrophage function.³²³

Other Proposed Therapies

A number of other therapies have been reported to be successful in single case reports or in small series of patients. Danazol, an attenuated androgen, has been effective in increasing platelet counts in patients with ITP in doses ranging from 50 mg/day³²⁴ to 800 mg/day.^{325, 326, 327} The mechanism of action is postulated to be a danazol-induced reduction of Fc receptors on phagocytic cells.³²⁸ Long-term results indicate a final response rate of >40% at a median follow-up of 10 years with a reasonable safety profile.³²⁹ Recombinant α -interferon can increase platelet counts in up to 50% of patients when injected subcutaneously three times a week, and some responses were durable after stopping treatment.^{330, 331}

Supportive Measures

Physical activity should be restricted to minimize the hazards of trauma, particularly head injury. Drugs, such as nonsteroidal anti-inflammatory drugs, that impair platelet function should be avoided. Blood loss should be treated as indicated, and platelet concentrates should be administered in the presence of significant bleeding.³³² However, transfusions typically produce only a slight and transient increase in the platelet count, no doubt because of the rapidity with which they are destroyed *in vivo*.³³³ Platelet transfusions, nevertheless, may produce some increase in platelet numbers in many patients,³³⁴ often diminish bleeding for a time, and can be effective in the management of serious complications such as subarachnoid hemorrhage. They should be reserved for such life-threatening emergencies or for the immediate preoperative treatment of patients with serious hemorrhage before splenectomy. A single large dose of IVIG followed by a platelet transfusion can be effective in arresting hemorrhage in some critically ill patients.²³⁵ In most patients with platelet counts >50,000/ μ l, preoperative platelet transfusions are not indicated. Platelet transfusions should be avoided in patients with chronic ITP because of subsequent development of alloantibodies. Exchange plasmapheresis may be valuable in critically ill patients and may be particularly effective in children.^{335, 336, 337} Anovulatory hormones are useful when menorrhagia is a major complaint. Because of the risk of septicemia, polyvalent pneumococcal vaccine, Haemophilus influenzae B vaccine, and quadrivalent meningococcal polysaccharide vaccine should be administered at least 2 weeks before elective splenectomy in both adults and children.³³⁸

Immune Thrombocytopenia in Pregnancy

Both ITP and non-ITP may occur during pregnancy.^{339, 340} Thrombocytopenia was present in 7% of women when they were admitted to hospital for a full-term delivery in a prospective 7-year study of 15,741 mothers and 15,932 newborns.^{341, 342, 343} Most platelet counts were between 100,000 and 150,000/ μ l, and 1% of women had platelet counts <100,000/ μ l. Thrombocytopenia was detected incidentally in the majority of women, and only 0.01% of their infants had fetal platelet

counts $<50,000/\mu\text{l}$. None of the infants had hemostatic impairment, and most mothers had normal or near-normal platelet counts by discharge. If the

P.1072

mothers had an obstetric or medical complication, the incidence of thrombocytopenia ($<50,000/\mu\text{l}$) in the infants was 0.35%. It is unclear when the incidental thrombocytopenia (called gestational thrombocytopenia) developed during pregnancy, and the etiology of this mild abnormality is likewise unknown. Antiplatelet antibody testing was not sufficiently specific to differentiate patients with gestational thrombocytopenia from those with ITP.³⁴⁴ Among those with maternal thrombocytopenia, 74% have incidental thrombocytopenia, and only 4% have ITP.³⁴⁵ It is therefore recommended that healthy women who have a platelet count of 70,000 to 150,000/ μl at delivery require no specific treatment, and the mode of delivery should be determined only by obstetric indications.

A recent retrospective 11-year analysis of obstetric patients with ITP examined 92 women with ITP during 119 pregnancies.³⁴⁶ For most women, the pregnancy was uneventful, although women had moderate to severe bleeding in 25 pregnancies (21.5%). Women in 37 pregnancies received treatment to increase platelet counts. During delivery, 44 women received epidural analgesia without complications, with most having a platelet count between 50,000 and 149,000/ μl . Most deliveries were vaginal (82.4%). Bleeding was uncommon at delivery. In most settings epidural analgesia is held if platelets are less than 80 to 90,000/ μl .

Platelet autoantibodies in pregnant patients with ITP cross the placenta and can produce thrombocytopenia and clinical bleeding in the infant. During pregnancy, both maternal and infant health must be considered, and management of women with ITP diagnosed before or during the pregnancy is therefore more difficult and still controversial.^{345, 347} Women with severe thrombocytopenia should be treated with IVIG or the lowest dose of steroids needed to maintain a platelet count $>50,000$ to 60,000/ μl ; it must be noted, however, that when mothers have been treated during pregnancy, changes in their platelet counts do not correlate with the fetal platelet counts when these have been sampled before and after treatment.³⁴⁸ When betamethasone or placebo was given for 4 weeks before delivery in a randomized trial, no differences were seen in either the maternal or infant platelet counts or the incidence of bleeding at delivery.³⁴⁹ Splenectomy during pregnancy may have higher complication rates, but it is not contraindicated. IVIG can be used before delivery to increase the platelet count rapidly. The safety of other forms of therapy used in nonpregnant ITP patients is uncertain.

At the time of delivery, it must be decided whether to deliver the infant by cesarean section or by vaginal delivery. When 474 infants were analyzed from series reported over a 20-year period, 10% of infants had platelet counts between 50,000 and 100,000/ μl , and 15% had platelet counts $<50,000/\mu\text{l}$.³⁵⁰ Intracranial hemorrhage occurred in 3%, but no significant association existed between intracranial hemorrhage and mode of delivery. More recent data indicate that morbidity and mortality in infants with neonatal thrombocytopenia is lower than originally reported. Burrows and Kelton published a systematic review of pregnancy in patients with ITP, selecting only those series with more than 10 patients and those that included fetal platelet counts and infant outcome.³⁵¹ They reported 288 live births and an incidence of fetal thrombocytopenia of 10% with platelet counts $<50,000/\mu\text{l}$ and 4% with platelet counts $<20,000/\mu\text{l}$. There were no deaths and no cases of intracranial hemorrhage, and there was no difference in morbidity between cesarean sections and vaginal births. During the decade from 1990 to 2000, these cumulative totals from 13 prospective studies were 9% and 4%.³⁴⁵ Minor bleeding complications occurred in 3% of infants, and 2% had major bleeding complications.

Many studies have been done to determine maternal characteristics that may correlate with severe thrombocytopenia in the newborn³⁴⁵ and to help with decisions regarding method of delivery. To date, only the birth of a previously affected infant correlates with the incidence of neonatal thrombocytopenia. Other variables that were analyzed, such as the mother's platelet count or prior splenectomy, were predictive in some studies but not in others. Fetal platelet counts might be able to predict newborn risks of bleeding, but scalp-vein platelet counts can be artifactually low, and the incidence of complications associated with percutaneous umbilical blood sampling is higher than the incidence of postnatal major bleeding. In all these reports, it was also noted that the infant platelet count could fall for several days after delivery. It is therefore currently recommended that the mode of delivery should be determined solely by obstetric indications.⁵

SECONDARY AUTOIMMUNE THROMBOCYTOPENIC PURPURA

Autoimmune thrombocytopenia can be associated with drugs and with several common diseases (i.e., collagen vascular disease, infections, lymphoproliferative disorders, and Graves disease). Secondary ITPs are discussed separately because of their unique features and the issues of diagnosis and management. ITP associated with human immunodeficiency virus infection is discussed in Chapter 64.

Autoimmune Thrombocytopenic Purpura Secondary to Drugs

Numerous drugs have been associated with ITP. In some cases, the evidence associating a given drug to ITP is circumstantial. However, a systematic review is available in which specific criteria were established to determine the likelihood of drug-induced ITP due to specific drugs (Table 47.6).^{162, 352, 353, 354} The most common drugs with level 1 evidence are quinidine, quinine, rifampin, trimethoprim-sulfamethoxazole, danazol, methyldopa (Aldomet), acetaminophen, and digoxin. The most common drugs with level 2 evidence are gold, procainamide, carbamazepine, hydrochlorothiazide, ranitidine, and chlorpropamide. Heparin, which causes ITP in as many as 1% of patients, is discussed in Chapter 55.

Pathophysiology

Drug-induced platelet antibodies are the result of an idiosyncratic reaction that develops in only a small percentage of persons exposed to a drug. This ranges from an estimated 38 cases per 1 million exposures for trimethoprim-sulfamethoxazole to as many as 1 in 100 patients for gold salts, and 3 in 100 patients for true immune-mediated heparin-induced thrombocytopenia.^{355, 356, 357} It is not clear whether there are predisposing risk factors for most of the drugs that cause ITP, although evidence suggests that the risk of developing antibodies to gold salts depends on host HLA type, with the majority of patients studied expressing HLA-DR3 antigen.³⁵⁷

Drug-induced antibodies may be complement- or noncomplement-activating antibodies that react with platelets, in either the absence (autoantibodies) or presence of drugs. The most completely studied antibodies are those that develop in response to quinidine/quinine and heparin.⁴⁰ Most nonheparin drug-induced antibodies bind specifically to platelet membrane glycoproteins in the IIb/IIIa or the Ib/V/IX complex through the Fab portion of the antibody molecule (Fig. 47.2B). In contrast, antibodies to heparin bind to a heparin-platelet factor 4 complex, and the immune complex then binds to the platelet membrane via the Fc portion of the antibody molecule (Fig. 47.2C).

Most of the drug-induced antibodies are developed in response to the parent drug, and drug-dependent antibodies can be demonstrated in a variety of in vitro tests. In some cases, however, these tests are negative when the parent compound is present but positive if known metabolites are used instead of the

P.1073

parent compound. Antibodies against drug metabolites have been reported with acetaminophen, para-aminosalicylic acid, naproxen, and trimethoprim-sulfamethoxazole.

TABLE 47.6 DRUGS ASSOCIATED WITH IMMUNE THROMBOCYTOPENIA AND CRITERIA FOR THEIR CLASSIFICATION

	Level 1 ^a	Level 2 ^b
Acetaminophen	Iopanoic acid	Acetazolamide
Alprenolol	Isoniazid	Ampicillin
Aminoglutethimide	Levamisole	Captopril
Aminosalicylic acid	Linezolid	Carbamazepine
	Lithium	
Amiodarone	Meclofenamate	Chlorpropamide
		Filgastrim (G-CSF)
Amphotericin B	Mesalamine	Fluconazole
Amrinone	Methicillin	Glibenclamide
Atorvastatin	Methyldopa (Aldomet)	Gold
	Methylprednisolone	
Cephalothin	Minoxidil	Hydrochlorothiazide
Chlorothiazide	Nalidixic acid	Ibuprofen
Chlorpromazine	Naphazoline	Oxyphenbutazone

Cimetidine	Nitroglycerine	Oxytetracycline
Danazol	Novobiocin	Phenytoin
	Orofiban	
Deferoxamine	Oxprenolol	Procainamide
Diatrizoate meglumine/diatrizoate sodium	Pentoxifylline	Ranitidine
	Piperacillin	Sulindac
Diazepam	Quinidine	Ticlopidine
Diazoxide	Quinine	Trastuzumab
Diclofenac	Rifampin	
Diethylstilbestrol	Sulfasalazine	
Difluormethylornithine	Sulfasoxazole	
Digoxin	Tamoxifen	
Ethambutol	Thiothixene	
Haloperidol	Tolmetin	
Indinavir	Trimethoprim-sulfamethoxazole	
Interferon- α	Vancomycin	

Criteria^{a, b}

1. The candidate drug preceded thrombocytopenia, and recovery from thrombocytopenia was complete and sustained after the drug was discontinued.
2. The candidate drug was the only drug used before the onset of thrombocytopenia, or other drugs were continued or reintroduced after discontinuation of the candidate drug with a sustained normal platelet count.
3. Other etiologies for thrombocytopenia were excluded.
4. Re-exposure to the candidate drug resulted in recurrent thrombocytopenia.

^a Level 1 evidence met criteria 1-4.

^b Level 2 evidence met criteria 1-3.

Modified from publications by George et al. (references 162, 352-354).

Clinical Features

Drug-induced thrombocytopenia is associated with a heterogeneous clinical picture and varying degrees of bleeding. Thrombocytopenia and bleeding usually appear abruptly and may be severe. Mucosal membrane bleeding from all sites and oral hemorrhagic bullae may occur, and patients often develop fever, chills, nausea, vomiting, and fatigue as part of a prodrome to the bleeding.

Severe thrombocytopenia usually develops within hours in sensitized patients ingesting quinidine or quinine; however, a minimum of 6 to 7 days is required to initiate a primary immune response in individuals taking the drug for the first time. Some patients do not develop thrombocytopenia for months or years, a characteristic that seems to be more dependent on the host than the type of drug. The amount of drug that is required to cause thrombocytopenia is quite variable; however, even the amount of quinine present in a gin and tonic (15 mg) is sufficient to produce severe thrombocytopenia and bleeding in a patient who has been previously sensitized to quinine ("cocktail purpura").³⁵⁸ After the drug is stopped,

platelet counts return to normal within days and usually are normal by 1 week. Thrombocytopenia induced by gold salts resolves more slowly, usually over weeks or months, because gold remains in the tissues.

Diagnosis

It is often difficult to make a definite diagnosis of drug-associated ITP because either the patient has taken the medication intermittently or a hospitalized patient is receiving more than one drug that may cause thrombocytopenia. Although it may be possible to demonstrate drug-dependent antibodies against the parent drug or its metabolites, this type of testing is beyond the scope of hospital laboratories. The readministration of the suspected drug in an attempt to confirm an etiologic relationship is not recommended as a routine diagnostic measure. Most of the level 1 drugs listed in Table 47.6 were demonstrated to cause immune-mediated thrombocytopenia because of patient response to an inadvertent *in vivo* challenge.

A detailed history, including all prescribed drugs, over-the-counter medications, and any herbal supplements, is of great benefit. Complete data from all English-language articles describing patients with assumed drug-induced thrombocytopenia have been catalogued on the Internet (<http://www.ouhsc.edu/platelets/ditp.html>).

Treatment

Ordinarily, no therapy is needed, because withdrawal of the offending drug is followed by recovery. IVIG and plasmapheresis may be helpful if life-threatening bleeding occurs. Many patients are treated with corticosteroids, and a normal platelet count is usually restored within 1 week. The major exception is gold-induced thrombocytopenia, which may persist for weeks or even months. British anti-Lewisite (dimercaprol) may accelerate the excretion of gold and speed recovery.³⁵⁹

Autoimmune Thrombocytopenia in Systemic Lupus Erythematosus

Thrombocytopenia may complicate collagen vascular diseases and other disorders associated with disordered immunologic responses such as thymoma³⁶⁰ and myasthenia gravis.^{361, 362, 363} In most instances, the ITP in SLE appears to result from immunologic platelet injury and is identical to primary ITP in most respects.

From 5% to 15% of patients with ITP fulfill the criteria for diagnosis of SLE at the time of presentation.^{364, 365} Other patients have a positive antinuclear antibody test when they are first diagnosed with ITP, and a small number of them may develop SLE within several years. Patients with high-titer antinuclear antibody in a speckled pattern and antibodies against native DNA and other nuclear antigens are the patients most likely to develop SLE.^{366, 367, 368, 369} SLE is a chronic and debilitating disease, so it is important to identify such patients so therapy can be directed at all aspects of the autoimmune disease.

ITP in SLE patients may be the result of either specific platelet autoantibodies or immune complex deposition on platelets. Only

P.1074

a few studies have been reported in which the newest platelet antigen-capture autoantibody tests have been used, and in these patients, platelet autoantibodies to platelet membrane glycoproteins have been detected.^{370, 371, 372, 373} Thrombocytopenia correlates with SLE disease activity³⁷⁴ but not the presence of antiphospholipid antibodies.^{375, 376, 377} These antibodies, which may be present in SLE or in otherwise healthy patients, also bind to platelet membrane gpIIb/IIIa or Ib/IX/V.^{372, 373} It is unclear, however, whether they are specific to these glycoproteins or cross-reactive.

Patients with ITP and SLE should be treated the same as patients with primary ITP, even though there are conflicting reports on the success rate of splenectomy in this population.^{378, 379}

Immune Thrombocytopenia in Other Disorders

ITP has been reported in association with a number of other medical conditions, including infections, neoplasms, and thyroid disease, and it is unknown whether this increased platelet destruction involves antibody binding, immune complex deposition, and/or antibody-mediated complement activation.

ITP has been documented in patients with infectious mononucleosis, cytomegalovirus, varicella or zoster,^{380, 381, 382, 383} hepatitis C,^{384, 385} tuberculosis,³⁸⁶ and human immunodeficiency virus infections (discussed in Chapter 64). During the last several years, ITP was also reported in patients with *H. pylori*, particularly in Europe and Japan. Platelet counts may or may not normalize with treatment directed only at *Helicobacter*.^{387, 388, 389, 390, 391, 392, 393, 394, 395} The ASH guidelines

recommend that *H. pylori* infection be considered in all adults with ITP for whom eradication therapy would be undertaken if testing were positive.⁵

ITP is a well-known complication of chronic lymphocytic leukemia,³⁹⁶ although it is not as frequent as autoimmune hemolytic anemia in these patients. It has also been reported in patients with other lymphoproliferative disorders including Hodgkin disease.^{397, 398, 399, 400} Thrombocytopenia in patients with a variety of solid tumors has also been thought to most likely be immune-mediated.^{401, 402}

Thrombocytopenia may accompany Graves disease and Hashimoto thyroiditis,^{403, 404, 405, 406} but it is not certain that it is immunologically mediated. Platelet-associated IgG has been increased when studied,⁴⁰⁶ but there may also be an element of enhanced reticuloendothelial phagocytosis.

ALLOIMMUNE THROMBOCYTOPENIA

Platelets express membrane-associated epitopes as a result of polymorphisms in discrete regions of the platelet membrane surface glycoproteins.⁴⁰⁷ No natural antibodies to human platelet antigens are known. Acquired platelet alloantibodies are of clinical importance in three circumstances: (a) Neonatal alloimmune thrombocytopenia (NAIT), which is the result of the placental transfer of alloantibodies formed by the mother to incompatible fetal platelet antigens;⁴⁰⁸ (b) posttransfusion purpura (PTP), a rare disorder in which the transfusion of platelet-containing blood products provokes the formation of alloantibodies that act as autoantibodies;⁴⁰⁹ and (c) passive transfer of platelet alloantibodies after transfusion from a multiparous or multiply transfused donor.^{410, 411, 412, 413}

Neonatal Alloimmune Thrombocytopenia

Pathophysiology

Immunologic thrombocytopenia in the newborn may result from the placental transfer of platelet antibodies formed as the result of active immunization of the mother by fetal platelet antigens. Pathophysiologically, such NAIT is similar to erythroblastosis fetalis. Thus, as a consequence of the inheritance by the fetus of platelet antigens lacking in the mother, alloantibodies are formed in the maternal circulation and cross the placenta, producing thrombocytopenia in the fetus. Antibodies can be detected as early as the 19th week, and thrombocytopenia has been found in utero by 20 weeks' gestation.⁴¹⁴ Immunization to human platelet alloantigen (HPA)-1a (PL^A, Zw^A)^{415, 416, 417} or HPA-5b (Br^A, Zav, Hc)^{418, 419} is most common; however, other antigens have been detected and found to be responsible for occasional cases of NAIT (Fig. 47.2D).^{415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426} One of the largest studies to date examined maternal sera for platelet-reactive antibodies in mothers of infants suspected of NAIT. Maternal HPA-1a (Pl^{A1}) alloimmunization accounted for 79% of confirmed NAIT cases.⁴²⁷ The overwhelming majority of platelet polymorphisms found to date are caused by a single base-pair mutation leading to a single amino acid substitution in the polypeptide chain of the specific glycoprotein.⁴²⁸ Rarely, HLA antibodies are responsible.^{415, 418}

Alloimmunization to platelet antigens commonly develops during the first pregnancy and then recurs in >80% of patients during subsequent pregnancies. However, not all mothers who are missing the antigens presented by the fetus develop antibodies, and not all fetuses and neonates develop thrombocytopenia in spite of antibody development.⁴¹⁸ HPA-1 mismatch is present in 1 in 50 births, yet NAIT occurs in only 1 in 1,000 to 2,000 births.^{414, 416, 417, 429} Maternal HLA Class II determinants appear to be important. A high incidence of maternal allotypes HLA-DR3 and HLA-DRw52a has been demonstrated in mothers isoimmunized to fetal alloantigen HPA-1,^{417, 430} and a high incidence of HLA-DR6 has been reported in mothers sensitized to PLA-5b.⁴¹⁸

Clinical Features

Infants with NAIT are born with signs of purpura and severe thrombocytopenia. Thrombocytopenia usually is present at birth, but the platelet count may fall further during the postpartum period. Intracranial hemorrhage occurs in 20% to 30%, with one half of the episodes occurring in utero.⁴³¹ An overall mortality rate of 6% to 14% has been reported.^{416, 419, 420} Thrombocytopenia usually resolves after 10 to 14 days. Platelet antibody titers during the second half of the pregnancy appear to correlate with the risk of thrombocytopenia or bleeding, or both, in NAIT.^{432, 433}

Laboratory Diagnosis

When infants are born with platelet counts <20,000 μ l, NAIT must be suspected. Maternal plasma should be studied with paternal or neonatal platelets as targets; maternal (antigen-negative) platelets and paternal plasma are appropriate negative controls. NAIT is diagnosed when platelet antigen incompatibility is found between the parents, maternal antipaternal platelet antibodies are present, and the antibody detected corresponds to the incompatibility of platelet antigens that have been noted.

Treatment

Severely thrombocytopenic children should be treated aggressively with IVIG and platelet transfusions of compatible irradiated platelets. Maternal platelets are usually obtained by pheresis, concentrated, irradiated, and transfused. Interestingly, a recent retrospective study reported that transfusion of platelet concentrates from random donors is an appropriate strategy in the management of unexpected severe NAIT predominantly in first pregnancies, pending the availability of compatible platelets.⁴³⁴

Prevention of NAIT In women with no personal or family history of NAIT, screening by platelet typing is currently not recommended.⁴³⁵ Maternal platelet antigen typing has been recommended for those with a sister whose pregnancy was complicated by NAIT or if personal or family history is suggestive of NAIT

P.1075

(e.g., neonatal thrombocytopenia of undetermined origin or fetal or neonatal intracranial hemorrhage of undetermined origin). In these cases, maternal and paternal platelet typing is performed simultaneously in order to look for incompatibility in the PHA-1 antigen system. Screening studies to detect neonatal thrombocytopenia during the first pregnancy have been limited to patients with known PL^{A1} incompatibility and an HLA allotype associated with an increased incidence of antibody formation.⁴¹⁷ However, after the birth of one child with NAIT, subsequent pregnancies should be evaluated antenatally.

When maternal and paternal platelet typing document a risk of NAIT, after the index case, over 85% of that couples' subsequent fetuses will be at risk for NAIT. In the absence of any intervention, thrombocytopenia in the second affected fetus is always as or more severe than in the previous fetus/infant.⁴³⁶ Because of the high risk of in utero bleeding, the majority of which include intracranial hemorrhage, initiating therapy antenatally, rather than waiting until birth, has become standard. Previously, it was recommended that fetal platelet typing^{402, 422, 423, 424, 425} and platelet counts should be obtained at 20 weeks' gestation.^{401, 426} If platelet incompatibility is noted and the infant is thrombocytopenic, in utero platelet transfusions or maternal treatment with IVIG should be instituted and maintained during the pregnancy.^{401, 427, 428} In the United States, the most common therapies include infusion of IVIG and/or oral prednisone.⁴³⁷ Combination therapy with IVIG plus steroids may lead to higher platelet counts in women with a previous child with intracranial hemorrhage or a current fetus with platelet counts <20,000/ μ l.⁴³¹ Fetal platelet transfusions have been advocated. However, because of the risk of fetal mortality, this has become a therapy of last resort, to be used only if IVIG or prednisone are ineffective.⁴³⁸ There is no consensus on whether fetuses affected by NAIT or at risk for NAIT should be delivered by cesarean section.⁴³⁹

Because the use of serial fetal blood sampling procedures is clearly associated with an increased risk of fetal morbidity and mortality, some practitioners prefer to avoid performing fetal blood sampling and choose to treat empirically. The precise role of this invasive procedure remains to be determined.^{440, 441} Studies of the cost-effectiveness of empiric treatment versus treatment directed by fetal blood sampling favored empiric treatment, decreasing perinatal deaths although increasing the number of infants with long-term neurologic deficits.⁴⁴¹ Follow-up studies of children after antenatal treatment for alloimmune thrombocytopenia show that general health and neurodevelopmental outcome is comparable to that of the general population. However, significantly more infections and hearing problems were observed in children who were not exposed to maternal IVIG treatment in comparison to children who were exposed to IVIG treatment or the normal population.⁴⁴²

Posttransfusion Purpura

Alloantibodies that develop as a result of transfusion of incompatible platelets are responsible for the destruction of the transfused platelets. This is a frequently encountered problem in patients who have received multiple platelet transfusions. Rarely, however, severe thrombocytopenia in the recipient—that is, destruction of host platelets—is produced by the transfusion of incompatible platelets, and this potentially fatal reaction is known as PTP.^{443, 444, 445} PTP is characterized by abrupt onset of thrombocytopenia and bleeding that occurs 1 week after the transfusion of packed red blood cells. PTP has also been described after the transfusion of other blood components, including plasma.⁴⁴⁶

The syndrome occurs most commonly in multiparous women who have been sensitized by pregnancy; however, previously transfused patients may also develop PTP. The antibody most commonly develops against PL^{A1} (HPA-1a) in PL^{A2} (HPA-1b) homozygous recipients, but the Bak (HPA-3a/HPA-3b), Pen (HPA-4a/HPA-4b), Br (HPA-5a/HPA-5b), and Nak^a polymorphisms have been implicated as well.^{409, 444, 445, 447, 448, 449, 450} (Table 47.7). The diagnosis of PTP is a clinical one, and physicians must therefore consider this diagnosis in any patient who develops thrombocytopenia within 3 to 14 days after transfusion of any blood product.

TABLE 47.7 PLATELET ALLOANTIGENS IMPLICATED IN THE DEVELOPMENT OF POSTTRANSFUSION PURPURA**Serologic Designation Alternative Designation Phenotype Frequency Antigen Location**

Serologic Designation	Alternative Designation	Phenotype	Frequency	Antigen Location
PL ^{A1} (HPA-1a)	Zw ^a		0.96-0.99	gpIIIa
PL ^{A2} (HPA-1b)	Zw ^b		0.27	gpIIIa
Bak ^a (HPA-3a)	Lek ^a		0.78-0.89	gpIIb
Bak ^b (HPA-3b)	Lek ^b		0.50-0.70	gpIIb
Pen ^a (HPA-4a)	Yuk ^b		0.99	gpIIIa ^a
Pen ^b (HPA-4b)	Yuk ^a		0.01	gpIIIa ^a
Br ^b (HPA-5a)	Zav ^b		0.99	gpIa
Br ^a (HPA-5b)	Zav ^a		0.18-0.20	gpIa

gp, glycoprotein; HPA, human platelet alloantigen.

^a Antigen appears to be distinct from PL^{A1} (HPA-1a).

Modified from McCrae and Herman.⁴⁰⁹

The pathophysiology of this rare but severe thrombocytopenia is still uncertain, but several hypotheses have been proposed: (a) Autologous platelets are destroyed because of binding of immune complexes to their surface; (b) recipient platelets acquire the phenotype of the donor's platelets because they bind soluble antigens from the transfused blood product, and the platelets are then destroyed by alloantibodies; and (c) exposure to foreign platelets in transfused products induces the formation of autoantibodies to the recipient's platelets.^{409, 451, 452}

PTP is self-limited, resolving within 1 to 3 weeks in most patients. Treatment with steroids, plasmapheresis, or IVIG may shorten the period of thrombocytopenia. Plasmapheresis is effective in 80% of patients,^{446, 453, 454, 455} but IVIG, in doses of 2 g/kg over 2 days, may be preferable because plasmapheresis requires central venous access with large-bore catheters and places the patient in danger of significant bleeding.^{456, 457, 458} Platelet transfusions should be reserved for life-threatening hemorrhage, because patients often develop a febrile reaction and an increase in platelet count is infrequent.

Chapter 48

Thrombotic Thrombocytopenic Purpura, Hemolytic-Uremic Syndrome, and Related Disorders

Han-Mou Tsai

The various forms of thrombocytopenia discussed in this chapter share the common features of thrombocytopenia and hemolysis with characteristic schistocytes on blood smears (microangiopathic hemolytic anemia, MAHA) (Fig. 48.1). It is believed that thrombocytopenia results from consumption of platelets, whereas erythrocyte fragmentation and hemolysis are due to mechanical injury of the red blood cells by abnormal levels of shear stress.

Fragmentation of the red blood cells occurs in two types of clinical conditions: vascular devices such as prosthetic heart valves, ventricular assist devices, and extracorporeal oxygenator and microvascular stenosis.

In the absence of mechanical devices, fragmentation of the red blood cells signifies stenosis in the arteriolar microvasculature. This is because wall shear stress, determined by blood viscosity, flow rate, and the inverse of the luminal diameter to the third order, is at its highest in the arterioles and may be further increased to exceed the threshold level of red cell fragmentation when the lumen is narrowed. Furthermore, the red cells are likely to be entrapped in the presence of microvascular stenosis. The combination of abnormal shear stress and cell entrapment accounts for red cell fragmentation in patients with arteriolar stenosis. Due to their lower shear stress profile, it is unusual that stenosis in the venules, veins, or arteries is sufficient to cause red cell fragmentation.¹

Arteriolar stenosis may result from one of five different types of pathology (Fig. 48.1): (1) von Willebrand factor (vWF)-platelet thrombosis, as typically observed in patients with thrombotic thrombocytopenic purpura (TTP) due to severe ADAMTS13 (a disintegrin and metalloprotease with thrombospondin type 1 motif, member 13) deficiency; (2) platelet fibrin thrombosis, as exemplified in patients with disseminated intravascular coagulopathy (DIC) but also may occur in a variety of other conditions; (3) tumor cell invasion of the microvasculature in patients with metastatic neoplasm; (4) microvascular vasculitis, as occasionally observed in patients with systemic lupus erythematosus and related autoimmune disorders or certain types of infections such as Rocky Mountain spotted fever and anthrax; and (5) thrombotic microangiopathy (TMA), as observed in patients with the typical shiga toxin-associated hemolytic-uremic syndrome (stx-HUS) following *Escherichia coli* infection, pneumococcal HUS, or atypical hemolytic-uremic syndrome (aHUS) due to defective regulation of the alternative complement pathway.

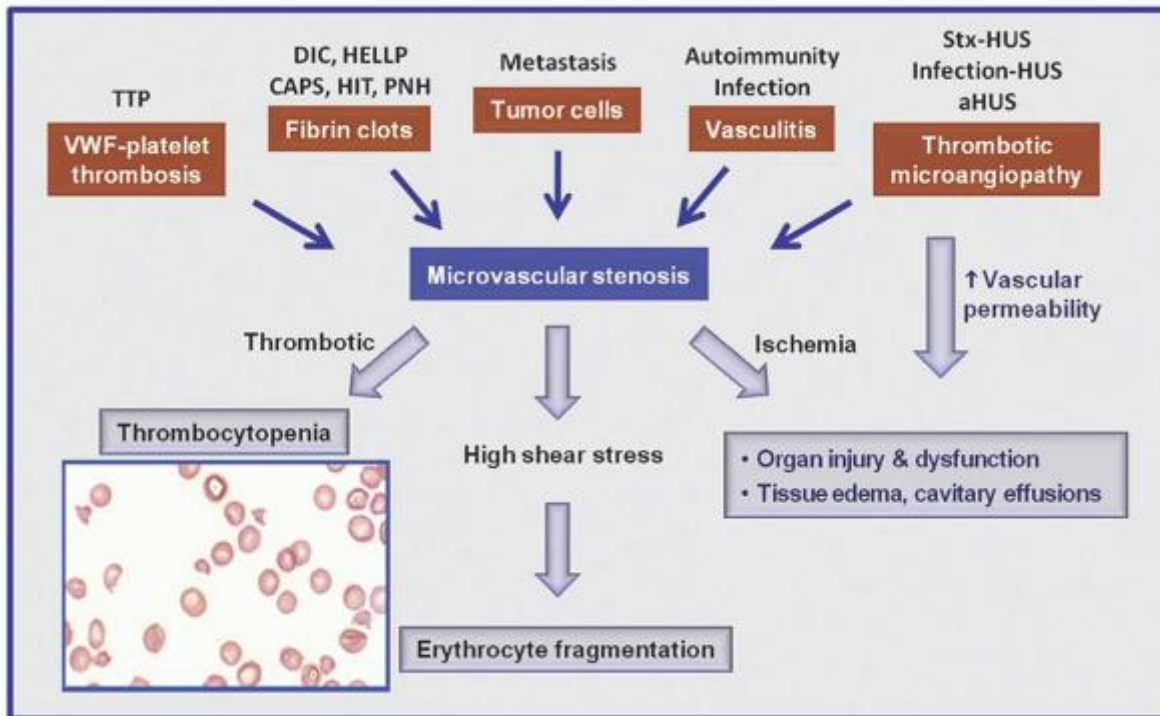

FIGURE 48.1. A scheme depicting how different types of pathology may lead to microvascular stenosis and the syndrome of thrombocytopenia and microangiopathic hemolysis (MAHA). Thrombotic microangiopathy may also lead to tissue edema and organ dysfunction by increasing vascular permeability. DIC, disseminated intravascular coagulopathy; CAPS, catastrophic antiphospholipid antibody syndrome; HELLP, hemolysis with elevated liver enzymes and low platelets; HIT, heparin-induced thrombocytopenia; HUS, hemolytic-uremic syndrome; PNH, paroxysmal nocturnal hemoglobinuria; Stx-HUS, shiga toxin-associated hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

A comprehensive classification of microangiopathic disorders is listed in Table 48.1. This classification includes four groups: TTP, TMA due to defective complement regulation (aHUS), TMA due to other mechanisms, and MAHA due to other types of pathology. In TMA, organ dysfunction may result from thrombotic stenosis, which causes thrombocytopenia and MAHA; non-thrombotic stenosis, which causes MAHA but not thrombocytopenia; and/or abnormal vascular permeability, which causes tissue edema and cavitory effusions but not thrombocytopenia or MAHA. Due to multiple pathogenetic pathways, organ dysfunction or clinical disease severity in patients with aHUS or other types of TMA does not always closely correlate with thrombocytopenia or MAHA. TTP, stx-HUS, and aHUS are further discussed in this chapter.

TABLE 48.1 CLASSIFICATION OF MICROANGIOPATHIC DISORDERS**I. TTP: a disease with propensity to microvascular thrombosis due to ADAMTS13 deficiency**

- Acquired: autoimmune inhibitors of ADAMTS13
- Hereditary: mutations of ADAMTS13

II. aHUS: a disease with propensity to TMA due to defective complement regulation**A: Idiopathic aHUS**

- Mutations or genetic variants of CHF, MCP, CFI, CFB, C3, THBD, etc.
- Autoantibodies to CFH, with or without CFHR1 genomic deletion

B: Co-morbidity as a trigger of aHUS presentation in patients with the disease

- Pregnancy, IV contrast, pancreatitis, infection, inflammation, surgery, trauma, etc.

C: Co-morbidity causing defective complement regulation (e.g., CFH autoantibodies)

- Hematopoietic stem cell therapy
- Suspected, but not yet proven: HIV infection, systemic autoimmune diseases, drugs, etc.

III. TMA via other mechanisms

- Shiga toxin-associated HUS: Shiga toxin-producing *E. coli* or *Shigella dysenteriae*
- Microbial neuraminidases causing T-antigen activation (e.g., *Streptococcus pneumoniae* or *influenza virus*)
- Angiogenesis inhibitor: e.g., bevacizumab
- Undefined mechanisms: hematopoietic stem cell therapy, HIV infection, systemic autoimmune diseases, drugs (e.g., gemcitabine, mitomycin, quinine, calcineurin inhibitors^{*}, cocaine, etc.), severe hypertension^{**}

IV. Other types of pathology

- Microvascular thrombosis comprised of fibrin and platelets
- DIC, CAPS, HELLP syndrome, HIT, PNH, etc.
 - Vasculitis:
- Autoimmune diseases (e.g., systemic lupus erythematosus)
- Infectious diseases (e.g., Rocky Mountain spotted fever, anthrax)
 - Intravascular clusters of neoplastic cells
 - Intravascular devices:
- Ventricular assist device, extracorporeal membrane oxygenator, prosthetic heart valves, etc.

ADAMTS13, a disintegrin and metalloprotease with thrombospondin type 1 motif, member 13; aHUS, atypical hemolytic-uremic syndrome; CAPS, catastrophic antiphospholipid antibody syndrome; CFB, complement factor B; CFH, complement factor H; CFHR1, complement factor H-related protein 1; CFI, complement factor I; DIC, disseminated intravascular coagulopathy; HELLP, hemolysis with elevated liver enzymes and low platelet count; HUS, hemolytic-uremic syndrome; HIT, heparin-induced thrombocytopenia; MCP, membrane cofactor protein (CD46); PNH, paroxysmal nocturnal

hemoglobinuria; THBD, thrombomodulin; TMA, thrombotic microangiopathy; TTP, thrombotic thrombocytopenic purpura; vWF, von Willebrand factor.

* Some patients are found to have aHUS with defective complement regulation.

** Severe hypertension may be a consequence of aHUS rather than cause of thrombotic microangiopathy

ACQUIRED THROMBOTIC THROMBOCYTOPENIC PURPURA

The current definition of TTP is based on the demonstration of autoimmune inhibitor for acquired TTP and genetic mutation of the ADAMTS13 gene for hereditary TTP. By this definition, TTP is a disease that is prone to, but does not always have, microvascular thrombosis, thrombocytopenia, microangiopathic hemolysis, or organ dysfunction.

This definition is different from the conventional diagnosis of TTP as a clinical syndrome. It requires the demonstration of ADAMTS13 inhibitors or mutations and encompasses patients who are asymptomatic and patients who do not have thrombocytopenia or microangiopathic hemolysis.

The problem of conventional TTP diagnosis based solely on clinical features is most clearly illustrated by the vast difference in the prevalence of severe ADAMTS13 deficiency among the patients in the Canadian Apheresis Group trial on the efficacy of plasma therapy and the patients in the Oklahoma TTP registry. Severe ADAMTS13 deficiency was detectable in more than 76% of the patients in the Canadian Apheresis Group trial, yet in less than 15% of the patients in the Oklahoma registry.^{1, 2, 3} Indeed, many clinical series of 'TTP' or 'TTP/HUS' included patients with atypical HUS or other causes of microangiopathic hemolysis, resulting in confusion in the diagnosis and management of patients presenting with microangiopathic hemolysis and thrombocytopenia.

Pathology

The pathology of TTP, as first described by Moschcowitz in 1925⁴, is quite distinctive: widespread hyaline thrombi in the terminal arterioles and capillaries, accompanied by no or little endothelial injury or inflammation (i.e., microangiopathy) (Fig. 48.2A). The thrombi are present most extensively in the heart, pancreas, spleen, kidney, adrenal gland, and brain (mainly cerebral cortex) and are composed primarily of platelets and vWF (Fig. 48.2B).^{5, 6, 7} Small amounts of fibrin may be present surrounding or sometimes penetrating the amorphous or granular material. Glomerular microthrombi are usually spotty, and cortical necrosis of the kidney is uncommon in TTP. Fibrinoid necrosis and vascular or perivascular inflammatory cell infiltration are characteristically absent or minimal.

FIGURE 48.2. Histopathology and histochemistry of thrombotic thrombocytopenic purpura (TTP) and other microangiopathic disorders. A: TTP (heart); B: TTP (brain); C: shiga toxin-associated hemolytic-uremic syndrome (HUS) (kidney); D-F: atypical HUS (kidney); G: disseminated intravascular coagulopathy (DIC) (kidney); H: tumor cell invasion of microvasculature in metastatic neoplasm (soft tissue); I: proliferative vasculitis of lupus causing microvascular stenosis (soft tissue). The endothelial cells and the vessel wall are intact in TTP and DIC. All images are H&E stains except panel B (immunohistochemical stain for vWF, brown), panels C and G (fibrin stain of Carstairs), and panel F (Jones silver stain).

P.1079

In chronic cases, the thrombi may be infiltrated by fibroblasts or converted to subendothelial deposits by proliferating endothelial cell lesions. Pseudoaneurysmal dilatation may also be present upstream of the stenosis or occlusion.

In the literature, some investigators have suggested that endothelial cell injury is prominent in TTP. A review of the clinical features in those reports suggests that those patients likely had shiga toxin-associated or atypical HUS rather than TTP.

Pathophysiology

Historically two schemes have been proposed to account for the microvascular thrombosis in TTP: endothelial cell injury and uncontrolled platelet aggregation. The scheme of endothelial cell injury is not consistent with the absence or paucity

of microangiopathy in TTP patients. The predominance of vWF and platelets in the thrombi and the integrity of vascular endothelial cells suggest that thrombosis results from dysregulation of vWF-platelet interaction in TTP.

vWF, a plasma glycoprotein derived primarily from vascular endothelial cells, supports platelet adhesion and aggregation at sites of microvascular injury under high shear stress conditions. Deficiency in vWF causes defective microvascular hemostasis and a bleeding diathesis in patients with von Willebrand disease.

vWF is synthesized in vascular endothelial cells as a disulfide-bonded polymer that is converted to a series of multimers in the circulation (Fig. 48.3). This conversion is mediated by repetitive cleavage at the Tyr1605-Met1606 bond by ADAMTS13.

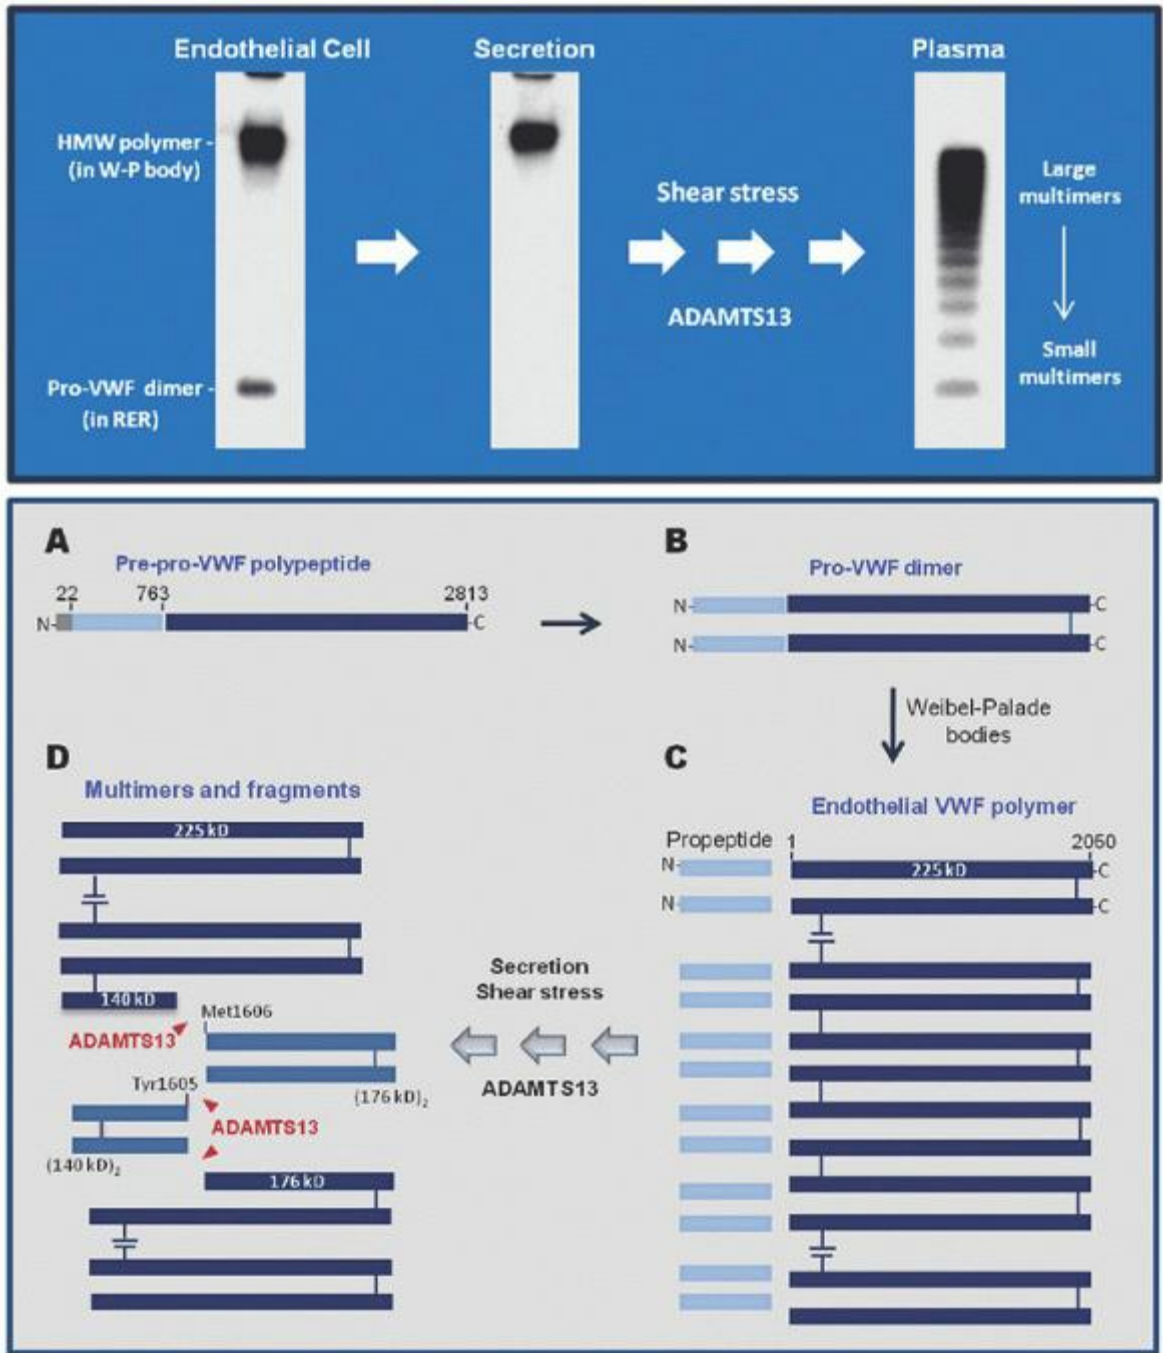

FIGURE 48.3. Gels and schemes depicting how vWF multimers are generated in the circulation. Upper panel: gels showing von Willebrand factor (vWF) polymer and multimers. In vascular endothelial cells vWF exists in two forms, a dimer of pro-vWF polypeptide in the rough endoplasmic reticulum (RER) and a polymer of mature vWF polypeptide in the Weibel-Palade bodies. Only the vWF polymer is secreted. Under the high shear stress conditions of the microcirculation, the vWF

polymer is cleaved by ADAMTS13. A repetition of this process converts a vWF polymer to a series of multimers in normal plasma. vWF is separated by SDS-agarose gel electrophoresis and visualized with a radio-labeled antibody to vWF. Lower panel: a scheme of vWF biosynthesis and proteolysis. A: Pre-pro-vWF with 2,813 amino acid residues. B: A dimer of pro-vWF with disulfide bonds near the C-terminus. C: In the Weibel-Palade bodies, a vWF polymer is formed through disulfide bonding near the N-terminus of vWF dimers and cleavage of the propeptide. D: Under the high shear stress conditions of the microcirculation, vWF is cleaved at the Tyr1605-Met1606 bond, generating dimers of the 140 kD and 176 kD fragments and a series of progressively smaller multimers.

vWF exists in a compact form with its cleavage sites and platelet binding sites cryptic. This explains why in a test tube vWF is not susceptible to cleavage by ADAMTS13 and is inactive in aggregating platelets. High levels of shear stress induce a conformational change of vWF, exposing its binding sites for platelet receptors (Fig. 48.4A). Due to its large molecular size and responsiveness to shear stress, vWF is uniquely capable of supporting platelet adhesion and aggregation under high shear stress conditions.

In the circulation, the activation of vWF by shear stress is prevented by ADAMTS13, which cleaves vWF whenever its cleavage sites are exposed by shear stress. The process of proteolysis is repeated during each cycle of circulation through the microvasculature, thereby converting vWF from a large polymer to a series of multimers while maintaining vWF in its compact inactive configuration (Fig. 48.4B).

A disruption in this proteolytic regulation of vWF occurs in TTP, in which ADAMTS13 deficiency, due to genetic mutation or autoimmune inhibitors, leads to incessant unfolding and activation of vWF by shear stress, resulting in vWF-platelet binding and microvascular thrombosis (Fig. 48.4C). This explains why a severe deficiency of ADAMTS13 can lead to microvascular thrombosis characteristic of TTP.

P.1080

FIGURE 48.4. A scheme depicting how ADAMTS13 deficiency leads to von Willebrand factor (vWF)-platelet aggregation and microvascular thrombosis seen in thrombotic thrombocytopenic purpura (TTP). A. The responsiveness of vWF to shear stress allows it to be activated at sites of microvascular injury to support platelet adhesion and aggregation. B. In the

circulation, vWF-platelet aggregation is prevented by ADAMTS13, which cleaves vWF whenever its cleavage sites are exposed by shear stress. This process maintains vWF in its compact inactive configuration while its size becomes progressively smaller. C. In the absence of ADAMTS13, vWF is relentlessly activated by shear stress, leading to vWF-platelet aggregation and microvascular thrombosis of TTP. Thrombosis increases the shear stress in the microcirculation, leading to further cycles of vWF-platelet aggregation.

Observations in patients with TTP reveal that vWF-platelet aggregation and thrombosis does not occur when the plasma ADAMTS13 activity level is greater than 10% of normal. On the other hand, a patient with ADAMTS13 activity less than 10% may be asymptomatic and may have a normal platelet count. This is because other factors such as platelet number, vWF level, shear stress profile in the circulation, and modifiers of vWF response to shear stress such as thrombospondin⁸ may affect the propensity to vWF-platelet aggregation when ADAMTS13 is deficient.

Distinction between Thrombotic Thrombocytopenic Purpura Disease and Its Complications

A patient with autoimmune inhibitors or genetic mutations of ADAMTS13 may be completely asymptomatic and have normal blood counts. Such asymptomatic individuals are considered to have TTP, the disease, and are prone to the development of microvascular thrombosis causing clinical features such as thrombocytopenia, microangiopathic hemolysis, neurologic deficits, and injury of other organs.

Animal Models of ADAMTS13 Deficiency

Animal models of severe ADAMTS13 deficiency have been created in mice by inactivation of the ADAMTS13 gene and in baboons by infusion of an inhibitory ADAMTS13 antibody.^{9, 10, 11} In both models, thrombi comprising vWF and platelets ensue in the arterioles. The findings in these animal models support the role of ADAMTS13 deficiency in causing microvascular thrombosis of TTP. Nevertheless, some mouse strains are phenotypically free of thrombosis. The difference in phenotypic severity among the mouse strains highlights the principle of epistasis in which the composition of other genes modifies the expression of a molecularly defined disease.

Interactions between von Willebrand factor and ADAMTS13

The vWF polypeptide comprises a series of homologous domains. The cleavage site of vWF, Tyr1605-Met1606, is located in the A2 domain, sandwiched between the A1 domain, which contains epitopes interacting with the platelet glycoprotein Ib, and the A3 domain, where a collagen-binding epitope is located (Fig. 48.5). This topographic arrangement facilitates the regulation of platelet thrombus formation, as cleavage of vWF at the A2 domain disengages the platelet from the vessel wall.

Structural studies confirm that shear stress induces vWF cleavage by altering the conformation of vWF.^{12, 13} Narrow-angle neutron scattering studies of vWF in guanidine hydrochloride, which also promotes vWF cleavage by ADAMTS13,¹⁴ or after exposure to shear stress, shows that conformational change at the subdomain level is sufficient for proteolysis to occur.^{15, 16} Unfolding of vWF to extended configurations at the multimeric level is not necessary for proteolysis.

ADAMTS13, comprising 1,427 amino acid residues, is a member of the ADAMTS metalloprotease family, which shares a conserved domain structure of metalloprotease (MP)-disintegrin (Dis)-thrombospondin type 1 repeat (TSR)-cysteine rich region (Cys) and spacer (Spa) domains. ADAMTS13 contains 7 additional TSR downstream of the Spa domain, followed by two unique CUB (complement C1r/C1s, Uegf, Bmp1) domains (Fig. 48.5).

ADAMTS13 is synthesized primarily in the stellate cells of the liver.^{17, 18} ADAMTS13 may also be expressed, albeit at much P.1081

lower levels by at least one to two orders, in the spleen and other organs. The localization of its biosynthesis to the stellate cells instead of hepatocytes may be instrumental in maintaining the ADAMTS13 activity in patients with hepatic insufficiency, as the stellate cells react to liver injury by activation and proliferation. The expression of ADAMTS13 in hepatic stellate cells and endothelial cells may be down-regulated by cytokines such as IFN- γ , TNF- α , and IL-4.¹⁹

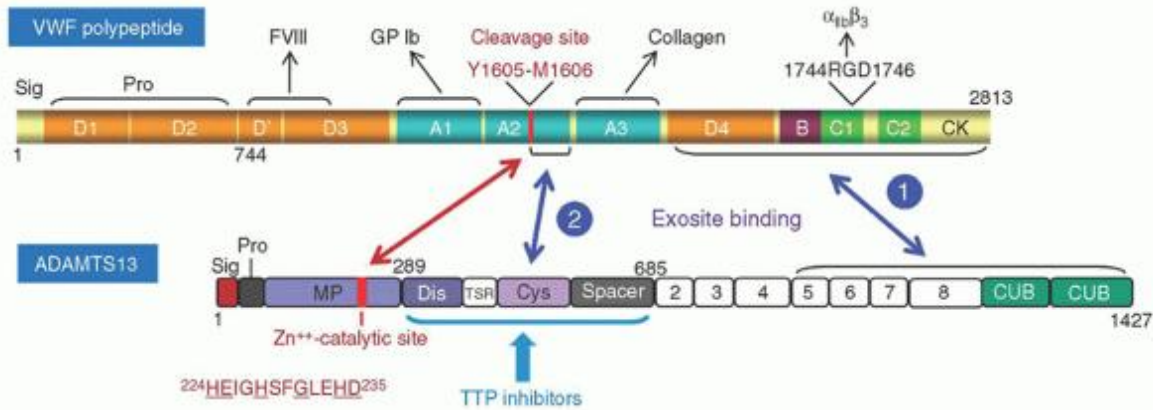

FIGURE 48.5. A scheme depicting the domain structures of von Willebrand factor (vWF) and ADAMTS13 and their interactions. The cleavage of vWF by ADAMTS13 involves exosite and catalytic interactions. It is believed that the exosite binding 1 occurs constitutively, whereas exosite binding 2 occurs only when the sequence in the A2 domain downstream of the scissile bond Tyr1605-Met1606 is exposed by shear stress. The exosite bindings orient the catalytic site of ADAMTS13 to attack the scissile bond of vWF (double-arrowhead red line). The inhibitors of thrombotic thrombocytopenic purpura (TTP) patients target the exosites of ADAMTS13 downstream of the metalloprotease domain.

Expression of ADAMTS13 has been described in the renal glomerular podocytes and endothelial cells and vascular endothelial cells in culture.^{20, 21} The ADAMTS13 expressed in renal glomeruli may cleave vWF before it is neutralized by autoantibodies, accounting for the generally milder renal injury observed in acquired versus hereditary TTP.

The metalloprotease domain of ADAMTS13 contains a catalytic 224-HEIGHSFGL EHD-235 module characteristic of the ADAMTS proteases (conserved residues are underlined). Structural analysis has identified three surface exosites of ADAMTS13 in the Dis, Cys, and Spa domains that react with discrete epitopes of the vWF A2 sequence around and downstream of the Tyr1605-Met1606 scissile bond.^{22, 23}

The exosite bindings greatly enhance the efficiency of catalytic reaction between ADAMTS13 and vWF. The vWF scissile bond and the exosite binding sites of the vWF A2 domain are normally cryptic, only exposed by tensile force to initiate interaction with ADAMTS13. Another exosite in the TSR5-CUB region of ADAMTS13 may interact with a constitutively exposed epitope in the N-terminal D4-CK region of vWF. This C-terminal binding may facilitate the interaction of the exosites upstream.

Alteration of von Willebrand factor Multimers in Thrombotic Thrombocytopenic Purpura

The involvement of vWF in the pathophysiology of TTP was first suggested by the intriguing observation that large multimers disappear during acute crisis of chronic relapsing TTP and yet ultra-large multimers are present during remission.²⁴

The complexity of vWF multimers in TTP is due to two opposing processes acting upon plasma vWF in patients with ADAMTS13 deficiency: deficiency of ADAMTS13 leading to the presence of ultra-large multimers; and the activation of vWF by shear stress leading to the consumption and depletion of ultra-large and large multimers.

Three types of vWF multimer abnormalities are observed in TTP (Fig. 48.6). A shift of vWF to ultra-large forms occurs when ADAMTS13 activity is <20% to 30%; at this stage, no platelet thrombosis occurs (lane 1). The ultra-large and large multimers are partially depleted when ADAMTS13 is <10% and vWF-platelet aggregation begins to occur (lane 2). The ultra-large multimers are depleted and the large multimers are further decreased or depleted in patients presenting with extensive thrombosis and severe thrombocytopenia (lane 3).

The vWF changes in TTP are a dynamic process, as the multimers in a plasma sample represent a snapshot of the balance of the two changes acting in opposite directions. Transition from one multimer pattern to another occurs swiftly during the course of the disease, reflecting the changes in ADAMTS13 level and the process of vWF-platelet aggregation.

FIGURE 48.6. von Willebrand factor (vWF) abnormalities in thrombotic thrombocytopenic purpura (TTP) reflect the balance of underlying ADAMTS13 deficiency and vWF-platelet thrombosis. Three types of vWF abnormalities are detected in TTP during its course: Lane 1: A shift of vWF to ultra-large forms occurs when ADAMTS13 activity is <20%-30%. Lane 2: The ultra-large and large multimers are decreased when ADAMTS13 is <10%, and vWF-platelet aggregation begins to occur. Lane 3: The ultra-large multimers are depleted and the large multimers are further decreased in patients presenting with extensive thrombosis and severe thrombocytopenia.

P.1082

In other types of microangiopathic hemolysis such as shiga toxin-associated or atypical HUS, depletion of the large vWF multimers also occurs. In these conditions, the loss of large multimers is due to excessive cleavage of vWF by ADAMTS13 under abnormal shear stress conditions.⁷

Other Pathogenic Mechanisms in Thrombotic Thrombocytopenic Purpura

Various hypotheses have been proposed to explain the thrombosis of TTP, including defects in fibrinolytic activity²⁵ or prostacyclin homeostasis,²⁶ increased circulating thrombomodulin, abnormal tissue plasminogen activator or plasminogen activator inhibitor-1 levels,²⁷ antiendothelial cell antibodies,^{28, 29, 30} immune complexes,³¹ platelet aggregating proteins,³² anti-CD36 antibodies,³³ calcium-dependent cysteine proteases,³⁴ endothelial cell apoptotic factors,³⁵ and activation of the complement system.³⁶ These observations are preliminary, represent secondary changes, or are not specific for TTP.^{37, 38, 39, 40, 41} Immune complexes and activation of the complement system detected in patients with TTP may result from ADAMTS13 binding with its antibodies.

Causes of ADAMTS13 Deficiency

Severe ADAMTS13 deficiency results primarily from autoimmune inhibitors of the protease,⁴² although in a small number of patients the deficiency is the consequence of homozygous or, more commonly, compound heterozygous mutations of the ADAMTS13 gene.⁴³

The ADAMTS13 activity level is also decreased in various pathologic conditions such as sepsis, malarial infection, multiorgan failure, major surgery, DIC, metastatic neoplasm, and pregnancy.^{44, 45, 46, 47, 48, 49, 50, 51} In these conditions, the decrease in ADAMTS13 levels is mild to moderate, and generally not sufficient to cause platelet aggregation. Yet the decrease induced by infection, surgery, or pregnancy may be sufficient to precipitate vWF-platelet aggregation and thrombosis in patients with pre-existing ADAMTS13 mutations or inhibitors, giving rise to the suspicion that these conditions cause TTP.

The ADAMTS13 activity is also less stable in pathologic samples, yielding falsely low ADAMTS13 levels if the samples are not properly handled.

Autoimmune Inhibitors of ADAMTS13

In patients with acquired TTP, which accounts for >95% of TTP cases, deficiency of ADAMTS13 results from autoimmune inhibitors of the ADAMTS13 protease.⁵² In most cases of acquired TTP the causes of the autoimmunity are unknown. It is speculated that an otherwise innocuous infection may induce autoimmune reaction to ADAMTS13 in genetically susceptible individuals. Indeed 10% to 40% of TTP patients exhibit positive autoimmune reactions to other antigens, suggesting they have defective immune regulation. Deranged immune regulation is consistent with the finding that the HLADRB1*11 allele is overrepresented among patients with acquired TTP.⁵³

Ticlopidine therapy increases the risk of developing ADAMTS13 antibodies by 50- to 300-fold.^{54, 55} The antibodies occur between 2 to 8 weeks after institution of ticlopidine therapy, respond to plasma exchange and discontinuation of the culprit drug, and generally do not recur. Although another anti-platelet thienopyridine, clopidogrel, has also been implicated,⁵⁶ an association between clopidogrel and TTP has not been confirmed.

HIV infection has been associated with TTP.⁵⁷ It is estimated that the risk is increased by 35-fold among patients not being treated with antiretroviral therapy. This higher risk may be related to the predisposition of HIV-infected individuals to autoimmunity.

An ADAMTS13 polymorphism (R1060W) is reportedly more prevalent in acquired TTP patients than in the population, raising the speculation that certain ADAMTS13 polymorphisms may predispose the affected individuals to develop ADAMTS13 inhibitors.⁵⁸ The validity of this association remains to be confirmed.

ADAMTS13 Mutations

DNA sequence analysis reveals that hereditary TTP patients have compound heterozygous or, less commonly, homozygous mutations of the ADAMTS13 gene on chromosome 9q34.⁵⁹ More than 80 mutations, including nonsense, missense, frame-shifting insertion or deletion, and splicing mutations, have been detected in patients with hereditary TTP.

Only a few mutations have been detected in seemingly unrelated families. One mutation, 4143insA, has been detected in at least 15 patients in central-northern Europe, Turkey, and Australia that appear to share a common haplotype.⁶⁰

More than 25 polymorphisms have also been detected in the coding sequence of ADAMTS13. One polymorphism, P475S, common among Japanese (5%), Koreans (4%), and Chinese (1%), makes the ADAMTS13 variant more susceptible to inhibition by urea,^{61, 62, 63} which is used in some ADAMTS13 assays.⁶⁴ It yields falsely low ADAMTS13 activity levels if urea-based assays are used.⁶⁵ Certain cis-combinations of polymorphisms or mutation-polymorphism may result in severe ADAMTS13 deficiency.⁶⁶

Characteristics of the Inhibitors

In most patients the levels of the ADAMTS13 inhibitors are low (<10 U/ml), and often further decrease to undetectable levels after a few weeks or months. Occasionally the inhibitor level may surge to very high levels.

The ADAMTS13 inhibitors of TTP are primarily IgG, with IgA and IgM antibodies detectable infrequently.⁶⁷ The VH1-69 germline heavy chain gene appears to be used most frequently in producing the ADAMTS13 antibodies.⁶⁸ All four subclasses of IgG have been detected, although IgG4 appears to be the most prevalent, detectable in ≥90% of the patients according to one study.

Targets of the ADAMTS13 Inhibitors

The cysteine-rich region and spacer domain are an integral part of the epitopes of ADAMTS13 reacting with the inhibitors of TTP patients. ADAMTS13 variants truncated upstream of the cysteine-spacer domain, but not those truncated downstream, exhibit markedly decreased but detectable vWF cleaving activity that is not suppressible by the inhibitors of patients with TTP.⁶⁹ This decreased activity is consistent with the existence of critical exosites in the deleted domains.

Such nonsuppressible ADAMTS13 species may be exploited to overcome the therapeutic difficulty posed by ADAMTS13 inhibitors.

Further mapping studies show that residues R660, Y661, and Y665 in the spacer domain are critical for binding with vWF A2 domain sequences.⁷⁰ They are also the target of TTP inhibitors. Substitution of residues Arg660, Tyr661, or Tyr665 in ADAMTS13 with Ala abolishes the binding targets of ADAMTS13 inhibitors. Intriguingly, two vWF variants with substitutions of these three residues exhibit increased vWF cleaving activity by several fold. Such “super” variants of ADAMTS13 may be potential candidates as a replacement therapy for patients with TTP, although immune responses to these foreign proteins may be a concern.⁷¹

Some studies found that TTP antibodies may also target other epitopes downstream of the spacer domain. However, it remains unclear whether these antibodies contribute to ADAMTS13 deficiency in TTP patients.⁷²

Clinical Presentation

The incidence of TTP is estimated to be 2 to 15 cases per 1×10^6 person-years.^{3, 48, 49} The broad range of the observed incidence

P.1083

rates is likely due to differences in demographics, particularly the prevalence rate of HIV infection in the population.

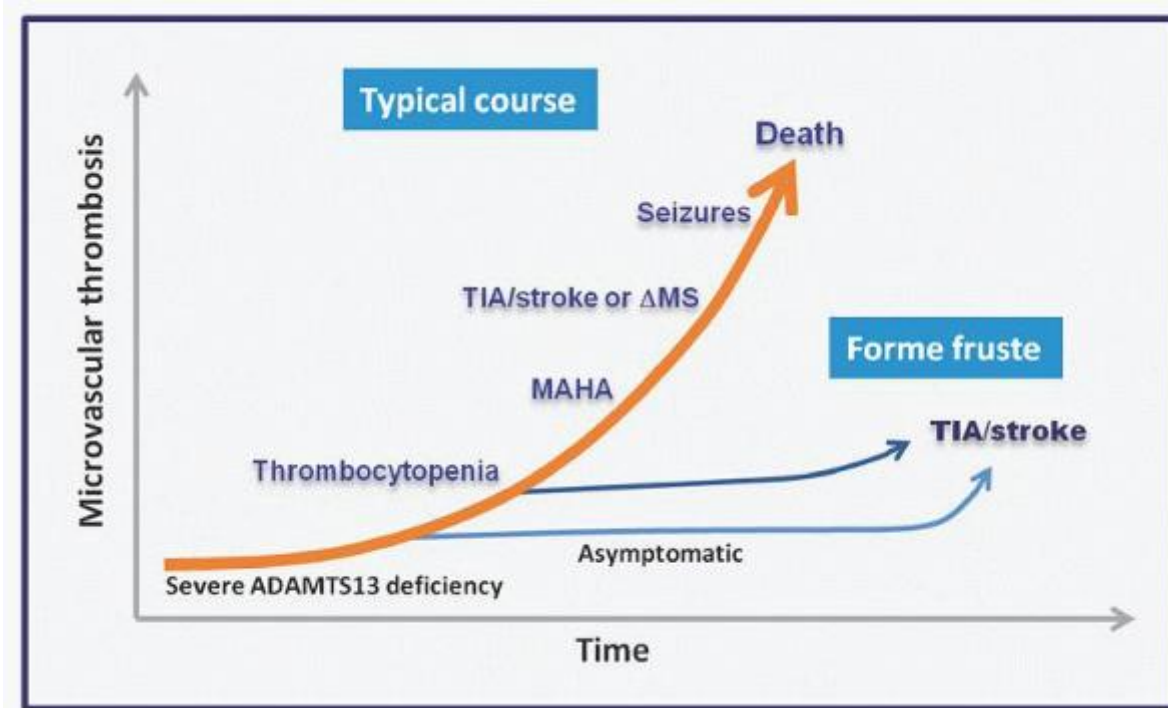

FIGURE 48.7. Progression of thrombotic complications in thrombotic thrombocytopenic purpura (TTP). When ADAMTS13 decreases below the threshold level, microvascular thrombosis begins to occur. In most patients, TTP evolves progressively from ADAMTS13 deficiency to thrombocytopenia, microangiopathic hemolytic anemia (MAHA), fleeting neurologic deficits (TIA), stroke, altered mental status, seizures, and death if it is not treated. Occasionally, a patient may be detected at the thrombocytopenia stage when a CBC is ordered for other reasons. TTP may also present in forme fruste, with microvascular thrombosis causing TIA or stroke before thrombocytopenia or MAHA occurs. Δ MS, altered mental status.

Acquired TTP primarily affects adolescents and adults, with median and mode ages between 30 and 40 years, although TTP may occasionally affect children <10 years of age. In most clinical series, the female-to-male ratio is 2 to 3:1.

Many patients present with the triad of thrombocytopenia, microangiopathic hemolytic anemia (MAHA), and neurologic deficits or the triad with fever and renal dysfunction (pentad); neither is invariably present or specific for the diagnosis of TTP. In a typical case, the course of TTP begins with the appearance of ADAMTS13 inhibitors, which progressively decrease

the plasma ADAMTS13 level, eventually leading to microvascular thrombosis, thrombocytopenia, microangiopathic hemolysis, and organ dysfunction (Fig. 48.7).

The duration of asymptomatic ADAMTS13 deficiency is quite variable, ranging from a few days to years. Serial monitoring of patients with a history of acquired TTP suggests that the plasma ADAMTS13 activity level may fluctuate for weeks to months before decreasing to less than 10% of normal and causing thrombosis.

Thrombocytopenia is detectable when platelet consumption exceeds compensatory platelet production. The stage of thrombocytopenia without overt hemolytic anemia may last for days to months, and the course of TTP at this stage is not invariably downhill; some patients may spontaneously revert to a normal platelet count. The patients at this stage may be given the incorrect diagnosis of immune thrombocytopenic purpura (ITP). On the other hand, infection, surgery, or pregnancy may worsen microvascular thrombosis in patients with subclinical ADAMTS13 deficiency, giving rise to the clinical impression that TTP is triggered by these events. Neurologic complications typically, albeit not invariably, present later, when thrombocytopenia is profound and microangiopathic hemolysis is evident.

Most of the patients have no other significant medical history and begin to notice ill-defined symptoms such as headache, dizziness, and fatigue that are often considered insignificant until more serious complications such as profound fatigue, focal neurologic deficits, syncope, mental status changes, or seizures ensue. Less frequently, a patient may present with abdominal pain, nausea, and vomiting, with or without pancreatitis, or chest pain due to myocardial infarction, or even sudden death.

Advanced renal failure causing oliguria, anuria, fluid retention, electrolyte abnormalities, or uremia is rare in acquired TTP. The creatinine generally increases only minimally. When advanced renal failure occurs in a patient with acquired TTP, it is likely due to other causes.

Thrombotic Thrombocytopenic Purpura without Microangiopathic Hemolysis or Thrombocytopenia

Thrombocytopenia and microangiopathic hemolysis are not invariably present at the time of acute presentation (Fig. 48.7). Relapse of TTP is also increasingly diagnosed before microangiopathic hemolysis ensues.

Until recently, TTP presenting with acute stroke or transient ischemic attack without overt microangiopathic hemolysis was diagnosed only in retrospect after the patients went on to develop thrombocytopenia and microangiopathic hemolysis. ADAMTS13 assays greatly facilitate the diagnosis of atypical TTP.

Hereditary Thrombotic Thrombocytopenic Purpura

Also known as Schulman-Upshaw syndrome or chronic relapsing TTP, hereditary TTP is rare, accounting for <5% of all TTP cases.^{73, 74} Because the diagnosis is not recognized in milder cases, the incidence is likely higher than presently appreciated.⁷⁵

Hereditary TTP typically has its initial manifestations during the neonatal period, but historically is often not recognized until later in life.^{76, 77} Some of these patients have siblings who died before birth presumably due to TTP complications. Milder cases may present with thrombotic complications or have their disease recognized later in their life.^{76, 77, 78}

In a typical case, the affected neonate is born with meconium stain or presents within a few hours after birth with neonatal distress, jaundice, and thrombocytopenia. Hemolysis may not be severe and schistocytes on blood smears may be overlooked. Occasionally, serious complications such as seizures and mental obtundation may occur.

The symptoms typically improve immediately after blood transfusion or exchange transfusion performed unknowingly for thrombocytopenia or hyperbilirubinemia. Consequently, the neonates may be discharged from the hospital without a correct diagnosis, only to present with complications of the disease weeks or years later.

Like most genetic disorders, hereditary TTP varies in its severity. Many patients with hereditary TTP invariably develop hematologic or other complications if not treated regularly with plasma infusion every 2 to 4 weeks. Others have no or only subtle symptoms and maintain normal or mildly subnormal platelet counts and develop more serious complications only intermittently. The severity may also vary during the lifetime of individual cases, with or without apparent exacerbating conditions such as pregnancy.

The thrombotic process may cause focal neurologic deficits, seizures, pancreatitis, or renal failure.^{79, 80} Of the patients not receiving regular plasma infusion, 10%-20% of the cases develop at least one episode of acute renal failure requiring dialysis during their course. The renal failure is reversible if the patients promptly receive plasma infusion. Chronic renal failure occurs in approximately 10% of the patients not being regularly treated with plasma infusion, likely a result of cumulative microinfarcts in the kidney.

The propensity to acute and chronic renal disease in hereditary TTP is quite different from its rarity in acquired TTP. It is speculated that local expression of ADAMTS13 in renal glomerular podocytes and endothelial cells²⁰ may provide protection against vWF-platelet aggregation before its activity is suppressed by the inhibitors. Such protection is not present in patients with genetic ADAMTS13 mutations. Rarely renal failure may occur because the patient also has concurrent atypical HUS.⁸¹

Laboratory Findings

In de novo TTP cases presenting at the emergency service, the diagnosis is typically raised by the laboratory findings of severe

P.1084

thrombocytopenia and hemolysis with the presence of schistocytes on blood smears. The haptoglobin level is decreased or undetectable. Other common laboratory tests for assessment of hemolysis, including reticulocyte count, LDH, and indirect bilirubin are often but not invariably abnormal. In chronic cases, hemolytic anemia may predominate, as active platelet consumption is masked by compensatory thrombopoiesis.

As mentioned above, a patient with TTP may have no symptoms or may present with acute focal neurologic deficits without thrombocytopenia and/or microangiopathic hemolysis. Therefore, absence of thrombocytopenia or microangiopathic hemolysis in laboratory tests does not exclude the diagnosis of TTP.

Hematuria and proteinuria reflect renal glomerular thrombosis. The increase in the creatinine level is minimal in most cases. This is consistent with the pathologic findings that the kidney is minimally affected and its architecture is well preserved in TTP patients at autopsy.

Overt renal failure causing hypertension, fluid retention, electrolyte derangement, oliguria, or anuria favors the diagnosis of typical or atypical HUS over autoimmune TTP, unless there is a concurrent renal disorder. As mentioned above, acute and chronic renal failure may occur in patients with hereditary TTP.

Imaging studies such as CT or MRI are often requested for neurologic dysfunction. In most cases, the studies yield negative results or reveal only subtle ischemic changes, although occasionally a TTP patient may present with macrovascular ischemic strokes detectable by conventional imaging studies. It is speculated that in such cases the macrovascular thrombosis may result from thrombotic injury of the vasa vasorum.

The literature includes reports of "TTP" case series with a high percentage showing abnormal CT or MRI findings. However, a review of cases in these reports reveals that most of these patients likely had typical or atypical HUS rather than TTP.

Abnormal electrocardiograms with nonspecific ST-T wave changes and elevated CPK or troponin levels are common. Occasionally thrombosis may affect large coronary arteries leading to myocardial infarction. Cardiac arrhythmia is uncommon. Electromechanical dissociation, heart failure, or pulmonary infiltrates or hemorrhage occur in advanced, pre-terminal cases.

The amylase and lipase levels may be elevated. Abnormal liver function is rare. Abdominal CT scans may detect focal pancreatitis, intestinal wall or mesenteric thickening, or stranding due to ischemia or infarction.

FIGURE 48.8. Plasma ADAMTS13 activity is undetectable in patients with thrombotic thrombocytopenic purpura (TTP). Patients (338 cases) presenting with thrombocytopenia and microangiopathic hemolysis segregate in two nonoverlapping groups based on their plasma ADAMTS13 activity levels. Severe ADAMTS13 deficiency defines the diagnosis of TTP in 219 patients (65%), of which 191 had autoimmune ADAMTS13 inhibitors and 28 had genetic mutation as the cause of the deficiency. ADAMTS13 activity is detectable in some patients after receiving plasma or blood transfusion (TTP tx). During remission, (TTP rem) most patients continue to have decreased ADAMTS13 activity levels, consistent with the chronic nature of their disease. The two upper dashed lines encompass the normal range of plasma ADAMTS13 activity. The lowest line marks the detection limit of the assay at 10%.

ADAMTS13 Activity Levels

Among patients presenting with thrombocytopenia and microangiopathic hemolysis, only TTP patients have severe ADAMTS13 deficiency (less than 10%), whereas patients with other disorders have detectable ADAMTS13 levels (Fig. 48.8). ADAMTS13 may be detectable if the assay is performed after the patients receive plasma or blood transfusions. The ADAMTS13 activity level remains decreased in most patients during their remission, suggesting that the autoimmunity is active. Severe ADAMTS13 deficiency provides the diagnosis of TTP in the patients with co-morbidities in whom the diagnosis would otherwise be difficult to make.

The assay used to obtain the data presented in Figure 48.8 uses purified vWF as the substrate and SDS-PAGE to detect the proteolytic products. This assay is technically demanding and not practical for use in clinical laboratories. Various assays using vWF peptides spanning the scissile bond have been developed for analysis of ADAMTS13 activity in clinical laboratories. The assays differ in their performance and reliability and may not provide a definitive diagnosis or exclusion of TTP.^{82 83 84 85 86 87 88}

Because some clinical assays may yield falsely high or low values of ADAMTS13, the diagnosis of TTP requires corroboration of the ADAMTS13 test results with clinical and other laboratory data.

ADAMTS13 Inhibitors

Inhibitors of ADAMTS13, measured by mixing patient and normal plasma samples, are detectable in 80% to 90% of the acquired TTP patients. A negative test for ADAMTS13 inhibitors does not exclude the presence of ADAMTS13 inhibitors. In such patients, the presence of inhibitors may be inferred if the increase of the ADAMTS13 activity level is less than expected after plasma therapy, or if the ADAMTS13 activity recovered to >10% during remission.

ADAMTS13 Antibody and Antigen Assays

Assays have been developed to measure ADAMTS13 antigen and antibody levels in enzyme-linked assay formats. These solid-phase microtiter plate-based assays have limited utility in practice. The antigenic assay detects free ADAMTS13 as well as ADAMTS13/inhibitor

P.1085

complex, yielding low ADAMTS13 antigen levels in <50% of TTP patients.⁸⁹ The ADAMTS13 antibody assay is highly

sensitive (>90%) for acquired TTP but may yield false-positive results in 5% to 10% of individuals without ADAMTS13 antibodies.^{90, 91}

ADAMTS13 Activity Levels during Plasma Therapy and Remission

ADAMTS13 activity assays are used not only for initial diagnosis of TTP, but are also used to assist management during plasma therapy and clinical remission.⁴³

In general, vWF-platelet aggregation does not occur when ADAMTS13 activity is >10% of normal. Thus, in a patient with persistent thrombocytopenia or declining platelet counts, an ADAMTS13 activity >10% of normal, either at initial presentation or during plasma therapy, precludes TTP as the cause of the low platelet count, and requires a search for other causes.

At the end of plasma therapy and during remission, persistently low (<10%) or steadily declining ADAMTS13 levels connote a high risk of immediate or impending relapse.

Hereditary Thrombotic Thrombocytopenic Purpura

The ADAMTS13 activity level should be ≤10% and the inhibitor and antibody tests should be negative in patients with hereditary TTP. Falsely-positive antibody results may cause confusion. Improvement of the ADAMTS13 level to greater than 10% during remission excludes the diagnosis of acquired TTP.

Familial studies may be performed to show that the parents have partial ADAMTS13 deficiency.⁵⁹ In practice, familial studies may be limited in the power to distinguish carriers from normal individuals.

Differential Diagnosis

Although the diagnosis of TTP depends on the demonstration of severe ADAMTS13 deficiency, it is essential to exclude other causes of microangiopathic hemolysis as listed in Table 48.1. On the other hand, the presence of a co-morbidity does not preclude the diagnosis of TTP.

A complete history and physical examination should be accompanied by appropriate laboratory tests such as ELISA or PCR tests for shiga toxins in the stool; blood or viral cultures or PCR analysis for pneumococcal or other bacterial or viral infections; autoimmune serology tests for lupus, scleroderma, and related autoimmune disorders; coagulation profile such as PT, PTT, fibrinogen, D-dimer assays, and additional clotting factor assays for disseminated intravascular coagulopathy; MRI for mental status changes; CT scan or other imaging studies and tissue biopsies for metastatic neoplasm; and flow cytometry for paroxysmal nocturnal hemoglobinuria.

Advanced renal failure, hypertension, and complications of abnormal vascular permeability such as brain edema, pleural or pericardial effusions, pulmonary edema, acute respiratory distress syndrome, ascites, and anasarca are rare in TTP. Any of these complications at presentation or during the course favors the diagnosis of thrombotic microangiopathy due to atypical HUS or other etiologies.

Management and Prognosis

Prompt plasma exchange is critical to prevent serious complications or death from TTP. The principles of management for patients with TTP are summarized in Table 48.2.

Plasma Therapy

Before plasma exchange or infusion was introduced in the 1970s,^{92, 93} more than 90% of patients died after presenting with symptomatic TTP. Plasma exchange and plasma infusion are the only therapies with proven efficacy for TTP presenting with thrombocytopenia and microangiopathic hemolysis.² With these treatments, a mortality rate of 10% to 20% and 40% to 50% is expected, respectively.

TABLE 48.2 PRINCIPLES OF MANAGEMENT FOR THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP)

- High index of suspicion is essential for patients presenting with thrombocytopenia or TIA/stroke.

-Some patients may not have thrombocytopenia or microangiopathic hemolysis at presentation.

- Prompt treatment is critical to prevent serious complications and death.
- Daily plasma exchange is the therapy of choice for acquired TTP presenting with active thrombosis.

- Plasma infusion is used as an emergent substitute until plasma exchange is available.
- ADAMTS13 activity assay should be obtained before the patients receive any blood products.
- The diagnosis should be re-assessed during the course of therapy.
- Monitoring of ADAMTS13 during plasma therapy and remission may help clinical assessment.

-For patients with persistent thrombocytopenia, ADAMTS13 >10% should suggest other causes of thrombocytopenia.

-Monthly ADAMTS13 monitoring may detect impending relapses.

- Rituximab therapy should be considered for patients

-Unable to wean off plasma exchange due to persistent and severe ADAMTS13 deficiency.

-With persistent and severe ADAMTS13 deficiency during clinical remission.

-Exhibiting a trend of declining ADAMTS13 levels.

- Hereditary TTP

-Plasma infusion is effective for patients presenting with acute symptoms.

-Plasma exchange is used if the patient has renal failure or fluid overload.

-For most patients, plasma therapy every 2-3 wk prevents acute crisis, strokes, and renal failure.

Plasma exchange is typically performed daily at 1-1.5 total plasma volumes until the platelet count is normal, then gradually tapered to ensure the platelet count is stable before the therapy is discontinued. It is believed that plasma exchange therapy removes antibodies and replenishes the deficient ADAMTS13.

Serial analysis shows that the plasma ADAMTS13 activity level often fluctuates in the first several weeks before it gradually stabilizes to a steady-state level. This explains why the response to plasma therapy may be unsteady for weeks to months and why it is important to monitor the blood counts closely after plasma exchange therapy is tapered.

ADAMTS13 levels persistently less than 10% of normal at the end of plasma therapy indicate a high risk of early relapse. On the other hand, a measurable ADAMTS13 level at the end of plasma therapy does not preclude the possibility that levels will subsequently decrease and cause later relapse. Thus, serial ADAMTS13 analysis is more informative than single tests.

Plasma infusion has the advantage that it does not require a large venous catheter and special equipment. Its efficacy is limited by the risk of fluid overload. Plasma infusion is used primarily as an emergent substitute until plasma exchange is instituted.

Cryoprecipitate-depleted plasma has been advocated as a more effective alternative of fresh-frozen plasma because it lacks large vWF multimers.^{94, 95} However, two small randomized-controlled trials failed to demonstrate that the use of cryoprecipitate-depleted plasma is superior to fresh-frozen plasma as initial replacement therapy.^{96, 97}

P.1086

Acquired TTP is a chronic autoimmune disease punctuated with episodes of acute exacerbation. The ADAMTS13 level during clinical remission is quite variable, ranging from normal to undetectable. Normal ADAMTS13 activity levels during remission do not preclude the risk of future relapses. Serial monitoring may detect trends of declining ADAMTS13 levels before the patients develop symptomatic relapses, providing a window for immunosuppressive intervention before a relapse occurs.⁴³

Immunosuppressive Therapy

Plasma therapy does not address the underlying ADAMTS13 autoimmunity of TTP. Patients are able to achieve sustained remission primarily because the inhibitors spontaneously decrease, allowing the recovery of the ADAMTS13 activity above the threshold level. Nearly all patients will experience at least one relapse in their later lives. Some patients develop refractory disease after years of quiescent periods or several sporadic relapses.

For patients who cannot be weaned off plasma exchange due to persistent ADAMTS13 deficiency, suppression of B-cells with rituximab, a chimeric monoclonal antibody to CD20, induces clinical remission in approximately 70% to 90% of the patients.^{98, 99, 100, 101} Rituximab increases the ADAMTS13 level by suppressing, but not necessarily eliminating, the ADAMTS13 inhibitors. A small increase in the ADAMTS13 activity level to 10% or higher is sufficient to induce clinical remission, allowing the patient to be weaned off plasma therapy. Rituximab is less effective in patients with high ADAMTS13 inhibitor levels.

Rituximab may decrease the risk of immediate relapse in patients with severe ADAMTS13 deficiency entering or during remission.^{102, 103, 104, 105} It may also be used pre-emptively to avert relapses in patients exhibiting a trend of declining ADAMTS13 activity levels during remission.⁴³ The efficacy of rituximab lasts for several months to a few years, with a median remission duration ~1.5 years. Patients may be re-treated with rituximab when their plasma ADAMTS13 activity begins to show a steady decline. The major side effects of rituximab include allergic reaction and reactivation or exacerbation of viral infections such as hepatitis B and progressive multifocal leukoencephalopathy.

Cyclosporin may be efficacious, but the experience of using cyclosporine in TTP patients remains limited.¹⁰⁶ Splenectomy, which decreases the number of B-cells and immunocytes, has been recommended for patients unable to be weaned off plasma exchange or who experience frequent relapses.¹⁰⁷ With rituximab demonstrating high response rates, splenectomy is performed less frequently. Other immunosuppressive therapies that have been used in TTP include corticosteroids, vincristine, cyclophosphamide, and azathioprine. These therapies are generally less effective than rituximab and more likely to cause serious side effects.

Antiplatelet Agents

For most patients, adding antiplatelet drugs such as aspirin, dipyridamole, ticlopidine, or clopidogrel is unlikely to improve the response to plasma therapy. These drugs may prevent relapses in patients whose ADAMTS13 levels are low enough to cause platelet thrombosis. Nevertheless, the response to antiplatelet therapy is unreliable.

Hereditary Thrombotic Thrombocytopenic Purpura

Hereditary TTP responds to 7.5-10 ml fresh-frozen plasma per kilogram of body weight. Plasma exchange therapy is reserved for patients with renal failure. Inasmuch as thrombotic complications are unpredictable and may result in serious sequelae such as chronic renal failure or strokes, maintenance plasma therapy is recommended for most patients with hereditary TTP. The regimen should be tailored to prevent not only acute symptomatic crisis but also the development or progression of chronic organ injury. To achieve these goals, maintenance of normal platelet counts is recommended. Most patients require fresh-frozen plasma every 2 weeks to achieve and maintain normal platelet counts and prevent acute exacerbations. For patients not receiving maintenance therapy, serial monitoring of CBC, renal function, and urinalysis is recommended.

Special Considerations: Thrombotic Thrombocytopenic Purpura in Pregnancy

An association between pregnancy and TTP has been suspected, but never confirmed. Because TTP affects women in their reproductive years, it may occur co-incidentally during pregnancy. Patients presenting with TTP during pregnancy should be treated as other patients with plasma exchange, and with tapering of the treatment to be guided by serial ADAMTS13 levels.

A more difficult challenge is counseling and management of women with a history of TTP who desire pregnancy. Pregnancy progressively decreases ADAMTS13 levels by 30% at term, and by nearly 65% if the pregnancy is complicated with preeclampsia or the HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome. Pregnancy also increases plasma vWF levels. Therefore, pregnancy may lead to exacerbation of TTP in patients with pre-existing ADAMTS13 deficiency. Microvascular thrombosis increases maternal and fetal morbidity and mortality, and therefore every effort should be made to prevent thrombosis and thrombocytopenia during pregnancy.

For women with a history of acquired TTP and low ADAMTS13 levels during their remission, pregnancy is not advised, as it involves real risks that cannot be reliably predicted or easily managed. ADAMTS13 levels may decrease to cause maternal TTP relapses. It may also cause fetal complications without overt maternal relapses.

If pregnancy is inevitable, rituximab may be an option to preemptively increase ADAMTS13 levels before pregnancy occurs. Rituximab is a class C drug for pregnancy, based on the adverse effect of lymphocytopenia observed in animal reproductive studies. In theory, its deleterious effects may last for 12 months. There are no adequate and well-controlled studies in humans. Rituximab use during pregnancy has been reported in a woman without causing adverse consequences. Thus, potential benefits may warrant use of the drug in pregnant women despite the theoretical risks.

Serial monitoring of ADAMTS13 levels is essential in pregnant patients. If ADAMTS13 exhibits a trend of decrease toward 10% of normal, pre-emptive plasma exchange or infusion therapy is used to prevent TTP relapses and fetal complications.

Patients with genetic ADAMTS13 mutations should receive adequate maintenance plasma therapy titrated to prevent thrombocytopenia and thrombosis. Some women with milder forms of hereditary TTP may become pregnant without knowing the diagnosis of the disease. These patients may develop thrombocytopenia that is often incorrectly attributed to immune thrombocytopenia or gestational thrombocytopenia, only to develop TTP exacerbation or fetal complications as the pregnancy progresses. A positive family history, a high index of suspicion, and liberal use of ADAMTS13 assays may help identify such patients for correct diagnosis and management.

Novel Therapeutic Modalities

Recombinant ADAMTS13 is under development for replacing deficient ADAMTS13 in patients with TTP. Truncated variants of ADAMTS13 or variants with substitutions at the residues critical for interaction with inhibitors may circumvent the difficulties posed by inhibitors. However, immunogenicity is a concern for variant ADAMTS13 molecules with substituted amino acid.

P.1087

N-acetylcysteine, presently used for acetaminophen liver toxicity and chronic lung disease, decreases the size of vWF by reducing the disulfide bonds of vWF multimers.¹⁰⁸ It may be an attractive therapy for TTP if its vWF-reducing activity is confirmed in human subjects.

Inhibitors of vWF-platelet aggregation such as the anti-vWF aptamer ARC1779¹⁰⁷ or nanobody ALX-0081¹⁰⁹ may prevent microvascular thrombosis in TTP patients. These drugs may best serve as a short-term measure to prevent serious complications or death before ADAMTS13 levels are raised by plasma replacement therapy or rituximab.

SHIGA TOXIN-ASSOCIATED HEMOLYTIC-UREMIC SYNDROME

First described by Gasser et al. in 1955,¹¹⁰ typical HUS refers to the constellation of renal failure, microangiopathic hemolysis, and thrombocytopenia following a bout of hemorrhagic diarrhea. This is a relatively uncommon disease but often draws public attention during outbreaks of food-borne illness.

Etiology

It is estimated that approximately 90% of North American and European children with HUS have infection with shiga toxin-producing *E. coli* (STEC) of the enterohemorrhagic serotype, typically serotype O157:H7. In the United States, approximately 4,000 cases of *E. coli* O157:H7 infections are diagnosed annually, with 15% of them developing the complication of HUS. STEC of non-O157 serotypes and even *Shigella dysenteriae* serotype I have also been implicated in causing HUS.

The offending organisms share the capacity of producing powerful shiga toxins, which are encoded by phage DNA and comprise several genotypes.¹¹¹ Most HUS cases are caused by shiga toxin genotype 2 or 1+2. With more laboratories conducting the shiga toxin assays, increasing numbers of non-O157 *E. coli* serotypes such as O26:H11, O103:H2, O111:H8, and O145:H28 are detected.

Enteropathogenic *E. coli* has a reservoir in bovine intestine and is transmitted by meat, milk, or water contaminated with ruminant feces. Most cases of shiga toxin-associated HUS result from ingestion of contaminated food such as beef, leafy vegetables, dairy, fruits, nuts, sprouts, poultry, or water. Other modes of transmission include direct animal contact and person-to-person contact during the acute diarrheal phase. Very low infectious doses (<100 organisms) are sufficient to cause clinical disease. Outbreaks account for only 20% of the cases. Approximately 50% of the cases occur during the summer months.

The outbreaks in Germany, France, and other countries in 2011 were due to contamination with *E. coli* O104:H4, which evolved from an unusual progenitor of enteroaggregative *E. coli* through acquisition of a *stx2*-encoding prophage and a plasmid encoding a CTX-M-15 extended-spectrum beta-lactamase (ESBL) gene.^{112, 113, 114, 115}

Many strains of STEC have not been associated with hemorrhagic diarrhea or HUS, indicating that other virulence factors of the organisms are also critical for pathogenesis. The expression of additional genes on a chromosomal locus of enterocyte effacement pathogenicity island, including intimin encoded by the *eae* gene for intimin attachment, has a strong association with the risk of HUS.¹¹⁶

STEC is one of the surveillance infections conducted by the Foodborne Disease Active Surveillance Network (FoodNet).

Pathology

The pathology of shiga toxin-associated HUS is quite different from that of TTP, as it is dominated by glomerular endothelial cell swelling or necrosis and subendothelial expansion in the kidney.^{117, 118} Fibrin-platelet thrombi are commonly present in glomerular loops and hila and may be seen extending into small and medium-sized arteries, including the interlobular arteries (Fig. 48.2C). Neutrophil infiltration may be present. Extensive thrombosis may result in renal cortical infarcts.

Other organs such as brain, heart, intestinal tract, and pancreas may also be affected, either with edema due to abnormal vascular permeability or with ischemic injury due to microvascular stenosis or thrombosis.

Pathophysiology

It is believed that injury of the kidney and other organs is a consequence of the cytotoxic effect of shiga toxins on vascular endothelial cells.^{119, 120, 121} A shiga toxin molecule comprises an A-subunit and a pentameric B-subunit. The shiga toxin molecule binds via its B-subunit to globotriaosylceramide (Gb3) expressed on the membrane lipid rafts of renal microvascular endothelial or other target cells. This binding is followed by internalization of the A-subunit via endocytosis. After proteolysis, a smaller fragment of the A-subunit is generated that is capable of disrupting the 60s ribosomes, blocking protein synthesis in the target cells. The sensitivity of endothelial cells may be enhanced by cytokines such as IL-1 and TNF- α released in response to endotoxins.

Additional studies suggest that shiga toxins may also alter the expression of vasoactive factors (e.g., endothelin and nitric oxide) and adhesive proteins (e.g., vWF, $\alpha_v\beta_3$, PCAM-1, and P-selectin), or activate the alternative complement pathway.^{122, 123, 124, 125} However, it is not clear whether the high concentrations of shiga toxins used in these studies are pathophysiologically relevant.

The cytotoxicity of shiga toxins leads to endothelial cell swelling, abnormal vascular permeability, and cell death. Endothelial cell disruption exposes the underlying thrombogenic glomerular basement membrane, triggering the activation of the coagulation cascade and subsequent thrombosis. Thrombosis leads to ischemic organ injury, thrombocytopenia, and abnormal shear stress causing red cell fragmentation. Vascular stenosis may also result from endothelial swelling and subendothelial expansion, causing tissue ischemia and red cell fragmentation without increasing platelet consumption. The microangiopathy may also increase vascular permeability, leading to brain edema, pleural or pericardial effusion, ascites, mesenteric or intestinal edema, and anasarca that do not correlate with thrombocytopenia or microangiopathic hemolysis.

Clinical Presentation

There is a spectrum of illness following ingestion of STEC, ranging from no symptoms to self-limited gastroenteritis, the HUS and death.

Symptomatic STEC infection leads to HUS in up to 15% of cases.^{111, 126} Diarrhea and other gastrointestinal symptoms develop between 2 and 12 days after ingestion of pathogenic *E. coli*. Bloody diarrhea develops 1 to 3 days later.

Symptoms and signs of HUS begin to manifest as the diarrhea begins to improve. Risk factors for HUS after infection with shiga toxin-producing *E. coli* include young or old age, long duration of diarrhea, elevated leukocyte count, antimicrobial or antidiarrheal drug use, and bloody diarrhea.¹²⁷

The onset of hemolysis and renal failure may be dramatic, with sudden pallor, abdominal pain, vomiting, and the appearance of dark-red or nearly black urine. These manifestations may quickly lead to oliguria or even anuria. On the other hand, mild or incomplete HUS with thrombocytopenia but no anemia or azotemia is almost as frequent as the complete form of HUS.

Extrarenal complications occur in approximately 50% of patients, and may include pancreatitis, glucose intolerance, P.1088

colonic necrosis and perforation, myocardial infarction, congestive heart failure, pericardial or pleural effusion, and acute respiratory distress syndrome.¹²⁸

Neurologic complications including irritability, confusion, transient paralysis, seizures, and coma are the most serious and often result from cerebral edema of thrombotic microangiopathy. Hemorrhagic or thrombotic stroke is quite infrequent.

Elderly individuals, especially frail nursing home residents, are more likely to experience cardiovascular and neurologic complications and death.¹²⁹

Laboratory Findings

Hematologic findings are similar to those of TTP, although the severity of thrombocytopenia is more variable and does not always reflect the severity of the clinical status. The anemia often is severe and may be accompanied by moderate polymorphonuclear leukocytosis. Hemoglobinemia may be marked. The prothrombin time and partial thromboplastin time usually are normal or minimally prolonged; fibrin degradation products or D-dimer tests are frequently elevated.¹³⁰ Serum haptoglobin levels are typically undetectable. The bilirubin level is usually elevated. The liver transaminases and amylase may also be elevated.¹³¹ The blood urea nitrogen and serum creatinine levels may be quite high. The urine usually contains hemoglobin and hemosiderin in addition to albumin. Microscopically, erythrocytes, leukocytes, and casts are seen.

CT and MRI studies of the brain in patients with neurologic complications may reveal various abnormalities including restricted water diffusion; edema or posterior reversible encephalopathy syndrome (PRES); contrast enhancement; or hemorrhage in the basal ganglia, thalamus, cerebellum, or brainstem.¹³² The lesions are most commonly due to abnormal vascular permeability and may resolve on follow-up examinations and are not necessarily associated with a poor long-term neurologic outcome. Similar lesions are also often detected in patients with atypical HUS.

With perhaps rare exception, patients with shiga toxin-associated HUS have normal or slightly decreased ADAMTS13 activity levels and no inhibitory antibodies.⁷ Large vWF multimers may be decreased as abnormal shear stress in the microcirculation augments proteolysis of vWF by ADAMTS13.⁷

Diagnosis, Management, and Prognosis

Conventionally, *E. coli* O157:H7 is detected by plating fresh feces on sorbitol-MacConkey agar. Direct detection of shiga toxins by ELISA or PCR analysis is more sensitive and also detects non-O157:H7 serotypes.¹³³

No specific treatment is available for shiga toxin-associated HUS. Early and careful management of acute renal failure and hypertension and the judicious use of packed red cell transfusions appear to constitute the safest and most effective approach to the management of HUS in children.

Plasma therapy is of no or little benefit in children.¹³⁴ Because of the excellent results achieved in the treatment of TTP and difficulty in distinguishing HUS from TTP, adult patients are often treated with plasma exchange, although evidence in support of this practice remains circumstantial.¹³⁵

Recently, based on laboratory observations of complement activation by shiga toxin and endothelial P-selectin,¹²² eculizumab, a humanized monoclonal antibody of C5 originally approved for patients with paroxysmal nocturnal hemoglobinuria and aHUS, was used in three patients with severe shiga toxin-associated HUS.¹³⁶ The patients promptly improved. This could represent a major therapeutic advance if its efficacy is reproduced in other trials.

Certain antibiotics such as ciprofloxacin may induce the expression of shiga toxins.^{126, 137, 138} Antibiotic usage increases the risk of HUS following *E. coli* O157:H7 infection.¹³⁹ Until future investigation shows otherwise, bactericidal antibiotics and antimotility drugs should be avoided in patients with shiga toxin-associated colitis.

Approximately 50% of patients with shiga toxin-associated HUS require dialysis. The usual indications for dialysis support include fluid overload unresponsive to diuretics, a rapidly rising creatinine value, anuria for more than 24 hours, severe electrolyte imbalance, and serious clinical signs of uremia.

Direct person-to-person transmission occurs during the acute diarrheal phase. In some cases, excretion of the microorganisms may persist for several months. Contact isolation and frequent hand washing are recommended to minimize the spread of infection.

The overall mortality in children with epidemic HUS is 12% (range 0 to 30%). The majority of patients recover without serious consequences. Long-term renal injury such as decreased glomerular filtration rate, proteinuria, hypertension, or renal failure may be present in as many as 1 of every 4 survivors.^{140, 141} However, this risk is quite variable. Some patients may develop irritable bowel syndrome.¹⁴² Young women may also be at higher risk of pregnancy-related hypertension, presumably due to subclinical kidney injury.¹⁴³ A few patients may require long-term dialysis or renal transplantation therapy. Shiga toxin-associated HUS is not expected to recur following renal graft transplantation.

ATYPICAL HEMOLYTIC-UREMIC SYNDROME

aHUS originally referred to the constellation of acute renal failure, microangiopathic hemolysis, and thrombocytopenia in children without a prodrome of hemorrhagic diarrhea or another apparent cause. It is now recognized that aHUS may present in adults as frequently as in children, although most of the adult patients have been given the diagnosis of TTP. Most patients with aHUS have defects in regulating the alternative complement pathway.¹⁴⁴ Defective complement regulation is also found in women with pregnancy-associated aHUS.¹⁴⁵ Preliminary evidence suggests that some of the patients with other co-morbidities such as bone marrow/hematopoietic stem cell transplantation also have defective regulation of the alternative complement pathway.¹⁴⁴ In such patients, aHUS is believed to be induced by the co-morbidity. In addition, severe hypertension may be a complication of aHUS instead of a cause of microangiopathic hemolysis as previously believed.

Because of overlapping clinical features, aHUS is not distinguished from TTP in many reports. In fact, most patients with the so-called "TTP without severe ADAMTS13 deficiency" really have aHUS instead of TTP. Interpretation of reports in the literature is difficult when the case definitions do not provide a clear distinction between TTP and aHUS. A comparison of the distinctive features of TTP and aHUS is summarized in Table 48.3.

Pathology

Although aHUS and TTP share the common features of thrombocytopenia and microangiopathic hemolysis, they are quite different pathologically.

In aHUS, the affected glomerular capillaries, arterioles, and interlobular small arteries typically exhibit endothelial cell swelling or death and subendothelial expansion due to edema and/or hypercellularity, often but not invariably accompanied by thrombosis.¹⁴⁶ The glomerular tufts may show mesangiolyis. Late changes may show double basement membranes, mesangial cell proliferation with expansion of the matrix and interstitial fibrosis. The lesions often include admixtures of acute and chronic changes (Fig. 48.2D-F). The prominence of chronic changes in

P.1089

patients at their first presentation suggests antecedent subclinical injury.

TABLE 48.3 COMPARISON OF THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP) AND ATYPICAL HEMOLYTIC-UREMIC SYNDROME (aHUS)

Disorder	TTP		aHUS	
• Transmission	Acquired	Hereditary	Acquired	Hereditary
• Molecular defects	ADAMTS13 inhibitors	ADAMTS13 mutations	CFH Ab	Genetic defects of complement regulation
• Age	Teens-adults	Children-adults		Children-adults
• Gender (female vs. male)	2-3:1	~ 1:1		~ 1:1
• Pathology	Microvascular thrombosis		Thrombotic microangiopathy	
• Presentation	- General: fatigue, headache - Neuro: focal deficits, confusion - Others: abdominal or chest pain, nausea, vomiting		- General: fatigue, headache, dizziness - Cardiovascular: chest pain, dyspnea - GI: abdominal pain, diarrhea, nausea, vomiting - Neuro: somnolence, confusion, seizures, focal deficits	
• Thrombocytopenia	Precedes MAHA and organ injury		May not reflect disease severity	
• Advanced renal failure	Rare	Occasional		Common
• Hypertension	Rare	Occasional		Common

• ↑ Vascular permeability	Rare	Rare	Common
- Cerebral edema, PRES			
- Pulmonary edema			
- Effusions, ascites			
- Anasarca			
• Treatment of choice	Plasma exchange	Plasma infusion	Ecuzumab
• Mortality	10%-20%	Very low if promptly treated	- 10%-30% with plasma exchange - Expected to be very low with ecuzumab
• Long-term prognosis ^a	Relapse	Relapse, stroke, CRF	Relapse, ESRD

Complement regulators: complement factor H, membrane co-factor protein, complement factor I, C3, complement factor B, or thrombomodulin; CFH, complement factor H; CFHR1, complement factor H-related protein 1; CRF, chronic renal failure; ESRD, end-stage renal disease; MAHA, microangiopathic hemolytic anemia; ND, not detectable; PRES, posterior reversible encephalopathy syndrome.

^a If treated only for relapses.

The pathology of thrombotic microangiopathy may also be demonstrable, albeit less conspicuously, in other organs. More common is tissue edema in the brain, lung, gastrointestinal tract, mesentery and cutaneous soft tissues. Fluid accumulation may be present in the pericardial, alveolar, pleural, or peritoneal space. These changes result from abnormal vascular permeability and are uncommon in patients with TTP.

Molecular Pathogenesis

The complement system, an important part of the innate host defense against invading microorganisms, may be triggered by immune complexes or microbial lectins. The alternative pathway, via complement factors B, D, and P, amplifies complement activation by promoting the generation of alternative C3b and C5b convertases (Fig. 48.9). Complement factor H (CFH), factor I (CFI), membrane cofactor protein (MCP, or CD46), thrombomodulin (THBD), and possibly complement factor H-related proteins 1-5 (CFHR1-5) are involved in regulating self-perpetuating complement activation.

Genetic mutations of the alternative complement activators or regulators have been found in approximately 50% of aHUS patients, with a higher prevalence among patients with a family history (75%) than in patients without a family history (40%). The molecular defects include inactivating mutations of CFH (25%), MCP, CFI, and THBD (5% to 10% each); gain-of-function mutations of activators C3 (5% to 10%) and CFB (a few pedigrees).^{144, 147, 148} Additionally, antibodies to CFH are detected in 5% to 10% of the cases, often with concurrent homozygous or heterozygous genomic deletion of CFHR1.^{149, 150}

The genetics of aHUS are more complex than involvement of single genes. Compound mutations are present in 10% or more of the patients. Atypical HUS may only develop in patients with more than one variant of the activators or regulators.¹⁵¹ Analysis of single nucleotide polymorphisms (SNP) of complement activators and regulators demonstrates that the risk of aHUS is significantly increased or decreased with certain SNPs and haplotypes of CFH, CD46, CFHR2, CFHR4, and intergenic CR1-CD46.¹⁵² Laboratory studies have demonstrated that certain combinations of common variants (complotype) of the complement activators and regulators increase the risk of the disease.¹⁵³

Complement factor H-related proteins 1-5 (CFHR1-5) are the products of a series of genes located immediately downstream of the CFH gene, that are mapped to a region of chromosome 1q containing multiple retrotransposon sequences. Genomic deletion of CFHR1 and CFHR3 is detected in only 3% of the control population, but is present in 28% of aHUS patients.^{150, 154, 155} Further analysis intriguingly reveals that genomic CFHR1 deletions are present in 90% of patients with CFH autoantibodies and 20% of patients with CFI mutations, but not different from its background prevalence in patients with other or no mutations.¹⁵⁶ The presence of CFHR1 deletion markedly increases the severity of aHUS in patients with CFI mutations.¹⁵⁷ CFHR1 may block the binding between CFH and its antibodies in autoimmune aHUS patients.^{144, 158}

The genetic lesions of complement regulation affect the prognosis of aHUS. Long-term survival without advanced renal failure is approximately 80%-90% for patients with only mutations affecting MCP, and is 20%-30% for patients with mutations of CFH.

P.1090

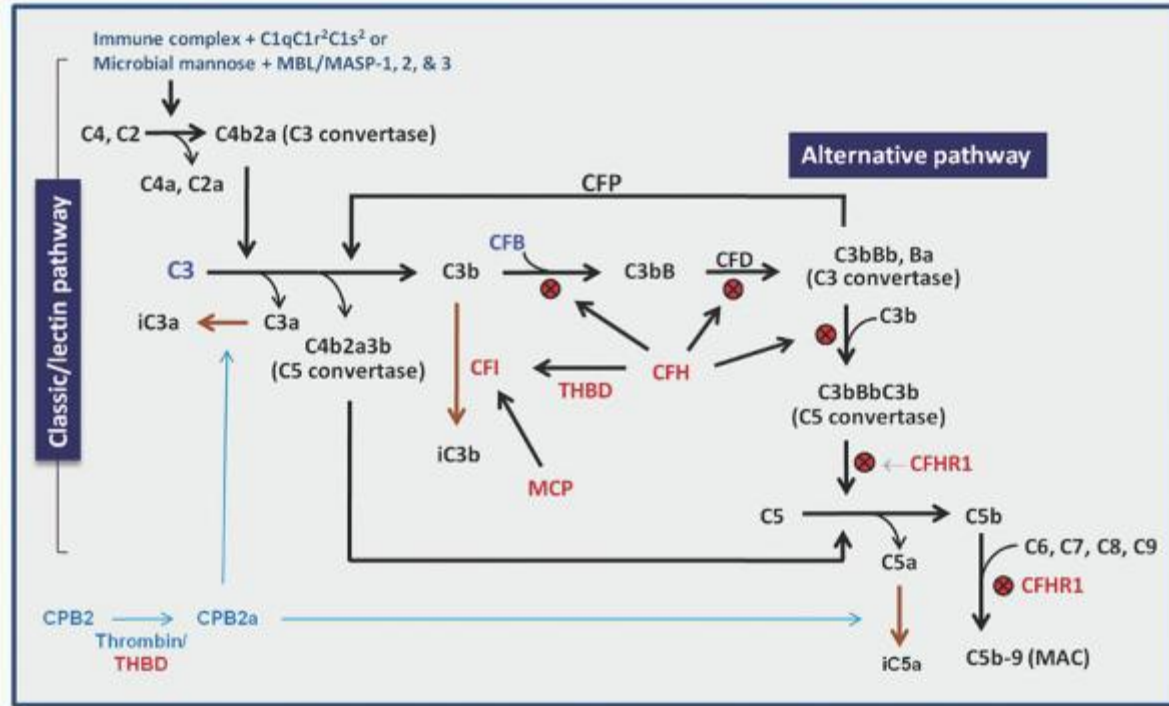

FIGURE 48.9. A scheme of the complement system highlighting the alternative pathway and its regulators (in red). Complement factor I is a plasma serine protease which, with the help of complement factor H (CFH) or membrane cofactor protein (MCP), cleaves C3b to its inactive form (iC3b). CFH also regulates other steps in the alternative pathway. Thrombomodulin (THBD) augments the cofactor activity of CFH and promotes the activation of carboxypeptidase B2 (CPB2) by thrombin, thereby accelerating the inactivation of C3a and C5a. CFB, complement factor B; CFHR1, complement factor H related protein 1; CPB2a, activated CPB2; iC3a, inactivated C3a; iC3b, inactivated C3b; iC5a, inactivated C5a; CFD, complement factor D; CFP, complement factor P; MBL, mannose binding lectin; MASP, mannose binding lectin associated protease.

More than 50% of patients with CFI mutation have concurrent mutations affecting other complement activator or regulatory proteins. Concurrency mutations increase the risk of serious aHUS complications.¹⁵⁷

As a consequence of the complexity in its genetics, atypical HUS due to complement mutations is transmitted as an autosomal dominant trait with incomplete and variable penetrance, which is greater than 50% with CFH and MCP mutations, but much lower with mutations of the other proteins.

Pathophysiology

The clinical features of aHUS are the consequence of microvascular stenosis, thrombosis, and abnormal vascular permeability resulting from uncontrolled activation of the complement system.

When the complement system is triggered by infection or other factors, defective regulation of the alternative pathway leads to unrelenting generation of complement activation products, including C3a, C5a, and C5b-9 (membrane attack complex, MAC). It is believed that C5b-9 causes direct injury of vascular endothelial cells, whereas C3a and C5a may cause abnormal vascular permeability (Fig. 48.10).

Endothelial cell injury and disruption expose the prothrombotic components in the subendothelium, leading to the activation of the coagulation system, microvascular thrombosis, thrombocytopenia, and ischemic organ injury. Microvascular thrombosis also creates abnormal levels of shear stress, causing fragmentation of the red blood cells.

Endothelial injury causes cell swelling, subendothelial edema, and cellular proliferation. These changes may directly result in marked luminal stenosis (Fig. 48.2E,F) and ischemic organ injury. Vascular stenosis also increases the shear stress and causes microangiopathic hemolysis without concurrent thrombocytopenia. Abnormal vascular permeability may lead to tissue edema and organ dysfunction without concurrent thrombocytopenia or microangiopathic hemolysis. The combination of multiple pathophysiology pathways explains why microangiopathic hemolysis, thrombocytopenia, and organ dysfunction do not always closely correlate with each other in patients with aHUS.

Other Phenotypes of Complement Dysregulation

Excessive complement activation is also associated with the phenotype of mesangiocapillary or membranoproliferative glomerulonephropathy type 2 (dense-deposit disease).^{159, 160, 161, 162, 163} Occasionally, a patient may present with HUS, evolving to renal failure with histopathologic features of mesangiocapillary glomerulonephropathy later in life.¹⁶⁴

Complement dysregulation is also associated with age-related macular degeneration. The Y402H polymorphism in the short consensus repeat-7 (SCR-7) of CFH has been linked to age-related macular degeneration among European patients.^{165, 166, 167} More than 20 cases of CFI deficiency have been described from 19 pedigrees linked to increased risk of pyogenic infection.¹⁶⁸ Uncontrolled complement activation also underlies the mechanism of hemolysis in patients with paroxysmal nocturnal hemoglobinuria.¹⁶⁹

P.1091

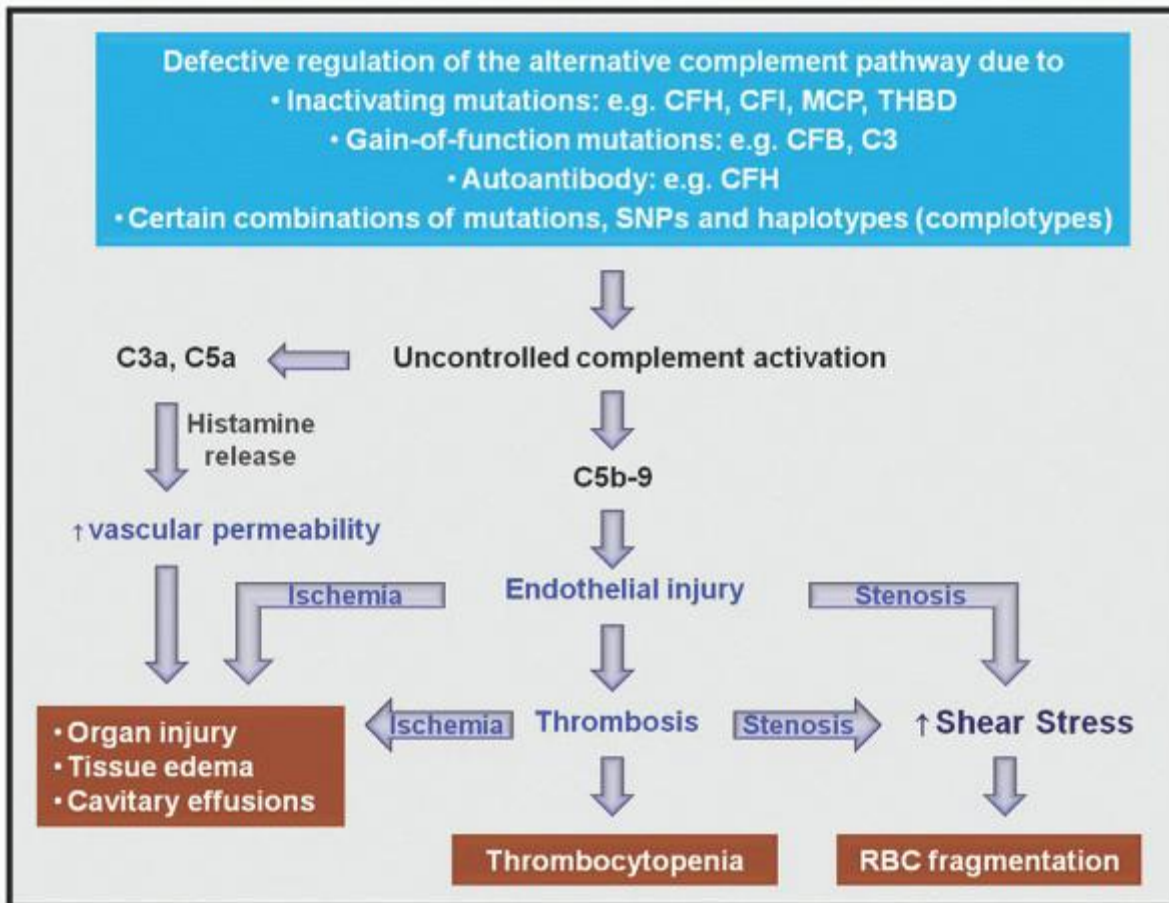

FIGURE 48.10. A scheme depicting how defective regulation of the alternative complement pathway may lead to atypical hemolytic-uremic syndrome (aHUS). Four types of molecular defects have been detected in patients with aHUS, in which organ dysfunction may result from ischemic injury or interstitial tissue edema. Consequently, it is not unusual that a patient with aHUS may continue to deteriorate neurologically due to brain edema while the platelet count is stable or increasing. CFB, complement factor B; CFH, complement factor H; CFI, complement factor I; MCP, membrane cofactor

protein; THBD, thrombomodulin.

Clinical Presentation

The prevalence of aHUS has been estimated at 3 per million children. Atypical HUS is likely to be as common as TTP in adults. Both males and females are equally affected.

The onset of an acute aHUS crisis may occur spontaneously or after trigger of stress conditions such as infection, surgery, trauma, inflammation, pancreatitis, intravenous contrast agents, or pregnancy. Although renal failure, microangiopathic hemolysis, and thrombocytopenia are its common features, aHUS is a systemic disease affecting multiple organs.

Gastrointestinal symptoms such as abdominal pain, bloody or nonbloody diarrhea, nausea, and vomiting are the most common acute presenting symptoms of aHUS. Some patients have recurrence of these symptoms for months to years before the diagnosis is recognized.

Laboratory tests may reveal elevated pancreatic enzymes such as amylase or lipase, diabetes mellitus, and/or abnormal liver function tests.

Imaging studies may reveal thickening, edema, and/or ischemic changes of the intestinal or bronchial wall, mesenteric edema, ascites and pancreatitis.

Headache and waxing and waning mental status changes are common. Impaired vision due to exudative or hemorrhagic retinopathy, seizures, and coma may ensue as the disease progresses. Focal neurologic deficits may occur although these are not as frequent as in patients with TTP.

The most common findings in brain imaging studies are cerebral edema or posterior reversible encephalopathy syndrome (PRES), a reflection of abnormal vascular permeability. Ischemic changes or overt infarction may be present, but are less common. Many of these changes may not be detectable with computerized tomography.

The severity of anemia and thrombocytopenia are quite variable in aHUS. Petechiae or other bleeding symptoms may occur but are uncommon. Rising platelet counts alone should not be taken as indication of disease improvement or remission.

Chest pain, dyspnea, respiratory failure, or congestive heart failure may result from pleurisy, pericarditis, airway edema, noncardiogenic pulmonary edema, or myocardial injury, which are detectable with chest radiograms, CT imaging, echocardiography, and EKG. Troponin and CPK levels may be elevated. Hypertension may be severe but often labile. Cardiac arrhythmias may lead to sudden death.

Proteinuria, hematuria, and renal function impairment are common. Hematuria is microscopic in most cases but may be gross occasionally. The severity of renal failure is variable. Some patients may present with very mild elevation of creatinine, and others present with anuric renal failure requiring dialysis support. Occasionally, a patient presents with aHUS only after receiving a renal graft for end-stage renal failure.

Diagnosis

No simple tests exist at this time for the diagnosis of defective alternative complement regulation. The C3 level is decreased in approximately 30%-50% of the patients. The C4 level is decreased in less than 10% of the cases. These changes are not specific for aHUS. In patients with mutations of CFH or CFI, the antigen levels of the affected proteins are decreased in approximately 30% of the cases.

Mutation analysis detects abnormalities in approximately 50% of the patients. Because compound mutations are common, all genes known to be involved in alternative complement regulation need to be analyzed. CFH antibodies are detected by ELISA in 5% to 10% of patients with aHUS. The genetics of aHUS also involve SNPs, haplotypes, and combinations of common or uncommon variants of complement activators or regulators. Due to its complexity and incomplete understanding of pathogenic mechanisms, genetic study is not required for the diagnosis of aHUS.

Presently the diagnosis of aHUS relies on a process of exclusion (Fig. 48.11). aHUS is suspected in patients presenting with the constellation of microangiopathic hemolysis, any degree of renal function impairment and thrombocytopenia, and the diagnosis is

P.1092

presumed after exclusion of TTP and groups III and IV disorders listed in Table 48.1.

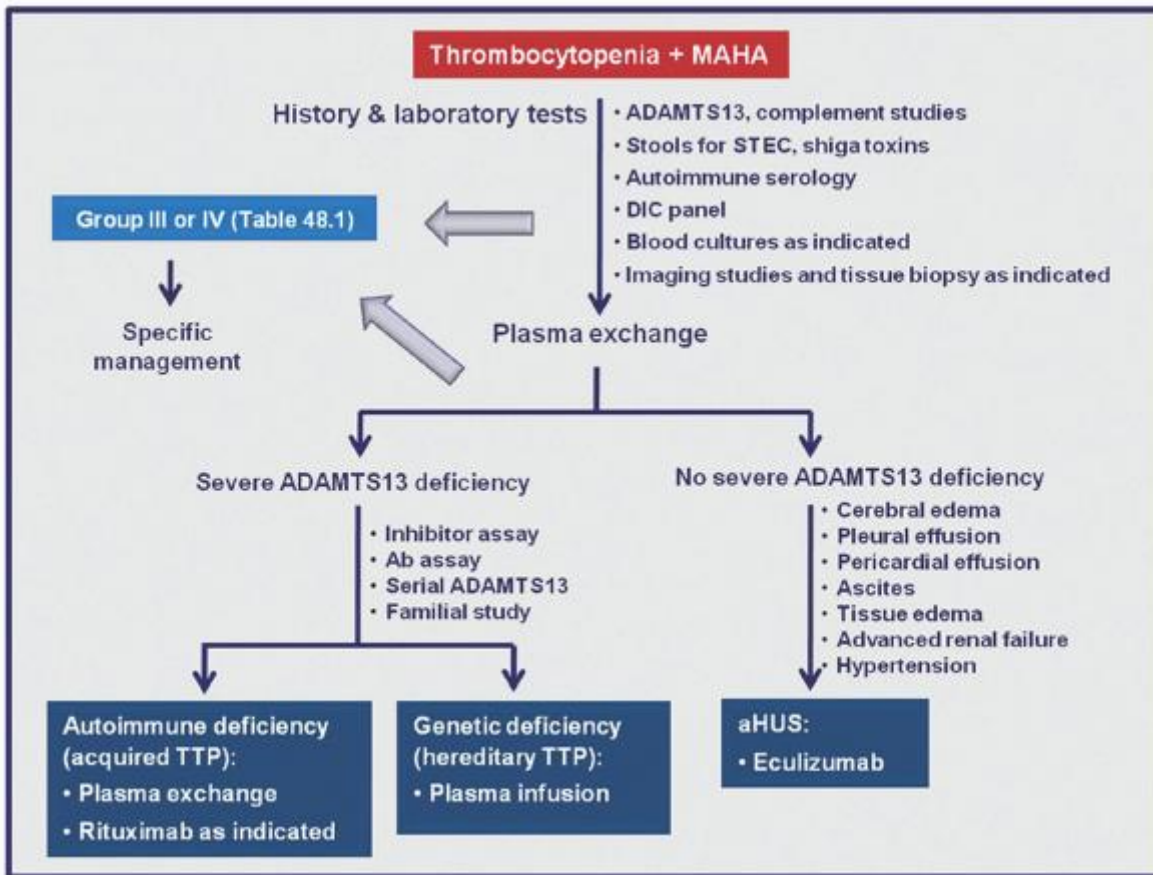

FIGURE 48.11. A scheme summarizing the current approach to patients presenting with thrombocytopenia and microangiopathic hemolytic anemia (MAHA). The patients should be empirically treated with plasma exchange unless history, physical examination, and laboratory tests strongly indicate otherwise. The indication of plasma exchange should be continually reassessed based on the evolution of clinical course and laboratory test results. Until ADAMTS13 assays are proven to be reliable, an ADAMTS13 level >10% should be correlated with clinical findings of advanced renal failure and/or abnormal vascular permeability for exclusion of thrombotic thrombocytopenic purpura (TTP). The role of eculizumab for treatment of shiga toxin-associated hemolytic-uremic syndrome (HUS) or other thrombotic microangiopathy of Group III disorders (Table 48.1) remains uncertain. DIC, disseminated intravascular coagulopathy.

aHUS needs to be distinguished from TMA via other mechanisms such as shiga toxins or microbial neuraminidases. Shiga toxin assays are indicated for patients presenting with diarrhea. Blood cultures or viral studies are indicated for patients with suspected systemic infections. There is insufficient knowledge to determine how frequent TMA occurs in patients with hematopoietic stem cell therapy, systemic autoimmune diseases, HIV infection, or various classes of drugs. Patients with autoimmune diseases may also develop MAHA due to vasculitis, which requires tissue biopsy for diagnosis. aHUS needs to be distinguished from hemolysis with elevated liver enzymes and low platelets (HELLP) syndrome and preeclampsia in women during pregnancy. Contrary to what is commonly believed, severe hypertension may be a consequence of aHUS rather than a cause of MAHA. The diagnosis of aHUS in patients without both MAHA and overt renal failure is more challenging and requires a high index of suspicion. The presence of hypertension, pleural or pericardial effusions, ascites, mesenteric or intestinal wall edema, anasarca, airway edema, acute respiratory distress syndrome, exudative retinopathy, brain edema, or posterior reversible encephalopathy syndrome (PRES) by CT or MRI strongly favors the diagnosis of aHUS over TTP.

Management

The principles of management for patients with aHUS are summarized in Table 48.4. Traditionally, aHUS patients were treated with plasma exchange. This practice was an extension of plasma exchange therapy for TTP, but its efficacy has never been rigorously investigated. It appears to be effective in a fraction of patients with aHUS.

Plasma Therapy

Many patients improve following the institution of plasma exchange therapy. Some patients deteriorate and even die after exhibiting an initial response. Others relapse after the therapy is discontinued, but do not respond to its reinstitution. Thus, the outcome with plasma therapy is uncertain for individual patients.

Knowledge of the molecular defects of aHUS may potentially predict which patients are likely to benefit from plasma exchange therapy. Plasma exchange or even plasma infusion is most likely

P.1093

to benefit patients with deficiency of plasma proteins such as CFH or CFI, but not patients with defective membrane-bound proteins such as MCP. Intensive plasma exchange may be effective for patients with gain-of-function C3 or CFH mutations, or CFH antibodies. For patients with multiple mutations or unknown mutations, it is impossible to predict whether they will respond to plasma therapy.

TABLE 48.4 PRINCIPLES OF MANAGEMENT OF ATYPICAL HEMOLYTIC-UREMIC SYNDROME (aHUS)

- Atypical HUS is a systemic disease
 - Gastrointestinal symptoms of nausea, vomiting, abdominal pain, diarrhea are common complaints.
 - Cardiopulmonary symptoms of chest pain and dyspnea may occur
 - Neurologic abnormalities such as headache, somnolence, confusion, seizures, or visual defects may occur.
 - Advanced renal failure, hypertension or complications of abnormal vascular permeability^a favors the diagnosis of aHUS over TTP.
 - Renal failure may be minimal or mild in some cases.
- Atypical HUS is a diagnosis of exclusion
 - TTP should be excluded with ADAMTS13 assays.
 - Stx-HUS should be excluded with stool shiga toxin assays for patients with diarrhea.
 - Other causes of MAHA should be excluded with history, coagulation tests, autoimmune serology, microbiology, and/or tissue biopsy as indicated.
 - Acute presentation of atypical HUS may be triggered by a co-morbidity (Table 48.1).
- Plasma exchange is the initial choice of therapy until TTP is excluded
- Eculizumab is the treatment of choice for aHUS
 - Improvement in thrombocytopenia and mental status change is evident after one or two doses of eculizumab.
 - Recovery of renal function may occur slowly over many months.
 - Vaccination is critical for prevention of meningococcal sepsis.
- Long-term therapy with eculizumab should be considered for patients who
 - have more than minimal renal dysfunction, or
 - are predisposed to relapse with serious complications.
- If eculizumab is discontinued, close monitoring is indicated for early detection of relapse or organ injury. Follow-up evaluation should include
 - Symptoms, physical findings, blood pressure.
 - CBC, renal function and hemolysis markers.

Stx-HUS, shiga toxin-associated hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic

purpura

^a As reflected by cerebral edema, posterior reversible encephalopathy syndrome, pleural or pericardial effusion, pulmonary edema, acute respiratory distress syndrome, ascites, or soft tissue swelling.

Some patients develop end-stage renal failure, months to years after plasma exchange is discontinued, without ever experiencing acute symptomatic relapses of aHUS. Thus, long-term maintenance plasma therapy is often needed for responsive patients to prevent relapses or progression of kidney injury. Long-term plasma therapy is technically demanding, poses a major stress on the patients, and its optimal regimen can only be determined empirically at best.

Eculizumab

A major advance in the treatment of aHUS is eculizumab, a humanized monoclonal antibody to C5 originally approved in 2007 for the treatment of paroxysmal nocturnal hemoglobinuria. Based on two prospective studies of 37 adult and adolescent patients, and a retrospective study of 19 pediatric patients,¹⁷⁰ the U.S. Food and Drug Administration and European Medicines Agency approved eculizumab in 2011 for the treatment of childhood and adult aHUS.

In the clinical trials, patients without identifiable mutations also responded to eculizumab, suggesting that defective regulation of the alternative complement pathway plays a pathogenetic role in most if not all patients of aHUS without identifiable molecular defects.

With eculizumab, clinical improvement in mental status, gastrointestinal symptoms, and increase in the platelet count are often apparent after one or two weekly administrations. Renal function improvement may be slow but continues for many months. Long-term eculizumab therapy may lead to gradual recovery of renal function, allowing some patients to come off dialysis therapy.

The aims of eculizumab therapy for aHUS include prevention of death, and avoidance of aHUS relapse. To achieve these aims, eculizumab should be instituted as soon as the diagnosis is reasonably established and TTP is excluded.

Atypical HUS is a chronic disease that often continues to cause subclinical injury of the kidney and other organs even in the absence of overt symptoms, thrombocytopenia, or microangiopathic hemolysis. Long-term eculizumab therapy should be considered for patients who are close to requiring renal replacement therapy and patients whose aHUS, if left untreated, may cause severe hypertension or other serious extra-renal complications. If eculizumab is discontinued, close monitoring of clinical status, blood pressure, blood counts, and renal function is indicated for early detection of aHUS relapse or progressive organ injury.

Eculizumab is well tolerated with minor adverse reactions. It is important to note that eculizumab therapy may predispose patients to fulminant *Neisseria meningitidis* infections. Patients should be given meningococcal vaccination and take prophylactic antibiotics until 2 weeks after the vaccination. Patients should also carry an identification card to facilitate emergency management of any infectious complications. Concern of serious infection has prompted some physicians to recommend long-term prophylactic antibiotic therapy.

The efficacy of eculizumab for patients with thrombotic microangiopathy in association with a co-morbidity such as those in Table 48.1 (group III), but no identifiable molecular defects in complement regulation has not been extensively investigated. Preliminary experience suggests that it is effective in some, if not all of such patients.

Eculizumab has been used in a small number of patients during pregnancy without causing adverse effects to the mother and fetus.^{171, 172}

Eculizumab versus Plasma Exchange Therapy

Compared to plasma exchange, eculizumab offers several advantages: the high efficacy of eculizumab is documented in clinical trials; it is expected to be effective for aHUS irrespective of the underlying molecular defects; and it is easier to administer, particularly for long-term maintenance therapy.

In contrast, the efficacy of plasma exchange has never been rigorously investigated in patients with aHUS; treatment failure is not uncommon; and plasma exchange requires a venous catheter that is inconvenient, uncomfortable, and carries the risk of infection or thrombosis.

Renal Transplantation

Due to high rates of disease recurrence, aHUS patients, except those with mutations of membrane proteins such as MCP, have a very high risk (>80% to 90%) of graft failure following kidney transplantation.

Previously, combined kidney and liver transplantation was performed based on the rationale that restoration of normal CFH in the circulation by the transplanted liver would prevent recurrence of aHUS and renal graft failure. However, because the complement system is triggered during major operations, the procedure was associated with a very high risk of morbidity and mortality. Pre-operative plasma exchange was advocated to prevent these complications.

Patients with mutations of membrane cofactor protein are expected to be cured, at least from the renal perspective, by a kidney allograft. Nevertheless, graft failure may occur if the donor is a family member who also carries the molecular trait, or if the patient carries other unidentified mutations. Due to the incomplete phenotypic expression of aHUS, family members of aHUS patients should not be organ donors. Extra-renal complications of aHUS may continue to occur after kidney transplantation. Maintenance eculizumab therapy is indicated for such patients.

If a patient with aHUS is to receive kidney transplantation, the patient should be treated with eculizumab prior to the operation.^{173, 174} Eculizumab should be continued post-operatively to prevent recurrence of the disease causing acute complications and graft failure. Because chronic eculizumab therapy is expected to be quite effective in preventing relapse of aHUS or organ injury, concurrent liver transplantation is no longer necessary.

Prognosis

Historically, approximately 10% to 30% of aHUS patients treated with plasma exchange died during their acute presentation. The overall risk of death or end-stage renal failure was ~60%. The risk was the highest (70% to 80%) for patients with CFH mutations, compound mutations, or CFI mutation with CFHR1 deletion, and the lowest mortality (10% to 20%) occurred in patients with MCP mutations.

Many of the patients never develop recurrence of overt thrombocytopenia or microangiopathic hemolysis while they progress to advanced renal failure. The absence of hematologic relapse leads to erroneous reports in the literature that "TTP" patients without severe ADAMTS13 are less likely to relapse and have a better long-term prognosis than those with severe ADAMTS13 deficiency. Eculizumab is expected to suppress systemic complications and prevent renal function, deterioration, and death.

PLATELET AND RED CELL DAMAGE BY ABNORMAL VASCULAR SURFACES

Platelets are subject to damage by interactions with "nonphysiologic" surfaces within the vascular system. Pathologic alterations of vessels that may produce such platelet damage include stenotic and roughened heart valves,¹⁷⁵ extensive atherosclerosis, metastatic cancer, and kidney disease associated with severe vascular changes in renal vessels.¹⁷⁶ An increasing number of surgical techniques involve the implantation of devices containing foreign material within the vascular system. Such circulatory prostheses include cardiac valves, vascular grafts of many types, indwelling catheters,¹⁷⁷ intra-aortic balloon pumps,¹⁷⁸ extracorporeal membrane oxygenators (ECMO),¹⁷⁹ and ventricular assist devices (VAD).¹⁸⁰ Extensive efforts have been made to render such materials nonthrombogenic, but most of these devices produce varying degrees of platelet destruction as well as hemolysis.¹⁸¹

Bleeding during cardiopulmonary bypass surgery appears to be multifactorial, including operative factors, dilution of clotting factors, inadequate neutralization of heparin, thrombocytopenia, platelet dysfunction,¹⁸⁰ and enhanced fibrinolysis. Hemodilution leads to a rapid reduction in platelet counts by as much as 50% shortly after cardiopulmonary bypass surgery begins. The platelet function defect is maximal during cardiopulmonary bypass surgery and usually disappears within 24 hours of surgery. The nature of the platelet defect is controversial. Investigators report partial platelet degranulation, circulating activated platelets by flow cytometry, and defects in platelet membrane glycoprotein Ib/IX and IIb/IIIa.^{182, 183} Efforts to minimize platelet and coagulation abnormalities in association with cardiac surgery include higher heparin doses to suppress thrombin generation,¹⁸⁴ heparin-coated circuit,¹⁸⁵ miniaturized closed circuit,¹⁸⁶ and offpump operations.¹⁸⁷ Avoidance of cardiotomy suction, perhaps in combination with a direct thrombin inhibitor such as bivalirudin as the anticoagulant, may substantially minimize activation of the coagulation system.¹⁸⁸ Bleeding is often reduced by infusion of normal platelets, 1-deamino-8-d-arginine vasopressin, epsilon aminocaproic acid, or aprotinin.^{189, 190, 191, 192} However, indiscriminate prophylactic platelet transfusion is ineffective and may increase the risk for adverse outcomes. A higher risk of end-organ damage has been observed with aprotinin, but not with tranexamic acid or aminocaproic acid.¹⁹³ Nitric oxide plus iloprost may reduce the deleterious effects of cardiopulmonary bypass on platelets and even reduce post-operative bleeding.¹⁹⁴

Red cell fragmentation and intravascular hemolysis are common in patients with left ventricular assist devices (LVAD), extracorporeal membrane oxygenator, or prosthetic heart valves. In such patients, monitoring of plasma hemoglobin

concentration is recommended, as an increase in plasma hemoglobin level may herald intradvice thrombosis or malfunction. Analysis of vWF may also demonstrate a decrease in the normal large multimers in patients with LVAD.^{195, 196, 197, 198, 199} Such vWF multimer changes, presumably due to excessive proteolysis induced by abnormal shear stress profiles, are more profound in patients with nonpulsatile than pulsatile devices. The vWF changes alone may not be sufficient to cause bleeding; yet they may contribute to the bleeding diathesis induced by anticoagulation or antiplatelet therapy, other hemostatic defects such as thrombocytopenia and platelet function defects, and acquired angiodysplasia of the gastrointestinal tract.²⁰⁰

MISCELLANEOUS FORMS OF NONIMMUNOLOGIC PLATELET DESTRUCTION

Extensive burns are associated with mild to moderate thrombocytopenia that results from nonimmunologic platelet destruction.²⁰¹ Thrombocytopenia may become severe and bleeding may develop when complications of sepsis or disseminated intravascular coagulation develop. Thrombocytopenia has been well described after hepatic cryotherapy²⁰² and in moderate hypothermia treatment.^{203, 204}

Certain drugs may produce thrombocytopenia by nonimmunologic phenomena. Ristocetin, an antituberculous agent no longer used clinically, promotes the attachment of vWF to its platelet receptor and initiates direct platelet-to-platelet interaction by means of an agglutination phenomenon. Studies of ristocetin-induced platelet aggregation have provided much information concerning von Willebrand disease.

Oxaliplatin may cause thrombocytopenia by causing liver injury and portal hypertension, leading to splenomegaly and hypersplenism.²⁰⁵ Protamine may produce reversible sequestration of platelets in the liver,²⁰⁶ but seldom is the cause of significant thrombocytopenia. Aggregation of platelets independent of immune mechanisms plays a role in type 1 heparin-induced thrombocytopenia. Thrombocytopenia is a common feature of post-decompression sickness in divers and has been attributed to intravascular platelet aggregation.²⁰⁷

Chapter 49

Miscellaneous Causes of Thrombocytopenia

Archana M. Agarwal

George M. Rodgers

This chapter summarizes miscellaneous forms of congenital and acquired thrombocytopenia (Table 49.1), including thrombocytopenia attributable to deficient platelet production, associated with abnormal platelet pooling in the spleen, and resulting from dilution with massive transfusions.

CONGENITAL THROMBOCYTOPENIA

Hereditary thrombocytopenias have been well documented and may be inherited as an autosomal dominant trait, an autosomal recessive trait, or an X-linked recessive trait. Bleeding can be mild, and in some instances the affected family members are virtually asymptomatic, being identified only through incidental platelet counts or family studies after the identification of the proband. It is important to recognize these mild forms of familial thrombocytopenia because, although they may resemble autoimmune thrombocytopenic purpura, patients do not respond to steroid treatment or intravenous immunoglobulin, and this therapy may be harmful. These disorders can be classified according to platelet size (Table 49.2).

Autosomal Recessive Thrombocytopenias

Congenital Amegakaryocytic Thrombocytopenia

The presence of severe thrombocytopenia, absence of megakaryocytes in the bone marrow, and absence of any physical anomaly in an infant characterize congenital amegakaryocytic thrombocytopenia (CAMT).¹ Because of the recessive nature of the disease, family history is usually negative, with both parents having normal platelet counts and function. Patients with CAMT have markedly elevated serum levels of thrombopoietin (TPO)² and mutations in the *c-mpl* gene. Multiple mutations in the *c-mpl* gene have been reported, including deletions, nonsense mutations, and missense mutations. Many of the patients studied are compound heterozygotes with one mutation inherited from each parent.^{3, 4, 5} Because patients with CAMT develop progressive bone marrow aplasia during the course of the disease, it is likely that Mpl signaling is essential for the production of mature megakaryocytes as well as maintenance of the hematopoietic stem cell population.⁶

Further subgrouping of CAMT patients into two groups has been proposed based on their clinical course: Group CAMT I, with a more severe type of thrombocytopenia with constantly low platelet counts and an early onset of pancytopenia; and group CAMT II, which is characterized by a transient increase in platelet counts during the first year of life and a later or no development of pancytopenia.⁴ The type of *mpl* mutation determines the clinical course of CAMT; a total loss of the TPO receptor due to homozygous nonsense mutations, deletions, and frameshift mutations causes the more severe form of disease found in CAMT I patients. In contrast, the transient increase in platelet counts and the later development of pancytopenia in patients with homozygous or compound heterozygous missense mutations are the result of a residual function of the TPO receptor.⁷ Hematopoietic stem cell transplant is the only curative treatment for these patients, and matched sibling transplants have been successful.

Thrombocytopenia with Absent Radius Syndrome

The thrombocytopenia with absent radius (TAR) syndrome is a congenital malformation syndrome characterized by bilateral absence of the radii but with thumbs present, hypomegakaryocytic thrombocytopenia, and a number of additional features including skeletal and cardiac anomalies.^{8, 9} Among the skeletal anomalies, bilateral absence of the radii may be accompanied by ulnar or humeral anomalies, and the most severe cases exhibit phocomelia. Lower limb involvement is variable and includes dislocation of the patella and/or of the hips, absent tibiofibular joint, and lower limb phocomelia. Among the cardiac anomalies, tetralogy of Fallot and atrial septal defects are common.^{10, 11} Studies have noted a high incidence (62%) of cow's milk intolerance, which presents as persistent diarrhea and failure to thrive.

P.1098

An episode of thrombocytopenia may be precipitated by introduction of cow's milk and relieved by its exclusion from the diet.¹²

TABLE 49.1 MISCELLANEOUS CAUSES OF THROMBOCYTOPENIA

Congenital Thrombocytopenia

- Autosomal recessive thrombocytopenias
- Congenital amegakaryocytic thrombocytopenia
- Thrombocytopenia with absent radius (TAR) syndrome
- Bernard-Soulier syndrome
- Autosomal dominant thrombocytopenias
- MYH9-related disorder
- May-Hegglin anomaly
- Sebastian anomaly
- Fechtner anomaly
- Epstein anomaly
- Familial platelet disorder with predisposition to acute myelogenous leukemia
- Mediterranean macrothrombocytopenia
- Paris-Trousseau syndrome (in association with deletion of *FLII* gene)
- Autosomal dominant thrombocytopenia with linkage to human chromosome 10 (THC2)
- Gray platelet syndrome
- Amegakaryocytic thrombocytopenia with radial-ulnar synostosis (ATRUS) syndrome
- Variant von Willebrand disease (type 2b and platelet-type) (see Chapter 53)
- X-linked thrombocytopenia
- X-linked microthrombocytopenia (*WAS* gene mutation)
- X-linked macrothrombocytopenia with dyserythropoiesis (*GATA-1* mutation)
- Others
- 22q11 deletion syndrome (DiGeorge Syndrome)

Acquired Thrombocytopenia

- Thrombocytopenia caused by deficient platelet production
- Acquired pure amegakaryocytic thrombocytopenic purpura
- Chemical and physical agents that produce generalized bone marrow suppression
- Drugs that selectively suppress the megakaryocyte
- Drugs that cause ineffective thrombopoiesis
- Thrombocytopenia caused by abnormal platelet pooling
- Thrombocytopenia caused by hypothermia
- Thrombocytopenia associated with infections
- Thrombocytopenia associated with viral infections
- Thrombocytopenia associated with bacterial and protozoal infections
- Thrombocytopenia after massive blood transfusions

TABLE 49.2 CLASSIFICATION OF INHERITED THROMBOCYTOPENIA BY PLATELET SIZE (MPV)

Low MPV	Normal MPV	Increased MPV
---------	------------	---------------

Wiskott-Aldrich syndrome	ATRUS syndrome	MYH9-related disorders
	Thrombocytopenia with absent radius syndrome	Mediterranean macrothrombocytopenia
	Congenital amegakaryocytic thrombocytopenia	Bernard-Soulier syndrome
	Familial platelet disorder with predisposition to AML	GATA-1 mutation
	THC2	Gray platelet syndrome
	X-linked thrombocytopenia with GATA-1 mutation	Paris-Trousseau syndrome
		vWD type 2B Platelet type vWD 22q11 deletion syndrome

GATA-1 mutation platelets may have normal or increased MPV.

AML, acute myelocytic leukemia; ATRUS, amegakaryocytic thrombocytopenia with radial-ulnar synostosis; MPV, mean platelet volume; THC2, autosomal dominant thrombocytopenia with incomplete megakaryocyte differentiation and linkage to chromosome 10; vWD, von Willebrand disorder.

Adapted from Drachman JG, Inherited thrombocytopenia: when a low platelet count does not mean ITP. *Blood* 2004;103:390-398; Lambert MP. What to do when you suspect an inherited platelet disorder. *Hematology Am Soc Hematol Educ Program* 2011; 2011: 377-383.

These patients have elevated serum TPO levels and normal c-mpl and HOX genes. However, they have a profound defect in megakaryocyte differentiation and platelet production and no response of megakaryocytes to TPO.^{13, 14, 15} There may be a slight increase in platelet count in response to recombinant human erythropoietin.¹⁶ Although specific microdeletion of chromosome 1q21.1 has been reported in the majority of individuals with TAR syndrome, it is not the disease-causing mutation.¹⁷ Compound inheritance of a rare null mutation in exon-junction complex subunit RBM8A has been found to be the cause of TAR syndrome. RBM8A controls the production of the protein Y14, and its low level is responsible for the cause of low platelets.¹⁸

Diagnosis is rarely difficult because of obvious morphologic abnormalities in association with thrombocytopenia. Prenatal diagnosis has been described by ultrasonographic detection of morphologic abnormalities and detection of low fetal platelet counts.^{19, 20, 21} Congenital rubella and some variants of Fanconi syndrome should be excluded. Platelet counts gradually increase during the first 2 years of life. The degree of thrombocytopenia is usually greatest at the time of birth; platelet transfusions are frequently required and are effective. Thrombocytopenia becomes less severe during the first year of life, and most affected individuals with TAR do not require platelet transfusions after infancy.^{10, 22}

Bernard-Soulier Syndrome

Bernard-Soulier syndrome is an autosomal recessive bleeding disorder associated with deficiency of platelet membrane proteins GPIb, GPIX, and GPV. This results in abnormal platelet interaction with ligands of these receptor proteins, which include thrombin, von Willebrand factor (vWF), P-selectin, and leukocyte integrin $\alpha_M\beta_2$, in addition to causing thrombocytopenia. This topic is described in more detail in Chapter 52.

Autosomal Dominant Thrombocytopenia

A number of families have been described who have autosomal dominant inheritance of isolated mild thrombocytopenia characterized by normal platelet survival and a normal number of bone marrow megakaryocytes, a constellation of findings that suggests ineffective thrombopoiesis.^{23, 24, 25} Thrombocytopenia (platelet counts between 20,000 and 100,000/ μ l) or a history of increased bruisability is apparent early in life, and examination of the peripheral blood smear

demonstrates platelet macrocytosis (mean platelet volume >10 μm^3). Splenic size is always normal. Platelet aggregation abnormalities have been described in some families, but platelet membrane glycoproteins (GPs) have been normal when studied.²⁴

MYH9-related Disorders

A group of autosomal dominant macrothrombocytopenias caused by mutations in the MYH9 gene with variable penetrance and expression has been defined.^{26, 27, 28, 29} These include May-Hegglin anomaly, Sebastian syndrome, Epstein syndrome, and Fechtner syndrome. These disorders are defined by the presence of mutations involving the MYH9 gene located at chromosome 22q12.3-13.1 and include single nucleotide changes, in-frame deletions or duplications, and frameshift and nonsense mutations.³⁰ The MYH9 gene encodes nonmuscle myosin heavy chain IIA (NMMHC-IIA).³¹ NMMHC-IIA is part of the nonmuscle myosin IIA hexamer that is a component of the contractile cytoskeleton in megakaryocytes, platelets, and other tissues. Thrombocytopenia is usually mild and derives from complex defects of megakaryocyte maturation and platelet formation. More specifically, these mutations likely affect the platelet release from the mature megakaryocytes.³⁰ All of these MYH9 gene mutation-related disorders have macrothrombocytopenia, leukocyte inclusion bodies (Döhle body-like inclusions) and can have various combinations of hereditary nephritis, deafness, and cataracts (Table 49.3). Sometimes, the inclusions are rarely appreciated on conventional May-Grunwald-Giemsa staining, especially in patients with mutations at codon 702 because of their low RNA content. These cases can be diagnosed by the use of immunofluorescence assays.³² Thrombocytopenia is generally mild to moderate. Peripheral blood smears reveal enlarged platelets with frequent giant platelets.

Clinically, patients have a mild platelet-type bleeding disorder. May-Hegglin anomaly and Sebastian syndrome both have macrothrombocytopenia and granulocyte inclusions, but ultrastructural analysis of the Döhle-like inclusions demonstrates diagnostic differences between these two syndromes, and both types of inclusions can also be distinguished from Döhle bodies seen in acute infection. Patients with Fechtner syndrome and Epstein syndrome have hearing disability and nephritis. In Fechtner syndrome, cataracts are also present.³³ These two disorders result from allelic mutations at amino acid 702, which cause conformational changes to the myosin head.^{31, 34, 35, 36} Diagnosis is suggested by detection of macrothrombocytopenia and the presence of one or more of the above-mentioned clinical features. Döhle-like inclusion bodies within neutrophils on May-Grünwald-Giemsa-stained peripheral blood are highly suggestive of an MYH9-related disorder. Abnormal staining of neutrophil inclusions with anti-NMMHC-IIA may offer greater sensitivity. Definitive diagnosis requires the demonstration of a causative mutation within the MYH9 gene.³¹ Treatment options for bleeding include platelet transfusion, allogeneic stem cell transplantation, or use of a thrombopoietic drug (eltrombopag).³⁷

Platelet-type von Willebrand disease is another autosomal dominant disorder associated with hereditary thrombocytopenia, characterized by abnormal binding of large vWF multimers to platelets. This intrinsic platelet defect results in mild thrombocytopenia, increased ristocetin-induced platelet aggregation, and a selective

P.1099

loss of high-molecular-weight vWF multimers from the plasma. This disorder resembles type 2b von Willebrand disease (see Chapter 53).

TABLE 49.3 SYNDROMES CAUSED BY MYH9 GENE DEFECTS

Syndrome	Macrothrombocytopenia	Döhle-like Bodies	Nephritis	Deafness	Cataracts
May-Hegglin	Yes	Yes	No	No	No
Sebastian	Yes	Yes	No	No	No
Fechtner	Yes	Yes	Yes	Yes	Yes
Epstein	Yes	Yes	Yes	Yes	No

Familial Platelet Disorder with Predisposition to Acute Myelogenous Leukemia

Familial platelet disorder with predisposition to acute myelogenous leukemia (FPD/AML) is an autosomal dominant disorder characterized by moderate thrombocytopenia, a defect in platelet function, and predisposition to develop myeloid malignancy.³⁸ The defect in platelet function is manifested by prolonged bleeding times and abnormal platelet aggregation. Expansion of megakaryocyte progenitors in the bone marrow or peripheral blood cells reveals diminished megakaryocyte colony formation. Bone marrow from affected patients shows decreased megakaryopoiesis. Linkage analysis of several pedigrees affected by FPD/AML has led to identification of germline heterozygous mutations in the

hematopoietic transcription factor AML1, also known as RUNX1 and CBFA2. These mutations include missense, frameshift, and nonsense mutations and a large intragenic deletion.^{39, 40} CBFA2 is a transcription factor that trans-activates the expression of a spectrum of genes required for normal development of hematopoietic cells. Mutation of CBFA2 has been implicated in the pathogenesis of human leukemias resulting from somatically acquired chromosomal translocations.⁴¹ Normal megakaryopoiesis requires TPO binding to the Mpl receptor. In FPD/AML, CBFA2 mutation leads to diminished Mpl receptor expression, resulting in impaired TPO signaling leading to thrombocytopenia. Consequently, serum TPO levels are usually elevated in these patients.⁴²

Mediterranean Macrothrombocytopenia

A relatively common and mild form of macrothrombocytopenia has been described in a group of 145 apparently healthy subjects from Italy and the Balkan peninsula. Because this abnormality was not detected in control subjects from northern Europe, the condition was named Mediterranean macrothrombocytopenia.⁴³ Linkage analysis localized the gene mutation to the short arm of chromosome 17, in an interval containing the GPIIb gene. GPIIb, together with other proteins, constitutes the plasma vWF receptor, which is altered in Bernard-Soulier syndrome. Sequencing of the gene identified a mutation of GPIIb (Ala156Val) shared by 10 of 12 pedigrees studied.⁴⁴ These data demonstrate that for most families with Mediterranean thrombocytopenia, the genotype and phenotype are equivalent to that of a carrier of Bernard-Soulier syndrome. Clinically, patients have a mild bleeding diathesis, usually diagnosed after incidental discovery of thrombocytopenia. Peripheral blood shows platelets that are larger than normal.

Paris-Trousseau Syndrome (in Association with Deletion of the FLI1 Gene)

Paris-Trousseau syndrome (PTS) is an inherited disorder characterized by several congenital anomalies including dysmegakaryopoiesis with two morphologically distinct populations of megakaryocytes and giant α -granules in a low percentage of platelets. These features occur in association with deletion of the long arm of chromosome 11 at 11q23.3 (which includes the FLI1 gene), a region that is also deleted in Jacobsen syndrome (a variant form of PTS). Clinical features include a combination of mild to moderate psychomotor retardation, trigonocephaly, facial dysmorphism, cardiac defects, and thrombocytopenia.^{45, 46} Hematologic history, biologic data, ultrastructural, and molecular investigations were reported from a case series of 10 patients.⁴⁷ Thrombocytopenia is chronic, with mild clinical bleeding. Peripheral blood smears and electron microscopy show abnormal platelets with giant granules. Bone marrow findings consist of dysmegakaryopoiesis with many micromegakaryocytes. Abnormal α -granules are not seen in the bone marrow and cultured megakaryocytes. Platelets have a normal lifespan in the circulation. The number of megakaryocytes in the bone marrow is increased, accompanied by impaired maturation. Together these findings suggest that platelet release is substantially impaired. PTS occurs as a result of hemizygous loss of the FLI1 transcription factor gene, which has been shown to be critical for megakaryocyte differentiation and release of platelets. FLI1 shows monoallelic expression during a brief window in megakaryocyte differentiation. This monoallelic expression explains the dominant inheritance pattern of PTS despite the presence of one normal FLI1 allele.^{48, 49}

Autosomal Dominant Thrombocytopenia with Incomplete Megakaryocyte Differentiation and Linkage to Chromosome 10

The genetic defect for this autosomal dominant thrombocytopenia has been mapped to a region on the short arm of chromosome 10 (10p11-12).⁵⁰ This disorder is characterized by moderate thrombocytopenia, abnormal platelet size, and incomplete differentiation of megakaryocytes. Clinical features consist of mild to moderate bruising but absence of major bleeding even with minor surgery and childbirth, suggesting that the residual platelets have normal hemostatic function. However, platelets are deficient in GPIa and α -granule content. Morphologically, the platelets appear normal. Bone marrow examination reveals impaired megakaryocyte maturation and small megakaryocytes. Colony assay on bone marrow and peripheral blood cells reveal expanded progenitors across all hematopoietic lineages, and tremendously increased expansion of immature megakaryocytes (CFU-Mk). Serum TPO level is only moderately elevated and is usually lower than expected for the degree of thrombocytopenia.⁵¹

Recently, mutations in ANKRD26 were identified in the original patients and in several additional families around the world; these mutations accounted for 10% of patients in an inherited thrombocytopenia database.⁵² The term "thrombocytopenia 2" (THC2) has been applied to this disorder.

P.1100

Gray Platelet Syndrome

The gray platelet syndrome for which both autosomal recessive and autosomal dominant inheritance have been described is characterized by macrothrombocytopenia with bleeding tendency, myelofibrosis, and classical abnormal platelet morphology.⁵³ The α -granules are absent or greatly reduced, giving the platelets a gray color on Wright-Giemsa stain. The α -granules are the principal storage site for hemostatic proteins such as fibrinogen, vWF, thrombospondin, and factor V and for growth factors such as platelet-derived growth factor and transforming growth factor- β .⁵⁴ One result of absence of α -granules is a continued leakage of growth factors and cytokines into the marrow, causing myelofibrosis.

Amegakaryocytic Thrombocytopenia with Radial-Ulnar Synostosis Syndrome in Association with HOXA11 Mutation

Homeobox genes encode regulatory proteins that are critical to bone morphogenesis as well as hematopoietic differentiation and proliferation.⁵⁵ This defect is the first reported germline HOX gene mutation associated with a human nonneoplastic hematologic disorder, and only the third HOX gene implicated in a human disorder.⁵⁶ HOXA11 is suggested to be endogenously expressed in very early hematopoietic precursor cells and involved in regulation of megakaryocytic differentiation.⁵⁷ Clinical features consist of CAMT, aplastic anemia, proximal radial-ulnar synostosis, clinodactyly, syndactyly, hip dysplasia, and sensorineural hearing loss.⁵⁸ Platelet transfusions are effective as initial symptomatic management. The only definitive treatment is hematopoietic stem cell transplantation.⁵⁹

X-linked Thrombocytopenia

X-linked Microthrombocytopenia (WAS Gene Mutation)

Wiskott-Aldrich syndrome (WAS), originally described in 1937, is now known as an X-linked hereditary disorder associated with combined immunodeficiency, thrombocytopenia, small platelets, eczema, and an increased risk of autoimmune disorders and cancers. It has a broad range of phenotypes.⁶⁰ At one end of the clinical spectrum, patients exhibit platelet abnormalities only, and at the other end, patients manifest thrombocytopenia, eczema, and immune abnormalities with progressive T-cell lymphopenia, and increased susceptibility to infection. The severe form of WAS and its milder manifestations—X-linked thrombocytopenia and X-linked neutropenia—are caused by mutations in the gene for the WAS, located at Xp11.22-p11.23 and cloned in 1994.^{61, 62, 63, 64} The WAS gene is composed of 12 exons and encodes a polypeptide of 502 amino acids. Most mutations consist of single-nucleotide substitutions, small insertions and deletions, and splice-site mutations, and these are distributed throughout the coding region and the intron-exon junctions.⁶⁵ Even within families, the same genotype can be associated with varying phenotypes. Measurement of the WAS protein (WASP) is now possible, making diagnosis less difficult.⁶⁶ The mature WASP contains numerous protein-interacting domains and appears to provide a critical link between the cellular cytoskeleton and signal transduction pathways. WASP is a key regulator of actin polymerization in hematopoietic cells. It has five well-defined domains that are involved in signaling, cell locomotion, and immune synapse formation. WASP facilitates the nuclear translocation of nuclear factor κ B and has been shown to play an important role in lymphoid development and in the maturation and function of myeloid monocytic cells.⁶⁷

Megakaryocyte mass is normal or increased in WAS. Platelet differentiation and production are normal, and platelets produced *in vitro* are normal in size. These observations suggest that increased destruction in the spleen is responsible for both the thrombocytopenia and decreased platelet size. Management of patients with WAS is challenging; however, early diagnosis is very important for prophylaxis and treatment.⁶⁸ Splenectomy definitely improves platelet counts in these patients, which frequently return to normal, suggesting a role of the reticuloendothelial system in platelet removal. Notably, antiplatelet antibodies are not present.⁶⁹ The only curative therapy remains hematopoietic stem cell transplantation, which corrects both thrombocytopenia and immunodeficiency. The administration of WAS gene corrected autologous hematopoietic stem cells may represent an alternative treatment option.⁶⁰

X-linked Macrothrombocytopenia with Dyserythropoiesis (GATA-1 Mutation)

The X-linked gene GATA-1 regulates the expression of a large number of genes in multiple cell types.^{70, 71} GATA-1 transcription factor contains both DNA binding and transactivation activity within three functional domains: Two zinc fingers (known as the N finger and the C-finger) and an N-terminal activation domain. The C-finger is responsible for binding of GATA-1 to typical GATA-binding sites (WGATAR consensus). The N terminus of GATA-1 constitutes an activation domain, as defined by the ability of this region to confer transcriptional activation in reporter assays in fibroblasts.⁷² Taken together, these domains act in a manner similar to a multitude of transcription factors that bind DNA and activate transcription of target genes. In addition to binding DNA, the N finger has a second essential function, recruitment of the co-factor Friend of GATA-1 (FOG-1).⁷³ FOG-1, as is GATA-1, is primarily expressed in hematopoietic cells, and is absolutely essential for the development of red blood cells and megakaryocytes. Five germline mutations of GATA-1 that cause X-linked disorders have been described, and all cluster in the N-terminal zinc finger.

GATA-1 mutation-associated thrombocytopenia is clinically distinguished from WAS by the presence of large or normal-sized platelets and the absence of immunodeficiency, eczema, and lymphomas.⁷⁴ Thrombocytopenia is more severe (10,000 to 40,000/ μ l). Clinically, bleeding and bruising in affected individuals are severe, and platelet aggregation studies have shown that platelet function is also diminished.⁷⁵ The bone marrow is hypercellular, with dysplastic features in the erythroid and megakaryocytic lineages.⁷⁶

Others

22q11.2 Deletion Syndrome (DiGeorge Syndrome)

This relatively common genetic disorder occurs in 1:4,000 live births, and in addition to thrombocytopenia, is associated with cardiac abnormalities, velofacial anomalies, hypocalcemia, immune defects, and a variety of other features.⁷⁷ One particular gene in the region of 22q11-TBX1 is likely responsible for cardiac defects.⁷⁷ The macrothrombocytopenia seen in this disorder is mild.⁷⁴

ACQUIRED THROMBOCYTOPENIA

Deficient Platelet Production

Deficient platelet production may result from three mechanisms: Hypoplasia or suppression of the precursor megakaryocytes; ineffective thrombopoiesis despite a normal precursor mass; or, rarely, deficiency or aberration of thrombopoietic control mechanisms.

P.1101

Acquired Amegakaryocytic Thrombocytopenic Purpura

Acquired amegakaryocytic thrombocytopenic purpura (AATP) is a rare cause of thrombocytopenia associated with decreased or absent megakaryocytes in otherwise normal bone marrow. The prevalence is possibly higher than reported, as many cases are underdiagnosed or misdiagnosed as immune thrombocytopenia.

The differential diagnosis of patients with severe thrombocytopenia and isolated amegakaryocytosis includes a misdiagnosis of immune thrombocytopenic purpura, as mentioned above; ethanol use or drug ingestion; immune suppression associated with diseases such as systemic lupus erythematosus; and prodromal manifestations of acquired aplastic anemia, myelodysplastic disorders, or acute leukemia.^{78, 79} Thrombocytopenia and amegakaryocytosis caused by chemotherapy or postradiation therapy should be apparent.

The pathogenesis of AATP is uncertain. AATP can occur individually or as a component of aplastic anemia secondary to exposure to environmental agents such as viruses (cytomegalovirus [CMV], parvovirus B19), and certain toxins such as benzene.^{78, 80} Both cell-mediated suppression of megakaryopoiesis and the role of humoral immunity in AATP have been proposed, but the exact role of either remains unclear. A marked increase of T-activated suppressor cells ($CD8^+/DR^+$) in association with AATP has been reported.⁸¹ AATP has also been associated with high levels of anti-TPO IgG antibodies.⁸² No cytogenetic abnormality has been shown to be consistently associated with AATP.⁸³ A defect in cytokine-mediated regulation of megakaryopoiesis is another proposed mechanism leading to AATP, but conclusive data are lacking.

Patients with AATP do not have a palpable spleen. The platelets are usually small or normal in size. An increased mean red cell volume is a common finding. In most patients, an etiology cannot be determined, and empirical therapy is necessary. Platelet transfusions should be used to treat bleeding and may be required prophylactically in some patients. Although there are occasional spontaneous remissions, most sustained remissions have occurred in patients receiving immunosuppressive therapy. Treatment with intravenous immunoglobulin, prednisone, cyclophosphamide, and vincristine has not been efficacious in AATP. Myeloablative chemotherapy (busulfan and cyclophosphamide) followed by allogeneic bone marrow transplant from a fully HLA-matched sibling is effective.⁸⁴ Danazol has been reported to be effective in two cases of AATP.⁸⁵ Antithymocyte globulin (ATG) alone,⁸⁶ rituximab,⁸⁷ azathioprine,⁸⁸ and cyclosporine alone or in combination with ATG, have been shown to be very effective in treatment of AATP.^{83, 89, 90} The role of recombinant interleukin-11 (IL-11, a thrombopoietic growth factor) in AATP is uncertain. The availability of thrombopoietic drugs,⁹¹ may offer another treatment option for AATP patients.

Chemical and Physical Agents That Produce Generalized Bone Marrow Suppression

Ionizing radiation, alkylating agents, antimetabolites, and cytotoxic drugs may produce thrombocytopenia as the result of predictable suppression of the marrow. The mechanisms by which these agents act are well defined, and

thrombocytopenia is a common complication when they are used in immunosuppression and cancer chemotherapy. In addition, many drugs, such as chloramphenicol, produce marrow hypoplasia as a result of idiosyncratic reactions. The pathophysiology in these cases is poorly understood.

Agents that produce thrombocytopenia may damage other bone marrow precursors as well as megakaryocytes, and the usual picture is one of diffuse bone marrow hypoplasia and pancytopenia. Rarely, only thrombocytopenia may be present. Platelets often are the last cell type to return to normal after recovery from bone marrow hypoplasia; in some patients, thrombocytopenia may persist indefinitely.

Drugs That Selectively Suppress the Megakaryocyte

Chlorothiazides. Chlorothiazides and various congeners may produce thrombocytopenia by one of at least two mechanisms: by the formation of platelet antibodies or by a poorly understood suppression of thrombopoiesis.⁹² The latter action is by far the most common. Evidence of marrow suppression is largely indirect.⁷⁹ Serologic tests for platelet antibodies usually yield negative results. Diminution in the number of megakaryocytes has been observed in infants born of mothers who were taking these drugs, but few instances of megakaryocytic hypoplasia have been documented in adults. Mild asymptomatic thrombocytopenia may occur in as many as 25% of patients taking these agents, an observation that implies that thrombocytopenia may be a pharmacologic rather than an idiosyncratic effect. Recovery from thrombocytopenia associated with the use of thiazide drugs is slow, and thrombocytopenia usually can be reproduced only by readministration of the drug for a protracted period.

Estrogens. Estrogenic hormones appear to affect platelet kinetics in animals both by facilitating reticuloendothelial phagocytosis and by impairing thrombopoiesis. Neither effect has been convincingly demonstrated in humans, but several instances of "amegakaryocytic" thrombocytopenia have been reported after the administration of diethylstilbestrol. In one patient, thrombocytopenia recurred when the hormone was readministered.⁹³

Ethanol. Ethanol can suppress platelet production, a phenomenon that may be a common cause of mild thrombocytopenia in the alcoholic patient. In most reported cases, nutritional factors, folate deficiency, and splenomegaly were excluded, but patients did have evidence of impaired hepatic function. Platelet counts $<100,000/\mu\text{l}$ occur in as many as 26% of acutely ill alcoholics.^{94, 95} The experimental administration of ethanol produces thrombocytopenia with decreased platelet survival and platelet turnover.⁹⁶ Bleeding is rare, and when ethanol is withdrawn, the platelet count begins to increase in 2 to 3 days and returns to normal or supranormal levels in 2 to 3 weeks.⁹⁵ Several patients developed venous thromboembolic disease when platelet counts reached values $>500,000/\mu\text{l}$.⁹⁷

Pathophysiologic studies in alcohol-induced thrombocytopenia reveal accelerated platelet destruction and a subnormal compensatory increase in thrombopoiesis. Platelet function abnormalities have also been described. The bone marrow usually reveals normal numbers of megakaryocytes. Studies using mice and guinea pig megakaryocytes demonstrate that the effect of ethanol is primarily on the maturing megakaryocytes, a finding consistent with ineffective thrombopoiesis.⁹⁸ Several cases of bone marrow hypoplasia secondary to consumption of excessive alcohol have also been described. Colony-forming unit (CFU) granulocytemacrophage-derived colony formation in one of these patients was inhibited by much lower concentrations of ethanol than that of normal volunteers.⁹⁹

Drugs That Cause Ineffective Thrombopoiesis

Ineffective thrombopoiesis may play a role in several different types of thrombocytopenia. Thrombocytopenia is a consistent feature of megaloblastic hematopoiesis that results from deficiency of vitamin B₁₂ or folic acid. Although seldom severe and rarely of clinical significance, this form of thrombocytopenia results from a distinctive abnormality of platelet production called ineffective thrombopoiesis. This abnormality was first demonstrated in thrombokinetic studies and is characterized by diminished platelet production despite the presence of an increased megakaryocyte mass. Thus, it is analogous to ineffective erythropoiesis,

P.1102

which is also characteristic of the megaloblastic anemias. Platelet production, whether calculated per megakaryocyte or per nuclear unit, is diminished. Although the number of megakaryocytes increases in response to thrombopoietic stimuli, the normal concomitant increase in their volume does not occur. This phenomenon presumably results from impaired DNA synthesis and the consequent limitation in nuclear endoreduplication. In stained smears, the megakaryocytes often appear hyperlobulated, and circulating platelets are abnormally large.¹⁰⁰ Moderate shortening of platelet survival and, rarely, hypoplasia of the megakaryocytes may be important contributory factors in the production of thrombocytopenia in some cases.

Thrombocytopenia Caused by Abnormal Platelet Pooling

The splenic pool normally contains approximately one third of the total platelet mass, and this pool may increase in size as a result of disorders that are associated with splenomegaly, such as cirrhosis with portal hypertension, sarcoidosis and other granulomatous infections, Gaucher and other lipid-storage diseases, leukemias and lymphomas, and Felty syndrome.^{101, 102, 103} This shift of platelets into the spleen may result in thrombocytopenia in the circulating blood despite a normal or even increased total platelet mass. The clinical picture in hypersplenic thrombocytopenia is usually dominated by the underlying disease, and numerous other hematologic abnormalities, such as neutropenia, anemia, and coagulation defects, may also be present.

The pathophysiology of thrombocytopenia in disorders associated with splenomegaly is not completely understood. Rat spleens demonstrate large numbers of platelets adherent to reticuloendothelial cells.¹⁰⁴ It is also hypothesized that the splenic pool increase may occur because of very slow passage of platelets through the tortuous splenic vasculature. The platelets in the splenic pool are in equilibrium with the circulating pool and can be mobilized with an infusion of epinephrine or during plateletpheresis.^{105, 106, 107} This is in contrast to the irreversible thrombocytopenia caused by splenic removal of damaged or antibody-coated platelets in disorders such as autoimmune thrombocytopenic purpura. There is some evidence for accelerated platelet destruction in many instances of thrombocytopenia associated with disorders of the spleen.^{108, 109} Survival of isotopically labeled platelets is shortened in some patients with cirrhosis and portal hypertension, even though the major mechanism of thrombocytopenia in these patients appears to be splenic pooling.

The usual laboratory findings are pancytopenia with mild thrombocytopenia and a normal or moderately increased number of megakaryocytes in the bone marrow. Platelet counts in cirrhotic patients have been as low as 20,000/ μ l, although thrombocytopenia of this severity is uncommon. Patients with hypersplenism have smaller platelets than those with autoimmune thrombocytopenia, so platelet sizing may provide a means of differentiating between thrombocytopenia related primarily to immunologic platelet destruction and that related to big-spleen syndromes. In general, the severity of the thrombocytopenia correlates poorly with the size of the spleen, but it is nonetheless difficult to entertain a diagnosis of thrombocytopenia caused by abnormal splenic platelet pooling in the absence of significant splenic enlargement.¹¹⁰

Therapy is seldom indicated for thrombocytopenia alone, but splenectomy, embolic occlusion of the splenic vasculature, and splenic damage secondary to infusion of radiolabeled particles can improve the thrombocytopenia and sometimes alleviate the pancytopenia completely.^{108, 111, 112, 113, 114, 115, 116} Patients with thrombocytopenia secondary to cirrhosis with portal hypertension may benefit from portocaval shunts or transjugular intrahepatic portosystemic shunts.^{117, 118}

Thrombocytopenia Caused by Hypothermia

In humans, mild reversible thrombocytopenia is a predictable consequence of surgical hypothermia below 25°C.^{119, 120} Thrombocytopenia has also been noted after hypothermia caused by environmental exposure.¹²¹ Finally, thrombocytopenia occurs in almost all patients undergoing one- or two-cycle cryotherapy for hepatic metastases from colorectal adenocarcinoma.¹²²

Adhesion of platelets to subendothelium is mediated through an interaction of the platelet GP Ib-IX-V complex and subendothelial vWF. The GP Ib-IX-V complex comprises four transmembrane polypeptide chains, GPIb α , GPIb β , GPiX, and GPV. Lipid rafts (also known as glycolipid-enriched membranes) are dynamic assemblies of cholesterol and sphingolipids that are more ordered in structure than the rest of the plasma membrane.¹²³ Receptor clustering is an essential feature of signaling through lipid rafts and occurs in platelet membrane at lower temperatures.¹²⁴ A subset of the GP Ib-IX-V complex is constitutively associated with lipid rafts in unstimulated platelets.¹²⁵ Upon exposure to cold, the cooled platelets irreversibly reorganize vWF receptors (the [GPIb α IX]₂V complex) into clusters on the platelet surface. The hepatic macrophage integrin receptor Mac-1 (CD11b/CD18) recognizes clustered GPIb α , leading to phagocytosis of cooled platelets. Cooling, however, does not grossly impair the interaction between GPIb and activated vWF, implying that the hemostatic and clearance functions of GPIb are distinct.^{126, 127}

Thrombocytopenia Associated with Infections

Purpura was recognized as a manifestation of pestilential fevers 2,000 years ago. Several factors are now known to cause bleeding in association with infections, of which thrombocytopenia is the most common.

Thrombocytopenia Associated with Viral Infections

Viruses may produce thrombocytopenia by several different mechanisms: Impaired platelet production as a result of invasion of megakaryocytes by the virus, impaired platelet production caused by toxic effects of viral proteins on

progenitor cells, viral-induced hemophagocytosis, destruction of circulating platelets by the virus, and increased platelet destruction caused by binding of viral-induced autoantibodies or viral antigen-antibody complexes.

The administration of live measles vaccine produced significant yet subclinical thrombocytopenia in most normal children.¹²⁸ Degenerating vacuolated megakaryocytes were evident 3 days after administration of the vaccine. The nadir of the platelet count occurred 7 days after vaccination. There are now several reports of thrombocytopenia occurring after immunization with measles-mumps-rubella vaccine, monovalent measles vaccine, and measles-mumps vaccine.¹²⁹ Thrombocytopenia has been severe (<20,000/ μ l), and some patients have had significant hemorrhagic complications. The majority of the patients have been <2 years of age, but the age range was 1 to 40 years.¹³⁰ Thrombocytopenia after vaccination for hepatitis A and B and varicella has also been noted.^{131, 132, 133} Children with neonatal infections with mumps and rubella are often thrombocytopenic,^{134, 135} and hepatomegaly and splenomegaly may also be present. CMV infection is usually asymptomatic in immunocompetent adults. However, there are reports of severe thrombocytopenia and even thrombocytopenia with hemolysis.^{136, 137} It is unclear whether the thrombocytopenia is caused by a direct cytopathologic effect of the virus on megakaryocytes, viral-induced hemophagocytosis, or immunologic destruction.

Parvovirus B19 is the etiologic agent responsible for erythema infectiosum. It is also cytotoxic to erythroid progenitors and can cause aplastic crises in patients with hemolytic anemia and chronic bone marrow failure in immunocompromised hosts. Thrombocytopenia may occur in some of these patients,

P.1103

and recent studies demonstrate cytotoxic effects of viral nonstructural-1 proteins on megakaryocytes.^{138, 139, 140}

Thrombocytopenia has been reported following the administration of adenoviral gene transfer vectors.^{138, 141} The interaction between adenovirus and platelets leads to platelet activation and rapid exposure of P-selectin on the platelet surface. P-selectin interacts with major P-selectin ligand on leukocytes, leading to the formation of platelet-leukocyte aggregates.¹⁴² Adenovirus also activates endothelial cells either directly or indirectly through activated platelets. It is followed by increases in total amounts of vWF and of ultralarge vWF multimers in plasma as well as an increase in the number of circulating endothelial cell-derived microparticles. Endothelial cell activation and the associated up-regulation of adhesion molecules (VCAM-1) contribute to leukocyte and/or platelet leukocyte aggregate rolling and transendothelial migration, a critical process for tissue macrophage influx. This is followed by removal of activated platelets by tissue macrophages.

Thrombocytopenia Associated with Bacterial and Protozoal Infections

Thrombocytopenia commonly is associated with septicemia resulting from both Gram-negative and Gram-positive bacteria. This complication is particularly common in infants and children, and the presence of unexplained thrombocytopenia, particularly in this age group, should always alert the physician to the possibility of septicemia. The etiology of thrombocytopenia may be multifactorial. Thrombocytopenia may be caused by disseminated intravascular coagulation (DIC), and the diagnosis of DIC may be apparent when coagulation studies are performed. Thrombocytopenia has also been described in patients with Gram-negative or Gram-positive septicemia, and 46% of these patients had elevated platelet-associated immunoglobulin G without evidence of DIC. These studies were interpreted as demonstrating the presence of platelet destruction caused by splenic destruction of immune complex-coated platelets. These data must be reinterpreted with third-generation immune complex capture assays that can better define platelet autoantibodies and immune complexes.

Platelet adherence to damaged vascular surfaces may also account for thrombocytopenia in certain bacterial infections, such as meningococcemia. Endotoxins, exotoxins, or platelet-activating factor may damage platelets, resulting in increased clearance. Patients with sepsis syndrome may develop hemophagocytic histiocytosis with phagocytosis of platelets, white cells, and platelets in bone marrow histiocytes.¹⁴³

Thrombocytopenia may also be caused by direct platelet toxicity caused by the microorganism. Thrombocytopenia occurs in >80% of patients with malaria, and platelets from malaria patients have been demonstrated to contain plasmodia.¹⁴⁴ Significant ultrastructural changes in platelets of patients with malaria are present, and the extent of abnormal findings correlates with the level of parasitemia.¹⁴⁵

The pathophysiology of thrombocytopenia in malaria has recently been studied in a mouse model of experimental malaria induced by *Plasmodium berghei*. Signaling through multipotent immunomodulator CD40L and its receptor CD40, expressed on activated platelets, initiates the caspase cascade, resulting in apoptosis of the platelet and the formation of platelet microparticles.¹⁴⁶ Early depletion of platelets leads to an altered immune response with significantly decreased

levels of proinflammatory cytokines, such as interferon- γ and interleukin-2 (IL-2), as well as increased levels of IL-10, indicating a role for platelets in the regulation of pathogenic cytokines and cell-mediated immune responses.¹⁴⁷ Cell-mediated rather than the humoral immune response has been shown to play a major role in development of thrombocytopenia.¹⁴⁸

Theoretically, any bacterial or protozoal infection can be associated with thrombocytopenia that is caused by one of the mechanisms hypothesized in this chapter. There are reports of thrombocytopenia in Lyme disease and *Mycoplasma pneumoniae* infections, a manifestation of these infections that appears to be uncommon.^{149, 150}

Patients with thrombocytopenia associated with infection should be tested for the presence of DIC. At this time, no other clinically available tests can be used to define the precise etiology in patients without evidence of DIC. The most important therapy for infection-related thrombocytopenia is that directed at the underlying infection. Platelet transfusions, with or without intravenous IgG, can be used to control bleeding until antimicrobial therapy is effective.

Thrombocytopenia after Massive Blood Transfusion

Massive blood transfusion is defined as complete replacement of a patient's blood volume within 24 hours, usually 10 units of packed red blood cells for an average-sized adult. Because packed red blood cells do not contain a significant number of functional platelets and do not replace labile clotting factors, there has been concern about the incidence of developing hemostatic abnormalities and clinical bleeding in patients given only packed red blood cells.

Some studies demonstrate a correlation between the number of units of packed red blood cells transfused and both reduction in platelet counts ("dilutional thrombocytopenia") and increases in prothrombin and partial thromboplastin times. However, significant changes (platelets, 50,000 to 100,000/ μ l) are not apparent until patients have received >15 units of blood.^{148, 149} Severe thrombocytopenia, defined as a platelet count <50,000/ μ l, is most common in patients receiving >20 units of blood.^{151, 152} Microvascular bleeding occurs in 20% to 60% of patients who are massively transfused, but neither the platelet count nor changes in coagulation studies can be used to predict which patients will bleed.¹⁵³ Although bleeding appears to be more dependent on thrombocytopenia than on coagulation abnormalities, prophylactic administration of platelets was no more effective than equivalent volumes of prophylactic fresh-frozen plasma infusions in preventing bleeding.¹⁵⁴ Therefore, it is recommended that platelet and plasma replacement during massive transfusions be guided by serial monitoring of platelet counts, prothrombin time, and partial thromboplastin time, and that platelet counts be kept >75,000/ μ l and prothrombin time and partial thromboplastin time <1.5 times normal.¹⁵² The coagulopathy associated with massive blood transfusion is discussed further in Chapter 54.

Chapter 50

Bleeding Disorders Caused by Vascular Abnormalities

George M. Rodgers

Matthew M. Rees

This chapter discusses causes of bleeding that are not the result of thrombocytopenia, coagulation factor deficiency, or qualitative platelet defects. Bleeding disorders caused by these various “vascular” abnormalities represent a heterogeneous group of diseases, and in considering the differential diagnosis, it is convenient to consider cutaneous causes, connective tissue abnormalities, vascular lesions, and intravascular causes.

CLINICAL APPROACH TO THE PATIENT

The initial approach to the bleeding patient is discussed in Chapter 45. When considering “vascular” causes of bleeding, the appearance of the lesions (petechiae vs. more extensive ecchymosis, size, shape, color), location and pattern of involvement, associated features (fever, ulcers, scars, livedo reticularis), and the clinical setting are helpful clues. Table 50.1 lists some common physical finding patterns helpful in considering the differential diagnosis of vascular disorders.

Purpura is the term used to describe the skin lesions that develop when red blood cells extravasate from capillaries. Purpura refers to either pinpoint lesions called petechiae or more widespread lesions known as ecchymoses. Purpura can be differentiated from other erythematous lesions by the use of diascopy, which is the application of a glass slide to the border of the lesions. True purpura does not blanch with pressure.¹

MECHANICAL PURPURA

External pressure such as blunt trauma results in ecchymoses when the force is sufficient to disrupt vascular integrity and allow extravasation of red blood cells. The size of the resulting lesion is dependent on the durability of the tissue traumatized, the vascularity of the region, the density of the surrounding tissue, and the time elapsed.^{2, 3} The extent of bruising can increase over time, and tracking through tissue planes can occur, resulting in bruises in areas remote from the area of trauma.⁴ The color of the lesion is in part dependent on the location of the red cells—lesions near the surface have a more reddish color, and deeper lesions appear bluish. This finding is due to optical scattering in the dermis, and the fact that blue wavelengths scatter and reflect more than red.⁵

Bruises change color with time, and the color of bruise has been used to determine the age of lesions. However, evidence suggests that there is more variability in color changes than previously recognized.^{4, 6}

Mechanical purpura can be seen on occasion with minor trauma such as blood pressure cuff monitoring in anticoagulated patients³ or even vigorous scratching. Young adults playing active sports such as basketball can develop calcaneal petechiae resulting from relatively minor, but repetitive, heel trauma.⁷ Periorbital, face, or neck purpura can occur after a sudden increase in intravascular pressure with a Valsalva maneuver⁸ and has been described after bungee jumping.⁹

Suction purpura occurs when negative pressure is applied to the skin in sufficient force to result in extravasation of erythrocytes. Young healthy people develop petechiae with 350 to 400 mm Hg negative pressure, but the required amount of pressure to induce purpura decreases with age to as low as 100 mm Hg.¹⁰ The application of rubber suction devices to the forehead can result in circumscribed purpura. This seems to occur mostly when new parents apply children's suction toys to their foreheads and has been termed cyclops purpura.¹¹ A similar, relatively common cause of

suction purpura is seen in adolescents who place a drinking glass over their chin and suck out the air to form a vacuum, ultimately causing chin or perioral purpura.¹² Adolescents are also prone to develop small purpuric lesions in the neck region from “hickeys” or “love bites,” another form of suction purpura.

Large areas of contusions develop with blunt force injuries. Certain patterns of contusion can help identify the type of device causing the injury. Skin bruises corresponding to the sites of seat belts are known as “seat belt mark” signs. It is important to recognize these, as the presence of this sign should alert physicians to the higher likelihood of internal injuries.¹³ A direct blow from a linear or cylindrical object causes parallel lines (“tram-line” appearance) with central clearing, as the blood beneath the site of highest impact is displaced laterally. Similarly, a bruise in the shape of a circle with central clearing may occur as a result of a blow from the circular edge of a pipe or spherical objects.¹⁴ Caution, however, should be used in interpreting these types of bruises, as simple bruises can sometimes occur with “ring resolution.”¹⁵ Circular contusions 1 to 1.5 cm in diameter may be due to fingertip pressure and grab marks or bite marks, and they show semicircular arch contusions, but are highly variable.¹⁴ Certain bruising patterns can suggest child or elder abuse, but results should be interpreted carefully.^{16, 17}

Larger ecchymotic areas also may demonstrate other patterns that can be a clue to underlying pathology. The well-known Cullen sign refers to bluish discoloration around the umbilicus, and Grey-Turner sign is flank ecchymosis. Both may indicate hemorrhagic pancreatitis or a rectus sheath hematoma.¹⁸ Scrotal ecchymosis may be a clue to intraperitoneal hemorrhage, and perianal ecchymosis has been described as a manifestation of aneurysmal rupture into the sigmoid mesocolon.^{19, 20} “Raccoon eyes” and mastoid ecchymosis (Battle sign) may indicate a basilar skull fracture after head trauma.²¹ Ecchymosis occurring in patients with swollen calves suggests a ruptured popliteal cyst with gravitational spread of the bruise down to the ankle and occasional linear appearance (“tide mark” appearance) with sparing of the foot and lower ankle due to the pressure of footwear.²²

STRUCTURAL MALFORMATIONS OF VESSELS

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT) was first described in 1864 by Sutton²³ and later recognized and reported by Rendu,²⁴ Osler,²⁵ and Weber,²⁶ and it is thus also known as Osler-Weber-Rendu syndrome. It is an autosomal dominant disorder characterized by multiple telangiectatic lesions involving the skin and mucous membranes associated with epistaxis and other bleeding complications. HHT has an estimated prevalence of 1 in 8,000,²⁷ with complete penetrance by 40 years of age.²⁸

Genetic studies have identified several mutations responsible for the vascular malformations. Mutations in the endoglin gene on chromosome 9 (HHT1) or in the activin receptor-like kinase

P.1107

(ALK1) gene on chromosome 12 (HHT2) account for ~85% of the cases. Currently more than 500 mutations in the ALK1 or endoglin genes have been identified, and each family studied appears to have a unique mutation.²⁷ Endoglin is an integral membrane glycoprotein expressed on endothelial cells in arterioles, venules, and capillaries. This glycoprotein and ALK1 serve as a binding protein for transforming growth factor-β (TGF-β).

TGF-β regulates many transcriptional targets and plays a crucial role in vascular development and homeostasis. Recently identified mutations in the MADH4 gene abnormalities are associated with juvenile polyposis and HHT,²⁹ and linkage studies suggest additional mutations exist on other chromosomes.^{30, 31} An HHT mutation database is available at <http://www.hhtmuation.org>.

TABLE 50.1 COMMON PHYSICAL FINDINGS AND ASSOCIATIONS OF VASCULAR DISORDERS

Pattern and Usual Location	Etiology	Associated Features
Subconjunctival and axillary petechiae	Fat emboli	Dyspnea
Periorbital, facial, and neck petechiae	Valsalva maneuvers	
Periorbital ecchymosis (“black eye”)	Trauma; in penetrating globe injuries without periorbital trauma, suggests posterior rupture	
“Raccoon eyes”	Basilar skull fracture	

“Battle sign” (mastoid ecchymosis)	Basilar skull fracture	
Palatal petechiae	Viral upper respiratory infection	
Ecchymosis of limbs and face of infant	AIHE	Inflammatory edema
Eyelid and periorbital edema and purpura, often after dependency; purpura in other areas with minimal trauma	Amyloid	
Glove and stocking petechiae with areas of confluence and sharp line of demarcation between normal and abnormal areas	PPGSS	
Palm and sole petechiae	Rat bite fever and other infections	
Purpuric lesions on the forearm in elderly patients	Solar or steroid purpura	
Bluish discoloration of the umbilicus (Cullen sign)	Hemorrhagic pancreatitis or rectus sheath hematoma	
Flank ecchymosis (Grey-Turner sign)	Hemorrhagic pancreatitis	
Periumbilical purpura with “thumbprint” signing	<i>Strongyloides</i> infection	
Scrotal/perineal ecchymosis	Intraperitoneal hemorrhage or iliac aneurysmal rupture (rupture into sigmoid mesocolon)	
Telangiectatic lesions along the face, lips, nares, tongue, and nail beds	HHT	
Lower extremity palpable, nonblanching purpura	Vasculitis	
Perifollicular lower extremity, with areas of confluence	Scurvy	Gingival, intramuscular bleeds
Urticarial lesions followed by purpura	Urticarial vasculitis	
Proximal thigh involvements often with a “kissing” or symmetric lesion	Calciphylaxis	
Mucosal oozing and easy bruising	EDS	Skin hyperextensibility, joint immobility
Hemorrhagic bulla	Bacterial infections (<i>Clostridium</i> , <i>Vibrio</i> , <i>Aeromonas</i>); hypersensitivity to insect bites, snakebites; pemphigus	
“Tram lines”	Blunt force with cylindrical or linear object	
“Ring” bruises	Blunt force with circular end or sphere; may also be seen in normal bruise resolution	

AIHE, acute infantile hemorrhagic edema; EDS, Ehlers-Danlos syndrome; HHT, hereditary

hemorrhagic telangiectasia; PPGSS, papular-purpuric gloves and socks syndrome.

The mechanisms by which these genetic defects result in telangiectatic lesions have not been identified. Ultrastructural analysis of cutaneous HHT lesions suggests that postcapillary venule dilation is the earliest identifiable morphologic abnormality.^{32, 33} As the venules enlarge, they become convoluted and interconnect with arterioles through capillary segments. The capillary segments eventually disappear, and direct arteriolar-venular communications are established (Fig. 50.1). An infiltrate of mononuclear cells appears in the perivascular region of the HHT lesions.

The bleeding manifestations are thought to occur because of mechanical fragility of these vessels. Common abnormalities in the hemostatic system do not seem to represent a major factor in the underlying bleeding tendency. HHT patients manifest a variety of other complications including shunting, emboli, and thrombosis.

Clinical Manifestations

The cutaneous lesions usually appear in affected persons by 40 years of age, and they increase in number with age. The lesions measure 1 to 3 mm in diameter and are sharply demarcated in appearance (Fig. 50.2). They blanch with pressure, but the blanching may be incomplete as a result of "strangulation" of coiled loops of vessels.^{34, 35} The telangiectatic lesions are most commonly found on the face, lips, nares, tongue, nail beds, and hands. Some patients have only a few lesions, necessitating a thorough search in anyone suspected of having HHT. Bleeding from these cutaneous telangiectasias is uncommon and rarely of clinical importance. One report suggests that capillaroscopy of the dorsal hands can detect morphologic changes in the skin microcirculation, including microscopic telangiectatic lesions, but the clinical utility of this is undefined.³⁶

P.1108

FIGURE 50.1. Arteriovenous malformations in hereditary hemorrhagic telangiectasia. In a fully developed cutaneous telangiectasia, the venule (V) and its branches have become dilated and convoluted throughout the dermis. The connecting arterioles (A) have also become dilated and communicate directly with the venules without intervening capillaries. A perivascular infiltrate is present. The thickened wall of a dilated postcapillary venule is also shown. L, lumen of the vessel. (From Guttmacher AE, Marchuk DA, White RI. Hereditary hemorrhagic telangiectasia. *N Engl J Med* 1995;333:918-924, with permission.)

Epistaxis is the presenting complaint in up to 90% of patients with HHT. This symptom results from bleeding telangiectatic lesions over the inferior turbinates and nasal septum. Symptoms usually occur before 35 years of age and are highly variable. Approximately one-third of patients have mild symptoms requiring no treatment, and another third have

moderate symptoms requiring only outpatient treatment. The remaining third have severe symptoms often requiring inpatient treatment, transfusions or chronic iron replacement therapy, and surgery.³⁵ The nosebleeds may become more difficult to control as the patient ages.

FIGURE 50.2. Telangiectasias of the tongue and lower lip in a patient with hereditary hemorrhagic telangiectasia. (From Guttmacher AE, Marchuk DA, White RI. Hereditary hemorrhagic telangiectasia. *N Engl J Med* 1995;333:918-924, with permission.)

Pulmonary arteriovenous malformations (PAVMs) occur in 30% of patients with HHT, and 85% to 90% of people with PAVM are found to have HHT.^{32, 34, 35, 37} Genetic linkage studies have found that patients with endoglin mutations have significantly higher rates of PAVMs (40%) than HHT patients with other mutations (14%).^{38, 39} The PAVMs are primarily located in the lower lung lobes and are multiple. These PAVMs may result in a significant right-to-left shunt, and patients may develop dyspnea, cyanosis, clubbing, fatigue, decreased exercise tolerance, migraine headaches, and polycythemia. Paradoxical emboli can occur and result in brain abscesses, transient ischemic attacks, and strokes. The prevalence of cortical infarcts has been reported to be as high as 14% in patients with a single PAVM and increases to 27% in patients with multiple PAVMs.⁴⁰ These lesions may also bleed and result in hemoptysis or hemothorax; pregnant women with PAVMs appear to be at increased risk.⁴¹

The detection of PAVMs may be difficult in patients with few or no symptoms. Physical examination may uncover an end-inspiratory bruit.³⁴ A chest radiograph may detect a coin lesion but often misses smaller lesions. Gravitational shifts in blood flow to the lung bases result in increased right-to-left shunting in the sitting or standing position. Physiologic tests such as measuring O₂ saturation in the supine and standing position (on room air and 100% O₂) can detect the positional change in shunting and can be used to screen patients for PAVMs. However, the best screening test for PAVM appears to be contrast echocardiography.⁴² Patients with a positive screening test should undergo an unenhanced spiral computed tomography (CT) to confirm and further characterize the PAVM.⁴³ Pulmonary angiography is a less sensitive study but is necessary in treatment planning.

Approximately 20% of patients with HHT develop significant upper and lower gastrointestinal (GI) tract hemorrhage. Bleeding is rare before the fifth decade of life. Approximately 40% of the bleeding episodes occur from upper GI tract lesions, whereas only 10% occur in the colon, and a full one-half are indeterminate after evaluation.³⁵ Spontaneous regression of GI bleeding is rare, and steady progression or chronic intermittent bleeding is the norm.

Hepatic involvement occurs in 70% of patients, but symptoms and complications are rare.⁴⁴ Patients may have hepatomegaly, a hepatic bruit or thrill, or elevated liver function studies.⁴⁵ Types of intrahepatic shunting include hepatic artery to hepatic vein (arteriovenous), hepatic artery to portal vein (arterioportal), and portal vein to hepatic vein (portovenous). These shunts can lead to clinical complications of high-output heart failure, portal hypertension, encephalopathy, biliary ischemia, and nodular regenerative hyperplasia. The dominant type of shunt identified on multiphase CT does not correlate strongly with the clinical syndrome.⁴⁶ Nodular regenerative hyperplasia is found with a 100-fold increased prevalence compared to the general population, and along with portal hypertension can lead to a misdiagnosis of cirrhosis (pseudocirrhosis).⁴⁴ It is important to consider this diagnosis in the setting of a liver mass, as biopsy should generally be avoided when suspected. Additionally, if patients with known focal nodular hyperplasia are being treated with estrogen or progesterone therapy, close monitoring is indicated with discontinuation of hormones in the case of symptomatic tumor enlargement.⁴⁴ Hepatic AVMs can be detected by dynamic CT,⁴⁵ color Doppler ultrasound, magnetic resonance imaging/magnetic resonance angiography (MRI/MRA), or celiac angiography. CT evidence for AVMs includes both the characteristic heterogeneous enhancement of the entire liver as well as a dilated common hepatic artery.⁴⁶

The neurologic manifestations of HHT result from PAVM in up to two-thirds of cases.³² The remainder of the neurologic symptoms are the result of cerebrovascular telangiectasias, AVMs, aneurysms, and cavernous hemangiomas. Ten to twenty percent of patients with HHT have cerebral AVM, but only 10% of people who have cerebral AVM are found to have HHT.⁴⁷ The cerebral

P.1109

AVMs are often multiple.⁴⁷ The annual risk of bleeding from cerebral AVM is low, reported as 0.41% to 0.72%/year (compared to 2% to 4% risk for sporadic, non-HHT AVM).^{47, 48} MRI is recommended for detecting these lesions.⁴¹

TABLE 50.2 CURACAO CRITERIA FOR THE DIAGNOSIS OF HEREDITARY HEMORRHAGIC TELANGIECTASIA (HHT)

1. Epistaxis—spontaneous and recurrent
2. Telangiectasias—multiple, at characteristic sites (lips, oral cavity, fingers, nose)
3. Visceral lesions—with or without bleeding (gastrointestinal, pulmonary, cerebral, hepatic)
4. Positive family history—a first-degree relative with HHT

The presence of three of the above criteria indicate definite HHT; the presence of two criteria are suspicious for HHT.

From Shovlin CL, Guttmacher AE, Buscarini E, et al. Diagnostic criteria for hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber Syndrome). *Am J Med Genet* 2000;91:66-67.

The clinical diagnostic criteria (Curacao criteria) are listed in Table 50.2.⁴⁹ Genetic testing is now available, but requires sequencing the entire coding regions of *ALK1* and *endoglin*, and is complex and expensive.²⁷ Consultation with a medical geneticist is recommended.

Management

Asymptomatic patients with HHT should be screened with a thorough history, careful physical exam, complete blood count (CBC), and stool guaiac studies. A brain MRI to screen for cerebral AVMs is recommended, and contrast echocardiography to screen for PAVMs should be performed in all patients at least once after the age of 10. Children younger than 10 should be screened with oxygen saturations in the sitting and supine position every 1 to 2 years, with further testing for saturations <97%.⁴¹ Hepatic AVM screening is controversial, but if considered, an ultrasound is the preferred study.⁴⁴

Recurrent epistaxis can be a perplexing problem, and few trials exist that compare various treatment modalities. Recent efforts to classify the nasal vasculature pattern⁵⁰ and develop an epistaxis severity scoring system should pave the way for randomized trials of the various approaches. Prophylactic measures include humidification and saline nose drops. Nasal trauma from vigorous nose blowing, straining, and finger manipulation should be avoided. Antihistamines should also be avoided to prevent drying of the nasal mucosa. Mild bleeding can be treated with absorptive packing and direct pressure. Cautery is commonly used to stop persistent bleeding, but repeated cauterizations can result in necrosis and septal perforation, and should be avoided.⁵¹ Fibrin glue spray was of benefit in a small study.⁵² The neodymium:yttrium-

aluminum-garnet (Nd:YAG) laser system has been shown to be effective treatment for epistaxis, and analysis of the vascular pattern appears to correlate with the success rates of laser therapies.⁵⁰ Argon plasma coagulation also appears promising, and application of topical estrogens may be useful.⁵³ Arterial embolization or ligation is effective in some patients. Septal dermoplasty is a technique of removing diseased nasal mucosa and the subepithelial telangiectasias and replacing abnormal tissue with an enduring barrier. In refractory cases, rhinotomy with forehead flap reconstruction may be required.⁵⁴ The use of estrogen and e-aminocaproic acid is discussed in the following section.

PAVMs are treated with transcatheter embolotherapy^{55, 56} to diminish the risk of paradoxical emboli and other complications. PAVMs with feeder artery diameters >3 mm should be treated. This procedure is effective at decreasing the right-to-left shunt and improving oxygen saturation, and it has a low complication rate. In cases in which embolotherapy is technically difficult, surgical resection should be used. After embolotherapy or surgery, small AVMs may enlarge and become clinically significant. For this reason, patients should undergo screening helical CT scans every 5 years.³² Because brain abscesses and septic emboli occur in 1% to 20% of patients with HHT and PAVM, these patients should receive prophylactic antibiotic therapy before dental or surgical procedures.⁵⁷

Bleeding GI vascular malformations can be treated with endoscopic thermal devices including bipolar electrocautery and laser techniques. The mucosa coagulates and sloughs, leaving a small ulcer in the place of the vascular lesion.⁵⁸ The ulcer re-epithelializes over the next few days. These treatments are rarely effective for the long term, however, because new lesions continue to develop and small intestinal lesions are not accessible. Estrogen and progesterone have been effective in decreasing the bleeding episodes.

Cerebral AVMs have been treated with surgery, stereotactic radiosurgery, and embolotherapy. A follow-up angiogram should be repeated at 1 year, followed by periodic MRI. Hepatic malformations resulting in high-output heart failure, portal hypertension, or cholangitis should be treated with intensive medical management. Refractory cases have been treated with transcatheter embolization, but the complication rate is significant.⁵⁹ The mortality rate of this procedure in HHT has been calculated to be as high as 25% to 40%.⁵⁸ Consensus recommendations suggest that the procedure be used only "as a last resort in patients who are not candidates for liver transplant," and should be absolutely avoided in patients with biliary signs or symptoms.⁴⁴ Other treatments that have been successfully used include hepatic artery ligation for localized vascular malformations⁵⁹ and liver transplant in patients with extensive lesions.⁶⁰

Medical Therapy

Observations in the 1950s that epistaxis decreased during pregnancy and increased after menopause led to the use of estrogens as therapy for HHT. Estrogens in large doses result in metaplasia of the nasal mucosa, resulting in thick layers of squamous epithelium, and electron microscopy studies indicated that estrogen reestablished endothelial cell continuity.⁶¹ A small randomized trial of 3 months' duration showed no benefit in reducing the number of bleeding episodes with estradiol valerate.⁶² However, another author reported 100% success in an uncontrolled series of 67 consecutively treated patients who continued with high-dose estrogen therapy.⁶¹ Several case reports and one small randomized controlled trial evaluated the use of low-dose estrogen-progesterone combination therapy in patients with severe GI bleeding. The bleeding episodes and transfusion requirements significantly diminished in treated patients.⁶³ Patients on tamoxifen have also been noted in case reports to have decreased episodes of bleeding. Recent reports suggest that either oral or intranasal tranexamic acid may be useful.^{64, 65, 66}

Several intriguing case reports describe regression of telangiectatic lesions and decreased bleeding in patients treated for unrelated reasons with interferon, sirolimus, and bevacizumab,^{67, 68, 69} suggesting a possible role for angiogenic inhibitors in managing HHT.

Virtually all patients with HHT have iron deficiency anemia. The treatment of iron deficiency anemia in this setting usually requires more than oral iron replacement. Patients with significant blood loss and anemia who do not respond or do not tolerate maximal doses of oral iron should be given intravenous iron therapy. Three products are recommended for parenteral iron therapy: low-molecular-weight iron dextran, iron gluconate, and iron sucrose.⁷⁰ Patients who have toxicity with iron dextran should receive one of the other products. With the currently available options for iron replacement in anemic HHT patients, red cell transfusion should rarely be necessary.

P.1110

Genetic counseling should be part of the treatment, and referral to a designated HHT center should be considered in most cases. Seventeen U.S. and Canadian HHT centers currently exist and are listed on the HHT Foundation International, Inc.

Web site (www.hht.org). Additional centers exist in Europe, South America, Israel, and Asia. A recent review summarizes all aspects of HHT diagnosis and management.⁷¹

Vascular Malformations

Vascular malformations result from localized errors of angiogenic development. The underlying molecular genetics of angiogenesis are complex (see Chapter 19). Mutations in angiogenic pathways can result in a variety of malformations, including capillary or venous angiomas, cerebral cavernous malformations (CCMs), and AVMs, either as isolated or multifocal lesions. Bleeding problems occur from rupture or leakage from these vascular anomalies, and the clinical sequelae depend on their location.

Skin lesions are the most common vascular malformation and include a variety of birthmarks. Hemoptysis can result from pulmonary vascular anomalies including AVM and a rare disease known as pulmonary capillary hemangiomatosis. Hematuria may rarely be due to genitourinary AVMs or hemangiomas.

GI bleeding may be due to vascular malformations such as the blue rubber nevus syndrome, gastric antral vascular ectasia, telangiectasias, and AVM. GI angiodysplastic lesions deserve special attention, given their frequency. They appear to be due to degenerative dysplasia and are the most frequent cause of obscure GI bleeding. The cause is thought to be intermittent obstruction of the submucosal veins where they penetrate the muscular layers of the colon, ultimately leading to dilated, tortuous submucosal veins and venules.⁷² Small intestinal angiodysplastic lesions can be particularly hard to detect, but wireless capsule endoscopy can facilitate this diagnosis. Endoscopic-based therapy or surgery may be required for treatment. This disorder is frequently associated with aortic stenosis, and there are reports of cessation of bleeding after aortic valve repair. Continuous estrogen-progestin treatment is not useful in the prevention of rebleeding from GI angiodysplasia.⁷³

Central nervous system vascular lesions include AVMs, berry aneurysms, and cavernomas. Bleeding from these lesions may account for 30% of spontaneous intraparenchymal lobar bleeds.⁷⁴ Autopsy studies show the presence of intracranial aneurysms in 1% to 5% of the adult population, and 20% to 50% of these aneurysms rupture. They are sporadically acquired, but patients with autosomal dominant polycystic kidney disease may have up to a 40% incidence. Screening is recommended for families with two immediate relatives with intracranial aneurysms and all patients with autosomal dominant polycystic kidney disease. Histologically, there is a decrease in the tunica media causing structural defects, leading to aneurysmal dilatation at branch points at the base of the brain. Rupture leads to subarachnoid hemorrhage with symptoms ranging from headache and nuchal rigidity to drowsiness, stupor, and coma.⁷⁵

CCMs are vascular lesions characterized by abnormally enlarged capillary cavities without intervening brain parenchyma. The most common presentation is with seizures and cerebral hemorrhage. Sporadic and familial forms exist, with the familial form showing autosomal dominant inheritance with incomplete penetrance. The familial forms usually have multiple CCM lesions. Three CCM loci have been identified, and the clinical and neuroradiologic features compared.⁷⁶ CCM3 carriers have an earlier age of onset of cerebral hemorrhage. CCMs are not usually visible on angiography, but T1- and T2-weighted images on MRI show characteristic findings.

Patients with brain AVMs present between the ages of 10 and 40. The risk of bleeding in patients with untreated AVMs is 2.8% per year, but varies between 1% in low-risk patients to 30% in high-risk patients.⁷⁷ Genetic abnormalities have been identified in CCMs; these defects result in abnormal blood vessel architecture, and interestingly, may be reversible by statin therapy (reviewed in Ref. 78).

Other Vasculopathies

Amyloidosis

Patients with multiple myeloma or systemic amyloidosis may have light chain deposits in the cutaneous blood vessels. These vessels are particularly fragile, and purpura can occur as a result of minor trauma ("pinch purpura"). The eyelids and periorbital regions are particularly prone to developing purpura (Fig. 50.3), and a classic sign is postproctoscopic periorbital purpura occurring after proctoscopies (for diagnostic rectal biopsies done in the past) or after Valsalva maneuvers. Purpura also commonly develops in other flexural skin areas such as the nasolabial folds, neck, axillae, and umbilicus.⁷⁹ Biopsies of the cutaneous vascular lesions demonstrate amyloid deposits in the dermis and subcutaneous tissues, and inflammatory cells are scarce. The diagnosis and treatment of these disorders are discussed in detail in Chapter 99.

Moyamoya Disease

Moyamoya disease is a chronic cerebral vasculopathy initially described in Japan. The disease is characterized by occlusion of the terminal portion of the internal carotid arteries, or the proximal aspects of the middle or anterior cerebral arteries. An abnormal vascular network of collaterals develops in the regional area of occlusion. Cerebral infarcts are common in children, but adults have a higher propensity for intracranial hemorrhage. The risk of bleeding appears to be highest in adult Asians. Features of moyamoya phenomenon differ in U.S. patients, with women aged 30 to 50 most commonly affected, predominantly with ischemic symptoms.⁸⁰ The etiology is unknown, and diagnosis rests on characteristic angiographic findings.

Cerebral Small Vessel Disease

Cerebral small vessel disease usually refers to arterioles <100 μm in size consisting of an internal elastic membrane and a tunica media one to two layers thick, or small arteries measuring 100 to 400 μm in size with tunica media composed of smooth muscle cells three to four layers thick. These vessels are usually end arteries. A constellation of syndromes is now recognized as causing cerebral small vessel disease, and these are mostly characterized

P.1111

by recurrent ischemic strokes with progressive cognitive impairment. Bleeding, however, is a recognized complication of most of these disorders, and it is important to recognize that many disorders have a substantially increased risk of bleeding with anticoagulants.

FIGURE 50.3. Periorbital purpura in a 58-year-old woman with immunoglobulin A κ plasma cell dyscrasia associated with secondary amyloidosis. (This photograph was kindly provided by Drs. Theresa Scholz and Pamela Nemzer, Department of Dermatology, University of Utah Health Sciences Center.)

Degenerative cerebral microangiopathy is characterized by lipohyalinosis of small vessels associated with aging and increasing in severity with vascular risk factors such as hypertension, diabetes, and hyperhomocystinemia. The vessel walls thicken due to sclerosis, hyalinosis, and lipid deposition. Most of the bleeding appears to occur at or near the bifurcation of affected arteries where prominent degeneration of the media and smooth muscles is most appreciated. Occlusion leads to lacunar infarcts, and rupture can lead to cerebral microbleeds and lobar intracranial hemorrhages.

Cerebral amyloid angiopathy typically presents with lobar hemorrhages in patients older than 70 years, and is due to several types of mutations that lead to the accumulation of β -amyloid material in the media and adventitia of small cortical and leptomeningeal vessels. This leads to a “vessel in vessel” appearance on pathology studies. Because of the higher risk of bleeding, strict avoidance of anticoagulation and antiplatelet agents are recommended.

Cerebral autosomal dominant arteriopathy with stroke and ischemic leukoencephalopathy (CADASIL) is a cerebral vasculopathy occurring in patients usually between the ages of 40 and 60. Patients present with subcortical strokes and a slowly progressive dementia and may have mood disorders, migraine headaches, and in the later stages, pseudobulbar palsy. The diagnosis is suggested by a characteristic finding of widespread leukoencephalopathy on MRI. White matter lesions located in the temporal poles of the brain are considered pathognomonic for CADASIL syndrome.⁸¹ Recent studies suggest that cerebral microbleeds are found in 31% to 69% of patients with CADASIL syndrome and intracranial hemorrhaging occurs in 25% of patients.⁸² The vascular defect lies in the smooth muscle cells, with electron microscopy showing exocytosis of granular osmophilic material from the vascular smooth muscle cells and pericytes.

Type 4 collagen is a component of the vascular basement membrane in the brain, and recent mouse studies indicate that mutations can lead to microvascular fragility and result in intracranial hemorrhage. Some familial forms of intracerebral hemorrhage also appear to be due to mutations in the COL4A1 gene.⁸³

BLEEDING DUE TO DISORDERS OF PERIVASCULAR TISSUE

Ehlers-Danlos Disease

The Ehlers-Danlos syndromes (EDSs) are a group of rare connective tissue disorders caused by abnormalities of collagen synthesis or processing. The prevalence is estimated to be 1 in between 10,000 and 20,000 births. A simplified classification system has identified six major types of EDS and their genetic defects.^{84, 85} The clinical features include hyperextensible, fragile skin associated with joint hypermobility. The majority of patients with EDS also report a history of excessive bruising and bleeding.⁸⁶ Other bleeding manifestations may include subcutaneous nodular hematomas, mucosal oozing after dental procedures, hemoptysis, and GI bleeding. In most patients, screening tests show no hemostatic abnormalities, and the bleeding is thought to result from abnormalities in the perivascular collagen leading to fragility of the subcutaneous vessels. However, several authors have noted abnormal bleeding times and platelet function studies, as well as factor deficiencies in individual patients.^{86, 87}

Certain types of EDS have an increased risk of major bleeding. In particular, vascular EDS (type IV) has unique clinical features of interest to hematologists. This disorder is due to quantitative or qualitative defects in type 3 collagen, which is particularly abundant in the arterial wall^{88, 89} and intestine. Patients with this disorder are prone to develop arterial aneurysms and dissections, significant bleeding from spontaneous rupture of medium-sized abdominal arteries, and intestinal rupture.

FIGURE 50.4. “Papyrus” scarring and thin skin with petechiae in a patient with Ehlers-Danlos syndrome. (From Anstey A, Mayne K, Winter M, et al. Platelet and coagulation studies in Ehlers-Danlos syndrome. *Br J Dermatol* 1991;125:155-163, with permission.)

Carotid-cavernous fistula is another well-documented complication, and clinical diagnosis is based on the findings of pulsatile exophthalmia, tinnitus, thrill, and headache. In addition to vascular abnormalities, patients with vascular EDS have characteristic facial features (prominent eyes, thin nose, small lips, and lobeless ears)⁹⁰ and thin translucent skin with a conspicuous venous network. Papyrus scarring (Fig. 50.4) may be present, but patients usually have minimal joint hypermobility (often limited to the hands) or skin hyperextensibility. Median life expectancy is 48 years with one-fourth of the patients developing complications by age 20, and 80% developing complications by age 40.⁹¹ The diagnosis can be confirmed by skin fibroblast cultures with biochemical analysis of type 3 collagen with or without screening for COL3A1 mutations. If vascular EDS is suspected but the above tests are negative, patients should be screened for TGF- β receptor gene mutations, as clinical features overlap with the newly described Loeys-Dietz syndrome (see below).

Patients with EDS, particularly vascular EDS, should generally avoid contact sports and isometric exercise and are advised to avoid medications with antiplatelet properties.⁸⁸ Arterial rupture should be considered in the differential diagnosis when these patients present with new-onset symptoms such as abdominal pain. Diagnostic procedures that involve arterial puncture are relatively contraindicated because of a high incidence of complications.^{88, 92} If surgery is mandatory, extreme care should be used in the manipulation of vascular tissues. Postpartum hemorrhage is a major risk for pregnant patients with EDS, and the management of pregnancy has been reviewed in case reports.^{93, 94} Patients with vascular EDS can develop uterine or vessel rupture in the peripartum period, and should be followed in high-risk centers.⁹¹ Genetic counseling and referral to the Ehlers-Danlos National Foundation (www.ednf.org) should be considered.

Marfan Syndrome

Marfan syndrome is a genetic disorder with characteristic ocular, skeletal, and cardiovascular abnormalities, affecting 1 in 5,000 individuals. Easy bruisability has been reported but does not seem to be a major feature of the Marfan syndrome.⁹⁵ However, the risk of postpartum hemorrhage is reported to be increased.⁹⁶

The basic defect is due to a mutated fibrillin gene on chromosome 15.⁹⁷ Fibrillin is a component of extracellular microfibrils

associated with elastin, and is necessary for connecting and anchoring tissue. Fibrillin was recently found to be important as a TGF- β receptor binding protein, holding TGF- β in an inactive complex. Dietz's group discovered that blocking TGF- β in affected mice prevents some of the developmental abnormalities (including aneurysms), suggesting that certain clinical manifestations are due to excess levels of TGF- β .⁹⁸ Further studies, in fact, showed that some families diagnosed with Marfan syndrome and familial thoracic aneurysms have a missense mutation in the TGF- β receptor 2, and this syndrome is now known as the Loeys-Dietz syndrome.^{98, 99}

Loeys-Dietz Syndrome

The pathogenesis of Loeys-Dietz syndrome has been described.¹⁰⁰ Patients with Loeys-Dietz syndrome have a phenotype characterized by hypertelorism, bifid uvula or cleft palate, and arterial tortuosity with vascular aneurysms, resulting in dissections and arterial rupture. The severity of the craniofacial abnormalities appears to correlate with the outcome.⁹⁸ The natural history of Loeys-Dietz varies from Marfan syndrome and EDS, with median survival of 37 years (vs. 48 and 70 years, respectively), but with a much lower complication rate after vascular surgery. It is of note that childhood aortic dissections occurred in patients with aortic diameters <5 cm, and it is recommended that repair occur when the maximum dimension of the ascending aorta exceeds the 99th percentile in children.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is an autosomal dominant disease characterized by brittle bones with pathologic fractures as a result of a deficiency in bone matrix. Approximately 95% of cases are caused by mutations in the genes COLA1 and COLA2, which code for the pro- α 1(1) and pro- α 2(2) peptides of type 1 collagen.¹⁰¹

There are two α ₁-chains and one α ₂-chain in each type 1 collagen, and many different mutations in the genes coding for these subunits have been characterized. Eight clinical types of OI are currently recognized.¹⁰¹ Approximately 25% of patients have been noted to bruise easily; this tendency appears to vary with the clinical type.¹⁰² Skin contains predominantly type 1 collagen, and bruising is thought to be the result of defective supporting structures. The ecchymoses are generally mild and insignificant compared to the broader clinical picture. Recent reports describe patients with extradural hematomas, subdural hematomas, and retinal bleeds after minor trauma in patients with OI, occasionally being misinterpreted as child abuse.^{103, 104} Excessive bleeding from wound sites after surgery has also been described.¹⁰⁵ Recombinant factor VIIa and desmopressin have been reported to be useful in postoperative bleeding in case reports.^{106, 107} The Osteogenesis Imperfecta Foundation can be accessed at <http://www.oif.org>.

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum is an inherited connective tissue disorder that results in calcification of elastic fibers,¹⁰⁸ especially in the internal elastic lamina of medium-sized arteries. The basic genetic defect is now known to be a variety of loss of function mutations in the gene encoding the transmembrane transporter protein ABC-C6.¹⁰⁹ This protein is in the multiple drug resistance family of proteins and may function as an efflux pump, but it is not yet known what the substance transported is or how the mutation causes the disease. It is possible that this defect could result in accumulation of compounds that could lead to the calcification of the elastin fibers.¹⁰⁹

Patients with pseudoxanthoma elasticum have skin that becomes grooved and thickened over time and has been described as resembling Moroccan leather.¹¹⁰ Other cutaneous features include the development of yellow cutaneous plaques usually in the neck or axillary region or in other flexural sites. Cardiovascular disease results from calcification of the arterial internal elastic lamina. Criteria for the diagnosis of pseudoxanthoma elasticum have been published.¹⁰⁸ Bleeding can result when the calcified vessels rupture. The manifestations include bruising, epistaxis, and bleeding from the uterus, bladder, and joints. GI bleeding occurs in 13% of patients, usually between 20 and 30 years of age, and is usually of gastric origin. Treatment should include the avoidance of gastric irritants and careful control of hypertension and hypercholesterolemia. Regular ophthalmology evaluations are also recommended, as is the avoidance of antiplatelet agents and trauma. First-degree relatives should be screened. The National Association for Pseudoxanthoma Elasticum can be contacted at <http://www.pxenape.org/>.

Scurvy

Humans require vitamin C in the diet to promote the peptidyl hydroxylation of procollagen. In the absence of vitamin C, collagen strands are weakened as a result of abnormal triple helical structures. The abnormal collagen results in defective perivascular supportive tissues, which predispose to capillary fragility and delayed wound healing.^{111, 112}

The clinical manifestations of scurvy depend on the severity of vitamin C deficiency. Patients classically develop perifollicular petechiae (Fig. 50.5).¹¹¹ The petechiae can coalesce and form purpura, particularly in a "saddle" distribution,

and patients may develop gingival or intramuscular hemorrhage. Up to 75% of patients have a multifactorial normochromic, normocytic anemia. Other manifestations include peripheral edema and fatigue.

Patients at risk for scurvy include elderly edentulous patients who cook for themselves, alcoholics, mentally ill patients, and people on unusual diets. The treatment is replacement of ascorbic acid in doses of 200 mg/day.^{111, 113}

Steroid-induced Purpura

Patients on chronic steroids develop thinning of the connective tissues, and minor trauma can result in extensive purpura, especially in older patients. Avoidance of trauma is the best prophylaxis for bleeding in these patients.

Solar Purpura

Senile purpura or solar purpura is a common phenomenon first described in 1817 by Bateman. The lesions are typically located

P.1113

on the extensor surfaces of the forearms and dorsum of the hands and occur without recognized preceding trauma (Fig. 50.6).¹¹⁴ The prevalence in hospitalized patients older than 65 years of age is approximately 5% but increases exponentially with age to include up to 30% of men 90 years of age or older.¹¹⁵ The skin in elderly people is thin as a result of loss of subcutaneous fat and changes in both the amount and quality of collagen. Skin lesions are thought to develop by incidental lateral displacement of slack skin with resulting capillary shearing. The lesions tend to last longer than other purpuric lesions and do not generally undergo the changes in hue that other ecchymotic lesions do.¹¹⁴ Hemostasis tests are normal, and no treatment other than reassurance is indicated.

VASCULITIS

The nomenclature of the vasculitides is quite confusing, but an international consensus conference has developed a system based on vessel size. This classification system recommends abandoning the term hypersensitivity vasculitis in favor of microscopic polyangiitis for small vessel vasculitides with few or no immune complexes and cutaneous leukocytoclastic vasculitis for small vessel vasculitis with isolated skin involvement.¹¹⁶

Cutaneous Leukocytoclastic Vasculitis

Leukocytoclastic vasculitis is characterized by immune complex deposition in postcapillary venules resulting in an inflammatory infiltrate, red cell extravasation, fibrinoid necrosis of the vessel wall, and fragmentation of nuclei (leukocytoclasia). The lesions typically develop 7 to 10 days after exposure to the offending antigen.

Palpable purpura is the classic clinical finding associated with cutaneous small vessel vasculitis. The lesions are the result of extravasation of erythrocytes into the inflamed dermis; therefore, the lesions do not blanch with pressure. The lesions range in size from pinpoint to several centimeters in diameter and are most prominent on the lower legs. The diagnosis should be confirmed by skin biopsy. Evaluation for the etiologic agent can be challenging and requires a detailed history to identify causative agents (Table 50.3).^{117, 118} Helpful laboratory studies include CBC, blood cultures, serum protein electrophoresis, cryoglobulins, hepatitis screen, rheumatoid factor, antinuclear antibody, antineutrophil cytoplasmic antibodies (ANCA), and complement. Systemic involvement should be determined by the history and physical as well as urinalysis, chest radiography, and electrocardiography.

TABLE 50.3 ETIOLOGIES OF LEUKOCYTOCLASTIC VASCULITIS

Underlying disorders

Malignancy (leukemia, lymphoma, myeloma, cryoglobulinemia)

Autoimmune disease (systemic lupus, ulcerative colitis, periarteritis nodosa, Sjögren syndrome, viral hepatitis, primary biliary cirrhosis, etc.)

Infections (viral, bacterial, mycobacterial, fungal)

Drugs/chemicals

Penicillin, aspirin, phenothiazines, tetracycline, retinoids, colony-stimulating factors, contrast dye, insecticides, herbicides

Idiopathic

Antineutrophil Cytoplasmic Antibody-Positive Vasculitis

A major advance in understanding and classifying the vasculitides has been the recognition of ANCA in specific vasculitic syndromes. Patients with ANCA-associated small vessel vasculitis include three major categories, which are histologically identical. Speed in the diagnosis of ANCA-associated small vessel vasculitis is critical, as early treatment with immunosuppressive drugs can prevent life-threatening organ damage.¹¹⁷

Wegener granulomatosis is distinguished by necrotizing granulomatous inflammation and pulmonary, upper respiratory, and renal involvement. Vascular inflammation in these areas can cause epistaxis, hemoptysis, and hematuria. Churg-Strauss disease is defined by the presence of necrotizing granulomas with asthma and eosinophilia. Vasculitis affects the nerves, GI tract, and skin primarily. Microscopic polyangiitis is recognized by the characteristic histology with the absence of asthma and granulomas. This vasculitis typically occurs in males older than 50 years of age. Prodromal symptoms include fever, myalgias, and arthralgias. Microhematuria, proteinuria, and oliguric renal failure may develop, and 30% to 40% of patients develop cutaneous lesions (splinter hemorrhages, palpable purpura). Pulmonary involvement occurs in one-third of patients.

Cryoglobulinemia

Essential cryoglobulinemic vasculitis is a vasculitis with cryoglobulin immune deposits. Cryoglobulins are immunoglobulins (Igs) that form a precipitate in cooled serum. They were first described by Wintrobe and Buell in 1933.¹¹⁹ The cryoglobulins can precipitate in dermal vessels and result in leukocytoclastic vasculitis¹²⁰ and palpable purpura. When the cryocrit is significantly elevated (e.g., in lymphoproliferative diseases), hyaline thrombi can form and result in vasculopathy without associated vasculitis.¹²⁰

Clinically, patients develop crops of purpuric macules, papules, and patches most prominently over the lower extremities that are occasionally associated with burning or pruritus. Cutaneous infarcts and petechiae are also occasionally present. Only rarely are these symptoms precipitated by exposure to cold; more commonly, prolonged standing or exercise is the inciting event. Systemic manifestations of cryoglobulinemia include arthralgias, asthenia, neuropathy, and renal disease.¹²⁰ Cryoglobulinemia is further discussed in Chapter 101.

Hypergammaglobulinemic Purpura

Hypergammaglobulinemic purpura (HP) is a syndrome first described by Waldenström in 1943; this disorder is characterized by polyclonal hypergammaglobulinemia associated with recurrent

P.1114

attacks of palpable or nonpalpable purpura.¹²¹ The syndrome has a marked predilection for women. The onset is often in the third and fourth decades of life, but young children and octogenarians have also been reported to develop this syndrome.¹²² The attacks of purpura are often sudden in onset and sometimes occur after prolonged standing, exercise, dancing, wearing tight-fitting clothes (e.g., jeans), and alcohol ingestion.^{122, 123} Some patients have premonitory symptoms such as stinging, itching, or mild pain before the development of purpura. The purpura typically involves the lower extremities and is palpable in approximately 75% of cases.¹²⁴ Associated systemic symptoms include arthralgias (particularly adjacent to the purpura), low-grade fever, and lower extremity edema. The purpura usually resolves over 2 to 10 days. Recurrences are common but highly variable. Some patients have up to four attacks per week; others have only rare recurrences.¹²⁴

HP can be divided into primary and secondary forms. Primary HP occurs with no underlying disease process; secondary HP is identified when the typical symptoms of HP develop in patients with underlying diseases such as Sjögren syndrome, systemic lupus erythematosus, or other autoimmune, inflammatory, or neoplastic diseases.^{123, 124} The purpuric lesions can occur years before or after the diagnosis of autoimmune disease.

The laboratory features of HP include hypergammaglobulinemia, elevated erythrocyte sedimentation rate, mild anemia, and mild leukopenia. Both primary and secondary HP have a high prevalence of positive rheumatoid factor (88% to 100%).^{123, 124} Anti-Ro antibodies are similarly elevated in both primary HP and HP associated with Sjögren syndrome¹²² and

in up to 100% of HP associated with systemic lupus.¹²⁴ Histopathologically, the lesions show inflammation of the superficial dermal vessels with an early neutrophil infiltrate followed by a mononuclear cell infiltrate and varying degrees of leukocytoclasia. Skin biopsies are often positive under direct immunofluorescence for IgM and IgG. Circulating immune complexes have also been identified.^{121, 124}

Treatment in the past has been described as unsatisfactory.¹²³ However, a recent prospective, nonrandomized trial of 17 patients suggests that milder cases respond to indomethacin or hydroxychloroquine (200 mg twice daily) and more severe cases respond to prednisone at doses more than 20 mg/day.¹²⁴ Plasmapheresis results in only temporary relief of symptoms.¹²⁵

A relative deficiency of IgG₂ has been reported in some patients despite the hypergammaglobulinemia. IgG subclass determination should be considered in HP patients with recurrent infections.¹²⁶

Urticarial Vasculitis

Patients who present with purpura after resolution of urticaria may have urticarial vasculitis. Typically, the urticarial lesions burn, sting, or itch and last longer than 24 hours. The trunk and proximal extremities are affected more than the distal extremities. Residual hyperpigmentation may be present after resolution of the skin lesions. The pathogenesis appears to be due to immune complexes that activate complement and lead to mast cell degranulation. Patients with normal complement levels usually have minimal, if any, systemic involvement, whereas patients with depressed complement levels may have more severe disease.¹²⁷ Hypocomplementemic urticarial vasculitis is due to anti-C1q precipitins.

Acute Infantile Hemorrhagic Edema

Acute infantile hemorrhagic edema is a leukocytoclastic vasculitis confined to the skin in infants 4 to 24 months of age. Patients present with the dramatic onset of ecchymotic purpura involving the limbs and face with inflammatory edema in an otherwise healthy child. Spontaneous and complete resolution occurs in 1 to 3 weeks. Pathology shows leukocytoclastic vasculitis. Perivascular IgA deposits are often identified, and some authors consider this disorder to be a variant of Henoch-Schönlein purpura (HSP).¹²⁸

Henoch-Schönlein Purpura

HSP is an acute vasculitic syndrome with features of colicky abdominal pain, nephritis, arthritis, and palpable purpura. The manifestations of the syndrome were initially described by Schönlein in 1837 and further developed by Henoch in 1874.^{129, 130} The disease occurs primarily in children, with a peak incidence occurring between 4 and 11 years of age. There appears to be a seasonal variation, with most reported cases occurring from fall to spring and a paucity of cases in the summer.^{129, 131} Many of the cases occur after upper respiratory infections. Epidemiologic studies generally suggest that HSP occurs as sporadic cases, but clustering does occasionally occur. In 1987, a series of 20 cases occurred in Connecticut in a 5-month span and were found to be clustered in one ethnic group.¹³² This space-time clustering suggests a possible role for an infectious agent in precipitating the disease. Other infections, medications, insect bites, and malignancy have also been described as potential precipitating factors.

Biopsies of the superficial dermis and bowel in HSP show an acute vasculitis of precapillary arterioles and postcapillary venules. Immunofluorescent staining commonly shows IgA deposits in the walls of the arterioles of both the involved and noninvolved skin.¹³³ In patients with renal involvement, a proliferative and necrotizing vasculitis is described, and IgA deposits are found in the glomerular mesangium.¹³⁴ Circulating immune complexes containing IgA are detected in approximately 70% of patients shortly after the onset of purpura, followed by the appearance of complement and IgA, IgM, and IgG immune complexes later in the disease course.¹³⁵ A variety of genetic polymorphisms that may predispose patients to developing HSP have been investigated.¹³⁶

The onset of symptoms is usually acute, with fever and palpable purpura involving the extremities and buttocks.^{129, 130} The purpuric lesions appear in symmetric crops with a predilection for extensor surfaces of the extremities (Fig. 50.7). They are most abundant around the knees, ankles, and elbows.¹³⁰ A transient oligoarticular arthritis involving the large joints occurs in approximately 40% of cases, and the pain is often out of proportion to the physical findings. Renal involvement is manifest as proteinuria or hematuria. The renal abnormalities are almost always transient in younger children, but up to 20% to 25% of older children and adults have progressive renal disease.^{129, 137} Poor prognostic factors for renal disease include nephrotic syndrome and >50% glomerular crescent formation on renal biopsy.¹³⁸

FIGURE 50.7. Lower extremity palpable purpura in a patient with Henoch-Schönlein purpura. (From Van Hale HM, Gibson LE, Schroeter AL. Henoch-Schönlein vasculitis: direct immunofluorescence study of uninvolved skin. *J Am Acad Dermatol* 1986;15:665-670, with permission.)

P.1115

Diffuse, crampy abdominal pain occurs in more than one-third of the cases and may occur before the characteristic purpura. The abdominal pain can be severe enough to mimic a surgical abdomen, and appears to be due to submucosal bleeding, edema, and ulcerations. Because abdominal pain is common, it is important to be aware that rare complications requiring surgery do occur, and include intussusception, perforation, and bowel necrosis.¹³⁹ An abdominal ultrasound should be considered in the evaluation of abdominal pain, as other studies may miss ileoileal intussusception. GI bleeding presenting as melena or hematochezia can occur and is occasionally severe. Scrotal involvement is not uncommon, affecting up to 20% males, and can mimic testicular torsion.¹⁴⁰

Criteria for the classification of HSP have been published.¹²⁹ The presence of two of the following four criteria can usually accurately differentiate HSP from other forms of vasculitis: Palpable purpura, age of onset 20 years or younger, acute abdominal pain, and biopsy showing granulocytes in the walls of arterioles or venules. A biopsy is not required in children with the classic presentation of HSP. The prognosis depends in part on the age at presentation. Children usually recover completely from HSP, but relapses may occur over a 3- to 6-week period before complete resolution of symptoms.¹²⁹ Adults have more severe disease at presentation, with a worse renal prognosis.¹⁴¹

Supportive care alone is used to treat mild cases. Steroids may be useful to alleviate symptoms in severe cases, but do not prevent renal complications from developing.¹⁴² Nonsteroidal anti-inflammatory drugs are beneficial for symptom relief in some patients, and plasmapheresis is of reported use with renal involvement.¹⁴³ Patients with crescentic nephritis are treated with methylprednisolone, immunosuppressive drugs, plasmapheresis, and renal transplant.

Serum Sickness

Serum sickness is a specific clinical syndrome with systemic features and immune complex-induced vasculitis. The clinical syndrome typically occurs 7 to 12 days after administration of heterologous serum. The features include fever, urticaria, palpable purpura or other rash, and lymphadenopathy.¹⁴⁴ The purpura is caused by immune complex deposition, and skin

biopsies show a necrotizing angitis. Drugs such as cefaclor, penicillin, hydralazine, sulfonamides, and thiazide diuretics have been associated with serum sickness-like reactions.

PURPURA ASSOCIATED WITH INFECTION

Infectious agents can cause petechiae, purpura, and diffuse bleeding manifestations through a variety of mechanisms including disseminated intravascular coagulation, vasculitis, septic emboli, vascular toxins, and direct vascular or endothelial invasion.¹⁴⁵ Certain clinical syndromes in the latter two categories are considered here. Septic emboli are briefly discussed under the section on vascular obstruction.

Acute Febrile Illness with Petechiae

Petechiae are often associated with acute febrile illnesses in children and immediately raise the concern for possible meningococemia. Although a florid meningococcal infection may be instantly recognizable, children who present with small skin hemorrhages and fever, but who are not acutely ill, can be a diagnostic challenge. Petechiae that are present only above the nipple line in the distribution of the superior vena cava are often due to the coughing or vomiting that accompanies the acute infection. Bacterial agents such as streptococcal infections, pneumococcus, and *Haemophilus influenzae* may cause fever and petechiae. Viral illnesses due to enterovirus and adenovirus are well-known causes of fever and petechiae as well. To help clinicians distinguish between the agents responsible (and to avoid missing an early meningococcal infection), algorithms have been developed.^{146, 147}

Papular-purpuric Gloves and Socks Syndrome

Patients with sharply demarcated purpura involving the hands and feet may have a syndrome known as papular-purpuric "gloves and socks" syndrome as shown in Figure 50.8. This syndrome was initially described in 1990¹⁴⁸ and has been confirmed in several other reports.¹⁴⁹ Patients are usually adolescents or young adults that present in the spring or summer with pruritic edema and erythema of the hands and feet. Petechiae and confluent purpura follow, with a relatively sharp demarcation at the wrists and ankles. Oral mucosal involvement is common, and patients may have other systemic signs or symptoms including lymphadenopathy, fever, elevated liver function studies, and cytopenias. Rare presentations may include a perioral petechial rash or more generalized petechial eruption.¹⁵⁰ The syndrome is self-limited and usually resolves within 1 to 2 weeks. The etiologic agent is usually parvovirus B19, but cytomegalovirus, hepatitis B, measles, rubella, and human herpesvirus 6 have also been implicated. Immunohistochemical studies show viral invasion of endothelial and epidermal cells.¹⁵¹

Rickettsial Diseases

Rickettsiae infection results in damage to the endothelial cell with a characteristic multifocal lymphohistiocytic immune response causing increased vascular permeability, decreased perfusion, and activation of coagulation.

Rocky Mountain spotted fever is transmitted by the bite of ixodid ticks and, therefore, has a peak incidence in the United States in May, June, and July. The incubation period is 2 to 14 days (mean, 7 days), and symptoms usually include the sudden onset of fever, chills, headache, and myalgia. A pink macular rash develops on the wrists, hands, and ankles and spreads to cover most of the body. After 2 to 7 days, the lesions become petechial, and hemorrhagic areas may coalesce to form large areas of ecchymosis. The major complications are a result of vascular injury, and multiple organs may become involved. Diagnosis is based on serologic studies showing a rise in antibody titers or biopsy of the skin lesions with immunofluorescent identification of the organisms. Treatment is with a tetracycline or chloramphenicol.

Other rickettsial diseases such as Mediterranean spotted fever, Asian tick typhus, and Queensland tick typhus are generally milder and have an eschar (tache noire) at the site of the primary tick bite. The treatment is the same as for Rocky Mountain spotted fever.¹⁵²

Brazilian Purpuric Fever

Brazilian purpuric fever is a disease of pediatric patients that usually begins with purulent conjunctivitis followed 7 to 16 days later by acute onset of fever, bacteremia, petechiae purpura, and vascular collapse. The etiologic agent is *H. influenzae* biogroup *aegyptius*. The purpuric tendency appears to be due to direct invasion of endothelial cells with subsequent vascular damage.¹⁵³

Rat Bite Fever

Rat bite fever is an acute illness caused by rodent bite or exposure due to organisms that are part of their normal oral flora. Over 200 cases have been reported in the United States.¹⁵⁴ Most U.S. cases are caused by *Streptobacillus moniliformis*, whereas cases in Asia are due to *Spirillum minus*. The onset of symptoms

P.1116

is usually within 1 week of the bite but can occur several weeks after the wound has healed. Initial symptoms include abrupt onset of fever, chills, headache, malaise, and cough followed in 75% by morbilliform or petechial rash involving the palms and soles. Hemorrhagic vesicles on the peripheral extremities may be particularly suggestive of the diagnosis.¹⁵⁴ Migratory polyarthritides develops in 50% of patients with the *Streptobacillus* type. The case mortality rate if untreated is 10%. Treatment is with procaine penicillin, tetracycline, or streptomycin.

with permission.)

Strongyloides

Strongyloides stercoralis is endemic to parts of South America, Central Africa, South East Asia, and the Southern United States (particularly Kentucky and Tennessee).¹⁵⁵ Disseminated strongyloidiasis can occur in patients receiving chemotherapy or steroids, and in otherwise immunocompromised patients. Periumbilical purpura that resembles “multiple thumbprints” has been described,¹⁵⁶ and it appears to be associated with a poor prognosis. More diffuse purpura may develop as well. Biopsy of the skin lesions frequently reveals larva.¹⁵⁷ Other bleeding manifestations include alveolar hemorrhage and GI bleeding.

Vibrio vulnificus

An increasing number of infections caused by *Vibrio vulnificus* are being reported in the United States, particularly in Gulf coastal communities. The consumption of raw oysters is one of the primary mechanisms of infection along with localized wound infections due to exposure to infected salt water. Almost all patients are immunocompromised because of liver disease, diabetes, hemochromatosis, or steroid use.¹⁵⁸ Patients present with abrupt onset of fever, chills, hypotension, and the development of hemorrhagic bullae. These bullae can develop into necrotic ulcers. The hemorrhagic complications appear to be due to a secreted metalloprotease, which has prothrombin-activating and fibrinolytic activities.¹⁵⁹

Hemorrhagic Fever Viruses

The hemorrhagic fever viruses are a diverse group of small RNA viruses with a lipid envelope. The clinical presentations vary, but symptoms usually begin with fever, headache, and myalgias progressing to generalized malaise. These symptoms last 3 to 4 days and are followed by petechiae, mucosal bleeding, and GI tract hemorrhage. However, infection of the endothelium may be common to all,¹⁶⁰ and direct disruption of endothelial cells may occur. Some of the viruses have almost no cytopathologic effect; however, others are highly destructive to the endothelial cells. Activation of immune cells with the release of cytokines and chemokines that target endothelial cells is another suggested mechanism of damage.¹⁶¹ Release of tissue factor from damaged cells can trigger coagulation abnormalities,¹⁶² and varying degrees of thrombocytopenia and disseminated intravascular coagulation are present and contribute to the bleeding diathesis.

The major etiologic agents and the distinctive clinical features are outlined in Table 50.4.¹⁶³ A high index of suspicion is required to diagnose hemorrhagic fever virus. Risk factors for naturally occurring cases include foreign travel, handling of animal carcasses, contact with sick animals or people, and arthropod bites within 21 days of the onset of symptoms. Lack of identifiable risk factors should raise the suspicion of a bioterrorist attack.

Rapid diagnosis is currently available only by sending clinical specimens to the Centers for Disease Control and Prevention or the U.S. Army Medical Research Institute of Infectious Disease in Frederick, Maryland. Suspected cases should be reported immediately to the health department. Protective measures from nosocomial spread should be followed.

PURPURA ASSOCIATED WITH VASCULAR OBSTRUCTION

Although oversimplified, it is often convenient to think of some disorders as causing purpura by intravascular obstruction with subsequent hemorrhage due to necrosis, vasculitic injury, or consumptive coagulopathy. Table 50.5 lists disorders that can be grouped together as causing abruptly decreased blood flow with

P.1117

subsequent bleeding. Note that cold agglutinins are not included because necrosis and bleeding are not expected complications.

TABLE 50.4 HEMORRHAGIC FEVER (HF) VIRUSES

Viral HF	Cytopathic Effect	Endothelial Cell Infection	Cytokine Activation	Disseminated Intravascular Coagulation
South American HF	±	++	++++	No
Lassa fever	±	++	+++	No
Rift Valley fever	++++	?	?	Yes
Crimean Congo HF	+	+	?	Yes

Hantavirus pulmonary syndrome	O	++++	++++	No
Filovirus HF	+++	+++	+++	Yes
Yellow fever	++	?	?	No

O, no effect; ±, negligible effect; +, through; +++++, minimal to major effect; ? = unknown.

TABLE 50.5 CLASSIFICATION OF BLEEDING DISORDERS ASSOCIATED WITH VASCULAR OBSTRUCTION

Vascular Obstruction

Component	Disease Examples
Thrombus	Warfarin-induced skin necrosis, disseminated intravascular coagulation
Emboli	
Thromboemboli	Atrial fibrillation
Septic emboli	Endocarditis
Marantic emboli	Sterile endocarditis
Cholesterol emboli	Invasive vascular procedures, warfarin blue-toe syndrome
Immunoglobulins	Waldenström macroglobulinemia, myeloma
Plasma proteins	Cryoglobulinemia
Fibrin	Cryofibrinogenemia
Red cells	Polycythemia
Platelets	Thrombocytosis, heparin-induced skin necrosis
Fat	Fat emboli syndrome

Cryofibrinogenemia

Cryofibrinogens are cold-precipitable plasma proteins that dissolve as plasma is rewarmed. The proteins are distinct from cryoglobulins, which precipitate on cooling of serum (after the plasma proteins have been removed). Approximately 3% to 13% of hospitalized patients have detectable cryofibrinogens when appropriate assays are used.^{164, 165} Cryofibrinogens can be associated with underlying malignancies or inflammatory processes (secondary cryofibrinogenemia) or be present as an isolated finding (essential cryofibrinogenemia).

Although patients with cryofibrinogenemia are often asymptomatic, they may present with symptoms of lower extremity or acral ulcers, cold intolerance, cutaneous purpura, livedo reticularis, gangrene, or Raynaud phenomenon.¹⁶⁶ Paradoxical bleeding may occur and appears to be proportional to the cryocrit.¹⁶⁵ Many patients have an elevated total fibrinogen level.¹⁶⁴ It is hypothesized that the abnormal cryofibrinogen is due to high levels of α_1 -antitrypsin and α_2 -macroglobulin that inhibit plasmin, resulting in decreased fibrinolysis.¹⁶⁵ The cutaneous lesions develop as a result of fibrin thrombi obstructing the small and medium-sized dermal vessels.¹⁶⁶ Biopsies from the edge of ulcers show eosinophilic thrombi with sparse lymphocytic infiltrate.¹⁶⁷ Leukocytoclastic vasculitis has also been described.¹⁶⁸ To measure cryofibrinogens, blood should be anticoagulated with ethylenediaminetetraacetic acid, citrate, or oxalate. The sample should be maintained at 37°C until centrifuged, and the separated plasma should be chilled at 4°C for 72 hours. Chilling the sample in this way increases the sensitivity for detection. The cryocrit is expressed as a percentage of the plasma sample volume.

Cryofibrinogenemia may be asymptomatic and require no treatment. Mild cases can be treated with avoidance of cold, and procedures that include cooling. Patients with more severe symptoms are usually treated with streptokinase, other fibrinolytic agents, or plasmapheresis. A small clinical trial and case reports have suggested that stanozolol, an androgenic steroid with fibrinolytic activity, can produce excellent results.^{166, 169} Immunosuppressant agents have been reported to be effective in some patients.¹⁶⁷ Heparin use is discouraged.¹⁶⁵

Cholesterol Embolization Syndrome

Cholesterol embolization syndrome is an increasingly recognized disorder caused by dislodged cholesterol crystals from atherosclerotic plaques. This occurs after vascular procedures or can be due to warfarin (blue-toe syndrome) and results in renal insufficiency, peripheral emboli, and possibly GI or central nervous system involvement. Livedo reticularis is the most common skin finding and can be best appreciated with the patient in the upright position. Cyanosis, purpura, ulcers, and gangrene can all occur.¹⁷⁰ Biopsies of the cutaneous lesions, including livedo reticularis, demonstrate thrombi with cholesterol "clefs," since the cholesterol is dissolved during fixation.

Fat Emboli Syndrome

Fat emboli syndrome is poorly understood. It is characterized by hypoxemia, tachypnea, petechiae, and changes in mental status occurring after long bone and pelvic fractures or intramedullary fixation. It may result from release of fat from bone marrow resulting in diffuse microvascular fat emboli. Although embolization of fat is common after trauma, only a few patients develop the fat emboli syndrome. Pulmonary dysfunction typically occurs 12 to 24 hours after fracture or operative fixation and is

P.1118

manifested as hypoxemia and tachypnea. The delay in symptoms suggests the role of a biochemical reaction leading to lung toxicity. Forty percent of patients develop petechiae, particularly in the axilla and subconjunctiva 24 to 48 hours after the event. Up to 70% of patients develop mental status changes.¹⁷¹ Fat droplets can be identified on bronchoalveolar lavage, and fat globules have been identified in pulmonary capillary blood obtained through a wedged pulmonary artery catheter.

Silicone Embolism Syndrome

Liquid silicone is an inert material used in illegal subcutaneous injections for breast augmentation and other cosmetic procedures. A recent review of the literature showed many similarities with the fat emboli syndrome in 33 patients. The most common symptoms are respiratory distress and hypoxemia occurring within 72 hours of the procedure with fever, alveolar hemorrhage (64%), and petechiae (18%). Six patients presented with neurologic symptoms occurring during or several hours after the injections and all patients deteriorated rapidly. Transbronchial biopsies show vacuolated globular deposits of silicone in the interstitial capillaries.¹⁷²

Septic Emboli

Calciophylaxis

Calciophylaxis is a small vessel vasculopathy characterized by calcifications of the tunica media of small to medium-sized cutaneous and subcutaneous vessels. The vasculopathy leads to development of tissue ischemia, necrosis of the skin and subcutaneous fat, and sometimes deeper tissues. Patients typically have end-stage renal disease and are on hemodialysis, but the disorder has now been described in a variety of other conditions. Clinically, painful dusky, purple-hued subcutaneous nodules and induration occur on the trunk, buttocks, or proximal extremity, and can progress to necrotic ulcers with eschars. In retrospective review, obesity, liver disease, steroid use, calcium phosphate product of >70 mg²/dl, and an aluminum >25 ng/ml were identified as risk factors. The diagnosis is usually made by biopsy of one of the lesions showing calcification of the tunica media with intimal proliferation and microthrombosis. Treatment involves lowering the calcium phosphate product when elevated by using sevelamer hydrochloride as a substitute for calcium phosphate binders, and decreasing the phosphate intake and calcium in the dialysate bath. Elevated parathyroid levels can be managed with calcimimetic agents or parathyroidectomy. Wound management is of key importance, as sepsis is the leading cause of death.¹⁷³

Livedoid Vasculopathy

Livedoid vasculopathy is a cause of lower extremity purpura progressing to shallow ulcerations that heal with atrophic hypopigmented scarlike plaques (atrophie blanche). Biopsy of the lesions shows hyaline vascular changes with intraluminal thrombosis. It is associated with multiple coagulation abnormalities.¹⁷⁴

PURPURA ASSOCIATED WITH SKIN DISEASES

Pigmented Purpuric Dermatitis

Pigmented purpuric eruptions encompass a group of related skin diseases that have in common the clinical appearance of red-brown skin pigmentation (caused by hemosiderin deposits) associated with purpura or petechiae. These lesions tend to develop on the lower extremities of middle-aged people and are usually chronic. Histologically, there is a mononuclear upper dermal infiltrate without evidence of leukocytoclasia. Extravasated red blood cells are present around the

capillaries, and hemosiderin deposits are found in older lesions. Six skin diseases are commonly classified as pigmented purpura. In Schamberg progressive pigmentary dermatosis, the lesions appear as orange-brown patches of skin with "cayenne pepper spots" at the borders or within the lesion (Fig. 50.9). Majocchi purpura annularis is distinguished by an annular 0.5- to 2.0-cm patch of reddish-brown macules. Eczematoidlike purpura has a seasonal pattern and appears as pinpoint lesions that spread rapidly over 2 to 4 weeks and develop a slight scale. The lesion in pigmented purpura lichenoid dermatitis (Gougerot-Blum purpura) is a reddish-brown macule with telangiectasias. These lesions tend to coalesce and form plaques. Itching purpura presents with an acute onset of pigmented macules associated with severe pruritus. Lastly, lichen aureus is described as "grouped copper-orange to purple lichenoid papules forming an irregular, usually singular, plaque."¹⁷⁵ The etiology of pigmented purpura is unknown, but some degree of venous stasis is apparent in many patients and may be a factor in its development. The importance of these lesions is to differentiate them from other causes of chronic purpura with hemosiderin deposits such as purpura associated with abnormal proteins. The lesions may clear in up to two-thirds of patients with long-term follow-up.¹⁷⁶ Some patients with longstanding pigmented and purpuric dermatitis develop mycoses fungoides, and the differentiation between mycoses fungoides and pigmented purpuric lesions can sometimes be difficult.¹⁷⁷

FIGURE 50.9. Skin lesions associated with Schamberg progressive pigmentary dermatosis. Note the irregular patches of punctate hemorrhagic lesions with yellow-brown discoloration of hemosiderin deposits. (From Sherertz EF. Pigmented purpuric eruptions. *Semin Thromb Hemost* 1984;10:190-195, with permission.)

Pigmented purpuric eruptions have been described in children¹⁷⁸ (Fig. 50.10), and may be familial. Treatment in the past has been with fluorinated steroids, but recently, psoralen

P.1119

plus ultraviolet light of A wavelength has been found to be effective in some cases.¹⁷⁹

Purpuric Contact Dermatitis

Purpura can be a presenting sign of allergic contact dermatitis and is often due to textile dyes in clothing. This diagnosis should be considered in patients who develop purpura only in areas of skin contact with clothing. Several allergens in textile dyes have been identified.¹⁸⁰ Other reported antigens include benzoyl peroxide, epoxy resin, and agave sap.¹⁸¹

Drug Reactions

Drug reactions can cause nonthrombocytopenic purpura by a number of different mechanisms, including leukocytoclastic vasculitis, serum sickness, and, occasionally, a pigmented purpura. Some of the drugs associated with pigmented purpuric dermatosis include acetaminophen, aspirin, glipizide, hydralazine, meprobamate, dipyridamole, creatine, thiamine, interferon, injected medroxyprogesterone acetate, and infliximab.¹⁸² A fixed drug reaction can occur, with an isolated purpuric appearing lesion occurring in a location without preceding trauma (Fig. 50.11).

FIGURE 50.11. A fixed drug eruption lesion. This 30-year-old woman developed this thigh lesion after taking ibuprofen. (This photograph was kindly provided by Dr. Pamela Nemzer, Department of Dermatology, University of Utah Health Sciences Center.)

PSYCHOGENIC PURPURA

Autoerythrocyte Sensitization

Autoerythrocyte sensitization is a rare disorder characterized by recurrent spontaneous ecchymotic lesions in patients with otherwise normal hemostasis. The syndrome was first described in 1955 by Gardner and Diamond after their discovery that intradermal injections of autologous red blood cells reproduced the skin lesion.¹⁸³ Since the original description, more than 200 cases have been described, with the largest series collected by Ratnoff.¹⁸⁴

The cutaneous lesions are usually preceded by localized symptoms, including pain and a burning or stinging sensation in the involved area. The area then becomes erythematous, raised, and warm, and within hours, ecchymoses occur in the inflamed area. The ecchymoses can range in size from 1 to 2 cm to extensive involvement of the trunk or an extremity. The erythema and swelling usually subside within 48 hours of the development of ecchymoses. The lesions can recur weeks to years later. The ecchymotic lesions are usually only one symptom among many. Patients commonly have systemic symptoms including headaches, paresthesias, syncopal episodes, abdominal pain, nausea, vomiting, chest pain, dyspnea, dysuria, and arthralgia.

Autoerythrocyte sensitization typically affects adolescent to middle-aged females who have significant underlying emotional problems. Patients are commonly found to suffer from depression, anxiety, and inability to handle hostile feelings, as well as hysterical and masochistic character traits. They have often sustained significant physical and emotional trauma in the past, and up to two-thirds of the patients describe significant emotional stress present at the time the initial purpuric lesions develop.

The skin lesions can classically be reproduced in most patients with the intradermal injection of 0.1 ml autologous whole blood, packed red blood cells, or red cell stroma. However, this test has limited sensitivity, and some authorities recommend using clinical criteria to diagnose this disorder.¹⁸⁵ No specific therapy is of proven value in psychogenic purpura. Psychotherapy appears to be beneficial in some younger patients but is less effective in the older population.¹⁸⁶

Autosensitivity to DNA

A similar syndrome of recurrent ecchymoses after a prodrome of localized itching was described in 1961 by Levin and Pinkus.¹⁸⁷ This patient developed the typical skin lesions described above after the intradermal injection of frozen and thawed buffy coat leukocytes or purified calf thymus DNA. There are few data concerning the emotional background of these patients. Since the initial description, a few other cases have been reported, but some of these also had a positive reaction to intradermal injection of blood or washed red cells. Chloroquine can induce remissions, and cyproheptadine was useful in one patient.^{188, 189, 190}

Factitious Purpura

Self-inflicted ecchymoses can be difficult to diagnose. This disorder should be considered when there is a clear secondary gain present, when the lesions only occur in accessible areas, or when ecchymotic lesions assume unusual shapes. Circular, wellcircumscribed lesions around the upper limbs and breasts may be a result of sucking of the skin.

Religious Stigmata

Purpuric religious stigmata are bruises that allegedly occur spontaneously and resemble the wounds of the crucified body of Christ. The phenomenon usually occurs in women, and many have belonged to a religious order. The etiology is unknown.¹⁸⁴

Chapter 51

Thrombocytosis and Essential Thrombocythemia

George M. Rodgers

Robert T. Means, Jr.

The normal reference interval for platelet counts in adults approximates 150,000 to 450,000/ μ l; patients with platelet counts higher than the upper limit of normal have thrombocytosis, which can be broadly classified as reactive (secondary), essential (clonal or primary), or inherited (Table 51.1). Routine screening of healthy individuals has identified persons with asymptomatic thrombocytosis; some of these people will have essential thrombocythemia (ET).¹ In contrast, hospitalized patients with elevated platelet counts usually have reactive thrombocytosis (RT).² At least 90% of all patients with thrombocytosis have RT due to an underlying clinical disorder.³ It is important to distinguish ET from RT or inherited thrombocytosis because patients with the former disorder may be at risk of ischemic or bleeding complications, or evolution to myelofibrosis or acute leukemia, whereas patients with the latter disorders usually require only treatment of their underlying medical condition, with minimal or no treatment in the case of inherited thrombocytosis.

REACTIVE (SECONDARY) THROMBOCYTOSIS

Epidemiology and Pathophysiology

A retrospective Turkish survey of the incidence and etiology of thrombocytosis over a 5-year period demonstrated that of 124,340 patients who had platelet counts determined, 2,000 patients (1.6%) had at least one platelet count \geq 500,000/ml.⁴ RT was identified in 96.7% of these 2,000 patients, with infection being the most common cause of RT.⁴ Another survey found that tissue injury (surgery) was the most common cause of RT.⁵

Increased thrombopoiesis seen in infectious, inflammatory, or malignant disorders results from cytokines and other acute-phase response mediators active in these circumstances. Mediators that have been linked to RT include interleukin (IL)-6⁶ and thrombopoietin (TPO).^{6, 7} TPO may act as an acute-phase protein in some, but not all circumstances.⁷ Both thrombocytosis⁸ and thrombocytopenia⁹ have been reported in iron-deficiency anemia. Patients with solid tumors (e.g., lung, ovarian cancers) have a 30% to 40% incidence of thrombocytosis.^{3, 6} Extreme thrombocytosis may occur after splenectomy³ or in patients with hyposplenism or asplenia.¹⁰

TABLE 51.1 CLASSIFICATION OF THROMBOCYTOSIS

Reactive (Secondary)	Clonal (Primary)	Inherited
Infection	Essential thrombocytosis	<i>THPO</i> mutations
Inflammation	Other myeloproliferative neoplasms: <i>MPL</i> mutations	
Malignancy	Polycythemia vera	
Iron deficiency	Chronic myeloid leukemia	
Hemolytic anemia	Myelofibrosis	
Post-splenectomy	Myelodysplasia	
Recovery from thrombocytopenia		
Tissue injury:		
Surgery		

Burns

MPL, thrombopoietin receptor gene; *THPO*, thrombopoietin gene.

Treatment

Although no trials have formally addressed the need for treating RT, the general recommendation is not to treat the elevated platelet count, either with antiplatelet or with myelosuppressive therapy.³ However, there are case reports describing thrombotic events in RT patients¹¹ and studies identifying a thrombosis risk in hospitalized patients or cancer patients with RT.¹² In general, these patients have well-established cardiovascular risk factors, such as smoking,¹¹ diabetes, older age, and the like, or they have venous thromboembolism risk factors such as cancer,¹² or as seen in a hospitalized population. One approach may be that when RT is encountered in such patients with cardiovascular risk factors, antiplatelet therapy can be considered. Hospitalized patients with RT should receive venous thromboembolism prophylaxis, and primary therapy for all RT patients should focus on treating the underlying disorder.

Inherited Thrombocytosis

Inherited thrombocytosis is suspected in patients with a lifelong history of asymptomatic thrombocytosis, especially if other family members are also affected. The genetic mutations in inherited thrombocytosis are heterogeneous and may or may not involve mutations in the thrombopoietin gene (*THPO*) or its receptor (*MPL*).³ At least four different mutations in *THPO* associated with increased TPO production and inherited thrombocytosis have been described in European and Japanese kindreds.¹³ Thrombocytosis was inherited in an autosomal dominant manner in all four families. The TPO molecule in these patients is normal, and increased translation appears to explain elevated levels of TPO in these patients.¹³ At least three different *MPL* mutations have been linked to inherited thrombocytosis; affected kindreds are of European, African-American, Arabic, and Japanese ancestry.¹³ Approximately 7% of African-Americans are heterozygous for the *MPL*-Baltimore mutation.¹⁴ Thrombocytosis in patients with *MPL* mutations appears to result from either constitutive receptor activation or reduced receptor binding affinity for TPO.¹³

Clinical findings in patients with inherited thrombocytosis can be classified by whether the patients have *THPO* or *MPL* mutations. In general, those with *THPO* mutations have elevated TPO levels and mild splenomegaly, but a low incidence of vascular complications and low risk of evolution to acute leukemia and myelofibrosis,¹³ although development of bone marrow disease was described in two family members with inherited thrombocytosis due to *THPO* mutations.¹⁵ Some patients with *MPL* mutations and inherited thrombocytosis have been reported to experience thrombosis, splenomegaly, and myelofibrosis, but these complications have not been reported in African-American patients with *MPL*-Baltimore.¹³

P.1123

Clonal Thrombocytosis Other Than Essential Thrombocytosis

Clonal or primary thrombocytosis includes not only ET (discussed later) but also a prominent feature of the other myeloproliferative neoplasms and certain myelodysplastic syndromes. Between 35% and 50% of patients with chronic myeloid leukemia (CML), polycythemia vera, or myelofibrosis may have elevated platelet counts.^{5, 16} The diagnosis, clinical aspects, and management of these disorders are discussed in Chapters 81, 82 and 83.

Clonal thrombocytosis is also seen in myelodysplastic syndromes associated with certain cytogenetic features (trisomy 8,¹⁷ 5q- syndrome,¹⁸ and chromosome 3 abnormalities¹⁹), as well as the presence of ringed sideroblasts.²⁰ However, the frequency of thrombocytosis in myelodysplasia is lower than in the myeloproliferative neoplasms. Myelodysplastic syndromes are discussed in Chapter 79.

DIFFERENTIAL DIAGNOSIS AND CLINICAL APPROACH TO THROMBOCYTOSIS

When evaluating a patient with thrombocytosis, the key consideration is to exclude ET and CML²¹ from reactive or inherited thrombocytosis and other disorders. Thrombocytosis may be a presenting feature of CML.²¹ Inasmuch as CML patients are at risk of conversion to acute leukemia, and there is targeted therapy for CML, BCR-ABL, and cytogenetic testing is important in patients with thrombocytosis who do not have inherited or reactive etiologies. Patients with RT usually will have major symptoms of an underlying inflammatory, infectious, or malignant disorder. However, patients with occult malignancy may initially present without obvious cancer symptoms. Post-splenectomy thrombocytosis will usually be obvious, but patients with asplenia or hyposplenia will be identified by observing Howell-Jolly bodies on the blood smear and by abdominal imaging showing a vestigial spleen or no splenic tissue. The World Health Organization (WHO) criteria for ET are discussed in the next section, and focus on distinguishing essential thrombocytosis from the

other myeloproliferative neoplasms. These criteria provide no direct definitions of RT. Thus, the physician is left with practical clinical criteria to suggest an RT if a patient does not have an obvious underlying disorder. Such criteria might include the presence of fever, an elevated C-reactive protein or erythrocyte sedimentation rate, a blood smear showing reactive or toxic changes in the leukocytes, the presence of iron deficiency, or the post-splenectomy state.^{3, 5}

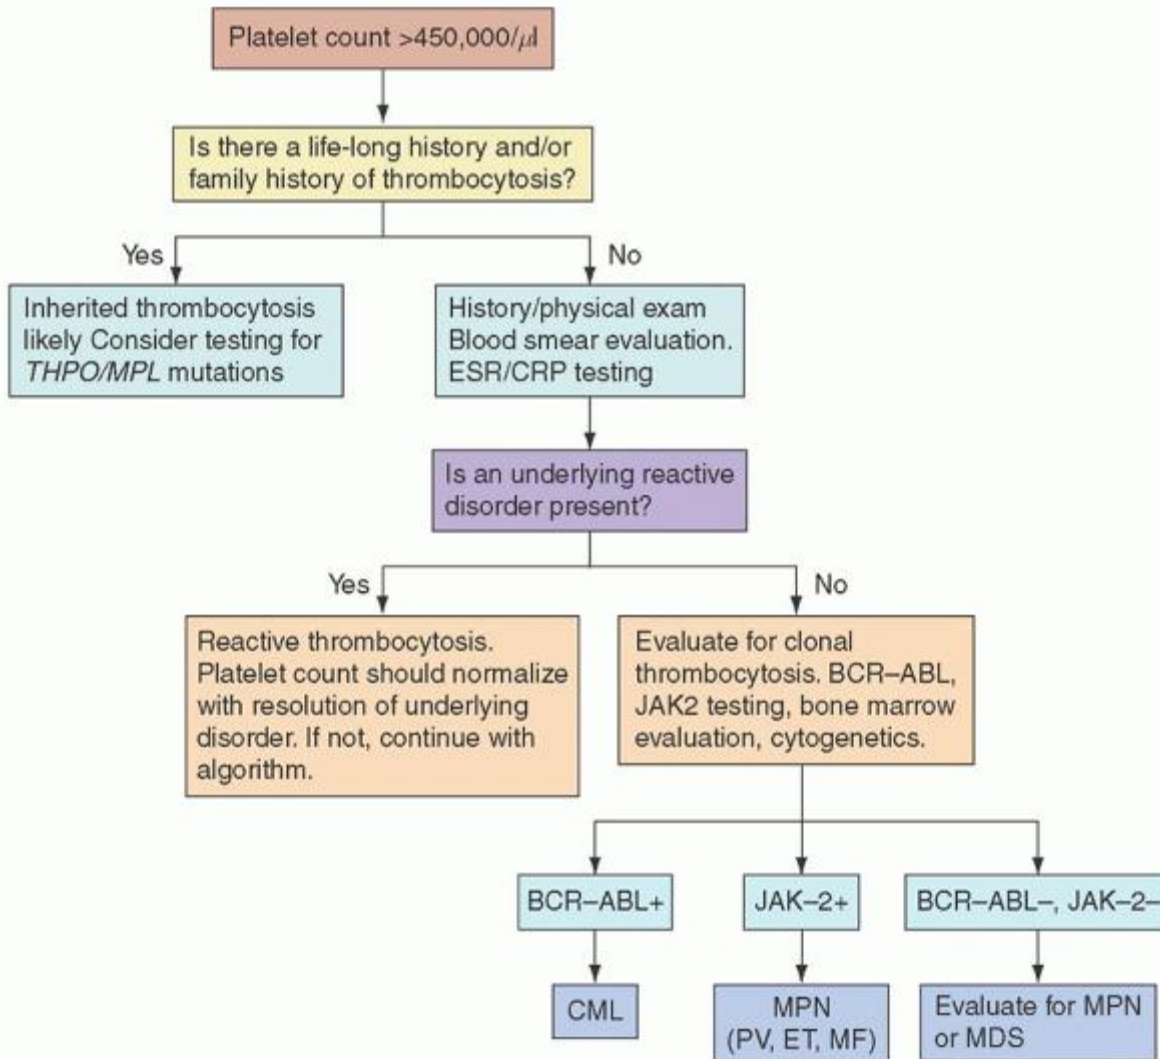

FIGURE 51.1. An approach to evaluating thrombocytosis. A life-long personal history and family history of thrombocytosis would suggest a diagnosis of inherited thrombocytosis. If that diagnosis is excluded, reactive etiologies should next be considered. If an underlying cause is identified and is treatable, thrombocytosis should resolve with appropriate therapy. If neither inherited nor reactive thrombocytosis is likely, testing for clonal thrombocytosis should be performed; this should include BCR-ABL and JAK2 testing. The appropriate tests include bone marrow evaluation and cytogenetics for myeloproliferative neoplasms and myelodysplasia. CML, chronic myeloid leukemia; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; MF, myelofibrosis; ET, essential thrombocythemia; MDS, myelodysplasia; MPL, thrombopoietin receptor gene; MPN, myeloproliferative neoplasms; PV, polycythemia vera; THPO, thrombopoietin gene.

One approach to the evaluation of thrombocytosis is shown in Figure 51.1. Inherited thrombocytosis can be rapidly excluded if there is no life-long history of thrombocytosis and the family history is negative. Patients who may possibly have inherited thrombocytosis can be further evaluated with testing for THPO and MPL mutations. Because >90% of patients with thrombocytosis will have a reactive etiology,^{3, 4, 5} significant effort should be made in excluding secondary thrombocytosis before considering testing for myeloproliferative neoplasms, including ET.

ESSENTIAL THROMBOCYTHEMIA

Definition

ET is a clonal myeloproliferative disorder characterized by excessive production of platelets that is independent of usual drivers of thrombocytosis. This thrombocytosis is in many ways analogous to the erythrocytosis characteristic of the related disorder, polycythemia vera. This “family resemblance” between what we now

P.1124

recognize as BCR/ABL-negative myeloproliferative disorders was initially pointed out by William Dameshek more than 60 years ago.²²

Epidemiology

Evolving diagnostic criteria (discussed below) make it difficult to characterize the incidence and prevalence of ET. In studies published between 2001 and 2008, an incidence of 1.5/100,000 was reported.^{23, 24} Prevalence based on insurance claims data in the northeastern United States has been reported to be 24 cases/100,000 population.²⁵ However, these reports antedate the 2008 revision of the WHO diagnostic criteria for ET, which includes a lower platelet threshold and could potentially alter the reported prevalence and incidence.

The median age at diagnosis is in the mid-50s in large reported series, and females represent 60% to 70% of cases.^{26, 27} Cases have been reported in children but are uncommon.^{28, 29, 30} First-degree relatives of ET patients have an increased risk of ET.³¹

Risk for developing ET appears to be associated with environmental factors linked to other myeloid neoplasms, such as radon and gamma irradiation.^{32, 33} Hairdressers, electricians, and farmers appear to be at increased risk to develop ET compared to other occupations, although it should be remembered that these risks are still quite low.^{32, 33}

Diagnostic Criteria

For many years, the diagnosis of ET was based on the demonstration of significant sustained thrombocytosis (typically greater than $600 \times 10^9/L$) in the absence of a reactive etiology.³⁴ However, the observation that a specific gain-of-function mutation in Janusassociated kinase 2 (JAK2V617F) is found in virtually all cases of polycythemia vera and in most cases of ET,^{35, 36} provided an additional positive criteria for the diagnosis of ET.

The 2008 revision of the WHO criteria for the diagnosis of ET is shown in Table 51.2.³⁴ The first criterion represents a reduction in the threshold for thrombocytosis from $600 \times 10^9/L$ to what is in essence the upper limit of the normal platelet count and addresses concerns that the higher threshold prevented the detection of early disease.^{37, 38, 39} The second criterion requires demonstration of the characteristic bone marrow morphology of ET.⁴⁰

As discussed earlier in this chapter, a number of other myeloid neoplasms may be associated with thrombocytosis. This is particular true when employing the lower platelet threshold of the 2008 criteria. Polycythemia vera is excluded by the absence of an elevated hematocrit or hemoglobin concentration with adequate iron stores demonstrated on a Prussian blue-stained marrow specimen or a normal serum ferritin: if iron stores are absent, a trial of iron replacement that does not elevate the hematocrit or hemoglobin above normal is required.³⁴ Primary myelofibrosis is excluded by the absence of excessive reticulin deposition on the marrow biopsy. Chronic myelogenous leukemia is excluded by the absence of the BCR/ABL mutation. Myelodysplastic syndromes and other myeloid neoplasms are excluded by absence of characteristic marrow abnormalities, such as ringed sideroblasts.⁴¹

TABLE 51.2 WORLD HEALTH ORGANIZATION DIAGNOSTIC CRITERIA FOR ESSENTIAL THROMBOCYTHEMIA

Diagnosis requires meeting all four criteria

1. Sustained platelet count $\geq 450 \times 10^9/L$
2. Bone marrow biopsy specimen showing proliferation mainly of enlarged mature megakaryocytes; no significant increase or left shift of neutrophil granulopoiesis or erythropoiesis
3. Not meeting criteria for polycythemia vera, primary myelofibrosis, chronic myelogenous leukemia, myelodysplastic syndrome, or other myeloid neoplasm (details discussed in text)
4. Demonstration of JAK2V617F or other clonal marker; or, in the absence of a clonal marker, no evidence for reactive thrombocytosis. However, the presence of a condition associated with reactive thrombocytosis does not exclude essential thrombocytosis if first three criteria are met

Modified from Tefferi et al., Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. *Blood* 2007;110:1092-1097.

In the absence of the JAK2V617F mutation, exclusion of nonclonal reactive processes remains a key element of the diagnosis of ET. Etiologies of RT specifically cited in the criteria that should be excluded by history or laboratory studies include iron deficiency, previous splenectomy, recent surgery, active inflammation, connective tissue disorders, metastatic cancer, and lymphoproliferative diseases.³⁴ In polycythemia vera, mutations of JAK2 in exons other than the site of the V617F mutation have been found in a significant number of JAK2V617F-negative cases.⁴² Similar findings have not been reported for ET.

The 2008 revised criteria have generally performed well in validation studies,^{43, 44} although at least one study suggests that they function poorly in distinguishing ET from early stage primary myelofibrosis.⁴⁵ They also may be of less utility in children with ET, who are often polyclonal and JAK2V617F-negative.^{46, 47}

Pathophysiology

In polycythemia vera, in vitro studies of erythroid progenitors have shown hypersensitivity to erythropoietin or erythropoietin independence,⁴⁸ as well as hypersensitivity to other growth factors such as IL-3 or granulocyte-macrophage colony stimulating factor (GM-CSF).^{49, 50} In an analogous manner, megakaryocyte progenitors from ET patients have been reported to show a similar response pattern to IL-3, GM-CSF, and/or IL-6 in vitro.^{51, 52} Such studies provide some rationale for a proposed hypothesis that inflammation may be a driver of clonal evolution in ET.⁵³

However, the primary focus of pathophysiologic investigation in ET is on specific mutations found in myeloproliferative disorders and their contributions to its pathogenesis. The involved or potentially involved genes include JAK2, ASXL1 (additional sex combs-like 1), CBL (Casitas B-lineage lymphoma), DNMT3A (DNA methyl transferase 3α), EZH2 (enhancer of zeste homolog 2), IDH1 (isocitrate dehydrogenase 1) and IDH2, LNK (lymphocyte specific adaptor protein), the TPO receptor/ligand MPL (myeloproliferative leukemia virus), SF3B1 (splicing factor gene B1), NF1 (nuclear factor 1), SUZ12 (suppressor of zeste 2 homolog), and TET2 (ten-eleven translocation oncogene family member 2).^{54, 55, 56} Brecqueville and colleagues studied several of these genes in 53 ET patients. A total of 70% of patients had mutations in one or more of the genes studied (Table 51.3).⁵⁴

JAK2V617F is the most common mutation found in ET, and is detected in 50% to 75% of patients.^{54, 57, 58} As Table 51.3 indicates, it may occur alone or with other mutations. As noted earlier, JAK2V617F is a gain-of-function mutation resulting in constitutive activation of signaling through the JAK/STAT pathway.³⁶

Expression of JAK2V617F in hematopoietic progenitors in vitro or in whole animals leads to a myeloproliferative disorder phenotype resembling polycythemia vera.^{59, 60, 61} It has been proposed that the extent of the JAK2V617F allele burden distinguishes ET from polycythemia vera.⁶² However, JAK2 mutations do not appear to be universally present in ET, and data from other myeloproliferative disorders suggest it is a late pathogenetic event.⁶³ The precise mechanistic contributions of JAK2 mutations to ET pathogenesis, their interactions with other genes and significant hematopoietic

P.1125

proteins such as ASXL1,⁵⁵ TET2,⁶⁴ and Mpl,⁶⁵ remain to be clarified.

TABLE 51.3 FREQUENCY OF SPECIFIC GENE MUTATIONS IN 53 ESSENTIAL THROMBOCYTHEMIA PATIENTS

Clinical and Laboratory Features

Most ET patients are asymptomatic at time of presentation,⁴⁴ although some may be diagnosed after a thrombotic event or in the course of evaluation of vasomotor symptoms such as dizziness and headache, which may reflect vascular occlusion.^{66, 67} Erythromelalgia (burning dysesthesia in the fingers or toes relieved almost instantly by aspirin) is a characteristic symptom of myeloproliferative thrombocytosis, whether from ET or polycythemia vera.⁶⁸ Distal ischemia (“blue toes syndrome”⁶⁹) and cutaneous changes such as livedo reticularis or ulceration⁷⁰ are occasionally found; frank limb gangrene is fortunately rare.^{71, 72}

Presenting blood counts and physical examination results from three series are shown in Table 51.4.^{27, 44, 66} Although hemoglobin concentration and white blood cell counts are typically normal, anemia and/or leukocytosis > 15 × 10⁹/L may be found in 15% to 20% of patients.²⁷ The white blood cell differential is usually normal but may show the basophilia, eosinophilia, or left-shift characteristic of myeloproliferative disorders. Splenomegaly, whether palpable or radiographic, is found in fewer than 25% of cases without transformation to myelofibrosis.^{27, 44, 66}

The characteristic bone marrow feature is proliferation of large, mature-appearing megakaryocytes (Fig. 51.2). Marrow cellularity is increased in approximately a third of cases,⁴⁴ but is otherwise normal. The presence of significant reticulin deposition, dyserythropoiesis, or dysmyelopoiesis should raise suspicion for other diagnoses.

Patients with ET exhibit evidence of aspirin-reversible increased platelet activation in vivo (increased circulating levels of beta thromboglobulin, platelet factor 4, and thrombomodulin and increased urinary thromboxane B2 excretion), whereas paradoxically exhibiting defective platelet function in vitro, both by classic platelet aggregation or platelet function analyzer (PFA)-100 studies.^{73, 74, 75} Some ET patients with platelet counts > 1,000 × 10⁹/L develop a bleeding diathesis due to an acquired type 2 von Willebrand syndrome which is reversed by platelet reduction.⁷³

Median values from the USA and Spanish series; mean values from Japanese series.

^a Patients with leukemic transformation excluded.

Natural History and Prognosis

The median overall survival of ET patients appears to exceed 22 years and does not significantly differ from that of the age-adjusted general population (Fig. 51.3).²⁶ A plurality (40%) of deaths is unrelated to ET; the next greatest contributor is thrombosis (26%). Solid tumors (14%) are the next most common cause of death, followed by leukemia, either de novo or post-myelofibrotic (8%) and myelofibrosis (4%).²⁶ Compared to polycythemia vera patients, the 15-year cumulative risks of thrombosis (27% vs. 17%), leukemia (7% vs. 2%) and myelofibrosis (6% vs. 4%) are lower in ET patients.²⁶

Reported risk factors for overall survival include age >60 years, history of thrombosis, anemia, and leukocytosis $>15 \times 10^9/L$; age, anemia, and platelet count $>1,000 \times 10^9/L$, are reported risk factors for leukemic transformation.²⁷ Studies have reported that JAK2V617F-negative ET patients have a lower arterial thrombotic risk than JAK2V617F-positive ET patients.⁷⁶ In contrast, the JAK2V617F allele burden itself may or may not predict a greater thrombotic diathesis.^{76, 77} Among JAK2V617F-negative ET patients, the presence of other markers of clonality such as mutations in human androgen receptor (HUMARA), TET2, ASXL1, or MPL, predicts an increased thrombotic risk.⁷⁸

P.1126

FIGURE 51.3. Survival curves of 435 patients with essential thrombocythemia, compared with life expectancy of the general population. From Passamonti et al., Life expectancy and prognostic factors for survival in patients with polycythemia vera and essential thrombocythemia. *Am J Med* 2004;117:755-761, with permission.

The standard model for thrombotic risk in ET has two components: age >60 years and history of thrombosis. The absence of both denotes low risk, and the presence of either denotes a high risk of thrombosis.⁷⁹ A model proposed more recently, the International Prognostic Score for ET-thrombosis (IPSET-thrombosis), incorporates the two elements of the standard model as well as the presence of cardiovascular risk factors and JAK2V617F mutation status.⁸⁰ The IPSET-thrombosis model defines low, intermediate, and high risk categories. Approximately half the patients in the low risk category from the standard model are relocated to the intermediate category in the IPSET-thrombosis model, whereas the standard model high risk patients are distributed essentially evenly between the three IPSET-thrombosis categories.⁸⁰ The two models are outlined in Table 51.5.

TREATMENT

The goal of treatment in ET is the prevention of thrombotic events, the primary cause of morbidity and mortality.²⁶ Therefore, treatment strategy is based on thrombotic risk stratification.^{79, 81, 82} At present, only the standard risk stratification model has been validated as a guide to therapy. Low risk patients can be managed with low dose aspirin or, under some circumstances, observation only. Cytoreduction of the platelet count is recommended for high risk patients.^{81, 82}

TABLE 51.5 PROGNOSTIC MODELS FOR THROMBOTIC RISK IN ESSENTIAL THROMBOCYTHEMIA

Standard Model⁷⁹

Age > 60 years

History of thrombosis

Low risk: Neither factor

High risk: One or both factors

IPSET-Thrombosis Model⁸⁰

Age > 60 years

1 point

Cardiovascular risk factors^a

1 point

History of thrombosis	2 points
<i>JAK2V617F</i> mutation present	2 points

Low risk: 0 or 1 point

Intermediate risk: 2 points

High risk: ≥ 3 points

^a Cardiovascular risk factors include diabetes, hypertension, and/or tobacco use.

The IPSET-thrombosis model has not been prospectively validated as a guide to therapy, but the developers of the model have suggested that cytoreductive therapy be considered in any patient with a history of thrombosis and in older patients with cardiovascular risk factors and/or *JAK2V617F* mutation. Aspirin therapy is recommended for younger patients without a thrombosis history but with either cardiovascular risk factors and/or *JAK2V617F* mutation.⁸⁰

The bleeding associated with acquired von Willebrand syndrome in ET can be resolved by reduction of the platelet count to a value approximating normal.⁸³

Aspirin

Aspirin therapy, usually at 100 mg/day or less, is generally well tolerated in ET patients, with a low risk of bleeding.⁸⁴ Antiplatelet agents such as aspirin reduce the risk of venous thrombosis in ET patients with the *JAK2V617F* mutation, and the risk of arterial thrombosis in patients with cardiovascular risk factors. Its benefits in other low risk patients are unclear.⁸⁵ Aspirin and antiplatelet agents should be avoided in patients with a history of bleeding. Although markedly elevated platelet counts are not a risk factor per se for aspirin-induced bleeding,⁸⁵ acquired von Willebrand syndrome may be unmasked by aspirin in patients with platelet counts greater than $1,000 \times 10^9/L$.⁷³ Many physicians regard it as prudent to assess von Willebrand factor activity prior to initiating aspirin in such patients.⁸³

Cytoreductive Therapy

Hydroxyurea

Hydroxyurea is considered the first-line cytoreductive agent in ET.^{81, 82, 86, 87} Some of the beneficial effects of hydroxyurea in ET and other myeloproliferative disorders may reflect reduction of leukocytosis and leukocyte-platelet interaction.⁸⁸ The extent to which hydroxyurea reduces *JAK2V617F* expression in ET patients is disputed.^{89, 90, 91, 92}

Anagrelide

The platelet-reducing drug anagrelide is a reasonable second choice for patients intolerant of, or unresponsive to, hydroxyurea.^{93, 94} As a first-line agent in ET, anagrelide has been reported to be non-inferior to hydroxyurea.⁹⁵ Unlike hydroxyurea, it does not affect leukocytosis.

Interferon

Administration of recombinant interferon can also be considered in patients refractory to hydroxyurea or to both hydroxyurea and anagrelide.^{96, 97, 98} The systemic side effects and need for subcutaneous injection limit its acceptability to some patients.⁹⁹ High risk pregnant females with ET can be successfully managed with interferon.¹⁰⁰

Other Agents/Modalities

Busulphan is an agent of established efficacy in myeloproliferative disorders such as ET,^{82, 101} however, its risk profile as an alkylating agent makes it less attractive than hydroxyurea, anagrelide, or interferon. Apheresis can be utilized to obtain rapid reduction in the platelet count in emergencies associated with severe thrombocytosis such as bleeding with acquired von Willebrand syndrome or limb gangrene or in preparation for surgery, but should be

P.1127

accompanied by cytoreductive drugs.⁸³ *JAK2* inhibitors currently available appear to be of primary benefit in post-ET myelofibrosis rather than in ET itself.

Post-essential Thrombocythemia Myelofibrosis

Myelofibrosis may be a late complication of ET, with an incidence of approximately 1.6 per thousand person-years of follow-up and is the cause of death in approximately 4% of ET patients.²⁶ Patients may develop transfusion-dependent anemia and/or thrombocytopenia, and symptomatic splenomegaly. *JAK2* inhibitors appear to have benefit in the

management of cytopenias and splenomegaly in myelofibrosis.^{102, 103, 104} In general, management follows the pattern outlined for primary myelofibrosis in Chapter 83.

Chapter 52

Qualitative Disorders of Platelet Function

Thomas J. Kunicki

Diane J. Nugent

Much of our current understanding of normal platelet structure-function relationships has been derived from the study of patients with congenital platelet disorders. These syndromes are the subject of excellent recent reviews.^{1, 2, 3, 4, 5}

NORMAL PLATELET FUNCTION: A SUMMARY

When a blood vessel is damaged, circulating platelets interact with components of the extracellular matrix, particularly collagen, and a complex series of receptor-ligand interactions ensue that ultimately lead to the formation of a stable platelet plug or thrombus (Fig. 52.1). This process is a continuum of at least three phases that we can describe as initiation, extension, and consolidation, each of which entails the cooperation of a different group of receptors.

In the initiation phase (Fig. 52.2), plasma von Willebrand factor (VWF) binds to collagen via its A3 domain and becomes structurally altered such that its A1 domain then binds to the platelet membrane receptor glycoprotein Ib-IX-V complex (GPIb complex). This association is a requisite step in the adhesion of platelets to exposed thrombogenic surfaces at sites of vessel wall injury or in regions of atherosclerotic plaque rupture. Concurrently, a more stable platelet monolayer is formed on the collagen surface mediated predominantly by the platelet-specific receptor GP VI (GPVI) and platelet integrin $\alpha_2\beta_1$.

The engagement of these receptors enhances platelet activation leading to the extension phase (Fig. 52.3), mediated largely by the conversion of prothrombin to thrombin at the activated platelet surface and the secretion of active compounds from platelet granules (α -granules and δ -granules) that can further stimulate platelets. One of these, adenosine diphosphate (ADP), plays a particularly important role in the platelet response, binding to its cognate platelet receptors to augment platelet activation. The activated platelet also produces and/or releases additional agonists, including the agonist thromboxane A₂ (TXA₂). Most of the receptors involved in the events of the extension phase are members of the G protein-coupled receptor family.

In the consolidation phase (Fig. 52.4), platelet-platelet cohesion (aggregation), mediated by the binding of fibrinogen and/or VWF to the activated platelet integrin $\alpha_{IIb}\beta_3$ (GPIIb-IIIa), together with the assembly of a fibrin network, results in the generation of platelet-rich aggregates or thrombi. Further complexity is inherent in this final phase of platelet plug formation, and current research indicates an essential role for outside-in signaling through integrins and via receptor tyrosine kinases, including members of the Eph kinase family.

FIGURE 52.1. Platelet thrombus formation. The formation of a platelet thrombus can be envisaged as occurring in three distinct phases. The initiation phase entails the transient tethering of the platelet followed by a firmer adhesion to components of the matrix, leading to platelet activation. In the extension phase, the activated platelets synthesize and/or release from granule stores potent agonists, such as adenosine diphosphate (ADP) or thromboxane A₂ (TXA₂). These augment platelet activation. At the same time, the procoagulant platelet surface facilitates the formation of thrombin, which is itself a potent platelet agonist. In the consolidation phase, platelet-platelet cohesion (platelet aggregation) mediates the formation of the stable platelet plug.

Inherited or acquired defects that affect any phase of this complex process can result in excessive thrombosis or bleeding. Hereditary disorders can be divided into groups (Table 52.1), based on whether they predominantly influence the initiation, extension, or consolidation phases of platelet-dependent hemostasis. Platelet dysfunction can also be a manifestation of many acquired disorders, and these are also discussed in this chapter.

DIAGNOSIS AND CLASSIFICATION OF PLATELET DYSFUNCTION: AN ALGORITHM

The preliminary diagnosis of platelet dysfunction must be made on the basis of patient history, and the diagnosis then confirmed by specific laboratory tests of platelet function. A practical algorithm for this purpose, depicted in Figure 52.5, is reproduced with permission from the excellent review by Bolton-Maggs et al.⁵

Bedside Exam and Patient History

An accurate and detailed patient and family history is a key element in the assessment of platelet disorders. One should bear in mind that bleeding histories are subjective and that bleeding can be variable, often evolving or decreasing throughout a person's lifetime. In particular, children may not have yet had enough hemostatic challenges to develop a strong clinical. The subjectivity of the oral history is reflected in a recent statistic that at least one quarter of persons who complain of serious bleeding do not have a bleeding disorder, whereas at least one third of persons who

P.1129

have no bleeding can be shown to have von Willebrand disease (vWD) or a platelet disorder.⁶

FIGURE 52.2. Initiation of platelet adhesion by matrix components, particularly collagen. Platelets employ a number of collagen receptors. These include VWF-mediated binding of collagen to the glycoprotein Ib (GPIb) complex (a heptamer composed of GPIb α , GPIb β , GPV, and GPIX), the direct engagement of collagen by the integrin $\alpha_2\beta_1$ and GPVI/FcR γ . Engagement and clustering of GPVI initiates tyrosine phosphorylation of FcR γ by a Src family kinase (SFK). The tyrosine kinase Syk then binds and is activated, in turn activating phospholipase C γ , which then initiates phosphoinositide hydrolysis, secretion of ADP, and the production of TXA₂. ADP and TXA₂ augment platelet activation by binding to their respective platelet receptors.

FIGURE 52.3. The extension phase of platelet plug formation accelerates and augments the activation of the platelet and is mediated largely by G protein-coupled receptors, including: the purinogenic receptors P2Y1 and P2Y12, which are bound by ADP; the α and β isoforms of the thromboxane A₂ (TXA₂) receptor TP; the protease-activated receptor (PAR) family members PAR1 and PAR4, that are recognized by thrombin; and the α _{2A}-adrenergic receptor that is specific for epinephrine.

To overcome the subjectivity of a history for superficial mucocutaneous bleeding, the International Society on Thrombosis and Hemostasis (ISTH) suggests that bleeding should be considered clinically significant when there are two or more distinct bleeding sites such as the skin, nose, gums, vagina, gastrointestinal tract, or genitourinary tract. This includes either spontaneous bleeding or provoked bleeding, such as that which might result from dental work, parturition, trauma, or surgery. In addition, a bleeding history involving only a single site should be considered significant when it is so severe as to warrant blood transfusions. Finally, a single bleeding symptom that recurs on three or more unrelated and separate occasions should also be considered significant.^{7, 8}

FIGURE 52.4. The consolidation phase of platelet thrombus formation occurs through the bridging of adjacent integrin $\alpha_{IIb}\beta_3$ complexes by fibrinogen or vWF, as well as other adhesive proteins.

TABLE 52.1 DISORDERS OF PLATELET FUNCTION

Hereditary platelet dysfunction

Initiation phase

Bernard-Soulier syndrome

GPVI deficiency

Extension phase

Secretion disorders/granule deficiencies

α -Granule abnormalities (gray platelet syndrome)

δ -Granule (dense body) abnormalities

Hermansky-Pudlak syndrome

Chediak-Higashi syndrome

Wiskott-Aldrich syndrome

α/δ -Granule deficiency

Defects of signal transduction and secretion

Impaired liberation of arachidonic acid
Cyclooxygenase deficiency
Thromboxane synthetase deficiency
Thromboxane A₂ receptor abnormalities
Defects in calcium mobilization
Defects of platelet procoagulant activity

Consolidation phase

Glanzmann thrombasthenia

Miscellaneous

Hereditary macrothrombopathy/sensorineural hearing loss

Acquired disorders of platelet function

Drug-induced platelet dysfunction

Analgesics
Antibiotics
Cardiovascular drugs
Psychotropic drugs

Secondary platelet dysfunction

Uremia
Paraproteinemia
Myeloproliferative disorders

A number of quantitative approaches to assess the relative severity of patient bleeding have been proposed, some including a normalization based on patient age.^{9, 10} However, such approaches work best for a comparison of cohorts of related individuals with comparable bleeding disorders, such as families of patients with vWD.

The distinction between normal individuals and those with bleeding disorders is not always clear cut. Care should be taken in all patients to note the use of medicines, either “over the counter,” herbal, or prescription, that are known to influence platelet function. This is particularly true of medications such as aspirin, other nonsteroidal anti-inflammatory drugs (NSAIDs), ticlopidine or clopidogrel, integrin α IIb β 3 antagonists (e.g., Abciximab, tirofiban, and eptifibatide), epoprostenol, statins, cilostazol, sildenafil, fluoxetine, and large doses of various β -lactam antibiotics (penicillins > cephalosporins).⁷

Bleeding manifestations typical of platelet dysfunction include: (1) Unexplained or extensive bruising; (2) epistaxis, particularly if lasting more than 30 minutes, causing anemia or admission to hospital; (3) menorrhagia, particularly if this has been present since the menarche; (4) oral cavity bleeding; (5) bleeding during

P.1130

childbirth; (6) bleeding following invasive procedures; and (7) bleeding following dental extraction.

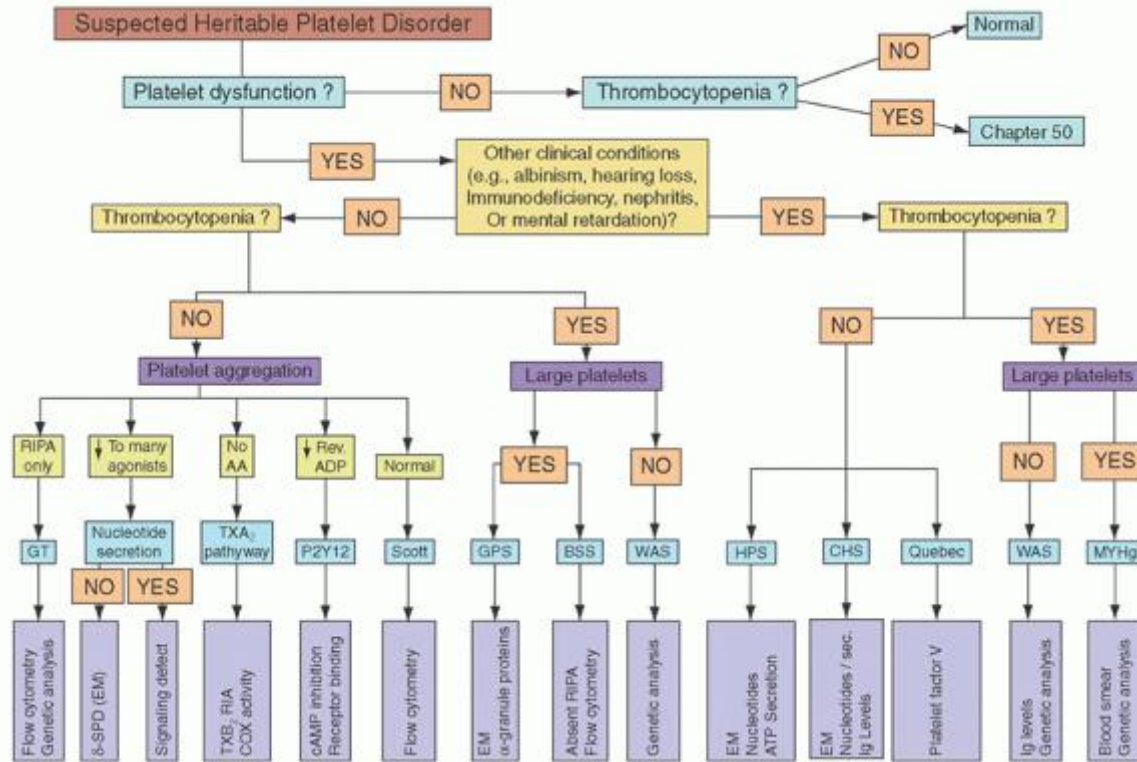

FIGURE 52.5. A scheme for the analysis of patients with suspected hereditary platelet dysfunction. In order to establish a precise diagnosis, specific laboratory tests are needed to establish a defect in platelet number or function. Generally, an automated full blood count, blood film, platelet aggregometry, and quantification of platelet nucleotides are necessary. The purpose of this algorithm is to assist the investigator in the systematic interpretation of laboratory results. To complete a diagnosis, specialty analyses may be necessary, and these are included for the specific disorder. Such assays might include flow cytometry to measure expression of surface glycoproteins, such as α IIb or β 3 (GT), GPIb or GPIIb/IIIa (BSS). In addition, quantitation of annexin V binding (Scott syndrome) and genetic analyses to identify specific gene mutations might be needed: α IIb or β 3 (GT), WAS (WAS and XLA) and MYH9. Certain disorders can be caused by mutations in more than one gene (e.g., HPS and BSS), so genetic analysis has not been considered as a definitive test in all cases. The algorithm includes the most frequent or best characterized heritable platelet disorders. Symbols and abbreviations: \downarrow , reduced aggregation; AA, arachidonic acid; BSS, Bernard-Soulier Syndrome; CHS, Chediak-Higashi syndrome; COX, cyclooxygenase; δ -SPD, dense-granule disorder; EM, electron microscopy; GPS, gray platelet syndrome; GT, Glanzmann thrombasthenia; HPS, Hermansky-Pudlak syndrome; MYH9, MYH-9-related disorder; P2Y12, deficiency of P2Y12 ADP receptor; QBS, Quebec platelet syndrome; Rev., reversible aggregation; RIA, radioimmunoassay; RIPA, ristocetin-induced platelet aggregation; Sec., secretion; TXA2, thromboxane A2; WAS, Wiskott-Aldrich syndrome. From Bolton-Maggs PH, Chalmers EA, Collins PW, et al. A review of inherited platelet disorders with guidelines for their management on behalf of the UKHCDO. *Br J Haematol* 2006;603-633.

Severe platelet dysfunction is present from early childhood onward. Following delivery of an affected infant one may find intracranial and/or subdural hemorrhage, excessive bleeding from the umbilical stump or after circumcision, or easy bruising after handling. As the infant becomes more mobile, easy or extensive bruising following relatively mild trauma can be indicative of platelet dysfunction. Prolonged epistaxis is a common finding throughout childhood and can even become life threatening. In adults, menorrhagia and bleeding during childbirth are common and potentially serious, whereas bleeding following any invasive procedure should be anticipated.⁵

Mild platelet dysfunction is more likely to manifest itself at any age most commonly following a definable hemostatic challenge, such as surgery or dental extractions. Easy bruising is a very nonspecific symptom, and many cases are difficult to distinguish from what would otherwise be considered a normal response.

Consanguinity increases the likelihood of an autosomal recessive platelet disorder, and a family history is invaluable in establishing the diagnosis of inherited platelet dysfunction.

Laboratory Assessment

A number of laboratory-based evaluations are critical for an accurate diagnosis of platelet dysfunction.

Whole Blood Platelet Count

A key element in assessing platelet dysfunction is an accurate whole blood platelet count. Automated counts should be viewed as provisional. Inasmuch as macrothrombocytes or platelet aggregates created inadvertently during blood processing will not be counted, the whole blood platelet count should be confirmed by an optical method.

Global Coagulation Tests

To rule out abnormalities in clotting factors, all patients should have a prothrombin time, activated partial thromboplastin time, and thrombin time performed. Laboratories should determine their own age-related normal range. It is also critical to investigate all patients for VWD, which is far more common than platelet function disorders and creates a similar bleeding phenotype.

Bleeding Time

The bleeding time is historically a common measure of platelet function. However, because the test is poorly reproducible, time consuming, and insensitive, the bleeding time has gradually fallen out of favor as a clinically useful test.¹¹ In cases of mild platelet dysfunction, the bleeding time is often normal or minimally prolonged;¹¹ in severe cases, it will usually be prolonged.

P.1131

Unfortunately, the bleeding time does not correlate well with the *in vivo* bleeding tendency within individual patients, and an accurate bleeding history is considered by many to be a more valuable screening test. Nonetheless, a prolonged bleeding time should be considered sufficient grounds to perform additional tests of platelet function.

Platelet Function Analyzer-100

The platelet function analyzer-100 (PFA-100) measures the rate of thrombus formation under high shear in citrated whole blood that is perfused through a membrane aperture coated with collagen/epinephrine or collagen/ADP. The closure time (CT) will be significantly prolonged in Glanzmann thrombasthenia (GT) and Bernard-Soulier syndrome (BSS) using either ADP/collagen or epinephrine/collagen membrane cartridges.^{12, 13} Consequently, the PFA-100 can be used to screen patients to exclude these diagnoses.

The PFA-100 may be sensitive to platelet storage pool disease (SPD), primary secretion defects, the Hermansky-Pudlak syndrome (HPS), and the Quebec syndrome. However, because falsenegative results occur in patients with all of these disorders, there are those who question its usefulness as a screening tool.^{12, 14} The PFA-100 is affected by platelet count and hematocrit, and is dependent on normal VWF levels and naturally occurring (genetic) differences in platelet membrane GPVI or $\alpha 2\beta 1$ expression.^{13, 14, 15}

Platelet Aggregation

Platelet aggregation in platelet-rich plasma remains an important test in the analysis of platelet function. The typical agonists that are used to induce platelet aggregation are ADP, epinephrine, collagen, arachidonic acid (AA), ristocetin, the TX receptor agonist U46619, thrombin or the thrombin receptor-activating peptide. Because the level and/or activity of each of the receptors for the agonists can vary among normal subjects, it is recommended that dose-response curves to each agonist be obtained from the patient under study and compared to a reference range obtained from multiple normal subjects.¹⁶ When thrombin is the agonist, an inhibitor of fibrin polymerization, such as glycine-proline-arginine-proline peptide, must be added to the PRP, or alternatively, plasma-depleted washed platelets must be used.

Platelet aggregation is sensitive to platelet count, and at counts $\leq 120,000/\mu\text{l}$, the response to some agonists will be impaired. In thrombocytopenic samples, the best options are to adjust a control sample to the same count as the patient or to perform studies on washed platelets where the platelet number can be normalized. Consideration should also be given to more specialized tests, such as a measure of P-selectin expression or integrin $\alpha\text{IIb}\beta 3$ activation by flow cytometry. The expected aggregation responses associated with specific diagnoses are covered in the appropriate sections.

Adenine Nucleotide Content and Release

Measurement of platelet adenosine nucleotide (ADP and adenosine triphosphate [ATP]) content and release can be used in the diagnosis of storage pool and release defects.¹⁷ A finding of normal platelet aggregation does not exclude the diagnosis of SPD. It is recommended that patients suspected of having platelet dysfunction should have both platelet aggregation and adenine nucleotide release performed, unless it is certain that the laboratory performing the platelet

aggregation assays can demonstrate that their assay conditions are sensitive to defects in platelet nucleotide amount or release.

Platelet nucleotide content and release varies with age. Ideally, age-related normal ranges should be established for total and released levels of ATP and ADP and their ratios. Platelet aggregation, nucleotide content, and nucleotide release in children over 12 months of age do not differ significantly from adult values, whereas collagen-induced platelet nucleotide release has been shown to be reduced in neonates compared with children older than 1 year. Agonist-induced secretion of platelet granule contents has been shown to be reduced in both term and premature babies due to immature signal transduction pathways.^{18, 19}

Flow Cytometry

Flow cytometry is routinely used to measure platelet surface receptor density, platelet activation, α -granule release, procoagulant phospholipid expression, and microvesicle production.^{20, 21} A common application of flow cytometry is the assessment of GPIb complex and integrin α IIb β 3 expression in the diagnosis of BSS and GT. Individuals who are heterozygous for these disorders are also readily distinguished. An important benefit of flow cytometry is the small quantities of blood required, an attractive feature in young children or thrombocytopenic individuals.

Electron Microscopy

Transmission electron microscopy (TEM) of fixed/embedded platelet thin sections can be performed by a limited number of specialized personnel, but is critical in the assessment of platelet granule defects and changes in platelet ultrastructure (e.g., in the evaluation of patients with MYH-9 defects). Whole-mount EM can be used to quantitate δ -granule content because this is readily identified in unstained preparations.²²

Additional Assays

Several additional assays are available in specialized laboratories that can provide further information relevant to the diagnosis of the particular platelet disorder, including analysis of receptor expression, specific molecular or genetic defects, protein phosphorylation, formation of signal transduction intermediates, or a characterization of the platelet proteome. The utility of these tests in clinical diagnoses is currently under intense investigation.

Overview of Treatment Options for Platelet Disorders

Although the number of clearly identifiable platelet dysfunction syndromes is growing, our choice of treatment options remains limited. Minor membrane bleeding may be controlled with topical agents in the nasal or oral cavities with antifibrinolytic agents. Epsilon-aminocaproic or tranexamic acids will decrease blood loss associated with epistaxis or menorrhagia. Some patients may benefit from Stimate as documented by DiMichele and Hathaway,²³ whereas others actually bleed more with this agent due to the fibrinolysis induced by this medication. For this reason many centers recommend the use of Stimate in conjunction with Amicar or Cyklokapron.

In the case of menorrhagia, hormonal suppression is the mainstay for women who do not wish to undergo endometrial ablation for hysterectomies. In combination with antifibrinolytics and Stimate, even severe bleeding may be controlled; however, more aggressive therapy including platelet infusion may be required to control bleeding before these agents take effect.

Platelet transfusion may pose a dilemma to those physicians wishing to avoid alloimmunization in patients who may require multiple transfusions throughout their lifetimes to control hemorrhage. This is particularly true for those patients who are lacking membrane GPs, such as α IIb β 3 or GPIb. In this setting patients are at risk of developing isoimmunization, making antibodies against the "foreign" proteins that they lack and thus becoming refractory to all subsequent platelet transfusions.

P.1132

Although rare, this creates a significant challenge in patients who require frequent platelet infusions to control life-threatening bleeding. Patients with GT have not only developed antibodies to α IIb and/or β 3 but also demonstrated anti-idiotypic antibodies that bind to fibrinogen, thus creating a hemorrhagic disorder far worse than the underlying platelet dysfunction. In general, physicians avoid platelet transfusion apart from cases of severe hemorrhage. Isoimmunization appears to be rare in Glanzmann but the risk of alloimmunization is still a major concern, therefore leukocyte depletion of transfused platelets is recommended to decrease the frequency of sensitization.

Activated recombinant Factor VII (rFVIIa) has been used to slow or arrest bleeding associated with platelet dysfunction.²⁴ Dosages have varied widely but many patients have responded to this regimen when others have failed. Used in combination with antifibrinolytics, minor bleeding can be controlled in certain patients. This treatment is often used prior to platelet transfusion in order to avoid blood product exposure and isoimmunization.

For those patients who present with recurrent life-threatening bleeds, bone marrow transplant or stem cell infusion following immune ablation is recommended before the patients have extensive blood product exposure.²⁵ Successful transplantation with normal stem cells represents long-term cure for these patients. Although complications related to stem cell transplantation cannot be overlooked, successful engraftment essentially eliminates the significant risk of mortality related to hemorrhage in patients with severe disorders.

Patients with rare platelet dysfunction syndromes are now included in many of the rare bleeding disorder international and regional registries that will aid physicians in understanding the natural course, optimal therapy, and life expectancy for each of the syndromes listed below, as well as the numerous platelet disorders that have yet to be defined. Definitive molecular and biochemical diagnoses will dictate appropriate therapy in these patients. With improvement in platelet function measurement and proteomic approaches one should see significant improvement in early diagnosis and medical management.

HEREDITARY DISORDERS OF PLATELET FUNCTION

Defects in the Initiation Phase: Bernard-Soulier Syndrome

BSS is a rare disorder first described in 1948 as “dystrophie thrombocytaire hemorrhagipare congenitale” caused by abnormal expression or activity of the platelet GPIb complex.²⁶

Etiology

BSS platelets have a quantitative or qualitative abnormality of the membrane GPIb complex, a heptamer composed of four leucine-rich GP that are the products of distinct genes (Fig. 52.2). The prominent member of the complex, GPIb, is a heterodimer composed of disulfide-bonded GPIb α and GPIb β subunits. GPIb then forms a noncovalent complex with GPIX, and two GPIb-IX trimers then associate noncovalently with one molecule of GPV. The amino-terminal type A domain of GPIb α binds directly to VWF, mediating normal platelet adhesion during the initial phases of primary hemostasis, whereas BSS platelets do not adhere to the extracellular matrix when perfused at a high shear rate.²⁷ The defect in the GPIb complex also explains the failure of affected platelets to agglutinate in the presence of ristocetin, even in the presence of normal plasma or VWF.

Mutations in the gene for GPIb α , GPIb β , or GPIX, but not GPV, have been shown to result in decreased expression of the GPIb complex and the BSS. Defects range from virtually absent GPIb to variant forms in which patients retain measurable amounts of apparently dysfunctional GPs.¹

BSS is usually inherited as an autosomal-recessive disorder, and consanguinity is common in reported kindreds. Heterozygotes typically have “giant” platelets and reduced levels of the GPIb complex and may or may not be symptomatic.

Clinical Features

Bleeding symptoms are usually evident shortly after birth or in early childhood. The clinical manifestations include purpura, epistaxis, gingival bleeding and menorrhagia, and more rarely gastrointestinal bleeding, major hematomas, or hematuria. Severe bleeding episodes can result from trauma and surgical procedures, such as tonsillectomy, appendectomy, splenectomy, oral surgery, and menses. However, individual bleeding can vary substantially in severity and frequency.

Laboratory Findings

The typical laboratory findings include an increased bleeding time, mild thrombocytopenia, giant platelets on blood smear, and defective adhesion to collagens *in vitro*. Platelet morphologic abnormalities are a hallmark of BSS, featured by large platelets with a diameter as high as 10 μm . A defective platelet agglutination in response to ristocetin, as measured by aggregometry *in vitro*, is a unique characteristic of BSS that differentiates this syndrome from other rare inherited disorders that are also associated with macrothrombocytopenia, such as the MHY9-related disorders.¹ A firm diagnosis requires the combined findings of increased bleeding times, macrothrombocytopenia, defective ristocetin-induced agglutination, and low or absent levels of platelet GPIb-V-IX (CD42a-d) by flow cytometry.

In bone marrow aspirates, megakaryocytes are normal or increased in number, but they reveal no characteristic morphologic abnormalities when viewed by light microscopy. Electron microscopic studies have revealed abnormalities of the dense tubular system and vacuolization of the demarcation membrane system.²⁸

Management

Therapeutic approaches include both general and specific treatment of bleeding. Patients should be warned to avoid trauma and antiplatelet medication, such as aspirin, and to maintain proper dental hygiene. Females may benefit from contraceptive therapy once they reach puberty. Treatment of bleeding or prophylaxis during surgical procedures usually requires blood or platelet transfusion with the associated risk of developing antiplatelet alloantibodies. Desmopressin and rFVIIa administration have been shown to shorten the bleeding time in some patients. In rare cases of life-threatening bleeding, a bone marrow or umbilical cord hematopoietic stem cell transplantation may be considered.²⁹ Responses to antifibrinolytic agents are more variable, and the administration of adrenal corticosteroids and splenectomy are usually ineffective.

Platelet-reactive isoantibodies have been generated by BSS who have received multiple blood or platelet transfusions.³⁰ These antibodies produce a particularly severe clinical complication because they will bind to and may neutralize the function of GPIb on transfused platelets. This results in impaired adhesion of the transfused platelets. The presence of such antibodies can be established by a finding of impaired in vitro aggregation of normal platelets induced by ristocetin and bovine VWF in the presence of patient plasma. Alloimmunization is also a common side effect of multiple platelet transfusions, and this may necessitate the subsequent use of HLA-matched platelets.

P.1133

Variation in the Initiation Phase: Collagen Receptor Polymorphisms

A lifelong bleeding disorder and the unique absence of in vitro platelet aggregation to collagen have been associated with a deficiency of either of the collagen receptors, integrin $\alpha_2\beta_1$ or GPVI,¹ yet specific gene defects have not been identified. Careful evaluation is needed to establish a specific molecular defect in either receptor.

The Integrin $\alpha_2\beta_1$

Among normal individuals, platelet $\alpha_2\beta_1$ levels can vary up to tenfold and correlate with differences in adhesiveness to type-I or type-III collagens and genetic variants of the α_2 subunit gene ITGA2. We identified several single nucleotide polymorphisms (SNPs) within the coding sequence of the α_2 gene ITGA2 that correlate with platelet $\alpha_2\beta_1$ density³¹ and define six major ITGA2 haplotypes.

Clinical Relevance of α_2 Polymorphisms

In VWD, platelet adhesive functions are impaired due to the decrease in functional VWF multimers in plasma and platelets. Inheritance of the ITGA2 haplotypes associated with lower $\alpha_2\beta_1$ density will increase the risk of bleeding in patients with either type I and type2 VWD.^{9, 10}

The association of ITGA2 haplotypes with risk for arterial thrombosis has been studied in acute coronary syndromes, diabetic nephropathy, and stroke. Although several studies have found that the inheritance of high-density ITGA2 haplotypes correlates with increased thrombosis, this association is not a consistent observation.³²

Platelet Glycoprotein VI

GPVI is a major platelet GP (60 to 65 kDa) that has been confirmed as an important receptor for collagen since the initial identification of a patient with a mild bleeding disorder whose platelets lacked GPVI and exhibited defective collagen-induced responses.³³ Autoantibodies against GPVI can cause substantial shedding of this receptor through metalloproteinase cleavage.^{34, 35}

Glycoprotein VI Polymorphism

Aside from isolated cases of GPVI defects, it is important to note that there is variation in platelet GPVI content among normal healthy subjects,³⁶ which is directly proportional to normal variation in mean platelet volume.³⁷ This variation is manifested in a significant difference in prothrombinase activity induced by GPVI-specific agonists such as the snake venom protein convulxin or collagen-related peptide (CRP).³⁶ The direct association between platelet $\alpha_2\beta_1$ density and GPVI content is also attributable to variation in mean platelet volume, which has a proportional effect on levels of other

receptors, including $\alpha\text{IIb}\beta\text{3}$.³⁷ Variation in GPVI content represents yet another genetically controlled risk factor predisposing individuals to hemorrhagic or thromboembolic disorders.

Defects in the Extension Phase

Secretion Defects: Storage Pool Disease

SPD is a heterogeneous group of congenital disorders that have in common a deficiency of granules or their constituents that results in a defect in ADP release from activated platelets and abnormal secretion-dependent platelet aggregation.¹ Defective platelet secretion can result from the absence of or defects in one or both of the dominant types of platelet granules: The α -granule or the δ -granule (dense body). Thus, three subgroups of SPD are now distinguished. The isolated deficiency of α -granules (α -SPD) has been studied for several years and is more commonly known as the Gray platelet syndrome (GPS)³⁸; the exclusive abnormality of dense-granules (δ -SPD) can be congenital or acquired, as in myeloproliferative syndromes or rheumatologic disorders;¹⁷ and abnormalities of both α - and δ -granules are classified as $\alpha\delta$ -SPD.¹⁷

α -Granule Storage Pool Disease: Gray Platelet Syndrome

GPS is a very rare disorder with less than 100 cases reported worldwide and is characterized by a selective deficiency in the number and content of α -granules.^{17, 38} The formation of α -granules in immature megakaryocytes proceeds normally, but the granule number then decreases during maturation, and the mature megakaryocytes are left with only small abnormal granules that are few in number. Some of the normal protein constituents of α -granule membranes, such as GPIV, integrin $\alpha\text{IIb}\beta\text{3}$, and P-Selectin remain in the abnormal granules and will be normally redistributed during platelet activation. The defect is limited to megakaryocytes and platelets. Recent evidence suggests that GPS is associated with mutations in NBEAL2 (neurobeachin-like 2 gene), which encodes a protein containing a BEACH domain that is predicted to be involved in vesicular trafficking and may be critical for the development of platelet α -granules.^{39, 40, 41}

Several proteins are synthesized but not stored properly in the abnormal α -granules. These include platelet factor 4, β -thromboglobulin, fibrinogen, fibronectin, vWF, platelet-derived growth factor, and thrombospondin. Other organelles, such as lysosomal granules, mitochondria, and δ -granules (dense bodies) are present in normal numbers, and δ -granules contain normal amounts of adenine nucleotides and serotonin.

Clinical Features

GPS is inherited as an autosomal trait and is associated with mild to moderate thrombocytopenia (20,000 to 150,000/ μl) and moderately enlarged platelets.^{17, 38} The bleeding time is usually prolonged, and platelet survival may be shortened, but splenomegaly is not common. As in other platelet function defects, a history of mild bleeding is the norm, and treatment is seldom required. The bone marrow exhibits normal megakaryocyte numbers and increased reticulin, occasionally around clusters of megakaryocytes, but myelofibrosis is not a feature of this disorder. In Wright-stained blood smears, the platelets appear large, misshapen, agranular, and gray. In electron photomicrographs, an almost total lack of α -granules is evident in platelets and in megakaryocytes.

When analyzed by EM, it is the only disorder that is characterized by the selective absence of platelet α -granules. Megakaryocytes show defective α -granule biogenesis, with impaired uptake and storage of endogenously synthesized proteins, such as platelet factor 4, β -thromboglobulin, or vWF, and defective sequestration of exogenous proteins, such as fibrinogen, albumin, or factor V. On the other hand, in the platelet, the α -granule marker P-selectin is retained and is redistributed to the surface upon activation. Both autosomal recessive and autosomal dominant inheritance have been reported, implicating more than one gene in the etiology of the disease. Myelofibrosis of bone marrow is an additional feature that is attributed to the spontaneous release of platelet-derived growth factor and transforming growth factor- β1 from megakaryocytes.

Laboratory Findings

Gray platelets have a normal aggregation and release in response to AA or ionophore and generate TX normally. Platelet aggregation induced by ADP, epinephrine, thrombin, or collagen is variably affected. Release from dense bodies usually is subnormal,

P.1134

particularly when induced by thrombin. Abnormal calcium influx and mobilization from intracellular stores have also been reported. The platelet count is often reduced and can be as low as 50,000 per μl . By EM, the platelets have reduced numbers or a complete absence of α -granules.

Management

Because of the rare nature of α -granule disorders, there is not a very extensive clinical database upon which to make generalizations about effective treatment of the bleeding problem. However, these patients should be managed in the same manner as other patients with mild bleeding disorders. In the case of major bleeding or surgical challenge, they may require platelet transfusion.

Isolated δ -Storage Pool Disease

δ -SPD is characterized by easy bruising, mucocutaneous bleeding, and excessive post-operative and post-partum hemorrhage.¹⁷

Clinical Features

The symptoms can become more severe if the patient ingests aspirin or other antiplatelet agents, and patients with SPD should be advised to avoid such drugs. Platelet counts are typically normal, and the bleeding time is usually prolonged. The platelets are morphologically normal on Wright-stained smears, but they are deficient in dense bodies by EM. The diagnosis of δ -SPD must be made by the finding of a decrease in dense granule constituents and/or EM to demonstrate the absence of dense granule-limiting membranes and contents. The most consistent finding is that adenine nucleotides are reduced with an increased ratio of ATP to ADP and normal levels of lysosomal enzymes.

The platelet content of serotonin, however, can be variably reduced. Whole-mount EM recognizes calcium, but it cannot differentiate the absence of a dense granule from the absence of its calcium. Dense granules can also be quantitated by fluorescent microscopy because, whether full and empty, δ -granules take up the fluorescent dye quinacrine (mepacrine).⁴²

Laboratory Findings

Because of the defect in δ -granules and the decreased level of ADP, primary aggregation responses in vitro are normal, but secondary aggregation may be diminished. Typically, there is an impaired response to collagen and a deficient secondary wave with ADP, epinephrine, and low concentrations of thrombin, but ristocetin aggregation is normal. Although this functional defect is often encountered in this disorder, it cannot be relied upon as a diagnostic criterion. The platelets are also deficient in serotonin, calcium, and pyrophosphate, which are stored in the δ -granules.¹⁷

The bleeding time is increased, with normal platelet counts and morphology. Subsets of patients have been identified who have a prolonged bleeding time, decreased dense bodies, and ADP release but normal platelet aggregation. The diagnosis of δ -granule SPD can best be made following a combination of studies, including bleeding time, platelet aggregation, an assessment of storage pool adenine nucleotides, thrombin-induced radioactive serotonin uptake and release, and TEM.

There is suggestive evidence that δ -SPD is inherited as an autosomal dominant characteristic, but neither the causative gene nor the molecular nature of the basic defect have yet been determined.

Management

To treat the symptoms of SPD, desmopressin (DDAVP) can normalize the bleeding time in some patients, often within 1 hour after infusion.²³ This treatment is particularly effective in improving hemostasis after procedures.

Combined $\alpha\delta$ -Storage Pool Disease

In $\alpha\delta$ -SPD, which is much less common than isolated δ -SPD, δ -granules and/or their contents are uniformly decreased, and the deficiency of α -granules and/or their constituents can vary.¹⁷ Platelets in these patients form significantly smaller thrombi in flowing blood than is seen with platelets from patients with δ -SPD. The defects are also not uniformly among the platelet population, such that α -granules and δ -granules may be completely absent in one portion of the population yet present in nearly normal levels in another.⁴³

The mode of inheritance appears to be autosomal dominant, but a basic molecular defect and a genetic basis have not yet been determined.

Animal Models and Etiology

The comparative study of granule deficiencies in the mouse or rat can provide clues to understanding the etiology of SPD. For example, the gunmetal mouse⁴⁴ and the fawn-hooded hypertensive rat⁴⁵ are characterized by reduced platelet α - and δ -granules, a disorganization of megakaryocyte internal membranes, and impaired α -granule protein retention. Mutations in RabggtA result in defective geranylgeranyl transferase, which catalyzes the attachment of lipid geranylgeranyl groups to Rab proteins.⁴⁴ Rab proteins are small guanosine triphosphatases (GTPases), which split GTP to provide energy for

membrane fusion events and for attachment to cytoskeletons. By analogy, it is possible that mutations in the human gene RABGGTA are also responsible for human $\alpha\delta$ -SPD, but this remains to be proven.

Clinical Features

Bleeding in this disorder is clinically similar to bleeding in δ -SPD and GPS, and is manifested by a prolonged bleeding time with normal platelet counts.¹⁷ Except for their bleeding tendency, patients with $\alpha\delta$ -SPD appear otherwise healthy.

Laboratory Findings

Defects in secondary platelet aggregation are typical, and defects in primary aggregation are even more extreme than seen in δ -SPD. Because of variability, in vitro platelet aggregation in $\alpha\delta$ -SPD is not an appropriate diagnostic criterion, and an accurate diagnosis requires measurement of δ - and α -granule constituents and/or EM of platelet organelles. The lysosomal enzyme content of $\alpha\delta$ -SPD platelets is normal.

Management

Because of the few numbers of patients with combined $\alpha\delta$ -SPD, there is little clinical information upon which to develop a treatment scheme. However, this disorder can likely be managed in the same manner as the isolated δ -SPD (see above).

Quebec Platelet Syndrome (Factor V Quebec)

The Quebec platelet syndrome is an extremely rare, autosomal dominant disorder that was originally identified by the finding of low levels of platelet α -granule factor V but normal plasma factor V.^{1, 17} It is characterized by protease-related degradation of many platelet α -granule proteins, including P-selectin. The α -granule ultrastructure is normal. Increased expression of α -granule urokinase-type plasminogen activator is thought to lead to spontaneous intracellular activation of the fibrinolytic pathway resulting in the generation of plasmin, which cleaves multimerin that would otherwise stabilize factor V.⁴⁶

Clinical Features and Laboratory Findings

Many cases may go undiagnosed because there are no characteristic morphologic features or platelet aggregation abnormalities. The main laboratory finding is defective procoagulant activity,

P.1135

reflected by a failure to assemble the prothrombinase complex. A related defect, platelet Factor V New York, is also characterized by decreased levels of platelet Factor V, although there is no indication of Factor V proteolysis, as in Factor V Quebec.⁴⁷

Management

The Quebec platelet syndrome is unresponsive to platelet transfusions. It is the current opinion that fibrinolytic inhibitors are the most effective means to control bleeding.⁴⁸ Otherwise, treatment should be similar to that given to patients with bleeding disorders.

Hermansky-Pudlak and Chediak-Higashi Syndromes

The HPS and Chediak-Higashi syndrome (CHS) are rare autosomal recessive disorders that have in common platelet dense granule deficiency, albinism, and lysosomal granule defects.⁴⁹

Hermansky-Pudlak Syndrome

HPS is as an autosomal-recessive trait that has a worldwide distribution but is most prevalent in Puerto Rico.

Etiology

The genetic causes of HPS are diverse. Mutations in at least seven genes have been linked to this disease, and the absence of platelet dense bodies is thought to result from a defect in organelle development.⁵⁰

Clinical Features and Laboratory Findings

A diagnosis of HPS is based on the presence of oculocutaneous albinism and absent platelet dense bodies on whole-mount EM.⁵¹ Typical findings are a lifelong history of easy bruising; minor bleeding episodes, such as mucus membrane bleeding; epistaxis, and metromenorrhagia. Many patients will require whole blood or platelet transfusions when bleeding symptoms become more severe. Pulmonary fibrosis and inflammatory bowel disease, associated with infiltration of ceroid-pigmented reticuloendothelial cells in the lung and colon, have been reported in several cases of this syndrome.⁵²

In platelet aggregation assays, there is an absence of the secondary wave in response to ADP and epinephrine, and the response to collagen is also abnormal. Usually, the template bleeding time will also be longer than normal.

Management

Localized and limited treatment of the bleeding symptoms is the norm in HPS.^{49, 53} The albinism necessitates skin and eye protection, and the bleeding can be controlled topically with thrombin and Gelfoam. Prophylactic use of intravenous 1-desamino-8-D-arginine vasopressin or Stimate is recommended for procedures such as tooth extractions or biopsies. Menstrual bleeding can be regulated by birth control pills. In the event of major surgeries or severe bleeding episodes, platelet or red blood cell transfusions may be required.

Chediak-Higashi Syndrome

SPD also may be associated with the CHS.^{1, 54} In addition to defective platelet dense granules and oculocutaneous albinism, CHS is also characterized by immune deficiency and progressive neurologic dysfunction. In CHS patients, the granule abnormalities are not restricted to the megakaryocyte lineage, and numerous cell types exhibit giant cytoplasmic inclusions that are enlarged vesicles.

Etiology

Numerous cases of CHS have been reported to result from mutations in the lysosomal trafficking regulator gene (LYST) located on chromosome 1q42.1-42.2. Mutations in the LYST protein can be associated with defective natural killer cell function.⁵⁵ However, LYST mutations cannot be identified in all CHS patients, suggesting the existence of causative defects in other genes.⁵⁶ Several proteins are known to interact with LYST, including the SNARE complex protein HRS, signaling protein 14-3-3, and casein kinase II.⁵⁷ It has been proposed that LYST may be an adaptor protein that brings into close proximity proteins that mediate intracellular membrane fusion reactions. Along this vein, LYST contains several consensus motifs that play distinct roles in vesicle transport and fusion.

Clinical Features and Laboratory Findings

Platelet counts are normal prior to development of the accelerated phase. The dense granule defect results in mucocutaneous bleeding and a prolonged bleeding time. The secondary wave of platelet aggregation is impaired, there is an increased ATP-to-ADP ratio, decreased platelet serotonin, and decreased platelet calcium. Some patients have a normal number and shape of dense bodies, but most often there is an absence of or marked reduction in dense bodies.

Management

Prior to the accelerated phase, hemostatic problems can be treated as in the case of other mild platelet disorders. With time, infections and a lymphoproliferative accelerated phase are serious developments that can result in death within the first decade.^{1, 54} Although experience is still limited, hematopoietic cell transplantation is a potentially effective therapy for correcting and preventing hematologic and immunologic complications of CHS.⁵⁸

Griscelli Syndrome

Mutations in RAB27A, a gene for a small GTPase involved in vesicular transport and organelle dynamics, are considered to be the cause of GS.⁵⁹ The ashken mouse with mutated RAB27A is a model of GS and exhibits a reduction in the number of platelet dense granules. However, the hemostatic phenotype of these mice is affected by the genetic background, and it is likely that additional modifier gene polymorphisms have an important influence on the hemostatic phenotype.

Clinical Features and Laboratory Findings

GS is a rare autosomal recessive disorder in which patients present with abnormal pigmentation, immunodeficiency, and development of the accelerated phase.⁶⁰ GS patients have no obvious bleeding prior to the accelerated phase, and it has not been firmly established that there is a characteristic platelet dense granule defect. Hypopigmented hair with a silvery-gray sheen and pigment clumps is a characteristic of GS, but these are larger and less homogeneously distributed than one sees with CHS patients. The giant cytoplasmic granules typical of CHS cells are not seen in GS cells.

Management

Like CHS, the disease is usually fatal by the first decade of life. The same management as observed with CHS will likely be effective in patients with Griscelli syndrome.^{1, 54}

Paris-Trousseau (Jacobsen) Syndrome

The Paris-Trousseau (Jacobsen) syndrome is an autosomal dominant disorder characterized by thrombocytopenia, a history of relatively mild bleeding, the presence of giant α -granules in a minor proportion of platelets, and two

morphologically distinct populations of megakaryocytes in the bone marrow, some of which exhibit signs of abnormal maturation. Additional congenital abnormalities include mental retardation, cardiac abnormalities, and cranio-facial abnormalities. This is an extremely rare disorder, and only 10 childhood cases have been reported.⁶¹

P.1136

These patients have deletions of the long arm of chromosome 11q that include the gene *FLI1*, which encodes a transcription factor that plays a critical role in normal megakaryocytopoiesis. Thus, the hemizygous deletion of *FLI1* generates a subpopulation of megakaryocyte progenitors that fail to differentiate normally, forming small immature megakaryocytes that undergo massive lysis.⁶² Those platelets with giant α -granules fail to release their contents normally upon stimulation.

Arthrogryposis-Renal Dysfunction-Cholestasis Syndrome

The gene *VPS33B* encodes a protein that is involved in protein trafficking. A mutation of the gene is the cause of ARC syndrome.⁶³ ARC is an autosomal recessive disorder with multiple systemic abnormalities, one of which is platelet dysfunction caused by a deficiency in platelet α -granules.⁶⁴ This disorder is diagnosed by severe distinguishing features other than the platelet dysfunction, and affected individuals usually do not survive their first year.

Inherited Disorders of Primary Membrane Receptors

Congenital Defects of P2Y₁₂

The adenine nucleotides ADP and ATP are both released from platelet δ -granules during activation induced by a variety of agonists, and both can augment or modulate the platelet functional response through autocrine and paracrine mechanisms by binding to platelet purinergic receptors.⁶⁵

Two platelet purinergic receptors are specific for ADP, the G_q-protein-coupled receptor P2Y₁ and the G_i-protein-coupled receptor P2Y₁₂. One receptor, the P2X₁ ion channel, is bound by ATP. The P2Y and P2X receptors operate in a temporally distinct manner and selectively trigger distinct intracellular signaling pathways. Recent advances in our understanding of P2Y receptor physiology suggest that these receptors are a potentially relevant target of antithrombotic therapy. P2Y₁ mediates ADP-induced intracellular calcium ion mobilization and shape change, and P2Y₁₂ is coupled to adenylyl cyclase inhibition and is responsible for ADP-induced macroscopic platelet aggregation.⁶⁶

At the same time, we have only a perfunctory understanding of the function of P2X₁ in platelet activation. It is known, however, that P2X₁ function is linked to calcium ion influx.⁶⁶

Etiology

P2Y₁₂ defects are inherited as autosomal recessive traits,⁶⁷ and heterozygous individuals display a mild abnormality in platelet function similar to that observed in patients with SPD. In two cases, different homozygous frameshift mutations cause premature termination of translation. In another case, one allele presented a reading frameshift caused by the deletion of two nucleotides, whereas the other case had a normal coding sequence but a reduced expression, possibly resulting from another mutation in a regulatory region of the gene.⁶⁸

Clinical Features and Laboratory Findings

A limited number of patients have been described with congenital abnormalities of P2Y₁₂ resulting in bleeding diatheses and abnormalities of platelet function.⁴ The common clinical findings in these patients are a lifelong history of mucosal bleeding, easy bruising and/or excessive post-operative bleeding, and mildly to severely prolonged bleeding times. Laboratory findings were a weak and rapidly reversible primary wave of aggregation induced by ADP and abnormal aggregation induced by collagen, arachidonate, and TXA₂ analogs. Aggregation induced by high concentrations of thrombin was normal. ADP-induced shape change is normal, but ADP fails to inhibit the expected normal rise in cAMP levels seen after stimulation with prostaglandin E₁.

Management

Inasmuch as there are generally no serious side effects, DDAVP is recommended for prophylaxis and treatment in these patients.²³

Thromboxane A₂ Receptor

Defective TXA₂ receptor function is characterized by impaired platelet aggregation in response to the TXA₂ analog U46619, a variable response to other agonists comprising a reduced primary wave and absent secondary wave, and defective secretion.⁶⁹

Epinephrine Receptor

A selective absence of an aggregation in response to adrenaline has been reported as a heritable trait in association with easy bruising and reduced expression of platelet α_2 -adrenoceptors.^{70, 71} However, the aggregation response to adrenaline among normal individuals is itself quite variable, and a relative decrease in the aggregation response to adrenaline may represent the lower segment of a common asymptomatic population variant.⁷²

Inherited Defects in Signal Transduction Pathways

Cyclooxygenase Defects

Defects in platelet cyclooxygenase (COX) or TX synthase⁷³ give the same laboratory findings as seen in TXA₂ receptor defects (see above), but can be distinguished from the latter by the preservation of platelet aggregation in response to prostaglandin-H₂ or the TXA₂ analog U46619.

Scott Syndrome

Scott syndrome is a rare autosomal recessive disorder characterized by a defect in calcium-induced phospholipid scrambling and prothrombin conversion on platelets and other blood cells.⁷⁴

When Scott platelets are activated, phosphatidylserine is not transported from the inner to the outer phospholipid leaflet of the membrane. The binding of factor Va-Xa and factor VIIIa-IXa complexes is impaired, resulting in decreased thrombin generation and impaired platelet-dependent fibrin formation on subendothelium. It has been reported that Scott syndrome may be explained, at least in part, by mutations in an ATP-binding cassette transporter A1 implicated in the exofacial translocation of phosphatidylserine.⁷⁵

Additional Defects

Patients have been described with: A lineage-specific G α_q subunit deficiency and impaired α IIb β 3 activation; reduced G α_i 1 expression and signaling; defective calcium ion mobilization and an abnormal response to ionophore A23187; a reduced production of inositol 1,4,5-triphosphate and phosphatidic acid, diminished plekstrin phosphorylation and defective phospholipase C activation; and a specific defect in phospholipase C β 2 expression.⁷⁶ Pseudohypoparathyroidism type 1b, which is associated with a mild bleeding disorder, is caused by a defect in the heterotrimeric G protein subunit G α_s , which regulates adenylyl cyclase.⁷⁷

Defect in the Consolidation Phase: Glanzmann Thrombasthenia

GT is an autosomal-recessive disorder characterized by defective in vitro platelet aggregation and a lifelong bleeding tendency due

P.1137

to quantitative or qualitative abnormalities of the platelet GPIIb-IIIa,² also known as the integrin α IIb β 3.

Etiology

A qualitative or quantitative defect of either GPIIb or GPIIIa is the basic biochemical basis for GT. GPIIb-IIIa is a calcium-dependent heterodimer that binds preferentially to fibrinogen or vWF, but also to fibronectin or vitronectin. The genes for GPIIb and GPIIIa are distinct but are physically located within 1 Mb of each other on the long arm of chromosome 17 (17q21-22). A genetic defect in either GPIIb or GPIIIa can inhibit synthesis of that subunit and/or prevent normal assembly and processing of the functional receptor. This results in the lack of a fibrinogen receptor and defective fibrinogen binding after platelet activation. Platelet aggregation, which requires this protein, is therefore deficient or completely absent.

A continually maintained database is accessible on the Internet (<https://haemgen.haem.cam.ac.uk/thrombogenomics/>) which contains a list of over 100 mutations that give rise to GT. The α IIb and β 3 genes (ITGA2B and ITGB3, respectively) are both affected, and although post-translational defects predominate, reduced mRNA stability can also be a cause. Integrin synthesis occurs in the megakaryocytes with α IIb β 3 complex formation in the endoplasmic reticulum. Noncomplexed or incorrectly folded gene products fail to undergo processing in the Golgi apparatus and are rapidly degraded intracellularly.⁷⁸

In GT, isoantibodies specific for the deleted GPs have been demonstrated in the blood of multiply transfused patients,² and these can reproduce the thrombasthenic defect in normal transfused platelets.

Clinical Features

Thrombasthenia is inherited as an autosomal-recessive trait, and consanguinity is common within affected kindreds, resulting in geographic clusters of patients.² Hemorrhagic symptoms occur only in patients homozygous for GT mutations, whereas the heterozygous condition is mostly asymptomatic, even though platelets from heterozygotes have only one half the normal level of $\alpha\text{IIb}\beta\text{3}$. The sites of bleeding in GT are clearly defined: Purpura, epistaxis, gingival hemorrhage, and menorrhagia are nearly constant features; gastrointestinal bleeding and hematuria are less common but can cause serious complications. Bleeding at menarche is severe enough to require transfusions in most patients. Deep visceral hematomas, a characteristic of coagulation disorders such as hemophilia, are not usually seen in GT. Bleeding symptoms normally manifest rapidly after birth, even if most patients are diagnosed before the age of five. Epistaxis is a common cause of severe bleeding, and is typically more severe in childhood. In general, the bleeding tendency in GT decreases with age. Post-traumatic and post-operative hemorrhage can be serious, and pregnancy and delivery represent a severe hemorrhagic risk, because bleeding may not always be preventable by platelet transfusions. Although GT can be a severe hemorrhagic disease, the prognosis is excellent with careful supportive care. Death from hemorrhage in diagnosed patients is rare unless associated with trauma, other disease (e.g., cancer), or chronic isoimmunization.

Laboratory Findings

A prolonged bleeding time, deficient clot retraction, and deficient platelet aggregation with ADP, collagen, epinephrine, or thrombin are typical findings. Ristocetin-induced aggregation, on the other hand, and coagulation tests are normal. Thrombasthenic platelets are present in normal numbers and are morphologically normal when viewed by light microscopy.

Management

With GT patients, it is important to anticipate bleeding risks before performing procedures, and because the risk for bleeding is so unpredictable, it is prudent to administer prophylactic platelet transfusions even in the absence of a prior history of bleeding.

Localized bleeding can be treated by limited measures, such as fibrin sealants or topical thrombin and antifibrinolytic agents (ϵ -aminocaproic acid, tranexamic acid). Epistaxis and gingival bleeding can be controlled by nasal packing or the application of gel foam soaked in topical thrombin. The risk of gingival bleeding can be minimized by regular, proper dental care. When tooth extractions must be performed or when hemorrhage accompanies the loss of deciduous teeth, bleeding can be significantly reduced by the application of individually prepared plastic splints that provide physical support for hemostasis.

Severe menorrhagia is common and can be effectively treated with high doses of progesterone, followed by maintenance treatment with birth control pills. Severe gastrointestinal bleeding is an isolated but severe problem. Iron deficiency anemia can develop insidiously with gingival oozing or minor menorrhagia. Confronted with a severe bleeding episode or as prophylaxis for invasive procedures, most GT patients receive blood transfusions, regardless of bleeding history.⁷⁹ Transfusions should be continued until wound healing is complete. However, a significant number of transfused patients can develop HLA-specific alloantibodies or GPIIb-IIIa-specific isoantibodies, which seriously complicate transfusion therapy and limit future treatment. Isoantibodies can block normal transfused platelet aggregation and/or lead to the rapid removal of transfused platelets by immune mechanisms. It is not yet possible to predict the propensity of individual GT patients to develop such antibodies. Antibodies may be successfully removed prior to surgery by immunoadsorption on Protein A Sepharose, but this is a complex procedure restricted to specialized centers.⁸⁰

Pregnancy and delivery represent a severe hemorrhagic risk. Platelet transfusions are required not only prior to delivery, but afterward as well. Successful delivery by cesarean section, with platelet transfusions, has been reported.

The use of rFVIIa (NovoSeven[®]; NovoNordisk A/S, Malov, Denmark) is an alternative approach for early cessation of bleeding in GT, especially in the case of patients who have developed antibodies and/or have a history of transfusion refractoriness.⁸¹ It seems that rFVIIa enhances deposition of $\alpha\text{IIb}\beta\text{3}$ -deficient platelets on the subendothelial matrix through an interaction with fibrin formed by the increased thrombin generation⁸² leading to increased clot stability.⁸³ However, some question the efficacy of rFVIIa in children with GT.⁸⁴

In a few GT patients, the bleeding symptoms have been considered sufficiently serious to warrant allogeneic bone-marrow transplantation.⁸⁵

Additional Hereditary Defects of Platelet Function (with Thrombocytopenia)

MYH-9-related Thrombocytopenia Syndromes

MYH-9-related disorder encompasses autosomal dominant macrothrombocytopenia syndromes previously classified as May-Hegglin anomaly, Sebastian, Fechtner, and Epstein syndromes and certain inherited thrombocytopenias that have in common mutations within MYH9, the gene for nonmuscle myosin heavy chain II-A (NMMHC-IIA).⁸⁶

Etiology

NMMHC-IIA is part of the nonmuscle myosin IIA hexamer that is a component of the contractile cytoskeleton in megakaryocytes, platelets, and other many other cell types. Mutations of MYH9

P.1138

that give rise to MYH-9-related disorder disrupt the stability of the nonmuscle myosin IIA hexamer or its association with regulatory proteins. This results in defective megakaryocytopoiesis that leads to thrombocytopenia. Additional platelet function defects arise from abnormal shape change or impaired expression of the GPIb complex.⁸⁷ As in many other inherited hematologic disorders, incomplete penetrance accounts for a poor correlation between the MYH9 genotype and clinical phenotype as well as variability in phenotype among individuals with identical mutations.⁸⁶

Clinical Features

Patients with MYH-9-related disorder present with bleeding, sensorineural hearing loss, glomerulonephritis, and/or eye abnormalities. The severity of the bleeding symptoms is out of proportion to the moderately decreased platelet count, suggesting the concurrence of a platelet function defect. Life-threatening bleeding has been reported, but is the exception. The combination of macrothrombocytopenia and one or more of the recognized clinical features of MYH-9-related disorder is strong evidence for this diagnosis.

Laboratory Findings

Platelet counts are normally from 20,000 to 130,000/ μ l, and are associated with an increased mean platelet volume and a conspicuous population of very large platelets. The presence of Dohle-like bodies within neutrophils on stained peripheral blood smears is highly suggestive of MYH-9-related disorder. An abnormal staining of neutrophil inclusions with antibodies specific for NMMHC-IIA is a more sensitive index of the syndrome, but a definitive diagnosis must be based on the identification of a causative mutation within MYH9.

Management

The symptoms of MYH-9-related disorders are highly variable, and therefore treatment of individual patients should be guided as much as possible by personal and family history.⁵ In general, management would be the same as for other mild platelet disorders.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked recessive disease characterized by microthrombocytopenia, eczema, and immunodeficiency.¹ The WAS gene encodes the WAS protein (WASP), and mutations in WAS result in decreased or absent expression of WASP, a key regulator of actin polymerization in hematopoietic cells playing a role as an adapter protein. The reduction in or absence of WASP results in premature proplatelet formation in the bone marrow and the microthrombocytopenia characteristic of WAS.

Etiology

WAS arises from mutations in WAS, the gene for the protein WASP that is expressed in all hematopoietic cell lineages. Isolated X-linked thrombocytopenia (XLT) is also caused by mutations in WAS and is a variant of the same disease but generally lacks severe immune deficiency.⁸⁸

Clinical Features

Infants with WAS often present with bruising and purpura in the neonatal period with an increased risk of intracranial hemorrhage. Gastrointestinal bleeding or prolonged bleeding after circumcision may be a presenting feature. Eczema develops during the first year of childhood and can vary in severity, from widespread and debilitating in children with "classic" WAS to mild or absent in those with the XLT. Infections begin in the first 6 months of life. Bacterial infections occur more often, particularly otitis media and respiratory tract infections, whereas severe viral infections and opportunistic infections occur less frequently. In the XLT phenotype, eczema and infection do not occur. With increasing

age, hemolytic anemia and vasculitis become the most frequent manifestations of the autoimmune component of this disease.⁸⁹ Another life-threatening complication of WAS is malignancy, usually but not exclusively lymphoreticular in origin.

Laboratory Findings

Thrombocytopenia (ranging from 5,000 to 50,000/ μ l) with small platelets is evident at birth. Despite normal bone marrow megakaryocyte numbers and morphology, there may be ineffective thrombocytopoiesis with reduced platelet survival.

Management

The management of WAS should address bleeding manifestations, recurrent infections, eczema, autoimmune disorders, and the risk of malignancy. When available, bone marrow or stem cell transplant is the treatment of choice as early as possible. Proper management is benefited by a multidisciplinary approach, which should include an immunologist. When transfusion is necessary, HLA-compatible and irradiated platelets should be used in order to avoid sensitization. Because of the immune deficiency, platelets to be transfused should always be irradiated and certified free of cytomegalovirus. Splenectomy can result in an increase both in platelet number and size, but the risk of sepsis is increased post splenectomy, and a risk-benefit analysis of this operation must be considered for individual patients. Splenectomy does not influence the development of malignancy or autoimmune disorders, and it may thus be more successful in the milder phenotype of XLT.

ACQUIRED DISORDERS OF PLATELET FUNCTION

Drug-induced Platelet Dysfunction

An adult patient that presents with a normal platelet count, mucocutaneous bleeding, and a negative family history, defined as no bleeding among first degree relatives, should be evaluated for an acquired disorder. Although inherited platelet disorders are rare, acquired disorders of platelet function are encountered frequently.

A diverse variety of medications, from ionophores to ADP analogs, certain systemic diseases, and various procedures can induce platelet dysfunction (Table 52.2). Even common dietary substances, such as garlic or fish oil, can impair platelet function.⁹⁰ This chapter focuses on commonly used drugs that can impair platelet function at therapeutic doses. Other drugs that are used to treat thromboembolic disorders are discussed in detail in Chapter 62.

The extent of platelet dysfunction produced by drugs in healthy individuals is usually not clinically significant. On the other hand, patients with coagulation disorders, uremia, thrombocytopenia, and patients receiving heparin or Coumadin as anticoagulant

P.1139

therapy, can exhibit serious bleeding when they receive a drug that attenuates platelet function. In addition, the inherent variation in platelet reactivity among normal individuals⁹¹ can greatly influence the susceptibility of an individual to the antiplatelet effects of dietary supplements or drugs.

TABLE 52.2 DRUGS AFFECTING PLATELET FUNCTION

Analgesics

Aspirin

Nonsteroidal anti-inflammatory drugs

Acetaminophen

Antibiotics

β -Lactams: Penicillins, cephalosporins

Cardiovascular drugs

Aspirin

Aspirin inhibits platelet function via irreversible acetylation of platelet COX-1 and the resulting inhibition of TXA₂ synthesis. A single high dose of aspirin (e.g., 325 mg or more) or consecutive smaller doses (e.g., 81 mg) taken for 3 or more days will produce essentially complete inhibition of TXA₂ production. The hemostatic risk following aspirin is

predictable, with a 5% to 10% incidence of minor bleeding and a 1% to 2% incidence of major bleeding, i.e., requiring hospitalization or red cell transfusion.⁹²

In *ex vivo* whole blood perfusion assays, aspirin-treated platelets will adhere normally to denuded arterial segments or collagen-coated surfaces, but they fail to form thrombi due to inhibition of aggregate formation. By EM, one notes an inhibition of organelle centralization that normally follows platelet stimulation by collagen. In platelet aggregation assays, aspirin-treated platelets exhibit decreased responses to collagen and an absence of the secondary wave of aggregation that is normally induced by epinephrine and low concentrations of ADP, which is reflected in a marked reduction in the release of δ -granule ADP, ATP, and serotonin.

Individual differences in platelet responsiveness to aspirin have been noted. In some normal individuals, aspirin ingestion can modestly elevate the bleeding time and have a small impact on platelet aggregation *in vivo*, more so in men than in women, but in certain patients with otherwise minor platelet dysfunction, the bleeding time can be markedly prolonged and platelet aggregation severely impaired after aspirin ingestion. The search for a genetic basis for this difference in aspirin sensitivity is a hotly contested area of investigation.

Other Nonsteroidal Anti-inflammatory Drugs

NSAIDs reversibly inhibit platelet COX-1, and normal platelet function is gradually restored when these drugs are stopped. For example, ibuprofen (600 mg daily) will prolong PFA-100 CTs, but these will conform to baseline within 24 hours after drug in-take is ceased.⁹³ It is uncommon to see clinical bleeding in normal individuals as a result of an NSAID, but gastrointestinal bleeding due to gastric ulceration is not uncommon. Paradoxically, ibuprofen can also exhibit a prothrombotic effect if it is ingested within 2 hours of taking aspirin, inasmuch as it can transiently block acetylation of the COX-1 target site.

Cyclooxygenase-2 Inhibitors

COX-2 inhibitors provide the anti-inflammatory effects of COX blockade without affecting platelet function. COX-2 is expressed in endothelial cells, fibroblasts, and monocytes and is up-regulated in response to growth factors, cytokines, endotoxin, and hormones. Even though COX-2 inhibitors have no direct effect on platelets, they increase the risk for thrombosis and cardiovascular disease because they inhibit vascular (endothelial) cell synthesis of prostacyclin, a natural inhibitor of platelet activation and thrombosis.⁹⁴

P2Y₁₂ Antagonists

Platelet responses to natural agonists are normally enhanced by the binding of released ADP to platelet purinogenic receptors. The thienopyridines clopidogrel and ticlopidine bind irreversibly to the platelet purinogenic receptor P2Y₁₂ and thereby inhibit platelet responses induced by both exogenous ADP and ADP released from platelet δ -granules. However, clopidogrel has replaced ticlopidine as the preferred medication because the latter is associated with potentially life-threatening hematologic side effects (thrombotic thrombocytopenic purpura, agranulocytosis, and aplastic anemia). Steady-state inhibition of platelet function occurs after 3 to 5 daily doses of 75 mg clopidogrel, but it can be achieved sooner with a 300-mg loading dose. Even though clopidogrel has a greater effect than aspirin on the bleeding time,⁹⁵ there is no greater risk of bleeding *in vivo*. The combination of clopidogrel and aspirin is currently used to prevent or treat arterial thrombosis.⁹⁶ The effect of clopidogrel on platelet function is irreversible, such that after cessation of clopidogrel, platelet function returns to roughly 50% of normal levels by 72 hours, and its effect is completely reversed by 7 days.⁹⁷

Antibiotics

Large doses of various β -lactam antibiotics (penicillins more often than cephalosporins) can cause clinical bleeding, abnormal platelet function *in vitro*, and increased bleeding times, because of a nonspecific effect on ligand-receptor interactions.⁹⁸ The effect on platelet function can be manifested by a dose-dependent reduction in platelet aggregation *in vitro* to ADP, epinephrine, and collagen. The clinical effect is exaggerated in hypoalbuminemic patients because the level of free drug is increased and thus more interact with the platelet surface. β -Lactam compounds influence clinical bleeding when there is co-existing hemostatic defect, such as in uremia, thrombocytopenia, or vitamin K deficiency.

β -Lactams appear to modify the platelet membrane and decrease agonist binding. The effect can become event after several days of treatment and will not resolve until 7 to 10 days after discontinuation. Moxalactam and cefotetan can produce clinical bleeding as a result of both platelet dysfunction and the N-methylthiotetrazole side-chain effect on vitamin K-dependent clotting factor synthesis.^{99, 100}

Integrin α IIb β ₃ Antagonists

Specific inhibitors of integrin $\alpha\text{IIb}\beta\text{3}$ are potent inhibitors of platelet function, and three are currently approved by the FDA: Abciximab is a chimeric human-mouse monoclonal Fab fragment; tirofiban is an arginine-glycine-aspartate-based peptidomimetic; and eptifibatid (integrelin) is a synthetic cyclic heptapeptide based on the lysine-glycine-aspartate motif of the snake venom disintegrin barbourin.

These antagonists, which inhibit platelet aggregation effectively because they prevent fibrinogen and VWF binding to $\alpha\text{IIb}\beta\text{3}$, are used commonly in patients undergoing percutaneous coronary intervention (PCI), concurrently with heparin and other antiplatelet therapy such as aspirin. Bleeding is a common side effect of these antagonists and occurs in ~10% of recipients, but intracranial bleeding (<0.5%) and death due to bleeding (<0.1%) are rare. The duration of the antiplatelet effect of these drugs varies: Although unbound abciximab is cleared rapidly, elimination of bound drug is significantly slower and some residual receptor blockade (~25%) can be detected for up to 7 days; the inhibitory effects of the other two small molecules are directly proportional to their elimination half-life and usually disappear within hours of drug removal.¹⁰¹

Uremia

Patients with uremia are at risk for bleeding complications because of a number of factors that include minor coagulation abnormalities, platelet dysfunction, thrombocytopenia, or the widespread use of medications that compromise hemostasis.¹⁰² Defects in all stages of platelet hemostasis including adhesion, secretion, and aggregation have been noted in studies of platelet function in uremic patients.

P.1140

Factors That Influence Hemostasis

Nitric oxide is a potent modulator of vascular tone that limits platelet adhesion to the endothelium and platelet-platelet interaction by increasing the formation of cGMP,¹⁰³ and enhanced nitric oxide synthesis has been demonstrated in uremic patients. The inhibition of nitric oxide formation in a rat model of uremia completely normalized the bleeding tendency in rats.¹⁰⁴

Additional platelet changes have been noted. Deficient platelet stores of ADP and serotonin have been described in uremic platelets, suggesting that these platelets have an acquired storage pool deficiency. Elevated cAMP levels may be responsible for an acquired defect of COX activity with reduced ability to synthesize TXA₂. Alterations in intraplatelet calcium mobilization have also been reported and theorized to be associated with uremic bleeding.¹⁰⁵

In uremic patients, integrin $\alpha\text{IIb}\beta\text{3}$ has a reduced ability to bind both VWF and fibrinogen,¹⁰⁶ most likely due to a conformational change in this integrin. Hemodialysis improved fibrinogen binding, leading to the hypothesis that a dialyzable toxic substance is responsible in part for altered platelet function. Uremic substances that inhibit platelet function in concentrations detectable in uremic plasma include: Urea, guanidine-succinate, parathyroid hormone, phenol, and tryptophan products.¹⁰⁷ Small peptides containing the RGD that could potentially inhibit $\alpha\text{IIb}\beta\text{3}$ function accumulate in uremic patients due to reduced clearance.¹⁰⁸

The Effects of Anemia

Anemia predisposes uremic patients to bleeding complications.^{109, 110} When the hematocrit is reduced, platelets travel closer to the center of the vascular lumen and are thus less likely to interact with the subendothelium. In addition, red blood cells release ADP and TXA₂ which enhances platelet aggregation.¹¹¹ Hemoglobin also scavenges nitric oxide and therefore a reduced hematocrit would be associated with enhanced nitric oxide activity and promoting platelet inhibition and vasodilatation. Finally, significant anemia in current vintage dialysis populations often co-occurs with other major problems such as iron deficiency, malnutrition, and inflammation in the sickest patients. This may further confound observational studies of bleeding risk in current dialysis patients.

Secondary Effects of Medications

The bleeding risk in uremic patients is increased by exposure to antiplatelet agents and anticoagulants, including aspirin, $\alpha\text{IIb}\beta\text{3}$ antagonists, heparin, and warfarin.¹¹²

Clinical Features

The bleeding sites in the uremic patient are gastrointestinal and intracranial. Through gastrointestinal bleeding, chronic renal failure patients may lose 4 to 6 times as much blood per day as normal individuals through peptic ulcer disease,

gastric bleeding, telangiectasias in the stomach, duodenum, jejunum, and colon, and duodenitis and esophagitis.¹¹³ In a long-term follow study of 1,609 chronic hemodialysis patients, there was a tenfold higher incidence of intracerebral hemorrhage compared to the general population.¹⁰⁷

Laboratory Findings

Platelet aggregation to exogenous agents is often but not always defective, such that the sensitivity to aggregating concentrations of collagen, ADP, and epinephrine is decreased, and TXB₂ generation and δ -granule ADP content are reduced relative to control platelets.¹⁰⁴

Management

The most effective treatment of uremic bleeding includes hemodialysis and peritoneal dialysis,¹¹⁴ although a transient worsening of platelet function may be encountered immediately following.¹¹⁵ When platelet function was prospectively evaluated after renal transplantation, platelet aggregation, F-actin, and platelet cytoskeletal abnormalities were completely normal by 8 weeks after renal transplant.

Red blood cell transfusions and/or administration of erythropoietin (rHUEPO) have been observed to decrease bleeding, shorten the bleeding time, and increase platelet adhesiveness when given to hemodialyzed patients.¹¹⁶ However, some patients may become hypercoagulable.

Administration of DDAVP can shorten the bleeding time and is effective for short-term control of bleeding in some uremic patients as a result of changes in vWF activity.¹¹⁷

Cardiovascular disease is common in patients with chronic renal insufficiency and end-stage renal disease. Antiplatelet medications are associated with an increased risk of bleeding, compared to the risk associated with their use in patients who do not have end-stage renal disease. Among patients undergoing PCI and treated with abciximab, those with renal insufficiency had a greater tendency of major bleeding.¹¹⁸

Paraproteinemias

Bleeding is a common complication of paraproteinemias associated with multiple myeloma, Waldenstrom macroglobulinemia, monoclonal gammopathies, and even polyclonal hypergammaglobulinemia.^{119, 120} The etiology is complex, but various mechanisms have been proposed, such as thrombocytopenia or platelet dysfunction, inhibitors of specific coagulation factors, circulating monoclonal proteins that bind to and promote clearance of coagulation factors, and hyperviscosity syndrome.

Clinical Features and Laboratory Findings

Hematologic findings that are limited to purpura and mucocutaneous bleeding are most often encountered in patients with IgA myeloma and macroglobulinemia. Platelet dysfunction likely results from nonspecific binding of immunoglobulins to the platelet surface.¹²¹

Myeloproliferative Disorders

Chronic myeloproliferative disorder (MPD) defines a group of Philadelphia chromosome-negative disorders that includes essential thrombocythemia (ET), polycythemia vera (PV), and agnogenic myeloid metaplasia and chronic idiopathic myelofibrosis.¹²² Various platelet defects have been reported in patients with MPD, including defective platelet aggregation and secretion, subnormal uptake of serotonin, abnormal expression of Fc receptors, specific defects in integrin α IIb β 3 expression or activity, and an acquired SPD.

Etiology

Vainchenker et al. showed that acquired JAK2 V617F mutation in hematopoietic precursors causes PV.¹²³ The V617F mutation results in the loss of inhibitory activity of the JH2 pseudokinase segment of JAK2 leading to enhanced activity of the JH1 kinase of JAK2, which renders hematopoietic precursors hypersensitive to thrombopoietin, erythropoietin (EPO), insulin growth factor 1, stem cell factor, and granulocyte colony-stimulating factor. The result is a trilinear myeloproliferation that explains the common proliferative features of ET, PV, and MF.^{124, 125}

P.1141

Clinical Features and Laboratory Findings

Microvascular disturbances in ET and PV, including erythromelalgia, and atypical and typical transient cerebral, ocular, and coronary ischemic attacks, are caused by platelet-mediated transient and occlusive thrombosis in the end-arterial circulation.¹²² An inconsistent pattern of laboratory abnormalities has been encountered, with poor correlation between lab results and bleeding severity. As in MDS and acute leukemia, platelet dysfunction appears to result from defective megakaryocyte maturation and/or thrombopoiesis.

The endogenous synthesis of TXA2 by platelets, reflected by the stable urine metabolite TXB2, is increased in ET and PV patients.¹²⁶ This increased biosynthesis of TXA2 is a reflection of spontaneous platelet activation in vivo.^{126, 127}

Management

Correction of hematocrit to normal by phlebotomy will reduce the major arterial and venous thrombotic complications, but fail to prevent the platelet-mediated microvascular circulation disturbances in PV patients because thrombocytopenia persists. Complete relief and prevention of microvascular and major thrombosis in ET and PV patients, in addition to phlebotomy, are obtained by treatment with aspirin but not with warfarin.¹²²
