Many of the prognostic factors that are relevant at the time of initial diagnosis continue to be important at the time of relapse. These include the International Staging System, the plasma cell proliferation rate, serum LDH, performance status, refractory status with respect to various drugs, cytogenetics and/or FISH findings, and the presence of circulating cells or extramedullary disease. Two key factors that become evident at the time of relapse are particularly relevant to the prognosis of patients with relapsed disease. The duration of response to the initial therapy is one of the most important prognostic factors at the time of relapse. Patients with short lasting responses to initial therapy or are primary refractory to the newer drugs have very poor OS. In fact, in a retrospective study the OS from relapse among a cohort of patients relapsing within 12 months of an ASCT was less than a year. Similar findings have been seen in nontransplant therapy settings as well. The second critical factor is the acquisition of new genetic abnormalities with disease evolution. The two most common abnormalities seen with increasing frequency among relapsed disease are loss of the TP53 gene and chromosome 1 abnormalities, both of which portend a poor outcome.

Treatment of Relapsed Disease: General Approach

Before the era of high-dose chemotherapy with stem cell support, IMiDs, and proteasome inhibitors, treatment guidelines were more straightforward. If the relapse had occurred during an unmaintained remission, resumption of the patient's original therapy was a good rule.⁵⁹⁷ If relapse occurred after unmaintained remission, 50% to 60% of patients responded to

repeat treatment^{414, 596, 597, 613} and median survival was about 10 months.^{597, 617} The current landscape, however, is more complicated. New combinations incorporating the new and the old agents are being tested worldwide,

P.2077

leaving clinicians with an assortment of options but little guidance on how to proceed. There are a few guidelines that can be kept in mind while deciding the management approach to relapsed disease in any given patient. Regimens that have been effective previously, and to which the patient is not refractory can and should be considered again. Combinations of two drugs, where the individual drugs have not been very effective may be able to capitalize on the synergy and produce meaningful responses. Given the clonal selection processes that occur in the myeloma cells as shown through elegant genomic studies,⁶¹⁸ drugs that have previously become ineffective can be of benefit later on, alone or as part of combinations. Although deep responses typically translate into prolonged disease control, minor responses can be quite meaningful in those patient populations from the point of clinical benefit. Therapeutic selection should take into account residual toxicities from earlier therapies in order not to exacerbate the ongoing symptoms and must be tailored to the patient's performance status. Care should be taken in terms of the use of drugs with cumulative toxicity, particularly hematological toxicity, that will preclude subsequent use of some of the newer drugs.

Until MM is a curable disease in all patients, clinical trials will play a critical role in the treatment of these patients. They will assist in defining a better classification system for relapsed disease, clarify which treatments offer the most value, and bring new effective agents into standard clinical practice. The subject of chemotherapy for relapsed or refractory disease is divided into six sections: IMiD-based therapies, proteasome inhibitor-based therapies, IMiD-proteasome inhibitor combinations, emerging new agents and finally older therapies that incorporate alkylators or anthracyclines. Many of the newer regimens have been utilized in the setting of newly diagnosed disease and have been described in that section.

Immune Modulatory Drugs-Based Therapy for Relapsed or Refractory Disease

Thalidomide (Table 98.15). Single-agent thalidomide can induce a response in 25% to 58% of relapsed/refractory patients,^{286, 288, 289, 290, 291, 292, 293, 294, 295} and higher response rates of 41% to 55%^{624, 625, 626, 627} when combined with dexamethasone.^{299, 625} Thalidomide doses have ranged between 100 and 400 mg per day in the different regimens, without any clear dose-response effect. In addition to corticosteroids thalidomide has been combined with a variety of different drugs, both old and new. Investigators have combined thalidomide with alkylators either with^{628, 629, 630, 631, 632, 633} or without corticosteroids^{634, 635} achieving overall response rates as high as 79%, including complete response rates as high as 26%. These have included combinations of thalidomide with melphalan, cyclophosphamide or bendamustine, with addition of dexamethasone or prednisone. DT-PACE is a combination of five drugs including thalidomide (Table 98.4) and is an integral part of "Total Therapy" programs piloted by Dr. Barlogie and colleagues at University of Arkansas.

*Abstract only.

†Minimal response.

Lenalidomide (Table 98.16). As a single agent approximately 18% to 25% of relapsed or refractory patients have achieved a partial response, and the median duration of response for responding patients is 20 months.³⁰⁷ In the randomized phase II trial of lenalidomide, the addition of dexamethasone (40 mg days 1 to 4 and 15 to 18) to patients not responding to 2 months of lenalidomide resulted in partial response rates in an additional 22% of patients.³⁰⁷ The combination of lenalidomide and dexamethasone has been studied in two large phase III trials.^{636, 647} The results of both were comparable with 59% of patients responding to the combination, including a 14% complete response rate. This was significantly better than what was observed with single-agent dexamethasone (PR 22.5% and CR 2%). In addition, both time to progression (11 to 13 months vs. approximately 5 months) and OS (not reached vs. 24 months) were superior in the lenalidomide/dexamethasone arm. The benefit with lenalidomide was independent of prior exposure to thalidomide.⁶⁴⁸ A significant number of patients who initially had a PR improved the response to a CR or VGPR with continued treatment, especially among those obtaining a PR within the first four cycles.⁶⁴⁹ As with other therapies, patients who achieved a CR/VGPR as their best response had significantly longer median response duration, time-to-progression,

P.2078

and OS compared with those with only a partial response.⁶⁴⁹ Continuation of lenalidomide treatment until disease progression in patients achieving a PR was associated with a significant survival advantage.⁶⁵⁰

As with thalidomide, lenalidomide has been combined with alkylators (melphalan, cyclophosphamide, or bendamustine) as well as anthracyclines. The results with these combinations are summarized in Table 98.17.^{651, 652}

Pomalidomide. Pomalidomide (CC-4047) is another thalidomide-based immunomodulatory drug that is currently undergoing clinical trials in relapsed myeloma.^{311, 312} The initial trials with pomalidomide were done several years ago, when the phase I trials established the maximum tolerated dose of pomalidomide as 2 mg daily or 5 mg on alternate days.^{310, 653} These studies used pomalidomide as monotherapy and have shown an excellent activity with an overall response rate of 52%.⁶⁵³ In the initial phase II trial from Mayo Clinic, pomalidomide 2 mg daily in combination with dexamethasone 40 mg weekly were given to a cohort of 60 patients with relapsed myeloma, who had two to three prior regimens.⁶⁵⁴ A total of 38 patients (63%) achieved confirmed response including CR in 3 patients (5%), VGPR in 17 patients (28%), and PR in 18 patients (30%). Responses were seen irrespective of their prior drug exposures, with 40% of lenalidomide-refractory patients, 37% of thalidomide-refractory patients, and 60% of bortezomib-refractory patients achieving a response. Subsequent cohorts of patients were enrolled studying different doses and schedules in different groups with respect to their refractoriness to bortezomib or lenalidomide.^{655, 656}

The optimal dose and schedule for pomalidomide remains an issue of debate. The studies done so far have examined either 2 mg or 4 mg, and given either continuously or for 3 out of every 4 weeks. Richardson and colleagues in a phase I/II dose escalation study showed that 4 mg pomalidomide daily given for 3 of 4 weeks is the MTD for that particular schedule.⁶⁵⁷ The IFM group performed a randomized phase II trial looking at two dosing schedules, 21/28 days or 28/28 days with pomalidomide administered at 4 mg daily with weekly dexamethasone. The overall response rate and the duration of response were comparable with the two strategies as was the overall toxicity.⁶⁵⁸

P.2079

Proteasome Inhibitor-based Therapies for Relapsed or Refractory Disease

Bortezomib (Table 98.17). Single-agent response rates in relapsed/refractory myeloma range from 28% to 38% with a median duration of response of 8 months.^{308, 320, 321, 322} In a phase III study, Richardson et al. randomly assigned 669 patients with relapsed myeloma to receive either an intravenous bortezomib or high-dose dexamethasone.³²¹ The overall response rate was significantly higher with bortezomib (38%) compared with dexamethasone (18%) and the median times to progression in the bortezomib and dexamethasone groups were 6.2 months and 3.5 months, respectively. Although the original studies using this drug included only eight cycles of therapy, 63 patients were treated on an extension study without significantly more serious adverse events than were seen on the parent studies of eight cycles alone.⁶⁵⁹

As with the IMiDs, the initial trials of bortezomib were followed by a series of trials examining various combinations including alkylator drugs and doxorubicin.^{660, 661, 662, 663} One of the most commonly used and effective combinations has been that of cyclophosphamide added to bortezomib and dexamethasone.^{664, 665, 666} In an international phase III study, 646 patients were randomly assigned to receive either intravenous bortezomib with or without PLD.⁶⁶⁰ The overall response rate was similar between bortezomib (41%) and PLD + bortezomib (44%). Median time to progression was increased from 6.5 months to 9.3 months with the combination and the 15-month survival rate for the combination was 76% compared with 65% for bortezomib alone.

Carfilzomib. Carfilzomib is a next-generation, selective proteasome inhibitor that has been approved for treatment of relapsed MM.^{221, 667, 672} In an open-label, single-arm phase II study (PX-171-003-A1), patients received single-agent carfilzomib 20 mg/m² intravenously twice weekly for 3 of 4 weeks in cycle 1, followed by 27 mg/m² at the same schedule.⁶⁷² Among the enrolled patients, 95% were refractory to their last therapy and 80% were refractory or intolerant to both bortezomib and lenalidomide. Overall response rate was 24% with a median duration of response of 7.8 months and OS of 15.6 months. Common toxicities encountered were fatigue, anemia, nausea, and thrombocytopenia. Neutropenia was limited to grades 1 and 2, occurring in 10% to 15% of the patients.

In another phase II trial, 35 patients with relapsed and/or refractory MM who have received at least one bortezomib-based regimen, received carfilzomib 20 mg/m² in a twice-weekly, consecutive-day dosing schedule.⁶⁶⁷ The best overall response rate was 17.1% and the clinical benefit response rate (ORR + Minor response) was 31.4%. The median duration of response was ~10 months and the median time to progression was 4.6 months. In a similar phase II study, 129 bortezomib-naïve patients with relapsed refractory MM received intravenous carfilzomib either at 20 mg/m² for all treatment cycles, or 20 mg/m² for cycle 1 and then 27 mg/m² for all subsequent cycles.²²¹ The overall response rate was 42.4% in the former group and 52.2% in the latter. The clinical benefit response (overall response rate + minimal

response) was 59.3% and 64.2%; the median duration of response was 13.1 months and not reached, and median time to progression was 8.3 months and not reached, respectively. Several combinations of carfilzomib along with the older and new agents are ongoing, and will lead to more treatment options for patients with relapsed disease.

Immune Modulatory Drugs-Proteasome Inhibitor Combinations (Table 98.18)

Some of the most effective regimens reported to date in the therapy of relapsed disease and also with newly diagnosed disease, are combinations involving bortezomib with thalidomide or lenalidomide. The results of these clinical studies are summarized in Table 98.18. Bortezomib has been combined with the DTPACE regimen previously described; the resultant VDTPACE regimen is the standard initial therapy in the “Total Therapy” protocols used at the University of Arkansas.

Other Novel Agents for Relapsed or Refractory Disease

Several new classes of drugs are being tested in clinical trials that are at different stages of development. Several promising drugs are already in phase III testing including pomalidomide and carfilzomib, both of which were discussed previously.

Histone Deacetylase Inhibitors. Acetylation and deacetylation of histone proteins play an important role in the regulation of gene expression. Deacetylated histones by binding tightly to the DNA limit access to transcription factors, leading to inhibition of transcription. Acetylation on the other hand, neutralizes the charge of histones and opens up the DNA conformation, allowing expression of the corresponding genes. The opposing activities of two sets of

P.2080

enzymes, histone acetyltransferase (HAT) and HDAC, control the acetylation status, with normal cells existing in a state of balance. Existing evidence suggests that aberrant recruitment of HDAC may play a role in the changes in gene expression in cancer cells. HDAC inhibitors are thought to affect multiple pathways in MM reversing the abnormalities of cell apoptosis and cell cycle, potentially sensitizing MM cells to apoptosis.^{673, 674} Several HDAC inhibitors have been studied in the context of myeloma, including suberoylanilide hydroxamic acid (SAHA; vorinostat),⁶⁷⁵ ITF2357,⁶⁷⁶ LBH589 (panobinostat),⁶⁷⁷ and romidepsin.⁶⁷⁸ Results thus far suggest modest single-agent activity in patients with MM.⁶⁷⁴

A phase I trial studied escalating doses of oral vorinostat 200, 250, or 300 mg twice daily for 5 days every week or 200, 300, or 400 mg twice daily for 2 of 3 weeks in patients with relapsed/refractory MM.⁶⁷⁹ There were 13 patients enrolled and MTD was not reached. Drug-related adverse experiences included fatigue, anorexia, dehydration, diarrhea, and nausea. Of 10 evaluable patients, 1 had a minimal response and 9 had stable disease.

Romidepsin is an intravenously administered HDAC inhibitor that was studied in a phase II trial, patients with MM who were refractory to standard therapy were treated with romidepsin (13 mg/m²) given as a 4-hour intravenous infusion on days 1, 8, and 15 every 4 weeks.⁶⁷⁸ No objective responses were seen among the 123 patients treated.

Significant single-agent activity has been less than convincing, however, combinations with bortezomib or lenalidomide appeared to hold promise based on the initial trials. A phase I trial evaluated escalating doses of bortezomib (1 to 1.3 mg/m² on days 1, 4, 8, and 11 and vorinostat at 100 to 500 mg orally daily for 8 days of each 21-day cycle).⁶⁸⁰ Among the 23 patients enrolled, overall response rate was 42%, including three partial responses among 9 bortezomib refractory patients. The most common toxicities were myelosuppression, fatigue, and diarrhea. In another phase I trial, patients with relapsed or refractory MM were randomized to oral vorinostat (200 mg twice daily or 400 mg once daily for 14 days) in combination with bortezomib (0.7 or 0.9 mg/m² on days 4, 8, 11, and 15 or 0.9, 1.1, or 1.3 mg/m² on days 1, 4, 8, and 11).⁶⁸¹ The best responses observed in the 33 evaluable patients included PR (36.4%), MR (18.2%), and SD (39.4%). Based on the initial results, a large phase III trial was performed comparing vorinostat with or without bortezomib. Overall, 636 patients were randomized to bortezomib in combination with vorinostat or placebo. Although the overall response rate was significantly higher with the vorinostat combination (56% vs. 41%), the PFS was only marginally improved (7.6 vs. 6.8 months) and no difference was seen in OS. Over a third of the patients had serious adverse events, with hematological and gastrointestinal toxicity and fatigue being the most common.⁶⁸²

The combination of panobinostat and bortezomib also has been explored in early stage trials. In a phase Ib trial, San Miguel et al. observed with 14 partial response or better (50%) among 28 evaluable patients, including 4 with complete response (CR).⁶⁸³ Common adverse events included hematologic toxicity, diarrhea, fever, nausea, fatigue, and asthenia. In another trial, panobinostat was combined with melphalan, prednisone, and thalidomide, with some activity, but was accompanied by significant hematological toxicity.⁶⁸⁴ A large phase III trial is currently evaluating the combination of panobinostat and bortezomib in patients with relapsed MM.

Harrison et al. studied the combination of romidepsin with bortezomib, identifying bortezomib 1.3 mg/m² on days 1, 4, 8, and 11, dexamethasone 20 mg (days 1, 2, 4, 5, 8, 9, 11, and 12), and romidepsin 10 mg/m² (days 1, 8, and 15) every 28 days as the MTD.⁶⁸⁵ Thrombocytopenia was the most common hematologic toxicity and peripheral neuropathy occurred in 76% of patients. The overall response rate was 60% including 52% PR and 8% CR. The median TTP was 7.2 months, and the median OS was > 36 months. This regimen shows activity with manageable toxicity and warrants further evaluation.

Heat Shock Protein 90 Inhibitors. Heat shock protein 90 (Hsp90) is a molecular chaperone that is induced in response to cellular stress and leads to stabilization of various client proteins involved in cell cycle control and apoptotic signaling. Hsp90 inhibitors have been shown to decrease MM proliferation, and sensitize MM cells to other anticancer agents.⁶⁸⁶ Several hsp90 inhibitors have been evaluated in early-stage clinical trials.

Tanespimycin was one of the early hsp90 inhibitors to be tested in myeloma. In a phase I dose-escalation study, tanespimycin (150 to 525 mg/m²) was given on days 1, 4, 8, and 11 of each 3-week cycle in patients with relapsed/refractory MM.⁶⁸⁷ One patient (3%) achieved an MR, and 52% had SD with a median PFS of 2.1 months. Common adverse events included diarrhea, back pain, fatigue, and nausea, anemia, and thrombocytopenia.

Preclinical studies suggested potent synergy when hsp90 inhibitors were combined with bortezomib, paving the way for combination clinical trials. In a multicenter phase I/II trial tanespimycin (100 to 340 mg/m²) was combined with bortezomib (0.7 to 1.3 mg/m²) given on days 1, 4, 8, and 11 of a 3-week cycle.⁶⁸⁸ The highest tested dose of tanespimycin at 340 mg/m² and bortezomib at 1.3 mg/m² was considered the phase II dose. The combination was well tolerated and among 67 efficacy-evaluable patients, there were 2 (3%) CR, 8 (12%) PR, and 8 (12%) minimal responses.

Signal Transduction Inhibitors. Various signal transduction pathways have been considered critical for the survival and proliferation of myeloma cells. Among these the PI3K-Akt pathway has been most studied from a therapeutic standpoint. Perifosine is the best-studied Akt inhibitor in the setting of myeloma.⁶⁸⁹ In a phase II trial of perifosine, alone or with dexamethasone, the best response to single agent among 48 enrolled patients was an MR in 1 patient and stable disease in 22 patients (46%).⁶⁹⁰ Addition of dexamethasone in 37 patients with disease progression led to a partial response in 13%. Most common adverse events included nausea, vomiting, diarrhea, fatigue, increased creatinine, and anemia. Subsequent trials have examined the combination of perifosine with lenalidomide or bortezomib with modest evidence of activity.^{690, 691}

The mTOR kinase, downstream in the PI3K/Akt pathway has been another target explored in myeloma. Both CCI779 and RAD001 have been studied in phase II trials in patients with relapsed disease with very little clinically relevant antimyeloma activity. Ghobrial et al. studied intravenous temsirolimus given at 15 or 25 mg with bortezomib at 1.3 or 1.6 mg/m² once a week enrolling 20 patients into the phase I study and 43 into phase II. The MTD was determined to be 1.6 mg/m² bortezomib on days 1, 8, 15, and 22 in combination with 25 mg temsirolimus on days 1, 8, 15, 22, and 29, given every 35 days. In the phase II study, the proportion of patients with a partial response or better was 33%. The most common treatment-related grade 3 to 4 adverse events were thrombocytopenia, hematologic disorders, and diarrhea.

Monoclonal Antibodies. Monoclonal antibody therapy has seen resounding success in B-cell malignancies, but has had minimal success with plasma cell disorders. Elotuzumab is a humanized monoclonal IgG1 antibody targeting human CS1, a cell surface glycoprotein. CS1 is highly and uniformly expressed on MM (MM) cells, with limited expression on natural killer (NK) cells and CD8 + cells and little to no expression in normal tissues. In a phase I study, escalating doses of elotuzumab (2.5, 5, 10, and 20 mg/kg IV) were administered on days 1 and 11 in combination with bortezomib (1.3 mg/m² IV) administered on days 1, 4, 8, and 11 of a 21-day cycle.⁶⁹¹ Dexamethasone 20 mg PO was added for patients with disease progression. The MTD was not reached and the most frequent grade 3/4 side effects were lymphopenia, fatigue, thrombocytopenia, neutropenia, hyperglycemia, peripheral neuropathy, pneumonia, and anemia. A partial response or better was observed in 13/27 (48%) evaluable patients, including 7% CR and 41% PR. Another study examined the drug in combination with lenalidomide, using escalating doses of elotuzumab with

P.2081

the standard lenalidomide dose.⁶⁹² No DLTs were observed at the maximum dose tested (20 mg/kg). A partial response or better was seen in 82% (23/28) of treated patients and 96% (21/22) of lenalidomide-naïve patients. Richardson et al. studied two doses of elotuzumab in combination with lenalidomide and dexamethasone in a randomized phase II trial: patients received elotuzumab 10 or 20 mg/kg IV (days 1, 8, 15, and 22 every 28 days in the first two cycles and days 1 and 15 of subsequent cycles), lenalidomide 25 mg PO (days 1 to 21) and dexamethasone 40 mg PO weekly.⁶⁹³ Among 63 enrolled patients, 81% had a PR including 37% with VGPR. The overall response rates were 90% in the 10 mg/kg group (n = 31) and 72% in the 20 mg/kg group (n = 32). Median time to response was 30 days (range, 21 to 100). The most common toxicities were hematologic and infusion reactions.

The inflammatory cytokine interleukin (IL)-6 is a survival factor for malignant plasma cells. CNTO328 is a novel human-mouse chimeric monoclonal antibody targeting IL-6 that has inhibitory effect on tumor burden and potentiates bortezomib-mediated apoptosis. Initial studies support the feasibility of combining the antibody with bortezomib in patients with relapsed myeloma.⁶⁹⁴

Several other drugs have been tried with very modest activity. IFN has been shown to modulate the multidrug resistance phenotype and to re-induce chemosensitivity in patients with chemoresistant MM. In one study, nonresponding patients received the same chemotherapy to which they were resistant, preceded by a 5-day course of IFN. An objective response was achieved in 4 of 14 patients (28.6%).⁶⁹⁵ Several investigators have combined IFN with dexamethasone^{454, 696} or methylprednisolone⁶⁹⁷ as therapy for patients with relapsed or refractory disease. With response rates of 29% to 66%^{696, 697} it is difficult to isolate the corticosteroid and IFN effects. There is no clear evidence that the response rate or the survival time improved compared with similar treatments without IFN.⁶⁹⁸

Because patients with MM refractory to alkylating agents frequently express P-glycoprotein, which is associated with the multi-drug resistance phenotype, cyclosporine, a multidrug resistance reversal agent, has been combined with VAD in patients with refractory or progressive disease. No benefit was observed.^{699, 700} As a result of the findings of a phase I/II trial in patients with myeloma,⁷⁰¹ PSC 833, a multidrug resistance glycoprotein modulator, was incorporated into a small phase III study of VAD versus VAD and PSC 833 in the relapsed/refractory setting.⁷⁰² There was no difference in response rate, PFS, or OS in PSC 833 arm, although there was more toxicity.

CTX, cyclophosphamide; DOR, duration of response; DT-PACE, dexamethasone, thalidomine, cisplatin, doxorubicin, cyclophosphamide, etoposide; EDAP, etoposide, dexamethasone, doxorubicin, cisplatin; hyperCVAD, cyclophosphamide, vincristine, doxorubicin, dexamethasone; mo, months; MOCCA, melphalan, vincristine, cyclophosphamide, lomustine, doxorubicin; N, number of patients; ORR, overall response rate (partial response or better); OS, overall survival; pred, prednisone; mel, melphalan; VAD, vincristine, doxorubicin, dexamethasone; VBAP, vincristine, carmustine, doxorubicin, prednisone.

The human anti-CD20 antibody has demonstrated some effect in patients with myeloma. About 20% of patients with myeloma have CD20 expression on their plasma cells. In one study 1 of 19 patients had a partial response to therapy; an additional 5 had stable disease.⁷⁰³

Alkylator-based Regimens for Relapsed or Refractory Disease (Table 98.19)

There is cross-resistance among the alkylators, but it is not absolute and may be circumvented by increasing dose intensity. Without extreme dose intensification, 5% to 20% of patients with melphalan-resistant disease respond to cyclophosphamide or BCNU as single agents or in combination with prednisone.^{617, 704, 705, 706, 707, 708, 709} Response rates as high as 30% to 38% can be obtained if prednisone is administered with the cyclophosphamide.^{710, 711, 712} Higher doses of cyclophosphamide (e.g., 600 mg/m² intravenously for 4 consecutive days) result in response rates of 29% to 43%.^{237, 713} Both response duration and OS tend to be short, approximately 3 and 9 months, respectively.^{237, 713} Consolidating the chemotherapy into a 1-day schedule rather than a 4-day schedule does not improve response rate but does increase the toxicity.⁷¹⁴ Similarly, administration of 3.6 g/m² over 2 days with prednisone appears to produce comparable responses.⁷¹⁵

Dose intensification of melphalan can also be quite effective and is the basis for high-dose therapy with stem cell support.²²⁰ Selby et al.²²⁷ reported that 66% of patients with resistant disease treated with 140 mg/m² without stem cell support responded, but median response duration was 6 months, with all patients relapsing within a year. Median times to leukocyte and platelet recovery were 42 and 37 days, respectively, and the regimen-related toxicity was 13%. Doses of 50 to 70 mg/m² resulted in a 50% response rate and leukocyte and platelet recovery time of 20 and 16 days, respectively.^{716, 717} Further reducing the intensity to 30 mg/m² every 2 months resulted in response rates of 38% and progression-free survival of 10 months.⁷¹⁸

VBMCP (the M-2 regimen) or MOCCA provided responses in 20% to 30% of refractory patients^{375, 719, 720} with a median survival of about 11 months.⁷²⁰ Combinations of cisplatin with BCNU, cyclophosphamide, and prednisone have produced response in heavily pretreated patients;³²⁸ however, the addition of cisplatin and bleomycin to VBAP did not appear to produce better outcomes than standard VBAP.^{274, 327, 328} The addition of etoposide to high-dose cyclophosphamide and granulocyte-macrophage

P.2082

conlon-stimulating factor resulted in a response rate of 42%, but with significant myelosuppression.⁷²¹

Bendamustine with or without corticosteroids can produce responses in approximate 55% of relapsed patients. Among patients relapsing after transplant PFS was 26 weeks (0 to 61). In another study among relapsed refractory patients, the median EFS and OS were 7 and 17 months, respectively.

Anthracycline-based Regimens for Relapsed or Refractory Disease (Table 98.19)

Various permutations of doxorubicin-containing chemotherapy regimens—doxorubicin and cyclophosphamide (AC);⁴¹³ doxorubicin, BCNU, cyclophosphamide, and prednisone (ABC-P);⁷²² CAP;⁷²³ VCAP;⁴¹⁴ VBAP;^{724, 725} and BAP⁷²³—have been tried in patients with relapsed and refractory disease, resulting in response rates of 7% to 28%.^{414, 722, 723, 724} Response duration and survival tend to be short: less than 6 and 12 months, respectively. Responding patients tend to live 7 to 10 or even 22 months longer than nonresponders.^{723, 724, 725} Patients who have relapsed disease, rather than resistant or refractory disease, have higher response rates (i.e., close to 30%). Augmenting these combinations with high-dose corticosteroids has been tried with some benefit,^{243, 246, 443} yielding response rates of 47% to 59%, but with a high rate of infection. Concurrent IFN^{435, 698} adds nothing to response rate or OS. In single-arm studies, there does not appear to be any advantage to the addition of cyclophosphamide to VAD, VAMP, or vincristine, epirubicin, and dexamethasone (VED).^{242, 246, 451, 726, 737}

After studying high-dose cytosine arabinoside, cisplatin, and etoposide as single agents, Barlogie et al.³²⁹ did preliminary studies of DAP (dexamethasone, cytosine arabinoside, and cisplatin) and later EDAP (etoposide and DAP). In patients with refractory disease, response rates with these treatments were 7%, 14%, 17%, 0%, and 40%, respectively. Median survival in patients treated with EDAP was 4.5 months. This regimen is myelosuppressive, with more than half of treated patients requiring platelet transfusions and 80% requiring hospitalization for neutropenic fever. In the first month, treatment-related mortality was 15%. In the complex Total Therapy 2 program wherein this regimen was used as part of induction, the respective incremental objective and complete response rates went from 55% and 9% to 65% and 15% after EDAP treatment.³²⁹

RADIATION THERAPY

As early as the mid-1920s there was recognition that external beam radiation therapy could promote immediate relief of pain, healing of pathologic fractures, and resolution of extramedullary plasmacytomas.^{23, 738, 739} Until the 1950s, radiation therapy was the only effective treatment available for the management of plasma cell tumors. With the advent of systemic chemotherapy, indications for irradiation were primarily palliation of bone pain and solitary plasmacytomas. Concern for maintaining bone marrow reserve also constrains the use of radiation in patients with MM. Sykes et al.^{730, 731} showed that radiation has long-term effects on the bone marrow; the majority of patients receiving concentrated local doses of 3,500 cGy or more showed persistent localized marrow aplasia. One must administer enough radiation to provide palliation, without jeopardizing opportunities for further systemic therapy. In a retrospective review, Norin⁷³² has found that objective improvement was lacking when the tumor dose was below a cumulative dose (single-dose equivalent) of 1,000 cGy. For palliation, the recommendation is, therefore, a cumulative dose of 1,500 cGy, corresponding to a tumor dose of 3,400 cGy in 10 to 15 fractions.^{732, 733} Leigh et al.⁷³⁴ recommended a total cumulative dose of 1,000 cGy in these same patients. There is controversy as to whether the duration of response correlates with the radiation dose in myeloma patients.^{734, 735}

In contrast, the conventional wisdom has been that patients with solitary plasmacytoma of bone should receive higher doses in an attempt at cure. Although the optimal dose has not been established by randomized controlled trials, 4,000 to 5,000 cGy encompassing all disease with a margin of normal tissue is recommended by most experts.^{736, 737, 738} A recent study of 203 patients with solitary plasmacytoma of bone has brought this principle into question.⁷³⁹ These authors found that therapeutic doses above 3,000 cGy had no bearing on local control.

Radiation can often spare patients from undergoing surgery.⁷⁴⁰ In a recent retrospective analysis of 35 cases of patients with cervical lesions and spinal instability, it was found that 19 of the 20 patients experienced resolution of pain, 15 of whom received radiation alone. Of the 10 patients with sufficient follow-up data, none showed clinical progression of instability.

The first report of using whole body irradiation to treat myeloma was by Medinger and Craver⁷⁴¹ in 1942. Partial or complete relief of pain was noted in the majority of patients. Once effective systemic chemotherapy came into wide use, this approach became less popular until 1971 when Bergsagel⁷⁴² postulated that sequential hemibody radiation could be a means of debulking tumor. He suggested that if a dose of approximately 725 cGy were given to the upper half of the body and 1,000 cGy to the lower half, a theoretical 3-log kill could be achieved and survival prolonged. After a series of retrospective studies^{743, 744, 745, 746, 747, 748, 749, 750, 751} and a randomized study^{417, 752} evaluating its role in the earlier phases of myeloma, hemibody irradiation has once again fallen out of favor. In patients who have end-stage disease, with poor pain control, this treatment may still be important.

The majority of series involving hemibody or sequential hemibody radiation are retrospective and include patients who were either resistant to or relapsing from alkylator-based therapy. Significant relief of bone pain occurred in 80% to 90%

of patients^{743, 744, 745, 746, 747, 748, 749, 750, 751} and the median duration of survival was 5 to 11 months^{733, 745}. Objective biochemical response occurred in 25% to 50% of patients.^{745, 746, 753} Pain relief typically occurred 1 to 2 days after institution of therapy, with a maximal response in 1 to 2 weeks.⁷⁴³ The most common side effects were moderate myelosuppression, pneumonitis, nausea, vomiting, diarrhea, and stomatitis.^{733, 743} If an oral lead shield was not used, mucositis also occurred.⁷³³ Nadirs occurred within 3 weeks⁷⁴⁵ and white cell count and platelet count recovery occurred by about 6 weeks.^{733, 745} Decrements in pulmonary function occurred in about half the treated patients.⁷³³ The most serious complication was radiation-induced pneumonitis, which was seen in 14% of patients.⁷⁴⁵ The option of sequential half-body radiation therapy must be balanced against unpredictable and varying degrees of pancytopenia and alternative treatment options.⁷⁵³

Bergsagel's postulate⁷⁴² and preliminary data from several small studies^{744, 749, 750} led two cooperative group studies (SWOG 8229 and CALGB 8003) to incorporate systemic radiation therapy as consolidation therapy.^{417, 752} Neither study demonstrated a meaningful advantage to patients receiving adjuvant hemibody radiation,^{417, 752} and hemibody radiation is used only for pain palliation in end-stage chemotherapy-refractory myeloma patients.

PROGNOSIS AND PATHOGENESIS

Prognosis and pathogenesis are covered together because in many instances there is an intimate relationship between them. To date no single molecular defect can account for the pathogenesis of MM, although by using single nucleotide polymorphisms and gene expression profiling, several candidate genes have been identified as being different between MGUS and MM.^{754, 755} It is not clear if a single critical genetic change in the clonal plasma cell of MGUS results in the "switch" to the malignant state of myeloma or if it represents the cumulative effect of

P.2083

a series of changes, which may be different in different patients. Malignant plasma cells are long-lived cells, typically with low proliferative rates.^{137, 756} A post-germinal cell origin is indicated by their somatically hypermutated, rearranged immunoglobulin genes.⁷⁵⁷ A multitude of abnormalities has been identified in signaling pathways, apoptotic mechanisms, the bone marrow microenvironment, and the cell cycle. Factors including the level of gene expression, protein expression, and phosphorylation status of cell cycle molecules may all be relevant for the propagation of the malignant plasma cells. Extracellular signaling alterations include changes in stromal cell, osteoblast, osteoclast, vessel endothelial cell, and immune cell interactions. These changes may in turn result in activation, adhesion, and cytokine production that fuel myeloma cell proliferation and survival (Fig. 98.10).

Prognosis and Staging

Survival of MM patients varies from months to more than a decade.^{599, 758} There are no precise methods of identifying the subset of newly diagnosed patients who are best served by standard intensity therapies, by maintenance therapies, by novel therapies, or by more intensive regimens such as hematopoietic stem cell transplantation. Prognostic factors are needed for patient counseling, therapeutic decision making, and clinical trial stratification. Given the disease heterogeneity and differing outcomes, it is important to understand the prognostic factors and develop adequate risk stratification systems in order to compare different groups of patients from different studies or clinical trials. However, prognostication is a dynamic process changing within a given patient during the disease course as dictated by the response to therapies and acquisition of new genetic changes. It is also constantly changing for the disease as a whole with incorporation of newer therapeutic strategies for the disease.

Staging is one form of prognostic modeling. The Durie-Salmon system (Table 98.20), which until the present had been the most widely accepted MM staging system, separates patients predominantly by tumor burden and renal function.²⁶ As the biology of myeloma is better understood, novel markers reflecting myeloma cell kinetics, signaling, genetic aberrations, and apoptosis have eclipsed the prognostic significance of tumor burden as a predictor of survival.^{415, 759, 760, 761, 762, 763, 764, 765} At the time of its inception, the Durie-Salmon staging system was an elegant system that incorporated information about immunoglobulin production and half-life, hemoglobin, calcium, creatinine, and extent of bone disease to derive mathematically the total myeloma cell burden.²⁶ Quantification of bone lesions used in this staging system, however, is not always reliable as a prognostic factor⁷⁶² in that patients classified as stage III solely on the basis of bone lesion criteria do not have a poorer prognosis.

FIGURE 98.10. Putative pathogenic mechanisms in myeloma. IGF, insulinlike growth factor; IL, interleukin; MIP, macrophage inflammatory factor; MMP, metalloproteinase; NCAM, neural cell adhesion molecule; TNF, tumor necrosis factor; VEGF, vascular-derived endothelial growth factor; VLA, very late antigen.

Other variables, including patient age, performance status, serum albumin, immunoglobulin isotype, and bone marrow plasma cell infiltration, have long been recognized to predict survival,^{766, 767, 768, 769} and subsequent models have incorporated these factors^{236, 599, 765, 770} whereas others have shown the prognostic value of serum β 2M, C-reactive protein, lactate dehydrogenase, elevations in serum immunoglobulin free light chains, presence and quantity of circulating plasma cells, bone marrow plasma cell proliferative rate, plasmablastic morphology, bone marrow angiogenesis, and chromosomal abnormalities.^{137, 138, 139, 415, 759, 760, 761, 763, 764, 765, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787} Most recently, MRI and PET-CT imaging has been shown to have some prognostic importance.^{788, 789, 790, 791, 792, 793} More esoteric prognostic factors include: decreased staining of bone marrow plasma cells for acid phosphatase,⁷⁹³ increased circulating plasma cells as measured by the peripheral blood labeling index,⁷⁹⁴ apoptotic index,⁷⁹⁵ increased sIL-6R,^{761, 796} serum neopterin,³⁷⁸ α 1-antitrypsin,⁷⁹⁷ C-terminal telopeptide of Type I collagen,^{798, 799} serum bone sialoprotein,⁸⁰⁰ B12 binding protein,⁸⁰¹ soluble CD56,⁸⁰² soluble Fc receptor (CD16),⁸⁰³ soluble syndecan or CD138,⁸⁰⁴ and serum IL-6 levels.^{797, 805, 806}

A staging system's relevance is based not only on its ability to predict outcome, but also on its availability and cost.⁸⁰⁷ An international consensus panel addressed this issue and developed the International Staging System (ISS) for MM (Table 98.21); it incorporates serum albumin levels and beta-2 microglobulin.⁸⁰⁸ Although this staging system is inexpensive and readily available, it does not get to the heart of myeloma cell biology as do genetic changes, as discussed below. However, it does rely heavily on β 2M concentration, which is the strongest and most reliable prognostic factor for MM that is routinely available.

P.2084

β 2M concentration is influenced by both tumor burden and renal function. Elevated β 2M values predict early death.^{229, 760, 763, 809, 810, 811, 812, 813, 814} Formulas to correct the β 2M concentrations for the effects of renal insufficiency have not improved its predictive value,⁸¹⁵ and the β 2M value is still prognostic in myeloma patients with normal renal function.⁷⁵⁹ As discussed below, investigators have tried to enhance the performance of the ISS by adding other soluble markers or

genetic risk features. An example is combining abnormal FLC ratio with the ISS risk factors to create four prognostic groups with median survival times of 51, 39, 30, and 22 months, respectively.⁷⁷⁶

TABLE 98.20 DURIE-SALMON STAGING SYSTEM

Criterion	Measured Myeloma Cell Mass, Cells × 10¹²/m²	OS, mo
Stage I	< 0.6 (low)	61
All of the following		
Hemoglobin > 100 g/L		
Serum calcium < 12 mg/dl		
On radiograph, normal bone structure (scale 0) ^a or solitary bone plasmacytoma only		
Low M-component production rates		
IgG < 50 g/L, IgA < 30 g/L, or urine		
M spike on electrophoresis < 4 g/24 h		
Stage II	0.6-1.2 (intermediate)	54 ^b
Fitting neither stage I or III		
Stage III	>1.2 (high)	30 / 15 ^c
One or more of the following		
Hemoglobin < 85 g/L		
Serum calcium > 12 mg/dl		
Advanced lytic bone lesions		
High M-component rates		
IgG > 70 g/L, IgA > 50 g/L, or urine light chain M spike > 12 g/24 hrs		

Subclassification

A: Serum creatinine < 2 mg/dl

B: Serum creatinine ≥ 2 mg/dl

^a Scale of bone lesions: normal bones, 0; osteoporosis, 1; lytic bone lesions, 2; and extensive skeletal destruction and major fractures, 3.

^b Includes Durie-Salmon Stage IB and IIB.

^c Includes Durie-Salmon Stage IIIA/IIIB.

Cytogenetics, Fluorescence In Situ Hybridization, and Other Genetic Abnormalities

The first cytogenetic abnormalities in myeloma were documented nearly 30 years ago (Fig. 98.11). In the past decade it has become increasingly apparent that cytogenetic testing is an integral element of establishing prognosis and a treatment plan for all newly diagnosed myeloma patients. Nearly all myeloma patients have abnormal chromosomes by fluorescence in situ hybridization (FISH), including deletions, aneuploidy, and translocations^{816, 817, 818} (Fig. 98.12A,B), although abnormal karyotypes are seen in only 18% to 30% of cases. This apparent discrepancy is explained by the

generally low proliferative rate of myeloma cells and the requirement of obtaining plasma cells (and not just the rapidly dividing normal myeloid precursors) in metaphase to generate conventional cytogenetics.^{819, 820, 821} Therefore, any abnormality in conventional cytogenetics identifies a group with a higher proliferative rate⁸²² and poorer prognosis. There is an excellent correlation between abnormal conventional cytogenetics and a high plasma cell proliferative rate.^{823, 824} With interphase FISH, several chromosomal abnormalities, such as immunoglobulin heavy chain translocations and deletion of chromosome 13, are observed at equal frequencies among the spectrum of plasma cell proliferative disorders from MGUS to MM to PCL.^{825, 826}

TABLE 98.21 INTERNATIONAL STAGING SYSTEM⁸⁰⁸

Stage	Criterion	Overall Survival, months
Stage I	$\beta_2M < 3.5$ mg/L and alb ≥ 3.5 g/dl	62
Stage II	Not Stage I or III	45
Stage III	$\beta_2M \geq 5.5$ mg/L	29

β_2M , beta-₂ microglobulin.

Monoallelic loss of chromosome 13 (del 13) or its long arm (del 13q), when determined by metaphase cytogenetics, is a powerful adverse prognostic factor in patients treated with standard chemotherapy^{764, 827, 828} or with high-dose chemotherapy and hematopoietic stem cell transplantation.^{329, 506, 778, 829, 830} Approximately 50% of newly diagnosed MM patients have del 13 or del 13q by FISH.^{824, 826, 831} Our group has shown that del 13q is associated with specific biologic features, including a higher frequency of λ -type MM, slight female predominance, higher PCLI, and a higher frequency of a serum M component of less than 10 g/L.⁸²⁷ Patients with the deletion by FISH have a worse OS with standard chemotherapy,^{764, 824, 827} high-dose therapy,^{831, 832} and IFN treatment.⁸²⁷ The absence of abnormalities of chromosome 13 and 11 by conventional cytogenetics is associated with longer complete response duration, EFS, and OS in patients treated with high-dose therapy.³²⁹ The prognostic significance of del 13q by FISH is less than that for del 13 by conventional cytogenetics, because the latter test incorporates both the chromosomal abnormality and a high rate of plasma cell proliferation, whereas the former captures only the chromosomal abnormality.

Hypodiploid myeloma has a worse prognosis than diploid or hyperdiploid myeloma. This has been demonstrated by flow cytometric methods^{828, 833, 834} and metaphase cytogenetics.^{830, 835, 836, 837, 838} Controversy exists about whether the deletion 13q adds any additional prognostic information to a hypodiploid karyotype.^{835, 838, 839}

Up to 50% of patients with MM have translocations involving the heavy chain gene on chromosome 14.⁸¹⁸ These translocations include illegitimate switch recombinations of the variable regions of the immunoglobulin heavy chain gene at 14q32. Partners of the translocations into the IgH switch region on chromosome 14 include chromosomes 11, 4, 6, and 16.⁸⁴⁰ The most common translocation in MM is t(11;14)(q13;q32),^{820, 839} which increases expression of cyclin D1,⁸⁴¹ a protein involved in cell cycle progression. The prevalence of t(11;14)(q13;q32) is 20% in MM.^{820, 839, 842} Previous publications had suggested that this translocation was associated with an adverse outcome in MM,^{764, 778} but more recent data refute this hypothesis.⁸⁴² The t(6;14)(p21;q32) is also associated with a neutral prognosis.⁸⁴³ The t(4;14)(p16.3;q32) is present in 15% of MM patients.^{844, 845, 846, 847, 848} This translocation results in the up-regulation of fibroblast growth factor receptor 3 (FGFR3) and in the hybrid transcript IgH/MMSET.^{844, 845} This abnormality had been thought to be as bad as deletion 17p, but there are emerging data that long-term bortezomib use can abrogate some of this poor prognosis. The t(14;16)(q32;q23) is also seen in a

P.2085

small subset (~5%) of patients with MM.^{839, 845} Both convey a very poor prognosis, although a recent French study has questioned the poor prognostic value of t(14;16).⁸⁴⁹ In one study there was a tight association of del 13 abnormalities and high β_2M values with the unfavorable t(4;14) and t(14;16) abnormalities,⁸³¹ suggesting that the poor prognosis associated with del 13 may be because of other nonrandom, associated chromosomal abnormalities.

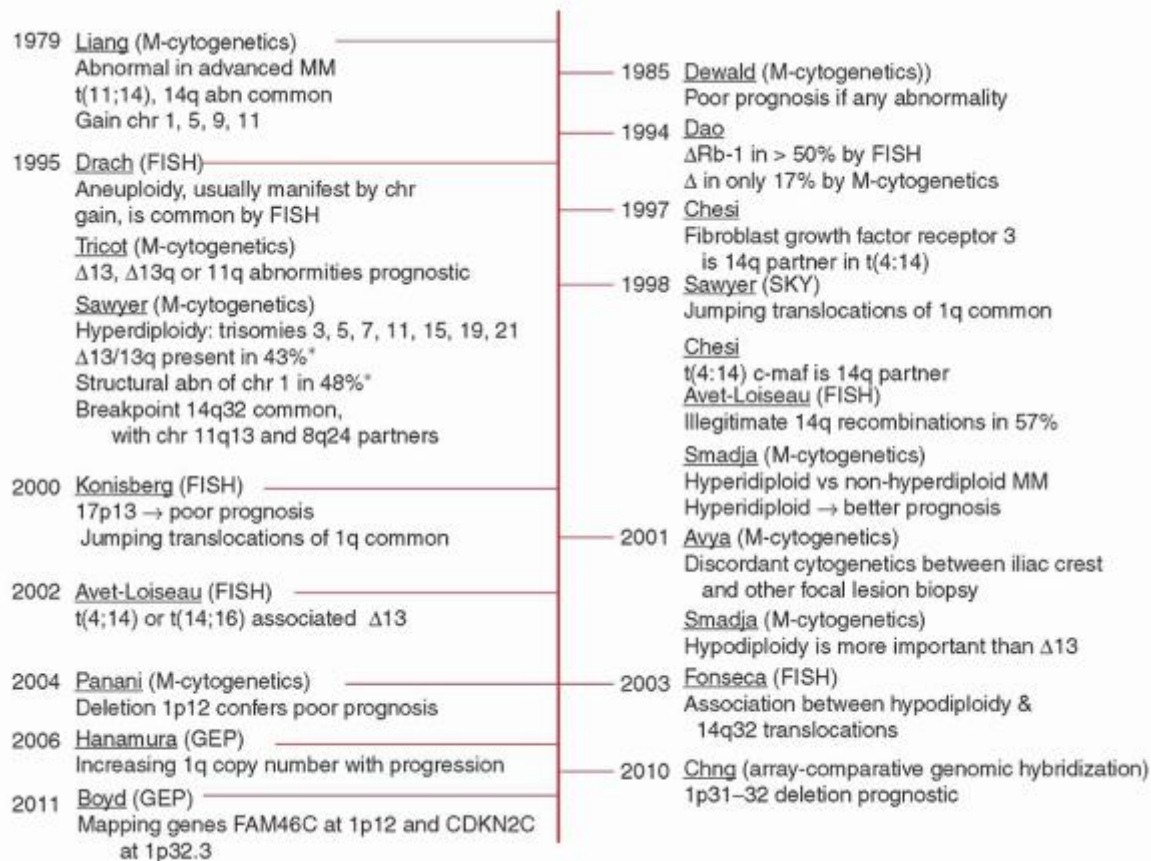

FIGURE 98.11. History of cytogenetic discovery in multiple myeloma.

Trisomy is common by FISH and most often includes chromosomes 3, 6, 9, 11, and 15.⁸⁵⁰ In another study trisomy of 3, 7, and 11 accounted for over 50% of the hyperdiploid cases.⁸⁵¹ Trisomies of chromosomes 6, 9, and 17 were associated with prolonged survival.⁸⁵² Recently it has been shown that presence of trisomies is associated with better outcomes even among patients with high-risk cytogenetic markers such as t(4;14), t(14;16) and 17p deletion (Fig. 98.12C).⁸¹⁸

Deletion of the TP53 gene locus as a result of monosomy 17 or deletion of 17p is seen in 10% of patients at diagnosis and is associated with very short median OS.^{818, 853, 854, 855} In contrast, inactivating mutation of TP53, locus 17p13, is rare in freshly explanted myeloma cells but is common in human myeloma cell lines and in patients with a terminal phase of myeloma.⁸⁵⁶ Such mutations have been observed in ~5% of cases of early MM versus 20% to 40% of cases of PCL.^{857, 858, 859, 860}

Another set of new cytogenetic prognostic markers are abnormalities involving chromosome 1,^{861, 862, 863, 864, 865} either gain of 1q21 or loss of 1p21, and have been associated with poor outcome.^{861, 862} Abnormalities of both the short and long arms of chromosome 1 have been noted since the first cytogenetic studies of myeloma.^{819, 866} Hanamura et al. demonstrated that the frequency of 1q21 amplifications increases from monoclonal gammopathy of undetermined significance (0%), to overt MM (43%), and finally to relapse (72%). In a prospective clinical trial of high-dose therapy (HOVON 24), abnormalities of chromosome 1p and 1q were found in 19 (36% of patients with an abnormal karyotype) and 21 patients (40%).⁸⁶² There was a strong association between chromosome 1p and/or 1q abnormalities and deletion of chromosome 13 or 13q. Patients with 1p/q abnormalities had a significantly shorter OS than patients with normal karyotypes. Amplifications of 1q21 are concurrent with dysregulated expression of c-MAF, MMSET/FGFR3, or deletion 13.⁸⁶⁷ Candidate genes for the molecular mechanism of prognosis imparted by the 1q21 amplification include CKS1B, BCL-9, or RAB25, but this has not been confirmed by others.⁷⁵⁵

Mutations of RAS have been noted in 30% to 50% of MM patients, with increasing prevalence in the advanced stages of the disease^{868, 869} and in patients who have shorter survival.⁸⁷⁰ Mutations of RAS were first observed in fulminant disease,⁸⁵⁶ but have also been observed in 27% to 39% of newly diagnosed cases.^{868, 870} Patients with RAS mutations had a median survival of 2.1 years versus 4 years for patients with wildtype RAS.⁸⁷⁰

Both metaphase cytogenetic and FISH testing each have their own advantages and disadvantages. The added value of metaphase cytogenetics is the additional negative prognostic information provided by the ability to generate a plasma cell karyotype, that is, capture proliferation in addition to information about ploidy status and specific structural abnormalities. The disadvantage is that certain interstitial abnormalities and translocations may be missed. In contrast, a standard myeloma FISH panel will contain probes for the common translocations and structural abnormalities and will detect them regardless of the proliferative rate of the plasma cells. FISH, however, provides no information on the proliferative index of the myeloma cells. Ideally, both metaphase cytogenetics and FISH should be done for all newly diagnosed patients, but if the cost is prohibitive, the test that is more readily available should be performed.

Boyd and colleagues combined FISH results with ISS among 1,069 patients with newly presenting myeloma treated in the MRC IX trial.⁸⁷¹ FISH lesions associated with short progression-free

P.2086

and OS in multivariate analysis were +1q21, del(17p13), t(4;14), t(14;16), and t(14;20). They defined a favorable risk group by the absence of any of these genetic lesions, an intermediate group with one lesion and a high-risk group defined by the co-segregation of >1 lesion. This genetic grouping was then combined with ISS to identify an high-risk group defined by ISS II or III and >1 adverse FISH finding. This high-risk group constituted 14% of patients and was associated with a median OS of 19.4 months.

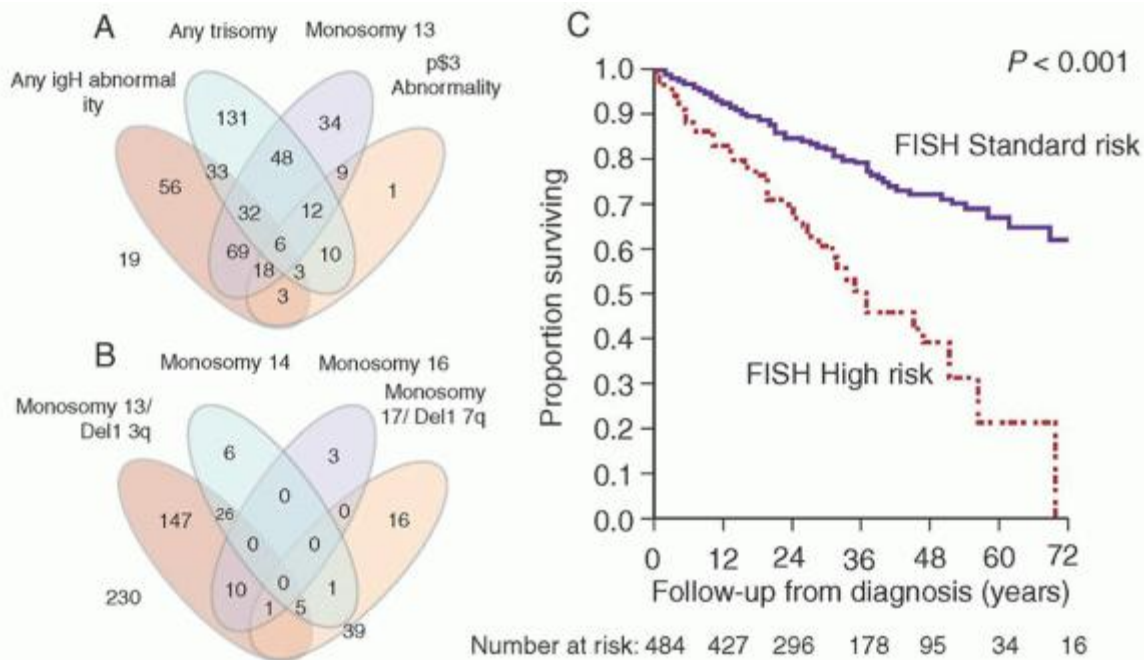

FIGURE 98.12. The relationship between genetic abnormalities among patients with multiple myeloma. A: Venn diagram demonstrating the overlapping nature between the common abnormalities seen with FISH in patients with newly diagnosed multiple myeloma. The actual number of patients with different abnormalities is presented from among 484 patients. The remaining 19 patients either had a normal FISH (n = 15) or another abnormality (n = 4). B: Distribution of various monosomies/deletions and their overlap. C: Modification of genetic risk system, using a hierarchical approach. High-risk includes deletion 17p, t(14;16), t(14;20), but with this new system, patients were reclassified into a new high-risk group, moving those patients previously classified as high-risk but with a trisomy into the standard-risk group. The survival of patients reclassified as high-risk (n = 66; 14%) was 3 years compared with not reached for the standard-risk group (P < 0.001). (From Kumar S et al. Blood 2012;119:2100-2105. Gene Expression Profiling

Many hematological malignancies have witnessed the development of prognostically relevant disease subclassification through microarray profiling. MM is no exception, and considerable progress has been made to predict accurately individual patients' clinical course and survival outcomes using a molecular classification. Zhan and colleagues have comprehensively studied the gene expression on purified plasma cells of 414 NDMM patients who underwent HDT with tandem transplants.⁸⁷² They introduced seven molecular subtypes of MM: PR(proliferation), LB(low bone disease),

MS(MMSET), HY (hyperdiploid), CD-1(CCND1), CD-2 (CCND3), and MF (MAF/MAFB). HY, CD1, CD2, and LB comprised the low-risk group with 3-year actuarial probabilities of 81% to 88%. The two high-risk groups, MS and PR, did not achieve a therapeutic benefit on Total Therapy 2.⁸⁷² The same group of investigators identified 70 genes linked to shortened survival, with 30% of 51 overexpressed and 50% of 19 underexpressed genes mapping to chromosome 1, in a cohort of 532 newly diagnosed patients who received tandem transplants. This model was supplanted by an extremely powerful 17-gene prognostic model to detect the high-risk disease. In addition, this model could successfully prognosticate the patients with relapsed disease on either single-agent bortezomib, or high-dose dexamethasone (APEX phase III trial).⁸⁷³ It has been validated using the Mayo Clinic dataset of 71 NDMM patients treated with HDT, but practical impediments remain in the routine clinical utilization of this model. The GEP70 signature has also been validated in the nontransplant setting among a group of patients with newly diagnosed MM receiving initial therapy with lenalidomide and dexamethasone.⁸⁷⁴

Zhan et al.^{754, 875} have studied the gene expression of 74 myeloma patients by using high-density oligonucleotide microarrays interrogating about 6,800 genes. On hierarchical clustering analysis, four distinct subgroups of myeloma (MM1, MM2, MM3, and MM4) were identified. The expression pattern of MM1 was similar to normal PCs and MGUS, whereas MM4 was similar to MM cell lines. Clinical variables linked to poor prognosis, including abnormal karyotype and high serum β 2M levels, were most prevalent in MM4. Overexpression of genes involved in DNA metabolism and cell cycle control were observed in MM4.

Several risk stratification systems have been proposed on the basis of GEP results in addition to the ones from the University of Arkansas, including those from the French and Dutch groups.⁸⁷⁶ These studies have helped us develop insights into the disease biology. However, the minimal overlap between different signatures raises questions as to the independence of these signatures from the type of therapy utilized as well as the potential influence of the sample preparation on the results and the ability to apply the method uniformly in a real-life clinical setting. Waheed et al. studied 612 patients in the context of the three Total Therapy regimens, showing an independent prognostic value for ISS and cytogenetic abnormalities even when the GEP-based risk stratification and presence of TP53 deletion were incorporated.⁸⁷⁷

P.2087

Routine incorporation of fluorescence in situ hybridization (FISH) as part of the initial work-up of MM has significantly improved our understanding of the disease biology, and a better appreciation of the genetic heterogeneity that underlies this disease.^{818, 878, 879} The majority of the FISH-detected abnormalities are seen at the time of diagnosis, and the prevalence of some of the abnormalities increases with time as patients suffer multiple disease relapses. More recently, application of advanced genomic technologies such as whole genome sequencing has given a different perspective of the genetic chaos that exists in this disease. Chapman et al. performed massively parallel sequencing of 38 tumor genomes and compared them with matched normal DNAs. The pattern of mutations suggested the presence of several new and unexpected oncogenic mechanisms including mutation of genes involved in protein translation in nearly half of the patients, genes involved in histone methylation, and genes involved in blood coagulation. In addition, mutations were observed in 11 members of the NF-kappaB pathway, a pathway that has already been the focus of several studies in myeloma. Activating mutations of the kinase BRAF were observed in 4% of patients, suggesting the evaluation of BRAF inhibitors in MM clinical trials. Additional studies are ongoing, and will help us further delineate the genetic evolution in myeloma. Keats et al., in a recent study, showed that tumors can follow several evolutionary paths over a patient's disease course.⁶¹⁸ With the use of serial genomic analysis of samples collected at different points during the disease course of 28 patients with MM, they showed that the genomes of standard-risk patients show few changes over time, whereas those of cytogenetically high-risk patients show significantly more changes over time. The results indicated that the pattern of genetic evolution over time can follow either a quiescent pathway with few changes, incremental changes with addition of new abnormalities over time (clonal evolution), or consist of a mixture of clones that wax and wane over time based on treatment selection pressure (clonal selection).

Plasma Cell Proliferative Rate

That the rate of clonal plasma cell expansion determines the disease outcome has been known for a long time, and several methodologies have been used to assess the degree of proliferation. One such test, the plasma cell labeling index (PCLI), is a slide-based method that measures the percentage of bone marrow myeloma cells in the S-phase of the cell cycle¹³⁷ which is a powerful prognostic factor in MM.^{759, 760, 765, 880} An increased PCLI predicts a short remission and

survival but does not predict response to therapy. All large studies published to date have confirmed the independent prognostic value of the PCLI for survival after treatment with conventional chemotherapy^{759, 761, 781, 881} or high-dose therapy.⁸¹¹ A recent study highlighted the prognostic relevance of PCLI in the patients treated with immunomodulatory agents, thalidomide and lenalidomide, with high PCLI (≥ 1) at the time of initiation of therapy predicting a poorer progression-free survival. However, lenalidomide appears to negate the adverse impact of high PCLI on OS, an effect not seen in the thalidomide arm. Undoubtedly, a longer follow-up of patients is required to determine the true impact of the PCLI in patients on lenalidomide therapy.⁸⁸²

Determination of S phase by flow cytometry using a DNA/CD38 double-staining technique is also possible.^{765, 883, 884} A high proportion of PCs in S phase ($>3\%$) indicated poorer prognosis. A poor correlation between the slide and flow cytometric LI assays has been demonstrated by the Australian Group who questioned the sensitivity and accuracy of the less objective slide-based PCLI requiring manual enumeration of the plasma cells. In the flow cytometric analysis, the PCLI of primitive plasma cells (CD38⁺⁺/CD45⁺) was higher than that of mature myeloma cells (CD38⁺⁺/CD45⁻), and correlated better with the disease status (mean PCLI of 9.2% in the progressive disease and 2.2% in the plateau, $P = <0.001$).

Ki-67 protein is a marker for proliferation that is expressed by all the cells in the "growth fraction" of the tumor, including the cells in the late G1, S, G2, and mitotic phases of the cell cycle. The Ki-67 proliferative index represents the fraction of myeloma cells expressing Ki-67 antigen as detected by a monoclonal antibody. A higher index indicates poorer prognosis, and a cut-off of 8% could categorize newly diagnosed MM patients into two groups with a difference in survival OS ($P < 0.07$).^{885, 886, 887}

Immunophenotype of Myeloma Cells

As discussed previously, the phenotype of malignant plasma cells is diverse^{143, 144, 145, 148, 149, 151, 152} and potentially dynamic.^{888, 889} Investigators have demonstrated that surface expression of CD45, CD56, and CD117 portends a better prognosis,^{145, 147} whereas, expression of CD28, CD44, a worse prognosis.^{145, 890} Patients with the t(11;14) translocation are more likely to have surface expression of CD56, and CD117. Patients with nonhyperdiploid myeloma have an increased expression of both CD20 and CD28 in the absence of reactivity for CD56 and CD117, all poor prognostic findings.¹⁴⁵ Over the course of the last few decades, a continuous effort to identify diagnosis-, prognosis-, and therapy-related immunophenotypic markers has been instrumental in the recognition of the correlations between certain cellular antigens and the different phenotypic entities of MM. The extramedullary extension of the neoplastic plasma cells has been associated with a reduced expression or total absence (as in de novo or secondary plasma cell leukemia) of the adhesion molecule, CD56,¹⁴⁸ and up-regulation of CD44 on the plasma cells. CD28 (a T-cell marker) expression correlates with disease progression, and is universally expressed in the human myeloma cell lines.^{148, 891} Its association with t(14;16) and del(17p) is notable. The absence of CD45 and CD27 portends a worse outcome. In a multivariate analysis of 95 newly diagnosed MM patients who underwent HDT, the lack of CD45 expression was the only significant variable that affected the outcome (median OS of 42 months for CD45⁻ versus not reached at 4 years for CD45⁺ MM, $P = 0.004$).¹⁴⁶ A small subset of CD45⁺ plasma cells constitutes the proliferative compartment of the bone marrow, and the expression of this antigen is required for IL-6 signaling, but prevents insulin growth factor 1 (IGF-1)-mediated AKT pathway activation. Furthermore, a lower degree of angiogenesis, likely due to reduced vascular endothelial growth factor production, was observed with CD45⁺ expression. CD27 expression is associated with a better OS (92% at 3 years for CD27⁺ MM versus 50% in CD27⁻ MM).⁸⁹²

CD221 (IGF-1 receptor) overexpression is linked with t(4;14) or t(14;16) whereas CD20 expression is tightly associated with the more favorable t(11;14) and small lymphoplasmacytic morphology. Aberrant CD117 (c-KIT) expression is predominant in the MGUS and indolent phases, and infrequent (8%) in the relapsed cases.⁸⁹³ It is associated with a superior outcome (3-year OS, 93% for CD117⁺ versus 64% for CD117⁻ MM; $P = 0.05$). CD200 is a membrane glycoprotein that imparts an immunoregulatory signal through CD200R, leading to the suppression of T-cell-mediated immune responses. Using Affymetrix microarrays, Moreaux et al. quantified the expression of the CD200 gene in myeloma cells of 112 patients with newly diagnosed MM.⁸⁹⁴ The CD200 gene expression was either absent or present in 22% and 78% of MMCs, respectively. Patients with low/absent CD200 had an increased EFS compared with the remaining patients in the context of high-dose therapy and stem cell transplantation.

The value of immunophenotyping newly diagnosed MM by multiparametric flow cytometry was clearly established by the Spanish group in a recent prospective analysis of 685 patients treated with HDT (GEM 2000 protocol).⁸⁹⁵ A prognostic model, risk-stratifying the newly diagnosed MM patients into three

categories, the poor risk (CD28 +/CD117-; 23%), the intermediate risk (CD28-/CD117- or CD28+/CD117+; 56%) and the good risk (CD28-/CD117+, 21%) with OS 45 months, 68 months and not reached, respectively, was promulgated by this group. The HDT followed by ASCT was not beneficial in approximately one quarter of those patients, that is, the high risk group.⁸⁹⁵

Magnetic Resonance Imaging

The superiority of the more sensitive tests, such as whole body/spinal MRI and PET, over conventional radiography is being exploited to prognosticate patients with MM accurately.⁷⁸⁸ One of the key features of the DS stage I patients is the absence of skeletal involvement detected radiographically. However, 29% to 50% of DS stage I patients demonstrate infiltration of the marrow by MRI. The extent of the BM infiltration influences survival and can be adequately estimated by MRI. Various MRI patterns of the BM infiltration—normal, focal, diffuse, and variegated—have been used to predict the OS (56, 51, 24, and 52 months, respectively). Within each ISS I and II stage, the concomitant detection of diffuse BM infiltration by MRI can segregate the patients into two groups with statistically different survival outcomes suggesting enhancement of the prognostic value of ISS with this test. This finding is similar to the previously described observation noted with the incorporation of PCL1 to the ISS. Dynamic contrast enhanced (DCE)-MRI has been shown to correlate with the degree of tumor infiltration in the bone marrow as well as the degree of vascularity or angiogenesis in the marrow.^{789, 790}

Positron Emission Tomography

The avidity of metabolically active myeloma cells for 18F fluorodeoxyglucose, a radiolabeled glucose analogue, may not be helpful only in making a diagnosis, but it may also be prognostic. Zamagni et al. prospectively studied the prognostic value of PET/CT at diagnosis, after thalidomide-dexamethasone induction therapy and double autotransplantation in 192 newly diagnosed MM patients.⁷⁹¹ Presence at baseline of at least 3 focal lesions, a SUV > 4.2, and presence of extramedullary disease adversely affected 4-year estimates of progression-free survival. In addition, SUV > 4.2 and EMD were predictive of a shorter OS. In a multivariate analysis, both EMD and SUV > 4.2 at baseline and persistence of FDG uptake after ASCT were independent prognostic factors for a shorter PFS.

The use of PET scan and MRI overcomes the limitation of conventional radiography in prognosticating patients by the DS-staging, and a DS-plus staging system that incorporates the findings of PET/MRI to the original DS staging system has been proposed for predicting OS. PET scan can detect both medullary and extramedullary lesions simultaneously, and can potentially upstage the patients due to its greater sensitivity (85%) and specificity (92%).⁷⁹² A drawback of the PET scan is its inability to detect very small lesions (<1cm). Radiation-induced inflammatory changes can lead to false-positive PET which should therefore only be performed at the time of diagnosis, or at least 2 months after the therapy.⁷⁹²

Renal Failure

Renal failure has been shown to portend a poor outcome in patients with MM. In a study from¹⁸⁴ the Nordic myeloma group, renal failure, defined as plasma creatinine > 130 micromol/l, was observed in 29% of the cases at the time of diagnosis. During the first year after diagnosis 58% achieved normalization of p-creatinine, and this was achieved mainly during the first 3 months. Patients who needed dialysis had a poor prognosis, with a median survival of 3.5 months. A 12-month landmark analysis showed that reversibility of renal failure was a more important prognostic factor than response to chemotherapy.

Prior to the 21st century, of those patients with MM and severe renal failure who survived the first 2 months on dialysis, only 40% would have an objective response to chemotherapy and a median survival of almost 2 years;⁸⁹⁶ however, these statistics have changed with highly effective regimens including bortezomib with hematologic response rates of more than 70%⁸⁹⁷ and renal improvements in 82% of patients with renal impairment.^{898, 899} In a study of 39 patients with biopsy-proven myeloma kidney with a median estimated glomerular filtration rate of 9 m/min/1.73 m², the relationship between renal recovery and serum immunoglobulin free light chain (FLC) reduction was linear. Achieving at least a 60% reduction in FLC by 21 days was associated with recovery of renal function for 80% of the population.⁹⁰⁰

Pathogenesis of Multiple Myeloma

There is a synergistic pathologic relationship between myeloma cells and the cells comprising the bone marrow microenvironment or stroma, including fibroblasts, endothelial cells, osteoblasts, and osteoclasts. The stromal cells of the marrow of myeloma patients produce high levels of interleukin-6 (IL-6) *in vitro*.⁹⁰¹ The IL-6 serves as a growth and survival factor for benign and malignant plasma cells, which produce IL-1 β ,^{902, 903} VEGF, and macrophage inflammatory protein-1 α (MIP-1 α).^{904, 905} In turn, IL-1 β and MIP-1 α regulate and activate osteoclasts.^{902, 906, 907}

Bone Marrow Microenvironment

A cell adhesion molecule belonging to the immunoglobulin superfamily, CD56 (N-CAM), is strongly expressed in most plasma cells of myeloma patients⁹⁰⁸ and is believed to play a role in myeloma homing and cell adhesion to the marrow. Increased levels of the adhesion molecules lymphocyte function-associated antigen (LFA)-3,¹⁵⁰ LFA-1 (CD11a),⁹⁰⁹ and very late antigen-4 (VLA-4) are expressed on the myeloma cells in the majority of patients. VLA-4 may act to bind myeloma cells to fibronectin in bone marrow,⁹¹⁰ which under appropriate conditions can significantly increase IL-6 production by stroma.⁹¹¹ Cell-cell contact between marrow stromal cells and myeloma cells via VCAM-1 and $\alpha\beta$ 1-integrin enhances production of osteoclast-stimulating activity.⁹¹² Hyaluronan, a glycosaminoglycan component of the bone marrow extracellular matrix, appears to be a survival and proliferation factor for myeloma cells.⁹¹³ Notch receptors are expressed in early hematopoietic stem cells and Notch ligands are expressed on BMSCs. Myeloma cells expressing Notch receptors are activated by the BMSC Notch ligand, protecting the myeloma cells from drug-induced apoptosis. In addition, this interaction also activates Notch signaling in BMSCs, leading to secretion of IL-6, VEGF, and IGF-1.⁹¹⁴ Cell-adhesion-mediated drug resistance (CAM-DR) is a well-recognized entity.⁹¹⁵ Another signaling pathway that has been implicated in myeloma pathogenesis is the Hedgehog (Hh) signaling pathway. Hedgehog (Hh) signaling is a highly conserved pathway that plays an important role in development in both vertebrates and invertebrates.⁹¹⁶ Hh ligands secreted by the stromal cells, namely Indian (Ihh), sonic (Shh), and desert (Dhh) bind to their receptor, patched (PTCH) on tumor cells. This binding alleviates the inhibition of PTCH on its downstream target, smoothed (Smo), thereby activating it. This activation leads to activation of the transcription factor involved in glioma formation (Gli) which promotes the transcription of its target genes leading to tumor development and progression.⁹¹⁷ In the myeloma setting it has been found that the Hh pathway is essential for maintaining a subset of tumor-causing stem cells.

The endothelial microvascular environment has also been shown to be important in MM biology.¹³⁹ There is a high correlation between the extent of bone marrow angiogenesis, evaluated as microvessel area, and the proliferating (S phase) fraction of marrow plasma cells in patients with MM and in those with

P.2089

MGUS.^{139, 918, 919, 920, 921, 922, 923} VEGF plays an important role in angiogenesis by acting as a potent inducer of vascular permeability as well as serving as a specific endothelial cell mitogen. Plasma cells in the bone marrow from MM patients express VEGF,^{924, 925} which can thereby interact with the Flt-1 and KDR high-affinity VEGF receptors highly expressed on bone marrow myeloid and monocytic cells surrounding the tumor.⁹¹⁸

Investigators are beginning to understand the complex interactions among osteoclasts, osteoblasts, and myeloma cells. Receptor activator of NF/B (RANK), which is found on osteoclasts, interacts with RANK ligand (RANKL) found on osteoblasts and bone marrow stromal cells. These interactions contribute to bone destruction.⁹²⁶ Myeloma cells also prevent differentiation of osteoblasts through secretion of the Wnt-signal antagonist DKK1.⁹²⁷ It has been shown that MM cell-derived DKK1, a soluble inhibitor of canonical Wnt signaling, disrupt Wnt3a-regulated OPG and RANKL expression in osteoblasts. This suggests that DKK1 may play a key role in the development of MM-associated bone lesions by directly interrupting Wnt-regulated differentiation of osteoblasts and indirectly increasing osteoclastogenesis via a DKK1-mediated increase in RANKL-to-OPG ratios.⁹²⁸ MIP-1a is produced by myeloma cells and it serves as an inducer of osteoclast formation.⁹²⁹ In turn, osteoclasts produce a number of factors that stimulate myeloma cells, including IL-6.¹⁵⁶

In addition to these cells, other cells that are part of the immune system also play a significant role in the myeloma pathophysiology. It has been shown that bone marrow macrophages, in particular tumor-associated macrophages, were protectors of myeloma cells.⁹³⁰ The protective effect was dependent on direct contact between macrophages and myeloma cells. Macrophages protected both myeloma cell lines and primary myeloma cells from spontaneous and chemotherapy drug-induced apoptosis by attenuating the activation and cleavage of caspase-dependent apoptotic signaling. Using both in vitro and in vivo MM xenograft models, Chauhan et al. showed that plasmacytoid dendritic cells (pDCs) in the bone marrow (BM) microenvironment both mediate immune deficiency characteristic of MM and promote MM cell growth, survival, and drug resistance.⁹³¹

Cytokines and Cell Signaling

The search for a growth factor for myeloma cells culminated in the identification of IL-6, formerly known as B-cell growth factor or hybridoma growth factor.⁹³² IL-6 is among the most important proliferation and survival factors in myeloma.⁹³³ Predominantly produced by bone marrow stromal cells—macrophages, fibroblasts, endothelial cells, osteoblasts, osteoclasts, and monocytes (Fig. 98.10)⁹³⁴—it serves as a growth factor and as an antiapoptotic factor.^{935, 936, 937, 938} IL-6 exerts its cellular effects through gp130, which can activate two pathways: the JAK-STAT pathway⁹³⁹ and the Ras-MAP

kinase pathway.⁹⁴⁰ Through the former pathway, which includes JAK-2 and STAT3, the antiapoptotic proteins MCL-1⁹³⁹ and BCL-XL⁹⁴¹ are up-regulated; through the latter pathway, transcription factors such as ELK-1, AP-1, and NF-IL-6⁹³⁹ are up-regulated. NF- κ B⁹⁴² and IL-6^{943, 944} may also mediate the observed increase in the antiapoptotic proteins BCL-2,^{945, 946} MCL-1,⁹⁴³ and BCL-XL.^{943, 944, 947, 948} The overall effect of these pathways is prevention of apoptosis and enhancement of MM proliferation. In addition, the constitutive activation of STAT3 may also be important in the pathogenesis of MM, independent of IL-6.⁹⁴⁹ Moreover, CD40 activation of myeloma cells can alter the cell surface phenotype, triggering autocrine IL-6 secretion regulating the myeloma cell cycle in a p53-dependent fashion.⁹⁵⁰

Other cytokines and growth factors produced by myeloma and stromal cells that maintain myeloma growth⁹⁵¹ include IL-1 β ,^{952, 953, 954} VEGF, insulinlike growth factor (IGF),^{955, 956, 957, 958, 959, 960} hepatocyte growth factor (HGF),⁹⁶¹ and tumor necrosis factor- α .^{962, 963} Aberrant expression of IL-1 β may be a critical step in the transition of MGUS to MM.^{902, 954} IL-1 β up-regulates production of IL-6, changes expression of cell adhesion molecules, and has been shown to have osteoclast-activating factor activity. Although IL-1 β does not stimulate myeloma cell proliferation directly, by virtue of its effect on stromal cells in the marrow it induces production of IL-6⁹⁰³ and IL-8.⁹⁶⁴ Myeloma cells are capable of expressing and secreting VEGF and responding to the cytokine in an autocrine fashion.^{904, 905} Moreover, stromal and microvascular endothelial cell exposure to VEGF induces an increase in IL-6 secretion,⁹⁰⁴ which then further stimulates myeloma cells. The precise role basic fibroblast growth factor (bFGF), another potent angiogenic factor, plays in the growth of myeloma cells is under active investigation.⁹⁶⁵ Higher bFGF levels have been found in more advanced stages of MM.⁹⁶⁵ IGF, which is believed to signal through the phosphatidylinositol-3'-kinase (PI-3K) pathway,⁹⁵⁵ is capable of directly stimulating myeloma cell growth and enhancing myeloma cell responsiveness to IL-6 through mitogen-activated protein kinase⁹⁵⁸ and also inhibiting apoptosis by increasing expression of BAD.⁹⁵⁵

Cell Cycle

Regulatory signals underlying proliferation of myeloma cells include increased cyclin D1 expression, hypermethylation of the cyclin-dependent kinase (CDK) pathway regulatory gene p16,⁹⁶⁶ mutations of the RAS oncogene,^{868, 870} loss of TP53,^{868, 870} and overexpression of MYC in progressive disease.⁹⁶⁷ Approximately one third of myeloma patients have up-regulation of cyclin D1 by immunohistochemistry; the plasma cells of these same patients tend to have higher proliferative rates.⁹⁶⁸ The t(11;14)(q13;q32) translocation, which juxtaposes the immunoglobulin heavy chain promoter and the cyclin D1 gene, is seen in approximately 25% of MM patients.^{778, 841, 969, 970, 971} Bergsagel et al. has postulated that activation of one of the three cyclin D genes is an initiating event in myeloma.⁹⁷²

Both p15 and p16 are important cell cycle inhibitors that suppress cell proliferation through inhibition of CDK4 or CDK6 or both, thereby preventing the phosphorylation of the retinoblastoma gene (RB). Although large deletions of p15 and p16 are rare in myeloma (0% to 12% of cases),^{973, 974, 975} selective methylation of these genes, a form of transcriptional inactivation, occurs in as many as 67% and 75% of cases, respectively.^{976, 977, 978} Most data suggest that methylation of p16 or p15 is associated with disease progression.⁹⁷⁹

K- and N-RAS mutations have been described in 25% to 100% of newly diagnosed MM patients,^{862, 870, 980} depending on the technique used for detection. A TP53 tumor suppressor gene deletion is present in plasma cells from nearly 10% of patients with newly diagnosed myeloma^{818, 981} and mutations are even less common.^{857, 858, 859, 860} The MYC protein and MYC RNA are overexpressed in about 25% of MM patients.^{982, 983} Rearrangements of the MYC gene are present in about 15% of patients with MM or primary PCL.⁹⁸⁴ Dysregulation of MYC appears to be caused principally by complex genomic rearrangements that occur during late stages of MM progression.⁹⁶⁷

SPECIAL CASES OF MYELOMA

Nonsecretory Multiple Myeloma

Nonsecretory MM accounts for 1% to 5% of myeloma cases.^{124, 985, 986, 987, 988, 989} With more sensitive testing such as immunofixation⁹⁹⁰ and free light chain assays,¹⁹ a majority of these "nonsecretory" patients are found to be low secretors or oligosecretory. More than 85% of cases have a cytoplasmic monoclonal protein; in the remainder, no monoclonal protein can be detected in the cytoplasm.^{988, 989, 991} Individuals in this latter group are referred to as "nonproducers."

P.2090

From a clinical standpoint, both are termed "nonsecretory." Median survival of these patients is at least as good as for those with secretory myeloma.^{985, 987, 988} Response is difficult to document, but with the new serum assays, quantitation of free light chains is possible in about two thirds of these patients.¹⁹

Immunoglobulin D and E Multiple Myeloma

IgD myeloma accounts for about 2% of all cases of MM.⁹⁹² The presence of a monoclonal IgD in the serum usually indicates MM, but three cases of IgD MGUS have been documented.⁹⁸⁶ Patients with IgD MM generally present with a small band or no evident M spike on serum protein electrophoresis. Their clinical presentation is similar to that of patients with Bence Jones MM (light chain MM) in that both have a higher incidence of renal insufficiency and coincident amyloidosis as well as a higher degree of proteinuria than in IgG or IgA MM.⁹⁹² IgD MM patients, however, appear to have a higher frequency of monoclonal lambda light chain than kappa light chains.⁹⁹² With an incidence of 19% to 27%, extramedullary involvement is more prevalent in patients with IgD MM.^{993, 994, 995} Survival of patients diagnosed after 1980 is comparable to patients with non-IgD MM.^{986, 996}

IgE myeloma is a rare form of MM. A disproportionate number of cases are PCL, although the sample size is small, with only about 40 cases of IgE myeloma reported in the literature.^{997, 998}

Plasma Cell Leukemia

PCL is a rare form of PCD. Between 2% and 4%^{850, 999, 1000} of malignant PCD cases are PCL. By definition, there are more than 20% plasma cells in the peripheral blood with an absolute plasma cell count of more than $2 \times 10^9/L$. Some authors accept the diagnosis with only one of these criteria.⁹⁸⁶ The presentation may be primary, de novo, or secondary, evolving from an existing case of myeloma as part of the terminal phase of the disease. About 60% to 70% of cases are primary.⁹⁹⁹

PCL plasma cells more frequently express the CD20 antigen⁸⁵⁰ than those of MM (50% vs. 17%), and they often lack CD56 antigen,^{148, 850} which is present on the majority of MM cells.⁸⁵⁰ CD56 is considered important in anchoring plasma cells to bone marrow stroma and is associated with a poor prognosis.^{149, 150} CD28 is more frequently expressed on malignant plasma cells in secondary than in primary PCL, which is consistent with an observation made in MM, i.e., that acquisition of the CD28 antigen on plasma cells appears to correlate with an increased proliferative rate and disease progression.⁸⁹¹

PCL plasma cells have higher proliferative rates⁸⁵⁰ and more complex karyotypes than myeloma plasma cells.¹⁰⁰⁰ By comparative genomic hybridization and by FISH techniques, losses on 13q^{1001, 1002} and monosomy 13⁸⁵⁰ exist in more than 80% of PCL patients.^{1001, 1002} Losses on chromosome 16 also occur in about 80% of cases.¹⁰⁰² Gains in 1q are present in about half of the patients by FISH,⁸⁵⁰ but in all by comparative genomic hybridization.¹⁰⁰² In addition, PCL patients have unique losses of 2q and 6p.¹⁰⁰² Overexpression of PRAD1/cyclin D1 and t(11;14) is commonly observed in PCL.¹⁰⁰³

The clinical presentation of primary PCL is more aggressive than that of MM, with a higher presenting tumor burden and higher frequencies of extramedullary involvement, anemia, thrombocytopenia, hypercalcemia, renal impairment,^{850, 999, 1000, 1004} increased levels of serum lactate dehydrogenase and $\beta 2M$, and plasma cell proliferative activity.⁸⁵⁰ The incidence of lytic bone lesions is slightly lower than that usually observed in MM.^{850, 1005}

Although the clinical and laboratory features of primary and secondary PCL are similar,^{1005, 1006} the response to therapy and OS in primary and secondary PCL go from poor to worse.^{999, 1000, 1004, 1005} Higher response rates can be achieved with multiagent chemotherapy rather than single alkylator programs (47% to 66% vs. 8% to 13%).^{850, 999, 1000, 1005} Regimens such as VMCP/VBAP, VAD, and combination cyclophosphamide and etoposide have resulted in median survivals of 18 to 20 months compared with 2 to 6 months when single-agent therapy is used.^{850, 999, 1000, 1005} When thalidomide and dexamethasone are used, responses are possible.^{1007, 1008} There are anecdotal reports of activity of bortezomib in these patients.^{1009, 1010, 1011} Some patients derive excellent responses and 2- to 3-year disease-free survivals after ASCT.^{1012, 1013, 1014, 1015, 1016} Saccaro et al.¹⁰¹⁷ reported on the cumulative outcomes of the literature of PCL patients undergoing hematopoietic stem cell transplantation. Median survival post autologous ASCT was 36 months, whereas it was only 12 months after allogeneic ASCT. Registry studies have shown that overall survival with primary PCL approaches that of multiple myeloma, and up-front ASCT appears to outperform AlloSCT even when reduced intensity protocols are used.¹⁰¹⁸

Response and survival rates with secondary PCL remain low.^{1005, 1006} See the recent review of PCL.¹⁰¹⁹

Osteosclerotic Myeloma (POEMS Syndrome)

Osteosclerotic myeloma is a rare variant of myeloma ($\leq 3.3\%$ of cases).¹⁰²⁰ There is a straight osteosclerotic variant that is similar to MM in that anemia, significant bone marrow plasmacytosis, hypercalcemia, and renal insufficiency occur.¹⁵⁸ Survival in these patients is comparable to that of classic MM patients. There is, however, a more interesting form, which is known as Crow-Fukase syndrome, PEP (PCD, endocrinopathy, polyneuropathy) syndrome, Takatsuki syndrome, and POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes).^{1021, 1022, 1023, 1024} This variant is discussed in Chapter 101.

TREATMENT OF COMPLICATIONS AND SUPPORTIVE CARE

Complications Specific to Novel Therapies

Thrombosis is an important complication in patients undergoing treatment with IMiDs. As a single agent, there does not appear to be any heightened risk; however, concomitant chemotherapy,³⁸⁹ especially anthracyclines,^{1025, 1026} high-dose corticosteroids,^{359, 407, 1027} and erythropoietin¹⁰²⁸ appears to increase the risk of thrombosis to as high as 58%. A phase III trial¹⁰²⁹ compared aspirin (100 mg/day), low-dose warfarin (1.25 mg/day), and enoxaparin (40 mg/day) in 667 patients with previously untreated myeloma receiving a thalidomide-based regimen. The primary endpoint was a composite that included serious thromboembolic events, acute cardiovascular events, or sudden deaths during the first 6 months of treatment. The most frequent complications were thromboembolic events that occurred in 5.9% in the aspirin group, 8.2% in the warfarin group and 3.2% in the LMWH group. Symptomatic pulmonary embolism episodes occurred only in the aspirin and warfarin groups. The absolute differences for serious thromboembolic events were +2.7% (P = 0.173) between aspirin and LMWH groups and +5.0% (P = 0.024) between warfarin and LMWH groups. These results did not reach a statistical significance. The same group conducted a prospective trial comparing aspirin (ASA) to low molecular weight heparin (LMWH) in 342 newly diagnosed patients¹⁰³⁰ who were treated with lenalidomide and dexamethasone or MPR. Patients were randomly assigned to receive ASA 100 mg/d (n = 176) or LMWH enoxaparin 40 mg/d (n = 166). The incidence of VTE was 2.27% in the ASA group and 1.20% in the LMWH group, a difference that was not significant. Based on this, ASA can be an effective and less-expensive alternative to LMWH thromboprophylaxis. Of note, however, patients considered high risk for VTE were excluded from both these studies. Those patients with advanced age, inherited thrombophilic

P.2091

abnormalities, recent surgery, or a history of VTE should be considered for full-dose anticoagulation.

Pharmacologic Therapy of Myeloma Bone Disease

Myeloma bone disease is a significant contributor to morbidity, and there is expanding information about the relationships between bone turnover and plasma cell growth and survival.^{157, 926, 1031, 1032, 1033} A randomized trial has demonstrated that treating with bisphosphonates not only helps prevent secondary bony events in patients with existing bone lesions, but that the use of monthly zoledronic acid as compared to clodronate increases median OS of ALL patients (whether they have bone lesions or not) by 6 months.¹⁰³⁴ Bisphosphonates inhibit dissolution of the hydroxyapatite crystals and down-regulate the major osteoclast functions. After internalization, the nitrogen-containing bisphosphonates interfere with the biosynthetic mevalonate pathway by inhibiting farnesyl diphosphonate synthase with resultant inability of osteoclasts to form the ruffled borders of their membrane needed to activate bone resorption.

The first study showing a reduction of almost 50% of secondary skeletal events among myeloma patients who received monthly intravenous administration of pamidronate was published in 1996.¹⁰³⁵ At 12 months, there were fewer skeletal-related events in the pamidronate group than in placebo-treated patients (28% vs. 44%; P < 0.001).^{1035, 1036} With longer follow-up of 21 months, the difference between groups persisted but narrowed slightly to 28% in the pamidronate group versus 51% in the placebo group (P < 0.015).¹⁰³⁷ This prospective study subsequently led the FDA to approve the use of the drug in this setting. Equivalency of pamidronate and zoledronic acid has been demonstrated in two randomized clinical trials, a randomized phase II¹⁰³⁷ and a randomized phase III.¹⁰³⁸ In the phase III trial, patients with MM or breast cancer, who had lytic disease, were treated with zoledronic acid (4 or 8 mg per dose) or pamidronate (90 mg) every 3 to 4 weeks. The infusion time for zoledronic acid was increased from 5 minutes to 15 minutes during the trial due to an increase in creatinine occurring more frequently among patients receiving the rapid infusion. Renal problems continued to occur more often among patients randomized 8 mg zoledronic acid and their dose was subsequently reduced to 4 mg. The sample size was based on showing noninferiority of zoledronic acid to pamidronate, and of 1,648 patients who were enrolled 510 had MM and the remainder had metastatic breast cancer. The portion of patients with any SRE after 13 months did not differ among the three treatments and did not differ between the breast cancer and MM patients. In February 2002, the FDA approved an expanded indication for zoledronic acid for the treatment of patients with bone metastases that included its use in MM.

Despite the fact that the longest follow-up of patients in these studies was 24 months, the recommendation by the American Society of Clinical Oncology was to continue these agents indefinitely at monthly intervals.¹⁰³⁹ The rationale for practice was not data driven, but based on several theoretical benefits. The first was that patients have continued bone disease throughout the course of their disease. The second was predicated on the in vitro and in vivo (murine) data that bisphosphonates exert antitumor activity.¹⁰³¹

In the short-term, the drugs were well tolerated, with occasional episodes of mild pyrexia, renal function impairment, myalgias, and hypocalcemia. However, by 2003, avascular osteonecrosis of the jaw (ONJ) has been described as a new

complication associated with their use.^{1040, 1041, 1042, 1043, 1044, 1045, 1046, 1047, 1048, 1049, 1050} Bisphosphonate-associated ONJ has been described in various malignancies including MM, breast cancer, and prostate cancer. A management algorithm for ONJ has recently been published.¹⁰⁵¹ It has been seen in both the mandible and the maxilla but is more frequent in the former. The etiology of ONJ is unclear, but is likely multifactorial in origin. Although most patients who develop ONJ have had recent dental or oral surgical procedures (70%), the remainder develop spontaneous ONJ.¹⁰⁴⁵ Proposed mechanisms include that inhibition of osteoclast activity reduces bone turnover and remodeling and that bisphosphonates prevent release of bone-specific factors that promote bone formation.¹⁰⁵² In addition, bisphosphonates, particularly zoledronic acid, may have antiangiogenic effects which has been implicated in the development of ONJ. Finally, healing of an open bony oral wound may be challenged by bacterial insult from oral microflora.

The true incidence of this complication is hard to estimate, but is somewhere around 6.8% to 9.9%.^{1047, 1048} Risk factors for ONJ are longer duration of treatment, zoledronic acid (as compared to pamidronate). In one study,¹⁰⁴⁷ patients who developed ONJ received a median number of 35 infusions (range, 13 to 68) compared to 15 infusions (range, 6 to 74) for patients with no ONJ. The optimal dosing schedule and duration of therapy has not been adequately defined by randomized clinical trials. One retrospective study suggested quarterly infusions of zoledronic acid are as effective as monthly infusions with less risk of ONJ.¹⁰⁵³

Most would agree that 1 to 2 years of IV bisphosphonate is standard after a dental check-up. The role of these drugs after this time-point is uncertain. Many opt to reduce the frequency of administration after 2 years, especially if disease is in remission. Once on these drugs, invasive dental procedures should be limited if possible. Other drugs such as bone seeking radionuclides^{561, 1054, 1055} and inhibitors of the receptor activator of nuclear factor κ B (RANK) signaling known as osteoprotegerin¹⁰⁵⁶ are being tested. Denosumab (a fully human monoclonal anti-receptor activator of nuclear factor kappa-B ligand antibody) was compared to zoledronic acid for delaying or preventing skeletal-related events.¹⁰⁵⁷ Denosumab was noninferior to zoledronic acid in delaying a first skeletal event. Hypocalcemia was more commonly seen in the denosumab-treated patients.

The standard method of following patients is with periodic (every 6 to 12 months) skeletal radiographs; the use of more sophisticated imaging modalities has been described in a previous section. Cross-linked N-telopeptides of Type I collagen, which can be measured in the serum or urine, appear to be a sensitive indicator of bone turnover,^{799, 1058} and urinary levels show a strong positive correlation with the dynamic histomorphometric indices of bone resorption.¹⁰⁵⁹ Serum levels of bone metabolism markers including osteocalcin, MIP-1 α , RANKL, and osteopetegrin have been studied and shown to be aberrantly expressed in patients with active myeloma.¹⁵⁷

Nonpharmacologic Treatment of Myeloma Bone Disease

When a lytic bone lesion is present, significant risk factors for fracture of a long bone include increased pain with use, and the involvement of more than the diameter of the bone. These lesions should be treated prophylactically with surgery if they are situated in weight-bearing bones.¹⁰⁶⁰ Endosteal resorption of one half the cortical width of the femur weakens the bone by 70%. Surgical treatment should be considered for these lesions as well.¹⁰⁶¹ Once a bone has fractured, healing can occur especially if proper internal fixation is performed and if patients have an anticipated survival of >6 months. Much of the data regarding malignant bone disease are derived from patients with carcinoma rather than MM. In patients with carcinoma metastatic to bone, modest post-operative radiation doses ($\leq 3,000$ cGy) as adjuvant therapy are associated with better healing,¹⁰⁶² but the role of adjuvant radiation therapy in MM patients is less clear. MM is often chemotherapy sensitive; adjuvant systemic chemotherapy in MM patients may be more appropriate than adjuvant radiation therapy. In general, radiation therapy should be used for pain

P.2092

relief in chemotherapy-refractory disease, because it relieves pain in 80% to 90% of patients with bony metastases,¹⁰⁶³ long-term in 55% to 70%.¹⁰⁶⁴

Percutaneous vertebroplasty is occasionally an option for patients with vertebral body compression fracture. Pain relief is generally apparent within 1 to 2 days after injection and persists for at least several months up to several years.¹⁰⁶⁵ Complications are relatively rare, although some studies reported a high incidence of clinically insignificant leakage of bone cement into the paravertebral tissues. Compression of spinal nerve roots or neuralgia due to the leakage of polymer and pulmonary embolism have also been reported. Percutaneous kyphoplasty is also an option.¹⁰⁶⁶ There is one published trial in patients with MM that randomized patients in an unblinded fashion to kyphoplasty or nonsurgical management.¹⁰⁶⁷ At 1 month, the back specific disability score was significantly better in the kyphoplasty group. Inasmuch

as patients in the control group had the option of crossing over to the kyphoplasty arm, there are no long-term data on outcomes.

Spinal Cord Compression

In a paper published in 1979, it was estimated that nearly 10% of patients with myeloma either present with spinal cord compression or that it develops during the course of the disease;¹⁰⁶⁸ with higher awareness of myeloma and better imaging technology, the incidence is likely lower now. Cord compression, however, remains an important and emergent subject. The usual standard treatment is high-dose corticosteroids and radiation therapy.^{1069, 1070, 1071, 1072} On rare occasions, surgical decompression may be considered. Because most myelomatous lesions arise from the vertebral body, an anterior surgical approach is generally used, which may contribute additional morbidity. One small randomized trial addressing the question of radiation versus laminectomy and radiation, showed no benefit attributable to laminectomy;¹⁰⁷⁰ similarly, a larger retrospective series found no benefit.¹⁰⁶⁹ If the deficit is due to compression by the plasma cell tumor (rather than a bone fragment retropulsed by a pathologic compression fracture), outcomes with radiation therapy are probably equal (or superior) to surgical intervention in a radiosensitive tumor such as myeloma.^{1069, 1070}

High-dose corticosteroids may provide immediate pain relief and improvement in neurologic function.^{1071, 1072} The optimal corticosteroid dose has not been established, but common dose schedules for metastatic disease include dexamethasone in an initial bolus of 10 mg intravenously or 100 mg intravenously followed by 4 mg orally 4 times daily;¹⁰⁷³ or a 100-mg intravenous bolus followed by 96 mg in four divided doses for 3 days followed by tapering doses.^{1071, 1072}

Hypercalcemia

Patients with MM are at risk of severe hypercalcemia that can precipitate acute renal failure, hypertension, nausea, vomiting, pancreatitis, cardiac arrhythmia, coma, and death. The extracellular volume depletion associated with hypercalcemia should be corrected by vigorous hydration^{745, 1074} followed by an antiresorptive agent such as intravenous bisphosphonate. Serum calcium values usually decline rapidly, reaching the normal range within 2 to 3 days in more than 80% of cases. It occasionally goes below normal at the nadir. Corticosteroids can also reduce serum calcium concentration in about 60% of patients with hypercalcemia.¹⁰⁷⁵

Gallium nitrate, mithramycin, and calcitonin are interesting from an historical perspective. Since the advent of bisphosphonates, they are not often used. Gallium nitrate therapy had been shown to be superior to maximally approved doses of calcitonin for acute control of cancer-related hypercalcemia.¹⁰⁷⁶

Hematologic Complications Including Anemia, Secondary Leukemia, Hyperviscosity, and Cryoglobulinemia

Anemia

The anemia of MM can result from many factors. When the anemia is due solely to myelomatous bone marrow infiltration, chemotherapy remedies the problem. Other patients have a relative erythropoietin deficiency related to renal injury due to the myeloma or to age-related changes. In these patients, as in any patient with renal insufficiency, modest doses of recombinant erythropoietin are effective. For patients with chemotherapy-induced anemia, recombinant erythropoietin may be effective at higher doses (150 to 300 IU/kg thrice weekly or 40,000 units weekly). Two placebo-controlled trials in myeloma patients demonstrate significantly improved hemoglobin levels and a reduced number of red cell transfusions in patients receiving erythropoietin.^{1077, 1078} Erythropoietin increases the risk of thrombotic events.

Secondary Myelodysplasia and Acute Leukemia

The most ominous cause of anemia in the setting of previously treated MM is a secondary myelodysplastic syndrome or acute leukemia. Kyle et al.⁵⁸³ were among the first to recognize that cytotoxic agents can induce myelodysplasia and acute myeloid leukemia.^{583, 584, 585, 586} The risk of a secondary myelodysplastic syndrome or acute leukemia is approximately 3% at 5 years and 10% at 8 to 9 years,^{1079, 1080} with estimates as high as 25% at 10 years,¹⁰⁸¹ with multiple other estimates somewhere in between.^{385, 587, 588} Some authors have suggested that higher cumulative doses of melphalan are implicated as a risk for acute leukemia.¹⁰⁷⁹ Others have shown no difference in incidence based on the number of courses of chemotherapy or the cumulative melphalan dose between the patients who did and did not develop acute leukemia.¹⁰⁸⁰ In a Finnish study, the mean number of chemotherapy cycles was 19.7 and 18.5 in patients with and without secondary leukemia; mean cumulative melphalan doses were 1,440 and 1,400 mg, respectively.¹⁰⁸⁰ Although cyclophosphamide has been shown to be leukemogenic, data suggest that it is less so than melphalan.^{1079, 1082, 1083} After secondary leukemia is diagnosed, median survival tends to be short, about 2 months.¹⁰⁸⁰

The occurrence of concurrent acute leukemia in MM suggests that there may be a proclivity for acute leukemia to develop in patients with myeloma.^{1084, 1085} After stem cell transplantation for myeloma, the risk of myelodysplastic syndrome appears to be related to prior chemotherapy rather than to the transplant itself, at least in one retrospective series.¹⁰⁸⁶

Cryoglobulinemia and Hyperviscosity

Approximately 5% of myeloma gammaglobulins exhibit reversible precipitation in the cold, so-called cryoglobulins, forming either a flocculent precipitate or a gel-like coagulum when the serum is cooled.¹⁰⁸⁷ Plasmapheresis relieves the symptoms of hyperviscosity, but the benefit of this treatment in the absence of concurrent chemotherapy is short lived.¹⁰⁸⁸

Renal Failure

Normal creatinine values are present in approximately 50% of MM patients at diagnosis,^{124, 125, 126, 127, 178, 179, 180, 181} and only 15% to 25% have a creatinine value above 2 mg/dl.^{126, 184} Patients in whom the renal failure is reversed have a better OS than those without improvement.^{182, 185} Factors that increase renal tubular cast formation include dehydration, infection, and hypercalcemia. There is some controversy around best management of patients with renal failure in terms of plasmapheresis and the relative

P.2093

importance of alkylizing urine, but there are four points that are incontrovertible: (1) achieve a deep hematologic response as soon as possible, (2) avoid nephrotoxic drugs, (3) correct hypercalcemia, and (4) correct dehydration (maintaining a 24-hour fluid intake of at least 3 liters can improve renal function).¹⁸²

In terms of best chemotherapeutic regimens to achieve rapid hematologic response, several have already been discussed. A bortezomib-based regimen such as CyBORd, VTD, or PAD is often favored in the setting of renal failure. In a recent trial in which patients were randomized to VAD or PAD followed by ASCT, the subset of patients presenting with creatinine above 2 mg/dl and who were randomized to PAD had a markedly improved median survival as compared to the VAD patients (54 months vs. 21 months, $P < 0.001$). Because light chains with the lowest isoelectric points tend to be more nephrotoxic in animal models, avoidance of a low or acidic urinary pH is recommended. Oral or intravenous bicarbonate is useful in the setting of acute renal failure.¹⁰⁸⁹ The MRC third myelomatosis trial randomized MM patients with significant renal failure to oral sodium bicarbonate to neutralize urine pH (or not), and there was a trend toward better survival in the bicarbonate recipients.¹⁸²

The use of plasmapheresis in the setting of renal failure remains controversial. There are three randomized trials addressing this question, with conflicting results. One small randomized study of patients with active myeloma and progressive renal failure suggested benefit in a subset of patients.¹⁰⁹⁰ There were 21 patients randomized to either forced diuresis and chemotherapy (10 patients) or forced diuresis, chemotherapy, and plasmapheresis (11 patients). There was a trend toward better outcome in the plasmapheresis group, but the difference was not statistically significant. It is unclear whether the lack of significance is due to the small sample size, or to an equivalence of the two therapeutic strategies. The study did demonstrate that the severity of myeloma cast formation directly correlated with lack of improvement regardless of treatment strategy.

Another randomized study in myeloma patients with severe renal compromise compared plasma exchange (and hemodialysis when needed) with peritoneal dialysis.¹⁰⁹¹ All patients received chemotherapy and corticosteroids. Of the 29 patients in the study, 24 received dialysis and 5 maintained serum creatinine concentrations of greater than 5 mg/dl without dialysis. Of the 15 patients in the plasmapheresis ± hemodialysis group 13 recovered renal function, reaching serum creatinine values of less than or equal to 2.5 mg/dl in most cases, whereas only 2 patients in the peritoneal dialysis group had enough improvement to stop dialysis. The 1-year survival rates were 66% and 28%, respectively ($P < 0.01$). The study's design was flawed in that one group received peritoneal dialysis and the other hemodialysis; the question about the role of plasmapheresis is not adequately settled.

The largest and most recent trial was a negative study.¹⁰⁹² A total of 104 patients with newly diagnosed myeloma and a creatinine of 2.3 mg/dl were randomized to conventional chemotherapy with or without five to seven sessions of plasma exchange over 10 days. The primary outcome was a composite measure of death, dialysis dependence, or glomerular filtration rate of less than 30 ml/min/1.73 m². At 6 months the endpoint was reached in 58% of the plasma exchange group and 69% of the control group. At 6 months, 7 of the 39 control patients (18%) and 5 of 58 plasma exchange patients (9%) were on dialysis. At 6 months, 33% of each group had died. Criticisms of this study included the patient selection, including the absence of renal biopsy, the use of relatively ineffective conventional chemotherapy, and small sample size.

Patients were eligible if the serum creatinine level was 2.3 mg/dl with an increase greater than 0.6 mg/dl in the preceding 2 weeks despite correction of hypercalcemia, hypovolemia, and metabolic acidosis. This would imply that institution of plasma exchange was delayed and that there could have been underlying pathologic renal lesions other than cast nephropathy, which would not be responsive to plasma exchange. More than twice as many patients on the plasma exchange group had MP as in the control group, which could have confounded the results because both overall response rates are lower and time to response is longer with MP than with VAD.

Infection Management

Infections are a major cause of morbidity in myeloma patients.^{1093, 1094} Pneumonias and urinary tract infections caused by *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Escherichia coli* are most frequent.^{193, 1095, 1096, 1097} The susceptibility to infection varies with the phase of illness.^{192, 1098} In one prospective study, the overall serious infection rate was 0.92 infections per patient-year and was four times higher during periods of active disease (1.90) than in plateau phase myeloma (0.49).¹⁹¹ In a retrospective study evaluating the sequential incidence of infection, the first 2 months of initial chemotherapy emerged as a particularly high-risk period, with nearly half of the patients experiencing at least one clinically significant infection.¹⁹² Infections late in the course of MM may be an inevitable result of long-standing immunosuppression and overwhelming tumor burden. Prevention of infection is a critical goal for improving survival.

Prevention of infections by use of vaccines is an attractive strategy. Unfortunately, responses to vaccines are poor among myeloma patients.^{198, 1099, 1100, 1101} Patients with MM were investigated to assess whether immunologic risk factors predisposing to serious infection could be identified.¹⁹¹ Specific antibody titers to pneumococcal capsular polysaccharides and tetanus and diphtheria toxoids were significantly reduced compared with the control population. Low antipneumococcal and anti-*Escherichia coli* titers correlated with risk of serious infection. In addition, among 41 immunized patients, responses to pneumococcus vaccine and tetanus and diphtheria toxoids were poor. IgG subclass levels were significantly reduced, and a poor IgG response to pneumococcus vaccine immunization was associated with an increased risk of septicemia. The predominant site of infection was the respiratory tract. Decreased concentrations of the uninvolved immunoglobulins were significantly associated with at least one serious infection.¹⁹¹

The two most common prevention strategies consist of prophylaxis with antibiotics¹¹⁰² or intravenous immunoglobulin (IVIg).¹¹⁰² A randomized, placebo-controlled trial of trimethoprim-sulfamethoxazole (TMP-SMX) demonstrated a significant decrease in severe infections among newly diagnosed myeloma patients randomized to TMP-SMX compared with controls.¹¹⁰³ A larger follow-up trial, however, failed to show a benefit from prophylactic antibiotics.¹¹⁰⁴ In that study 212 untreated, symptomatic myeloma patients who were on chemotherapy were randomized to receive ciprofloxacin (n = 69), trimethoprim-sulfamethoxazole (n = 76), or observation (n = 67) for the first 2 months of treatment. The use of prophylactic antibiotics did not decrease the incidence of infection.

A randomized, double-blind placebo-controlled trial demonstrated that IVIg significantly reduced the number of infections in high-risk patients with plateau phase MM.¹¹⁰² Eighty-two such patients received either IVIg (0.4 g/kg per month) or an equal volume of placebo for 1 year. There were no episodes of septicemia or pneumonia in patients receiving IVIg compared with 10 in placebo patients (P = 0.002). There were 38 serious infections in 470 patient-months for the placebo group, compared with 19 in 449 patient-months for the IVIg group (P = 0.019). A poor antibody response to pneumococcal vaccination (less than twofold increase) identified patients who had maximum benefit from IVIg. However, IVIg is expensive and inconvenient and can be associated with toxicity. Therefore, use of this agent is recommended only for patients with a significant history of severe infections.

P.2094

DIFFERENTIAL DIAGNOSIS

The diagnosis of MM is made from a constellation of findings, including anemia, monoclonal proteins, bone lesions, renal complications, hypercalcemia, and bone marrow plasmacytosis. Often the diagnosis is straightforward, but other disease entities associated with hypergammaglobulinemia or monoclonal bone marrow plasma cells must also be considered. These include reactive plasmacytosis, MGUS, primary systemic amyloidosis, Waldenström macroglobulinemia, light chain deposition disease, acquired Fanconi syndrome, solitary plasmacytoma, osteosclerotic myeloma or POEMS syndrome, and PCL.

Reactive plasmacytosis and polyclonal hypergammaglobulinemia must be distinguished from a clonal process. Patients with liver disease, chronic infections including human immunodeficiency virus, connective tissue diseases, other

lymphoproliferative disorders, and carcinoma can have increased bone marrow plasmacytosis (polyclonal) and hypergammaglobulinemia (polyclonal).^{22, 123} These conditions should not be confused with MM or MGUS, which are clonal processes.

MGUS patients do not have bone marrow suppression, lytic bone lesions, hypercalcemia, renal failure, or susceptibility to infection. Standard clinical features do not accurately predict which patients will remain stable, and in approximately 1% per year MM develops.¹³³ The clinical distinction between MGUS and asymptomatic MM is derived from an arbitrary definition (Table 98.1), although the underlying biologic conditions may prove to be different.

The greatest challenges in differentiating MGUS (or asymptomatic MM) from MM occur in patients who have MGUS and (1) senile osteoporosis, (2) renal insufficiency from another cause, or (3) hypercalcemia due to hyperparathyroidism. Approximately 50% of women older than age 60 years have osteoporosis, and a fraction of these have vertebral compression fractures. Computed tomographic scan of the spine may help distinguish between senile osteoporosis and myelomatous bone disease. Similarly, renal insufficiency due to long-standing diabetes, hypertension, or nonsteroidal drug use is not uncommon. In such cases, a patient may still have MGUS (or smoldering MM) and "end-organ damage." The key is whether the damage is attributable to the plasmaproliferative disorder or another cause. In some instances, renal biopsy may be required to clarify this issue.

Immunoglobulin light chain amyloidosis (AL amyloidosis) is a rare disorder that is characterized by the deposition of amyloid fibrils and is discussed in Chapter 99. The diagnosis should be suspected when a patient with a monoclonal protein in the serum or urine presents with nephrotic-range proteinuria (primarily albumin) with or without renal insufficiency, cardiomyopathy, hepatomegaly, or peripheral neuropathy. A histologic diagnosis is made by demonstrating the amyloid fibrils: green birefringence under polarized light by using a Congo red stain, or 8- to 10-nm nonbranching fibrils by electron microscopy.

The nonamyloidogenic light chain deposition diseases (LCDDs) are due to pathologic protein deposition in various tissues and organs. Unlike the light chain deposits observed in patients with primary systemic amyloidosis, these infiltrates are not congophilic by light microscopy, and nonbranching fibrils are not observed by electron microscopy. Instead, amorphous nodular deposits are seen. LCDD may occur with or without co-existent MM. Renal involvement is most common, followed by cardiac and hepatic deposits. Clinically, LCDD can be differentiated from MM and primary systemic amyloidosis by the following findings. As in primary systemic amyloidosis, early in the disease course the light chain deposits have a predilection for the renal glomeruli rather than the tubules. This results in nonselective proteinuria, that is, a predominance of albuminuria, which is not usual in MM. It is impossible without tissue biopsy to distinguish clinically the cardiomyopathy and hepatopathy from primary systemic amyloidosis. In LCDD, the underlying clone is more commonly monoclonal κ rather than λ . The prognosis of patients who have this disorder depends on whether there is underlying MM. In one retrospective study of 19 patients with LCDD, 5-year actuarial patient survival and survival free of end-stage renal disease were 70% and 37%, respectively.¹¹⁰⁵

Fanconi syndrome is a rare complication of PCDs characterized by diffuse failure in reabsorption at the level of the proximal renal tubule and resulting in glycosuria, generalized aminoaciduria, and hypophosphatemia.¹⁸⁹ Fanconi first described the syndrome in children. Subsequently, acquired forms were described in adults. Acquired Fanconi syndrome is usually associated with MGUS. Overt hematologic malignancies may occur, such as MM, Waldenström macroglobulinemia, or other lymphoproliferative disorders. The prognosis is good in the absence of overt malignant disease. Clinical manifestations include slowly progressive renal failure and bone pain due to osteomalacia. The diagnosis of Fanconi syndrome can be made when a patient with a monoclonal plasma cell disorder presents with aminoaciduria, phosphaturia, and glycosuria. Electrolyte abnormalities typically include hypokalemia, hypophosphatemia, and hypouricemia. Bence Jones proteinuria is usually present and is almost always of the κ type. Rare patients have been reported with Fanconi syndrome associated with λ Bence Jones proteinuria. Treatment consists of supplementation with phosphorus, calcium, and vitamin D. Chemotherapy may benefit patients with rapidly progressive renal failure or symptomatic malignancy.

Waldenström macroglobulinemia should not be confused with IgM myeloma, which comprises only about 1% of myeloma cases.¹²⁶ Patients with Waldenström macroglobulinemia may have anemia, hyperviscosity, B symptoms, bleeding, and neurologic symptoms. Significant lymphadenopathy or splenomegaly may also be present. Lytic bone disease is markedly uncommon; if present, consider whether the patient has IgM myeloma. In Waldenström macroglobulinemia, bone marrow biopsy typically reveals infiltration with clonal lymphoplasmacytic cells (CD20 positive). The natural history and treatment options for Waldenström macroglobulinemia are different from those of MM¹¹⁰⁶ (Chapter 100).

Solitary plasmacytoma of bone is a rare form of plasmaproliferative disease. Its true incidence has not been described, but it accounts for about 2% to 5% of malignant plasma cell dyscrasias treated at large referral centers.^{208, 1107, 1108} In most series, the definition has required the following characteristics: (1) histologic proof that the solitary lesion is a plasmacytoma; (2) no other bone lesions on metastatic bone survey; (3) less than 5% plasma cells from a random bone marrow biopsy site; and (4) the absence of anemia, hypercalcemia, or renal insufficiency that had no attributable cause. Some definitions allow for <10% bone marrow plasma cells⁷³⁶ and others have restricted the quantity of the serum or urine M spike. Others have excluded patients who developed disseminated myeloma within a year after diagnosis of the solitary plasmacytoma.¹¹⁰⁹ The International Myeloma Working Group has adopted the above definition, but adds that if done, MRI should not demonstrate any other areas of marrow involvement.²⁰⁵

There is a clear male preponderance, and the median age is 55 years.^{740, 1109, 1110, 1111} Plasmacytomas most commonly arise from the axial skeleton, particularly the vertebral bodies. Pain is the usual presentation. Spinal cord or nerve root compression may also be present. If the patient also has evidence of a peripheral neuropathy, and especially if the bone lesion is sclerotic, one should consider the diagnosis of POEMS syndrome (Chapter 101). Monoclonal proteins are present in about 50% of patients.^{736, 1109}

Careful staging should be done in all patients, including a complete blood cell count, protein electrophoresis and immunofixation of the serum and urine, serum immunoglobulin free light

P.2095

chains, a complete radiographic skeletal survey, and random bone marrow aspiration and biopsy. At a minimum, immunohistochemical stains should be done on the bone marrow to identify a clone apart from the solitary plasmacytoma. MRI of the entire spine and pelvis should also be done to determine whether the lesion is solitary. Using MRI, Mouloupoulos et al.¹⁷² found unexpected bone marrow involvement in 4 of 12 patients with apparently solitary plasmacytomas of bone. FDG-PET may also provide useful information.

From an historical perspective, solitary plasmacytomas of bone were treated surgically with or without adjuvant radiation.¹¹¹² Present day, single modality, definitive radiation therapy is the treatment of choice. Although the optimal dose has not been established by randomized controlled trials, 4,000 to 5,000 cGy encompassing all disease with a margin of normal tissue is recommended by most experts on the basis of retrospective local relapse rate data.^{736, 737, 738, 1113} This principle, however, has been challenged by recent data which show no difference in local control as long as the therapeutic dose is over 3,000 cGy.⁷³⁹

Median 10-year disease-free survival is about 25% to 40%.^{736, 1114} Median time to failure, that is, local relapse, appearance of another plasmacytoma, or disseminated myeloma, is about 2 years,^{736, 739, 1114} but these figures are contaminated by inadequate staging of patients. In a retrospective study at a major academic institution, fewer than 5% of patients referred for a diagnosis of solitary plasmacytoma of bone had adequate baseline staging.¹¹¹⁵ The majority of patients with a solitary "plasmacytoma of bone" had a low burden of clonal plasma cells in their marrow. Because these patients are typically not offered immediate chemotherapy, a novel term was used to label these patients, "plasmacytoma plus." The 21-month disease-free survival of patients that did not satisfy criteria for "plasmacytoma plus" was 100%.

Risk factors for evolution to myeloma include absence of a monoclonal protein at presentation (nonsecretory disease), depression of immunoglobulin values at presentation, persistence of the monoclonal protein after treatment,¹¹¹⁴ abnormal immunoglobulin free light chain ratio at presentation,¹¹¹⁶ tumor size of more than 5 cm, and a nonvertebral presentation.⁷³⁹ The persistence of a monoclonal protein after radiation therapy does not guarantee relapse,^{208, 736} even after more than 10 years of followup.¹¹¹⁴ In rare instances, the maximum reduction of myeloma protein may take several years after completion of the radiation therapy.^{208, 736} Median survival for all patients presenting with solitary plasmacytoma of bone—based on data from patients staged before routine use of MRI and bone marrow clonality studies—was approximately 10 years.^{736, 739, 1108, 1114, 1115} For those who progressed to myeloma, the median survival was 44 months after the start of chemotherapy.²⁰⁸ Adjuvant chemotherapy has not been shown to produce a survival advantage and carries the risk of treatment-related myelodysplastic syndromes or acute leukemia; it cannot be recommended.

Solitary extramedullary plasmacytomas represent about 3% of all plasma cell neoplasms.¹¹¹⁸ They most commonly affect men in their early 60s and occur in the upper respiratory tract (paranasal sinuses, nose, nasopharynx, and tonsils). They also occur in lymph nodes, lung, thyroid, gastrointestinal tract, liver, spleen, pancreas, testes, breast, or skin.¹¹¹⁹ Amyloid involvement of the plasmacytoma occurs on occasion. Although extramedullary plasmacytomas are not common in newly diagnosed MM, classic myeloma must be excluded by thorough staging. A monoclonal protein in the serum and urine,

lytic bone lesions, anemia, renal insufficiency, and hypercalcemia should be excluded. Histologically, an extramedullary plasmacytoma should be differentiated from reactive plasmacytosis, plasma cell granuloma, poorly differentiated neoplasms, and immunoblastic lymphoma. Some extramedullary plasmacytomas may represent marginal zone B-cell lymphomas that have undergone plasmacytic differentiation.¹¹²⁰ Dimopoulos et al.¹¹¹⁸ compiled 128 extramedullary plasmacytoma patients from eight published series^{1108, 1119, 1121, 1122, 1123, 1124, 1125, 1126} and summarized their clinical course. The local failure rate was 7%, multifocal extramedullary relapse occurred in 13%, and classic myeloma developed in 15%. Local radiation therapy is the treatment of choice and adjuvant chemotherapy is not recommended. The 10-year disease-free survival is 70% to 80%. Ozsahin et al.¹¹¹⁶ compiled 52 patients through a Rare Cancer Network study. Their findings were similar with a 5-year progression rate of about 25% and a 5-year survival approaching 90%.

HISTORY

The term lardaceous change has ... come more into use chiefly through the instrumentality of the Vienna School.... The term, lardaceous changes ... has but very little to do with these tumours, and rather refers to things, upon which the old writers ... who were better connoisseurs in bacon than our friends in Vienna, would hardly have bestowed such a name.... The appearance of such organs ... are said to look like bacon, bears ... a much greater resemblance to wax, and I have therefore now for a long time ... made use of the term waxy change.... These structures ... by the simple action of iodine ... assume just as blue a colour as vegetable starch....¹

Schleiden, a German botanist, first used the term amyloid in 1838 to describe a normal constituent of plants.^{2, 3, 4} In 1858, Virchow, head of a pathology department in Berlin, gave a lecture entitled "Amyloid Degeneration" and described amyloid deposits that stained blue with iodine and sulfuric acid, similar to the chemical reaction markers of starch. Virchow

concluded that the substance was composed of starch⁵ and used the word amyloid to describe it.⁶ During the lecture, Virchow also criticized his chief competitor in Vienna, Rokitansky, who believed that amyloid was a lardlike substance—perhaps because amyloid deposits were white and glistening—found in patients with syphilis, tuberculosis, or malaria.⁷ In 1859, Friedreich, Nikolau, and Kekule recognized that the waxy spleen described by Virchow did not contain any starchlike substances and that the deposits probably were derived from modified proteins.⁸ Kekule was famous in his own right at the time for describing the structure of benzene from his dream of a serpent biting its own tail. In addition, Friedreich gave the first description of a form of ataxia that now bears his name.^{9, 10}

Budd analyzed the liver of a patient with amyloidosis and found that it was not lardaceous¹¹; he also wrote original descriptions of rickets and scurvy.¹² Probably the first reported case of primary amyloidosis (AL; described as “idiopathic” at the time) was identified by Wilks, who detailed a 52-year-old patient with lardaceous change unrelated to an obvious cause.^{13, 14, 15} Wilks was the first physician to use bromide in the treatment of epilepsy and wrote an original description of myasthenia gravis.

The amino acid composition of amyloid deposits was first described by Schmiedeberg in 1920.¹⁶ Amyloid proteins strongly resembled serum globulin and therefore were neither fat nor carbohydrate. The first use of Congo red as the specific stain for detection of amyloid was reported in 1922 by Bennhold.¹⁷ In 1927, Divry and Florkin¹⁸ reported green birefringence under polarized light when amyloid-laden material from the brain of a patient with Alzheimer disease was stained with Congo red. However, the association between the neurodegeneration of Alzheimer disease and amyloid was forgotten for nearly 50 years. Magnus-Levy¹⁹ postulated that Bence Jones proteins were a precursor of the amyloid substance and noted a relationship among amyloid deposits, Bence Jones proteins, and multiple myeloma.

The finding that amyloid proteins consisted of fibrils was credited to Cohen and Calkins in 1959.⁵ They determined that all forms of amyloid were nonbranching and fibrillar. The fibril length varied, but the width was 9.5 nm. Apitz²⁰ claimed that amyloid in the tissues was analogous to the excretion of immunoglobulin (Ig) light-chain proteins by the kidneys; he coined the term paraprotein to describe monoclonal immunoglobulins. Isobe and Osserman²¹ reported in 1974 that Bence Jones proteins had a direct role in the pathogenesis of AL. Physiologically normal proteins primarily have an α -helix configuration. In 1968, Eanes and Glenner²² reported that they used x-ray diffraction to determine that amyloid proteins formed an alternate configuration of β -pleated sheets, similar to the configuration of silk proteins.²³

As with silk, amyloid proteins are highly resistant to solvents, and this resistance is a feature of the purification process. Amyloid-laden tissue is homogenized repeatedly in saline and centrifuged. The supernatant, which contains soluble components, is discarded, and the residual pelletized material contains amyloid proteins. After the pellet is resuspended in distilled water, a relatively pure preparation of amyloid fibrils is obtained. Pras et al.²⁴ first described the purification of amyloid in 1968. Levin et al.²⁵ were the first to sequence amyloid protein, and they designated it as amyloid A. Benditt et al.^{26, 27} independently sequenced amyloid A at the same time. The first sequence of an immunoglobulin light-chain form of amyloid was reported in 1970 by Glenner et al.²⁸ and was recognized as an N-terminal fragment of the immunoglobulin light chain.^{28, 29, 30, 31, 32}

CLASSIFICATION

The diagnosis of amyloidosis requires biopsy tissue specimens with deposits that are positively stained by Congo red.³³ With hematoxylin and eosin staining, amyloid deposits resemble hyalin. Deposits are always extracellular and appear amorphous. Apple-green birefringence is seen when Congo-red-stained material is viewed under polarized light.³⁴ The Congo red stain can be technically difficult to use and can form precipitates, yielding false-positive results.³⁵ Pathologists need to perform diagnostic assays regularly to be experts in the interpretation of stains. All forms of amyloid have a fibrillar appearance when viewed with electron microscopy, and the fibrils are rigid and nonbranching. However, not all fibrils identified with electron microscopy are amyloid proteins.^{36, 37, 38} Such findings are strongly suggestive of amyloidosis, but in the absence of a positive result on Congo red stain and apple-green birefringence, the diagnosis remains unconfirmed. Studies of recombinant-derived variable region fragments of immunoglobulins have shown a relationship between thermodynamic instability and fibrillogenic potential. Structural parameters and overall thermodynamic stability contribute to the fibril-forming propensity.³⁹ Human monoclonal immunoglobulin light chains can be converted to amyloid fibrils in vitro by digestion with pepsin.³⁰ Synthetically, amyloid fibrils can be produced by breaking the disulfide bonds of intact immunoglobulins. In the past, all forms of amyloid were thought to be derived from misfolded fragments of immunoglobulin light chains, but heavy-chain fragments have also been shown to produce amyloid (designated as AH).⁴⁰

The classification scheme of amyloidosis has undergone revision as understanding of the pathophysiology of the disease has improved. In the 19th century, involvement of the liver, spleen, and kidneys was incorrectly thought to represent

secondary amyloidosis (AA); amyloid that involved the heart, tongue, and peripheral nerves was classified as AL or idiopathic amyloidosis. Later, amyloidosis was classified by the site of first deposition and was referred to as pericollagenous or perireticular amyloidosis.^{41, 42} Familial amyloidosis (AF) was recognized generally by the P.2099

presentation of progressive painful peripheral neuropathy with an autosomal dominant inheritance pattern.^{43, 44} Families with inherited renal amyloidosis were also described.^{45, 46} Mutations in transthyretin (TTR), apolipoprotein A1, fibrinogen A- α chain, lysozyme, leukocyte chemotactic factor 2 (LECT2),⁴⁷ and apolipoprotein A2 are associated with hereditary amyloidosis. TTR amyloidosis is the most common form of AF, and it is associated with peripheral neuropathy.⁴⁸

In the 19th century, when tuberculosis, leprosy, syphilis, and chronic infections were prevalent, patients with these infections often had concomitant AA. However, in the postantibiotic era, chronic inflammatory polyarthritis (e.g., ankylosing spondylitis, juvenile rheumatoid arthritis) is more commonly associated with AA. Crohn disease and chronic osteomyelitis have also been associated with a small number of AA patients in the Western hemisphere.⁴⁹ Hereditary periodic fever syndromes, such as familial Mediterranean fever (FMF; the most common entity of this disorder), hyperimmunoglobulinemia-D syndrome, and tumor necrosis factor (TNF) receptor-associated periodic syndrome (TRAPS), are characterized by recurrent fever and inflammation, and reactive amyloidosis is a complication of these hereditary periodic fevers. The causative genes of these syndromes have been identified. Anticytokine-based therapies are a new treatment option for these inflammatory conditions, and they potentially may prevent amyloidosis.⁵⁰ Etanercept, adalimumab, and infliximab have all been reported to be effective for patients with AA.

One hundred years ago, the term primary amyloidosis referred to idiopathic amyloidosis and included all cases that were neither familial nor secondary; cases of unrecognized AF and AA for which a cause could not be established were mistakenly classified as AL. Currently, AL refers only to systemic or localized amyloidosis that is immunoglobulin light chain derived. A clonal plasma cell disorder exists for all patients with systemic AL, and the disease spectrum ranges from a barely detectable plasma cell clone to overt multiple myeloma.⁵¹ A classification of the various forms of amyloidosis is shown in Table 99.1.

TABLE 99.1 NOMENCLATURE OF AMYLOIDOSIS

Protein	Precursor	Clinical
AL or AH	Immunoglobulin (light or heavy chain)	Primary or localized amyloidosis; associated with myeloma or macroglobulinemia
AA	SAA	Secondary or familial Mediterranean fever; familial periodic fever syndromes associated with mutated tumor necrosis factor receptor
ATTR (form of AF)	Transthyretin	Familial and senile amyloidosis
Fibrinogen A- α chain (form of AF)	Fibrinogen	Familial renal amyloidosis (Ostertag amyloidosis)
A β ₂ M	β ₂ -Microglobulin	Dialysis-associated carpal tunnel syndrome
A β	A β PP	Alzheimer disease
Apo1, Apo2 (form of AF)	Apolipoprotein	Renal, nephrotic syndrome
Lysozyme (form of AF)	Lysozyme	Renal, hepatic rupture
LECT2 (form of AF)	Leucocyte chemotactic factor 2	Renal autosomal dominant inheritance

AA, secondary amyloid; A β , amyloid β ; A β ₂M, amyloid β ₂-microglobulin; A β PP, amyloid β protein precursor; AF, inherited amyloid proteins; AH, immunoglobulin heavy-chain amyloid; AL, primary

amyloid; Apo1, apolipoprotein A1 amyloid; Apo2, apolipoprotein A2 amyloid; ATTR, amyloid transthyretin; LECT, leucocyte chemotactic factor; SAA, serum amyloid A.

In AL, the tertiary structure and amino acid sequence of immunoglobulin light chains are abnormal.^{52, 53} For patients with AL, three fourths of immunoglobulin light chains are of the λ type. In contrast, for patients with multiple myeloma and monoclonal gammopathy of undetermined significance, two thirds of the light chains are of the κ type (Fig. 99.1).⁴⁹ The implication is that λ immunoglobulin light chains have a greater tendency to form a β -pleated sheet. AL-associated immunoglobulins generally tend to have more β -pleated sheet proteins than α -helical proteins.

Certain immunoglobulins have "amyloidogenic" properties. No renal dysfunction is seen after mice are injected with purified immunoglobulin light chains derived from the urine of patients with multiple myeloma who do not have amyloidosis.⁵⁴ However, deposits of human AL develop in the kidneys of mice after injection of light chains purified from the urine of patients with AL.

Amyloid-associated germline gene usage has been determined.⁵⁵ The $\lambda 6$ subgroup of immunoglobulin light chains is always associated with amyloid proteins, which suggests that unique amino acid sequences may result in formation of amyloidogenic proteins.⁵⁶ The $\lambda 3$ family appears most frequently in amyloidosis and polyclonal states. Two germline genes that belong to the $\lambda 3$ and $\lambda 6$ families encode 42% of λ variable regions. The gene segment 3r accounts for 22% of λ variable regions and is newly associated with the disease; gene segment 6a accounts for 20%. These gene segments have a strong association with amyloidosis; they are represented in less than 11% of polyclonal conditions (Table 99.2). Overuse of 3r and 6a likely accounts for the λ light-chain overrepresentation that is typical of amyloidosis. Germline gene usage may also influence the organ tropism of AL.⁵⁷ Patients with clones derived from the 6a germline gene are more likely to present with dominant renal involvement. Those with clones from 1c, 2a2, and 3r are more likely to present with cardiac and multiorgan disease.⁵⁸

The distinction between AL and amyloidosis associated with multiple myeloma is somewhat arbitrary (considerable overlap exists between them). However, a patient with amyloidosis and symptomatic multiple myeloma (e.g., widespread lytic bone disease, rib fractures, and lumbar spine compression fractures) is uncommon.⁵⁹ Renal insufficiency in amyloidosis is almost never a consequence of the formation of light-chain cast nephropathy, as is the case in multiple myeloma. For patients with amyloidosis, renal failure is attributable to tubular atrophy, a

P.2100

consequence of long-term albuminuria.^{60, 61} Often, the distinction between multiple myeloma-associated amyloidosis and AL is made on the basis of the percentage of plasma cells in the bone marrow.⁶² For patients with AL, serial bone marrow biopsies performed over several years do not show a progressive increase in the plasma cell percentage. In amyloidosis, the process is clonal but typically is not proliferative, and the unrestrained growth associated with malignancy is absent. If it is not present at diagnosis, multiple myeloma does not develop subsequently in patients with AL who present with 10% to 30% bone marrow plasma cells; multiple myeloma develops in fewer than 0.5% of patients with amyloidosis.⁵¹ We have established an arbitrary threshold of 30% plasma cells to fulfill the criteria of multiple myeloma-associated amyloidosis if no other clinical features of multiple myeloma are present. For patients who have greater than 30% plasma cells in the bone marrow, the clinical course is dominated by AL and not by myeloma bone disease or myeloma-induced anemia.

^aFor polyclonal conditions, λ_1 usage is 25%, λ_2 usage is 24%, and λ_3 usage is 43%. Data from Perfetti V, Casarini S, Palladini G, et al. Analysis of V λ -J λ expression in plasma cells from primary (AL) amyloidosis and normal bone marrow identified 3 r (λ III) as a new amyloid-associated germline gene segment. *Blood* 2002;100:948-953; Comenzo RL, Zhang Y, Martinez C, et al. The tropism of organ involvement in primary systemic amyloidosis: contributions of Ig V(L) germ line use and clonal plasma cell burden. *Blood* 2001;98:714-720; Abraham RS, Geyer SM, Price-Troska TL, et al. Immunoglobulin light chain variable (V) region genes influence clinical presentation and outcome in light chain-associated amyloidosis (AL). *Blood* 2003;101:3801-3808. Epub 2002 Dec 19.

The incidence of AL is eight per million per year and has been stable for more than 50 years.⁶³ Multiple myeloma is five times more prevalent than amyloidosis.⁶⁴ Amyloidosis is uncommon; its incidence is similar to that of Hodgkin lymphoma (nodular sclerosing variant), chronic granulocytic leukemia (Philadelphia chromosome-positive), and polycythemia rubra vera.^{65, 66, 67} Bone marrow plasma cells from AL patients typically show chromosomal abnormalities.⁶⁸ Trisomies of chromosomes 7, 9, 11, 15, and 18 are seen in 42%, 52%, 47%, 39%, and 33% of patients with amyloidosis, respectively. Fifty-four percent of male patients and 13% of female patients have trisomy X, and 72% have deletions in chromosome 18. The finding of aneuploidy in monoclonal plasma cells is indicative of their neoplastic nature, despite the fact that these

plasma cells are nonproliferative and are present in small numbers (median, 5% plasma cells).⁶⁹ An early pathogenetic event in the development of multiple myeloma is translocation at the immunoglobulin heavy-chain locus (band 14q32).⁷⁰,⁷¹ A total of 16 of 29 patients with AL (55%) showed translocations at the immunoglobulin heavy-chain locus. An additional 17% showed a pattern compatible with a possible IgH translocation.⁷² Overall, an IgH translocation was seen in 21 of 29 patients by using fluorescent in situ hybridization analysis. Of the 21 patients, 16 had t(11;14)(q13;q32) translocations. For 15 of the 16 patients, cyclin D1 overexpression accounted for 76% of all IgH translocations.

SYMPTOMS AND SIGNS

Weight loss, paresthesia, edema, dyspnea, and fatigue are the most common symptoms of AL (Fig. 99.2).⁷³ These nonspecific complaints provide little help to a clinician evaluating patients. Patients with extreme weight loss frequently undergo evaluation for an occult malignancy. The fatigue, usually caused by early cardiac involvement with AL, generally is not associated with overt congestive heart failure and easily may be diagnosed incorrectly as stress-related or functional fatigue.⁷⁴ We have seen many patients undergo coronary angiography because of fatigue and breathlessness, only to have the evaluation end when angiogram findings are normal.⁷⁵

Light-headedness occurs frequently in amyloidosis, but this is a common and nonspecific complaint in the primary care setting. In AL, the cause of light-headedness is multifaceted.⁷⁶ Patients with nephrotic syndrome have dizziness because of hypoalbuminemia and marked intravascular volume contraction, which leads to orthostatic hypotension.⁷⁷ Patients with cardiac AL have a low end-diastolic volume (because of restriction to filling during diastole)⁷⁸ and low cardiac output, but a normal ejection fraction is maintained until late in the course of the disease. The echocardiographic finding of a normal ejection fraction may be highly misleading and may hinder recognition of cardiac involvement in AL. Patients may have orthostatic hypotension as a consequence of autonomic neuropathy. Syncope is not unusual.⁷⁹,⁸⁰

The physical findings of amyloidosis are specific and diagnostic; however, they are present in only 15% of patients and may easily be overlooked. Amyloid purpura is seen in only one of every six patients with AL (Fig. 99.3).⁸¹ Purpura may be periorbital but also may occur in the face, webbing of the neck, and upper chest. Purpura on the arms is not characteristic of AL, but petechial lesions on the eyelids should not be overlooked. The liver is palpable 5 cm below the right costal margin in only 10% of patients. Splenomegaly, if present, is usually of modest degree. Overall, any degree of hepatomegaly is present in one fifth of patients.⁸²

Macroglossia is the most specific finding of AL (Fig. 99.4). In our experience, enlargement of the tongue is never found in AF, AA, or senile systemic amyloidosis.⁸³ Tongue enlargement is seen in 1 of 11 patients with AL and may be overlooked easily unless the physician knows to look for dental indentations on the underside of the tongue. However, presentation with fatigue, edema, breathlessness, or paresthesias would not immediately lead the physician to examine the patient's tongue. Tongue enlargement is almost always accompanied by concomitant enlargement of the submandibular salivary glands,⁸⁴ but salivary gland involvement should not be

P.2101

misinterpreted as submandibular lymphadenopathy. Major and minor salivary gland involvement may result in sicca syndrome.⁸⁵

Clinical and laboratory features in 474 cases. *Semin Hematol* 1995;32:45-59. Used with permission.)

FIGURE 99.3. Classic truncal purpura in primary amyloidosis. (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. *Hematol Oncol Clin North Am* 1999;13:1211-1233. Used with permission.)

Vascular involvement without visceral organ dysfunction produces occlusion and ischemic symptoms, such as jaw claudication, when the temporal arteries are involved⁸⁶; calf and limb claudication may occur when the microvasculature that supplies the extremities is involved.⁸⁷ Monoclonal protein in the serum may increase the sedimentation rate, and it is not unusual for amyloidosis and jaw claudication to be misdiagnosed as polymyalgia rheumatica.⁸⁸ Amyloid deposits may be found if a temporal artery biopsy is performed, but Congo red staining typically is not performed on such specimens.⁸⁷,⁸⁹ The shoulder-pad sign is a consequence of periarticular infiltration with amyloid and may produce pseudohypertrophy.

Although the musculature of the shoulder and hip girdle is enlarged, patients present with diffuse muscular weakness^{90, 91} and may have muscular atrophy because of chronic vascular occlusion.

DIAGNOSIS OF AMYLOIDOSIS

When should a clinician initiate a diagnostic algorithm to confirm the presence of AL? The symptoms and physical findings of AL generally are nonspecific and unhelpful to the clinician. Nevertheless, eight critical clinical syndromes commonly associated with amyloidosis should trigger screening: (1) gastrointestinal tract symptoms of pseudo-obstruction or steatorrhea, (2) tongue enlargement, (3) carpal tunnel syndrome, (4) hepatomegaly, (5) peripheral neuropathy, (6) nephrotic-range proteinuria, (7) infiltrative cardiomyopathy with restrictive hemodynamics, and (8) atypical multiple myeloma. The diagnosis of AL must be considered when any one of these syndromes is seen (Table 99.3). AL also must be considered for any patient for whom the diagnosis of multiple myeloma is being considered and who has associated, unexplained weight loss or fatigue or a percentage of plasma cells in the bone marrow that does not meet the criteria for multiple myeloma.

FIGURE 99.4. Tongue enlargement in primary amyloidosis. (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. Hematol Oncol Clin North Am 1999;13:1211-1233. Used with permission.)

TABLE 99.3 SYNDROMES IN PRIMARY AMYLOIDOSIS

Syndrome	Patients (%)
Nephrotic or nephrotic and renal failure	30
Hepatomegaly	24
Congestive heart failure	22

Carpal tunnel syndrome	21
Neuropathy	17
Orthostatic hypotension	12

A clonal population of plasma cells is observed in AL patients, even when the marrow percentage is less than 2%.⁹² The insoluble, fibrillar β -pleated sheets of amyloid proteins are derived from the monoclonal immunoglobulin light chains produced by a clonal population of plasma cells. For any patient with a compatible clinical syndrome that includes monoclonal gammopathy, tests to confirm the diagnosis of AL should be pursued aggressively. Important screening tests for a patient with cardiomyopathy, neuropathy, hepatomegaly, or proteinuria are immunofixation of the serum and of the urine⁹³ and immunoglobulin free light-chain measurement.⁹⁴ The urine must be evaluated because serum assays may fail to detect monoclonal light chains (Fig. 99.5). Serum electrophoresis tests are inadequate because the light chains in AL are frequently present only in trace amounts and they do not produce a spike on an electrophoretic pattern. Monoclonal protein in the urine frequently is difficult to detect because most patients have proteinuria to the extent that small amounts of light chains are obscured (Fig. 99.6). If amyloidosis is being considered in the differential diagnosis, immunofixation of serum or urine (or both) is essential. The immunoglobulin free light-chain assay is tenfold more sensitive than serum immunofixation for the detection of serum light chains.⁹⁵ If all three tests are negative, systemic AL is not present.

For patients with a suggestive clinical syndrome, immunofixation is a good noninvasive screening test. For patients with light-chain levels in the serum or urine that are below the threshold of detection by immunofixation,⁹⁶ the bone marrow often shows a clonal population of plasma cells when examined by flow cytometry, immunofluorescence, or immunohistochemistry.^{97, 98} Such patients frequently have abnormal κ -to- λ ratios of free light chains. In patients with confirmed AL who did not have detectable levels of monoclonal protein in the serum or urine, 94% had a clonal population of plasma cells in the bone marrow when a slide-based immunofluorescence test was used to detect expression of clonal cytoplasmic immunoglobulin. If the patient does not have monoclonal protein in the serum or urine, has a normal free light-chain ratio, and has no detection of clonal population of plasma cells in the bone marrow, the diagnosis of systemic AL is very unlikely. If amyloidosis is present, it likely is not immunoglobulin light-chain derived, and further evaluation for familial, secondary, or localized amyloidosis should be performed.

P.2102

FIGURE 99.5. Serum monoclonal protein levels from patients with primary amyloidosis (N = 488). Inset, immunofixation results.

Our ability to recognize AL has been improved by the nephelometric assay for free light chains in the serum; the assay detects free immunoglobulin light chains that are not associated with an intact immunoglobulin molecule.^{99, 100} For 100 consecutive AL patients tested with the nephelometric assay, the assay sensitivity was 90% for patients with confirmed AL- κ , and similar sensitivity was noted for patients with confirmed AL- λ . For patients with detectable urinary light chains (but no detectable monoclonal protein in the serum with immunofixation assays), the nephelometric light-chain assay detected free light chains in the serum of 85% of patients with AL- κ and 80% of patients with AL- λ . For patients with AL

who had no monoclonal protein detected in the serum or urine with immunofixation assays, the nephelometric light-chain assay identified free κ light chains for 86% of patients with AL- κ and free λ light chains for 30% of patients with AL- λ . The free light-chain serum assay is convenient and adds an important diagnostic tool for classifying and monitoring AL patients.

All forms of amyloid deposits contain the amyloid P component, a pentagonal glycoprotein that may represent as much as 10% of the amyloid fibril by weight. It is structurally similar to C-reactive protein and has been identified in all vertebrates. However, it does not function as an acute-phase reactant in humans because the concentration in plasma is relatively stable.¹⁰¹ Amyloid P component maintains a dynamic circulating equilibrium between the serum and amyloid deposits. Because serum amyloid P (SAP) exchanges readily with the amyloid P component of amyloid fibrils, binding and release of SAP from amyloid deposits may be observed with an ¹²³I-labeled SAP scan.^{102, 103} In addition, the clearance rate of radiolabeled P components (¹²⁵I-labeled SAP) from the plasma may be used to assess the total-body burden of amyloid and to evaluate the effect of therapy.¹⁰⁴ Patients with large burdens of amyloid have rapid clearance, which is associated with shorter survival, but those with trace amounts of systemic amyloid deposits have plasma clearance rates similar to those of healthy individuals. Healthy adults have 50 to 100 mg of amyloid P component in the extravascular and intravascular compartments, whereas patients with amyloidosis may have up to 20,000 mg. Antibodies to P component have been used as therapy against amyloidosis.¹⁰⁵

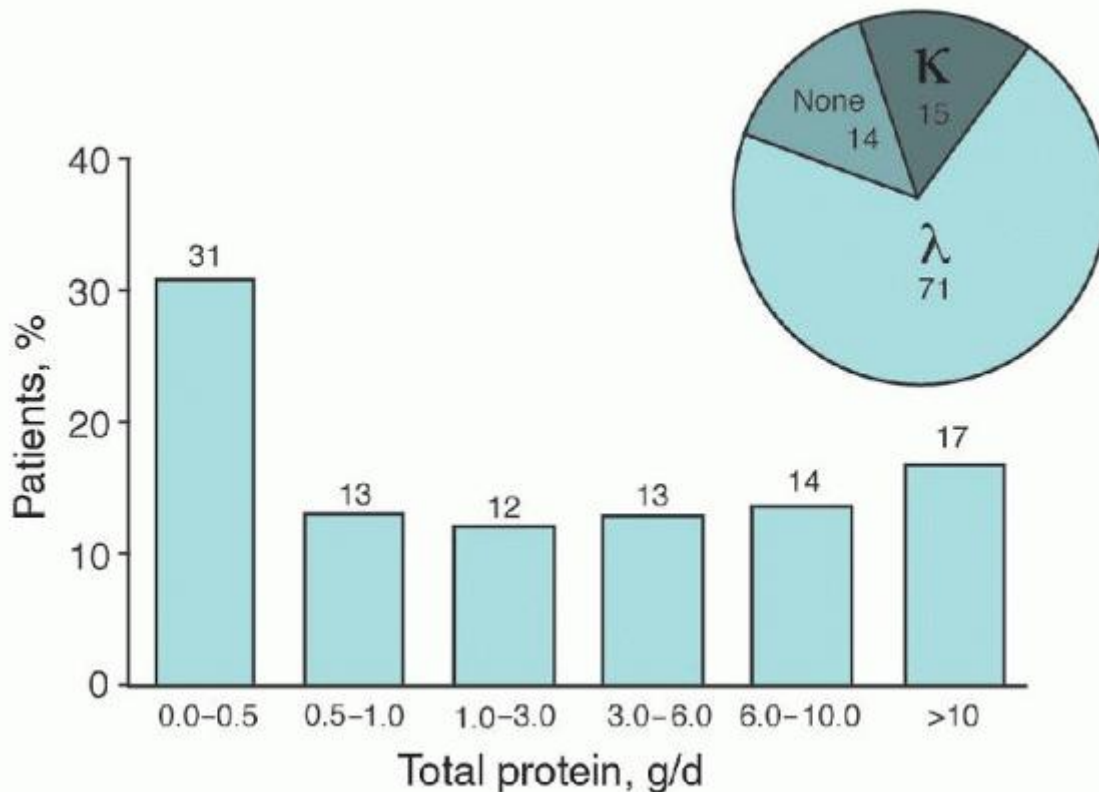

FIGURE 99.6. Total protein excreted in the urine of patients with primary amyloidosis (24-hour period). Inset, identification of immunoglobulin light chains, %. (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. In: Mehta J, Singhal S, eds. Myeloma. London: Martin Dunitz, 2002:445-463. Used with permission.)

The P component scan may be performed serially to determine whether patients have increasing rates of amyloid deposition. However, the technique does not determine whether the amyloidosis is AL, AF, AA, or localized. Cardiac amyloid deposits are not detected through the use of SAP scans,¹⁰⁶ but uptake of ¹²³I-labeled amyloid P component is seen in the spleen, liver, and kidneys in 87%, 60%, and 25% of patients, respectively. Imaging does not consistently show deposits in the carpal tunnel, kidneys, and gastrointestinal tract. The correlation is poor between imaging and the extent of organ dysfunction assessed clinically.

The diagnostic sensitivity of SAP scintigraphy for systemic AA, AL, and amyloid TTR origin amyloidosis is 90%, 90%, and 48%, respectively; specificity is 93%. Splenic amyloid is observed in 80% of AL patients, even though it rarely is detected

clinically. Bone marrow uptake is specific for AL in 21% of patients. More widespread organ involvement is identified with a scan than with a clinical examination.¹⁰⁷ Amyloid is distributed heterogeneously within individual organs. Presently iodine-labeled SAP scanning was not available in the United States.

The diagnosis of amyloidosis must always be confirmed by tissue biopsy.¹⁰⁸ For patients who have neuropathy, nephrotic syndrome, cardiac failure, or hepatomegaly, the diagnosis could be established by direct biopsy of the involved organs,¹⁰⁸ but an invasive visceral biopsy usually is not required to confirm AL. Because amyloid deposits typically are widespread at diagnosis and have involved the vasculature extensively,¹⁰⁹ biopsy procedures that are less invasive, lower risk, and lower cost may be used to establish the diagnosis.

For a patient with a syndrome consistent with AL and confirmed presence of monoclonal protein, we begin the diagnostic evaluation with a subcutaneous fat aspirate and bone marrow biopsy.¹¹⁰ The subcutaneous fat aspirate is a 75%-sensitive, riskfree procedure that is performed by registered nurses.¹¹¹ Results are available within 24 hours (Fig. 99.7). Amyloid deposits are seen in half of the bone marrow biopsy specimens of patients with AL and generally are identified in blood vessels.¹¹² To exclude the diagnosis of multiple myeloma, a bone marrow biopsy is justified for any patient who has monoclonal immunoglobulin light chains. Knowledge of the percentage of bone marrow plasma cells is important prognostically.¹¹³ Table 99.4 shows the findings of bone marrow biopsies and fat aspirations of patients with AL. With Congo red studies of fat and bone marrow, the diagnosis is established in 87% of patients. For the other 13%, the diagnosis may be established by a biopsy of the affected organ.

Less invasive biopsy procedures may be used to establish a diagnosis of AL. Xerostomia in amyloidosis is attributable to salivary gland infiltration, and lip biopsy findings have high sensitivity (up to 87%).^{114, 115} Subcutaneous blood vessels may be accessed through a skin biopsy and may show AL deposits.^{116, 117} Amyloid deposits regularly were confirmed by rectal biopsy in the

P.2103

1970s and 1980s.¹¹⁸ Rectal biopsy is an outpatient procedure, although occasionally it results in bleeding. Endoscopic biopsy specimens frequently are inadequate because submucosa is essential for specimen adequacy.

FIGURE 99.7. Subcutaneous fat aspirate showing amyloid deposits (congo red, original magnification $\times 100$). (Courtesy of Paul J. Kurtin, MD, Mayo Clinic, Rochester, Minnesota. Used with permission.)

All patients who have nephrotic syndrome should undergo screening with immunofixation assays of serum and urine and free light-chain assays. Among 110 patients with AL, the sensitivity of the free light-chain assay was 92%, but in combination with serum and urine immunofixation assay findings, the sensitivity increased to 99.1%.¹¹⁹ If either assay finding is positive, a fat aspiration is performed, which eliminates the need for a diagnostic renal biopsy for 70% of patients. The net result is reduced expense and reduced risk of bleeding and hospitalization.

Congo red may precipitate in tissue, and the resultant overstaining, particularly in subcutaneous fat, may produce a false-positive result.¹²⁰ Skin and subcutaneous fat have a high content of elastin and collagen; both bind Congo red and may also be interpreted as a false-positive result.¹²¹ Rectal biopsy specimens containing amyloid may be misinterpreted as collagenous colitis if stained only with hematoxylin and eosin.¹²² To recognize amyloid in the myocardium, our cardiac pathologists prefer to use sulfated Alcian blue stain.¹²³ The Peripheral Nerve Laboratory at Mayo Clinic stains sural nerve biopsy specimens with crystal violet during screening and confirms the diagnosis subsequently with Congo red.¹²⁴

DIFFERENTIATING AMYLOIDOSIS FROM OTHER FORMS OF AMYLOIDOSIS

It is important that the diagnosis of amyloidosis be confirmed as AL, AF, or AA because therapy for the three syndromes differs.^{125, 126} Localized amyloidosis,¹²⁷ AF,¹²⁸ AA,¹²⁹ and senile systemic forms of amyloidosis¹³⁰ are not associated with a plasma cell dyscrasia. Except for the rare case of a patient who has one of these forms of amyloidosis and an incidental monoclonal gammopathy of undetermined significance, only AL patients have monoclonal light chains in the serum and urine or clonal plasma cells in the marrow. Patients with localized amyloidosis may present with hematuria,¹³¹ respiratory difficulties,¹³² and visual disturbances¹³³; such symptoms may easily be confused with those of systemic amyloidosis. The localized amyloidosis syndrome, which usually involves the skin, tracheobronchial tree, or urogenital tract, never becomes systemic. The fibrils of localized amyloidosis may be immunoglobulin light-chain derived,¹³⁴ but clonal plasma cells are not seen in the bone marrow.

The site of amyloid deposition provides an important clue for recognizing localized amyloidosis. The most frequent sites of localized amyloid deposits are the respiratory tract, genitourinary tract, and skin.^{126, 135} Pulmonary amyloid may be subdivided into nodular, tracheobronchial, or diffuse interstitial deposits. Only the last type of deposit is a manifestation of systemic AL.¹³⁶ The diagnosis of tracheobronchial amyloidosis is made by bronchoscopy during evaluation of a patient with obstruction, cough, dyspnea, wheezing, or hemoptysis. The usual treatment is resection of the tissue with an yttrium-aluminum-garnet laser.¹³⁷ Tracheobronchial amyloid deposits are derived from immunoglobulin light chains.¹³⁸ Nodular amyloidosis presents as a solitary pulmonary nodule or multiple nodules, and the nodules do not indicate systemic AL.¹³⁹ Nodules are not calcified, and they often require resection to exclude a diagnosis of malignancy. The AL diagnosis is established during a thoracotomy or a video-assisted thoracoscopic surgical procedure. Amyloid can involve the vocal cords and false vocal cords and cause traction on the structures, leading to hoarseness. This form of laryngeal amyloidosis is always localized.¹⁴⁰

TABLE 99.4 FINDINGS OF NONINVASIVE BIOPSIES IN PRIMARY AMYLOIDOSIS

Biopsy Finding

+, tissue positive for amyloid deposits; -, tissue negative for amyloid deposits. Modified from Gertz MA, Lacy MQ, Lust JA, et al. Prospective randomized trial of melphalan and prednisone versus vincristine, carmustine, melphalan, cyclophosphamide, and prednisone in the treatment of primary systemic amyloidosis. *J Clin Oncol* 1999;17:262-267. Used with permission.

Obstructive ureterovesicular amyloidosis is always localized. Patients present with hematuria and have a prebiopsy diagnosis of cancer. Amyloid deposits are found when cystoscopic biopsies are performed. Eighty-five percent of patients with this type of amyloidosis present with hematuria. Patients may undergo partial cystectomy, fulguration, or transurethral resection.¹⁴¹ Dimethyl sulfoxide (DMSO) instillation in the bladder has been reported to reduce these deposits.¹⁴² Colchicine has also been reported to be beneficial. Amyloid involving the renal pelvis or ureter is a localized amyloid syndrome.^{143, 144} These patients present with colic because of obstruction or hematuria, and deposits are found

during surgery. Nephrectomy is commonly performed because the ureteral mass preoperatively is thought to represent a transitional cell malignancy, but the recognition of amyloidosis avoids nephrectomy. Patients may present with dysuria and hematuria when amyloidosis involves the urethra.¹⁴⁵ The preoperative diagnosis is usually a urethral malignancy. Resection is the treatment of choice.

Three forms of cutaneous amyloidosis are recognized. The lichen and macular forms are localized,¹⁴⁶ innocuous conditions that usually are associated with a history of local skin trauma or inflammation. Nodular amyloidosis is associated with AL,¹⁴⁷ and evidence of nodular deposits may be an important clinical clue to an underlying life-threatening process. Degraded keratin molecules are the source of macular and papular amyloid deposits.¹⁴⁸ Dermabrasion and other forms of local therapy adequately control cutaneous amyloidosis.

Carpal tunnel amyloidosis may be observed in systemic AL and AF, but it may also be localized.^{149, 150} For patients who present

P.2104

with carpal tunnel syndrome as the only manifestation of amyloidosis, the median survival is 12 years. Virtually all patients with carpal tunnel amyloidosis have localized disease, and one study reported that only 2 of 124 patients with localized carpal tunnel amyloidosis had development of AL.¹⁵¹ TTR is often found in localized carpal tunnel amyloid deposits.

Localized amyloidosis is seen in the conjunctiva and orbits. The best treatment is surgical excision. Amyloid has also been localized to breasts,¹⁵² mesenteric lymph nodes, colonic polyps, thyroid,¹⁵³ retroperitoneum, and ovaries. Localized deposits of amyloid commonly are observed in trace amounts within the cartilage on the hip surface after a total hip arthroplasty.¹⁵⁴ Similarly, localized deposits are found in resected knee arthroplasty specimens. These deposits are not associated with systemic disease.¹⁵⁵

AA is a consequence of poorly controlled, long-term systemic inflammation. From a simple syndrome standpoint, its presentation is similar to that of AL. AA is more common than AL in underdeveloped countries because of the persistence of tuberculosis,⁶¹ syphilis, malaria, and leprosy, but in the United States, AA is not easily distinguished from AL. AA is not associated with a monoclonal protein or clonal marrow plasma cells. Patients with AA most commonly present with nephrotic-range proteinuria.¹⁵⁶ At Mayo Clinic, AA accounts for only 2% of all patients with amyloidosis.¹⁵⁷

The underlying cause of AA most commonly includes ankylosing spondylitis,¹⁵⁸ juvenile rheumatoid arthritis,¹⁵⁹ psoriatic arthritis,¹⁶⁰ and rheumatoid arthritis¹⁶¹; for most patients with AA, the cause is clear because the arthritis is disabling and develops a median of 15 years before the development of AA.¹⁶² Of patients with rheumatoid arthritis, AA develops in 3.1%.¹⁶³ With the introduction of anti-TNF therapies for inflammatory arthropathy, the prevalence of AA in industrialized nations continues to decrease as these disorders are better controlled. AA is also seen in patients with Crohn disease,¹⁶⁴ bronchiectasis¹⁶⁵ (including long-term survivors of cystic fibrosis), and chronic osteomyelitis.¹⁶⁶ These are conditions in which the infected tissue is not amenable to surgical excision and antibiotic therapy results in poor control. For most patients with AA and Crohn disease, the inflammatory bowel disorder has been present for decades. The first clinical manifestation is proteinuria. No monoclonal protein is detectable. AA has been described in individuals who subcutaneously inject contaminated illegal substances (i.e., "skin poppers").^{167, 168} Skin abscesses develop at the site of injection and cause the inflammation that is necessary for the development of AA. Patients with Hodgkin lymphoma^{169, 170} or hypernephroma^{171, 172} and paraplegic patients with chronic infected decubitus ulcers or chronic urinary tract infection^{173, 174} have been reported to have AA. Amyloid deposits are identified during autopsy for half of all patients who sustained a spinal cord injury 10 years or more before death.¹⁷⁵ AA from Castleman disease has been recognized. Surgical excision leads to remission.^{176, 177} AA has also been reported for patients with hyperimmunoglobulin D syndrome and periodic fever syndromes, so-called TRAPS.¹⁷⁸

AF is more common than AA in the United States. Presentation of AF is clinically indistinguishable from AL; patients may have cardiomyopathy,^{179, 180} neuropathy,¹⁸¹ and nephrotic syndrome.¹⁸² The most common form of AF is attributable to TTR mutations. More than 100 different mutations in the TTR gene have been involved in amyloid neuropathy.¹⁸³ Nearly half of the patients with AF seen at Mayo Clinic do not have a family history of the disease, but absence of a family history is a poor screening method to exclude AF.¹⁸⁴ The most common TTR mutation seen at Mayo Clinic is Thr60Ala, caused by a nucleotide substitution in TTR DNA of 238A>G. Amyloid neuropathy without monoclonal protein or clonal plasma cell disorder should raise clinical suspicion of AF. Cardiac amyloid deposition may occur with mutated and wild-type TTR genes.¹⁸⁵ Cardiac amyloid deposits¹⁸⁶ that consist of normal TTR proteins occur in 8% to 25% of people older than 80 years. In this form of senile systemic amyloidosis, only cardiac symptoms are seen.

AF involving only the heart (without peripheral neuropathy) was first described in a Danish kindred.¹⁸⁷ Since then, AF cardiomyopathy has been described throughout the world. The US patients in AF pedigrees usually have symptoms after age 60 years. Patients with cardiomyopathy from AF present with heart failure or arrhythmias, and the clinical picture is virtually indistinguishable from that of senile cardiac amyloidosis or AL. Twenty-one percent of patients older than 90 years (the general patient population) have senile systemic amyloidosis from deposition of wild-type TTR.¹⁸⁸ The Val122Ile mutation of TTR is a major cause of inherited cardiac amyloidosis for African Americans. The first report of the mutation described an African American man aged 68 years.¹⁸⁹ The TTR Val122Ile allele is carried by 3.9% of African Americans, which translates to 1.3 million people in the United States.¹⁹⁰ Therefore, a finding of cardiac amyloidosis without monoclonal gammopathy could represent AF-based cardiomyopathy (even without a family history), and clinicians should not assume that the patient is affected by AL.¹⁹¹

Mutations in the fibrinogen,¹⁹² lysozyme,¹⁹³ or apolipoprotein A1 and A2^{194, 195, 196} and LECT2 proteins may produce inherited forms of renal amyloidosis. The amyloidosis associated with these mutations has a much better prognosis than that of renal AL. We have regularly seen patients who have proteinuria for more than a decade without renal failure. Because these patients present with proteinuria and the renal biopsy specimen shows amyloid deposits, their condition is easily confused with AL. The absence of a monoclonal immunoglobulin disorder or the absence of free light chains in the serum is an important distinguishing feature. However, only immunohistochemical staining or sequencing of the amyloid can differentiate these entities definitively. Of 285 renal amyloid samples, 31 were unclassified and subsequently 7 were found to be LECT2 related by tandem mass spectrometry.¹⁹⁷ Isolation of genomic DNA and polymerase chain reaction amplification of LECT2-encoding exons showed no mutations. However, all were homozygous for the G allele encoding valine at position 40 in the mature protein. LECT2-associated renal amyloidosis represents a unique form of renal amyloidosis, especially in Mexican Americans, and has only recently been recognized.

The treatment of TTR-derived AF includes liver transplantation, which makes the distinction between AF and AL critical for treatment decisions.¹⁹⁸ TTR is produced in the choroid plexus and the liver. Regression of amyloid deposits has been reported¹⁹⁹ when liver transplantation is performed before the development of disabling peripheral neuropathy, autonomic neuropathy, or advanced cardiomyopathy. Patients with the Val30Met mutation in the TTR gene appear to have the best outcome after liver transplantation.²⁰⁰ Progressive cardiac amyloidosis has been reported after liver transplantation for patients with other TTR mutations.²⁰¹ After mutant TTR is deposited in the myocardium, it may serve as a nidus for further deposition of native TTR produced by the transplanted liver. Autopsy findings show cardiac amyloid fibrils with mutant and wild-type TTR.^{202, 203} AF may be initially diagnosed as AL unless the patient has a clear family history of AF. When the referral diagnosis was AL, 34 of 350 patients (9.7%) were reported to have AF.²⁰⁴ The most common mutation in AF was identified in the gene encoding the fibrinogen A- α chain, and the second-most common mutation occurred in the gene encoding TTR. A low-grade monoclonal gammopathy was detectable in eight patients. All patients who have clinical syndromes consistent with AF should be screened for a genetic cause when AL cannot be confirmed unequivocally.²⁰⁴ Of 178 consecutive patients referred for amyloidosis, 54 underwent screening with polymerase chain reaction assays to detect AF variants.²⁰⁵ Three patients had monoclonal gammopathy and a hereditary variant; this finding justified routine screening of patients with apparent AL for hereditary variants and showed the necessity of

P.2105

immunohistochemical or mass spectroscopic confirmation of the type of amyloid protein subunit.

Screens for mutant forms of TTR may be performed using immunoaffinity chromatography and immunoprecipitation; both are convenient methods for assessing circulating TTR in serum.²⁰⁶ In addition, TTR variants may be examined using immunoprecipitated serum proteins and matrix-assisted laser desorption ionization mass spectrometry.²⁰⁷

The gold standard for protein identification is mass spectroscopic analysis of the tissue and direct sequencing to identify the amyloid protein, and this evaluation is now standard for all pathologic specimens that test Congo red positive seen at Mayo.^{208, 209} The procedure can be performed on subcutaneous fat. The distinction between immunoglobulin and nonimmunoglobulin amyloidosis is important because nonimmunoglobulin amyloidosis does not benefit from chemotherapy.

In summary, any patient with amyloidosis who does not have a detectable monoclonal light chain in the serum or urine and does not have a clonal population of plasma cells in the bone marrow should be considered for AA, AF, or localized amyloidosis. Laser capture microdissection mass spectroscopic analysis is the most direct method to identify the protein subunit comprising the amyloid and is recommended for all positive tissue biopsies.

PRESENTATION AND CLINICAL FEATURES

We reviewed records of all patients who received a diagnosis of AL over a 10-year period at Mayo Clinic. All patients received the diagnosis within 30 days of presentation at our institution. All had a clonal plasma cell disorder and histologic proof of amyloid deposits. Patients with overt multiple myeloma were excluded. The male preponderance of AL (67.3%) has been constant at our institution for 40 years, and we believe this finding reflects a true higher prevalence of the disorder in men. Multiple myeloma also is more common in men, but the male-to-female ratio is 52:48. Although we have seen patients with amyloidosis who were as young as 27 years, the median age of patients with amyloidosis was 67 years (range, 39 to 89 years). The median age of patients who present with AL in Olmsted County, Minnesota, is 73 years⁶³; this age difference suggests that a referral bias to amyloidosis treatment centers may exist.

Echocardiographic examinations have dramatically increased the ability to recognize cardiac amyloid deposits.^{210, 211} Cardiac amyloidosis was seen in 37.4% of patients with AL at Mayo Clinic. Congestive heart failure was present in only half of these patients; for the other half, the presenting symptoms of cardiac amyloidosis were fatigue and dyspnea. These patients had poor cardiac filling and low cardiac output, but the ejection fraction was preserved. Syncope and arrhythmias also occurred.

Renal amyloid deposits were seen in 30% of patients with AL; kidneys were the second-most common organ affected by AL.²¹² Nephrotic-range proteinuria was observed for 95% of patients with renal AL; the other 5% had amyloid deposits in the interstitium and mesangium of the kidney but not the glomeruli, so proteinuria was not present. Sensorimotor symmetrical ascending peripheral neuropathy was present in 15.3% of AL patients.²⁴ Palpable hepatomegaly was observed in 17.7% of AL patients, but a dominant hepatic syndrome was seen in only 4.6%. Gastrointestinal tract amyloidosis occurred for 7.1% of patients with AL, and they presented with intestinal bleeding, pseudo-obstruction, or diarrhea. The other 7.8% of patients had amyloid deposits that were identified in only the tongue, lung, joints, or soft tissues.

At Mayo Clinic, 29.9% of AL patients had two or more organs affected, 6% had three affected organs, and 0.5% had four or more affected organs.²¹³ When multiple organs were involved, the liver was most likely to be affected. Clinically significant bleeding (excluding purpura) occurred for only 2.3% of our patients.^{214, 215} Congestive heart failure was observed for 22% of patients, and carpal tunnel syndrome was observed for 21% of patients.²¹² Edema was noted for 44.8% and fatigue for 46.4%. Lower-extremity paresthesias, nephrotic-range proteinuria, orthostatic hypotension, and weight loss were observed for 34.9%, 21.0%, 12.5%, and 51.7% of patients, respectively. The median survival of our entire cohort was 12 months, and the 2- and 5-year survival rates were 33.6% and 14.9%, respectively.

Amyloidosis is rarely associated with anemia.²¹⁶ The hemoglobin level was greater than 100 g/L for 90% of patients and greater than 120 g/L for 64.4%. Only 1.5% had hemoglobin levels less than 90 g/L, and the cause was usually active gastrointestinal tract bleeding or renal failure. The median platelet count of patients with AL was $257 \times 10^9/L$ (range, $46 \times 10^9/L$ to $809 \times 10^9/L$). A platelet count greater than $500 \times 10^9/L$ was seen for 5.5% of patients. The most common cause of thrombocytosis in AL is hepatic involvement with associated hyposplenism.^{217, 218} A serum creatinine value of 2 mg/dl or greater was present for 13.6% of patients, and 6.7% had alkaline phosphatase levels greater than twice the maximum normal value. The number of patients with elevated alkaline phosphatase levels was close to the number of patients with clinical hepatic amyloid involvement.

The median bone marrow plasma cell percentage of patients with AL is 7% (range, 1% to 30%; Fig. 99.8).²¹² In 11.3% of patients with AL, greater than 20% of plasma cells were found in the bone marrow, but no other clinical evidence of multiple myeloma was observed. Proteinuria is exceedingly common in AL, and the median urine protein loss is 790 mg per 24 hours (Fig. 99.6).²¹⁹ Monoclonal λ and κ light chains (in the serum and urine) were found in 70.1% and 18.9% of patients, respectively, and 11% had no detectable light chains. For patients with intact monoclonal γ globulins, the serum heavy chain was IgG, IgA, and IgM for 58%, 10%, and 8.2% of patients, respectively. The presence of an IgM monoclonal protein in 8.2% is important because we have seen many referred patients with a diagnosis of Waldenström macroglobulinemia, for whom the amyloid syndrome was overlooked.²²⁰ Amyloid arthropathy occasionally occurs in amyloidosis. Synovial membrane biopsy may establish the diagnosis, and chemotherapy may effectively alleviate the joint manifestations.²²¹

Heart

The heart is the organ that determines the patient outcome, and it is the organ most frequently involved in AL.^{222, 223, 224} Amyloid is deposited extracellularly and results in a noncompliant and thickened left ventricle (Fig. 99.9).^{225, 226} The clinical presentation is infiltrative cardiomyopathy with restricted diastolic ventricular filling. Many patients with cardiac AL

present only with fatigue and unexplained weight loss. Early cardiac AL produces diastolic dysfunction without systolic dysfunction,^{227, 228} and chest radiographs do not show evidence of pulmonary vascular

P.2106

congestion or cardiomegaly. Moreover, the ejection fraction is preserved because amyloid deposition is an infiltrative process with diastolic dysfunction only.²²⁹ Indeed, because of a low stroke volume, a hyperdynamic myocardium may develop with an elevated ejection fraction. This constellation of findings is frequently misinterpreted, and the presence of amyloid may be overlooked completely. An echocardiographic examination usually shows that contractility is normal, but because of poor diastolic filling, the end-diastolic volume is reduced and cardiac output is low. The electrocardiogram shows low voltage, but this also may be easily overlooked.²³⁰ The pseudoinfarction pattern of amyloidosis, with nearly two thirds of patients showing loss of anterior forces in V_1 through V_3 ,²³⁰ may be misinterpreted as ischemic heart disease. Electrocardiographic findings are clinically suspicious of silent ischemic disease, and patients invariably undergo coronary arteriography. Coronary angiogram findings are generally normal.²³¹ A characteristic echocardiogram shows wall and valve thickening, diastolic dysfunction, and a sparkling myocardium (Fig. 99.10). The median septal thickness for patients with AL was 14 mm.²¹⁰ The septal wall thickness was less than 15 mm for 52.9% and greater than or equal to 15 mm for 47.1%.²¹⁰ Wall thickening frequently is misinterpreted as concentric left ventricular hypertrophy or asymmetrical septal hypertrophy, rather than infiltrative cardiomyopathy.^{232, 233, 234} When ventricular hypertrophy is diagnosed from the thickened walls, the electrocardiogram typically shows low voltage and does not reflect hypertrophy.²³⁵ Screening tests for monoclonal protein in the serum or urine should be performed for any patient with diastolic heart failure, restrictive hemodynamics, or thickened walls.

FIGURE 99.8. Distribution of bone marrow plasma cells of patients with primary amyloidosis (N = 486).

FIGURE 99.9. Myocardial wall diffusely thickened with amyloid. The whitish deposits represent the amyloid and are the lardaceous changes first recognized by Rokitansky. (From Gertz MA, Kyle RA. Amyloidosis [AL]. In: Wiernik PH, Goldman JM, Dutcher JP, et al., eds. Neoplastic diseases of the blood, 4th ed. New York: Cambridge University Press, 2003. Used with permission.)

Patients with cardiac amyloidosis have restriction to blood inflow that is characteristic of the disease. Doppler studies are best for accurate assessment of myocardial function for AL patients. The Doppler filling patterns accurately indicate the extent of amyloid infiltration.²³⁶ For patients with advanced cardiac amyloidosis, a short deceleration time is consistent with restrictive physiologic characteristics, but in the early stages of cardiac amyloidosis, abnormal relaxation is observed.²³⁷ Decreased fractional shortening and increased ventricular wall thickness are the best predictor of outcome in AL. Patients with a wall thickness greater than 15 mm and a fractional shortening less than 20% have a median survival of 4 months. An important measurement is the deceleration time; a short deceleration time is indicative of restrictive physiologic characteristics, and a deceleration time shorter than 150 milliseconds is associated with worse outcomes than that of a deceleration time longer than 150 milliseconds.

FIGURE 99.10. Echocardiographic image of concentric thickening of the wall of the left ventricle (LV) due to amyloid. RV, right ventricle. (From Gertz MA, Kyle RA. Amyloidosis [AL]. In: Wiernik PH, Goldman JM, Dutcher JP, et al., eds. Neoplastic diseases of the blood, 4th ed. New York: Cambridge University Press, 2003. Used with permission.)

The most common echocardiographic feature of cardiac amyloidosis was thickening of the right ventricular wall, septum, and left ventricular free wall. The size of the left ventricular cavity was reduced. Approximately 20% of patients had congestive heart failure, but echocardiographic studies showed that twice as many had cardiac amyloid deposits. Patients with overt cardiac amyloidosis often presented with mild symptoms of fatigue and dyspnea on exertion. The median survival time of patients with cardiac amyloidosis and a septal thickness greater than or equal to 15 mm or less than 15 mm at diagnosis was 1 year and 4 years, respectively. Syncope with exercise developed for almost one third of patients with cardiac AL. A median survival time of 2 months is reported with exercise-induced syncope in AL.²³⁸ Immunofixation of the serum and urine and a free light-chain assay are required for any patient who presents with cardiomyopathy or congestive heart failure that does not have an obvious ischemic cause.⁷⁴ The echocardiogram is the diagnostic standard for recognizing amyloid cardiomyopathy; occasionally, a patient has a nondiagnostic echocardiogram and amyloidosis is subsequently proven through endomyocardial biopsy, but these occurrences are rare.²³⁹ Pulsed tissue Doppler imaging, when combined with strain imaging, may disclose early signs of amyloidosis. However, functional abnormalities may be detected before any morphologic echocardiographic abnormalities are evident. Both the left- and right-side heart functions may be affected.²⁴⁰

A poor prognosis is associated with right ventricular dilatation and atrial systolic failure.²⁴¹ For patients who are assumed to have hypertrophy because of thickened ventricular walls, the finding of thickened mitral and tricuspid valves is a common and important clue: thickened valves are not found in hypertensive cardiomyopathy.²⁴² Valvular regurgitation is commonly seen by Doppler echocardiography, but it does not appear to have a clinically significant effect on myocardial performance.²⁴² Atrioventricular sequential pacing does not benefit cardiac hemodynamics.²³⁶ Implantation of a cardioverter-defibrillator does not prevent death from cardiac amyloidosis.²⁴³ Distinguishing pericardial disease from restrictive cardiomyopathy may be difficult.²⁴⁴ It is rare for surgical pericardiectomy to provide clinical benefits to patients

with AL. The hazards of surgery for patients with cardiac amyloidosis are well established.^{244, 245} As discussed previously, a bone marrow biopsy and a fat aspirate will establish the diagnosis of cardiac amyloidosis for most patients with the disease, but for those with infiltrative cardiomyopathy, endomyocardial biopsy will provide the correct diagnosis for all patients when at least three endomyocardial specimens are obtained.²⁴⁶ Magnetic resonance imaging may be a useful diagnostic technique.

P.2107

The combination of subtle, widespread heterogeneous myocardial enhancement on delayed postcontrast inversion recovery in T1-weighted images, with ancillary features of restrictive cardiac disease, may be highly suggestive of cardiac amyloidosis.²⁴⁷ The presence of a positive cardiac magnetic resonance imaging in AL was associated with a significantly increased risk of death, in particular of cardiac origin, but was not independent of clinical congestive heart failure.²⁴⁸

Ventricular thrombi may develop in AL patients because of stasis of blood within the cardiac chambers. Embolism may result, and the first manifestation of AL may be a stroke.²⁴⁹ For AL patients in sinus rhythm, atrial thrombi may develop.²⁵⁰ Anticoagulation therapy is indicated for AL patients with atrial standstill. Most AL patients present with cardiac muscle infiltration and pump failure, but patients rarely present with symptoms of exertional angina and myocardial infarction from amyloid deposition in the coronary arteries.²⁵¹ Angiographic findings are normal because epicardial coronary arteries are spared. For such patients, standard exercise tests show ischemia,²³¹ but the diagnosis of intracoronary amyloid is difficult to establish before death. Right ventricular myocardial biopsy may show amyloid deposits in small intramural vessels. We previously have described 11 AL patients who presented with angina or an unstable coronary syndrome.²⁵² A classic low-voltage electrocardiogram was seen in only two patients. The median survival after symptom development was 18 months. Virtually all patients were assigned the diagnosis of cardiac amyloidosis during autopsy, which reflects the difficulty of recognizing small-vessel coronary arteriolar amyloidosis. A follow-up report of obstructive intramural coronary amyloidosis showed that 63 of 96 patients (66%) did not have obstruction of epicardial coronary arteries.²⁵³ Myocardial ischemia affected 25% of patients with obstructive intramural coronary amyloidosis. Most patients with primary systemic amyloidosis and cardiac involvement have obstructive intramural coronary amyloidosis and microscopic changes of myocardial ischemia.²⁵³

Not all patients with cardiac amyloid have AL. Familial amyloid cardiomyopathy, particularly in elderly African American men, must be distinguished from AL.¹⁹¹ The clinical presentations are similar,²⁵⁴ but patients with AF do not have a monoclonal protein in the serum and urine. The most common mutation identified in patients with AF in the United States is TTR Val122Ile. A screen for TTR mutations helps differentiate between patients with AF (have the mutation) and AL (do not have the mutation). Senile cardiac amyloidosis, which results from the deposition of nonmutated TTR, must also be distinguished from AL.²⁵⁵ Echocardiographic features of AL, AF, and senile cardiac amyloidosis are indistinguishable. All amyloid deposits are positive for Congo red stain, so positive staining cannot be used as a criterion to classify patients with different types of amyloidosis. The main distinguishing clinical feature is the presence of the monoclonal protein for patients with AL (patients with the TTR forms of cardiac amyloid lack monoclonal protein).¹⁸⁶

Patients with senile systemic amyloidosis tend to be older than those with AL, and virtually all patients with senile systemic amyloidosis are men. Proteinuria is not present. Patients tend to have a greater left ventricular wall thickness. The severity of heart failure is less, and the median survival time is much longer than that of patients with cardiac AL.²⁵⁶ The mechanism of amyloid deposition in senile systemic amyloidosis is not understood. A quarter of patients older than 90 years (general patient population) have cardiac amyloid deposits. Clinicians must remember that all forms of cardiac amyloidosis are not derived from immunoglobulin light chains.¹⁸⁸

Kidney

When a patient has free monoclonal light chains in the urine, the differential diagnosis is cryoglobulinemia,²⁵⁷ amyloidosis, Randall-type light-chain deposition disease,²⁵⁸ and myeloma cast nephropathy.²⁵⁹ The presence of proteinuria does not always indicate albuminuria. All patients presenting with proteinuria should have immunofixation of the urine performed during the first evaluation to exclude light-chain-associated syndromes. Kidneys are affected in 28% of AL patients. An Italian group has reported that amyloid deposits affect the kidneys for half of their patients with AL.²⁶⁰ For nondiabetic adults with nephrotic syndrome, amyloidosis is observed in 12% of renal biopsy specimens²⁶¹; 2.5% to 2.8% of all kidney biopsy specimens contain amyloid deposits.

The serum creatinine level at AL diagnosis has prognostic value. Patients with a creatinine value less than or greater than 1.3 mg/dl had a median survival time of 25.6 or 14.9 months, respectively. Urinary protein loss did not affect survival. Patients with higher levels of albumin loss have a shorter time from diagnosis to the development of end-stage renal

disease.²¹⁹ The presenting serum creatinine value exceeded 2 mg/dl for 14% of patients. The median urinary protein excretion for all AL patients was 0.75 g in 24 hours, but 30% had greater than 3 g of urinary protein in 24 hours. Only 5% of AL patients had urinary protein loss in the reference range. Monoclonal light-chain proteins were more likely to be found when the urinary protein loss was high; for example, 85% of patients with urinary protein loss exceeding 1 g/day had detectable monoclonal light chains.

The ratio of patients with underlying λ clones to patients with κ clones is 5:1 among those with nephrotic-range proteinuria. Median urinary protein loss for patients with κ or λ amyloidosis is 1.1 or 4.6 g/day, respectively. The λ light chain may predispose patients to a higher level of renal involvement, but no difference in the frequency of renal failure in κ or λ amyloidosis is observed. The median survival of patients with urinary λ light chains, urinary κ light chains, or no detectable urinary light chains is 1, 2.5, and 2.5 years, respectively. Severe hypoalbuminemia is the result of nephrotic-range proteinuria.⁷⁷ Diuretics typically are required to control edema, but diuretics further aggravate intravascular volume contraction, increase hypotension, and decrease renal blood flow. Bilateral catheter embolization of renal arteries reduces the loss of urinary protein and increases the serum total protein of patients with advanced anasarca.²⁶²

Continuous urinary protein loss results in tubular damage, and the principal long-term complication is end-stage renal disease.²⁶³ Prognostic factors for development of end-stage renal disease were serum creatinine value at presentation and 24-hour urinary protein loss. The median time from the diagnosis of AL nephrotic syndrome to dialysis was 14 months. After initiation of dialysis, the median survival time was 8 months. Most deaths of dialysis patients with AL were attributable to cardiac amyloid. No survival difference has been recognized between hemodialysis and peritoneal dialysis.²⁶⁴ The 1-year survival rate from the start of dialysis was 68%.

Patients younger than 45 years had a better survival rate. Chemotherapy slowed progression to end-stage renal disease and showed a trend toward improved survival. In addition to younger age, normal values of serum calcium and creatinine at presentation favor longer survival. Heart failure, cardiac arrhythmias, and refractory hypotension are the most common extrarenal complications of AL. Cardiac amyloidosis with renal failure regularly results in dialysis that is complicated by severe hypotension (a difficult clinical condition to manage). The amount of protein in the urine and the extent of amyloid deposits in a kidney biopsy specimen correlate poorly.²⁶⁵ Severe nephrotic syndrome may occur, even with low levels of amyloid deposits. All patients with nephrotic syndrome undergo ultrasonography, and the kidneys of patients with AL are virtually always normal size.²⁶⁶ The urine of patients with AL contains fat or fatty acid crystals but no casts or red blood cells.²⁶⁷ Of 118 patients with monoclonal gammopathy undergoing renal biopsy, 30% had AL. In that cohort, the median time from diagnosis to dialysis was 15 months, the median overall

P.2108

survival time was 24 months, and the main cause of death was cardiac amyloidosis.

Only 2% of patients with amyloidosis have proteinuria eventually if it is not present at diagnosis. Of patients with cardiac AL who underwent cardiac transplantation and antirejection therapy, we have seen nephrotic syndrome develop in two patients. It is possible that patients treated before routine organ transplantation might not have survived long enough for renal amyloid nephrotic syndrome to develop. Amyloid deposits penetrate the glomerular basement membrane and result in proteinuria.²⁶⁸ Adult Fanconi syndrome,²⁶⁹ renal vein thrombosis,²⁷⁰ and retroperitoneal fibrosis have been reported with renal amyloidosis. Fibrillary (immunotactoid) glomerulopathy refers to the deposition of fibrils in the kidney that initially may be confused with AL.²⁷¹ However, examination by electron microscopy shows that the fibrils of fibrillary glomerulopathy are twice the width of amyloid fibrils,²⁷² and extrarenal disease does not develop in patients with fibrillary glomerulopathy. The fibrils are negative for Congo red stain. Monoclonal protein typically is not detected in the serum or urine. Randall-type light-chain deposition disease indicates granular deposition of nonamyloid immunoglobulin light chain along the glomerular basement membrane.²⁷³ It produces nephrotic syndrome and renal insufficiency. Light-chain deposition disease and amyloidosis in the same patient has been reported.²⁷⁴ Electron microscopy studies of tissues affected by light-chain deposition disease do not show fibrils.

Fifteen patients with systemic amyloidosis who underwent renal transplantation had SAP scintigraphy studies.²⁷⁵ Abnormal uptake of radioactive iodine in the transplanted kidney was observed in 4 of 10 patients, and none had a reduction in the level of fibril precursor protein. Patients with renal amyloidosis had a high prevalence of adrenal dysfunction. Of 22 patients with renal amyloidosis, poor cortisol reserves were identified for 7, and hypoadrenalism resulted in the death of 4.²⁷⁶ Amyloid deposits are regularly found in the adrenal glands at autopsy.

Liver

In one fourth of patients with AL, hepatomegaly is noted during physical examination.²⁷⁷ Hepatomegaly is not synonymous with hepatic involvement because the high prevalence of right-sided heart failure may produce congestive hepatomegaly. One sixth of patients had a symptomatic hepatic amyloid syndrome, which typically included an increased serum alkaline phosphatase or γ -glutamyltransferase level and unexplained hepatomegaly. Most clinicians suspect that unexplained hepatomegaly is due to hepatic metastases, but radionuclide imaging, computed tomography, or magnetic resonance imaging demonstrate homogeneous patterns. A high proportion of patients with hepatic amyloidosis also have renal involvement.

Half the patients with hepatic amyloidosis have proteinuria in excess of 1 g every 24 hours. A patient who presents with an increased serum alkaline phosphatase value and proteinuria may have liver dysfunction resulting from a systemic disorder such as amyloidosis. Several key clues may be helpful in establishing the diagnosis of hepatic amyloidosis: (1) hepatomegaly out of proportion to the degree of liver function abnormality; (2) presence of Howell-Jolly bodies in a peripheral blood film (suggestive of reduced splenic function, a consequence of splenic replacement with amyloid deposits); (3) monoclonal protein (detectable by immunofixation) in the serum or urine; (4) proteinuria; and (5) increase of the alkaline phosphatase value with minimal increase in transaminase values. Biochemically, patients with hepatic amyloidosis tend to have low levels of aspartate aminotransferase and alanine aminotransferase—almost always less than twice the maximum normal value at diagnosis—and the bilirubin value is typically normal. Hyperbilirubinemia, when present, is usually a preterminal finding.

Hepatic rupture is rare but results in massive intra-abdominal hemorrhage that is generally fatal. Computed tomography is useful for diagnosing hepatic rupture with subcapsular hematoma.²⁷⁸ On physical examination of patients with a confirmed diagnosis of hepatic AL, the median measurement of the liver edge extending below the right costal margin was 7 cm. Hepatomegaly was not present in one tenth of patients with biopsy-proven liver AL involvement. Hepatic AL was usually diagnosed in these patients on the basis of an increased alkaline phosphatase value. At diagnosis, the median increase of the serum alkaline phosphatase level was 2.3 times the maximum normal value. The serum alkaline phosphatase value was the most important screen for determining whether a patient had clinically significant hepatic involvement. Thirty-six percent of patients with hepatic AL excreted more than 3 g of protein in the urine per day. Patients with hepatic AL also have higher levels of C-reactive protein than those without hepatic involvement.²⁷⁹ The proportion of patients with hepatic AL whose amyloid deposits were derived from κ clones was identical to that of patients with other affected organs. It has been suggested that an increased incidence of κ light chain may be seen in hepatic AL,²⁸⁰ but this suggestion was not supported by our data. In a study of 98 patients,²⁸¹ 72% had involuntary weight loss and 89% had proteinuria. Clinicians considered amyloidosis as the cause of the hepatic dysfunction in only 26% of patients. None had hepatic rupture or death resulting from liver biopsy, and only 4% had bleeding. The predictors of a poor prognosis were heart failure, elevated bilirubin levels, and thrombocytosis.

Although symptomatic hepatic amyloid is identified in only 16% of AL patients, SAP scans show that hepatic amyloid is present in virtually all AL patients.²⁸² Cholestatic jaundice is a preterminal finding.²⁸³ In hepatic AL, portal hypertension with varices and bleeding is rare.²⁸⁴ Presumably, patients succumb to hepatic or extrahepatic complications of AL before portal hypertension develops.²⁸⁵ It is common to see ascites in patients with hepatic AL, but most of these patients also have nephrotic-range proteinuria, hypoalbuminemia, or congestive heart failure, all of which are more likely to cause ascites. Amyloid deposits are found in liver biopsy specimens distributed in the portal tract and perisinusoidally.²⁸⁶ At autopsy, involvement of the portal triad vasculature frequently is seen, but the effect of amyloid deposits in the vasculature is not clinically significant.²⁸⁷ After the diagnosis of AL is confirmed by liver biopsy, the median survival time is less than 1 year.

Scintigraphy generally is not useful for establishing the diagnosis of hepatic AL. The findings are nonspecific and include irregular distribution of the radionuclide and, occasionally, splenic uptake is absent.^{288, 289, 290} Sinusoidal amyloid deposits may compress branches of the hepatic artery, which results in the angiographic appearance of luminal irregularity and abrupt changes in vascular caliber.²⁹¹

Amyloidosis is not a contraindication for liver biopsy. Although spontaneous hepatic rupture has been described,²⁹² rupture after a percutaneous liver biopsy has not been reported. The risk of complications after liver biopsy ranges from 0.31% to 3.00%.²⁸¹ In our experience, 4% of patients with amyloidosis had bleeding after liver biopsy and none died of the bleeding. Physicians should remember that biopsy specimens from subcutaneous fat or bone marrow show amyloid deposits in 85% of patients with AL. Despite the relative safety of the procedure, if amyloidosis is suspected appropriately, liver biopsy usually is not required.

In a statistical analysis, hepatomegaly had a significant impact on survival within the first year after diagnosis, perhaps because hepatomegaly for some patients may be due to congestive heart failure rather than hepatic infiltration. In an

autopsy series of nine patients with amyloidosis and hepatomegaly,²⁹³ three did not have anatomical evidence of deposits, and liver enlargement was attributable to passive congestion. In a second autopsy study,²⁹³ 20% of patients with palpable hepatomegaly and amyloidosis did not have histologically evident deposits.

P.2109

In patients with AL, the finding of Howell-Jolly bodies is highly specific for splenic involvement, but their absence does not exclude it. Twelve patients with autopsy-proven diffuse splenic involvement have been reported in whom Howell-Jolly bodies were not found.²⁹⁴ Scanning of the spleen also does not correlate well with the presence of Howell-Jolly bodies observed on a peripheral blood smear. In patients with hepatic AL, splenomegaly is present in 11%. Splenic rupture is a recognized complication in patients with hepatic amyloid.^{295, 296}

In summary, the cardinal features of hepatic AL are hepatomegaly, monoclonal protein in serum or urine, proteinuria, an increase of the alkaline phosphatase value with minimal increase of transaminase values, and Howell-Jolly bodies in the blood smear of patients with advanced hepatic and splenic involvement.

Gastrointestinal Tract

No correlation exists between the presence of gastrointestinal tract amyloid deposits and liver amyloid deposits. Only 15% of our patients with gastrointestinal tract amyloidosis had hepatomegaly, and less than one third had increased alkaline phosphatase values.²⁹⁷ When routine screening biopsies are performed on the rectum or intestinal tract, amyloid deposits are found in most patients with AL.¹¹⁸ Generally, deposits are vascular, but occasionally, they are in the submucosa of the bowel; they produce symptoms (e.g., steatorrhea, nausea, vomiting, abdominal pain, hematemesis, and hematochezia) for only a few patients.²⁹⁸ Bowel dysfunction in AL may result from direct infiltration of the bowel lining or from a motility disturbance attributable to damaged regulatory nerves of the intestinal tract.²⁹⁹ The high prevalence of anorexia and weight loss does not correlate with the presence of gastrointestinal tract amyloid deposits. Typically, patients had a median delay of 7 months between the onset of gastrointestinal symptoms and the histologic recognition of AL, although one patient had a delay of 4 years. Four of our 19 patients with gastrointestinal tract AL underwent laparotomy for evaluation of intestinal symptoms. For three of these four patients, diagnosis was delayed because the surgical specimens were not routinely stained with Congo red.²⁹⁷

Steatorrhea and low serum carotene levels were seen in less than 5% of patients with gastrointestinal tract amyloidosis. These patients were not distinguishable clinically from those with celiac sprue, Whipple disease, or bacterial overgrowth. Small-bowel biopsy findings showed amyloid deposits for 19 of our patients with AL. This number constitutes only 1% of the AL population at our institution,²⁹⁷ and it does not include patients who had clinical evidence of malabsorption, for whom a small-bowel biopsy was not performed (widespread amyloidosis was evident in other organs). Diarrhea, anorexia, dizziness, and abdominal pain were the most common symptoms. All patients had weight loss (median loss, 30 pounds). Half the patients had orthostatic hypotension. A prolongation of prothrombin time, primarily from malabsorption of vitamin K, was present in one fourth of patients. Factor X deficiency also was seen in one fourth, but only one patient had factor X activity below 30%. A multivariate analysis showed that the degree of weight loss and the hemoglobin value at diagnosis affected survival. For patients presenting with a weight loss of 20 pounds or more, the median survival was 10 months. Ten patients died as a consequence of nutritional failure and five died of heart failure. The severe diarrhea of patients with systemic amyloidosis could not be explained by malabsorption generally, bacterial overgrowth, or malabsorption of electrolytes by epithelial cells. Transit of polyethylene glycol was 10 times faster than that of healthy subjects. Autonomic neuropathy was the likely cause of rapid gastrointestinal tract transit.³⁰⁰

Patients with amyloidosis may have esophageal dysmotility or gastroesophageal reflux of the upper gastrointestinal tract.³⁰¹ Multiple reports describe patients who had surgical intervention for obstruction, only to have amyloid deposits identified histologically.^{302, 303} The most frequent symptoms of pseudo-obstruction are nausea (even during fasting) and emesis,³⁰⁴ and abdominal distention and pain are common.³⁰⁵ Dilatation of small-bowel loops is rare.³⁰⁶ The typical radiographic findings of a patient with intestinal amyloid deposits include increased fluid accumulation in the small bowel, loop dilatation with delayed transit, and thickening or nodularity. Computed tomography may show mild splenomegaly or lymphadenopathy, but it generally does not help establish the diagnosis. Esophagitis, duodenitis, and gastritis are commonly found during endoscopic procedures.³⁰⁷ It is rare for these changes to cause symptomatic bleeding.

Ischemic colitis rarely is the presenting feature of AL.³⁰⁸ The amyloid deposits obstruct vessels of the muscularis mucosa and lamina propria. The obstructed blood supply leads to mucosal ischemia, sloughing of the bowel lining, and hemorrhage.³⁰⁹ Barium studies show luminal narrowing, mucosal fold thickening, and ulcers. The most common location

of ischemia is the rectosigmoid and descending colon.³¹⁰ Vascular obstruction from AL has been reported to cause duodenal perforation.³¹¹ Hematemesis and hematochezia were rare in patients who did not undergo stem cell transplantation. In our experience, treatment of the underlying AL does not result in recovery of intestinal motility after pseudo-obstruction develops. For patients with pseudo-obstruction, extensive replacement of the muscularis propria by amyloid is prominent.³¹²

Nervous System

In 1938, the first description of peripheral nerve amyloidosis was published.³¹³ Among patients with AL, 15% to 20% have paresthesias and neuropathy symptoms.³¹⁴ The clinical picture is often dominated by cardiac or renal involvement, and the peripheral neuropathy is minimally symptomatic. Echocardiographic abnormalities are found in 44% of patients who present with AL neuropathy. When a predominant neuropathy is seen in a patient with biopsy-proven amyloidosis, the possibility of AF should be considered. The absence of a monoclonal protein in the serum or urine is clinically useful for distinguishing between AL and AF.³¹⁵ Paresthesias, pain, numbness, muscle weakness, impotence, urinary retention, and orthostatic symptomatology are the most frequent symptoms of amyloid neuropathy.³¹⁶ Twelve percent of the patients have syncope. Dysesthesia that manifests as distal burning is present in one fourth of the patients. Of those with peripheral neuropathy, autonomic neuropathy is seen in two thirds, and lower-extremity involvement precedes upper-extremity involvement for nearly 90%. Involvement of the cranial nerves in AL is rare.^{317, 318} Half the patients with amyloid peripheral neuropathy also have carpal tunnel syndrome, a soft-tissue manifestation of amyloidosis. Frequently, it is difficult to distinguish electrodiagnostically between upper-extremity neuropathy and carpal tunnel syndrome. Weight loss was recognized in one third of patients. Rarely is painful sensory neuropathy, mononeuropathy multiplex, or demyelinating polyneuropathy the presenting manifestation of AL neuropathy.³¹⁹

An important diagnostic clue for amyloid neuropathy is its association with autonomic neuropathy.³²⁰ Voiding difficulties are often due to detrusor weakness and impaired bladder sensation. The underlying mechanism of urinary dysfunction seems to involve postganglionic, cholinergic, and afferent somatic nerves.³²¹ However, when patients present with peripheral neuropathy, amyloidosis usually is not considered in the differential diagnosis. The median delay between onset of paresthesias and biopsy proof of amyloidosis is 29 months.

Amyloidosis typically causes loss of small myelinated and unmyelinated fibers. Electromyography does not sensitively detect changes in small unmyelinated fibers. Consequently, patients may have symptoms of amyloid neuropathy and have normal

P.2110

electromyographic findings. As it progresses, the neuropathy of amyloidosis is axonal and demyelinating. The loss of myelin results in an elevation of cerebrospinal fluid protein value in one third of patients. Axonal degeneration is detected in 96% of patients with amyloid neuropathy. Typical electromyographic changes consist of reduced amplitude of compound muscle action potentials, decreased or absent sensory responses, mild slowing of nerve conduction velocity, and fibrillation potentials on needle examination.³²²

Although sural nerve biopsy is the standard method of diagnosing amyloid neuropathy, less invasive fat or bone marrow biopsies may also confirm the diagnosis.³¹⁶ With sural nerve biopsy, amyloid deposits are found in the endoneurial capillaries or in the epineurium.³²³ Teased fibers show axonal degeneration and a marked decrease in myelin fiber density. Although Mayo Clinic uses sural nerve biopsy as the standard diagnostic method, the biopsy is not 100% sensitive. Nine patients were reported to have amyloid neuropathy, but six had negative sural nerve biopsy findings.³²⁴ Amyloid proteins may have been deposited at the nerve root, which resulted in distal demyelination without recognizable deposits in the sural nerve. Amyloid is deposited focally in the nerve, and multiple sections of the sural nerve need to be examined to confirm the diagnosis.

For AL patients who present with a dominant neuropathy, the median survival time is 25 to 35 months.^{325, 326} Clinical improvement in peripheral neuropathy is rare with traditional chemotherapy, and it is infrequent even with high-dose therapy. The clinical course for most cases of peripheral neuropathy is progressive neuropathy over time. One third of patients ultimately are bedridden, and three fourths have marked restriction in their mobility and a reduced ability to perform the activities of daily living. The serum albumin value is the only prognostic factor that is associated with survival for patients who present with a dominant neuropathy. The median survival was 31 months for patients with an albumin value greater than 3 g/dl but only 18 months for those with serum albumin levels less than 3 g/dl (Fig. 99.11).

All patients who present with a peripheral neuropathy should be screened with immunofixation assays of serum and urine and with immunoglobulin free light-chain measurement. A patient with peripheral neuropathy and monoclonal light

chains has a restricted differential diagnosis that includes (1) amyloidosis; (2) cryoglobulinemia; (3) the polyneuropathy, organomegaly, endocrinopathy, M protein, and skin change syndrome (POEMS-osteosclerotic myeloma)³²⁷; and (4) neuropathy associated with monoclonal gammopathy of undetermined significance.

FIGURE 99.11. The effect of serum (S) albumin level on the survival of patients with isolated amyloid peripheral neuropathy. (From Rajkumar SV, Gertz MA, Kyle RA. Prognosis of patients with primary systemic amyloidosis who present with dominant neuropathy. *Am J Med* 1998;104:232-237. Used with permission.)

Respiratory Tract

We have reviewed our experience with pulmonary deposition of amyloid.¹³⁶ Most patients who present with amyloidosis involving the respiratory tract have only localized tracheobronchial or nodular pulmonary amyloid deposits. A patient with laryngeal amyloidosis was treated with adjuvant external beam radiation to a dose of 45 Gy. At 11 months, the patient's voice, breathing, and swallowing had improved substantially.³²⁸ Neither localized tracheobronchial nor nodular pulmonary amyloid deposits are associated with systemic disease, and both have a good prognosis.^{220, 329, 330} Nodular pulmonary amyloidosis, if recognized, does not always require intervention. It frequently may be nonprogressive for 5 years or longer.³³¹

Patients who present with systemic amyloidosis may have diffuse, interstitial pulmonary involvement and concomitant cardiac involvement that usually overshadow any respiratory symptoms.³³² Gas exchange is preserved until amyloid deposition in the alveolar interstitial space is advanced.³³³ Diffuse alveolar septal amyloid deposits rarely cause hemoptysis.³³⁴ Minor salivary gland involvement is shown histologically in a high proportion of patients with AL,³³⁵ and many patients report xerostomia.^{336, 337} Patients with AL have received incorrect diagnoses of Sjögren syndrome. Skeletal muscle and diaphragmatic involvement can produce muscular weakness and ventilatory failure.^{336, 338, 339} Rarely, pleural deposits of amyloid cause pleural effusions.^{340, 341} Bevacizumab has been used to treat effusions in AL.³⁴² Occlusive amyloid deposits in the pulmonary circulation system may occasionally cause pulmonary hypertension with resultant right-sided cardiac failure.^{343, 344} After a diagnosis of diffuse interstitial pulmonary amyloidosis was established, the median survival time was 16 months; for the small percentage of patients with pulmonary hypertension, the median survival was 2.8 years.

Patients whose amyloidosis is associated with an IgM monoclonal protein or Waldenström macroglobulinemia have a higher prevalence of pulmonary amyloid deposits.²²⁰ Monoclonal protein is not seen in nodular pulmonary amyloidosis or

tracheobronchial amyloidosis; only interstitial pulmonary amyloidosis is associated with free immunoglobulin light chains in serum or urine. Pulmonary involvement, when part of a systemic immunoglobulin light-chain amyloid syndrome,³⁴⁵ appears radiographically as a nonspecific interstitial or reticulonodular pattern.³⁴⁶ The diagnosis is easily obtained by a transbronchial lung biopsy, which is not associated with excessive bleeding.

Autopsy studies of pulmonary amyloidosis have been published.³⁴⁷ In one study,³⁴⁸ histologic specimens from 11 of 12 patients had deposits in the lung. Deposition was seen in blood vessel walls and the alveolar septum. Only 4 of the 12 had clinical dyspnea, and pulmonary amyloidosis was responsible for the death of 1 patient. Thus, patients with unexplained dyspnea or fluid overload who have normal left ventricular diastolic and systolic function should be evaluated for pulmonary hypertension attributable to AL.

Coagulation System

Amyloidosis increases the fragility of blood vessels because of infiltration of the vessel wall,³⁴⁹ and complications may include clinically significant hemorrhage²¹⁵ or thrombosis. The most common manifestation of hemorrhage is purpura. Prolonged thrombin time is a frequently observed abnormality of amyloidosis,³⁵⁰ and it is attributed to the presence of an inhibitor of fibrin polymerization in the plasma or the effects of prolonged nephrotic-range proteinuria with severe serum hypoalbuminemia. Acquired hemostatic abnormalities include coagulation factor deficiencies, hyperfibrinolysis, and platelet dysfunction.

Acquired factor X deficiency is an uncommon, but well-documented, complication of AL^{81, 214, 351, 352}; nevertheless, bleeding is unlikely if factor X levels are higher than 25%. Fewer than

P.2111

5% of patients have a serious deficiency of factor X with plasma levels less than 10% of the reference level for factor X,^{81, 214} and patients with cardiac and renal involvement in the absence of hepatic involvement do not show clinically significant reductions in factor X levels. However, clinically significant bleeding complications may occur, especially for patients with ischemic colitis attributable to vascular occlusions.^{351, 352} For one patient, factor X deficiency was treated with recombinant human factor VIIa during preparation for surgical splenectomy.³⁵³ Bleeding disorders resulting from low levels of α_2 plasmin inhibitors, increased levels of plasminogen activators, and abnormal platelet aggregation also have been reported.³⁵⁴ Life-threatening bleeding from acquired factor V deficiency has been reported.³⁵⁵ Fatal retroperitoneal hemorrhage developed, despite infusions of fresh frozen plasma. Autopsy findings showed that the patient had massive deposits of AL in the liver, spleen, and heart.

In one study, 36 AL patients were evaluated for coagulation disorders.³⁵⁰ Only one patient had severe bleeding, and mild to moderate hemorrhage was observed in nine patients. The most common abnormalities were prolongation of the reptilase and thrombin times. A severe factor X deficiency was seen in only one patient. The activated partial thromboplastin time was prolonged for 25 patients, and the prothrombin time was prolonged for 8. A lupus anticoagulant was not detected in any patient.

Black et al.³⁵⁶ described patients with amyloidosis who had documented episodes of thromboembolism. Similarly, Halligan et al.³⁵⁷ described patients with documented thromboembolism. Of 2,132 patients, those with myocardial infarction, peripheral vascular disease, and stroke were excluded, and records of 40 patients (19 women, 21 men; median age, 65 years) with documented thromboemboli were examined. In 11 of the 40 patients, thromboembolism preceded the diagnosis of amyloidosis, and for 9 of these 11 patients, the thromboembolic event occurred 1 month or more before the diagnosis of amyloidosis was established. In 20 of the 40 patients, the thromboembolism occurred 1 month or more after the diagnosis of AL was established. The thrombosis was venous for 29 patients and involved (in decreasing order of frequency) vessels in the calf, subclavian veins, popliteal regions, inferior vena cavae, common femoral veins, and atrioventricular fistulae. Arterial thrombosis was seen in 11 and involved femoral, popliteal, or multiple arteries, and the atria were affected in 2 patients. Of the 40 patients, 37 had additional risk factors for thrombosis, including nephrotic syndrome (20 patients), immobilization (13 patients), tobacco use (6 patients), heart failure (8 patients), estrogen therapy (1 patient), obesity (4 patients), aortic aneurysm (1 patient), prosthetic material (4 patients), and disseminated intravascular coagulation (2 patients). Five patients had activated protein C resistance. Eight patients died within a month of the thrombosis, and 18 of the 40 died within the first year. Thus, thrombosis appears to be a strong predictor of imminent death within the first month (or perhaps the first year) after the event for patients with AL. The type of heavy or light chain and the organ distribution of amyloid deposits did not predict the development of a thromboembolic event.

PROGNOSTIC FEATURES

After amyloidosis has been confirmed (histologic evidence from a fat aspirate or bone marrow biopsy specimen, a compatible clinical syndrome, and monoclonal protein in the serum or urine), the patient needs to be advised of his or her prognosis. Congestive heart failure (caused by progressive cardiomyopathy) and sudden death (caused by asystole or ventricular fibrillation) are the most common causes of death for patients with AL. The most important determinant of clinical outcome is the extent of cardiac involvement. Other recognized adverse predictors of survival include referral status, heart failure, hyposplenic peripheral blood film, free light chains in the urine, elevated serum creatinine level, bone marrow plasmacytosis greater than 30%, circulating plasma cells in the peripheral blood, elevated bone marrow plasma cell labeling index, and increased β_2 -microglobulin levels.

Exertional syncope is a predictor of early death.^{238, 358} More subtle cardiac findings also have prognostic value. Echocardiography is an important tool for assessing the prognosis of patients with AL. Two-dimensional and Doppler echocardiography shows that 40% of AL patients have cardiac involvement, although only 17% have symptoms of heart failure. In a Mayo Clinic study of 64 patients,³⁵⁹ cardiac relaxation was abnormal in the early stages of amyloidosis, but patients with advanced amyloidosis had restrictive filling and a shortened deceleration time.³⁶⁰ Doppler echocardiography may be performed serially to monitor diastolic dysfunction in cardiac AL. The 1-year survival rate of patients who had a deceleration time greater than 150 milliseconds (measured by Doppler echocardiography) was 92%; in contrast, the 1-year survival rate was 49% for patients with a deceleration time less than 150 milliseconds. The Doppler-measured left ventricular diastolic filling parameters^{359, 361} are also independent prognostic features. Doppler studies of right ventricular diastolic function show filling abnormalities that correlate with the degree of amyloid infiltration (measured by right ventricular free-wall thickness).^{362, 363} Patients with elevated serum cardiac troponin levels have a shortened overall survival.³⁶⁴

Detection of Howell-Jolly bodies during examination of a peripheral blood film indicates advanced splenic involvement that usually is associated with advanced hepatic involvement and a median survival of 4.4 months.³⁶⁵ Findings from a renal biopsy may provide prognostic information.³⁶⁶ Patients have a better prognosis if they have a lower percentage of thickened glomerular capillary walls, a higher incidence of amyloid deposits in vessels but not glomerular capillaries, and deposits of IgG and C3 in mesangial and glomerular capillary walls. The serum creatinine value at diagnosis and the presence of a urinary light chain are both important prognostic indicators. If the serum creatinine value at diagnosis is abnormal, the median survival is 15 months. Patients who have free light chains in the urine have a shorter survival (12 months) than those who do not (35 months).

In a multivariate analysis, heart failure and orthostatic hypotension were associated with a median survival of less than 1 year in a cohort of 229 patients.⁷³ An analysis was performed for 147 AL patients to identify cytoplasmic immunoglobulin-positive plasma cells by using a sensitive slide-based immunofluorescent technique. The percentage of circulating cytoplasmic immunoglobulin-positive cells was calculated by measuring the number of circulating monoclonal plasma cells. Circulating blood plasma cells were observed for 16% of AL patients. The median survival of patients with and without circulating cells was 10 and 29 months, respectively.³⁶⁷ Independent prognosticators of survival included the presence of peripheral blood plasma cells and the serum β_2 -microglobulin value. When AL patients with co-existing multiple myeloma and dominant cardiac amyloidosis were excluded, the presence of peripheral blood plasma cells had independent prognostic value. A slide-based immunofluorescence technique was used to detect circulating peripheral blood plasma cells in 16% of AL patients.³⁶⁸ Overall survival was 13 or 31 months for patients with or without circulating blood plasma cells, respectively. The identification of circulating peripheral blood plasma cells may help select treatment for patients with AL.³⁶⁸

When serum β_2 -microglobulin levels were compared, AL patients with values within the reference range had a median survival time of 33 months, and patients with elevated values had a median survival of 11 months.³⁶⁹ The prognostic value of β_2 -microglobulin levels was independent of the presence of renal failure or heart failure. The median survival of patients with normal renal function and elevated β_2 -microglobulin values was 9 months, but it was 39 months for patients with normal β_2 -microglobulin

P.2112

values. Congestive heart failure and serum β_2 -microglobulin values remain important predictors of outcome (Fig. 99.12).³⁷⁰

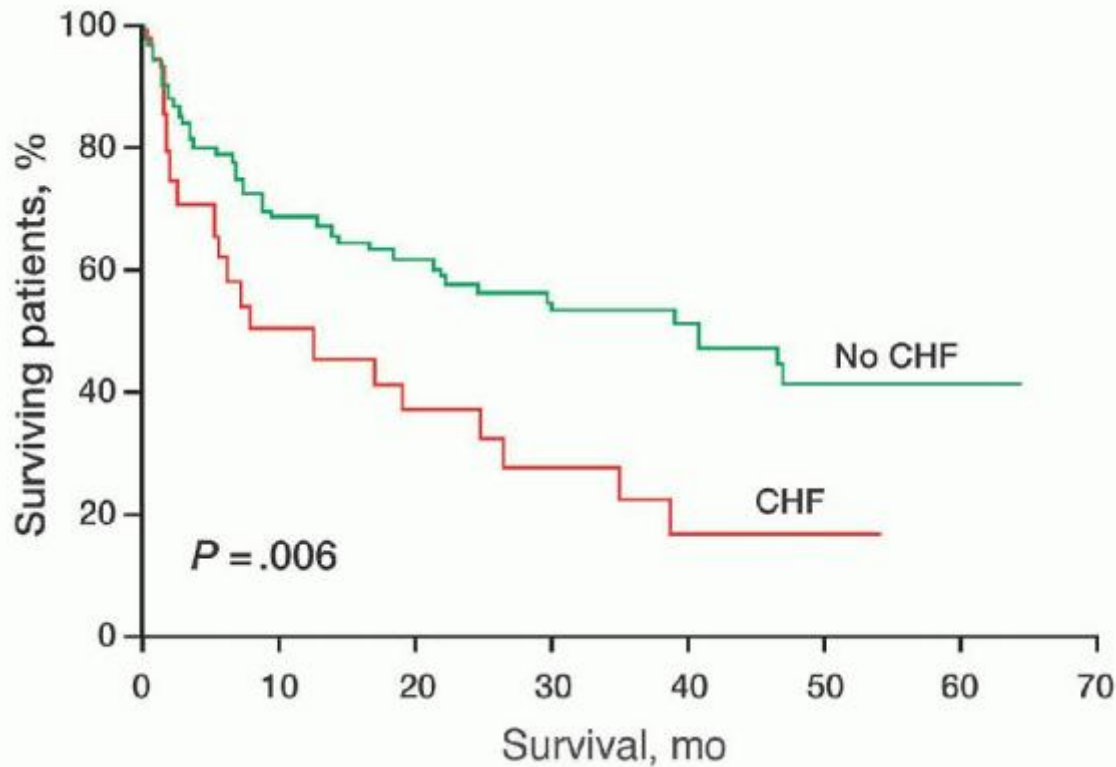

FIGURE 99.12. The effect of congestive heart failure (CHF) on survival of patients with amyloidosis. (From Gertz M, Lacy MQ, Dispenzieri A. Amyloidosis. In: Mehta J, Singhal S, eds. Myeloma. London: Martin Dunitz, 2002. Used with permission.)

In a cohort of 153 patients with AL, the median survival time of the entire group was 20 months; the 5-year survival rate was 20%.³⁷¹ Of the patients who presented with congestive heart failure, the 5-year survival rate was 2.4% and the median survival time was 8 months. When peripheral neuropathy was the sole manifestation of AL, the 5-year survival rate was 32% and the median survival time was 40 months. When assessing the long-term prognosis, the investigators found it useful to classify patients into four groups by clinical manifestations of AL: (1) heart failure, (2) peripheral neuropathy, (3) nephrotic syndrome, and (4) other. Women had a slightly longer survival time than men.

Referral bias definitely is evident at large treatment centers for amyloidosis. To be treated at a distant center, the patient a priori must physically be able to travel. This type of information must be considered when attempting to interpret the results of clinical trials reported from a single center. Of patients with amyloidosis who were evaluated at Mayo Clinic, the median survival was 2 years. If the cohort was limited to patients who were evaluated within 30 days of diagnosis, however, the median survival decreased to 13 months.²¹²

When uniform statistical criteria were applied to a large cohort of patients with AL, the median survival of the entire group was 12 months (range, 4 months [for patients with congestive heart failure] to 50 months [for patients with peripheral neuropathy]).³⁷⁰ Within the first year after diagnosis, the significant prognostic factors included heart failure, urinary light chains, multiple myeloma, and hepatomegaly. After the first year, the predictors of poor outcome were an increased serum creatinine value, multiple myeloma, monoclonal serum protein, and orthostatic hypotension. When studies of treatment outcomes are compared, stratification of variables that affect survival is important.

All patients being assessed for AL should have an echocardiographic evaluation that includes Doppler studies of diastolic performance, ejection fraction, and mitral deceleration time. The absolute values of immunoglobulin free light chains have prognostic value for patients with AL. Patients with higher baseline levels of free light chains have an increased risk of death (hazard ratio, 2.6), and achievement of a free light-chain response is a better predictor of survival than the standard defined complete hematologic response.³⁷² A staging system that includes serum cardiac troponin levels and N-terminal probrain natriuretic peptide (NT-proBNP) levels was developed for patients with AL. Depending on whether troponin and NT-proBNP levels were both low, both high, or high for only one component, three stages were defined with median survivals of 26.4, 10.5, and 3.5 months, respectively (Fig. 99.13). This staging system should facilitate more consistent and reliable comparisons of therapeutic outcomes.³⁷³ A similar result was seen when this staging system was

applied to patients who underwent stem cell transplantation. Patients with stage 3 who underwent transplantation had a median survival of 26.1 months, but patients with stage 1 and stage 2 who underwent transplantation had a median survival of 66 months.³⁷⁴ Reducing the level of amyloidogenic free light chain by more than 50% has been associated with substantial survival benefit, regardless of the type of chemotherapy used. Organ improvement is delayed, but the treatment strategy may be guided by the early effect of therapy on the free light-chain concentration.³⁷⁵

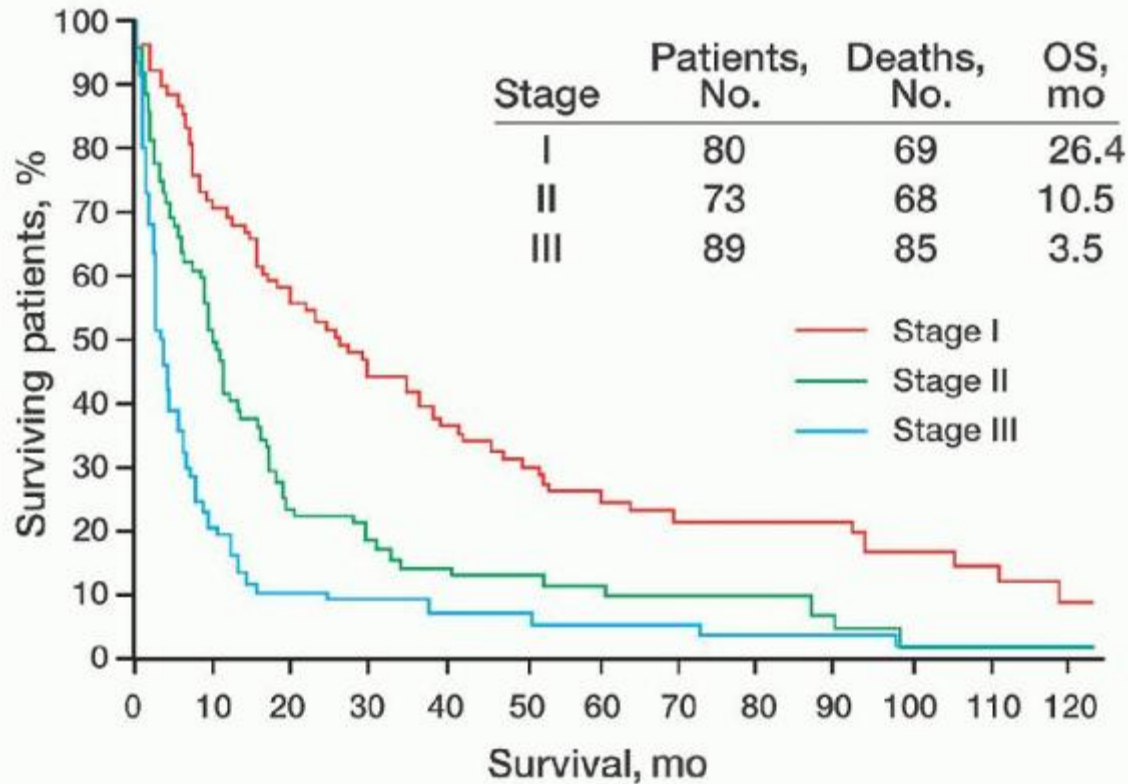

FIGURE 99.13. Survival of patients with primary amyloidosis who were treated with nontransplant therapy. Patients were categorized into three stages by level of brain natriuretic peptide and troponin T levels ($P < .01$). OS, overall survival.

The 4-year overall survival after AL diagnosis has improved during every recent decade of follow-up: 21%, 24%, and 33%, respectively, for the decades 1977 through 1986, 1987 through 1996, and 1997 through 2006 ($P < .001$).³⁷⁶ Yet, the 1-year mortality rate continued to be high during these three decades. A risk stratification score that used cardiac troponin T, NT-proBNP, and uric acid identified the patients at risk for early death. The 1-year mortality rate was 19%, 37%, 61%, and 80%, respectively, for patients with zero, one, two, or three risk factors.³⁷⁶

A 90% reduction in dFLC (the involved less the uninvolved free light-chain level) after stem cell transplant best predicted survival at 3 or 5 years. The median overall survival among those patients with a 90% decrease was not reached compared with 37.4 months for the rest of the patients ($P < .001$). The free light chain level used as a response criterion is a more useful measure than M-protein response. A minimum of a 90% reduction in the dFLC is associated with the best outcomes.³⁷⁷ One study reported that interphase-fluorescence in situ hybridization coupled to cytoplasmic staining of specific Ig is an important test for patients with light-chain amyloidosis³⁷⁸ in whom t(11;14) is an unfavorable prognostic factor. Risk of death for patients who had t(11;14) translocation was 2.1 (95% confidence interval, 1.04 to 6.4), which on multivariate analysis was independent of therapy received.

TREATMENT

Supportive Therapy for Amyloidosis

Cardiac Amyloidosis

Diuretic agents are the mainstay of therapy for patients with cardiac AL.³⁷⁹ Diuretic therapy is complicated because many patients have orthostatic hypotension and intravascular

volume contraction, which are consequences of the nephrotic syndrome.^{380, 381} Diuretic therapy may precipitate a decrease in renal blood flow; the associated increase in serum creatinine concentration may induce syncope.³⁸² Loop diuretics are typically used to control edema. Doses of furosemide may be as high as 120 mg three times per day. If loop diuretics fail to control edema, metolazone may be beneficial.

Patients with recurrent syncope may receive permanent pacemakers.^{383, 384} Those with exertional syncope should be considered for the placement of an implantable cardioverter-defibrillator because most patients with cardiac AL die within 2 months after syncope develops.^{238, 359} For some patients with recurrent syncope, an implantable cardioverter-defibrillator has been placed.³⁸⁵

The standard treatment of patients with heart failure includes orally administered angiotensin-converting enzyme inhibitors.³⁸⁶ Whether these agents result in similar survival benefits for patients with cardiac AL is unknown.^{387, 388} Their use is problematic for AL patients because of the high incidence of associated hypotension. Sudden cardiac death is well recognized in patients with cardiac AL.³⁸⁹ Congestive heart failure may be precipitated by use of calcium channel blockers, such as nifedipine and diltiazem. Amyloid fibrils selectively bind nifedipine, which could result in high intracellular levels of the medication.^{390, 391}

Fludrocortisone acetate (0.1 mg orally two or three times per day) may be used to treat AL orthostatic hypotension.³⁹² The dose has been escalated from 0.4 to 2.0 mg daily.³⁹³ Adverse effects of fludrocortisone include supine hypertension, increased fluid retention with aggravation of heart failure, severe hypokalemia, and edema.³⁹⁴ Fludrocortisone is not well tolerated in elderly patients with AL. Midodrine is another agent that has been used to treat hypotension in AL patients.³⁹⁵ Midodrine dosage starts at 2.5 mg three times per day at 4-hour intervals. Supine hypertension is an adverse effect of midodrine, and the drug is normally given only during waking hours.³⁹⁶ The drug is absorbed rapidly from the intestinal tract, and peak serum levels are attained within 30 minutes. The initial dose may be increased as needed to achieve therapeutic endpoints. The maximum recommended daily dose for midodrine is 40 mg. Active metabolites of midodrine are excreted by the kidney, and patients with renal insufficiency should begin with a reduced dose. Evidence of midodrine toxicity includes restlessness, supine hypertension, and tachycardia. Severe orthostatic hypotension that was not affected by midodrine and fludrocortisone may be treated successfully with erythropoietin, but success is not correlated with the correction of anemia.³⁹⁷

Patients with cardiac AL have received heart transplants. Seven patients who received cardiac allografts had a mean age of 46 years.³⁹⁸ For five of the patients, the mean survival time after transplantation was 32 months. Recurrent amyloid deposits were reported in the allograft for two patients at 3.5 and 4.0 months; one died 13 months after transplantation. There was one operative death. One patient retained heart function (class I) 1 year after transplantation, but amyloid deposits were seen in an endomyocardial biopsy specimen at 14 weeks after transplantation. A successive report of 10 patients³⁹⁹ noted that 4 of 9 patients survived longer than 1 month, and patients had a high prevalence of recurrent amyloid deposition in the transplanted heart. One patient with amyloidosis survived 9 years after cardiac transplantation, and we have experience with a patient who did well 11 years after cardiac transplantation.

A report of 10 patients who received a cardiac transplant between 1984 and 1997 indicated a 20% perioperative mortality rate; the 8 surviving patients had a 50-month follow-up period.⁴⁰⁰ Endomyocardial biopsy specimens showed recurrent amyloid deposits in the grafted heart for five of the eight patients at 5, 11, 12, 28, and 30 months. No patient had echocardiographic evidence of amyloid deposits. Overall, 7 of the 10 patients died after transplantation (median survival, 32 months; range, 3 to 116 months). For four of these seven patients, extracardiac amyloid deposits developed. The 1- and 5-year survival rates were 60% and 30%, respectively. The perioperative mortality rate of 20% was attributable to extracardiac amyloid deposits.

Heart transplantation is feasible technically, but treatment to eliminate the underlying plasma cell proliferative disorder is necessary for a favorable outcome.⁴⁰⁰ Thirteen Mayo Clinic patients with cardiac AL have received a heart transplant.⁴⁰¹ The actuarial 5-year survival rate was 50%, which was inferior to the survival of patients who underwent transplantation for primary cardiomyopathy. Eleven cardiac transplant recipients have received stem cell transplantation at our institution; of these patients, six are alive at 2 to 7 years after the transplantation.

Heart transplantation has been reported by a number of groups for the management of amyloid cardiomyopathy. The United Network for Organ Sharing database contained records of 69 patients with a diagnosis of amyloidosis who received a heart transplant. The records noted 5 operative deaths and 29 late deaths. Nine recipients died of amyloid-related complications. Patient sex influenced survival: The 1-year survival rate was 84% for men and 64% for women.⁴⁰² Five patients had sequential heart transplantation and stem cell transplantation in an effort to prevent recurrent amyloid

deposition. Two patients died of progressive amyloidosis at 33 and 90 months after heart transplantation. Three of five patients were without biopsy evidence of amyloid accumulation.⁴⁰³ One patient had successful allogeneic bone marrow transplantation and cardiac transplantation.⁴⁰⁴ In the United Kingdom, 24 patients with amyloid heart disease had cardiac transplantation; of these patients, 17 had AL. Survival was superior for seven patients with AL who also received chemotherapy; the 1-, 2-, and 5-year survival rates of the seven patients were 86%, 86%, and 64%, respectively. Two were alive at the end of the study period. These survival rates were less than those of patients undergoing transplantation for other indications. Progression of amyloidosis contributed substantially to the increased mortality rate.⁴⁰⁵ In a single-center report of five patients (four of whom received a heart transplant),⁴⁰⁶ two were alive at 60 and 41 months. One patient had a combined heart-liver transplantation, and two patients died after intervention at 23 months.

Nine patients underwent heart transplantation. Eight of the patients received high-dose chemotherapy followed by an autologous stem cell transplant. Six of seven evaluable patients achieved a hematologic complete remission, and one was a partial remission. At a median follow-up of 56 months from heart transplant, five of seven patients are alive without recurrence. Their survival was compared with 17,389 patients who received heart transplant for nonamyloid heart disease: 64% in nonamyloid versus 60% in amyloid patients at 7 years ($P = .83$). Seven of eight patients who received a transplant have had no evidence of recurrent amyloid in their cardiac allograft.⁴⁰⁷

Renal Amyloidosis

Diuretics, compressive support hose, low-sodium diets, and selective use of albumin diuresis are the mainstays of renal therapy for amyloidosis. Angiotensin-converting enzyme inhibitors may reduce proteinuria for patients with nephrotic syndrome. The mechanism appears to be postglomerular vasodilatation. Symptoms of toxicity of angiotensin-converting enzyme inhibitors include hyperkalemia and hypotension. Enalapril and lisinopril have been reported to decrease proteinuria and corticosteroid-resistant nephrotic syndrome that is due to focal segmental glomerulosclerosis. The possibility that angiotensin-converting enzyme inhibitors may be active in amyloid nephropathy has not been explored.^{408, 409}

The results of hemodialysis for AL patients are inferior to those for patients with primary kidney disorders. The 2-year survival rate for all dialysis patients is 76%, but it is 53% for patients

P.2114

with renal AL.⁴¹⁰ The first report of patients with amyloidosis who underwent continuous ambulatory peritoneal dialysis was published in 1984; the three patients survived between 10 to 18 months.⁴¹¹ One of the three patients received a renal transplant and survived 57 months; however, autopsy findings showed widespread amyloidosis. In a review of 61 AL patients receiving dialysis, 18 died within a month after initiating dialysis.⁴¹² Of the 43 other patients, the median survival time was 61 months. Hemodialysis and chronic ambulatory peritoneal dialysis had identical long-term survival rates. Younger patients had superior outcomes. Patients most commonly succumbed to development of extrarenal amyloid deposits in the gastrointestinal tract and heart. In the Mayo Clinic experience, two thirds of the deaths of dialysis patients with AL resulted from extrarenal progression (mostly cardiac amyloidosis). Most reports of the outcome of dialysis for renal amyloidosis describe patients with AA.^{275, 413, 414} In a report of 12 patients (2 with AL), only 4 survived 2 years after kidney transplantation. Renal biopsy specimens from two of the four survivors showed amyloid deposits. Among patients presenting with renal AL, 42% received renal replacement therapy compared with 5% of patients who did not present with renal involvement. Patients with kidney amyloid who ultimately required dialysis support had significantly higher serum creatinine and 24-hour urine protein levels at diagnosis. Patients with λ light chains were significantly more likely to have kidney involvement and had significantly greater urinary protein loss than those with κ light chain. Serum creatinine level was an independent predictor of survival even when corrected for heart involvement. For the 38 patients reported who received dialysis, median survival from the initiation of dialysis was 10.4 months and 26% of patients with AL ultimately received renal replacement therapy compared with 42% of patients who presented with renal AL.⁴¹⁵

The development of amyloidosis in a transplanted kidney is well recognized.⁴¹⁶ Eleven amyloidosis patients were studied after undergoing renal transplantation.⁴¹⁷ Three amyloid recurrences were observed at 11, 28, and 37 months. Two AL patients who underwent renal transplantation died; one had renal failure attributable to new deposits of amyloid in the grafted kidney, and the other had cardiac amyloidosis (renal function was stable). Another report described 45 patients with amyloidosis who underwent kidney transplantation.⁴¹⁸ The 3-year survival rate of these patients was 51%. Patient age greater than 40 years was the major determinant of a poor outcome. The median age of AL patients in the study was 62 years. Recurrent amyloid deposits in the allograft were established histologically for four patients. The authors of the study estimated that the chance of amyloidosis recurrence at 1 year after transplantation was 20%. Two AL patients had

renal biopsies showing recurrent amyloid deposition after transplantation.⁴¹⁹ In that study, no factors predicted recurrence. Two additional AL patients receiving renal transplants were reported. Glomerular amyloidosis developed in one and caused renal failure and death. The other patient died of cardiac amyloidosis. Pasternack et al.⁴¹⁸ reported inferior survival of patients with renal AL.

Living-donor kidney transplantation and autologous stem cell transplantation have been reported in patients with amyloidosis. Eight patients underwent living-donor kidney transplantation. Two had complications and died 3 and 10 months after the procedure. Stem cells were harvested successfully for six patients, and five underwent stem cell transplantation. Renal function was stable for four patients; it was reduced for one patient because of infections and bleeding complications. Sequential living-donor kidney transplantation and autologous stem cell transplantation are feasible,⁴²⁰ although there is controversy about whether the stem cell transplantation should precede the kidney transplantation.⁴²¹ Nineteen patients with AL underwent living (n = 18) or deceased (n = 1) kidney transplantation at our institution from 1999 to 2008 (median age, 57 years⁴²²). Six of the patients were women. Outcome data were stratified in accordance with three treatment regimens: group 1, kidney transplantation followed by autologous stem cell transplantation (n = 8); group 2, autologous stem cell transplantation followed by kidney transplantation (n = 6); and group 3, kidney transplantation after complete remission achieved with nonmyeloablative therapy (n = 5) (median follow-up, 41.4 months). At the time of the study, 79% of the patients were still alive. The treatment groups did not differ in their survival rates. Recurrent amyloidosis was diagnosed through biopsy in a patient in group 2 (before an autologous stem cell transplantation) and in another patient in group 3.

Hepatic and Gastrointestinal Tract Amyloidosis

No specific supportive care measures are available for hepatic amyloidosis. Ascites seen in these patients is more commonly associated with concurrent right-sided heart failure or nephrotic syndrome because portal hypertension is not common. Diuresis and, on occasion, paracentesis are the mainstays of support. Patients with hepatic AL have been treated with transjugular intrahepatic portal systemic shunting,⁴²³ which results in resolution of ascites and hydrothorax. For a patient with renal and hepatic amyloidosis, bilateral nephrectomy resulted in markedly improved liver function and normalization of a previously elevated bilirubin value.⁴²⁴ The median survival of 98 patients with amyloidosis (histologically proven with liver biopsy specimens) was 8.5 months.²⁸¹ Stem cell transplantation performed in tandem at 10 and 14 months after liver transplantation resulted in a good clinical outcome 28 months after liver transplantation.⁴²⁵

Amyloid deposits are commonly seen in the gastrointestinal tract. Intestinal symptoms include alternating diarrhea and constipation in the same patient. Bowel disturbances may result from massive deposits in the gastrointestinal tract; malabsorption syndrome or dysmotility may be a consequence of autonomic involvement. Therapy for diarrhea includes diphenoxylate, tincture of opium, loperamide, or paregoric, but results vary. Octreotide (a somatostatin analog) has been reported to reduce diarrhea. In the short-acting form, the dose is 200 to 300 µg/day, divided into two or three doses. A long-acting form of octreotide, which comes in 10-, 20-, and 30-mg doses, may be used. (This is a sustained-release formulation of injectable octreotide that lasts for 2 months.) A dose may be given on a monthly basis for 2 months, and it may then be adjusted according to the patient's response. Patients who are disabled because of diarrhea and fecal incontinence may undergo a diverting colostomy, which may result in excellent patient satisfaction. Patients with intestinal AL sometimes have such severe nutritional failure that long-term total parenteral nutrition is required. We have not found metoclopramide or cholinergic agents to be effective. A colon biopsy showing amyloid deposits might be localized, not systemic, disease.⁴²⁶

Respiratory Amyloidosis

For patients with localized tracheobronchial or laryngeal amyloidosis, neodymium:yttrium-aluminum-garnet laser therapy is standard treatment. Low-dose irradiation has been reported to improve obstructive symptoms.¹³⁷ Nodular pulmonary amyloidosis may be observed or be treated with surgical excision. For patients with diffuse interstitial pulmonary amyloidosis and true disruption of the alveolar arterial gradient, low doses of prednisone produce symptomatic benefits, although radiographic changes are not evident. The therapy for pulmonary hypertension includes vasodilators and calcium channel blockers. Many patients with amyloidosis are intolerant of these medications because of the associated orthostatic hypotension. Pulmonary amyloidosis may be part of systemic amyloidosis or may be organ limited. Interstitial amyloid deposits affect gas exchange. Airway stenosis from tracheobronchial amyloid deposits may necessitate iterative laser treatment.⁴²⁷

P.2115

Factor X Deficiency

Therapy for factor X deficiency has included the use of oral melphalan, prednisone, and stem cell transplantation.⁴²⁸ For a patient who is an appropriate candidate, splenectomy results in improvement of factor X levels,⁴²⁹ and infusion of activated factor VII can temporarily normalize coagulation factors and permit safe splenectomy.³⁵⁹ The management of factor X deficiency with recombinant human factor VII and splenectomy has resolved intractable hematuria.⁴³⁰ Prothrombin complex concentrates containing high levels of factor X have also been used before performing a hemicolectomy in AL.⁴³¹

Nonchemotherapy Treatment

Dimethyl Sulfoxide

The best results of DMSO treatment were achieved when it was used in topical applications for patients with cutaneous amyloidosis⁴³² and after cystoscopic treatment for patients with bladder amyloidosis.^{142, 433} DMSO is not used in the management of AL today.⁴³⁴

Colchicine

FMF is associated with the development of AA in an autosomal dominant inheritance pattern. Clinical features of FMF are pleuritis, peritonitis, synovitis, and migratory skin rash.⁴³⁵ This disorder is rarely seen in the Western hemisphere, and it primarily affects individuals of Sephardic Jewish, Armenian, Arabic, and Turkish ethnicity. Recurrent attacks of polyserositis are not required for development of amyloidosis. Fully one fourth of patients in whom AA develops do not have any history of arthritis or polyserositis. In the Middle East, one fourth of renal amyloidosis cases are attributable to the presence of FMF.⁷⁷ With the introduction of colchicine therapy, the survival of FMF patients has improved (median, 25 months) and the 5-year survival rate is 20%. For patients with FMF, the clinical manifestation of AA is proteinuria, nephrotic syndrome, and dialysis-dependent renal failure. Colchicine has been shown to prevent attacks of polyserositis effectively in two double-blind placebo-controlled studies^{436, 437}; the frequency of attacks was reduced by 82% and 78%.

Colchicine decreased the incidence of renal amyloidosis by nearly two thirds for patients with FMF.^{438, 439} When patients were adherent with colchicine therapy, development of amyloidosis was rare. Occasionally, colchicine in FMF reversed the proteinuria associated with established renal amyloidosis. When 350 children younger than 16 years (with clinically evident FMF) were given prophylactic colchicine, amyloidosis developed in none.⁴⁴⁰ After renal failure develops from AA in FMF, colchicine prevents recurrent amyloid deposition in the grafted kidney. Colchicine can be administered safely to children and pregnant women.⁴⁴¹ The classic clinical picture of FMF is recurrent, acute, short-lived, febrile, and painful attacks. The gene that causes FMF (MEFV) has been fully sequenced.⁴⁴² Hereditary periodic fevers with amyloidosis have also been described as a cryopyrin-associated periodic syndrome. Colchicine is only effective in the management of FMF and is not effective for any other periodic fever syndrome.⁵⁰

Measuring Responses in Primary Amyloidosis

Surrogate measurements typically are used to assess responses in amyloidosis. For example, responses to treatment may be defined by clinical improvement in dysfunctional organs or by reduced levels of the amyloid precursor protein. The latter involves measuring the monoclonal protein component and applying criteria that were established for patients with multiple myeloma. The third method of defining response is by SAP scan findings, but this technique is not widely available. All patients who have detectable serum or urine monoclonal proteins or free light chains must have this variable monitored after any therapeutic intervention. A reduction in the size of the M component peak or light chain suggests that production of amyloid precursor protein is decreased. The immunoglobulin free light-chain nephelometric assay has been invaluable for quantifying monoclonal proteins that previously were classified only as present or absent. In assessment of response with the free light-chain assay, the criterion conventionally accepted as a partial response is a 50% reduction in the concentration of the free light chains. A very good partial remission is defined as a dFLC less than 40 mg/L. When the free light-chain assay findings are negative (<2% of AL patients) and the M component is not measurable, a response is defined as the disappearance of light chains when examined by immunofixation.⁴⁴³ The median number of plasma cells at diagnosis is 5%, which makes estimation of plasma cell reductions difficult. In addition, even when the percentage of plasma cells is 1% or 2%, sophisticated studies using immunofluorescent assays to detect a clonal population through gene rearrangements suggest that molecular complete responses are rare.⁴⁴⁴

The quantitative serum free light-chain assay has become mandatory for assessing the treatment response of patients with AL. Patients with a hematologic partial response can show evidence of improved cardiac function by echocardiography and by reduction of cardiac biomarkers. The decreased concentration of free light chains is associated with improved survival. Similarly, when free light-chain levels are not reduced after chemotherapy, patients have a high

risk of early death.⁴⁴⁵ The free light-chain test is also useful after histologic tissue diagnosis of amyloidosis to determine whether the patient has AL.⁴⁴⁶ We have found that absolute values of immunoglobulin free light chains have prognostic value for patients undergoing stem cell transplantation. Achievement of a free light-chain response was a better predictor of survival than achievement of a complete hematologic response as defined by serum and urine immunofixation assays. The free light-chain measurements before and after stem cell transplantation are important predictors of outcome.³⁷² When the free light-chain analysis was performed after chemotherapy for 25 patients, the levels of free light chain decreased significantly, and all patients with a κ -to- λ ratio of 0.26:1.65 had a good prognosis.⁴⁴⁷ The circulating free light-chain concentration was measured in 262 patients with AL. Of the 86 patients who had at least a 50% decrease in free light-chain concentration, the 5-year survival rate was 88%; in contrast, patients who did not have a light-chain decrease of 50% had a 5-year survival rate of 39%.³⁷⁵ Used to measure hematologic response, the free light-chain response is a more useful gauge than the M-protein response. Attaining a dFLC reduction of 90% or more is important to improved outcome of patients with light-chain AL.³⁷⁷ Amyloid deposition in fat tissue undergoes substantial histologic regression only after normalization of the level of serum free light chain.⁴⁴⁸

Organ response criteria have been defined. Ideally, a response in amyloidosis is accompanied by improved function of a previously involved organ. A 50% reduction in the amount of albumin excreted in the urine within 24 hours, with no increase in serum creatinine levels and no decrease in serum albumin concentration, is the generally accepted definition of a response for patients with renal amyloid nephrotic syndrome. A 50% reduction in serum alkaline phosphatase with no increase in transaminase or bilirubin levels is considered an organ response for hepatic AL. Reduction in liver size is less common. Documentation of amyloid regressions in the heart is difficult with echocardiography. A reduction in wall thickness of 2 mm, measured by two-dimensional echocardiography, has been proposed as confirmation of a response. Interprocedural variability is considerable, however, and caution is required when confirming a cardiac response or progression on the basis of echocardiographic criteria only. New criteria using NT-proBNP define cardiac response

P.2116

as a reduction of more than 30%, with a minimum decrement of 300 pg/ml. Although rare, a response in amyloid peripheral neuropathy should be documented by an electromyogram showing improved nerve conduction velocities. A consensus definition of organ involvement and treatment response incorporating the free light-chain assay was developed at the Tenth International Symposium on Amyloid and Amyloidosis.⁴⁴⁹

Chemotherapy for Amyloidosis

To date, most therapies for AL have been directed toward killing the underlying plasma cell clone. The cornerstone of therapy, described in the following section, has been alkylation or corticosteroid based. However, with advances made in the last decade for myeloma treatment, new regimens have been tested, but none have been subjected to randomized clinical trials. Successful cytotoxic chemotherapy to induce regression of AL was reported in 1972.⁴⁵⁰ The use of alkylating agents to suppress plasma cell clones in the bone marrow of AL patients occurred after the recognized success of these agents in the treatment of patients with multiple myeloma.⁴⁵¹ More recently, high doses of chemotherapy with peripheral blood stem cell support have been applied.⁴⁵² Unlike in multiple myeloma, recognition of an organ response in AL may take up to 1 year. In the case of intermittent low-dose chemotherapy, it is difficult to distinguish between patients who will respond after longer exposure to therapy and those who will not benefit from therapy and who should be offered an alternative therapeutic approach.^{453, 454} In vitro studies of the plasma cells from AL patients show aberrant light-chain synthesis. In one study,⁴⁵⁵ the cytoplasm of the plasma cells contained light-chain tetramers. After successful alkylating agent-based chemotherapy, light-chain synthesis was suppressed and a clinical response was observed.

The two earliest reports of melphalan and prednisone therapy^{456, 457} showed responses and prolongation of survival for a minority of patients. Patients with renal, cardiac, or liver AL appeared to benefit, but elevated β_2 -microglobulin levels and cardiac involvement were predictors of failure of response.^{458, 459} Although therapy with melphalan and prednisone has been shown repeatedly to benefit a subgroup of patients with AL, the majority of patients did not respond. Even with subset analysis, no cohort had a response rate that exceeded 40%, including patients with single-organ renal involvement and normal serum creatinine values. Moreover, even when patients showed an organ response, follow-up tissue biopsy specimens showed persistent deposits of amyloid.⁴⁶⁰ Because follow-up biopsies are performed infrequently, it is unclear whether clinical improvement is regularly associated with histologic regression. SAP scans suggest, however, that these deposits may be mobilized and that the total amyloid body burden is reduced.

When the Mayo Clinic experience with melphalan and prednisone therapy was reviewed,³⁷¹ the overall response rate was only 18%. Increased serum creatinine concentration also had an adverse impact on survival; patients with serum

creatinine values that exceeded 3 mg/dl at the initiation of therapy did not have a response. The highest response rate (39%) was observed with the small group of patients with nephrotic syndrome, no extrarenal involvement, normal serum creatinine values, and normal echocardiographic findings. Responses were noted for patients with amyloid cardiomyopathy, suggesting that no patient is too ill for treatment. The response rate, however, was low (15%).³⁷¹ Clinical regression of neuropathic symptoms, such as pain, paresthesias, and numbness, is rare after melphalan-based chemotherapy. Although only 18% of patients responded to melphalan, their median survival time was 89 months. The 5-year survival rate of this small subgroup was 78%. The median time to response was 1 year. Nonresponders had a median survival of 15 months. It is often difficult to know when to discontinue low-dose melphalan-based therapy. If alternative therapies, such as high-dose chemotherapy with peripheral blood stem cell support, are not viable, a trial of alkylating agent-based chemotherapy for AL may be beneficial and is a reasonable consideration for virtually all patients.

Long-term survival is possible for patients with AL. One report described 841 patients with AL who were studied over a 21-year period.⁴⁶¹ The actuarial survival rate for the patients at 1, 5, and 10 years was 51%, 16%, and 4.7%, respectively. The 10-year survivors (30 patients) received treatment with melphalan and prednisone. Fourteen had a documented hematologic response with eradication of M protein from the serum and urine. Ten patients had nephrotic-range proteinuria, and four had a reduction in urinary protein excretion of greater than 50%. Unfavorable prognostic features for 10-year survival included heart failure, older age, creatinine values greater than 2 mg/dl, greater than 20% bone marrow plasma cells, and a platelet count greater than $500 \times 10^9/L$. In a report of 10 patients with AL, 8 were treated with cyclophosphamide and melphalan.⁴⁶² No patient responded to treatment. Four patients received infusion of vincristine, doxorubicin, and dexamethasone over 96 hours. Two patients showed a 50% reduction in the serum M component level.

A randomized crossover study of melphalan and prednisone versus colchicine was reported.⁴⁵⁶ The 101 eligible patients were stratified by the clinical manifestation of amyloidosis: (1) heart failure, (2) neuropathy, (3) nephrotic syndrome, and (4) other. Patients were also stratified by age. Significant differences that favored melphalan and prednisone therapy were observed.

Two prospective, randomized noncrossover studies were performed to evaluate melphalan and prednisone therapy for patients with AL. In one study, 219 patients were enrolled.⁴⁵⁷ Patients were stratified by age, sex, and clinical manifestation. Half of the patients had nephrotic-range proteinuria, and 20% had heart failure. The median survival was significantly longer in the groups treated with melphalan and prednisone (17 months) than in the colchicine group (8.5 months).

The second study⁴⁶³ randomly assigned 100 patients to receive colchicine therapy or a combination of melphalan, prednisone, and colchicine. The overall survival of the patient group was 6.7 months in the colchicine-only group and 12.2 months in the melphalan group. With multivariate analysis, melphalan had a significant impact on survival when heart failure was not present.

Although melphalan is a superior therapy in the treatment of AL, the frequency of response with melphalan is low, and the treatment itself is potentially leukemogenic. Of 153 patients receiving melphalan, cytogenetic abnormalities were recognized in 10.⁴⁶⁴ All cytogenetic changes were consistent with damage to hematopoietic stem cells. Eight of the 10 patients died of pancytopenia, one died of progressive renal amyloidosis, and one was alive at the time of publication. Morphologically, four patients had acute leukemia and five had myelodysplasia. Overall, bone marrow damage consistent with alkylation-induced toxicity was observed for 7% of the patient population. The actuarial risk was 21% for myelodysplasia or acute leukemia developing 42 months after initiation of therapy. The median survival period was 8 months after receiving the diagnosis of leukemia or myelodysplasia.

In one study, nine consecutive patients were treated with dexamethasone alone (dosage, 40 mg on days 1 through 4, days 9 through 12, and days 17 through 20, every 5 weeks for three to six cycles).⁴⁶⁵ This treatment was followed by maintenance levels of interferon. Three patients received maintenance levels of dexamethasone (dosage, 40 mg on days 1 through 4, every month for 1 year). An AL organ improvement was reported in eight of the nine patients. Of seven with nephrotic-range proteinuria, six had a 50% reduction in proteinuria, with a median time to response of only 4 months. Organ function improvement was reported in amyloid neuropathy, hepatic involvement, and gastrointestinal involvement. Neither patient with heart failure

P.2117

showed improvement. Dexamethasone has no tendency to cause leukemia, and the responses are faster than with melphalan. When we treated 19 patients with high-dose dexamethasone in an identical regimen without interferon, only 3 had an objective organ response.⁴⁶⁶ The median survival of the entire group was 11.2 months. When cardiac amyloid is

not present, high-dose dexamethasone treatment may produce benefit in some patients with AL. We also have used dexamethasone when melphalan and prednisone therapy failed.⁴⁶⁶ Among 25 patients who received high-dose dexamethasone treatment, three objective responses with organ-specific improvement were observed. The median survival of the entire group was 13.8 months. Dexamethasone may be beneficial when treatment with melphalan fails,⁴⁶⁷ but toxicity may be formidable and may include fluid retention, gastrointestinal bleeding, and colonic perforation.

The combination of melphalan with high-dose dexamethasone treatment has been reported in the management of amyloidosis.⁴⁶⁸ Patients were selected on the basis of their ineligibility for stem cell transplantation. Of 46 patients, a hematologic response was seen in 31 (67%); of these, a hematologic complete response was seen in 15 (33%). Improvement in organ dysfunction was observed in 22 patients (48%). A strong correlation was noted between hematologic response and organ response. Of the patients who achieved a hematologic complete response, 87% had organ improvement. Among the patients who achieved a hematologic response (at least 50% reduction of the M component), organ function improved in 56% of patients. The 15 who had no response also had no improvement in organ function. Advantages of this regimen included a 4% mortality rate on day 100 and resolution of cardiac failure for 6 of 32 patients. The median time to response was short (4.5 months), and only 11% had adverse effects. Using a similar melphalan- and dexamethasone-based regimen, physicians at Weill-Cornell School of Medicine reported a median survival of only 10.5 months. Outcomes appear to be strongly linked to the proportion of patients with cardiac amyloidosis.⁴⁶⁹ With melphalan administered parenterally with dexamethasone in patients who had immunoglobulin light-chain amyloidosis, the median survival of 61 patients was 17.5 months. The 3-month all-cause mortality rate was 28%.⁴⁷⁰ In Boston, a study of 70 patients who were treated with melphalan and dexamethasone showed that, among 48 patients who survived and returned for follow-up assessment, 6 patients (13%) had a full hematologic response and 12 patients (25%) had a partial response. Responses of the patients who received weekly "low-dose" dexamethasone treatment were not inferior compared with those who received 4-day pulses. Median survival for the 70 patients has not yet been reached (median follow-up, 17 months).⁴⁷¹ There appear to be two factors that help account for at least some of this difference. First, the assessment of response using the immunoglobulin free light-chain assay did not exist in the early studies of melphalan-based therapy but has been used regularly since 2005, resulting in improved ability to monitor hematologic responses. Second, the mix of patients, particularly those with cardiac amyloidosis, is very important in determining overall outcomes.

Reduced-dosage dexamethasone produces high response rates for patients with AL⁴⁷² compared with response rates of patients receiving the traditional dosage.⁴⁷³ Among 93 patients with biopsy-proven AL, hematologic complete remissions were observed for 24%, and improvement in AL-related organ dysfunction occurred for 45%.⁴⁷³ Median survival of the entire cohort was 31 months, and the 2-year event-free survival rate was 52%. Heart failure and the β_2 -microglobulin levels were predictors of adverse outcome. Front-line therapy with dexamethasone may lead to durable reversal of AL-related organ dysfunction and to prolonged survival.

Use of thalidomide has been explored in the treatment of amyloidosis. Sixteen patients (median age, 62 years) were treated,⁴⁷⁴ and the median maximum tolerated dose was 300 mg. Exacerbation of peripheral neuropathy and pulmonary edema occurred frequently, and 50% of patients had Grade 3 or 4 toxicity. No patient had a complete hematologic response; 25% had a significant reduction in light-chain proteinuria. Twelve patients at our institution were treated with thalidomide.⁴⁷⁵ Nine patients had cognitive difficulty, edema, and constipation, and two had deep vein thrombosis and syncope. The median time receiving thalidomide therapy was 72 days. Two patients died, and the other 10 withdrew from treatment (6 because of toxicity and 4 because of disease progression). Patients with AL had poor tolerance of thalidomide. In another study,⁴⁷⁶ thalidomide was combined with dexamethasone in doses of up to 400 mg per day. A hematologic response was achieved in 48% of patients, 19% had a hematologic complete response, and 26% had organ responses. The median time to response was 3.6 months. Treatment-related toxicity occurred for 65%. Thalidomide, dexamethasone, and cyclophosphamide have been reported to produce a hematologic response rate of 74%.⁴⁷⁷

A phase 2 trial of 35 patients receiving lenalidomide showed therapeutic activity when lenalidomide was combined with dexamethasone.⁴⁷⁸ When lenalidomide was used alone, four patients showed a response. Eight of 13 evaluable patients had a measurable hematologic response. Three responses were complete or near complete. Lenalidomide is well tolerated by patients with AL and may result in excellent hematologic responses. In an update, progression-free survival of patients with complete response was 49.8 months.⁴⁷⁹ In a second study, 41% of patients receiving salvage treatment with lenalidomide who had renal amyloid had a reduction in urinary protein, but the response duration and overall survival were not reported.⁴⁸⁰ In that study, high-risk patients were less likely to respond to lenalidomide. Therapy with lenalidomide can change cardiac biomarkers⁴⁸¹ and alter renal function in amyloidosis.⁴⁸²

Lenalidomide also has been combined with melphalan and dexamethasone.⁴⁸³ The maximum tolerated dose of lenalidomide is 15 mg. This three-drug oral combination produced hematologic responses in 58% and complete responses in 42%. The 2-year event-free survival rate and the overall survival rate were 54% and 81%, respectively. In addition, lenalidomide was combined with cyclophosphamide and dexamethasone in the treatment of 35 patients.⁴⁸⁴ Hematologic response rate was 60%. In those patients receiving at least 4 treatment cycles, the response rate was 87% (median overall survival, 16.1 months).

A randomized study of cyclophosphamide-thalidomide-dexamethasone treatment compared with melphalan-dexamethasone treatment suggested a greater complete response rate with the three-drug regimen, albeit with greater toxicity.⁴⁸⁵ One cautionary note when using lenalidomide or thalidomide in patients with AL is that the NT-proBNP level appears to increase after the initiation of therapy. Recognition of potential immunomodulatory drug-induced cardiac toxicity is important when these agents are used. High levels of NT-proBNP are predictive of an inability to tolerate immunomodulatory agents for amyloidosis.⁴⁸⁶

Pomalidomide, a derivative of thalidomide with structural similarity to thalidomide and lenalidomide, was given to 29 evaluable patients in one study.⁴⁸⁷ All patients had received treatment previously and 13 of the patients had received a prior autologous stem cell transplantation. Previously, an immunomodulatory agent was given to 15 patients and bortezomib to 12. Twenty-nine patients evaluable for hematologic response were seen. The overall response rate was 38% (11 patients). Combined treatment with pomalidomide and dexamethasone is promising. One-year survival and progression-free survival rates were 77% and 56%, respectively. Pomalidomide was considered effective and safe for patients, including those in whom prior lenalidomide or thalidomide therapy had failed.

Eighty percent of evaluable patients in the first reported study of bortezomib for amyloidosis had a hematologic response.⁴⁸⁸

P.2118

Among 18 patients, the hematologic response rate was 77%, with a 16% complete response rate. A phase 1 dose-escalation study of bortezomib given either twice weekly on days 1, 4, 8, and 11 every 21 days or on days 1, 8, 15, and 22 every 35 days reported hematologic responses in 50% of patients. The weekly regimen was associated with decreased neurotoxicity. There was a 1-year hematologic progression-free rate of 72.2% and 74.6% and a 1-year survival rate of 93.8% and 84%, respectively, for the twice-weekly and once-weekly doses.⁴⁸⁹ Among 70 patients, 29% had renal responses and 13% had cardiac responses. Discontinuation and dose reduction due to the toxicity were greater with the twice-weekly than once-weekly dose. Both dose schedules represent active, well-tolerated regimens in relapsed AL.⁴⁹⁰

The combination of bortezomib and dexamethasone has been used after stem cell transplantation as consolidation to improve the depth of response.⁴⁹¹ Of 23 patients, 17 received bortezomib posttransplantation; 74% achieved a complete response and 58% achieved an organ response. A multicenter study of 94 patients receiving bortezomib and dexamethasone showed hematologic responses in 71% of patients; responses were complete in 25%.⁴⁹² Cardiac response was seen in 29% of patients. The NT-proBNP predicted survival. In a study of bortezomib-dexamethasone therapy in 26 patients, the overall response rate was 54%, with complete responses in 31% of patients. Median time to response was 7.5 weeks, but the median progression-free and overall survivals were 5 and 18.7 months, respectively, suggesting short durability with bortezomib combined with dexamethasone. No grade 3 to 4 neuropathy was observed.⁴⁹³

Stem Cell Transplantation

Hematopoietic stem cell transplantation for AL is inherently different from transplantation for other hematologic cancers.⁴⁹⁴ Patients with lymphoma, multiple myeloma, or leukemia typically have considerable bone marrow abnormalities that manifest as multiple cytopenias, but these patients generally have excellent cardiac, hepatic, and renal function and a performance status of 0 or 1. In contrast, AL patients often have clinically significant visceral organ dysfunction, which puts them at a high risk for complications after high-dose chemotherapy. Hematologic abnormalities such as anemia, leukopenia, and thrombocytopenia are uncommon.

Syngeneic transplantation was reported in the treatment of a patient with AL in 1995.⁴⁹⁵ A SAP scan showed a reduction in amyloid deposits. In one report, two AL patients had ablative allogeneic bone marrow transplantation.⁴⁹⁶ The first had a hematologic response and underwent an allogeneic transplantation after melphalan treatment (110 mg/m^2) and total body irradiation (1,200 cGy). The patient achieved a complete hematologic response and was alive 29 months after transplantation. The second patient received a stem cell transplant from a human leukocyte antigen-identical sibling after treatment with melphalan (140 mg/m^2) and total body irradiation (800 cGy). The urinary protein loss decreased from 9.15

to 1.3 g/day. The patient had chronic graft-versus-host disease of the skin and liver but was alive 18 months after transplantation.

Allogeneic stem cell transplantation may be a promising treatment, but the mortality rate is high. The European Group for Blood and Marrow Transplantation reported 19 patients with AL.⁴⁹⁷ Fifteen underwent allogeneic transplantation: seven had full-intensity conditioning and eight had reduced-intensity conditioning. Overall survival and progression-free survival at 1 year were 60% and 53%, respectively. The treatment-related mortality rate was 40%. Eight patients had a complete response and two had a partial response. For five of seven evaluable patients who had a complete response, chronic graft-versus-host disease was observed, which implied existence of a graft-versus-amyloidosis effect. Cardiac failure was a clinically significant problem. It is unlikely that allogeneic or nonmyeloablative allogeneic transplantation will be applicable to a large proportion of AL patients because of the age restrictions and the need for good performance status and adequate renal function. Allogeneic hematopoietic cell transplantation after reduced-intensity conditioning should be discussed as a treatment option for relapse after autologous hematopoietic cell transplantation in patients younger than 60 years with preserved organ functions and a HLA-identical donor.⁴⁹⁸

Most reported experiences with myeloablative chemotherapy involve progenitor cell replacement with autologous peripheral blood stem cells. The blood stem cells are used because they are easy to collect and have relatively rapid engraftment kinetics. Most AL patients who receive blood stem cells show clonotypic cells in the apheresis product. CD34⁺ cell selection to eliminate the clonotypic stem cells may be performed, but its impact on outcome is uncertain.⁴⁹⁹ It is known that CD34⁺ selection yields no survival benefit for patients with multiple myeloma who undergo stem cell transplantation,⁵⁰⁰ and we have no reason to believe that the outcome would be different for patients with AL. Clinicians at Boston University first reported five patients with AL receiving stem cell transplants, and all showed a clinical response.⁵⁰¹ When the cohort was expanded to 25 patients, a hematologic response was reported for 62% and an organ response for 65% of surviving patients.⁵⁰²

Another report described 250 patients who received melphalan (100 to 200 mg/m²) before stem cell transplantation.⁵⁰³ The median patient age was 57 years, and 53% of patients had echocardiographic evidence of amyloidosis. The 3-month transplant-related mortality rate was 14%; 11% of patients who initiated stem cell collection did not undergo transplantation because of death or mobilization toxicities that precluded safe transplantation. During mobilization, 23 patients had major morbidities; 18 did not undergo stem cell transplantation. Four patients had cardiac arrest during stem cell infusion, and six additional cardiac arrests were noted during the weeks after transplantation. Febrile neutropenia occurred in 62 patients, 17 had gastrointestinal tract hemorrhage, and 12 had progressive renal failure that required dialysis. At a mean follow-up time of 23 months, 66% of the patients were alive. The best responses were from patients with isolated renal amyloidosis. Lower toxicity grades were observed in patients who received lower conditioning doses of melphalan (100 mg/m²).

Multicenter surveys that reported the outcome of transplantation were first published in 1998.⁵⁰⁴ In France, 21 patients with systemic AL received transplants: 18 were treated with melphalan alone and 3 had regimens that included total body irradiation. The death rate was 43%, and 9 of the 21 died within 1 month after transplantation. All deaths were attributable to multiorgan failure, including one patient with intractable bleeding. Of the 12 survivors, 10 achieved a response. Patient selection clearly affected the results because the median time between diagnosis and transplantation was 11 months. We suggest that the lengthy period before transplantation excluded patients with a worse prognosis. Outcome was predicted by the number of organs involved at the time of transplantation. For patients with two or more affected organs, the 4-year survival rate was 11%. The risk of toxic death when two organs were involved was 75%, which reflected the need for careful patient selection. One study from the United Kingdom described 27 patients who received high-dose melphalan therapy before stem cell transplantation.⁵⁰⁵ Eight treatment-related deaths (30%) occurred: four deaths were attributable to multiorgan failure, two to gastrointestinal tract hemorrhage, one to sepsis, and one to cardiac complications. Despite the high death rate, a clonal response of the bone marrow plasma cells was seen in 64% and organ regression in 57%. Seventeen of the 27 patients were alive at the end of the study. Of the nine patients who received a transplant, four died within a year after transplantation (treatment-related mortality rate, 44%).⁵⁰⁶ Three of the four deaths were attributable to cardiac amyloidosis; the fourth death was of a patient with amyloid involvement of the kidney, nerve,

P.2119

and intestinal tract. The median follow-up of the five survivors was 12.6 months; four patients responded to therapy and one patient had disease progression.

Multiorgan failure and gastrointestinal tract bleeding are more common in transplantation for AL than transplantation for any other indication. Gastrointestinal tract bleeding appears to be highly specific for AL. We reviewed the first 45 patients who received transplants for AL at our institution.⁵⁰⁷ Eleven died after transplantation (median survival time, 2 months). Gastrointestinal tract bleeding was observed in nine (20%). The median time to onset of bleeding was 9 days after transplantation, and the median platelet count was $22 \times 10^9/L$. Bleeding was seen in the upper gastrointestinal tract for two patients, the lower tract for three, and the lower and upper tract for four. Endoscopy was performed for five patients, and all had inflamed, friable gastric and esophageal mucosa. Four of the nine patients with bleeding died, three of multiorgan failure. Gastrointestinal tract bleeding was associated with female sex and poor engraftment of platelets. During the first 100 days after transplantation, the median number of packed red blood cell units administered was 20 for those with gastrointestinal tract bleeding. The exact mechanism underlying bleeding after stem cell transplantation is unknown. The widespread vascular deposits of amyloid may render the vessels rigid and friable, however. High-dose chemotherapy, which causes clinically significant mucosal damage, may also cause bleeding. In our patient cohort, abnormalities of the coagulation system were not involved in the bleeding.

We have described three patients who did not undergo stem cell infusion because of complications related to mobilization.⁵⁰⁸ Two patients died of progressive amyloidosis at 1 and 3 months after mobilization. In the past, we have used two different mobilization schemes. One used filgrastim only ($10 \mu\text{g}/\text{kg}/\text{day}$), and apheresis commenced on day 5. The other scheme used cyclophosphamide ($1.5 \text{ g}/\text{m}^2$) on 2 consecutive days, followed by sargramostim ($5 \mu\text{g}/\text{kg}/\text{day}$), and apheresis began when the white blood cell count exceeded $1,000 \text{ cells}/\mu\text{l}$. The median overall yield was $6.4 \times 10^6 \text{ CD34}^+$ cells/kg. Of patients who received mobilization treatment with cyclophosphamide, the median number of apheresis was three. Of patients receiving filgrastim alone, the median number of apheresis was two, a statistically significant difference.

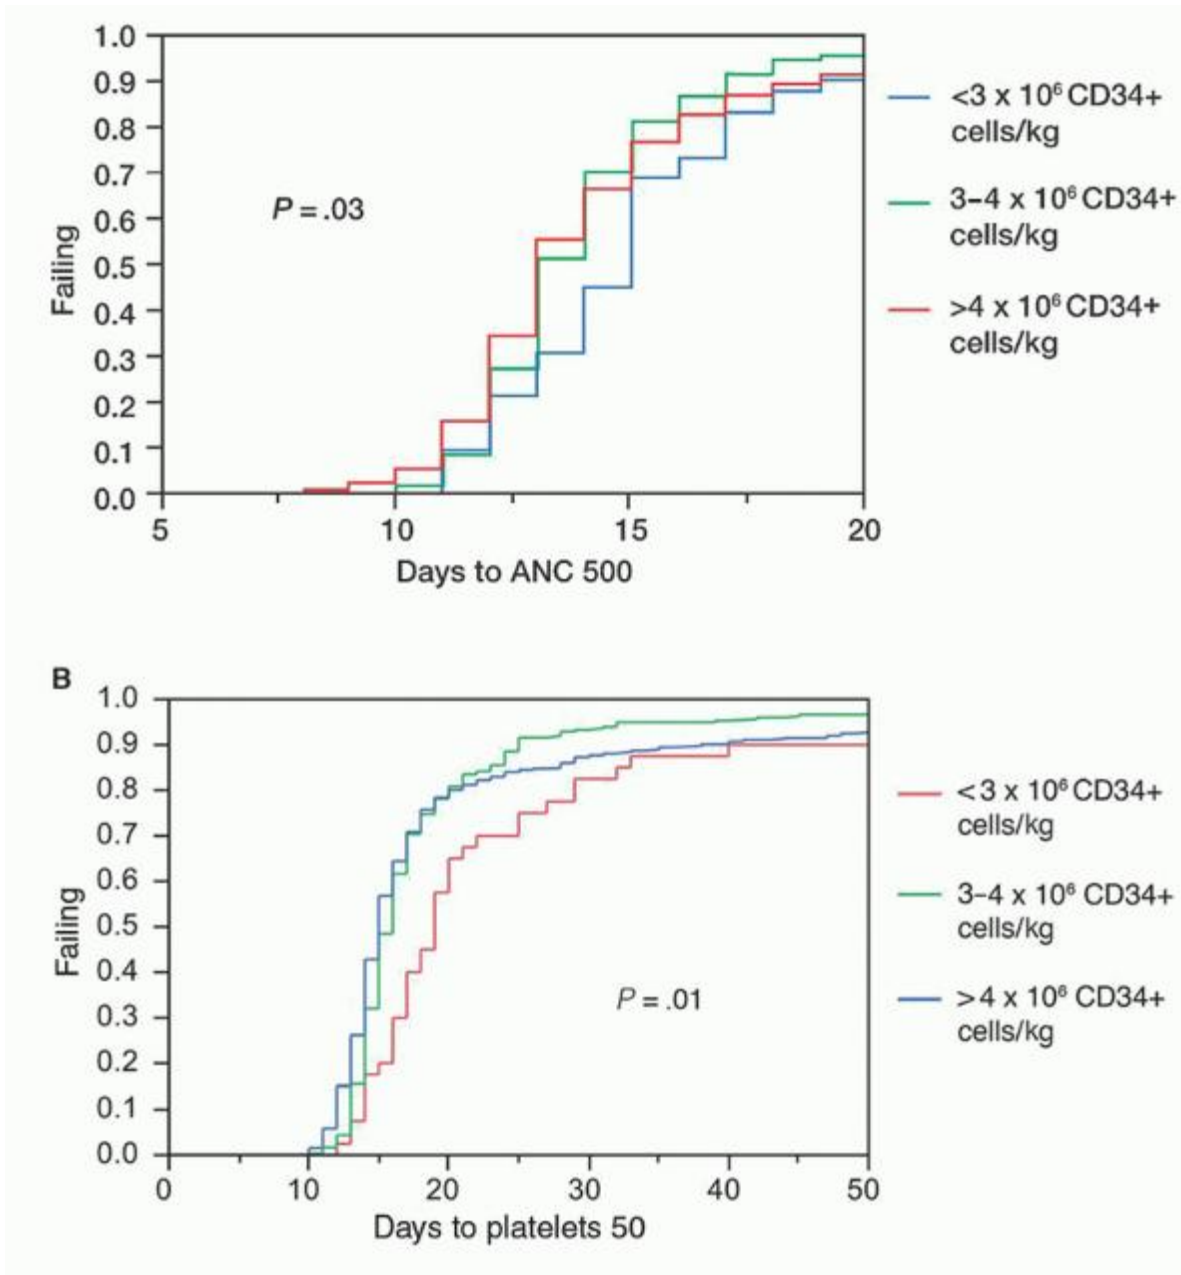

FIGURE 99.14. Engraftment kinetics for neutrophils (A) and platelets (B) posttransplantation. The ideal minimum for CD34⁺ cells is $>3.0 \times 10^6$ cells/kg. ANC, absolute neutrophil count.

At Mayo Clinic, 434 patients with amyloidosis received their transplants at a median of 4.0 months after histologic diagnosis: One fourth within 3 months and three fourths within 6.6 months (median actuarial survival for the entire group, 94.9 months). Predictors of survival included weight gain of greater than 2% during stem cell mobilization and an absolute lymphocyte count at day 15 of greater than 500 cells/ μ L. The number of organs involved appeared to be relevant to predicting the outcome successfully. Patients with two-organ involvement had a median survival rate of 70% at 60 months; and those with three-organ involvement, a median survival of 58 months. The levels of serum creatinine, troponin T, and NT-proBNP and the septal thickness were all significant predictors of outcome.⁵⁰⁹

Engraftment kinetics were similar to those of patients with multiple myeloma. We did not administer growth factor after transplantation because of its impact on fluid retention and the ability of growth factors to precipitate congestive heart failure in amyloidosis patients. A neutrophil count of 500 cells/ μ L was achieved at a median of 14 days (range, 7 to 116 days). Twenty-five percent of patients showed engraftment on or before day 13, 75% by day 16, and 90% by day 22. A platelet count of 20×10^9 /L was achieved at a median of 14 days (range, 6 to 406 days); 25% of patients achieved 20×10^9 /L by day 12, 75% by day 19, and 90% by day 27. A platelet count of 50×10^9 /L was achieved at a median of 18 days;

25% achieved the count by day 14, 75% by day 27, and 90% by day 47. CD34⁺ cell collection had an important impact on the time to platelet engraftment (Fig. 99.14). When the

P.2120

number of infused CD34⁺ cells was greater than 3×10^6 but less than 4×10^6 , engraftment was not significantly different from that of patients who received an infusion with more than 4×10^6 CD34⁺ cells. However, the time to engraftment was significantly longer for platelets and neutrophils when 2×10^6 to 3×10^6 CD34⁺ cells were infused. We therefore set a goal of more than 3×10^6 stem cells for rapid engraftment. Safe engraftment may be achieved by infusing only 2×10^6 cells, but the time to engraftment is prolonged, and the risk of infection, bleeding, and an increased number of transfusions is increased.

Studies have demonstrated that patients with stage III disease should be excluded from transplant studies. The troponin level predicts early death from stem cell transplantation and can be used as an exclusion criterion for this therapy.⁵¹⁰ Troponin T levels should be measured in all patients before transplantation. Data have recently been reported on 10-year survivors: 25% of patients who received a transplant survived 10 years, and the 10-year survival rate was 53% for complete responders. Transplant-related mortality rates are decreasing from as high as 40% to the now-reported 7%. The median actuarial survival for the entire group was 94.9 months.

Our conditioning regimens are typical of those used for patients with multiple myeloma: 62% receive melphalan at a full dose of 200 mg/m², 26% receive a dose of 140 mg/m², and 12% receive lower doses primarily because of advanced cardiac amyloidosis or elevated creatinine levels. We have previously reported that the intensity of chemotherapy is important for the overall outcome and that patients receiving full-dose melphalan appear to survive longer.⁵¹¹ It is difficult to exclude the possibility that patients selected for reduced-intensity chemotherapy had more advanced amyloidosis. At Mayo Clinic, only one quarter of AL patients ultimately undergo stem cell transplantation. Our case-matched control study⁵¹² compared 63 patients who underwent stem cell transplantation with 63 patients who received conventional treatment. The patients were matched for age, sex, cardiac function, creatinine level, and urinary protein loss. We identified an overall survival advantage for patients who underwent transplantation. The Center for International Blood and Marrow Transplant Research reported data results of 107 patients with primary systemic amyloidosis from 48 transplant centers.⁵¹³ The day-30 treatment-related mortality rate was 18%, whereas the Mayo Clinic day-30 mortality rate was 7.4%. The center reported high response rates, and only 11% of patients had disease progression after transplantation. The median projected survival was 47 months; the clinical experience of the centers was the most important predictor of survival. Patients who underwent transplantation within the study's last 5 years survived longer than patients who underwent the procedure more than 5 years earlier. The response rate was 34%, and 33% of patients had stable disease.

An unanswered question is whether transplantation for AL patients should be performed preferentially in specialized centers that have extensive amyloidosis experience or in centers that have extensive transplantation experience for nonamyloidosis diseases. An Eastern Cooperative Oncology Group study suggested that treatment-related mortality rates were not higher in multicenter cooperative group settings.^{514, 515} Stem cell transplantation is not a proven therapy in the management of amyloidosis, despite reports of organ disease remission for 50% of patients.^{516, 517} One study has also shown an improvement in the quality of life of patients who underwent stem cell transplantation.⁵¹⁸ A Group Myélome-Autogreffe and Intergroupe Francophone du Myélome study suggested that overall survival after stem cell transplantation may not be better than survival after a regimen of melphalan and high-dose dexamethasone.⁵¹⁹ This trial randomly assigned 100 patients; the median actuarial survival was 57 months with melphalan and high-dose dexamethasone and 49 months after stem cell transplantation. The patients who underwent transplantation received melphalan (140 or 200 mg/m²) and were mobilized only with granulocyte colony-stimulating factor. The hematologic response rates were 65% and 64% for the patients who did and did not undergo transplantation, respectively. Caution is required when interpreting these results, however; the treatment-related mortality rate was high (24%). Furthermore, only 29 of the 100 patients who underwent transplantation were evaluable for response. On the basis of these small numbers, it is premature to abandon transplantation as a treatment modality for amyloidosis.

The extent of cardiac amyloidosis measured with echocardiography in the transplant population is less than that expected of an unselected nontransplant cohort. The median intraventricular septal thickness was 12 mm; one quarter of patients had a septal thickness of 10 mm or less, and three quarters had less than 14 mm.⁵⁰⁹ The median ejection fraction was 65%; three quarters of patients had an ejection fraction of less than 70%, and one quarter had an ejection fraction of less than 60%. The median actuarial survival is depicted in Figure 99.15. The absolute lymphocyte count 15 days after stem cell transplantation may have an impact on survival.⁵²⁰ The number of organs involved appeared to be a relevant prognostic

factor (Fig. 99.16). Other prognostic factors included the intraventricular septal thickness; the levels of serum creatinine, serum troponin T, and NT-proBNP; and excessive weight gain during stem cell mobilization.⁵²¹ The NT-proBNP levels have profound effects on survival after transplantation, presumably because they reflect progression due to cardiac failure.⁵²² The median level of NT-proBNP among 117 amyloidosis patients at Mayo Clinic was 170 pg/ml; using this concentration as a threshold, the difference in survival is highly significant (Fig. 99.17).

Response has a profound impact on overall survival.⁵²³ Patients who have a 50% reduction of light-chain levels have superior survival compared with those who do not have a 50% decrease. The pretreatment free light-chain value also affects outcome and survival. In a proportional hazards model, overall survival is linked to the pretransplantation free light-chain levels and the number of organs involved. In large medical centers that perform stem cell transplantation, the treatment-related mortality rate is 6% to 18%. Hematologic responses range from 16% to 50%, and reported organ responses range from 34% to 64%. Organ response is a time-dependent variable, and organ responses may be delayed up to 36 months after transplantation. Tandem stem cell transplantations are feasible and have been performed in patients with amyloidosis, but the ultimate effect on outcome is unknown.⁵²⁴ In a published meta-analysis of stem cell transplantation in AL, transplantation did not appear to be superior to conventional chemotherapy in improving survival for

P.2121

patients. But the quality of evidence is low, indicating a need for well-designed and adequately powered randomized clinical trials to better address the role of autologous hematopoietic cell transplantation in AL.⁵²⁵

FIGURE 99.15. Survival of patients with primary amyloidosis who underwent stem cell transplantation at Mayo Clinic (N = 492). The median survival time was 80 months. Mortality rate at day-100 was 11%.

FIGURE 99.16. Effect of the number of affected organs on survival (N = 486). Tick marks indicate censored patients (alive).

The toxicities associated with high-dose chemotherapy are listed in Table 99.5. The response rates that we observed exceeded those of our previous experience with conventional-dose chemotherapy. However, patients receiving high-dose chemotherapy were highly selected, and it is difficult to predict the response rate or survival of an age- and organ-matched population. The most common type of response is the resolution of nephrotic syndrome. Table 99.6 summarizes reported data on stem cell transplantation in nearly 300 patients. Comenzo and Gertz⁵¹⁷ published a risk-adapted strategy for selecting patients with AL and assigning melphalan doses. A review of four single-center studies showed that the day-100 mortality rate was 21%. The contraindications for stem cell transplantation are given in Table 99.7, and the risk-adapted approach is shown in Table 99.8.

Patients with AL who undergo transplantation are highly selected by age, number of organs involved, the absence of advanced heart failure, and performance status. Therefore, a true control group is lacking for comparison. Dispenzieri et al.⁵³³ reviewed 1,288 AL patients seen at Mayo Clinic between 1983 and 1997 and identified patients ineligible for stem cell transplantation using the criteria in Table 99.7. Eligible patients had to have symptomatic amyloidosis without multiple myeloma, an age less than 70 years, an interventricular septal thickness no more than 15 mm, and an ejection fraction greater than 55%. In addition, the serum creatinine value had to be less than 2 mg/dl and the direct bilirubin value had to be less than 2 mg/dl. After the application of these selection criteria, only 229 patients (18%) were eligible for transplantation. The median survival of this nontransplantation cohort was 42 months, and the 5- and 10-year survival rates were 36% and 15%. Clearly, patients who were eligible for transplantation had much better outcomes than those who were ineligible. The predictors of survival included the amount of M protein in the 24-hour urine measurement and the number of involved organs (Fig. 99.18). The alkaline phosphatase value, performance status, and degree of weight loss were also factors that influenced survival. Patients eligible for stem cell transplantation inherently are a low-risk population; certainly, their anticipated median survival time far exceeds the 18 months reported by other studies of patient cohorts that received melphalan and prednisone.^{216, 534}

FIGURE 99.17. Effect of N-terminal brain natriuretic peptide level on survival (N = 358).

CONCLUSION

Amyloidosis should be considered in the differential diagnosis of any patient with nephrotic-range proteinuria, monoclonal gammopathy, heart failure, neuropathy, or hepatomegaly. The symptoms of amyloidosis are vague and not useful for establishing a diagnosis. The pathognomonic physical findings are seen in less than one fifth of patients and therefore are not reliable for disease detection. When a patient has a compatible clinical syndrome, the best screening tests include immunofixation of the serum and urine and a free light-chain assay. Monoclonal light chains may be detected in the serum or urine (or both) of nearly 90% of AL patients, and 99% of those who have free light-chain assays of the serum have abnormal findings. Noninvasive studies, such as fat aspiration and bone marrow biopsy, confirm the diagnosis for

P.2122

85% of patients with AL. For patients with biopsy-proven amyloidosis who do not have detectable monoclonal protein in the serum or urine, a nonimmunoglobulin form of amyloidosis should be considered. The prognosis should be assessed by two-dimensional Doppler echocardiography, and levels of NT-proBNP, troponin T, and β_2 -microglobulin should be measured. Systemic therapy is appropriate for most patients. Treatment with melphalan and prednisone provides marginal survival benefit for a minority of patients. High-dose dexamethasone therapy with or without melphalan may be beneficial for a subset of patients. The role of thalidomide and lenalidomide is investigational. Bortezomib appears to have significant activity as a single agent.

TABLE 99.5 TOXIC RESPONSES (SOUTHWEST ONCOLOGY GROUP GRADE, ≥ 2)

Toxic Response	Frequency, % (n)	
	200 mg/m ²	100 mg/m ²

Dember et al. ⁵³² and Sanchorawala et al. ⁵⁰³	205 (20 never received transplants)	28/205 (14%)	115/152 (76%) at >12 mo	115 at >12 mo	>	>12 mo	54/115 (47%) CR 18/50 (36%) renal CR at 12 mo

ARF, acute renal failure; CHF, congestive heart failure; CMV, cytomegalovirus; CR, complete response; GI, gastrointestinal; MI, myocardial infarction; NA, not applicable; PR, partial response.

TABLE 99.7 CONTRAINDICATIONS FOR STEM CELL TRANSPLANTATION

- Absolute contraindication
 - Clinical congestive heart failure
 - Total bilirubin >3.0 mg/dl
 - Echocardiographic ejection fraction <45%
 - Troponin *T* > 0.06 ng/ml
 - Relative contraindication
 - Serum creatinine >2.0 mg/dl
 - Interventricular septal thickness >15 mm
 - Age >65 y
 - More than two visceral organs involved
- P.2123

TABLE 99.8 RISK-ADAPTED APPROACH TO STEM CELL TRANSPLANTATION FOR AMYLOIDOSIS

- Low risk (all of the following)
 - 1 or 2 organs involved
 - No cardiac involvement
 - Creatinine clearance \geq 51 ml/min
 - Any age
- Intermediate risk (all of the following)
 - 1 or 2 organs involved
 - Asymptomatic cardiac or compensated cardiac involvement
 - Creatinine clearance <51 ml/min
 - Age <61 y
- High risk (1 of the following)
 - 3 organs involved^a

Advanced cardiac involvement

Melphalan Dosage (mg/m²) Based on Risk Group and Age

Low Risk	Intermediate Risk	High Risk
200 if age ≤60 y	140 if age ≤50 y	Standard therapy
140 if age 61-70 y	100 if age 51-60 y	Clinical trials
100 if age ≥71 y	-	-

^a Organ involvement includes heart, kidney, nerves, liver, and vascular or soft tissue; it does not include bone marrow, skin, tongue, or gastrointestinal tract.

Modified from Comenzo RL, Gertz MA. Autologous stem cell transplantation for primary systemic amyloidosis. *Blood* 2002;99:4276-4282. Used with permission.

FIGURE 99.18. Effect of the number of involved organs on survival. Patients with amyloidosis were eligible for stem cell transplantation but were treated with melphalan and prednisone. MS, median survival. (From Dispenzieri A, Lacy MQ, Kyle RA, et al. Eligibility for hematopoietic stem-cell transplantation for primary systemic amyloidosis is a favorable prognostic factor for survival. *J Clin Oncol* 2001;19:3350-3356. Used with permission.)

The more aggressive approach of stem cell transplantation may have long-term benefits. Response rates with stem cell transplantation approach 60%, and responders have the potential for long-term survival. However, firm evidence-based data that prove the survival benefit of stem cell transplantation do not exist.

Waldenström Macroglobulinemia

Rafael Fonseca

Suzanne R. Hayman

Stephen M. Ansell

INTRODUCTION

Waldenström macroglobulinemia (WM) is a malignancy of mature B cells characterized by a monoclonal IgM in the serum and the presence of lymphoplasmacytic lymphoma (LPL) in the bone marrow.^{1, 2, 3} The disease is now defined at the molecular level by the near-universal presence of mutations of the myeloid differentiation primary response gene MYD88, believed to be the key step in disease pathogenesis. The classical clinical findings in this disease include anemia, organomegaly, lymphadenopathy, and hyperviscosity. The vast majority of patients typically present with a monoclonal IgM in the serum and anemia.^{1, 2, 3} In this chapter, we review the biology and management of WM, including discussions of its preceding state IgM monoclonal gammopathy of undetermined significance (IgM MGUS).

EPIDEMIOLOGY

General Principles

WM is rare in the United States, with only 1,500 new cases diagnosed per year,^{4, 5} an incidence of only one sixth that of multiple myeloma (MM). Although it is now possible to conclusively identify patients by the presence of the MYD88 mutation, this aberration is not exclusively seen in WM⁶ and can be present in other B-cell neoplasms. In future classification schemes for the disease, it is likely that molecular confirmation will be needed. Patients with WM need to be distinguished from patients with a monoclonal IgM in the serum, but no evidence of LPL and no disease-related symptoms or signs (Table 100.1). These patients are felt to have an IgM MGUS.⁷ The disease is slightly more common in males than

females, and more common with advancing age (median age at diagnosis 63 years).⁴ WM is rare in patients of Mexican-mestizo or African descent, and more common among Caucasians.^{4, 5, 8}

Kristinsson identified an association between WM and autoimmunity using a population-based registry from Sweden, finding that WM patients were more likely to have a history of autoimmunity.⁹ This risk was observed both in patients with a personal history of WM, but also in those with a familial predisposition. Among the various autoimmune disorders, Sjögren syndrome and autoimmune hemolytic anemia were notable risk factors for subsequent development of WM. Recent observations by Koshiol and colleagues using a large database from the US Veterans Administration showed that there is a heightened relative risk (RR) for WM among patients who have a history of autoimmunity (RR, 2.23), autoimmune antibodies (RR, 2.3 to 2.5), hepatitis (RR, 3.39), human immunodeficiency virus infection (RR, 12.05), and rickettsiosis (RR, 3.35).¹⁰ Because of the rarity of the disease, these increased relative risks do not pose major consequences for individuals with these conditions. However, these observations present an hypothesis that chronic stimulation may either drive excessive traffic through the germinal center, with an increased risk of clonal establishment or that a cytokine-enriched milieu allows for further expansion of WM precursor clones normally dormant.

TABLE 100.1 RELATION AMONG IGM-MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE, SMOLDERING WALDENSTRÖM MACROGLOBULINEMIA, AND WALDENSTRÖM MACROGLOBULINEMIA

	IgM-MGUS	SWM	WM
Monoclonal serum protein	Usually <1.5 g/dl	Usually >1.5 g/dl	Usually >3 g/dl
Anemia	Not seen	Common but mild	Common
Other cytopenia	Not seen	Rare (15%)	Rare (15%)
Organomegaly	None	May be present	~15-20% of patients
Hyperviscosity	None	None	~15% of patients
Constitutional symptoms	None	None	Present
Bone marrow clonal cells	Usually <5-10%	Usually >20%	Usually >20%
Therapy	Not needed	Not needed	Indicated

IgM MGUS, IgM monoclonal gammopathy of undetermined significance; SWM, smoldering Waldenström macroglobulinemia; WM, Waldenström macroglobulinemia.

Familial Disease and Genetic Predisposition

In some WM, there appears to be a familial component with more than one member of the family affected.^{11, 12, 13, 14, 15, 16, 17} This implies that a single gene defect may be capable of creating heightened susceptibility. The relationship between this heightened susceptibility and MYD88 mutations has yet to be elucidated. McMaster has shown that the prevalence of IgM monoclonal gammopathies is as high as 10% among relatives of individuals diagnosed with WM.¹⁸ They also showed that the risk of monoclonal gammopathy decreases with genetic distance, further indicating genetic predisposition. Linkage analyses that include IgM MGUS have shown positive associations.¹⁹ McMaster studied 11 high-risk WM families with WM informative for linkage and collected DNA samples from 122 individuals. Genotypic analysis using microsatellite mapping showed linkage at chromosomes 1q and 4q. In addition, chromosomes 3 and 6 were also suggested as linked.¹⁹

In another study, Kristinsson and colleagues looked at genetic predisposition for WM by studying 2,144 LPL/WM patients diagnosed in Sweden (1,539 cases with WM (72%) and 605 cases of LPL (28%).²⁰ They compared them with 8,279 population-based matched controls, and linkable first-degree relatives of patients

P.2125

(n = 6,177) and controls (n = 24,609). They reported that first-degree relatives of LPL/WM patients have a 20-fold increased risk for LPL/WM.

To further investigate familial predisposition and environmental factors, Royer and colleagues used a questionnaire-based survey in the hope of identifying environmental influences that could modulate this predisposition.²¹ They analyzed data on 103 WM patients and 272 unaffected relatives from 35 multiple-case WM and 46 mixed WM/B Cell disorders (BCD) kindred and 28 nonfamilial (sporadic) WM patients. Once more, autoimmunity was notable (overall response [OR], 2.27),

as well as infections (OR, 2.13). Other factors identified included farming (OR, 2.70), pesticide exposure (OR), exposure to wood dust (OR, 2.86), and exposure to organic solvents (OR, 4.21). Although the net effect of these risks is small, they do point to possible environmental modification of germline genetic susceptibility.

DIAGNOSIS AND LABORATORY TESTING

The diagnosis in WM is confirmed by the presence of a monoclonal IgM protein in the serum in association with bone marrow infiltration by monoclonal lymphoplasmacytic cells. These diagnostic criteria are the consequence of various consensus meetings to establish standardized diagnostic criteria for WM (see below).²² As mentioned above, the utilization of molecular techniques will likely become essential in the final confirmation of the diagnosis.

The use of the serum monoclonal protein is a cornerstone of disease diagnosis and monitoring, similar to its use in MM. There are multiple laboratory tests that exist for monitoring the serum concentration of the protein. The treating physician needs to be consistent in using the tests that are used for monitored. The serum protein electrophoresis (SPEP) is the preferred method of detecting the monoclonal protein, but quantitative detection of the IgM is also appropriate because the baseline concentration of the normal IgM (polyclonal) is low enough that it does not substantially alter the monoclonal protein concentration. Initially, immunofixation is needed to characterize a new monoclonal protein (in cases where no IgM has been measured) and also to confirm a complete response (CR). In our practice, we measure both the quantitative IgM and the SPEP because discrepancies are sometimes associated with technical aspects of the measurement. The β_2 -microglobulin should be determined, in addition to standard laboratory testing, as it is a prognostic factor for the disease (see below).^{23, 24}

At the time of diagnosis, serum viscosity should be determined and repeated as needed. For any given patient, it is usually possible to determine a level at which an IgM protein will result in hyperviscosity.²⁵ Determining viscosity, therefore, at each visit is not really needed (see section "Hyperviscosity, Neurologic and Retinal Complications"). Urine collections can be performed to measure the monoclonal light chain excreted, but the clinical value of this is not clear. Many series have shown that a significant fraction of patients who have WM can have Bence-Jones proteinuria (i.e., light chains).⁷ For unknown reasons, WM patients rarely develop intrinsic renal failure despite elevated serum-free light chains (SFLC) in some. Perhaps the large size of the monoclonal IgM prevents most of the intact molecule from reaching kidney tubules, unlike myeloma where the intact immunoglobulin molecule can also be detected in the urine, and possibly contributes to cast formation when large amounts of free light chains are excreted. Studies are not available that address the clinical significance of serum-free light-chain detection; however, it is clear that this assay can be used as a surrogate tumor marker as well.

The use of the serum-free light chain (SFLC) has also been explored in WM.²⁶ Leleu studied 72 patients (15 new diagnosis and 57 previously treated) and found a correlation between the serum concentration of sFLC and negative prognostic indicators.²⁷ Itzykson reported on 42 cases of WM (all at diagnosis) and observed similar associations, with elevated levels predicting shorter times to treatment initiation.²⁸ Larger studies are needed to better quantify these associations and associated clinical implications.

It is useful to obtain a computed tomographic (CT) scan of the chest, abdomen, and pelvis at baseline to assess the spleen and liver size and the presence or absence of lymphadenopathy. Obtaining a metastatic bone survey for patients with WM has little value because, in most cases of WM, bone disease is not present. Obtaining a bone survey is recommended in cases with bone symptoms or in those where the bone marrow pathology is purely plasmacytic.^{29, 30, 31, 32, 33} The use of positron emission tomographic scan is not considered routine, but can be useful in determining the extent of disease bulk in selected patients.³⁴ In some cases, discordant results have been observed, however, a global recommendation for its use has not been made. In patients with proven bone lesions, a diagnosis of IgM myeloma rather than WM needs to be considered. Until recently, the entity of IgM myeloma had not been defined at the genetic level, making the distinction between WM and IgM myeloma extremely difficult (see below).

IgM MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE AND SMOLDERING WALDENSTRÖM MACROGLOBULINEMIA

Diagnosis

Having a minimal concentration of a monoclonal protein (e.g., 1.5 or 3.0 g/dl) has classically been required to establish the diagnosis of WM; however, a consensus panel eliminated this requirement.²² The rationale was that having a required minimal concentration could underdiagnose patients early in the course of their disease who may already be symptomatic. It is still unclear how to differentiate IgM MGUS from WM.⁷ Inasmuch as most patients with a monoclonal IgM do not necessarily have WM, better diagnostic tools are needed, perhaps including molecular detection of MYD88 mutations. Asymptomatic patients with a small monoclonal protein and minimal involvement of the bone marrow by

lymphoplasmacytic cells or clonal lymphocytes (e.g., less than 10%), still need to be considered as having an IgM MGUS. Patients like these, according to many epidemiology studies, may have no disease progression for decades.³⁵ One study found that patients with IgM MGUS, as well as patients with asymptomatic WM, have a better survival than patients with symptomatic WM, emphasizing the critical importance of symptoms over laboratory values.³⁶ The importance of segregating IgM MGUS from symptomatic WM is highlighted by this last study.

Evolution to Waldenström Macroglobulinemia from Asymptomatic Stages

The evolution of the monoclonal gammopathy is different for patients with non-IgM disease versus those with IgM MGUS.³⁵ IgM MGUS, in contrast to non-IgM disease, tends to evolve to WM and not to myeloma³⁵ (Table 100.1). Therefore, the greatest risk factor for the development of WM is having an IgM MGUS.³⁵ These patients have a 46-fold greater risk of developing WM than the general population.³⁵ Identification of risk factors for the progression of IgM MGUS is therefore needed. Identification of such risk factors will not only shed new light on the mechanisms of progression, but will also provide a mechanism by which to monitor patients at risk for progression.

In another series, Kyle reported on the outcome of patients with IgM MGUS.³⁷ In contrast to those with non-IgM MGUS, these

P.2126

patients have a heightened risk of progression to WM (and not myeloma per se). He identified a total of 213 patients with IgM MGUS seen at the Mayo Clinic—Rochester from 1960 to 1994.³⁷ These patients were followed for a median of 6.3 years (cumulative 1,567 person-years). Interestingly, a lymphoma not otherwise specified developed in 17 patients (RR 14.8), and WM developed in 6 (RR, 262). Risk factors predictive of progression included the concentration of the serum monoclonal protein and albumin at diagnosis (for progression to lymphoma or a related disorder).

Morra reported on risk factors for progression from IgM MGUS to WM.³⁸ She studied 384 asymptomatic IgMMGUS and a total of 74 other IgM-related disorders.³⁸ At 5 and 10 years, the risk of progression was 8% and 29%, respectively for IgM MGUS. A total of 41 patients evolved to WM after a median follow-up of 45 months. Factors predictive of progression included the extent of bone marrow infiltration, sedimentation rate, hemoglobin, serum concentration of the IgM, and lymphocytosis. However, in the multivariate analysis, only the serum IgM concentration and lymphocytosis remained predictive. Among patients with smoldering Waldenström macroglobulinemia (SWM), the risk of progression seems to be greater in patients who have a monoclonal spike greater than 3 g/dl, and/or a lymphoplasmacytic infiltrate of the bone marrow, greater than 30%, or diffuse infiltration of the bone marrow, or anemia.³⁹ Likewise, Alexanian reported that a hemoglobin less than 11.5, M-spikes greater than 3 g/dl, and an elevated β_2 -microglobulin correlate with a heightened risk of progression.⁴⁰

Gobbi and colleagues reported on a large series of patients with various IgM monoclonal gammopathies.³⁶ A large cohort of 698 patients with IgM gammopathy was subdivided into 4 unique clinical entities; IgMMGUS, SWM, WM, and other IgM-related disorders (excluded from further analysis). Not surprisingly, IgM MGUS and SWM had median survivals similar to that of the general population. The standardized mortality rate for patients with symptomatic WM was 5.4.

Baldini and colleagues evaluated 217 patients with IgM MGUS and another 201 patients with SWM.⁴¹ The median time to progression was not reached for IgM MGUS, and was 142 months for those with SWM (median duration of follow-up of 56 and 60 months). Progression was more likely in patients with elevated serum monoclonal proteins, anemia, and male sex.

Likewise, Greco et al. evaluated risk factors for progression from IgM MGUS and SWM to active disease.⁴² Their series included a total of 287 patients: 201 with IgM MGUS, and 86 with SWM. After a median of 50 months, 32 cases evolved (11.1%): 26 to WM and 6 to other non-Hodgkin lymphoma. In the univariate analysis, risk factors for progression included the degree of bone marrow infiltration, elevated sedimentation rate, the concentration of the serum monoclonal protein, and IgA levels. The highest risk of progression was identified for patients with SWM, serum monoclonal protein ≥ 3 g/dl and/or those with $\geq 10\%$ BM infiltration.

Kyle presented a recent update on the risk of transformation from SWM to WM.⁴³ SWM was defined as those patients having an elevated monoclonal IgM to greater than 3 g/dl and/or greater than 10% involvement of the bone marrow by the clonal process. By definition, these patients must have no evidence of end organ damage (anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly). A total of 48 patients were identified who fulfilled these criteria. After a median follow-up of 15.4 years, a total of 34 patients progressed to WM. In two other patients, other complications were observed (amyloidosis [AL] in one and lymphoma in the other). Based on these data, the cumulative risk of progression was estimated at 6% at 1 year, 39% at 3 years, 59% at 5 years, and 68% at 10 years. Risk

factors predictive of progression included the degree of bone marrow involvement (hazard ratio [HR] 1.31), concentration of the serum M-spike (HR 2.1), reduction of the serum IgA (HR 2.4), and hemoglobin (HR 0.7). As in the Greco et al. study, it seems that progression is a stochastic event and, therefore, tumor bulk (i.e., cells at risk) predicts likelihood of progression.

PATHOLOGY

The WHO classification and the Revised European-American Lymphoma classify WM as LPL because of its immunophenotypic and morphologic characteristics.⁴⁴ Some cases of LPL have no associated monoclonal protein,⁴⁵ a more aggressive clinical course, and a different set of genetic abnormalities.²³ It is now believed that there are several subsets of LPL, of which WM is only one subtype.

Estimation of clonal involvement in the bone marrow is routinely performed at diagnosis with a unilateral trephine aspirate and biopsy. The disease is typically a pleomorphic infiltrate of lymphoplasmacytic cells,^{46, 47, 48} and variability in cell morphology is common (Fig. 100.1). The infiltrate can range from purely lymphocytic to one that is predominantly plasmacytic.^{46, 47, 48} The co-existence of mast cells in association with the lymphomatous infiltrate is a unique feature of WM.^{46, 47, 48, 49, 50} The role of these mast cells as part of the disease pathogenesis has not been fully elucidated. A complex network of interactions between the WM cells and the bone marrow microenvironment has been suggested in preliminary observations.⁵⁰ In addition, infiltration by malignant B cells can be seen in lymphoid structures and multiple other organs (giving rise to organomegaly and lymphadenopathy).⁴⁴ The detection of clonal cells in other organs is not known to have particular prognostic implications; however, clinically evident organomegaly is usually a negative prognostic factor for the disease^{51, 52} and usually indicates a large tumor burden.

The nature of the clonal B-cell populations is remarkable.^{53, 54} Sahota has identified the normal counterpart of WM cells as mature B cells that have undergone somatic hypermutation, but that have not yet completed isotype class switching.⁵⁵ In that particular study, they did not find evidence of intraclonal heterogeneity. It is notable that in many cases of WM, one can observe co-existent populations of monoclonal B cells and plasma cells. Recently, Zehentner and colleagues demonstrated that only in 40% of cases are the clonal B-cell and plasma cell populations related.⁵⁶ Conversely, in 60% of cases, they represent two separate and independent clones. By performing sequencing of the immunoglobulin genes, and in some cases using fluorescence

P.2127

in situ hybridization (FISH) analysis, they conclusively show the separate nature of these clones in 60% of cases.

FIGURE 100.1. Lymphoplasmacytic morphology of the clonal cells of Waldenström macroglobulinemia. As shown in the graph, the cells have variable morphology but most show transition between mature lymphocytes and plasma cell morphology. The cells have been called in the past “plymphs.” The morphology can be variable with some cases showing more extreme plasma cell morphology, whereas others have more lymphocytic predominance.

Flow cytometry is usually indicated as part of the pathologic work-up to make the diagnosis of WM. Flow cytometry is helpful in differentiating WM from other morphologically similar neoplasms, such as mantle cell lymphoma, marginal zone lymphomas, and B-cell chronic lymphocytic leukemia (CLL).^{49, 57, 58, 59} WM cells are characterized by the surface expression of CD19, CD20, CD22,^{49, 57, 58, 59, 60, 61} are light chain restricted, and commonly express CD79a. They are also typically CD10 and CD23 negative, in contrast to follicular lymphoma and B-cell CLL, respectively. The associated plasma cells are monoclonal and express CD138.^{49, 57, 58, 59, 60} CD5 is not expressed on the malignant cells (in contrast to mantle cell lymphoma and B-cell CLL) in the majority of cases; however, some cases can be positive.^{49, 57, 58, 59, 60}

Cell proliferation markers are usually indicative of the indolent nature of the disease. The fraction of cells incorporating 5-bromo-2'-deoxyuridine (BrdU),⁶² indicating cell replication, is usually minimal, and frequently no such fraction is detected at all. The evolution of WM to a more aggressive lymphoproliferative disorder has been previously reported,^{63, 64} and the presence of a highly proliferative fraction may suggest transformed disease. The role of karyotype analysis in the clinical management of patients is not felt to be necessary and, in most patients, the metaphases will be normal.^{65, 66, 67} Therefore, this analysis should be reserved for patients suspected of having treatment-associated myelodysplasia.⁶⁸

WM variants have been described where patients have a similar pathology to WM, but present with IgG monoclonal proteins.⁶⁹ These patients appear to be clinically different from WM and tend to have a lymphocytosis present in the peripheral blood. It is not clear if these diseases have a similar pathogenesis, as only one series of patients with this variant tumor has been reported. Also, some patients have been described as having WM with associated bone lesions.^{29, 30, 33} This makes distinguishing WM from IgM myeloma very difficult. Given the availability of molecular testing that can identify MYD88 mutations and also chromosome abnormalities seen in IgM MM, this distinction should now be possible. If some cases of true WM indeed have bone lesions, it is likely that these will be due to the same mechanisms operative for myeloma.⁷⁰ In a recent study of patients with IgM myeloma, it was found that the t(11;14)(q13;q32) was nearly universally present.⁷¹ Another recent study did not find it as universal, but still common in IgM myeloma patients (38%).⁷² Also, the

t(14;16) (q32;q23) has been reported in one case of IgM myeloma.⁷³ In addition, we have found that translocations of the IGH locus seen in IgM myeloma are not typically observed in patients with WM, and when present, they are secondary genetic events, seen only in cell subsets.⁶⁷ This, along with the new-found mutation of MYD88, clearly separates WM and IgM myeloma as separate disease entities.

BIOLOGY AND GENETICS

Somatic Mutations

There is compelling evidence for a postgerminal center origin of the clonal B cells in WM.^{31, 32, 74, 75, 76} To ascertain the lack of class switch rearrangements involving the mu switch region, we studied cases using a Southern blot assay, with no rearrangements identified (concordant 5' and 3' switch μ bands after digestion).⁶⁷ The aggregate of these studies thus shows that cell arrest just prior to class switching is the likely stage of neoplastic transformation, and genetic defects of the class switch machinery may be involved in the disease pathogenesis. It is important to note that lymphoplasmacytic cells of WM can mature to clonal plasma cells *in vitro*⁷⁷ suggesting that additional mechanisms may play a role.

MYD88 L265P

Just recently, a mutation of the gene MYD88 has been described by Treon et al. in almost all cases of WM.⁷⁸ The mutation is associated with intracellular signaling and is believed to be key in the pathogenesis of the disease.⁷⁸ The prevalence of this mutation in IgM MGUS cases is still being investigated. In the initial reports it was felt to be uncommon in IgM MGUS cases, but the actual prevalence is still being investigated, with some reports showing up to 50% of IgM cases harboring the mutation. The MYD88 L265P activating mutation has been reported in 90% of WM cases.⁷⁸ MYD88 encodes for an adapter protein that affects the interleukin (IL)-1 and Toll-like receptor pathway, and the L265P leads to the dysregulation of the nuclear factor kappa B (NF- κ B) and JAK signaling pathways.⁶

Other Mutations

Two other genes have been found to be inactivated in WM: TNFAIP3 and TRAF3. TNFAIP3 is a tumor suppressor gene whose inactivation results in the constitutive activation of NF- κ B.⁷⁹ We reported biallelic inactivation/deletion of TNFAIP3 in 5% of WM patients.⁸⁰ In addition, 38% of patients were found to have monoallelic deletions of TNFAIP3 with associated diminished transcription of the gene, with proposed associated haploinsufficiency. Inactivating mutations of TRAF3 (located at 14q32.32) have been described and also result in the constitutive activation of NF- κ B in about (~5%) of patients.⁷⁹ TRAF3 is a negative regulator of the noncanonical NF- κ B signaling pathway, with a consequent increase in serine/threonine protein kinase NIK.^{79, 81, 82} Similar observations have been made using novel high-throughput genomic tools.⁸³

6q Deletions and Other Genetic Changes

The most common cytogenetic abnormality in WM is deletion of 6q. We know through multiple studies that in at least one half of cases, large deletions of chromosome 6 are observed in WM by a combination of FISH and aCGH (array comparative genomic hybridization).^{66, 67, 84, 85} Usually, these deletions involve chromosome bands 6q21-q23, with the most commonly deleted being the q23 region. These deletions are clonally selected in the majority of cases.⁶⁷ The clinical relevance of the presence of a 6q deletion has not been well defined, but a recent study suggested that these patients tend to have more aggressive disease and a shorter survival.⁸⁶ These observations, however, need to be confirmed in additional studies.⁶⁷ Although the data are limited, chromosome 6q deletions seem to be rare in cases of IgM MGUS, suggesting that deletions in 6q are involved in the progression to WM⁸⁷ (Fig. 100.2). Although there is no direct link yet made between 6q deletions and MYD88 mutations, and given the ubiquitous nature of the latter,

P.2128

and the high prevalence of the former, it is only logical to conclude that both are important in disease pathogenesis. The second most common observation by aCGH was the gain of 6p (16.6%), always occurring as a secondary event following the loss of 6q.⁷⁹

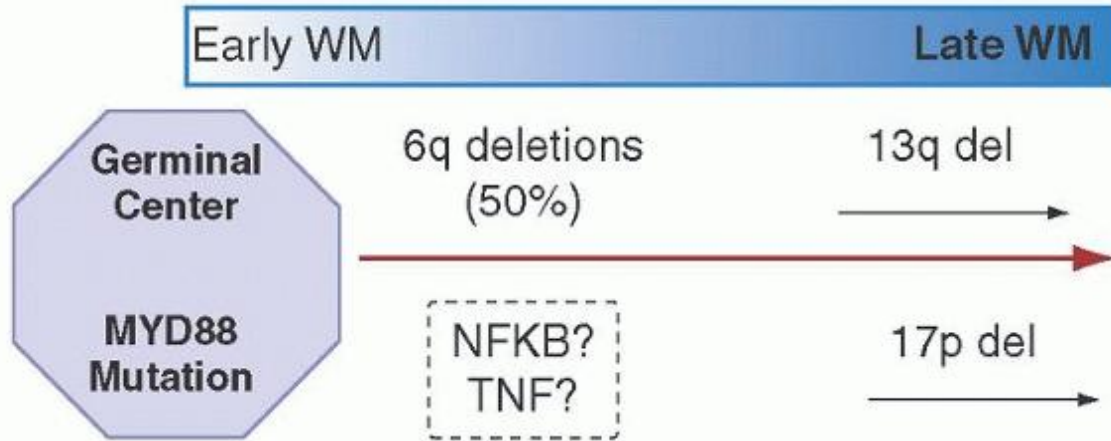

FIGURE 100.2. Biology of progression for Waldenström macroglobulinemia (WM). Mutations of MYD88 are likely founder lesions for the disease. In 50% of cases, deletion of the long arm of chromosome 6 may be the culprit in the initiation of the clonal process of Waldenström macroglobulinemia. In some cases, deletions of chromosomes 13 and 17 may represent progression events. Emerging data suggest that abnormalities of tumor necrosis factor (TNF) and nuclear factor kappa B (NF- κ B) signaling may also be contributing factors in the pathogenesis of the disease.

Originally, due to the presence of LPL in the bone marrow, it was believed that WM must contain the t(9;14)(p13;q32) (described originally in at least 50% of LPL cases, none of which had detectable IgM monoclonal protein).⁸⁸ The t(9;14)(p13;q32) results in upregulation of PAX-5,⁸⁹⁻⁹¹ implicating this gene as a putative oncogene in the pathogenesis of LPL cases without monoclonal IgM.^{45, 92} PAX-5 prevents expression of high levels of immunoglobulin and diminishes production of the J-peptide needed for the pentameric IgM assembly; therefore, the presence of PAX-5 up-regulation by this translocation is inconsistent with the phenotype of WM. In contrast to many other B-cell malignancies, it has been shown that WM never harbors the t(9;14), or any other 14q32 translocations.⁶⁷ In a significant number of cases, review of the karyotype also failed to identify IGH translocations on chromosome 14.^{65, 66, 67} Although some rare cases have clones with IGH translocations,⁹³ these events are now believed to be secondary genetic events associated with disease progression. In most WM cases, the karyotype results are usually normal.^{65, 66, 67, 94, 95, 96}

In sporadic cases of WM, the t(11;18)(q21;q21), usually associated with a subset of marginal zone lymphomas, has been reported.⁹⁷ Using an interphase FISH-based strategy, others have been unable to detect this translocation.⁶⁷ Again, molecular confirmation of MYD88 mutations will be important in redefining whether these entities should be considered under the WM diagnosis. Other chromosomal abnormalities, such as deletions of 17p13.1 and 13q14, are not common at the time of diagnosis, but at the time of disease progression, may be observed in 15% of patients.⁹⁸ The clonal cells of WM are usually diploid,⁶⁷ and this has been confirmed by DNA content analysis in a subset of patients.⁹⁹

Additional data have suggested that WM may have features in common with other disease entities, as well as with MM. At the gene expression level, WM resembles B-cell CLL more than it does MM.¹⁰⁰ In addition, studies of patients with IgM MGUS show clustering together with WM.¹⁰⁰ Furthermore, the clonal cells of WM express high levels of IL-6, which likely would explain the clinical observation of high C-reactive protein levels in the serum of WM patients.^{100, 101} In a manner similar to the anemia of chronic disease, the high levels of IL-6 likely contribute to the anemia, of WM.¹⁰² Experiments of gene expression profiling in WM were performed, separating the CD19+ cells from the CD138+ cells, and have found remarkably similar patterns of gene expression.¹⁰³

Epigenetic Aberrations; Micro-ribonucleic Acid and Histone Acetylation

Roccaro et al. reported on a unique miRNA profile in WM cells, something that was different from the normal B-cell counterparts.¹⁰⁴ Their studies showed that miRNA-363*, -206, -494, -155, -184, -542-3p were up-regulated and miRNA-9* was underexpressed.¹⁰⁴ Many of the predicted targets for these miRNAs include genes associated with the cell cycle, apoptosis, transcription factors and oncogenes. Because of its previous descriptions in other B-cell malignancies, miRNA-155 has been more extensively studied in WM.¹⁰⁴ For a more detailed analysis, the reader is referred to a recent review article.^{105, 106} Likewise, alteration of the balance between histone acetyl transferases and histone deacetylases has been postulated as important in the pathogenesis of WM. This is important as two miRNAs are associated with histone acetylation: miRNA-206 and -9*.¹⁰⁷

Cytokines and B-cell Signaling

A tumor necrosis factor family member, B-lymphocyte stimulator (BLyS), is critical for maintenance of normal B-cell development and homeostasis. Elsawa and colleagues found that WM cells variably express the BLyS receptors BAFF-R, TACI, and BCMA and bind soluble BLyS.¹⁰⁸ Also, they documented elevated serum BLyS levels in patients with WM and expression of BLyS in bone marrow samples by immunohistochemistry.¹⁰⁸ BLyS, in vitro, increased the viability and proliferation of WM cells and stimulated secretion of the monoclonal IgM. She also found that chemokine (C-C motif) ligand 5 (CCL5), granulocyte colony-stimulating factor, and soluble IL-2 receptor are overexpressed in WM, with CCL5 correlating quite closely with the serum levels of IL-6. As mentioned earlier, up to 50% of WM have up-regulation of IL-6, a cytokine critical in B-cell development and implicated in various B-cell malignancies. Furthermore, WM cells also express the IL-6 receptor, and CCL5 results in increased secretion of IL-6 by bone marrow stromal cells in WM, further enhancing IL-6 stimulation, occurring both in an autocrine and paracrine fashion. This stimulation resulted in increased secretion of IgM in a process mediated via JAK/STAT signaling.

AKT

Leleu et al. reported increased activity of AKT in the clonal cells of WM.¹⁰⁹ They also showed that down-regulation of AKT and use of an AKT inhibitor, perifosine, resulted in diminished proliferation and induction of apoptosis.¹⁰⁹

CLINICAL FEATURES

It is best to differentiate the clinical symptoms of this disease based on their causes: those signs and symptoms secondary to the effects of the monoclonal protein and other paraneoplastic phenomena, and those related to the clonal proliferation in the bone marrow and other lymphoid organs.³ It should be noted that most patients with WM have a limited symptom complex at the time of diagnosis, consisting of a monoclonal IgM and various degrees of anemia.^{24, 110} This anemia is often secondary to the clonal expansion of cells in the bone marrow, but may also be due to hyperviscosity (by reducing erythropoietin production) or the increased plasma volume.¹¹¹ In many cases, anemia can be a consequence of treatment. Recent data suggest that some patients may have an anemia secondary to elevated levels of IL-6 emanating from the clonal cells, and will present with a picture reminiscent of the anemia of inflammation.¹⁰⁰ Given the high level of expression of IL-6 and IL-6 receptors in at least half of WM, it is not surprising that elevated levels of hepcidin have been postulated as key mediators in the anemia of WM.¹⁰² In cases with significant involvement of the bone marrow by the WM clonal cells, thrombocytopenia may also be observed.^{24, 110}

In 20% of cases, the clonal cells of WM can infiltrate other organs and result in hepatomegaly and splenomegaly in 15% of patients.^{23, 24, 51, 52, 110, 112} Splenomegaly can result in hypersplenism, with worsening pancytopenia. Although patients may have liver involvement, this is usually asymptomatic. Lymphadenopathy can be seen in 15% to 20% of patients,^{23, 24, 51, 110, 112} and involvement of other organs, such as the lung, can be seen in WM, although this is present in only a minority of cases.^{113, 114}

Hyperviscosity, Neurologic and Retinal Complications

Hyperviscosity is one of the most characteristic features of WM; however, it is only seen in 15% of cases.^{25, 115, 116} The details of the physical properties of the pentameric IgM molecule leading to hyperviscosity have been previously described.^{25, 116} The large dimensions of the IgM molecule make the serum more viscous, and results in slower transit in capillaries.²⁵ The increased viscosity is not just the result of the large size of the IgM molecule, as

P.2129

other large particles such as albumin do not have the same effect on the serum viscosity.²⁵ Although the overt clinical syndrome of hyperviscosity is obvious, subtler symptomatology can also be seen. Typical symptoms include neurocognitive effects (sometimes with overt hemorrhage and neurologic abnormalities), retinal bleeding, and mucosal bleeding in gums and nose. In different patients, different serum concentrations of the monoclonal IgM will give rise to hyperviscosity, and there is no absolute value at which hyperviscosity will be observed.^{25, 115, 116} However, for a given patient, a given IgM level will usually again result in symptoms when the serum IgM reaches that level again.^{25, 115, 116} Despite having a high serum viscosity, some patients will have no symptoms, whereas others will have prominent symptoms at lower viscosity levels. To see symptoms of hyperviscosity at values less than 4 cps is uncommon. In contrast, nearly all patients with a viscosity greater than 8 will be symptomatic, and most patients with a viscosity of 5 to 8 cps will have symptoms.^{25, 115, 116} Also, to have hyperviscosity with an IgM less than 4,000 mg/dl is very rare.²⁵ The patient's hydration and the red cell mass are other factors that contribute to blood viscosity. Red cell transfusions should therefore be used with caution, and sometimes in conjunction with pre-transfusion plasmapheresis, in patients with high IgM concentrations.

Since the original reports by Waldenström,¹¹⁷ neurologic abnormalities in patients with WM have been described (Bing-Neel syndrome). Plasma exchange should be entertained in any patient presenting with a focal or global neurologic deficits that potentially could be attributed to hyperviscosity, even if a clear causal association is not immediately established. The symptoms may be nonspecific and the spectrum can include headache, fatigue, impaired cognition, confusion, stroke, or frank dementia.^{118, 119}

Peripheral neuropathies associated with the presence of monoclonal proteins include, demyelinating polyneuropathy (both associated and not with antimyelin-associated glycoprotein antibodies),^{120, 121} other demyelinating neuropathies, cryoglobulinemia-associated symptoms, and neuropathies associated with light-chain AL. The monoclonal protein, in most cases, has affinity for the myelin sheath and results in demyelination,¹²² which can be observed in up to one half of WM patients with peripheral neuropathy.¹²³ Patients can also have abnormalities of proprioception resulting in ataxia, in addition to the sensory deficits.^{123, 124} Some of the new therapeutic agents, namely bortezomib, can also be associated with treatment-induced peripheral neuropathy. As a direct consequence of the increased viscosity, patients can have retinal complications of WM, and these present on physical examination as venous engorgement, hemorrhage, and cotton-wool exudates.^{125, 126} In some severe cases, WM can precipitate retinal vein occlusion.^{125, 126}

Clinical features of light-chain-associated AL can develop in some patients with WM.^{7, 127, 128} In these cases, there appears to be a higher incidence of pleural and pulmonary AL, and a greater tendency for amyloid-associated cardiomyopathy than in other AL cases (44% vs. 27%).^{127, 128} In these patients, therapy should be tailored to control the WM rather than the AL. The fact that AL can be observed in association with WM suggests that AL is merely a complication of any monoclonal protein-producing neoplasm.

PROGNOSIS

The prognosis of WM is highly variable, and until recently, there were few models validating putative prognostic factors. The median survival for patients with WM has been estimated to be 5 years,^{51, 68} however, 10% of patients remain alive at 15 years.⁶⁸ Although the survival appears short for a disease felt to have an indolent nature, the fact that patients present at an advanced age presents a significant problem in determining the survival associated with this disease. The precise disease-specific survival is often difficult to determine, as these patients have “competing causes for death.” One study addressed disease-specific survival associated with WM, with the median felt to be closer to 11.2 years.⁵² In this study, organomegaly and age > 65 years were associated with poor prognosis in a multivariate analysis. Similarly, a longer survival of 108 months has been reported in another series, suggesting that this disease may truly behave in an indolent fashion.¹²⁹ It is likely that the survival of patients continues to increase given the availability of various new therapeutic classes of agents.

Several prognostic models for WM have been previously proposed. Morel⁵¹ and Facon¹¹⁰ studied 232 patients treated prior to 1989 (mostly alkylators and no purine nucleoside analogues [PNAs]). They found that the prognostic factors associated with a shorter survival were age > 65, albumin < 40 g/L, hemoglobin < 12 g/dl, platelet count < 150 × 10⁹/L, and WBC < 4 × 10⁹/L. They developed a prognostic model based on a point system that discriminated groups with different outcomes. If the patients had one cytopenia, they were assigned 1 point, and if they had two or more, they were given 2 points. The proportion of patients alive at 5 years was 87% (0 to 1 points; 27% of cases), 62% (2 points; 27% of cases), and 25% (3 to 4 points; 46% of cases) for the low-, intermediate-, and high-risk groups, respectively. Differences in outcome based on time of therapy initiation (initial observation vs. initial treatment) were not found in this series. It is interesting that they did not find systemic symptoms, pathologic features, or splenomegaly to be useful in determining prognosis. This prognostic model has been further validated by Kyrtsonis¹²⁹ and by the same group (Morel and colleagues) in a separate cohort of patients with advanced WM.¹³⁰

A second model was developed by Gobbi and colleagues.¹³¹ They were able to show that the following variables were associated with a shorter survival: anemia (hemoglobin less than 10 g/dl), age greater than 70, weight loss, and cryoglobulinemia.¹³¹ This model divided patients into low- and high-risk groups, the latter defined by patients having two or more adverse prognostic factors.

Dhodapkar proposed a different model, studying 182 patients treated with fludarabine in a clinical trial.²³ He showed that patients with an elevated serum β_2 -microglobulin (≥ 3 mg/dl), low hemoglobin (<12 g/dl), and low IgM (<4,000 mg/dl) fared the worst. From this model, it is unclear why patients with a lower concentration of the monoclonal protein would fare worse; but it may be explained by the inclusion of patients with LPL, which may be a different biologic entity. In a follow-up report, they reported that overall survival (OS) and event-free survival in the presence of lower levels of serum β_2 -microglobulin were significantly longer in all cohorts.¹³² It is interesting that achieving a response, or the time needed

to achieve this response, did not predict event-free survival or OS.¹³² Unfortunately, the Dhodapkar model was not reproduced in a series of patients with advanced WM reported by Levy and colleagues.¹³⁰

Recently, Dhodapkar updated the SWOG series, with a median follow-up of 10 years for live patients.¹³³ Of the 59 previously untreated patients who initially were observed, only 12 patients (21%) required therapy, at a median follow-up of 100 months.¹³³ Among the 183 patients requiring therapy, the long-term observations confirmed that advancing age (>70), previous treatment, and the serum concentration of β_2 -microglobulin (3 mg/dl or greater) were negative factors, but with additional follow-up, an elevated serum LDH became important too. They propose a new and improved model that uses advanced age, β_2 -microglobulin, prior treatment, and LDH (above upper limit of normal) to segregate patients into 3 groups, with 8-year OS of 55%, 33%, and 5% ($P < 0.001$). In the multivariate model, a low serum monoclonal protein did not remain significant.

P.2130

TABLE 100.2 INTERNATIONAL PROGNOSTIC INDEX

Factors Associated with Prognosis	Value
Age (years)	>65
Hemoglobin (g/dl)	≤11.5
Platelet count (n/μl)	≤100,000
β_2 -Microglobulin (mg/L)	>3
Monoclonal IgM (g/dl)	>7

Risk Stratum and Survival		
Risk Category	Score	Median Survival (Months)
Low	0 or 2 (except age)	142.5
Intermediate	2 or age >65 years	98.6
High	>2	43.0

One point is assigned for each risk factor and the risk score is the sum of these factors. Adapted from Morel P, Duhamel A, Gobbi P, et al. International prognostic scoring system for Waldenstrom macroglobulinemia. *Blood* 2009;113:4163-4170 and Morel P, Duhamel P, Gobbi PG, et al. International prognostic scoring system for Waldenstrom macroglobulinemia. *Haematologica* 2007;92:84.

An international effort has been focused on the development of an international prognostic model for WM. A total of 587 patients were entered into this model who fulfilled the diagnostic criteria recommendations by the Second International Workshop of WM.^{134, 135} In the univariate model, seven factors were associated with a shortened survival, and included age over 65, platelet count ≤ 100 (n/μl), β_2 -microglobulin greater than 3 mg/dl, M-spike greater than 7 g/dl, granulocytes ≤ $1.5 \times 10^9/L$, hemoglobin ≤ 11 g/dl, and albumin ≤ 3.5 g/dl.

An updated model has been published by the same group.¹³⁶ Using a bootstrap analysis, the following factors were selected to develop a risk-factor-based classification: age, hemoglobin, platelet count, β_2 -microglobulin, and M-spike.¹³⁶ Low risk was defined as having only one risk factor or less, high risk as having greater than two, and all others, intermediate, or if only age was greater than 65. The 5-year survival rates were 87%, 68%, and 36% ($P < 0.0001$). (Table 100.2)

CONVENTIONAL TREATMENTS AND MANAGEMENT

No standard response criteria in WM have been available until recently. A consensus statement regarding criteria for response was published and subsequently updated.^{137, 138} Aside from defining CR and PR (partial response), these criteria define a “minor response” (MR) category, thereby recognizing that patients may sometimes have a dramatic clinical

improvement with only a minor decrease in the serum monoclonal protein. The criteria also stressed the importance of delayed responses and recommended an assessment of response over an extended duration follow-up period.

The development of novel therapeutics in WM has had to rely solely on the results of clinical trials, as no good pre-clinical models for the study of WM have existed. Clinical trials have had slow accrual rates due to the small numbers of patients with this disorder, and many therapeutic strategies have been extrapolated from observations in other lymphoid neoplasms. A potential pre-clinical model of WM was published by Tassone and colleagues.¹³⁹ They were able to develop a SCID-Hu murine model that mimics human WM. Human fetal bone grafts (embedded subcutaneously) were used to support the ex vivo growth of WM cells. In this study, the model reflected the usual response to rituximab as is observed in patients. It is hoped that this model will allow pre-clinical testing of novel compounds or combinations for use in WM prior to initiating clinical studies.

Observation

Many patients with WM may not be in need of immediate treatment, and for many, the disease may follow an indolent course.^{23, 36, 131} Although no specific criteria exist, the absence of overt symptoms or complications may be used as reason for continuing careful monitoring of patients. Because WM is considered an incurable malignancy, the goal of treatment must be to provide symptom relief for patients, as those without symptoms are not known to benefit from therapy. This paradigm has, however, been challenged in other similar disease settings, and it is possible that in the future, recommendations will be made for the treatment of the asymptomatic patient with impending progression. Previous studies have clearly described pre-symptomatic stages for WM (including IgM MGUS),^{36, 117, 140} and the treating physician should first decide whether the patient really needs therapy.

Alkylating Agents

Classic Alkylators

Chlorambucil is a well-tolerated oral agent used in the treatment for WM.¹⁴¹ This drug is currently used in selected situations, predominantly in the treatment of the elderly, given the high tolerability of the drug, its ease of administration, and despite the leukemogenic potential. For a summary of response rates of most published clinical trials in WM, see Table 100.3. The aforementioned study by Facon (n = 167), demonstrated a median survival of 5 years for patients treated with chlorambucil as initial therapy.¹¹⁰ The only prospective randomized phase III clinical trial for WM patients was performed at Mayo Clinic by Kyle and colleagues.⁶⁸ In this study, patients received oral chlorambucil, either continuously at a dose of 0.1 mg/kg/day, or pulsed doses in an intermittent fashion every 6 weeks (0.3 mg/kg/day for 7 days). The median OS was the same (5.4 years, P NS) and the response rates between both groups were similar (79% and 68%, respectively; P NS). This is the first trial that highlighted that response to any therapy in WM can occur late, and that usually at least 6 months of therapy are needed prior to concluding lack of efficacy.⁶⁸

Other alkylator-based combinations, such as VBMCP (vincristine, carmustine, melphalan, cyclophosphamide, and prednisone), have resulted in high response rates.^{142, 143, 144} In recent years, alkylators have been used less frequently, as a result of a study by Leblond and colleagues that showed the superiority of fludarabine over a cyclophosphamide containing regimen (higher response rate and duration of response),¹⁴⁵ and a number of other therapeutic options for patients. In addition, the risk of myelodysplasia with long-term use makes alkylators a less desirable option for younger patients. However, given the convenience of oral dosing and the minimal toxicity, alkylators are particularly suitable for the elderly.

Bendamustine

Bendamustine has been used with success in the treatment of WM. Rummel reported on the use of bendamustine in low-grade B-cell lymphomas, which included patients with WM. In a phase II study (n = 63 patients) of mantle cell lymphoma and low-grade B-cell neoplasias, he reported an overall response rate (ORR)

P.2131

of 90% with 60% CRs.¹⁶⁸ In a larger study, Rummel compared bendamustine in combination with rituximab, with cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) chemotherapy.¹⁶⁹ Of a total of 546 patients, 40 had WM.¹⁶⁹ Among WM patients the ORR was 96% for bendamustine-R and 94% for R-CHOP. After a median of 26 months, 87% of bendamustinetreated patients, (20/23) remained free of progression, and only 53% of those treated with R-CHOP were so (9/17) (M Rummel, International WM Workshop, 2012). Treon et al. reported on a retrospective analysis of 30 previously treated WM patients who received bendamustine.¹⁷⁰ Bendamustine was given on days 1 and 2 of a 28-day cycle, along with rituximab (in most cases, n = 24). The median number of treatment cycles was 5. The reported ORR was

83%, with 5 (17%) very good partial responses (VGPRs) and 20 PRs (67%). The estimated median time to progression was 13 months. The contribution of the addition of rituximab still needs to be elucidated. In at least a quarter of patients, therapy had to be discontinued due to toxicity, and sometimes, prolonged myelosuppression.

TABLE 100.3 TREATMENT REGIMENS

Investigator	Regimen	N	Response Rate (%)
Alkylators/Cytotoxic			
Facon ¹¹⁰	Chlorambucil	167	75
Kyle ⁶⁸	Chlorambucil	22-24	68-79
Case ¹⁴³	VBMCP	33	82

Treon ¹⁶⁷	Rituximab	30	27

Purine Nucleoside Analogues

Fludarabine

Among the most active agents available for the treatment of WM are PNAs. Most patients treated with PNAs will respond within 3 to 6 months of therapy initiation, however, a small fraction of patients will show delayed responses (5% after 12 months).¹⁷⁰ Kantarjian first reported the treatment of 11 patients with fludarabine (10 previously treated) and 5 responded, having a median duration of response >1 year.¹⁴⁶ Dimopoulos, in a later publication, reported on the treatment of 28 patients (only 2 were treatment naive) where he showed a response rate of 36%,¹⁴⁷ and many of the responses were durable (median duration of response 38 months). Leblond reported on the treatment of 71 patients with relapsed WM treated with a median of 6 cycles of fludarabine, resulting in a response rate of 30% (21/71 cases).¹⁴⁹ In a separate study, 78 patients with previously untreated WM were given fludarabine at 25 mg/m² daily, for 5 days every 4 weeks¹⁵¹ resulting

P.2132

in an ORR of 79% (15% CR), many of them durable (median 30 months). The treatment-related mortality was 5% in this study, predominantly due to infection. It should be noted that patients treated with almost all active agents in WM, including PNAs, can take a long time to respond to treatment,¹⁷¹ and concluding early in the treatment course that a therapy has failed may be a mistake.

These high response rates were, unfortunately, not confirmed in a subsequent larger series. Dhodapkar studied 231 patients of whom 182 required therapy, 118 were treatment naive, and 64 were relapsed cases.²³ Patients treated with 4 to 8 cycles of fludarabine at a dose of 30 mg/m² daily for 5 days repeated monthly. They reported a response rate of 36%, and only 2% of cases were complete responders. Prior treatment did not predict for a lower likelihood of response, but older age was associated with a low likelihood of response. The treatment-associated myelosuppression led to a 4% mortality from infections, similar to what was previously reported. It should be noted that the use of purine nucleoside analogues should be done with caution in patients needing to collect hematopoietic stem cells.¹⁷² More recently, the development of treatment-associated myelodysplasia has been reported in patients treated with fludarabine combinations, although the definitive risk of development has yet to be defined.¹⁷³

A prospective randomized trial comparing fludarabine against chlorambucil is ongoing, and was reported in a preliminary fashion at the 2011 ASH meeting.¹⁷⁴ Leblond reported that fludarabine is more effective than chlorambucil as initial therapy for WM, including significantly greater disease-free survival (DFS), progression-free survival (PFS), and OS. Patients were randomized to 8 mg/m² oral chlorambucil administered for 10 days every 28 days (to a maximum of 12 cycles), or to 40 mg fludarabine (5 days every 28 days for a maximum of 6 cycles). Response rates were higher with fludarabine than with chlorambucil (PR 47% vs. 41%; CR 6% vs. 2%, NS). Fludarabine resulted in a significant advantage in PFS (36.3 vs. 27.1 months; P = 0.012), DFS (38.3 vs. 19.9 months; P = 0.0005) and OS at 5 years (69.4% vs. 61.8%; P = 0.046). The median duration of response was longer with fludarabine (38.3 vs. 19.9 months; Leblond Personal Communication IWMW, August, 2012). Negative predictive factors included, age >70, low albumin (<4 g/dl), and treatment arm (OR 1.34). The main toxicity was, as expected, greater myelosuppression in the fludarabine arm. She also reported that secondary malignancies were less common in the fludarabine arm (3.7% vs. 21% at 6 years). This trial included other entities other than WM, such as LPL and marginal zone lymphomas.

Cladribine (2-Chlorodeoxyadenosine)

Cladribine also has documented activity against WM and is structurally similar to fludarabine. In one series, Dimopoulos treated 29 patients with a continuous intravenous infusion of 2-CDA (2-chlorodeoxyadenosine) 0.1 mg/kg/day for 7 days, for a total of two courses.¹⁵⁸ An ORR of 59% (100% in previously untreated patients; 40% for relapsed patients) was reported. Likewise, Delannoy and colleagues reported an ORR of 39% in 18 patients treated with cladribine.¹⁵⁹ Cladribine can also be administered intermittently, obviating the need for an intravenous central catheter with similar response rates.¹⁵⁶ Using the intermittent schedule, Liu et al. reported a median duration of response of 28 months. In another study, the OR to cladribine was 41% in 22 patients with WM.¹⁶¹ A very high response rate was seen in 10 newly diagnosed patients treated with 2-CDA (followed by interferon). In this study, all patients responded (1 CR, 8 PR, and 1 MR).¹⁵⁷ Another multicenter study treated 25 naive patients, and attempted to use a longer duration of cladribine, for up to 6 cycles (median 3 cycles).¹⁷⁵ They reported a response rate of 40%, with a median remission duration of 8 months.

Very limited data exist documenting the value of using different PNAs in patients who progress after treatment with a purine analogue.¹⁷⁶ In one study, 14 patients were treated with cladribine after prior fludarabine exposure. Only 1 of 10 patients with fludarabine-resistant disease responded. In the patients who had demonstrated a previous response (and subsequently progressed) to fludarabine, however, 3 of 4 patients responded. In another study, 6 patients were treated with fludarabine who were resistant to cladribine, and 2 responded.¹⁷⁷ It seems who those who are refractory to a PNA, overall, are unlikely to respond to an alternate agent in this class.

Monoclonal Antibody Therapy

Rituximab

All WM cells express CD20, which allows for the use of anti-CD20 monoclonal antibody-based strategies. Initial studies using rituximab documented a tumor burden reduction, resulting in improved cytopenias,¹⁷⁸ neurologic symptoms,¹⁷⁹ and a decrease in the clonal cells in the bone marrow.¹⁸⁰ Byrd and colleagues then documented PRs to rituximab by treating seven patients with relapsed disease.¹⁶⁶ Treon and colleagues also treated 30 patients with relapsed disease,¹⁶⁷ 14 of whom (47%) had been previously treated with a PNA. They showed convincing evidence of antitumor activity by documenting reductions of the serum monoclonal protein (median IgM decline 2,403 to 1,525 mg/dl), increases in the hematocrit (19/30, 63%), and increases in the platelet count (15/30, 50%). In Treon's study, the ORR was 60%, with 8 of 30 patients achieving a PR (27%).¹⁶⁷ Dimopoulos treated 27 patients with rituximab (15 that were treatment naive) with 4 infusions at standard doses (375 mg/m²).¹⁶⁴ Patients received an additional 4-week course 3 months after the first course, if they had not progressed. The probability of response was the same in relapsed patients as in treatment-naive patients (44%), with a median time to response of 3.3 months and a median duration of response of 16 months.

It has become clear that the best response to rituximab may be seen only after several months of drug administration. We believe that the true clinical benefit of rituximab may be greater than that originally reported in these clinical trials because the response rates may have been underestimated due to the responses being evaluated too early in the treatment course. This delayed response effect is likely to be observed with other biologic therapies as well. This delayed effect was partially addressed by administering an extended course of therapy with rituximab in a study by Treon.¹⁸¹ Treon et al. evaluated the administration of 8 cycles of rituximab (as opposed to four infusions) in this study. They reported on 26 patients who completed the intended therapy: 14 (48.3%) patients had a PR, and 5 (17.2%) patients achieved an MR. The median time to best response was 17 months, with 2 of 19 responding patients subsequently progressing at the time of the report (median follow-up of 29 months).¹⁸¹

The identification of patients likely to respond to therapy has become of paramount importance given the increased usage of rituximab. Because of its overall ease of administration it is important to recognize those patients who are not likely to respond, and in whom pursuing other treatment alternatives may be preferable. Dimopoulos reported on the higher likelihood of response to rituximab among patients with lower serum IgM (<4 g/dl) and higher β_2 -microglobulin.^{182, 183} Although the median time to progression was 14 months, these variables predicted patients with shorter duration of response.¹⁸² In the study by Treon et al., patients were more likely (75% response rate, 18/24 cases) to respond to rituximab monotherapy if they had an IgM of <6,000 mg/dl, compared to a response rate of only 20% with higher protein concentrations.¹⁸¹ Polymorphisms in the Fc γ receptor have similarly been postulated to predict the likelihood of response.¹⁸⁴

Rituximab has become the de facto first-line treatment for most patients with WM because of a favorable profile and

P.2133

risk-benefit ratio.¹⁸⁵ In addition, rituximab can be easily combined with other chemotherapeutic agents because of the lack of additive toxicity, and is now commonly used in combination regimens for WM. Also, rituximab retains activity when patients are given repeated courses of therapy and can be administered in a maintenance fashion. Unfortunately, the use of radiolabeled anti-CD20 monoclonal antibodies is limited in WM due to the larger extent of bone marrow involvement by the clonal cells and the risk of significant toxicity. A strategy for using radiolabeled monoclonal antibodies will therefore require an initial "debulking", with clearance of the bone marrow using rituximab or other agents, followed by the use of a radioactively labeled monoclonal antibody.

A total of 50% of patients will have a paradoxical rise of the monoclonal protein after rituximab administration: the so-called rituximab flare.^{186, 187} This phenomenon was first reported in two patients treated with cladribine,¹⁸⁸ but has been reported more frequently in patients treated with rituximab. The elevations of the serum concentration of the IgM can be of such magnitude that patients might experience symptoms of hyperviscosity. Patients who have higher concentrations of the IgM should be considered for prophylactic or concurrent plasmapheresis when treated with rituximab.¹⁶⁴ Reports

have also emerged of patients who have worsening of peripheral neuropathy after treatment with rituximab, and the hypothesis is that this is also a manifestation of the flare phenomenon.^{189, 190, 191}

Rituximab Maintenance

Treon has shown the benefit of maintenance rituximab in patients with WM.¹⁹² He studied 248 rituximab-naive WM patients who showed disease sensitivity after receiving rituximab. Of these 86, (35%) went on to receive maintenance. In 36 of 86 (41.8%) patients receiving maintenance, the quality of the responses improved. PFS (56.3 vs. 28.6 months; $P = 0.0001$) and OS (not reached vs. 116 months; $P = 0.0095$) were longer for patients receiving maintenance. Although this study was retrospective, it does provide compelling evidence to consider rituximab maintenance after prior rituximab-containing regimens.¹⁹² Prospective studies will be needed to address this question fully in WM.

Corticosteroids

WM historically has not been considered a steroid-responsive malignancy; however, reports exist suggesting that steroids alone can be beneficial, particularly in patients who are not candidates for cytotoxic therapy or who have severe pancytopenia. Steroids have also had an additive effect when used in combination with other agents. Gomez et al. treated two patients with WM with vincristine, 0.25 mg/m², and bleomycin, 5 units, given for 4 consecutive days with prednisone, 1,000 mg/m², given orally on alternate days.¹⁹³ In both patients, the bone marrow tumor cell infiltration was reduced by 50% (remission duration 4 to >35 weeks) and they had a greater than 50% decrease in the M protein. Two additional patients with resistant WM demonstrated marked decreases in viscosity and total M protein after short periods of high-dose dexamethasone.¹⁹⁴ Steroids have been reported to be particularly useful in patients with WM with an associated cryoglobulin because of their anti-inflammatory properties and effect on immune complex vasculitis.¹⁹⁵

Combination Therapy

Overview

Despite an overall higher response rate to combination therapy for the up-front treatment of WM, its ultimate clinical worth is clouded by the difficulty of being able to document an impact on patient outcome due to the indolent nature of WM. The response rates undoubtedly seem superior with combination strategies and the duration of response is also likely to be longer. However, these combinations burden patients with additional toxicities. How does one decide on the best treatment approach for patients? Most trials available for WM are phase II clinical trials with a primary endpoint of ORR, but no assessment of long-term outcome. Therefore, the identification of novel combinations capable of retaining a favorable toxicity profile and increasing the duration of response would likely constitute significant progress in this field. Combinations that include rituximab would seem most likely to increase the quality and duration of responses and result in the best safety profile. At a minimum, combination therapies need to show a very substantial enhancement of OR to be considered suitable for use in the "off-study" setting.

The value of combination treatment has been the focus of a recent panel review.¹⁷⁰ This review stressed that the results of combination strategies were encouraging enough that they would be considered reasonable treatment¹⁷⁰ options for patients with WM (alongside extended treatment with rituximab) in a nonstudy setting. However, the panel properly recognized the need for additional clinical trials to better evaluate their clinical utility. For patients with evidence of slowly evolving progression, but no significant cytopenias or organomegaly, it would seem that single-agent rituximab may be more appropriate than combination approaches. Combination strategies should be considered for individuals in need of rapid reduction of tumor burden. Secondary gains, such as blunting of a rituximab flare, will also have important practical implications that may favor the use of secondary agents with rituximab.

Purine Nucleoside Combinations

In an attempt to combine PNA with alkylating agents, Laurencet and colleagues used IV cyclophosphamide 500 mg/m² and oral prednisone monthly, in combination with 2-CDA at 0.1 mg/kg/day SQ, for 3 consecutive days, for up to six courses.¹⁶² The ORR was 88%, with grade 4 neutropenia seen in 11% (2/19) of patients, but no treatment-related deaths. A dose-escalation study of the combination was subsequently performed: 2-CDA 5.6 mg/m² QD was given as a 2-hour IV infusion, followed by a 1-hour infusion of cyclophosphamide QD for 3 days.¹⁹⁶ A dose of cyclophosphamide 200 mg/m² was given initially and was escalated in 100 mg/m² increments. The maximal tolerated dose of cyclophosphamide was 300 mg/m², and an ORR of 58% was seen. Neutropenia was the dose-limiting toxicity and severe infections were seen in 4% of cycles. A total of 31% of patients could not be given repeated cycles because of prolonged thrombocytopenia.

Tamburini and colleagues described 49 patients with WM treated with cyclophosphamide and fludarabine, 14 of whom were treatment naive.¹⁵³ The doses used were cyclophosphamide 300 mg/m² IV and fludarabine 30 mg/m² IV, days 1 to 3, every 4 weeks, for a median of 4 cycles. The ORR was 78% (38/49 cases all PRs), 2 had progressive disease, and 9 had

stable disease. The median time to treatment failure was 27 months. It is interesting that the two factors associated with an adverse outcome were a serum monoclonal protein concentration of less than 4 g/dl and age greater than 65 years (an observation previously made in the Dhodapkar model, but not repeated since).²³

Purine Nucleoside, Alkylators, and Rituximab Combinations

Hensel and colleagues reported on 14 patients with WM treated with the combination of pentostatin, cyclophosphamide, and (in 8 cases) rituximab.¹⁹⁷ There were eight patients who had been

P.2134

previously treated with 1 to 3 regimens, and nine patients were untreated. Patients received pentostatin 4 mg/m² plus cyclophosphamide 600 mg/m². Rituximab was administered at the standard dose of 375 mg/m² on day 1 (every 3 weeks). Two patients achieved a CR (12%) and the ORR was 65%. The ORR for patients receiving rituximab was increased at 77%. Three patients had further improvement with additional follow-up.

Tam and colleagues described a group of 18 patients with WM treated with fludarabine, cyclophosphamide, and rituximab (FCR) (n = 5); fludarabine plus mitoxantrone (n = 3); plus cyclophosphamide (n = 9); or rituximab alone (n = 1).¹⁹⁸ The median response duration in this study was 38 months, with an ORR of 76%. In a follow-up report, they expanded the report to include an additional nine patients with WM who were treated with the same FCR combination. The attained ORR was 56% (5/9 patients), but no CRs were observed.¹⁵⁵

Weber and colleagues have reported on the combination of Rituximab (375 mg/m² q week × 4 weeks), cyclophosphamide (40 mg/m² PO BID for 7 days), plus cladribine (1.5 mg/m² SQ TID for 7 days), repeated at 6 weeks.^{138, 199} With a median follow-up of 69 months, they reported an ORR of 94% and a CR rate of 17%.^{138, 199} The median time to remission was reported at 2.4 months, with duration of remission of 58.6 months, clearly surpassing the median response duration of 26 months reported by the same authors when the combination did not include rituximab. Likewise, the time to re-treatment was not reached at 56.3 months when the combination without rituximab was used.^{138, 199}

Tedeschi reported on a phase II trial of the combination of fludarabine, rituximab, and cyclophosphamide.²⁰⁰ A total of 43 WM patients (new diagnosis and previously treated) received rituximab on day 1; and fludarabine 25 mg/m² and cyclophosphamide 250 mg/m² intravenously on days 2 through 4. Treatment was administered monthly and patients could receive a total of up to 6 cycles of treatment. The ORR was 79%, and the quality of responses was high: 12% of patients achieved a complete remission and 21% had a very good partial remission. However, nearly one half of patients (45%) had grades 3 and 4 neutropenia, and in a similar proportion, this neutropenia was long lasting. Only one patient had progressive disease.

Dimopoulos and colleagues have also explored the combination of rituximab (375 mg/m² repeated every 21 days for a total of 6 cycles) plus cyclophosphamide (100 mg/m² PO BID for 5 days), given with concurrent dexamethasone (20 mg IV).²⁰¹ They report an OR of 70% with 7% of patients achieving a CR. With a median follow-up of 24 months 60% of patients remain free of progression.

A study by Treon addressed the therapeutic benefit of rituximab combined with CHOP chemotherapy.²⁰² There were 13 patients with WM who were treated with R-CHOP, 10 of whom had been previously treated.²⁰² The intended treatment was 6 cycles, and then they received rituximab as maintenance therapy. They reported 3 CRs, 8 PRs, 1 MR, and concluded that the regimen was highly effective. Currently, an Eastern Cooperative Oncology Group study is testing the combination of bortezomib, rituximab, dexamethasone, and temsirolimus in relapsed WM (and other malignancies) in a phase I/II study.

New Treatment Options

Thalidomide and Lenalidomide

Thalidomide is an antiangiogenic and immunomodulatory agent that has been found to be effective as salvage therapy of MM.²⁰³ Dimopoulos and colleagues have reported the results of a phase II trial of thalidomide for 20 patients with WM (10 untreated, 10 previously treated).²⁰⁴ Patients received thalidomide 200 to 600 mg/day and the ORR was 25% (5 of 20 patients, 2 previously treated). The time to progression was less than 3 months however, suggesting that thalidomide as a single agent has minimal activity in WM. One study by Treon and colleagues explored the combination of lenalidomide with rituximab as primary treatment for WM. Although 50% showed antitumor activity, there was a sharp drop in hematocrit in most patients, and further study of the combination is warranted.²⁰⁵

Bortezomib

Responses to the proteasome inhibitor, bortezomib, have been documented in WM. Bortezomib's precise mechanism of action is largely unknown, although it is thought to exert its antitumor effects by deregulating the NF- κ B pathway. Bortezomib has been used alone or in combination with rituximab and corticosteroids.

Dimopoulos and colleagues reported on the use of bortezomib in patients with WM.²⁰⁶ They used the medication in 10 previously treated patients (3 patients treated with 3 prior lines of therapy) and 6 achieved a PR.

Treon reported on the outcome of bortezomib as treatment for relapsed and refractory WM in a multicenter study (WMCTG Trial 03-248).²⁰⁷ A total of 27 patients were treated with single-agent bortezomib on days 1, 4, 8, and 11. The OR was 85% with 13 (48%) patients achieving a major response, and 10 (37%) patients having an MR. The median time to response was 1.4 months. The main toxicity was sensory peripheral neuropathy: grade 2 in 5/27 (22.22%) and grade 3 in 6/27 (22.2%) of patients. The study reported that, in most cases, peripheral neuropathy improved after treatment. In a recent study, Chen and colleagues treated symptomatic WM patients (treatment naive and relapsing) with bortezomib at doses 1.3 mg/m² intravenously days 1, 4, 8, and 11 on a 21-day cycle. The response rate in this study was low (26%), probably due to treatment discontinuation due to neuropathy. There were 20 patients (74%) who developed new or worsening peripheral neuropathy (5 patients with grade 3, no grade 4).^{208, 209}

Bortezomib has also been used in combination strategies against WM. Treon and colleagues were able to show a high response rate, including CRs, in one study of bortezomib in combination with rituximab and dexamethasone.²¹⁰ They treated 23 patients with bortezomib, weekly dexamethasone at 40 mg, and rituximab 375 mg/m² on day 11. The treatment schedule first used an induction phase with monthly cycles, followed by maintenance treatment (one same treatment) every 3 months.²¹⁰ The reported ORR was 96% with 83% of patients attaining a deep response (3 CR, 2 near CR, 3 VGPR, 11 PR, and 3 MR). At a median duration of follow-up of 23 months, 78% of patients remained free of disease progression (18 of 23). As is true in other situations where bortezomib is used, herpes zoster was a common complication. All patients treated with bortezomib should receive acyclovir-based prophylaxis. Similar results have been reported by Ghobrial in two separate phase II trials addressing the role of bortezomib, but administered in a weekly schedule to prevent peripheral neuropathy, in combination with rituximab, in both treatment-naive and previously treated WM.^{211, 212} For untreated patients (n = 26), she reported a MR or better in 23 (88%) with 1 CR (4%), 1 near CR (4%), 15 PR (58%), and 6 MR (23%). She also reported an estimated 1-year event-free rate of 79%, and no grade 3 or 4 peripheral neuropathy.²¹¹ Among previously treated patients, (n = 37) an MR or better was observed in 81%, 2 CR or near CR (5%), 17 in PR (46%), and 11 (30%) in MR.²¹² The median time to progression was 16.4 months. Peripheral neuropathy was again lessened by the weekly administration of bortezomib, and grade 3 occurred in only 2 patients (5%). PFS was 16 months, and estimated at 57% at 12 months, and 45% at 18 months.²¹² Agathocleous also

P.2135

reported as well a high level of activity in 10 WM patients treated with bortezomib.²¹³

Everolimus and Perifosine

A phase II study of everolimus reported 42% PRs and 70% minimal responses or better.²¹⁴ The main toxicities seen were myelosuppression, but up to 50% of patients required dose reductions due to toxicity. Roccaro et al. have shown that everolimus interacts with and inhibits TORC1 and induces cell cycle arrest and apoptosis (both caspase-dependent and -independent).²¹⁵ The mTOR kinase system is responsive to AKT and ultimately signals via TORC1. As mentioned earlier, AKT has been found to be up-regulated in WM. Furthermore, the same group proposes that dual targeting of the PI3K/mTOR pathway may be advantageous in treating WM, such as with the dual inhibitor NVP-BEZ235.²¹⁶

Because of the increased activation of AKT, perifosine has been explored in the clinic for WM.²¹⁴ In a phase II study, 37 patients were treated with single-agent perifosine (oral agent) for a total of up to 6 cycles. There were 4 PRs (11%) and 9 minimal responses (24%). Correlative studies showed that perifosine did inhibit AKT and also down-regulate NF- κ B.

Alemtuzumab

The use of anti-CD52 monoclonal antibodies (alemtuzumab) has also been proposed by Hunter and colleagues.²¹⁷ In one pilot study, the investigators were able to show that clinical responses can be observed, but there appears to be significant toxicity. Alemtuzumab as treatment for WM is being further evaluated, but it may have more of a role in patients with relapsed and refractory disease. The WMCTG has reported on the use of a monoclonal antibody targeting CD52 in patients with WM. They enrolled 28 patients in the study WMCTG 02-079 where patients were treated with 30 mg alemtuzumab, 3 times per week, for up to 12 weeks.²¹⁸ Among evaluable patients, the ORR was 81%, including 1 CR (4%) and 10 PR cases (37%). The major toxicities included myelosuppression (more common among previously treated

patients), anemia, fatigue, and infection. Of note, two patients had treatment-related death, including one CMV infection, and the other with thrombocytopenia complications.

Imatinib Mesylate

Another trial conducted by the WMCTG (05-140) addressed the role of imatinib in the treatment of WM. A phase II study using imatinib started at 400 mg per day and, if tolerated, the doses were escalated to 600 mg per day for up to 2 years.²¹⁸ The reported ORR was 26%, with 2 PR and 5 MR cases. Further studies of imatinib in the setting of relapsing disease are warranted.

Sildenafil

Anecdotal observations have suggested that for some patients, sildenafil results in clinical improvement of WM.²¹⁹ To better define its activity in WM, additional studies are needed.

Oblimersen Sodium

Gertz and colleagues have reported on early data using oblimersen sodium, a BCL-2 antagonist.²²⁰ It is an antisense oligonucleotide to the first 6 codons of the B-cell leukemia gene 2 (BCL-2) that prevents the expression of the BCL-2 gene. This process alone can enhance vulnerability of cells exposed to fludarabine, dexamethasone, and rituximab, and is believed to enhance apoptosis. To assess the value of this therapy for WM, the final results of ongoing clinical trials will be needed.

HIGH-DOSE CHEMOTHERAPY WITH STEM CELL SUPPORT

Autologous

Although there are limited data regarding long-term outcomes of WM after autologous or allogeneic transplant in WM, it has been recently argued that autologous (stem cell transplantation [SCT]) should be more often considered in suitable candidates.²²¹ It is unlikely that SCT will be fully vetted using a randomized phase III trial, however, the utilization of the procedure in related conditions, such as CLL and MM, has made this a safe and, arguably, routine procedure. It has been shown that higher doses of chemotherapy can be safely administered to patients with WM, resulting in disease control.^{222, 223, 224}

Registry series have been reported describing the outcome of WM patients after autologous stem cell transplant.^{222, 225, 226} Overall, the nonrelapse mortality at 1 year was 6% in the largest series thus far reported. Kyriakou and colleagues reported a retrospective analysis of 158 patients treated with high-dose chemotherapy and autologous stem cell support.²²⁵ The median age of patients was 49 years, and they reported 23 PR, 77 VGPR, and 34 CR.²²⁷ It seems that, given the availability of other effective regimens, stem cell transplant done as up-front treatment for the disease should still be done in the context of clinical trials. Stem cells need to be collected in patients who may be potential stem cell transplant candidates, and high-dose chemotherapy with stem cell support is an effective disease-controlling strategy for patients experiencing relapsing disease. However, a stem cell transplant should be considered more often in cases of first relapse, where the disease is still chemosensitive, and where the clinical results have been thus far encouraging. For a summary of published SCT series on WM, please refer to Table 100.4.^{172, 222, 225, 226, 228, 229} The optimal conditioning regimen has not been identified, but both BEAM and high-dose melphalan have been used.

Allogeneic

There are even fewer reports of allogeneic transplantation in WM. The overwhelming majority of patients may not be eligible to be treated with this modality because the median age at onset of WM is 65 years. The originally reported series have been small and predominantly retrospective cases.^{230, 231} Anagnostopoulos and colleagues reported on 26 patients with WM treated with SCT between 1986 and 2002.²²² Over one half (58%) of patients were treated with myeloablative conditioning regimens. The relapse rate at 3 years was no different between those undergoing an allogeneic versus an autologous SCT (24% vs. 29%). The survival at 3 years was 46% in the allogeneic group and 70% in the autologous group. These data indicate that allogeneic strategies may only be appropriate for select patients with WM and probably should not be pursued for WM patients outside the context of a clinical trial. In an updated report from the European Bone Marrow Transplant (EBMT) registry, Kyriakou and colleagues describe the outcome of 106 patients treated with allogeneic stem cell transplant.²³² A total of 30 patients had nonrelapse mortality (28%). A second report of 37 patients undergoing myeloablative therapy, and 49 with reduced-intensity conditions, showed similar results.²²⁷ For a more detailed discussion on the various high-dose therapy options, please refer to Gertz et al. (Table 100.5).^{221, 222, 233} In our opinion, although allogeneic strategies may be feasible, the high treatment-associated mortality suggests this treatment should be mostly conducted in the setting of clinical trials and not as up-front therapy for the disease.

TABLE 100.4 SUMMARY OF AUTOLOGOUS STEM CELL TRANSPLANT STUDIES FOR WALDENSTRÖM MACROGLOBULINEMIA

Study	N	Regimen	Median Age		OR	RFS	OS
			n	at SCT

OTHER THERAPEUTIC INTERVENTIONS

Splenectomy

There are patients with hypersplenism or spleen-dominant disease who benefit from splenectomy, despite the fact that a splenectomy does not address the marrow infiltration associated with WM.²³⁴ Splenectomy has also been reported as correcting a factor VIII deficiency in a WM patient.²³⁵ Furthermore, some anecdotal cases have been reported of patients with disease limited to the spleen who had long durations of response after splenectomy.²³⁶

Plasma Exchange

Plasmapheresis with total plasma exchange as treatment for the symptoms of the hyperviscosity syndrome in WM is very useful, but has no impact on the tumor burden. When acute hyperviscosity symptoms develop, usually with a viscosity value above 4, small changes in plasma volume can produce large reductions in serum viscosity because the serum viscosity is not linearly correlated with IgM. IgM reductions as small as 20% can result in viscosity reductions of as much as 50%. Dramatic effects on symptoms can occur with even small reductions in serum viscosity.²³⁷ In a survey conducted in Canada from 1981 to 1997, WM was among the top five indications for plasma exchange.²³⁸ Plasma exchange has also been used as a long-term maintenance treatment in patients who become resistant to cytotoxic drugs.²³⁹

TOXICITY OF STANDARD THERAPY

WM patients have baseline immunosuppression because of decreased levels of uninvolved immunoglobulins and treatment-related granulocytopenia, all of which increase the risk of infection. In addition, treatment with PNA increases the risk of opportunistic infections, and there are occasional reports of post-transplant-like lymphoma²⁴⁰ secondary to a reduction in the level of circulating CD4+ T cells.^{241, 242} Other infections, such as opportunistic viral enteric infection²⁴³ and Cryptococcus meningitis, have been reported in WM patients treated with fludarabine.²⁴⁴ Furthermore, 2-CDA interferes with lymphocyte proliferation and activity resulting in associated fever and potential infection.^{242, 245} Autoimmune phenomena in patients exposed to 2-CDA have been reported and may be the result of suppression of T-lymphocyte function. Four WM patients have been reported in whom immunemediated hemolysis developed after 2-CDA therapy (median, 40 months after initial administration). Hemolytic anemia has also been reported.²⁴⁶ In a small series, one patient responded to oral corticosteroids and two died.²⁴⁷ Neurologic, renal, and local skin reactions have also been reported.²⁴⁸

Cladribine and fludarabine are both associated with myelosuppression,¹⁷⁵ including severe neutropenia and thrombocytopenia. In one study using cladribine, grade 3 or 4 neutropenia was seen in 60% of patients.¹⁵⁶ Similarly, high rates of neutropenia (77%) and thrombocytopenia (32%) have been reported in other studies.¹⁶¹ We therefore recommend that when cladribine is to be used, it should be limited to 2 cycles and empiric preventive antimicrobial and antiviral prophylaxis be considered.

Alkylating agents are well known to induce chromosomal changes and to be mutagenic. Acute myelogenous leukemia or the development of myelodysplasia are clearly the most devastating complications associated with alkylating agent therapy; although these occur in a small minority of patients. Reports of acute leukemia appeared shortly after the introduction of alkylating agents for the management of WM.^{249, 250, 251} In a study of 46 patients, acute leukemia or refractory anemia developed in 4 patients.⁶⁸ Acute leukemia has also been reported with chlorambucil treatment.²⁵² Two patients, without any prior exposure to alkylating agents, have been reported with myelodysplastic syndrome (MDS) and chromosomal abnormalities, including monosomy-5 and monosomy-7.²⁵³ A metabolite of cyclophosphamide, acrolein, is toxic to the urinary bladder, and bladder cancer has been reported in patients treated with oral cyclophosphamide (50 to 100 mg/day).²⁵⁴

Treatment has also been reported as being associated with an increased risk of secondary malignancies. Several reports have shown an increased incidence in retrospective series of patients treated with these agents, with rates ranging from 0% to 7%. The validity of these observations has been questioned due to the retrospective nature of these reports, which lacked controls. The baseline rate of secondary malignancies plus the increment associated with the use of alkylators has not been fully elucidated. In one of the largest series, Facon reported a rate of 1.2% (2/167 patients). It is possible to conclude that, as single agents, PNAs have a low incremental risk of MDS and acute myeloid leukemia. However, the risk may be higher when they are combined with alkylators such as cyclophosphamide^{155, 255, 173} (Table 100.6).

Studies on the use of fludarabine reported an incidence of secondary malignancies of 1.4% to 8.9%. Once more, these studies were small in size and retrospective. Morel and colleagues reported an increased incidence of second cancers in WM patients.⁵¹ An Italian group reported a large incidence of secondary malignancies of 12%, at 10 years and 17% at 15 years.²⁵⁶ One report using the Surveillance, Epidemiology, and End Results (SEER) database evaluated 1,618 WM patients and found an increased risk of myeloma, melanoma, and colon, uterus, lung, and kidney cancers.²⁵⁷ However, the Leblond study (a randomized study) showed a rate of secondary malignancies of 3.7% at 6 years versus 20.6% (P = 0.001) for those treated with chlorambucil, with a combination of both solid tumors and hematologic

P.2138

malignancies (Personal communication, V Leblond, International Waldenström Macroglobulinemia Workshop, August, 2012). In this same study, there was no evidence of an effect of PNAs on the risk of Richter transformation (Table 100.7).

Rituximab is also associated with toxicity that is thought to be secondary to the immunosuppressive effects of the medication. It has been reported that reactivation of a variety of viral infections, including hepatitis B, can occur after rituximab treatment.^{258, 259, 260, 261, 262, 263} One patient with WM developed a fatal adenoviral hepatitis after rituximab treatment. Reports also exist of rituximab-associated progressive multifocal leukoencephalitis.^{264, 265} A case of nasal skin necrosis after rituximab therapy has also been reported.²⁶⁶

MAYO CLINIC TREATMENT RECOMMENDATIONS

It remains of paramount importance to identify patients who have IgM MGUS or smoldering WM who do not need therapy, and for whom expectant observation is appropriate. It is important to emphasize, however, that close monitoring is indicated, as there can be substantial decrements in quality of life of individuals who progress to symptomatic WM. In our institution, most patients who require initial therapy and who cannot, or do not want, to be enrolled in clinical trials, are treated with the combination of rituximab, cyclophosphamide, and dexamethasone. This is a very well-tolerated regimen that will not interfere with subsequent collection of stem cells. In suitable candidates, stem cells are collected for a future SCT. In some rare instances, the use of single-agent rituximab can be considered, but in the majority of cases, combination therapy is indicated. In elderly patients who have significant comorbidities or limited mobility, single-agent chlorambucil can be considered as well. Plasma exchange is only indicated in cases of symptomatic hyperviscosity, and is used only as a "bridge" procedure until effective cytotoxic therapy is instituted. Our consensus group recommendations have been published and presented as Figure 100.3.

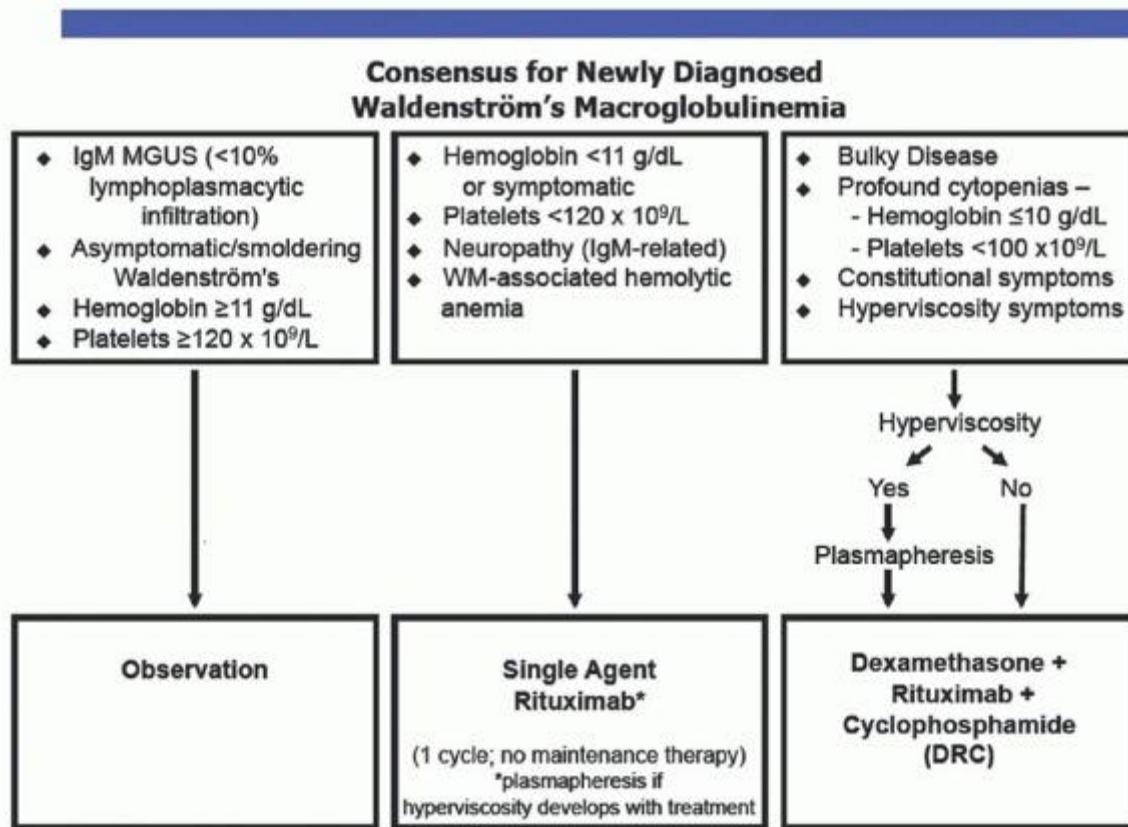

FIGURE 100.3. Consensus for newly diagnosed Waldenström's macroglobulinemia. MGUS, monoclonal gammopathy of undetermined significance. From Ansell SM, Kyle RA, Reeder CB, Fonseca R, et al. Diagnosis and management of Waldenström macroglobulinemia: Mayo stratification of macroglobulinemia and risk-adapted therapy (mSMART) guidelines. Mayo Clinic Proc 2010;85:824-833.

CONCLUSIONS

The mainstay of therapy for WM has changed recently and more broadly uses rituximab-based combinations with other novel agents, such as bortezomib and others. The new developments in understanding disease biology, mainly by the identification of MYD88 as a disease-defining mutation, will allow a more rational approach to disease identification, classification, and possibly targeted therapy. A recent consensus statement discussed this dilemma and conceded that single-agent therapy or combination approaches were equally appropriate treatment for WM patients. Issues to be considered when selecting therapy include factors associated with the disease, such as tumor bulk, hyperviscosity, and cytopenias, as well as patient-related factors, such as comorbid diseases and prior therapy. For some patients, achieving rapid cyto-reduction of tumor may be important (and may favor a combination therapy approach), but for most, this is not necessary and single-agent therapy may be more appropriate. It is also important to remember that there may be a long latent period before one observes the full clinical benefit of the selected treatment. Based on the small population of patients with this disease and the paucity of information available regarding the best therapy, however, patients should be considered for clinical trials whenever possible.

Chapter 101

Poems Syndrome, Cryoglobulinemia, and Heavy-Chain Disease

Angela Dispenzieri

David Dingli

Morie A. Gertz

INTRODUCTION

This chapter addresses three types of immunoglobulin-based orphan diseases: the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes), cryoglobulinemia, and immunoglobulin heavy-chain disease (HCD). These diseases are characterized by lymphoproliferative, lymphoplasmacytic proliferative, or plasma cell proliferative disorders and specific serum immunoglobulin findings that serve as markers to define each entity.

POEMS SYNDROME

POEMS syndrome is a rare paraneoplastic syndrome due to an underlying plasma cell disorder. The acronym, which was coined by Bardwick in 1980,¹ refers to several, but not all, of the features of the syndrome: polyradiculoneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes. There are three important points that relate to this memorable acronym: (1) not all of the features within the acronym are required to make the diagnosis; (2) there are other important features not included in the POEMS acronym, including papilledema, extravascular volume overload, sclerotic bone lesions, thrombocytosis/erythrocytosis (P.E.S.T.), elevated vascular endothelial growth factor (VEGF) levels, a predisposition toward thrombosis, and abnormal pulmonary function tests; and (3) there is a Castleman

disease variant of POEMS syndrome that may be associated with a clonal plasma cell disorder. Other names of the POEMS syndrome that are less frequently used are osteosclerotic myeloma, Takatsuki syndrome, Crow-Fukase syndrome, and PEP syndrome.^{2, 3}

The disease was initially thought to be more common in patients of Japanese descent, given the most numerous initial reports from Japan.^{2, 3} However, over the years, large series have also been reported from France, the United States, China, and India.^{4, 5, 6, 7, 8} A national survey conducted in Japan in 2003 showed a prevalence of approximately 0.3 per 100,000.⁹

ETIOLOGY OF POEMS SYNDROME

The pathogenesis of the syndrome is not understood. Distinctive presenting characteristics of the syndrome that differentiate POEMS syndrome from standard multiple myeloma (MM) include the following: (1) dominant symptoms have little or nothing to do with bone pain, extremes of bone marrow infiltration by plasma cells, or renal failure; (2) dominant symptoms are typically neuropathy, endocrine dysfunction, and volume overload; (3) VEGF levels are high; (4) sclerotic bone lesions are present in the majority of cases; (5) overall survival is typically superior; and (6) λ clones predominate.¹⁰

To date, VEGF is the cytokine that correlates best with disease activity,^{11, 12, 13, 14, 15, 16, 17, 18, 19, 20} although it is likely not the driving force of the disease, based on the mixed results seen with anti-VEGF therapy.^{21, 22, 23, 24, 25, 26, 27} VEGF is known to target endothelial cells, induce a rapid and reversible increase in vascular permeability, and be important in angiogenesis. It is expressed by osteoblasts, in bone tissue, macrophages, malignant plasma cells,^{28, 29, 30} and megakaryocytes/platelets.³¹ Both IL-1 β and IL-6 have been shown to stimulate VEGF production.²⁸ Little is known about the plasma cells in POEMS syndrome except that more than 95% of the time they are λ -light chain restricted with restricted immunoglobulin light chain variable gene usage (IGLV1).^{32, 33, 34} Aneuploidy and deletion of chromosome 13 have been described, but hyperdiploidy is not seen.³⁵

DIAGNOSIS OF POEMS SYNDROME

The diagnosis is established based on a composite of clinical and laboratory features. The most notable symptoms include the constellation of neuropathy and any of the following: monoclonal protein (especially λ -light chain), thrombocytosis, anasarca, or papilledema. All the features of the acronym are not required to make the diagnosis. The requirements set forth in Table 101.1 are designed to retain both sensitivity and specificity, potentially erring on the side of specificity. Making the diagnosis can be a challenge, but a good history and physical examination followed by appropriate testing—most notably radiographic assessment of bones,³⁸ measurement of VEGF,^{13, 17, 20, 39, 40} and careful analysis of a bone marrow biopsy⁴¹—can differentiate this syndrome from other conditions like chronic inflammatory polyradiculoneuropathy (CIDP), monoclonal gammopathy of undetermined significance (MGUS) neuropathy, and immunoglobulin light chain amyloid neuropathy.⁴² Figure 101.1 demonstrates several classic findings among patients with POEMS syndrome.

CLINICAL PRESENTATION OF POEMS SYNDROME

Polyradiculoneuropathy

The peripheral neuropathy is the dominant characteristic,^{2, 3, 5, 7, 36} and it is ascending, symmetrical, and affecting both sensation and motor function.⁴³ In our experience, pain may be a dominant feature in about 10% to 15% of patients, and in one report as many as 76% of patients had painful neuropathy.^{9, 44} Nerve conduction studies in patients with POEMS syndrome show slowing of nerve conduction that is more predominant in the intermediate than distal nerve segments as compared to CIDP, and there is more severe attenuation of compound muscle action potentials in the lower than upper limbs.^{9, 45, 46, 47, 48} In contrast to CIDP, conduction block is rare.^{9, 46, 48} The conduction findings suggest that demyelination is predominant in the nerve trunk rather than the distal nerve terminals, and axonal loss is predominant in the lower limb nerves.⁹ Axonal loss is greater in POEMS syndrome than it is in CIDP.⁴⁸ The nerve biopsy is not specific, but uncompact myelin lamellae, endothelial cytoplasmic enlargement, opening of the tight junctions between endothelial cells and presence of many pinocytotic vesicles adjacent to the cell membranes, and absence of macrophage-associated demyelination have been described.^{49, 50, 51, 52, 53, 54, 55, 64}

P.2142

TABLE 101.1 CRITERIA FOR THE DIAGNOSIS OF POEMS SYNDROME^a

		% Affected^b
Mandatory major criteria	1. Polyradiculoneuropathy (typically demyelinating)	100
(both required)	2. Monoclonal plasma cell disorder (almost always λ)	100 ^c
Other major criteria	3. Castleman disease ^d	11-25
(one required)	4. Bone lesions, usually sclerotic	27-97
	5. Vascular endothelial growth factor elevation ^e	
Minor criteria (one required)	6. Organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy)	45-85
	7. Extravascular volume overload (edema, pleural effusion, or ascites)	29-87
	8. Endocrinopathy (adrenal, thyroid ^f , pituitary, gonadal, parathyroid, pancreatic ^f)	67-84
	9. Skin changes (hyperpigmentation, hypertrichosis, glomeruloid hemangiomas, plethora, acrocyanosis, flushing, white nails)	68-89
	10. Papilledema	29-64
	11. Thrombocytosis/polycythemia ^g	54-88
Other symptoms and signs	Clubbing, weight loss, hyperhidrosis, pulmonary hypertension/restrictive lung disease, thrombotic diatheses, diarrhea, low vitamin B ₁₂ values	

POEMS, polyneuropathy, organomegaly, endocrinopathy, M-protein, skin changes.

^aThe diagnosis of POEMS syndrome is confirmed when both of the mandatory major criteria, one of the three other major criteria, and one of the six minor criteria are present.

^b Summary of frequencies of POEMS syndrome features based on largest retrospective series.^{2, 3, 5, 7, 36, 37}

^c Takasaki and Nakanishi series are included even though only 75% of patients had a documented plasma cell disorder. Since these are among the earliest series describing the syndrome, they are included.

^d There is a Castleman disease variant of POEMS syndrome that occurs *without* evidence of a clonal plasma cell disorder that is not accounted for in this table. This entity should be considered separately.⁴²

^e A plasma VEGF level of 200 pg/ml is 95% specific and 68% sensitivity for a POEMS syndrome.²⁰

^f Because of the high prevalence of diabetes mellitus and thyroid abnormalities, this diagnosis alone is not sufficient to meet this minor criterion.

^g Approximately 50% of patients will have bone marrow changes that distinguish it from a typical MGUS or myeloma bone marrow.

From Dispenzieri A. How I treat POEMS syndrome. *Blood* 2012;119(24):5650-5658, with permission.

Organomegaly, Endocrinopathy, Skin Changes, Papilledema, and Extravascular Overload

Depending on the series, 45% to 85% of patients will have any combination of splenomegaly, hepatomegaly, and/or lymphadenopathy. With the exception of lymph node biopsies, the histology of the liver and spleen tends to be nonspecific. Lymph nodes may appear reactive or reveal frank Castleman's Disease or merely "Castleman's Disease-like" changes. Historically, it was estimated that between 11% and 30% of POEMS patients with documented clonal plasma cell disorder also have documented Castleman disease or Castleman-like histology.^{1, 3, 5, 7, 36, 42} More recent data would suggest that among individuals with POEMS who undergo lymph node biopsy, about 50% show angiofollicular hyperplasia typical of Castleman disease,^{3, 7} and 84% of these are hyaline vascular type.⁷ Only those with peripheral neuropathy AND a plasma cell clone should be classified as standard POEMS syndrome; without both, patients can be classified as Castleman disease variant of POEMS if they have other POEMS features.⁵⁶

Endocrinopathy is a central but poorly understood feature of POEMS. In a recent series,³⁷ approximately 84% of patients had a recognized endocrinopathy, with hypogonadism as the most common endocrine abnormality, followed by thyroid abnormalities, glucose metabolism abnormalities, and lastly by adrenal insufficiency. The majority of patients have evidence of multiple endocrinopathies in the four major endocrine axes (gonadal, thyroid, glucose, and adrenal). Gynecomastia may be present on physical examination.

The characteristic skin changes include hyperpigmentation, a recent outcropping of hemangioma, hypertrichosis, dependent rubor and acrocyanosis, white nails, sclerodermoid changes, facial lipodystrophy, flushing, or clubbing.^{2, 4, 5, 6, 7, 8, 57, 58} Rarely, calciphylaxis is also seen.^{59, 60} The histologic findings of the dermis have been reported to range from nonspecific to glomeruloid hemangiomata to vascular abnormalities in apparently normal dermis.^{61, 62, 63, 64}

Papilledema is present in at least one-third of patients⁶⁵; the majority of these patients do not have specific symptoms relating to this finding but a minority will report blurred vision, diplopia, or ocular pain.

Peripheral edema, ascites, and effusions are the symptoms and signs that cause the next most morbidity after peripheral neuropathy. The manifestations of extravascular overload occur in 29% to 87% of patients with POEMS syndrome and are not typically associated with severe hypoalbuminemia. Severe third spacing can lead to worsening renal function. Serum creatinine levels are normal in most cases, but serum cystatin C, which is a surrogate marker for renal function, is high in 71% of patients.⁶⁶ In our experience, at presentation, fewer than 10% of patients have proteinuria exceeding 0.5 g/24 hours, and only 6% have a serum creatinine greater than or equal to 1.5 mg/dl. Four percent of patients developed renal failure as preterminal events.³⁶ In another series from China, however, 37% of patients had a creatinine clearance (CrCl) of less than 60 ml/minute, 9% had a CrCl of less than 30 ml/minute, and 15% had microhematuria. In POEMS syndrome, the renal histologic findings are diverse, with membranoproliferative features and evidence of endothelial injury being most common.⁶⁷ On both light and electron microscopy, mesangial expansion, narrowing of capillary lumina, basement membrane thickening, subendothelial deposits, widening of the subendothelial space, swelling and vacuolization of endothelial cells, and mesangiolysis predominate.^{68, 69, 70, 71, 72, 73, 74} Standard immunofluorescence is negative,^{69, 75} which differentiates it from primary membranoproliferative glomerulitis.⁶⁷ Rarely, infiltration by plasma cell nests or Castleman-like lymphoma have been described.⁷⁴

P.2143

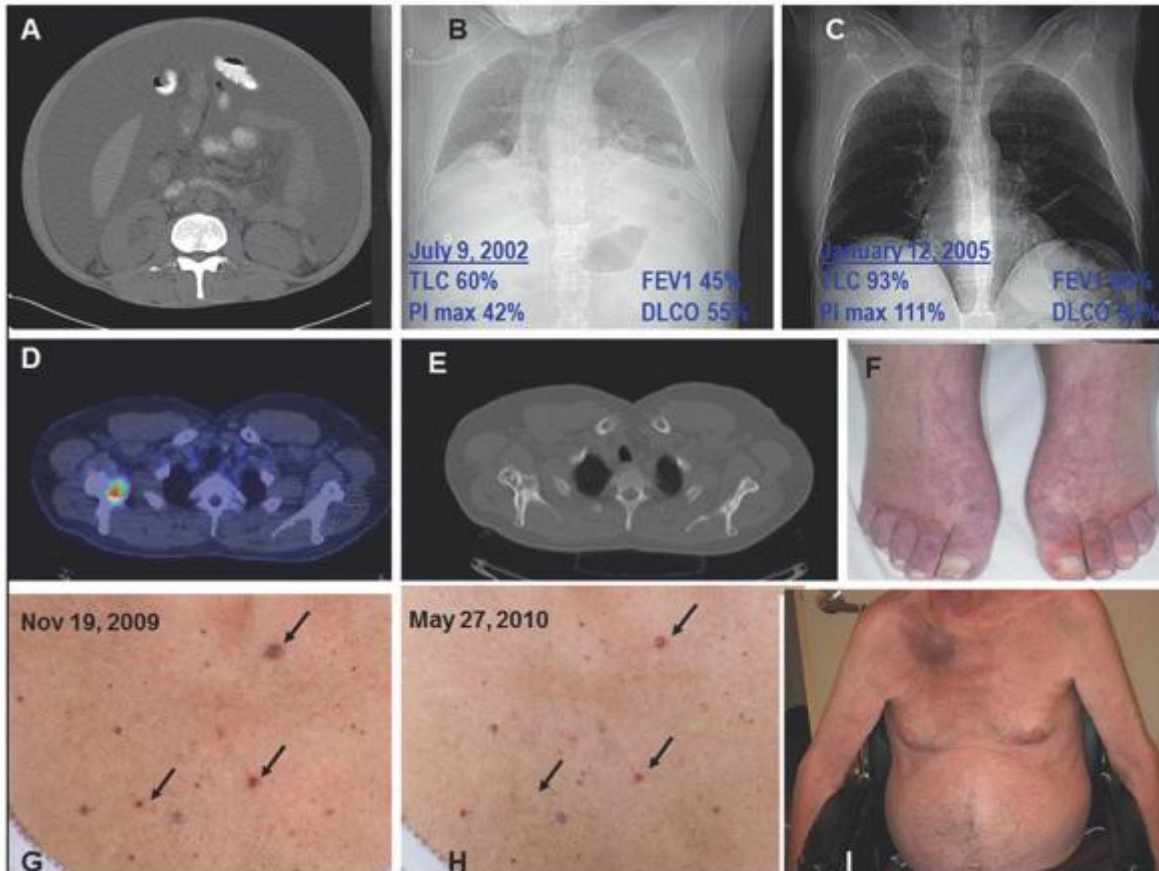

FIGURE 101.1. Classic findings of POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes) syndromes. A: Massive ascites and lipodystrophy. B: Chest radiograph and pulmonary function test results demonstrating reduced lung volumes due to neuromuscular weakness, small effusions, and reduced diffusing capacity of carbon monoxide. C: Improved chest radiograph and pulmonary function tests 2.5 years after ASCT (same patient as H). D: Fusion CT PET of mixed lytic/sclerotic lesion in right scapula. E: Bone windows of CT of mixed lytic/sclerotic lesion in right scapula. F: Hyperemia of extremities and white nails. G: Outcropping of cherry angiomata at diagnosis. H: Shrinkage and disappearance of cherry angiomata after radiation to solitary osteosclerotic lesion right femur. I: Plasmacytoma right scapula with overlying erythema as well as gynecomastia, muscle wasting, and ascites. Also present but unrelated is florid tinea corporis due to chronic steroid used for the incorrect diagnosis of CIDP. (From Dispenzieri, A. How I treat POEMS syndrome. *Blood* 2012;119(24):5650-5658, with permission.)

Monoclonal Plasma Cell Disorder, Sclerotic Bone Lesions, and Myeloproliferation

Among patients with POEMS syndrome, the CBC is notable for an absence of cytopenias. In fact, nearly half of patients will have thrombocytosis or erythrocytosis.³⁶ In a recent series from China, 26% of patients had anemia, which the authors attributed to impaired renal function.⁷ Their series was enriched with Castleman disease cases (25%), which may have also contributed to this unprecedentedly high rate of anemia.

The bone marrow biopsy reveals megakaryocyte hyperplasia and megakaryocyte clustering in 54% and 93% of cases, respectively.⁴¹ These megakaryocyte findings are reminiscent of a myeloproliferative disorder, but JAK2 V617F mutation is uniformly absent. One-third of patients do not have clonal plasma cells on their iliac crest biopsy. These are the patients who present with a solitary or “multiple solitary” plasmacytomas. The other two-thirds of patients have clonal plasma cells in their bone marrow, and 91% of these cases are clonal λ . The median percent of plasma cells observed is less than 5%. Immunohistochemical staining is more sensitive than is 6-color flow cytometry, since the former provides information on bone marrow architecture, which is key in making the diagnosis in nearly half of cases. In our study of 67 pretreatment bone marrow biopsies from patients with POEMS syndrome, lymphoid aggregates were found in 49% of cases. Of these, there was plasma cell rimming in all but one, and in 75% and 4% the rimming was clonal λ and κ , respectively. This finding was not seen in bone marrows from normal controls or from patients with MGUS, MM, or amyloidosis. Overall, only 8/67

(12%) of POEMS cases had normal iliac crest bone marrow biopsies, i.e., no detectable clonal plasma cells, no plasma cell rimmed lymphoid aggregates, and no megakaryocyte hyperplasia.

Osteosclerotic lesions occur in approximately 95% of patients and can be confused with benign bone islands, aneurysmal bone cysts, nonossifying fibromas, and fibrous dysplasia.^{3, 36, 76, 77} Some lesions are densely sclerotic, while others are lytic with a sclerotic rim, while still others have a mixed soap-bubble appearance. Occasionally patients will have a lytic lesion without any evident sclerosis. Bone windows of CT body images are often very informative, often even more so than FDG-uptake, which can be variable and most useful when there is an obvious lytic component to the bone lesion.

P.2144

Elevated Vascular Endothelial Growth Factor and Other Cytokines

Plasma and serum levels of VEGF are markedly elevated in patients with POEMS^{11, 20, 28, 78} and correlate with the activity of the disease.^{13, 17, 20, 28} The principal isoform of VEGF expressed is VEGF165.¹³ VEGF levels are independent of M-protein size.¹³ IL-1 β , TNF- α , and IL-6 levels are often also increased. Serum VEGF levels are 10 to 50 times higher than plasma levels of VEGF,⁷⁹ making it unclear which test is preferred. In patients with POEMS, VEGF is found in both plasma cells^{29, 30} and platelets.⁷⁸ The higher level observed in serum is attributable to the release of VEGF from platelets *in vitro* during serum processing. Our group has recently demonstrated that a plasma VEGF level of 200 pg/ml had a specificity of 95% with a sensitivity of 68% in support of a diagnosis of POEMS syndrome. Other diseases with high VEGF include connective tissue disease and vasculitis.²⁰

Pulmonary and Coagulation Abnormalities

Respiratory complaints are usually limited, given patients' neurologic status impairing their ability to induce cardiovascular challenges.⁸⁰ The pulmonary manifestations are protean, including pulmonary hypertension, restrictive lung disease, impaired neuromuscular respiratory function, and impaired diffusion capacity of carbon monoxide, but improve with effective therapy.^{7, 80, 81} Whether the digital clubbing seen in POEMS is a reflection of underlying pulmonary hypertension and/or parenchymal disease is yet to be determined. Fingernail clubbing is seen in about 4% to 49% of cases.^{3, 80}

Patients are at increased risk for arterial and/or venous thromboses during their course, with nearly 20% of patients experiencing one of these complications.^{10, 82} Ten percent of patients present with a cerebrovascular event, most commonly embolic or vessel dissection and stenosis.⁸³ Thrombocytosis and increased bone marrow infiltration are associated with risk for cerebrovascular accidents.⁸³ Aberrations in the coagulation cascade have been implicated in POEMS syndrome, but are not usually clinically apparent.⁵⁵

TREATMENT OF POEMS SYNDROME

Despite the relationship between disease response and dropping levels of VEGF, the most experience with successful outcomes has been associated with directing therapy at the underlying clonal plasma cell disorder rather than solely targeting VEGF with anti-VEGF antibodies. The treatment algorithm is based on the extent of the plasma cell infiltration (Fig. 101.2). The approach to therapy differs based on whether there is bone marrow involvement as determined by blind iliac crest sampling.⁸⁴

The course of POEMS syndrome is usually chronic, with modern estimated median survivals of nearly 14 years.^{36, 80} Only fingernail clubbing, extravascular volume overload—i.e., effusions, edema, and ascites³⁶—and respiratory symptoms⁸⁰ have been associated with a significantly shorter overall survival. The number of POEMS features does not affect survival.^{5, 10} In our experience and in a recent report from China, patients with coexisting Castleman disease may have an inferior overall survival as compared to patients without.⁷ In a series of 11 patients, lower VEGF levels predicted for better response to therapy, with resolution of the skin changes, improvement of the neuropathic disturbances, and improvement of all of the features assumed to be related to increased permeability, like papilledema and organomegaly.¹⁷

Management of POEMS Syndrome without Disseminated Bone Marrow Involvement

In the case of patients with an isolated bone lesion without clonal plasma cells found on iliac crest biopsy, radiation is the recommended therapy, as it is in the case of a more straightforward solitary plasmacytoma of bone. Not only does radiation to an isolated (or even two or three isolated) lesion(s) improve the symptoms of POEMS syndrome over the course of 3 to 36 months, but it can be curative.

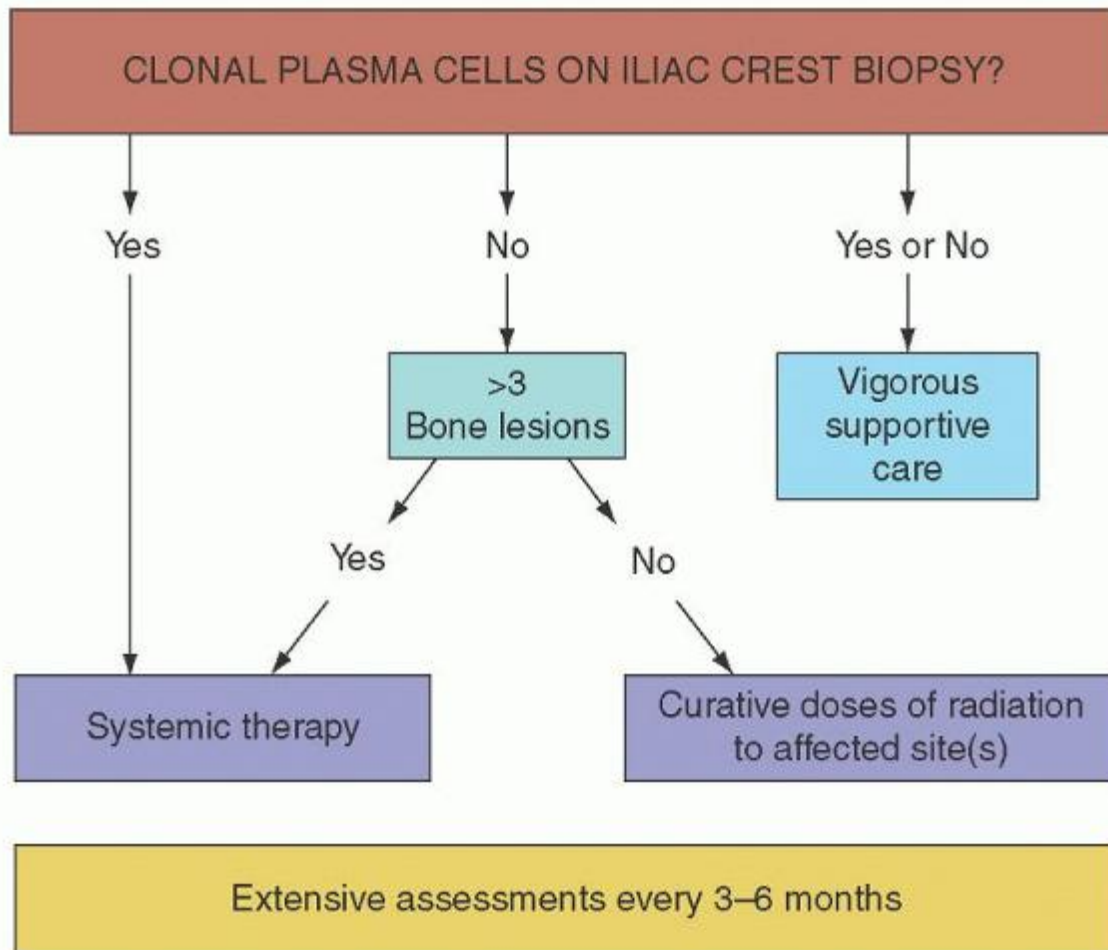

FIGURE 101.2. Algorithm for the treatment of POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes) syndrome. (From Dispenzieri, A., How I treat POEMS syndrome. *Blood* 2012;119(24):5650-5658, with permission.)

Management of POEMS Syndrome with Disseminated Bone Marrow Involvement

Once there is disseminated bone marrow involvement, albeit even with a low plasma cell percentage, radiation is not expected to be curative. Typically, once there is disseminated disease identified, systemic therapy is recommended with the caveat that large bony lesions with a significant lytic component may require adjuvant radiation therapy.⁸⁴ Decisions about adjuvant radiation should be made on a case by case basis, and typically not until a minimum of 6 months after completing chemotherapy. It is important to remember that there is a lag between completion of successful therapy and neurologic response, often with no discernible improvement until 6 months after completion of therapy. Maximal response is not seen until 2 to 3 years hence. Other features like anasarca, papilledema, and even skin changes may improve sooner. Optimal FDG-PET response may also lag by 6 to 12 months.

Since there are no randomized clinical trials among patients with POEMS syndrome, treatment recommendations are based on case series and anecdote. The treatment armamentarium is borrowed from other plasma cell disorders, most notably MM and light chain amyloidosis. Table 101.2 summarizes regimens and observed outcomes. Corticosteroids may provide symptomatic improvement, but response duration is limited. The most experience has been with alkylator-based therapy, either low-dose or high-dose, with peripheral blood stem cell transplant. The first prospective clinical trial to treat POEMS syndrome was reported from China.⁸⁹ They treated 31 patients with 12 cycles of melphalan and dexamethasone and found that 81% of patients had hematologic response, 100% had VEGF response, and 100% had at least some improvement in neurologic status. A limitation of this study is that follow-up was only 21 months, so long-term outcomes are not yet available. Personal experience and retrospective reports of the use of cyclophosphamide-based therapy are also promising.⁸⁴

TABLE 101.2 ACTIVITY OF THERAPY FOR THE TREATMENT OF POEMS SYNDROME

Regimen	Outcome
Radiation ^{36, 85, 86, 87, 88}	≥50% of patients have significant clinical improvement
Mel-Dex ⁸⁹	81% hematologic response rate; 100% with some neurologic improvement
Corticosteroids ⁵⁶	≥15% of patients have significant clinical improvement
ASCT ⁵⁶	100% of surviving patients have significant clinical improvement
Thal after MP ⁹⁰	No hematologic response but improved ascites; stabilized PN, splenomegaly, pulmonary hypertension
Thal + Dex after CAD ⁹¹	CD/POEMS: improved ascites, effusions, pulmonary hypertension, PN, renal function, IL-6 level
Thal + Dex ⁹²	<i>Nine patients.</i> VEGF improved in all; PN improved in 66%; stable in 33%; improved edema; no HCR
Thal after VAD, CTX, Bev ²⁵	Improved cardiopulmonary status, but no improved PN and rising VEGF
Len + Dex ⁹³	Improved ascites, PS, PN, VEGF, testosterone, pulmonary function tests
Len + Dex ⁹⁴	<i>Nine patients.</i> All had hematologic response; clinical responses in all evaluable patients including PS, neurologic syndrome, edema, and VEGF
Len ± Dex ⁹⁵	<i>Ten patients.</i> All had prior therapy a median of 4 mo (range 1-36 mo) prior to starting len. For 7, only Pred and IVIG were used as prior therapy, making it improbable that the salutatory effect was related to anything other than len. After a median of 7.5 cycles of len, all had clinical improvement despite the fact that only half achieved CR. Five were consolidated with ASCT
Len + CTX + Dex ⁹⁶	After 4 cycles of therapy, patient was able to walk without support, and after 6 cycles, papilledema and IgA disappeared. 1 y after 9 cycles, she remains in remission
Bortez+AD after VAD, CTX, Mel-Pred, + AD ⁹⁷	Improved M-protein, VEGF, paresthesias, splenomegaly, effusions, muscle strength, gynecomastia, and skin changes
Bortez + Dex ⁹⁸	Improved M-protein, polyneuropathy, hepatomegaly, testosterone; no change in electromyelography
Bortez × 5 cycles + Thali added at cycle 6 (prior Dex and Mel-Pred) ⁹⁹	Improvement of anasarca, PN, VEGF, and PET scan with Bortez alone, but thali added because of persistent edema, M-protein, PN, and barely elevated VEGF. With thali, disappearance of pleural effusion, ascites, and M-protein and normalization of VEGF
Bortez Dex ^{a100}	Improvement by 3 cycles, but continued for 6. Complete remission 4 y after completing therapy. Improvement in adenopathy, pleural effusion and ascites, hepatosplenomegaly, and IL-6

Bortez, CTX, Dex ¹⁰¹	Clinical response of anasarca within 6 wk and tolerated therapy for 18 mo achieving a near complete response and a VEGF response. PN, hyperpigmentation, pulmonary hypertension improved significantly
Bev alone ²¹	Death within 6 wk
Bev + mycophenolate + Dex ¹⁰²	One month after starting therapy, patient deteriorated further with worsening ascites and shortness of breath. Bev and Dex were discontinued. Mel and Pred were begun. Patient died 1 mo later
Bev alone ²²	Worsening PN, anasarca, multiorgan failure; died of pneumonia 5 wk after therapy
Bev alone ²³	Improved pain, breathing, and walking
Bev + Mel-Dex ²⁴	Improved effusions/ascites
Prior VAD/CTX ²⁵	Improved edema, pain, weakness, and VEGF
Bev + CTX-Dex ²⁶	Initial worsening; repeat with Bev → improved pulmonary HTN, anasarca, skin changes
Bev + CTX-CS ²⁷	Initial improvement, but multiorgan failure and death
Bev + CTX-radiation ¹⁰³	<i>Two patients.</i> First patient treated with radiation and CTX and then Bev. Clinical improvement started before Bev. At radiologic relapse, Bev no use, so lenalidomide plus Dex used with benefit. Second patient treated with same sequence, but course complicated by sepsis. Biochemical and early neurologic response before Bev started
Bev + CTX ²⁰	Clinical and biochemical relapse. No response to CTX, so bevacizumab added. Death

Bev, bevacizumab; Bortez, bortezomib; CS, corticosteroids; CTX, cyclophosphamide; Dex, dexamethasone; HCR, hematologic complete response; HTN, hypertension; Len, lenalidomide; Mel, melphalan; PN, polyneuropathy; POEMS, polyneuropathy, organomegaly, endocrinopathy, M-protein, skin changes; Pred, prednisone; PS, performance status; Thali, thalidomide; VAD, vincristine, doxorubicin, dexamethasone; VEGF, vascular endothelial growth factor.

^a Castleman's variant of POEMS syndrome.

High-dose chemotherapy with peripheral blood stem cell transplant can also be quite effective, but selection bias may confound these reports. Case series suggest 100% of patients achieve at least some neurologic improvement.^{18, 57, 67, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 124, 125} Doses of melphalan ranging from 140 mg/m² to 200 mg/m² have been used, with the lower doses used for sicker patients. In addition, tandem transplant has been applied in one patient, but again, no information is available regarding any added value of the second transplant.¹²⁶ Anecdotally, responses are durable, but relapses have been reported.^{27, 127} Of the 59 patients with POEMS syndrome treated at the Mayo Clinic Rochester, progression-free survival was 98%, 94%, and 75% at 1, 2, and 5 years, respectively.¹²⁸ Symptomatic progressions were rare, whereas radiographic and VEGF progressions were most common. Treatment-related morbidity and mortality can be minimized by recognizing and treating an engraftment-type syndrome characterized by fevers, rash, diarrhea, weight gain, and respiratory symptoms and signs that occur anytime between days 7 and 15 post-stem cell infusion.¹¹³

Other promising treatments include lenalidomide, thalidomide, and bortezomib, all of which can have anti-VEGF and anti-TNF effects. Enthusiasm for the latter two therapies should be tempered by the high rate of peripheral neuropathy induced by these drugs. We have observed dramatic improvements in one patient

P.2146

treated with lenalidomide.⁹³ In France, nine patients, one of whom was newly diagnosed, were treated with lenalidomide and dexamethasone.⁹⁴ Serious side effects were noted in three patients, with two hematologic toxicities and a cutaneous allergy. All patients evaluable for hematologic response had at least a partial hematologic response. Clinical responses, including improvement in performance status and neurologic symptoms, were documented among the 8 who had sufficient follow-up. One patient relapsed 5 months after discontinuing therapy, but responded to reintroduction of the drug. Bortezomib use has been reported in three patients.^{97, 98, 101} The first report is difficult to interpret, since the patient had a number of chemotherapies prior to receiving a bortezomib, doxorubicin, and dexamethasone combination. There was early evidence of improvement even before starting the bortezomib regimen. The second and third reports are more convincing: in the first, 7 cycles of bortezomib and dexamethasone resulted in patient improvement; and in the second, 18 months of cyclophosphamide, bortezomib, and dexamethasone resulted in dramatic improvements in a patient with refractory paracentesisdependent ascites. Although an anti-VEGF strategy is appealing, the results with bevacizumab have been mixed.^{22, 23, 24, 25, 26, 27} Five patients who had also received either radiation or alkylator during and/or predating the bevacizumab had benefit,^{24, 25, 26, 103} including three who had improvement but were then consolidated with high-dose chemotherapy and autologous stem cell transplant.^{25, 103} Three patients receiving bevacizumab died.^{21, 22, 27}

Both our experience and the literature would support that single-agent IV IG or plasmapheresis is not helpful. Other treatments like interferon (IFN)- α , tamoxifen, transretinoic acid, ticlopidine, argatroban, and strontium-89 have been reported as having activity, mostly as single case reports.¹⁰

Managing Symptoms of Disease

Attention to supportive care is imperative. Orthotics, physical therapy, and CPAP all play an important role in patients' recovery. Ankle foot orthotics can increase mobility and reduce falls. Physical therapy reduces the risk of permanent contractures and leads to improved function both in the long and short term. For those with severe neuromuscular weakness, CPAP and/or BiPAP provides better oxygenation and potentially reduces the risk of complications associated with hypoventilation like pulmonary infection and pulmonary hypertension.

Monitoring Response

Patients must be followed carefully on a quarterly basis, tracking the status of deficits and comparing these to baseline.¹²⁸ VEGF responses may occur as soon as 3 months,¹²⁴ but they can be delayed. VEGF is an imperfect marker since discordances between disease activity and response have been reported,¹³⁷ so trends rather than absolute values should direct therapeutic decisions. Serum M-protein responses by protein electrophoresis, immunofixation electrophoresis, or serum immunoglobulin free light chains also pose a challenge. The size of the M-protein is typically small, making standard MM response criteria inapplicable in most cases. In addition, patients can derive very significant clinical benefit in the absence of an M-protein response.^{89, 113} Finally, despite the fact that the immunoglobulin free light chains are elevated in 90% of POEMS patients, the ratio is normal in all but 18%,⁶⁶ making the test of limited value for patients with POEMS syndrome.

Recommendations about how to approach organ response have recently been suggested for the purposes of clinical trials, since there are more than two dozen parameters that can be assessed in a given patient with POEMS syndrome, given the multisystem nature of the disease.^{128, 138} Alternatively, response criteria for POEMS syndrome could be abridged as follows: (1) hematologic response using modified amyloid response criteria; (2) VEGF response; and (3) a simplified organ response, which is limited to those systems causing the most morbidity, like peripheral neuropathy assessment, pulmonary function testing (diffusion capacity of carbon monoxide), and extravascular overload (grading ascites and pleural effusion as absent, mild, moderate, or severe).

CRYOGLOBULINEMIA

In 1933, Wintrobe and Buell¹³⁹ originally reported observing cryoglobulins in a serum sample from a patient with MM. These cold precipitable immunoglobulins were observed in some patients with vasculitis, viral infection, or lymphoproliferative disorders, and were found to be byproducts of lymphoid dysfunction—unchecked and misdirected stimulation and proliferation that cause dysfunction and pathologic changes. An understanding of cryoglobulins and the cells that produce them, along with their interaction with tissue matrix, systemic cytokines, and the remainder of the immune system, may provide insight into basic control pathways and the earliest steps of malignant transformation.

The term “cryoglobulin” was coined by Lerner and Watson¹⁴⁰ in 1947. Precipitation of cryoglobulins is dependent on temperature, pH, cryoglobulin concentration, and weak noncovalent factors.¹⁴¹ Meltzer and others delineated a distinct

syndrome of purpura, arthralgias, asthenia, renal disease, and neuropathy—often occurring with immune complex deposition or vasculitis, or both.^{129, 142} Brouet et al.¹²⁰ popularized a system of classifying cryoglobulinemia on the basis of the components of the cryoprecipitate: type I, isolated monoclonal immunoglobulins; type II, a monoclonal component, usually IgM, that binds to the Fc component of polyclonal IgG (i.e., has rheumatoid factor activity); and type III, polyclonal immunoglobulins of more than one isotype.¹²⁰ This classification provided a framework by which clinical correlations could be made. Associated conditions, such as lymphoproliferative disorders, connective tissue disorders, infection, and liver disease were observed in some patients^{121, 143} (Table 101.3). Since early studies failed to identify an associated underlying condition in 34% to 71% of cryoglobulinemia cases, the majority of patients were thought to have essential or primary cryoglobulinemia^{120, 121, 144}; however, with the discovery of hepatitis C virus (HCV) came the recognition that the majority of these cases were actually related to HCV.^{145, 146} (Fig. 101.3). Essential cryoglobulinemia now accounts for fewer than 10% of cases of cryoglobulinemia.¹³⁴

EPIDEMIOLOGY OF CRYOGLOBULINEMIA

It is difficult to determine the prevalence of cryoglobulinemia since the syndrome is clinically heterogenous and it may be difficult to distinguish incidental laboratory findings from the symptomatic disease state. Although only a minority of patients with serum cryoglobulins have symptoms referable to them, cryoglobulins may be found in patients with cirrhosis (up to 45%), alcoholic hepatitis (32%), autoimmune hepatitis (40%), subacute bacterial endocarditis (90%), rheumatoid arthritis (47%), Sjögren syndrome, IgG myeloma (10%), and Waldenström macroglobulinemia (19%).^{120, 121, 122, 123, 136, 143} The presence of cryoglobulins should alert the physician to the possibility of undiagnosed chronic infections such as subacute bacterial endocarditis, Lyme disease, and Q fever.¹⁴³ Case reports describe cryoglobulinemia associated with hepatitis A virus, hepatitis B virus, Hantavirus, cytomegalovirus, Epstein-Barr virus, human T-cell lymphotropic virus type I, hepatitis G virus, human immunodeficiency virus,

P.2147

P.2148

and parvovirus B19.^{116, 143, 147} The association with HCV was reported in 1990 and 1991,^{145, 146} and the majority (42% to 100%) of patients with mixed cryoglobulinemia were found to be infected with HCV.^{146, 148, 149, 150, 151, 152, 153, 154, 155}

ETIOLOGY OF CRYOGLOBULINEMIA

Cryoglobulinemia is driven primarily by 4 classes of disease: liver disease (predominantly HCV), infection (again, predominantly HCV), connective tissue disease, and lymphoproliferative disorders. Type I and II cryoglobulins are associated with monoclonal expansion of B cells or plasma cells, while type III cryoglobulins result from polyclonal B cell expansion. Infection and/or inflammation ostensibly induce a nonspecific stimulation of B cells, frequently resulting in polyclonal hypergammaglobulinemia. When these various antibodies are produced, antibodies to autoantigens may also result. In animal models, a strong B cell stimulus disrupts the sequential order of idiotype-anti-idiotype interactions, resulting in both immunosuppression and idiotype-anti-idiotype immune complexes.¹⁵⁹ Furthermore, poorly regulated

production and clearance of IgM-rheumatoid factor contributes to immune complex formation.^{141, 121} Deposition of these antibody complexes in tissue leads to a variety of pathologic conditions, including vasculitis, nephritis, and vascular occlusion.

Complement components, fibronectin, and lipoproteins have been found along with antigen-antibody complexes within cryoprecipitates. Although hepatitis B virus, Epstein-Barr virus, and bacterial products may also be present, by far the most common pathogen within cryoprecipitates is HCV.¹⁶⁰ HCV-RNA, HCV-specific proteins, and anti-HCV antibodies are found in the supernatant of the cryoprecipitate and in the cryoprecipitate itself in 42% to 98% of patients with essential mixed cryoglobulinemia.^{149, 150, 151, 152, 153, 154, 155} Cryoprecipitates contain 20 to 1,000 times more HCV-RNA than is present in the supernatant.¹⁶¹ The IgG component to which the IgM-rheumatoid factor fraction binds is directed against the HCV proteins.¹⁶²

The biochemical basis for the temperature-dependent precipitation of these proteins is not completely understood. They may precipitate at temperatures substantially higher than the 4°C that is used to determine their presence in the laboratory. Precipitation also depends on temperature, pH, the ionic strength, and the structure (sequence) of the immunoglobulin components.

Relationships among Predisposing Conditions and Cryoglobulinemia

Hepatitis C Virus

The exact relationship between HCV and cryoglobulinemia is unknown, although the lymphotropism of HCV is well established. The virus can infect B lymphocytes through CD81 or the LDL receptor.^{163, 164} There is considerable evidence that (1) HCV can serve as a chronic immune stimulus, (2) cryoglobulins are present in up to 50% of HCV-infected patients,^{165, 166, 167, 168} (3) HCV is associated with autoimmune phenomena even in the absence of cryoglobulinemia, and (4) HCV may predispose patients to lymphoma.^{143, 169, 170, 171, 172} Predisposing factors for cryoglobulinemia in HCV patients are female gender, alcohol consumption, detectable serum HCV-RNA, longer duration of hepatitis, higher serum γ -globulin levels, higher rheumatoid factor levels, steatosis, and extensive liver fibrosis or cirrhosis.^{155, 165, 166, 173, 174, 175, 176}

P.2150

The major envelope protein of HCV (HCV-E2) binds with high affinity to CD81, a tetraspanin expressed on several cell types, including B and T lymphocytes.¹⁶³ CD81 expression on CD19⁺ B lymphocytes is significantly higher in patients with mixed cryoglobulinemia compared to those without mixed cryoglobulinemia, patients chronically infected with hepatitis B virus, and healthy controls.¹⁷⁷ Moreover, CD81 expression is higher on CD5 positive B cells relative to other circulating B cells.¹⁷⁸ Engagement of CD81 on human B cells by a combination of HCV-E2 and an anti-CD81 monoclonal antibody triggers the JNK pathway and leads to the preferential proliferation of the naive (CD27⁻) B cell subset.¹⁷⁹ The interaction between CD19/CD21 and CD81 provides a strong activation signal for B cells that drives the polyclonal proliferation of naive B lymphocytes and may be a key initiating factor for the development of the HCV-associated B lymphocyte disorders.¹⁷⁹ This interaction may explain the frequent finding of clonal B cells in patients with HCV in the absence of an overt malignancy.^{180, 181} These B cells have a biased usage of rheumatoid factor encoding V_H1-69 and V_K3-20 gene segments, similar to what is observed in patients with HCV-related lymphoma.¹⁸² Interestingly, these cells express low levels of CD21 and are associated with an anergic phenotype.¹⁸³ Eradication of HCV infection by IFN therapy leads to normalization of the activation markers' expression on B lymphocytes¹⁷⁹ as well as restoration of immune homeostasis, especially after therapy with rituximab.^{184, 185} The potential host-specific predisposing factors for the development of cryoglobulinemia are being deciphered. In a large series of patients with HCV-related cryoglobulinemic glomerulonephritis, HLA DRB1*11 was more frequent in patients with nephrotic syndrome, while HLA DRB1*7 appeared to be protective.¹⁵⁸

Connective Tissue Disease

The incidence of cryoglobulinemia, most commonly type II or III, in relation to specific connective tissue diseases is quite variable.¹²⁹ Among patients with systemic lupus erythematosus, 25% have detectable cryoglobulins,¹⁸⁶ and cryoglobulins have been detected in 12.5% of patients with systemic sclerosis.^{122, 187} Measurable amounts of cryoglobulins, usually polyclonal, can be found in up to 46% of patients with active rheumatoid arthritis.¹⁸⁸ Among patients with Sjögren syndrome, 16% to 37% have serum cryoglobulins^{122, 189, 190}; conversely, 5% to 15% of patients with mixed cryoglobulinemia have Sjögren syndrome.^{120, 121, 144} Patients with Sjögren syndrome and mixed cryoglobulins have a 7-fold risk of lymphoma developing (86% versus 12.5% in patients without cryoglobulins) and a worse survival.^{189, 191}

Lymphoproliferative Disorders

The relationship between cryoglobulinemia and lymphoproliferative disorders is complex; cause can be difficult to distinguish from effect. At a minimum, approximately 31% of all cases of secondary symptomatic cryoglobulinemia already have a diagnosis of lymphoproliferative disorder when cryoglobulinemia is diagnosed.¹⁴⁴ Higher percentages are found in series in which bone marrow biopsies, flow cytometry, Southern blot tests, and polymerase chain reaction are performed routinely.^{192, 193, 194, 195, 196} In another 6% to 28% of patients, symptomatic lymphoma develops at follow-up^{170, 195, 197, 198}; 50% of these are intermediate- or high-grade lymphoma.¹⁹⁸ The most common histologic diagnoses among the remaining low-grade lymphomas are immunocytoma,^{192, 199} followed by mucosa-associated lymphoid tissue (MALT) and centrocytic follicular lymphoma.²⁰⁰ Among patients whose conditions transform to overt lymphoma, the malignant clone is derived from one of the dominant baseline B cell clones in only a minority of patients,¹⁹⁴ implying a predisposition for clonal production and evolution.

Associations among Cryoglobulinemia, Hepatitis C Virus, Connective Tissue Disease, and Lymphoma

A recognized model for progression from chronic antigenic stimulation to benign or malignant lymphoproliferation is *Helicobacter pylori* and MALT lymphoma.²⁰¹ HCV, Sjögren syndrome, cryoglobulinemia, and immunocytoma may abide by this model. There is remarkable conservation of and homology among the antigen-combining sites (variable regions) of the IgM- κ rheumatoid factors in patients with HCV, HCV-associated lymphoma, and cryoglobulinemia.^{202, 203, 204, 205, 206, 207, 208} Similar degrees of homology are seen between the immunoglobulin receptors in the lymphoproliferation of patients with Sjögren syndrome and those in the lymphomas of HCV-infected patients with or without type II mixed cryoglobulinemia.²⁰⁹ This finding supports the concept that the combination of chronic antigenic stimulation, ineffectively regulated autoreactive B cells (which make restricted rheumatoid factor), and continued B cell proliferation may predispose B cells to subsequent oncogenic mutation and transformation to malignant lymphoma.

Among HCV-positive patients with mixed cryoglobulinemia, HCV-RNA is detected in peripheral blood mononuclear cells in up to 81% of patients²¹⁰ and in bone marrow cells in up to 100% of patients.^{195, 211, 212, 213, 214, 215} Clonal immunoglobulin gene rearrangements can be detected by reverse transcriptase polymerase chain reaction in all HCV-positive patients with type II mixed cryoglobulinemia and in 24% of HCV-infected patients without cryoglobulinemia.¹⁹⁶ These clones are usually, but not always, associated with the presence of type II cryoglobulins. In one series, HCV-infected patients with clonal B cell proliferation in both the blood and liver were older and had longer duration of HCV infection, higher serum cryoglobulin levels that were more frequently symptomatic, and liver disease that was more severe than that in patients without a clonal B cell population.¹⁸⁰

In a series of 1,255 patients in Italy with HCV and symptomatic mixed cryoglobulinemia, there was a 35-fold increase over the general population, with 224.1 new cases of aggressive non-Hodgkin lymphoma (NHL) subtypes per 100,000 patient-years.²¹⁶ The median time from the diagnosis of cryoglobulinemia to the clinical onset of NHL was 6.3 years (range, 0.81 to 24 years). The clinical course and response to chemotherapy in the patients with cryoglobulinemia and NHL were similar to those usually described for patients with NHL without cryoglobulinemia.

Productive t(14;18) translocations with resultant BCL-2 overexpression occur in about 12% to 38% of HCV-positive patients without symptomatic cryoglobulinemia and in 39% to 85% of their cryoglobulin-positive counterparts.^{217, 218, 219, 220} Patients with cryoglobulinemia in whom lymphoma develops have been found to have genomic sequences of HCV in their lymphoma specimens.^{200, 221, 222, 223} The NHL subgroup most commonly observed in patients with HCV is lymphoplasmacytoid lymphoma/immunocytoma.²²⁴ An increased rate of HCV infection (8% to 50%) has also been reported in idiopathic B cell NHL by many investigators.^{143, 169, 170, 171} Splenic lymphoma with villous lymphocytes has been associated with HCV and mixed cryoglobulinemia.¹⁷²

CLINICAL PRESENTATION OF CRYOGLOBULINEMIA

Involvement of the skin, peripheral nerves, kidneys, and liver is common (Table 101.4). Lymphadenopathy is present in approximately 17% of patients.^{129, 121} On autopsy, widespread vasculitis involving small and medium vessels in the heart, gastrointestinal tract, central nervous system, muscles, lungs, and adrenal glands may also be seen.^{121, 225} The interval between the onset of symptoms and the time of diagnosis varies considerably (range,

P.2151

0 to 10 years).¹²¹ Type I cryoglobulinemia is usually asymptomatic. When symptomatic, it most commonly causes occlusive symptoms rather than the vasculitis of types II and III.^{120, 121, 129} Symptoms of hyperviscosity may occur (Fig. 101.4). Type II cryoglobulinemia is more frequently symptomatic (61% of patients) than type III (21% of patients).²⁶⁶ The most common

causes of death include renal failure, infection, lymphoproliferative disorders, liver failure, cardiovascular complications, and hemorrhage.^{120, 121, 131, 135, 144} With improved therapy, the main cause of death appears to be cardiovascular disease.¹⁵⁸

In a series of 231 patients seen between 1972 and 2001, the mixed cryoglobulinemia syndrome followed a relatively benign clinical course in more than 50% of cases, whereas a moderate-severe clinical course was observed in one-third of patients whose prognosis was severely affected by renal or liver failure. For 15% of individuals the disease was complicated by malignancy: B cell NHL was more common than hepatocellular and thyroid malignancies. Ten year overall survival was 56%. Lower survival rates were seen in males and in individuals with renal involvement.¹³³

Dermatologic and Joint Manifestations of Cryoglobulinemia

Purpura is the most frequent symptom, being present in 55% to 100% of patients with mixed cryoglobulinemia^{120, 121, 131, 144} (Table 101.4 and Fig. 101.4). The incidence varies from 15% to 33% in type I, from 60% to 93% in type II, and from 70% to 83% in type III.²⁶⁷ Petechiae and palpable purpura are the most common lesions, although ecchymoses, erythematous spots, and dermal nodules occur in as many as 20% of patients. Bullous or vesicular lesions are distinctly uncommon.¹²⁰ Successive purpuric rashes, which may be preceded by a burning or itching sensation, occur most commonly on the lower extremities, gradually extending to the thighs and lower abdomen. Occasionally the arms are involved, but the face and trunk are generally spared.¹²⁰ Head and mucosal involvement, livedoid vasculitis, and cold-induced acrocyanosis of the helices of the ears are more frequently observed in type I; infarction, hemorrhagic crusts, or ulcers, occur in 10% to 25% of all patients with mixed cryoglobulinemia.²⁶⁸ Showers of purpura last for 1 to 2 weeks and occur once or twice a month. Cold precipitates these types of lesions in only 10% to 30% of the patients.^{120, 268} Raynaud phenomenon occurs in about 19% to 50% of patients^{120, 121, 131, 144}; in a quarter of these, the symptoms may be severe, including necrosis of fingertips.¹²⁰ Skin necrosis, urticaria, and livedo, which are all rare, are more commonly associated with exposure to cold.

FIGURE 101.4. Cryoglobulin-associated physical findings. A: Hyperviscosity manifested as retinopathy with venous engorgement and hemorrhage. B: Purpura. C: Gangrene.

Arthralgias are common, affecting 35% to 92% of patients, with the highest incidence in type III cryoglobulinemia (Table 101.4). The small distal joints are affected more frequently than the larger proximal joints. Symmetrical polyarthralgia is often exacerbated by the cold.^{120, 121, 131, 134, 144} Frank arthritis is rare.

Nervous System Manifestations of Cryoglobulinemia

Peripheral neuropathy is the more common presentation, although central nervous system involvement may occur. Peripheral nerve involvement is described in 12% to 56% of patients^{120, 121, 131, 134, 144} (Table 101.4). Signs and symptoms of sensory neuropathy usually precede those of motor neuropathy.^{120, 269} The presentation may be an acute or subacute distal symmetric polyneuropathy or a mononeuritis multiplex^{269, 270, 271} with a chronic or chronic-relapsing evolution.²⁷² The neuropathy is most often characterized by axonal degeneration. Epineurial vasculitis is a common finding on sural nerve biopsy.^{270, 271, 273, 274, 275} Even when other manifestations of mixed cryoglobulinemia are stable over time, there is typically worsening of the peripheral neuropathy.²⁷⁶

Central nervous system abnormalities are not uncommon in patients with mixed cryoglobulinemia. Casato et al. compared 40 patients with mixed cryoglobulinemia vasculitis and chronic active HCV infection with normal controls and HCV patients without mixed cryoglobulinemia. Twenty-four of the 27 (89%) patients with HCV-mixed cryoglobulinemia had a deficiency in one or more of 10 cognitive domains examined. The most commonly involved domains were those of attention (70%), executive functions (44%), visual construction (37%), and visual spatial functions (33%). Magnetic

P.2152

resonance imaging analysis showed that HCV-mixed cryoglobulinemia patients had a higher mean number of total and periventricular white matter high intensity signals than HCV controls and healthy controls, respectively.²⁷⁷ Cappellari et al. have also found central nervous system abnormalities in a majority of patients studied.²⁷⁸

Renal Manifestations of Cryoglobulinemia

Approximately 21% to 39% of patients with mixed cryoglobulinemia have renal involvement.^{120, 134, 279} The incidence of renal injury is highest in patients with type II cryoglobulins.^{144, 280} Although renal and extrarenal manifestations may occur concurrently, renal involvement usually follows the onset of purpura by approximately 4 years.^{121, 281} Proteinuria greater than 0.5 g/d and hematuria are the most common features of renal disease at diagnosis (present in 50% of patients)²⁸²; nephrotic syndrome affects approximately 20% of patients and acute nephritic syndrome affects approximately 25% of patients.^{281, 282} Although cryopathic membranoproliferative glomerulonephritis portends a poor prognosis,^{121, 122, 280, 282, 283} progression to end-stage renal failure due to sclerosing nephritis is uncommon.²⁸² Among patients with mixed cryoglobulinemia-associated membranoproliferative glomerulonephritis followed up for a median of 11 years, 15% had disease progression to end-stage renal failure, and 43% died of cardiovascular, hepatic, or infectious causes.²⁸²

Liver Manifestations of Cryoglobulinemia

Approximately 39% of patients with symptomatic cryoglobulinemia¹⁴⁴ and as many as 77% with mixed cryoglobulinemia^{121, 284} have documented liver abnormalities at the time of diagnosis (Table 101.4). Furthermore, hepatomegaly is present in up to 70% of patients, and splenomegaly is present in up to 52% of patients.^{121, 130, 142} Among patients with symptomatic cryoglobulinemia, liver failure is the cause of death in 2.5% to 7.6% of patients^{121, 132, 282} and in 5.6% to 29% of all reported deaths.^{121, 132, 282}

Histologic findings include portal fibrosis, chronic persistent hepatitis, chronic active hepatitis, chronic active hepatitis with cirrhosis, and postnecrotic cirrhosis.^{158, 284} Most specimens are characterized by a diffuse lymphocytic infiltrate ranging from minimal periportal to extensive infiltration with nodule formation. These changes correlate with the severity of other pathologic findings. Plasma cell infiltration has also been noted in several specimens.^{266, 284} The lymphoid population in the liver may show the histologic and immunophenotypic findings of lymphoplasmacytoid lymphoma/immunocytoma, and frequently the lymphoid elements arrange in pseudo-follicular structures in the liver with morphologic features similar to those previously reported in chronic HCV without cryoglobulinemia.¹⁹⁸ These liver lymphoid nodules contain B cells predominantly with a CD5⁺/Bcl-2⁺/Ki67⁻ phenotype—that is, low apoptotic and proliferative rates.²⁸⁵

Other Manifestations of Cryoglobulinemia

Given the propensity of immune complexes to deposit in blood vessels and activate complement, in principle, cryoglobulinemic vasculitis can affect any vascular distribution including the mesenteric vessels,^{134, 286} leading to intestinal ischemia, cholecystitis, and pancreatitis. Pulmonary vascular involvement in severe cases may lead to acute alveolar hemorrhage and diffuse pulmonary infiltrates.^{287, 288} Rarely, coronary vasculitis may lead to myocardial infarction.

DIAGNOSIS OF CRYOGLOBULINEMIA

By definition, all patients with cryoglobulinemia have serum cryoglobulins. The collection and processing of the specimens are critical because these cold-induced reversible precipitates can be lost with improper handling.^{143, 289} A minimum of 10

ml of blood is required, and the specimen must be allowed to clot at 37°C for 30 to 60 minutes before centrifugation. The serum supernatant is stored at 4°C for up to 7 days and inspected daily for cryoprecipitate. Methods to evaluate the composition of the cryoglobulin include immunoelectrophoresis, immunofixation, immunoblotting, and capillary electrophoresis.

Concentrations of cryoglobulins tend to vary by type: type III, less than 1 mg/ml; type II, 1 mg/ml or greater; and type I, greater than 5 mg/ml.^{120, 290} The type or quantity does not reliably predict the presence or nature of symptoms. On serum protein electrophoresis, polyclonal hypergammaglobulinemia is the most common finding, although normal patterns or hypogammaglobulinemia may also be seen.^{121, 129, 136} Even among patients with type II cryoglobulinemia, only 15% have a visible monoclonal spike on serum protein electrophoresis. Frequently, serum¹²¹ IgM levels are elevated; cryoprecipitable IgM may comprise up to one-third of the total serum IgM concentration.¹²¹ Hyperviscosity occurs only occasionally.¹⁴² Marked depression of complement CH50, C1q, and C4 in the presence of relatively normal C3 levels is usual.^{121, 134, 291} Neither C4 concentrations nor cryoglobulin levels correlate with overall clinical severity, although for individual patients the cryoglobulin level can sometimes serve as a marker for disease activity.^{121, 242, 291, 292} Rheumatoid factor activity—that is, anti-Fc activity—is detectable in the sera in 87% to 100% of patients with mixed cryoglobulinemia,^{120, 129, 132} and levels may decrease with response to therapy.²⁹³ An elevated erythrocyte sedimentation rate and a mild normochromic, normocytic anemia are fairly common.^{121, 242} Cytopenias have been described, as have pseudoleukocytosis and pseudothrombocytosis.¹⁴² Among patients with cryoglobulinemia, the antinuclear antibody results may be positive in as many as two-thirds of the patients²⁹⁴ and in as many as one-third of the HCV-positive patients.¹³⁴ Because HCV is frequently concentrated in cryoglobulins,¹⁴⁹ serial measurements of plasma or serum HCV-RNA levels in these patients are not reliable.¹⁷⁵

TREATMENT OF CRYOGLOBULINEMIA

Since cryoglobulinemia has a fluctuating course with spontaneous exacerbation and remission, it is essential that controlled clinical trials are used to evaluate the response to therapy. Unfortunately, such studies are rare in the field of cryoglobulinemia. Although there are several “accepted” or “standard” treatments that have no randomized trials to support their practice, there are several reported strategies (Table 101.5) that have questionable, if any, benefit.¹⁴³ Although therapies such as use of histamine (H) H1 and H2 blockers and penicillamine have sound scientific basis for consideration, they have shown no clear clinical benefit.^{121, 143} Figure 101.5 outlines a strategy for managing symptomatic cryoglobulinemia.

The standard treatment of mild symptomatic cryoglobulinemia (purpura, asthenia, arthralgia, and mild sensory neuropathy) has included bed rest, analgesics, low-dose corticosteroid therapy, low-antigen content diet, and protective measures against cold; the treatment of severe disease (glomerulonephritis, motor neuropathy, and systemic vasculitis) has included plasmapheresis, high-dose corticosteroid therapy, and cytotoxic therapy. With the recognition of the association between HCV and mixed cryoglobulinemia, immunosuppressive therapy has been viewed less favorably, and IFN with or without ribavirin has generally been considered to be first-line therapy for HCV-positive patients who are in nonemergent situations.^{226, 227, 228, 230, 295} For patients with symptomatic type I cryoglobulinemia, anti-CD20 therapy or cytotoxic therapy appropriate for the lymphoproliferative disorder remains the therapy of choice. Similarly, treatment of an underlying connective tissue disease or infection would be first-line

P.2153

therapy in the appropriate situation. The importance of not overtreating patients must be emphasized.

TABLE 101.5 TREATMENT STRATEGIES FOR SYMPTOMATIC CRYOGLOBULINEMIA

Reference	Treatment	Effective?
226, 227, 228, 229, 230, 231, 232	Interferon/PEG-Interferon	Yes
233	Ribavirin	Probably
234, 235, 236, 237, 238, 239, 240	Rituximab	Yes
241	Low-antigen diet	Probably (mild disease)
242, 243, 244, 245, 246, 247, 248	Plasmapheresis, plasma exchange	Probably
121, 122, 130, 142, 249, 250	Low-dose corticosteroids	Probably

251, 252	High-dose corticosteroids	Probably
243	Chlorambucil	Probably
248, 253, 254, 255	Cyclophosphamide	Probably
249	Melphalan	Probably
256, 257	Thalidomide	Probably
258	anti-TNF- α antibody	Probably not
121	Azathioprine	Possibly
198, 259	Cyclosporin	Possibly
260	Colchicine	Probably not
261, 262	Immunoglobulin IV	Variable ^a
263, 264	Cladribine and fludarabine	Variable
142, 253	Splenectomy	Variable
142	Chloroquine	Probably not
121	H ₁ and H ₂ blockers	Probably not
121	Penicillamine	Probably not

PEG, pegylated; IV, intravenously; TNF, tumor necrosis factor; V, variable.

^a One case report of precipitating acute renal failure²⁶¹ and another of systemic vasculitis²⁶⁵.

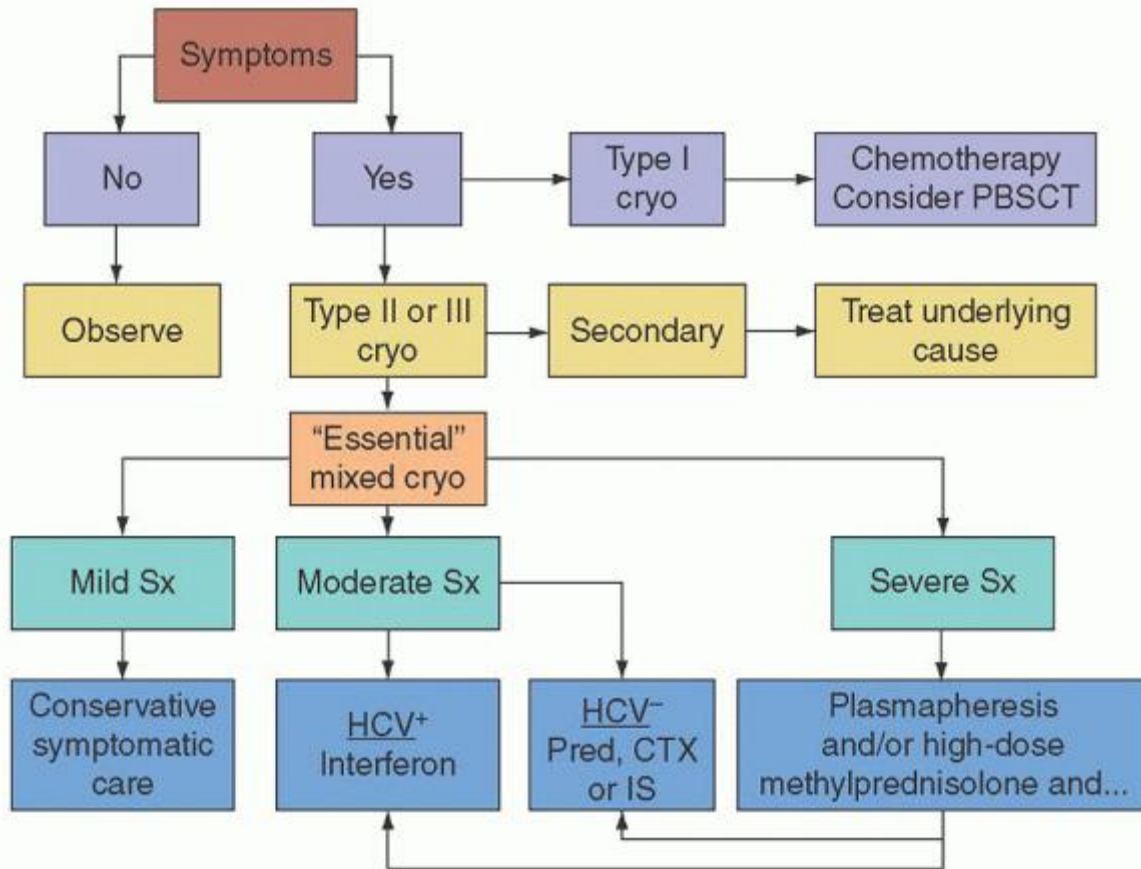

FIGURE 101.5. Possible treatment schema for cryoglobulinemia. If interferon therapy fails, combination therapy with

interferon- α and ribavirin may help; however, contraindications for ribavirin should be considered. Cryo, cryoglobulin; CTX, cyclophosphamide; HCV, hepatitis C virus; IS, immunosuppressant; PBSCT, peripheral blood stem cell transplantation; pred, low-dose therapy with prednisone; Sx, symptoms.

Treatment of Life-threatening Disease

For emergent situations (acute nephritis or severe vasculitis), initial measures are aimed at reducing the inflammatory activity of renal lesions (corticosteroids), removing circulating cryoglobulins (plasmapheresis) and reducing the formation of new antibodies (e.g., cyclophosphamide).^{281, 296} Plasma exchange or plasmapheresis alone can reverse serious complications, but these procedures are typically used in combination with cytotoxic agents or corticosteroids for more durable responses.^{292, 243, 244, 245} According to case reports, responses may be seen in 60% to 100% of patients.^{292, 243, 244, 245} Skin manifestations and arthralgias usually respond the most quickly, whereas the degree of neural and renal responses depends on the acuity of their occurrence, with poorer responses occurring in chronic cases.²⁴⁴ With combination immunosuppressive therapy and plasma exchange, reversal of catastrophic complications such as encephalopathy and acute glomerulonephritis has been documented.^{244, 292, 297} High-dose pulse therapy with methylprednisolone is also a favored therapeutic intervention for acute events, with 90% response rates in rapidly progressive glomerulonephritis.^{251, 281} Once the acute exacerbation has been mitigated, antiviral strategies are implemented in HCV-positive patients to consolidate and maintain response. One should be cognizant of reports of peripheral neuropathy (personal observation and²⁹⁸), nephritis,²⁹⁹ vasculitis,³⁰⁰ and ischemic manifestations being exacerbated by IFN- α .³⁰¹

Antiviral Therapy

Five randomized trials evaluating the efficacy of IFN therapy in HCV-positive patients with symptomatic type II mixed cryoglobulinemia conducted in the 1990s documented clinical responses in 60% to 89% of the patients.^{226, 227, 228, 229, 230} However, when compared with HCV-related chronic hepatitis, treatment of mixed cryoglobulinemia with IFN monotherapy was associated with a relatively poorer response and a high relapse rate, especially in severe cases. A majority of patients relapsed within 6 months of discontinuation.^{227, 228, 229, 230, 295, 302} Lack of response after 3 to 4 months predicted for monotherapy failure.²⁹⁵ Factors associated with a poorer response to therapy or rapid relapse include liver cirrhosis, advanced age,²³⁰ male sex,²⁹⁵ and high levels of

P.2154

HCV-RNA at the onset of therapy.²²⁸ Purpuric lesions and liver function abnormalities are the features that tend to respond rapidly (within weeks), but neuropathy and nephropathy respond more slowly.^{295, 298}

The frequent relapse of both HCV replication and mixed cryoglobulinemia syndrome at the end of IFN treatment suggested the combination with ribavirin: this therapeutic option appeared valid in several studies.^{303, 304, 305, 306} Even ribavirin monotherapy has been shown to decrease transaminase levels and mixed cryoglobulinemia-related symptoms. IFN- α and ribavirin is now the preferred strategy for patients with symptomatic HCV-associated cryoglobulinemia.^{303, 305, 307} More than 60% of patients with symptomatic mixed cryoglobulinemia who do not respond to IFN therapy alone respond to combined therapy, and 80% of patients who relapse with IFN- α therapy alone respond to combined therapy.³⁰³

Ribavirin plus weekly pegylated IFN- α is at least as effective as the combination using standard three times weekly IFN- α .^{231, 232} Saadoun et al. compared the outcomes of 72 consecutive patients who received treatment with IFN- α (n = 32 patients) or pegylated IFN- α (n = 40 patients), both in combination with oral ribavirin, for at least 6 months. Compared with patients treated with IFN- α plus ribavirin, those receiving pegylated IFN- α plus ribavirin had higher sustained clinical (67.5% versus 56.3%), virologic (62.5% versus 53.1%), and immunologic (57.5% versus 31.3%) responses, regardless of HCV genotype and viral load. In multivariate analyses, an early virologic response was independently associated with a complete clinical response of mixed cryoglobulinemia. A glomerular filtration rate less than or equal to 70 ml/minute was negatively associated with a complete clinical response of mixed cryoglobulinemia.²³²

Rituximab Therapy

Anti-CD20 therapy with rituximab has been shown to produce responses in patients with all types of cryoglobulinemia^{235, 236, 237, 238}; however, those patients with HCV are at risk for increased HCV replication.^{235, 236} Initial studies reported responses in the majority of patients, including improvements in skin vasculitis manifestations (ulcers, purpura, or urticaria), subjective symptoms of peripheral neuropathy, low-grade B cell lymphoma, arthralgias, fever, nephritis, levels of rheumatoid factor, cryoglobulins, and C4.^{308, 309} In a randomized trial, 59 patients with cryoglobulinemia vasculitis were randomized to either rituximab or conventional therapy, which included glucocorticoids, azathioprine, cyclophosphamide,

or plasmapheresis. Time to treatment failure at 1 year was superior in the rituximab group (64% versus 3%). The vasculitis activity also improved significantly on rituximab, whereas it did not for the other treatment arm. The median duration of response to rituximab was 18 months.³¹⁰

The combination of pegylated IFN- α , ribavirin, and rituximab (the so-called PIRR regimen) has been tested in two trials.^{185, 311} Both studies reported similar results: the triple combination leads to a faster response with respect to symptoms, organ (renal) response, cryoglobulin clearance, and elimination of HCV viremia. The response was generally more durable, with a median duration of response in excess of 3 years.¹⁸⁵ The two trials used a similar regimen for the IFN- α and ribavirin but differed in the use of rituximab. While Saadoun et al. started therapy with rituximab alone (weekly for 4 doses),³¹¹ Dammacco et al. started the triple combination simultaneously and subsequently give additional single doses of rituximab at 6 and 11 months after the initiation of therapy.¹⁸⁵ The addition of Rituxan to the combination of antiviral agents did not lead to an increase in the HCV burden as measured by quantitative PCR, and therapy was associated with a significant reduction or elimination of clonal B cells from the circulation.

Other Therapies for Cryoglobulinemia

Although not formally studied, high-dose therapy with autologous stem cell transplantation may be considered for patients with symptomatic, refractory cryoglobulinemia that results from a plasma cell proliferative disorder. There is an increased risk of lethal veno-occlusive disease in patients with chronic hepatitis C who are undergoing stem cell transplantation.³¹²

Dramatic reductions in the cryocrit and the cryoglobulinemic symptoms, including membranoproliferative glomerulonephritis, have been reported in several patients who underwent splenectomy for hypersplenism.^{253, 313} In contrast, in the series reported by Meltzer and Franklin, the one patient who underwent splenectomy died of acute renal failure.¹⁴² Because this intervention has not been studied thoroughly, and because of the high risk involved, it should not be considered as standard therapy, but rather as a potential option for patients without cirrhosis who have disease that is difficult to manage because of cytopenias resulting from hypersplenism.

HEAVY-CHAIN DISEASE

The HCDs are a rare group of disorders with diverse clinical presentations. The 3 conditions (α -, γ -, and μ -HCD) are discussed together because they are lymphoproliferative or plasma cell proliferative disorders that share the generation and secretion of an isolated heavy-chain fragment (Table 101.6). α -HCD (Mediterranean lymphoma or immunoproliferative small intestinal disease [IPSID]) is the most common and has the most uniform presentation; γ - and μ -HCD have variable clinical presentations and histopathologic features. In the majority of cases, the heavy-chain fragment is not secreted in large quantities and immunofixation or immunoelectrophoresis is required to detect the abnormality. Screening the serum and urine of patients with lymphoplasmacytoid NHL would most likely identify more patients with α -, γ -, or μ -HCD. Cases of α -, γ -, and μ -heavy-chain monoclonal gammopathy of unknown significance have been reported.^{314, 315, 316}

α -Heavy-chain Disease

Mediterranean lymphoma, originally described in the 1960s as a condition in young adults, is a primary small intestinal lymphoma coupled with intestinal malabsorption.³¹⁷ An isolated IgA immunoglobulin heavy-chain fragment was recognized in association with this condition. Because some patients had benign-appearing lymphocytes in their small bowel, the term " α -HCD" was preferred over "Mediterranean lymphoma" by some authors.³¹⁸ A consensus panel in 1976 concluded that α -HCD and Mediterranean lymphoma represented a spectrum of disease with benign, intermediate, and overtly malignant stages, and the term "immunoproliferative small intestinal disease" came into use.³¹⁹ This entity has been recently reviewed.³²⁰

The majority of reported patients with α -HCD are from northern Africa, Israel, and surrounding Middle Eastern or Mediterranean countries, with fewer patients from central and southern Africa, eastern Asia, and South and Central America.³²¹ Patients present with malabsorption syndrome, weight loss, and abdominal pain. On physical examination, peripheral edema, clubbing, and an abdominal mass are not uncommon findings.^{319, 320, 321, 322} On endoscopy of the small intestine, one may find thickened mucosal folds, nodules, ulcers, a mosaic pattern, or submucosal infiltration. Intestinal parasites and bacterial overgrowth in the small intestine are common. Anemia, vitamin deficiencies, and hypogammaglobulinemia are also common. The IgA level is generally not increased, but on immunofixation or immunoelectrophoresis, a monoclonal component is present, especially in the earlier phases of the disease. An immunoglobulin

light chain is not found. The monoclonal IgA fragment may be found in jejunal secretions as well as in blood and urine.³²² The monoclonal protein in patients with α -HCD is of the α 1 subclass and consists of multiple polymers. The length of the basic polypeptide subunit is typically between one-half and three-fourths that of a normal α -heavy-chain; the shortening results from an internal deletion involving most of the VH and the CH1 domain.³²³ In about one-half the cases, the electrophoretic pattern of α -HCD protein contains a broad band extending from the α 2 region to the β -globulin region because of the tendency of these chains to polymerize. The remainder of the patients may have a normal serum protein electrophoresis pattern.

TABLE 101.6 FEATURES OF HEAVY-CHAIN DISEASES

	Type of Heavy-Chain Disease		
Feature	α	γ	μ
Monoclonal protein	IgA	IgG	IgM
Year described	1968 ¹⁶⁶	1964 ¹⁶⁷	1970 ^{168, 169}
Incidence	Rare	Very rare	Very rare
Median age	Young adults	61 y	57 y
Associated diseases	Bacterial overgrowth; malabsorption	Autoimmune diseases	-
Site	Small intestine; mesenteric lymph nodes	Lymph nodes, bone marrow, and spleen	Liver, spleen, lymph nodes, and bone marrow
Pathologic features	Extranodal marginal zone lymphoma (MALT or IPSID)	Lymphoplasmacytoid lymphoma	Small lymphocytic lymphoma/chronic lymphocytic leukemia
Therapy	Antibiotics; chemotherapy	Chemotherapy	Chemotherapy

IPSID, immunoproliferative small intestinal disease; MALT, mucosa-associated lymphoid tissue.

Histologic features of IPSID range from early lymphoplasmacytic intestinal infiltration to overt malignant diffuse large B cell lymphoma. This entity shares morphologic features of MALT in that there are lymphoepithelial lesions, centrocyte-like cells, and plasma cell differentiation.³²⁴ The histologic findings are classified into stages A, B, and C. Stage A includes a diffuse, dense, compact, and apparently benign lymphoplasmacytic infiltration of the mucosal lamina propria. Stage B has features of stage A but also has circumscribed “immunoblastic” lymphoma in either the intestinal or mesenteric lymph nodes. Stage C comprises a diffuse “immunoblastic” lymphoma with or without demonstrable lymphoplasmacytic infiltration.³¹⁹ Villous broadening or effacement and shortened sparse crypts are also observed. These histopathologic findings can be distinguished from those of celiac sprue because celiac sprue includes total villous atrophy, hyperplastic and elongated crypts, intraepithelial lymphocytosis, and surface epithelial flattening. The lymphoma that arises from celiac sprue is T-cell lymphoma³²⁵ rather than B cell lymphoma, as in the case of α -HCD. A study of 11 cases of IPSID demonstrated higher expressions of syndecan-1 in Stage A samples relative to Stage B; conversely, Stage B samples showed higher expression of BCL-6 and p53.³²⁶ IPSID lacks the t(11;18) translocation that is not uncommon in other MALT lymphomas. Other cytogenetic abnormalities have been seen including t(9;14), t(2;14), and t(5;9).³²⁰

The hypothesis that chronic antigenic stimulation by intestinal organisms is the cause of this disorder is credible and can be modeled after the MALT lymphoma paradigm. This hypothesis is further supported by the fact that the incidence of α -HCD (or IPSID) is most common in patients who live in areas with poor sanitation and who also have a high prevalence of intestinal microbial infestation. *H. pylori* had been a candidate organism,³²⁷ but its association was subsequently challenged.³²⁴ *C. jejuni* is now considered to be a possible offending organism,³²⁸ but this will need to be confirmed.

Although no data exist from randomized prospective studies, the standard accepted treatment for the early stage is broadspectrum antibiotics, with or without corticosteroids. This protocol has resulted in clinical or histologic remission (in 33% to 71% of cases), which is generally short-lived but occasionally durable.^{320, 321} In the absence of a documented

parasite or an intestinal bacterial overgrowth, therapy with tetracycline or metronidazole and ampicillin is appropriate.³²⁹
³³⁰ Any documented parasite should be eradicated. Treatment of *H. pylori* has led to complete remission in two patients with α -HCD,³³¹ one of whom was unresponsive to prior combination chemotherapy. Lecuit et al. demonstrated response of IPSID after clearance of *C. jejuni*.³²⁸ Response to antibiotics usually occurs promptly; however, a minimum 6-month trial of tetracycline (1 to 2 g/d) is recommended for establishing responsiveness of the lesion.³³² In patients with more advanced stages, or unresponsive early stages, total abdominal radiation or combination chemotherapy, or both, have been used (remission rate, 64%).^{320, 333, 334, 335, 336, 337, 338} Overall 5-year survival rates are 60% to 70%. Immunotherapy with rituximab, an anti-CD20 monoclonal antibody, has been a major advance in the treatment of indolent NHL,³³⁹ but to date there have been no reports of rituximab use in patients with α -HCD.

μ -Heavy-chain Disease

First described in 1970, μ -HCD is a rare condition.^{340, 341} The median age of patients with μ HCD is about 57 years and equal numbers of males and females are affected.^{314, 342, 343} Common clinical presentations include splenomegaly and hepatomegaly. Lymphadenopathy is less common. About one-third of patients have chronic lymphocytic leukemia. Some patients with μ -HCD have features resembling those of lymphoma or MM with amyloid arthropathy.³⁴⁴ Hypogammaglobulinemia is present in about one-half of the patients and a free monoclonal IgM fragment is found in the serum of all patients. The μ -heavy-chain is missing most, if not all, of its VH region.³⁴⁵ A free monoclonal light chain has been described in the urine in about one-half of the cases.^{314, 346} Lytic bone lesions or osteoporosis occurs in a minority of patients. Bone marrow plasma cells tend to be vacuolated. Survival ranges from less than 1 month to 11 years (median, 24 months).³¹⁴ There is no standard treatment for this disorder, but it is generally treated as a low-grade lymphoproliferative disease with observation alone

P.2156

for asymptomatic patients and low-intensity chemotherapy for symptomatic patients.

γ -Heavy-chain Disease

First described in 1964 by Franklin et al.,³⁴⁷ γ HCD has a diverse clinical phenotype. The median age of patients with γ -HCD is 61 years, with 54% of the patients being male.^{343, 348} Originally, γ HCD was considered to be merely a lymphoma-like illness; Kyle et al.³⁴³ challenged this concept. Since the original description, there have been approximately 100 cases reported in the literature.³¹⁵ Although most patients present with weakness, fatigue, fever, lymphadenopathy (62%), hepatomegaly (58%), splenomegaly (59%), and lymphoma, other features, such as autoimmune hemolytic anemia and idiopathic thrombocytopenic purpura, may also be seen.^{315, 343} Cutaneous and subcutaneous involvement is not uncommon.³⁴⁹ Several cases have arisen in patients with long-standing connective tissue disorders such as rheumatoid arthritis,^{315, 350, 351, 352} lupus,^{315, 353} keratoconjunctivitis sicca,^{354, 355} vasculitis,³⁵⁵ and myasthenia gravis.³¹⁵ A normochromic anemia is a presenting feature in about 79% of patients. About 10% have either a Coombs-positive or Coombs-negative autoimmune hemolytic anemia.^{314, 315, 355} Lymphopenia and lymphocytosis each occur in less than 10% of patients. Thrombocytopenia may be present in as many as 22% of patients.³¹⁵

The γ chain in this disorder is truncated with deletions at the CH1 domain.^{356, 357} The mobility pattern of the immunoglobulin fragment on protein electrophoresis is quite variable, with the band present anywhere from the α 1-globulin region to the slow γ -globulin region; most commonly, however, it runs in the β region.³¹⁵ The subclass is IgG1 in 76%, IgG2 in 19%, and IgG4 in 5% of cases. With the normal distribution of subclasses, one would expect a higher occurrence of IgG2 and a lower occurrence of IgG3 and IgG1. Proteinuria can range from none to 20 g/d.

Bone marrow most commonly demonstrates an increase of plasma cells, lymphocytes, or plasmacytoid lymphocytes; occasionally eosinophilia is seen. The lymphoproliferative disorders range from benign lymphoplasmacytoid proliferative disorder to plasmacytoma, to chronic lymphocytic leukemia, to angioimmunoblastic lymphoma, to diffuse large cell lymphoma.^{315, 358} Lytic bone disease occurs rarely. Amyloid deposits may be present.³⁴³

The median survival is 7.4 years, with a range of 1 month to more than 25 years.³¹⁵ Treatment is not standardized. Single-agent therapy with prednisone and combination chemotherapy with cyclophosphamide, vincristine, and prednisone have been used with benefit. Wahner-Roedler et al. reported a rituximab response in one patient.³¹⁵ Patients with aggressive lymphomas should receive a regimen containing anthracycline.

Part VIII - Transplantation

Chapter 102 Hematopoietic Cell Transplantation

Transplantation of hematopoietic cell grafts containing pluripotent hematopoietic stem cells (HSCs) after myeloablative or nonmyeloablative conditioning regimens reconstitutes immunohematopoiesis. Sites from which HSC can be harvested and then used for transplantation include bone marrow, peripheral blood, and the umbilical cord. Patients may serve as their own donors (autologous) or may receive HSC from other individuals (related or unrelated). Hematopoietic cell transplantation (HCT) is done for a variety of therapeutic indications: (1) to support hematopoiesis after myeloablative doses of total body irradiation (TBI) and chemotherapy, (2) to establish a graft-versus-leukemia or tumor (GVL or GVT) reaction, or (3) to replace diseased tissues of hematologic or immunologic origins. The advances in supportive care after transplantation have resulted in improved outcomes, and HCT has become more accepted as a therapeutic modality that can be successful in otherwise life-threatening diseases. In the 2003-2007 period as compared with the 1993-1997 period, a 60% reduction in day 200 nonrelapse mortality and a 41% reduction in overall mortality was observed.¹ There were also significant reductions in severe graft-versus-host disease (GVHD), opportunistic infections, and organ damage.

The focus of this chapter is on the general indications for HCT, sources of stem cells, conditioning regimens, transplant biology issues, and complications of HCT; other chapters provide detailed discussions of the indications and results of HCT in relation to specific diseases (Table 102.1).

HISTORICAL PERSPECTIVE

Early Preclinical Studies

After the effects of radiation on hematopoiesis became evident during World War II, Jacobson and colleagues reported that mice survived an otherwise lethal exposure to TBI if the spleen was shielded (Fig. 102.1).² Radiation protection was also conferred by infusion of bone marrow.³ A runting syndrome developed after recovery of hematopoiesis when the infused marrow was from a donor of a different mouse strain.⁴ This syndrome was due to GVHD, a complication that was soon recognized to limit the use of allogeneic marrow transplantation in humans. In further studies in mice, methotrexate and 6-mercaptopurine were found to be effective in inducing immune tolerance or ameliorating the graft-versus-host (GVH) reaction.⁵

The dog served as a random-bred large animal model for studies of principles and techniques of bone marrow transplantation applicable to humans. The dog was the first random-bred species in which it was demonstrated that the results of *in vitro* histocompatibility typing could predict the outcome of marrow transplantation.⁶ Littermates genotypically identical for the major histocompatibility complex (MHC) survived longer after marrow transplantation than did their MHC-nonidentical siblings. However, despite the MHC genotypic identity, GVHD was still potentially severe in many but not all dogs. This indicated that other factors identified as minor histocompatibility antigens (mHC) were involved in the development of GVHD. Pharmacologic immunosuppression with a calcineurin inhibitor

P.2160

(i.e., cyclosporine or tacrolimus) or methotrexate for prevention of GVHD improved survival after allogeneic marrow grafting.^{7, 8} It was then established that methotrexate and cyclosporine in combination were more effective than either used alone.⁹ The efficacy of a calcineurin inhibitor and methotrexate combined for GVHD prevention was subsequently confirmed in clinical trials and remains the standard in many transplant programs.

Early Clinical Studies

Bone marrow was the first commonly used source of HSC for transplantation. Bone marrow transplantation from human leukocyte antigen (HLA)-identical sibling donors was first successfully used by two groups in 1968 to treat patients with immunologic deficiencies.^{10, 11} After extensive preclinical studies of GVHD, Thomas et al. then reported the successful transplantation of marrow from a HLA-identical sibling donor for aplastic anemia in 1972.¹² Five years later, the same group reported their experience in 100 patients with end-stage leukemia treated with allogeneic marrow transplantation.¹³ Allogeneic HCT from an HLA-matched related or unrelated donor is now considered standard therapy for many malignant and nonmalignant hematologic diseases.

HEMATOPOIETIC STEM CELLS

The HSC is defined as a cell with the ability to achieve long-term reconstitution of both myeloid and lymphoid lineages. To fulfill these criteria, HSC must be able to self-renew and be pluripotent. In vitro colony-forming units (e.g., CFU-GM, CFU-Meg, CFU-E, BFU-E) are progenitor cells that cannot reconstitute hematopoiesis, whereas populations of cells enriched for long-term culture-initiating cells can, at least in the mouse, rescue lethally irradiated recipients.^{14, 15} No accepted in vitro assays for human HSC are available currently. A population of small mononuclear cells enriched for HSC can be identified by (1) the presence of the CD34 and CD133 antigen, the absence of lineage-specific antigens, and high content of aldehyde dehydrogenase and (2) the exclusion of fluorescent vital dyes including Rhodamine¹²³ and Hoechst 33 342 (Table 102.2).^{16, 17, 18, 19, 20} In humans and other species, successful sustained engraftment was achieved with isolated CD34-positive cells confirming that a true "stem cell" is contained within this population.^{21, 22, 23, 24}

The true extent of the pluripotency of adult marrow-derived stem cells remains under investigation. Several studies have reported that populations of HSCs may contribute to regeneration of muscle, osteoblasts, hepatocytes, and neuronal and nonneuronal cell types of the brain.^{25, 26, 27} However, some of the

P.2161

experimental observations may have resulted from cell fusion, technical artifact, or culture induced changes in cellular gene expression. Nevertheless, there is agreement that if "plasticity" of circulating HSCs occurs, it is likely to be a rare event.²⁸

Identification of Cell Populations Enriched for Hematopoietic Stem Cells

The CD34 antigen is a cell surface type 1 transmembrane protein which is highly O-glycosylated and expressed primarily on hematopoietic progenitor cells and vascular endothelium from many tissues.^{29, 30, 31} It is also expressed on stromal cell precursors identified by the STRO-1 antibody. Cell surface expression of CD34 is developmentally regulated in hematopoiesis and is inversely related to the stage of differentiation such that CD34 expression is absent beyond the committed progenitor stage. The functional significance of CD34 expression on hematopoietic progenitor cells, stromal cells, and developing blood vessels is unknown, except that CD34 on vascular endothelial cells binds to L-selectin.³² The CD34 antigen is expressed on 1% to 5% of normal human adult marrow cells, up to 1% of mobilized peripheral blood cells, and by 2% to 10% of normal fetal liver and marrow cells.^{29, 33} Approximately 90% to 95% of the CD34-positive cells express antigens indicating commitment to the lymphoid or myeloid lineages.^{34, 35} Purified populations of HSC can be obtained with strategies that lineage-deplete a CD34-positive population of cells using monoclonal antibodies specific for DR, CD33, CD38, CD71, and B and T cell markers (Table 102.2). Other work suggests that human HSC are Thy-1^{low}, c-KIT^{low}, Rhodamine¹²³^{low}, and CD133-positive.^{36, 37, 38, 39, 40, 41} In vivo preclinical models for studying populations of purified human HSCs based on the aforementioned characteristics include transplantation into SCID-Hu mice or into fetal sheep.^{40, 42, 43}

Enriched populations of autologous CD34-positive marrow cells or blood cells, in both animal and human studies, have been shown to protect from myeloablative doses of radiation or chemotherapy.^{22, 44, 45} Conversely, the CD34-negative subset of the marrow was not protective.^{46, 47} Complete and stable donor hematopoietic chimerism has also been shown in humans after transplantation with allogeneic CD34-enriched cells from the peripheral blood.^{24, 48} Thus, CD34-positive hematopoietic cells are capable of long-term stable reconstitution of multiple hematopoietic lineages.

Sites of Hematopoiesis and for Collection of Hematopoietic Stem Cells

In the developing human embryo, the production of hematopoietic cells shifts to the liver from the yolk sac after 6 weeks of gestation. At 16 weeks of gestation, the most active site of hematopoiesis is the fetal liver. At the end of gestation, essentially all hematopoietic production derives from the marrow with only small contributions from the liver and spleen. Umbilical cord blood is enriched for HSC. The number of progenitors in one cord blood unit were comparable to the number of progenitors from adult marrow that had been reported to achieve successful engraftment.⁴⁹

Historically, the bone marrow served as the routine collection site for HSC.⁵⁰ Marrow is a clinically reliable and easily accessible source of long-term reconstituting cells. The presence of HSC in peripheral blood was first documented in preclinical studies.^{51, 52} In early clinical studies, transplantation of autologous peripheral blood HSC resulted in reconstitution of hematopoiesis following myeloablative chemotherapy or chemoradiotherapy; however, obtaining sufficient HSC required a prolonged period of collection.⁵³ To overcome this problem, granulocyte-colony-stimulating factor (G-CSF) can be administered to mobilize HSC from the marrow to the peripheral blood. Collections from G-CSF-mobilized peripheral blood yielded similar or greater numbers of HSC than that harvested from marrow.⁵⁴ Combining chemotherapy and G-CSF administration for mobilization resulted in higher yield of CD34-positive cells than G-CSF alone.⁵⁵ Plerixafor is a small molecule that reversibly inhibits chemokine stromal cell-derived factor-1 α binding to its cognate receptor CXCR4. In a randomized clinical trial, G-CSF with plerixafor was more effective than G-CSF alone for collection of stem cells in patients with myeloma.⁵⁶ In this study, a total of 54% of plerixafor-treated patients collected a target number of 6.0×10^6 CD34⁺ cells/kg after one apheresis, whereas 56% of placebo-treated patients required 4 daily aphereses to achieve this target. Other cytokines have been demonstrated to mobilize HSC into peripheral blood, including stem cell factor, granulocyte/macrophage-CSF, interleukin-6 (IL-6), IL-8, and flt-3 ligand.^{57, 58} While most normal donors receive only G-CSF for mobilization of HSC for allogeneic transplant, mobilization strategies including plerixafor or chemotherapy are now routinely used for the collection of autologous HSC from the peripheral blood of patients with hematologic malignancy.^{59, 60, 61} Plerixafor is not indicated for use in patients with acute leukemia.

Monoclonal antibodies specific to the adhesion molecule VLA-4 (very late antigen-4 or $\alpha 4\beta 1$ integrin) and VCAM-1 (vascular cell adhesion molecule-1) can also mobilize hematopoietic progenitors in nonhuman primates.^{62, 63} An essential step contributing to the release of hematopoietic progenitors from the marrow may be the cleavage of VCAM-1 expressed on stromal cells by neutrophil proteinases following the administration of G-CSF.⁶⁴ Hematopoietic progenitors reversibly downregulate VLA-4 expression and adhere significantly less to stroma and fibronectin during mobilization.⁶⁵ VLA-4 integrin expression is restored after progenitors are removed from the in vivo mobilizing milieu, which may account for their homing properties after transplantation.

SELECTION OF STEM CELL SOURCE

Autologous, syngeneic, and allogeneic are the three general categories of HSC grafts (Table 102.3). In general, the origin of HSC used for HCT is based on both the availability of the donor and the type of disease for which the patient is being

transplanted. While autologous HSC should be available for most patients, extensive prior cytotoxic therapy or heavy involvement of marrow with malignant cells may preclude the use of this source of HSC. Although the preferred allogeneic donor is an HLA-identical sibling, fewer than 30% of patients have access to this source. Availability of HLA-identical sibling donors for pediatric patients may be less than this because of the smaller family sizes now compared to previous generations. Syngeneic donors are available in less than 1% of cases, and phenotypically HLA-matched or one-antigen-mismatched haploidentical family donors are available in less than 5% of cases.⁶⁶ Approximately 30% to 40% of patients may identify a phenotypically HLA-matched unrelated donor from the volunteer registries.⁶⁷ The availability of unrelated (or related) umbilical cord blood banks increases the chances of successfully identifying a compatible allogeneic graft source for both pediatric and adult patients.^{68, 69, 70} HLA-haploidentical donors are also available for the majority of patients.

The disease for which transplantation is being considered is another important determinant for choice of stem cell source. Autologous, syngeneic, or allogeneic HSC can support hematopoietic recovery after myeloablative chemoradiotherapy for malignant hematologic and nonhematologic diseases. For acquired disorders of marrow function (e.g., aplastic anemia), syngeneic or allogeneic HSC are required.⁷¹ Patients with congenital hematopoietic or immunologic defects (e.g., thalassemia, severe combined immunodeficiency (SCID) syndrome) require transplantation with allogeneic stem cells or gene-modified autologous stem cells.^{72, 73, 74, 75}

P.2162

TABLE 102.3 POTENTIAL SOURCES OF HEMATOPOIETIC STEM CELL (HSC) FOR HEMATOPOIETIC CELL TRANSPLANTATION

	Relationship of Donor	MHC (HLA)-Identical Matching	Genetically Identical Haplotype	mHC ^a Matching	Site of HSC Collection
I. Syngeneic	Sibling	Identical	2	Identical	Marrow or peripheral blood
II. Allogeneic	Sibling	Identical	2	Shared	Marrow, peripheral blood, or umbilical cord blood
	Sibling, Parent, Child	0-3 Antigen ^b Mismatch	1	Shared	Marrow, peripheral blood, or umbilical cord blood (sibling or child)
	Unrelated	Identical 1 Antigen Mismatch or 2 Allele Mismatch	0	Divergent	Marrow or peripheral blood
	Unrelated	0-3 Antigen Mismatch	0	Divergent	Umbilical cord blood
III. Autologous	Self				Marrow or peripheral blood

HLA, human leukocyte antigen; mHC, minor histocompatibility complex; MHC, major histocompatibility complex.

^a Shared indicates a higher probability of sharing mHC antigens within the family. Divergent indicates that the probability of sharing mHC antigens is no better than what is expected by matching two unrelated individuals who were randomly chosen. There is currently no routine testing for mHC compatibility.

^b Two or three antigen mismatched transplants of unmanipulated marrow grafts from adult or pediatric family donors have in general a higher transplant-related mortality.

Autologous Source of Stem Cells

Autologous marrow or mobilized peripheral blood stem cells are the grafts of choice for many patients. Autologous stem cell support is most commonly derived from “mobilized” peripheral blood stem cells instead of marrow because of faster hematopoietic recovery in the recipient.⁶⁰ Peripheral blood stem cell transplants have decreased the time required for hospitalization. Autologous stem cell support after myeloablative therapy has been successful for treatment of acute myelogenous leukemia (AML), non-Hodgkin lymphoma, and Hodgkin lymphoma.^{76, 77, 78, 79} Disease-free survival was prolonged in patients with multiple myeloma receiving a single autologous or two sequential autologous transplants.^{80, 81} Significant transplant-related complications encountered most frequently include infections and organ toxicity of the liver or lung, caused in large part by the high-dose myeloablative cytotoxic therapy. A GVHD-like syndrome (also known as the engraftment syndrome or pseudo-GVHD) of the skin and gastrointestinal tract has been described, but it is generally not frequent or severe.^{82, 83}

Allogeneic Source of Stem Cells

Transplantation from Related Donors

Hematopoietic cell grafts from related donors may be HLA-identical or HLA-haploidentical. The preferred allogeneic donor has been a genotypically HLA-identical sibling. A genetic match at the HLA loci between siblings is confirmed by the genotyping of 5 HLA loci including HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1. If an HLA-identical sibling is available, patients with hematologic malignancies should be transplanted with peripheral blood stem cells rather than marrow. Two phase 3 studies have now shown an improved disease-free and overall survival with transplantation of peripheral blood stem cells (Fig. 102.2).^{84, 85} Ten year follow-up of the study by Bensinger et al. showed that the benefit persisted for disease-free survival, but the likelihood of overall survival was not significantly different between the 2 groups.⁸⁶ The 10-year cumulative incidence of chronic GVHD and the duration of systemic immunosuppression were similar between the 2 groups. A third study concluded that peripheral blood was an equivalent source of HSCs compared with marrow if administered to patients with standard-risk leukemia, since a significant difference in survival could not be demonstrated.⁸⁷ All 3 studies showed an accelerated recovery of neutrophil counts in the group receiving peripheral blood stem cells. Although most studies have not shown a significant increase in the incidence of acute GVHD in the peripheral blood stem cell group, the incidence of chronic GVHD was significantly greater.^{84, 85, 87, 88} Higher doses of CD34-positive cells in the peripheral blood stem cell graft ($>8.0 \times 10^6/\text{kg}$) have been significantly associated with the development of chronic GVHD.⁸⁹ Since outcome is unlikely to be improved if there is an increased risk of chronic GVHD from the use of peripheral blood stem cells, patients with nonmalignant disorders are still being transplanted with marrow in some centers. With a median follow-up of 6 years, survival of aplastic anemia patients transplanted with marrow was 88% (Fig. 102.3).⁹⁰ In a retrospective analysis by CIBMTR, rates of chronic GVHD and overall mortality were greater after transplantation with peripheral blood stem cells than marrow, especially in the younger patient population (<20 years of age).⁹¹ Similar survivals to those observed after HCT for aplastic anemia have been reported in patients transplanted with marrow for hemoglobinopathies.^{72, 92}

FIGURE 102.2. Probability of overall survival after myeloablative conditioning and transplantation with either peripheral blood stem cells or marrow. Survival at 2 years was improved in the peripheral blood stem cell group as compared to marrow (66% vs. 54%; $P = 0.006$). Disease-free survival was also improved in the peripheral blood stem cell group ($P = 0.003$). (Reprinted with permission from Bensinger WI, Martin PJ, Storer B, et al. Transplantation of bone marrow as compared with peripheral blood cells from HLA-identical relatives in patients with hematologic cancers. *N Engl J Med* 2001;344:175-181. FIGURE 102.3. Overall survival among 94 patients with aplastic anemia who underwent transplantation from HLA-identical siblings after conditioning with cyclophosphamide (CY) and antithymocyte globulin. With a median follow-up of 6.0 (0.5 to 11.6) years, the Kaplan-Meier estimate of survival was 88%. Cyclosporine and methotrexate were administered after transplantation for graft-versus-host disease (GVHD) prophylaxis. (Reprinted with permission from Storb R, Blume KG, O'Donnell MR, et al. Cyclophosphamide and antithymocyte globulin to condition patients with aplastic anemia for allogeneic marrow transplantations: the experience in four centers. *Biol Blood Marrow Transplant* 2001;7:39-44.)

An HLA-haploidentical donor (parent, sibling, child) is available for almost all patients, but haplotype differences (genotypically identical at one HLA haplotype but nonidentical at the other HLA haplotype) are associated with a high risk of severe GVHD, graft rejection, and increased mortality with conventional posttransplant immunosuppression. However, transplants for hematologic malignancies from HLA-haploidentical family members mismatched for only one HLA antigen in the nonidentical HLA haplotype may have a similar overall survival to transplants from HLA-identical siblings.⁹³ In this situation, although the higher incidence of GVHD results in an increased transplant-related mortality, relapse is less frequent, resulting in no overall difference in long-term survival compared to transplants from HLA-matched siblings. Patients transplanted from HLA-haploidentical family members mismatched for 2 or more HLA loci had significantly lower overall survivals compared to patients transplanted from phenotypically HLA-matched unrelated donors.⁹⁴ In patients with advanced leukemia, transplantation with high-dose CD34-positive cell grafts which had been highly T cell-depleted resulted in 12 of 43 patients being alive and disease-free at 18 months.⁹⁵ Immune reconstitution after transplantation was poor, however.⁹⁶ High-dose cyclophosphamide (CY) early after HCT from an HLA-haploidentical donor appears effective in preventing the development of severe acute and chronic GVHD.^{97, 98} In a report of parallel phase 2 studies, transplantation of HLA-haploidentical marrow grafts appeared to have favorable outcomes at 1 year compared to transplantation of umbilical cord blood grafts.⁹⁹ Patients who lack a closely matched family donor should be offered a phenotypically HLA-matched unrelated donor before considering a transplant from an HLA-haploidentical donor.

Transplantation from Unrelated Donors

After the initial success with transplantation of marrow from matched unrelated volunteers, large databanks were established around the world, including the National Marrow Donor Program (NMDP) in the United States. Available through the world-wide registries and the NMDP are approximately 20 million volunteer donors who have been typed for HLA-A and -B antigens, and many of these are also typed for HLA-DR (www.bmdw.org). Certain racial and ethnic groups are underrepresented in the registry and therefore there is a lower probability that an HLA-matched donor will be found.

Outcomes have improved after HCT from HLA-matched unrelated donors because of improved supportive care and high-resolution HLA typing. Outcomes after HCT from an unrelated donor are now comparable to what is observed after HCT from an HLA-identical sibling. In a study of 2,223 adult AML patients, the overall survival after transplantation from 8/8 HLA-matched donors was similar to that observed after transplantation from an HLA-identical sibling (RR = 1.03; P = 0.62).¹⁰⁰ The risk of acute GVHD, however, was lower after transplantation from an HLA-identical sibling.

The relative importance of the various HLA loci has been defined for HCT from unrelated donors. In a study from CIBMTR of 3,857 transplants performed from 1988 to 2003, it was observed that high-resolution DNA matching for HLA-A, HLA-B, HLA-C, or HLA-DRB1 (8/8 match) was the minimal level of matching associated with the highest survival.¹⁰¹ A single mismatch at HLA-A, HLA-B, HLA-C, or HLA-DRB1 (7/8 match) was associated with an increased mortality compared to an 8/8 match. A single mismatch at HLA-B and HLA-C appeared better tolerated than a mismatch at HLA-A and HLA-DRB1. A mismatch at HLA-DQ or HLA-DP loci did not have an effect on survival. Ninety-four percent of the transplants in this study were performed with marrow grafts. In a follow-up study, the association between HLA matching and outcomes was investigated for transplantation of peripheral blood stem cells from unrelated donors.¹⁰² Survival was better with 8/8 HLA matching compared to 7/8 HLA matching. Single HLA-C antigen mismatches were associated with an increased risk of treatment-related mortality and grade III-IV acute GVHD. HLA-B antigen/allele mismatching was associated with an increased risk of grade III-IV acute GVHD with no effect on survival. No significant differences in outcomes were observed with HLA-C allele mismatches, HLA-A antigen/allele mismatches, or HLA-DRB1 mismatches compared to 8/8 HLA-matched pairs. The differences in the reported associations for HLA mismatches between marrow and peripheral blood stem cell grafts may result from differences in cell numbers in the graft as well as the graft composition.

Disease status is an important consideration in the search process. In patients with advanced malignancies, survival after transplantation from an HLA-matched or 1-antigen/allele HLA-mismatched unrelated donor was similar.¹⁰³ Therefore, when transplants cannot be delayed because of disease status, selection of a donor with the fewest HLA mismatches may be an alternative choice for patients without a completely HLA-matched donor.

Because of the possible higher risk of acute GVHD, studies of peripheral blood stem cell transplantation from unrelated donors started later than those done from HLA-identical donors. A recently completed randomized clinical trial (BMTCTN 0201) comparing marrow to peripheral blood stem cells observed that there was no difference in overall survival, disease-free survival, nonrelapse mortality, relapse, or acute GVHD outcomes at 2 years between the 2 arms. There was a significantly increased risk of chronic GVHD.

Transplantation with Umbilical Cord Blood Grafts

There are several advantages to the use of umbilical cord blood when compared to unrelated donor peripheral stem cell or marrow product harvested from adults. First, umbilical cord blood represents a potentially nonlimiting donor source for transplantation. At present, over 550,000 HLA typed cord bloods are banked and are conceivably available with several days notice (www.bmdw.org). Many of the banked specimens are from underrepresented ethnic and racial groups, thus expanding the potential donor pool for individuals poorly served by the unrelated donor marrow registries. The total nucleated cell dose required for successful engraftment is 10-fold less than that required for conventional peripheral blood or marrow transplant. The transmission

P.2164

of Epstein-Barr virus (EBV) or cytomegalovirus (CMV) is negligible compared to conventional allogeneic transplantation. HLA allele mismatches (up to 2 to 3 loci) are permissible in cord blood transplantation. Notable disadvantages to cord blood transplantation are the potential for prolonged pancytopenia and lower rates of overall engraftment.

The first successful cord blood cell transplant in a pediatric patient was done in 1988.⁶⁹ Two studies were then successfully conducted of cord blood transplantation from HLA-matched or HLA-haploidentical allogeneic siblings (44 patients) and partially HLA-mismatched unrelated donors (25 patients).^{104, 105} In the first report of a large experience in 562 recipients (including 18% adults) after transplantation with umbilical cord blood grafts from unrelated donors, the probability of engraftment at 42 days and grade III-IV GVHD, was 81% and 23%, respectively.¹⁰⁶ It was concluded from this study that umbilical cord blood grafts regularly engraft and cause a low rate of GVHD relative to the number of HLA mismatches, and produced survival rates comparable to those with transplantation of marrow from unrelated donors. This experience was confirmed in a retrospective analysis of 541 children with leukemia transplanted with stem cell grafts from unrelated donors of which 99 were from umbilical cord blood.¹⁰⁷ Recipients of cord blood had an increased number of HLA mismatches but a lower risk of both acute and chronic GVHD compared to recipients of unmanipulated marrow from unrelated donors. The day 100 mortality was higher, however, in the cord blood group, possibly because of the significantly delayed recovery of hematopoiesis and immunity after transplantation. These results were later confirmed by another group.¹⁰⁸ It was concluded that the use of umbilical cord blood was an option for children with acute leukemia lacking an acceptably matched unrelated marrow donor. In children who had received umbilical cord blood or bone marrow grafts from HLA-identical siblings, the umbilical cord blood group had a lower risk of acute and chronic GVHD (relative risk 0.41 [P = 0.001] and 0.35 [P = 0.02]), respectively.¹⁰⁹ Survival was similar in both groups. The progenitor cell and CD34-positive cell content of the umbilical cord blood graft predicted the rate of neutrophil recovery after transplantation.¹¹⁰

The reported low incidence of severe GVHD after transplant of umbilical cord blood cells from unrelated donors (relative to the degree of HLA disparity) may be related to the decreased immunocompetence of the fetal blood cells compared to adult cells.¹¹¹ Two years after transplantation, T cell receptor rearrangement excision circles (TRECs), a measure of recent thymic output, were greater in recipients of umbilical cord blood than in recipients of marrow grafts, suggesting complete immune recovery despite the low number of cells infused.¹¹²

Initially, recipients of umbilical cord blood cell transplants had been mostly children. Even though, at first, there was a concern about the low cell count for the larger body size, outcomes in adults were comparable to those reported in children.¹¹³ Prospective trials comparing cord blood transplantation to unrelated peripheral blood/marrow transplants are not available; however, two large registry or retrospective studies summarizing consortia experience for acute or chronic leukemias have been published.^{114, 115} Slower engraftment kinetics, reduced engraftment rates, and decreased acute and chronic GVHD rates and severity were observed in the cord blood transplantation groups. Rates of relapse reported for the two studies were similar between the 2 groups. Transplant-related complications, including delayed recovery of blood counts after cord blood transplantation, may be reduced in the adult population with reduced intensity conditioning.¹¹⁶

Transplantation of multiple cord blood units was investigated to determine if recovery of neutrophil and platelet counts after transplantation could be improved.¹¹⁷ After the infusion of two umbilical cord blood grafts into adult patients, the median day to neutrophil recovery was 24 (range 12 to 28) in 23 adult patients compared to 27 (range 13 to 59) in another

study of 68 adult patients transplanted with a single cord blood unit.¹¹³ This observation of improved recovery times was not confirmed in a retrospective study at a single institution.¹¹⁸ After transplantation with 2 cord blood units, only one unit eventually dominates and engrafts long-term.¹¹⁹ Higher CD3⁺ cell dose and percentage of CD34⁺ viability were associated with unit dominance. Higher dominant unit total nucleated cells, CD34⁺ cells, and colony-forming unit doses were associated with higher sustained engraftment and faster neutrophil recovery. Mechanistically, the dominant cord mounts an allogeneic immune response mediated by CD8⁺ T cells against the nondominant unit.¹²⁰ Outcomes after double cord blood transplantation were compared with outcomes after transplantation from HLA-matched related donors, HLA-matched unrelated donors, and 1-antigen HLA-mismatched unrelated donors.¹²¹ Leukemia-free survival at 5 years was similar for all donor types. The risk of relapse was decreased in the double cord blood transplantation group compared to the other donor types, but the risk of nonrelapse mortality was increased. The lower risk of relapse after transplantation from a double cord blood unit compared to a single cord blood unit had been previously seen in another retrospective study, although a significantly increased risk of acute GVHD was also observed.¹¹⁸ Sharing of one or more HLA-A, B, or DRB1 loci between the inherited paternal MHC alleles (IPA) of the donor and the recipient after unrelated cord blood transplantation leads to superior leukemia-free survival with no increase in acute GVHD, a result attributed to maternally derived anti-IPA elements persisting in the cord blood.¹²²

Umbilical cord blood grafts should be considered for both pediatric and adult patients lacking a suitably matched unrelated donor or unable to wait for an unrelated search to be completed.

COLLECTION OF HEMATOPOIETIC STEM CELLS FOR TRANSPLANTATION

Marrow

Marrow is obtained by multiple aspirations from the posterior iliac crest under general or epidural anesthesia.¹²³ The anterior iliac crest (or the sternum) may also be harvested if larger quantities of marrow are required. The target volume of marrow for transplant is 10 to 15 ml/kg of recipient or donor weight, whichever is the smaller individual. Marrow is collected with heparinized syringes through large bore needles and placed into small amounts of culture medium. The collected marrow must be filtered prior to intravenous transfusion into the recipient to remove small particles or clots. If the patient and donor are ABO-incompatible and there are high anti-A or -B titers, the marrow can be red blood cell-depleted or plasma-depleted, depending on whether it is a major or minor ABO mismatch.¹²⁴ In some cases of a major ABO mismatch, plasmapheresis of the recipient may be effective in reducing the high anti-A or anti-B titers so that RBC depletion of marrow is not required. Marrow is infused immediately after harvesting, but delays of 24 hours may occur without adverse consequences. Such delays are common when marrow is shipped to a transplant program after harvest from an unrelated donor. In an analysis of marrow harvest characteristics of 1,549 donors, the median total nucleated cell count from the marrow was 2.5 (range 0.3 to 12.0) $\times 10^8$ /kg recipient weight.¹²⁵ Life-threatening complications from marrow harvesting, usually related to the administration of anesthesia, were reported in 0.27% to 0.4% of the donors.¹²⁶

Peripheral Blood

HSC circulate in the peripheral blood but the concentration is very low and it requires multiple aphereses to collect adequate

P.2165

numbers. The number of aphereses may be reduced to one or two sessions when HSC are mobilized to the peripheral blood after the administration of cytokines alone or in combination with chemotherapy or plerixafor. An effective mobilization strategy of autologous HSC for patients with malignancy is chemotherapy in conjunction with G-CSF, 6 $\mu\text{g}/\text{kg}/\text{day}$.⁶¹ After chemotherapy, patients are apheresed when the total white blood cell count has recovered to 1,000/ μl or the CD34-positive cell count in the peripheral blood is at least $>10/\mu\text{l}$. For patients not requiring chemotherapy or normal allogeneic donors, mobilization is with G-CSF alone (5 to 16 $\mu\text{g}/\text{kg}$) by daily subcutaneous injections for 5 to 8 days.^{48, 127, 128} These doses of G-CSF are generally well tolerated, with common side effects of bone pains, myalgias, and flu-like symptoms that are managed with acetaminophen or low-dose narcotics. Plerixafor in combination with G-CSF was effective for increasing the yields of circulating CD34⁺ progenitor cells and is indicated for patients with lymphoma or multiple myeloma who are being collected for autologous HCT.⁵⁶ The recommended dose is 0.24 mg/kg/day administered subcutaneously 11 hours before the apheresis procedure. The maximum dose is 40 mg/day. Common side effects included diarrhea, nausea, fatigue, headaches, and arthralgias. Apheresis was performed as early as day 4 after the start of G-CSF using a continuous blood flow separation technique. Apheresed products may be cryopreserved in 5% dimethylsulfoxide (DMSO) for use after thawing on the day of transplant. A more rapid sustained hematopoietic recovery of both neutrophil and platelet counts occurs with increasing numbers of CD34⁺ cells in the hematopoietic cell graft (up to

$5 \times 10^6/\text{kg}$). Some investigators consider $2.5 \times 10^6/\text{kg}$ of recipient weight a minimum dose of CD34^+ cells from the peripheral blood to achieve complete autologous recovery. Platelet recovery is more rapid at higher CD34^+ cell doses.^{60, 61} Since the cell dose used in the autologous transplant setting yields consistent and prompt engraftment, it is also considered an appropriate target for collection of allogeneic HSC from the peripheral blood. Donors of peripheral blood avoid general anesthesia and other complications of marrow harvesting. If peripheral veins are inadequate, a large bore double lumen catheter for vascular access may be required. In a large analysis of safety from the NMDP ($n = 2,408$ donors), it was concluded that collection of peripheral blood stem cells was safe but that nearly all patients will experience bone pain and 1 in 4 will have headache, nausea, or citrate toxicity.¹²⁹ Serious and unexpected toxicities were experienced by 0.6% of the donors, but complete recovery was universal.

Cord Blood

Umbilical cord blood cells are now being routinely collected and cryopreserved for storage in a cord blood bank.^{130, 131} Directed-donor banking of cord blood for siblings in a current good tissue practices environment has also now been reported.¹³² After the separation of the placenta, umbilical cord blood cells are collected into a closed system which utilizes a sterile donor blood collection set. The placenta and umbilical cord can be suspended on a frame and the blood drained as a "standard gravity phlebotomy" into CPD (citrate, phosphate, dextrose) anticoagulant. The median volume of umbilical cord blood collected in one study of 44 patients was 100 ml (range 42 to 282 ml).¹⁰⁴ The median number of total nucleated cells per kilogram of recipient weight for banked umbilical cord blood is 2.5×10^7 (range 1 to 33) and corresponds to a CD34^+ cell dose of 1.5×10^5 per kilogram of recipient weight.¹¹⁰

ABO INCOMPATIBILITY

ABO incompatibility between the donor and the recipient occurs in about 30% of cases. A major ABO incompatibility is considered to occur when the isohemagglutinins in the recipient plasma are directed against the donor red blood cell antigens. A minor ABO incompatibility is when the isohemagglutinins in the donor plasma are directed against recipient red blood cell antigens. ABO incompatibility between the donor and the recipient has no significant effect on the incidence of graft rejection, GVHD, or survival, although bidirectional ABO mismatches were associated with a higher risk of grade III-IV acute GVHD.¹³³ ABO incompatibilities may result in severe hemolytic episodes after transplantation. For major ABO incompatibilities, if the recipient isohemagglutinin titers in the plasma are high, an acute hemolytic event can be prevented by red cell depletion of the graft. Conversely, plasmapheresis may be effective in reducing the anti-donor isohemagglutinin in the recipient plasma. If the latter approach is chosen, the goal should be to reduce the isohemagglutinin titer to 1:16 or lower.¹³⁴ If there is continued production of anti-donor isohemagglutinins in the recipient plasma after transplantation, delayed erythropoiesis or even pure red cell aplasia and persistent hemolysis may result.¹³⁵ Although plasmapheresis and erythropoietin may be of some benefit, the hemolytic episode may persist for months after transplantation. If there are no contraindications, early withdrawal of immunosuppression may result in a more rapid resolution of the delayed hemolytic event, possibly because of a GVH reaction against the isohemagglutinin-producing cells of the recipient.¹³⁶ To prevent hemolytic events related to minor ABO incompatibilities, the isohemagglutinins can be removed from the stem cell graft if the anti-recipient titers are high. The risk of hemolysis from a minor ABO mismatch appears to be increased after peripheral blood stem cell transplantation, possibly related to the higher content of lymphoid cells (B cells) in the graft. The development of severe hemolysis may be prevented with the administration of methotrexate after transplantation.¹³⁷

CONDITIONING REGIMENS

Myeloablative

Myeloablative conditioning regimens are sufficiently intense that recovery of hematopoiesis would not be expected without the support of transplanted hematopoietic progenitor cells. The ideal myeloablative conditioning regimen should fulfill the following criteria: (1) eliminate or reduce the tumor load; (2) suppress the host immune system to prevent graft rejection (not applicable to hematopoietic support with autologous cells); and (3) have tolerable nonhematopoietic toxicity. The first conditioning regimens consisted of TBI, alone or in combination with cyclophosphamide (CY).⁵⁰ TBI is an effective antineoplastic modality that is both cell cycle nonspecific and immunosuppressive. CY is a chemotherapeutic agent with immunosuppressive properties that has few nonhematopoietic toxicities that are similar to TBI, and therefore can be used in combination. Other conditioning regimens which have since been developed include: (1) the replacement of CY with other chemotherapeutic agents (e.g., etoposide, Ara-C, and melphalan) in combination with TBI.^{138, 139}; (2) other chemotherapeutic agents in combination with both CY and TBI^{140, 141}; (3) chemotherapeutic agents used in combination with CY but without TBI, including busulfan (BU)/CY or carmustine-cyclophosphamide-etoposide (BCV)^{142, 143}; and (4) replacement of CY with fludarabine and used in combination with BU or melphalan.^{144, 145} In one study, BCV was

associated with a significant incidence of transplant-related complications and mortality.¹⁴⁶ Other high-dose cytotoxic regimens have been used, especially with autologous stem cell support.^{147, 148}

Most preparative regimens used for the treatment of malignant diseases have not been tested in Phase III studies, so it is generally unclear if any one regimen represents an improvement over those previously used. Two Phase III studies in allogeneic marrow transplantation have compared differing intensities of TBI

P.2166

(1,200 cGy versus 1,575 cGy).^{149, 150} The relapse rate was reduced in the group of patients receiving the higher dose of TBI, but was associated with an increase in complications from regimen-related toxicity and GVHD which negated any improvement in disease-free survival compared to the group receiving the lower dose of TBI. In a more recent study, conditioning with TBI 800 cGy and fludarabine was compared with TBI 1,200 cGy and CY and there was no difference in overall survival, relapse, or treatment-related mortality.¹⁵¹ The combination of BU/CY was determined to be an acceptable alternative to CY/TBI for patients with leukemia in several studies.^{152, 153, 154} However in one study, patients in the BU/CY group had an increased risk of sinusoidal obstruction syndrome (SOS) of the liver and other transplant-related complications.¹⁵⁵ Since this last study, it has been demonstrated that targeting of busulfan levels in the plasma may decrease the risk of relapse and severe regimen-related toxicities, contributing to an improved disease-free survival (Fig. 102.4).¹⁵⁶ Monitoring levels of metabolites from cyclophosphamide may also be important to decrease the risk of liver toxicity and nonrelapse mortality.^{157, 158}

In patients already profoundly immunosuppressed with SCID syndrome, engraftment of allogeneic stem cells from matched related siblings may occur without conditioning therapy.¹⁵⁹ High-dose CY in combination with antithymocyte globulin (ATG) as a preparative regimen for patients with aplastic anemia was associated with graft rejection in less than 5% of cases.⁹⁰ The actuarial survival rate was 88% at 6 years after transplantation (Fig. 102.3). For transplantation of patients with thalassemia or sickle cell disease, a myeloablative conditioning regimen, usually consisting of the combination of BU and CY, was thought to be necessary to prevent a high incidence of graft rejection, since most patients with these disorders had received multiple blood transfusions and were potentially sensitized to donor-derived mHC.^{160, 161} However, reduced intensity conditioning regimens have now been shown to successfully overcome the risk of graft rejection associated with these hematologic disorders.¹⁶²

Although HSC engraftment may be achieved after transplantation and some patients are cured, relapse remains an important problem in patients with advanced hematologic malignancies. Since further intensification of the conditioning regimen using current modalities is unlikely to improve overall survival because of associated increases in toxicity, new strategies will be required to achieve a cure. Radiolabeled monoclonal antibodies (i.e., radioimmunoconjugates) specific for certain lineage-specific cell surface antigens on tumor cells or sites from which the malignancy originates might enhance the efficacy of the conditioning regimen and decrease the rates of relapse.^{163, 164, 165, 166}

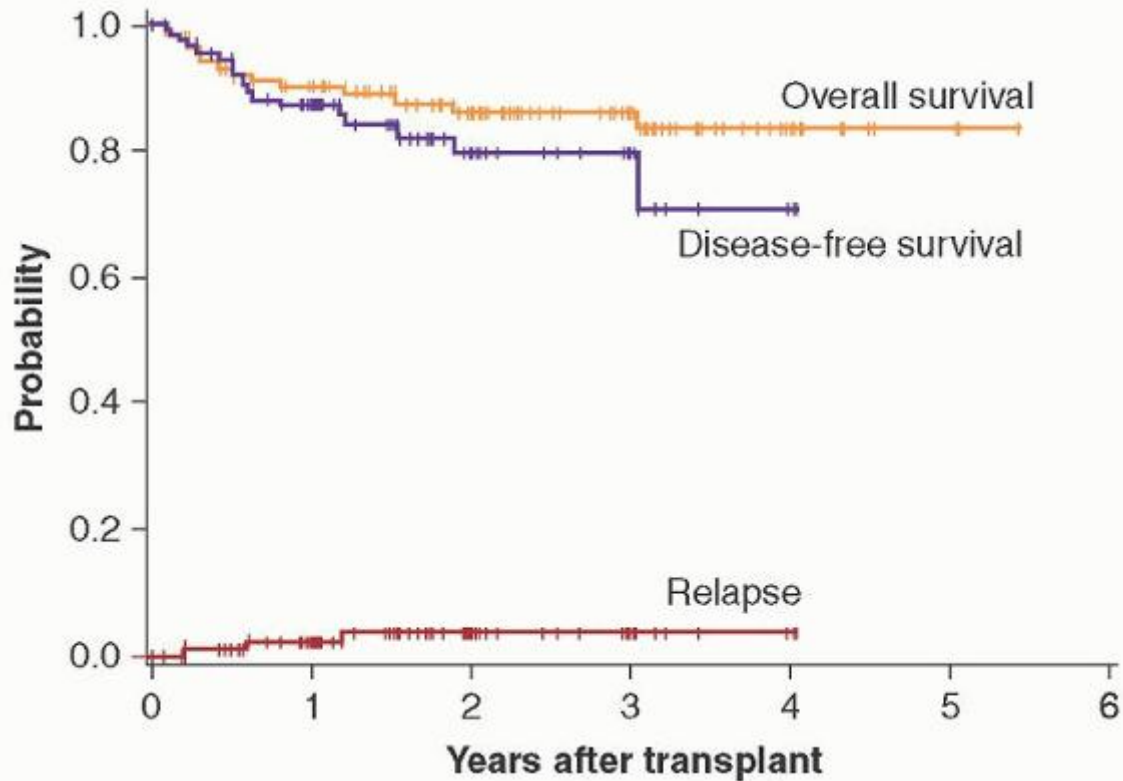

FIGURE 102.4. Outcomes for 131 patients after conditioning with cyclophosphamide and targeted busulfan followed by hematopoietic cell transplantation (HCT) from human leukocyte antigen (HLA)-identical siblings for chronic myelogenous leukemia in chronic phase. Graft-versus-host disease (GVHD) prophylaxis was with the combination of cyclosporine and methotrexate. The probability of survival was 86% at 3 years. (Reprinted with permission from Radich JP, Gooley T, Bensinger W, et al. HLA-matched related hematopoietic cell transplantation for chronic-phase CML using a targeted busulfan and cyclophosphamide preparative regimen. *Blood* 2003;102:31-35. Copyright American Society of Hematology.)

Nonmyeloablative

The development of nonmyeloablative or reduced intensity regimens permitted the application of potentially curative allogeneic HCT to older patients and those patients with contraindications to intensive cytotoxic regimens.¹⁶⁷ The success of the nonmyeloablative conditioning regimens in preclinical and clinical studies established new biologic principles which formed the basis of our understanding of the engraftment process after allogeneic HCT. The findings in these studies were consistent with the following conclusions about successful engraftment:

- Myeloablative therapy is not needed, since stem cell grafts can “create their own marrow space” with a GVH effect.
- Engraftment is promoted by posttransplant suppression of the host-versus-graft reaction.

There are multiple different nonmyeloablative conditioning regimens which have been piloted. The conditioning regimens fall into 2 broad categories: (1) reduced intensity regimens and (2) minimally myelosuppressive regimens.^{145, 168, 169, 170, 171, 172, 173} In general, after reduced intensity conditioning, recipients usually become aplastic from the regimen and complete chimerism is established early after transplantation. Reduced intensity conditioning regimens are of sufficiently low intensity that recovery of hematopoiesis would be expected without the support of hematopoietic progenitor cells. Although reduced in intensity, the regimen may contribute a substantial antitumor effect resulting in a tumor response early after transplantation. The minimally myelosuppressive or nonmyeloablative regimens rely on pretransplant and posttransplant immunosuppression to prevent graft rejection. After transplantation, a mixed chimeric state may persist for months before converting to full donor hematopoietic chimerism (Table 102.4).¹⁷² The regimen may be only mildly myelosuppressive resulting in a reduction in the requirements for blood products (Fig. 102.5).¹⁷⁴ The conditioning regimen would not be expected to have a substantial antitumor effect, so efficacy of the treatment is largely from a GVT effect.

TABLE 102.4 MEDIAN PERCENT AND CHIMERISM STATUS

	Day 28^a	Day 56^b
Median % (range) of donor cells		
T cells	60 (10-100)	91 (5-100)
PB neutrophils	91 (0-100)	99 (4-100)
Bone Marrow	87 (0-100)	95 (2-100)
Chimerism		
% Mixed ^c	86	79
% Full Donor ^d	14	21

^a 44 evaluable patients. One additional patient-donor pair had no identifiable DNA polymorphism, and evidence of donor cell engraftment was based on red blood cell polymorphisms.

^b 41 evaluable patients.

^c ≥ 1 and $\leq 95\%$ T cells of donor origin.

^d $>95\%$ T cells of donor origin.

P.2167

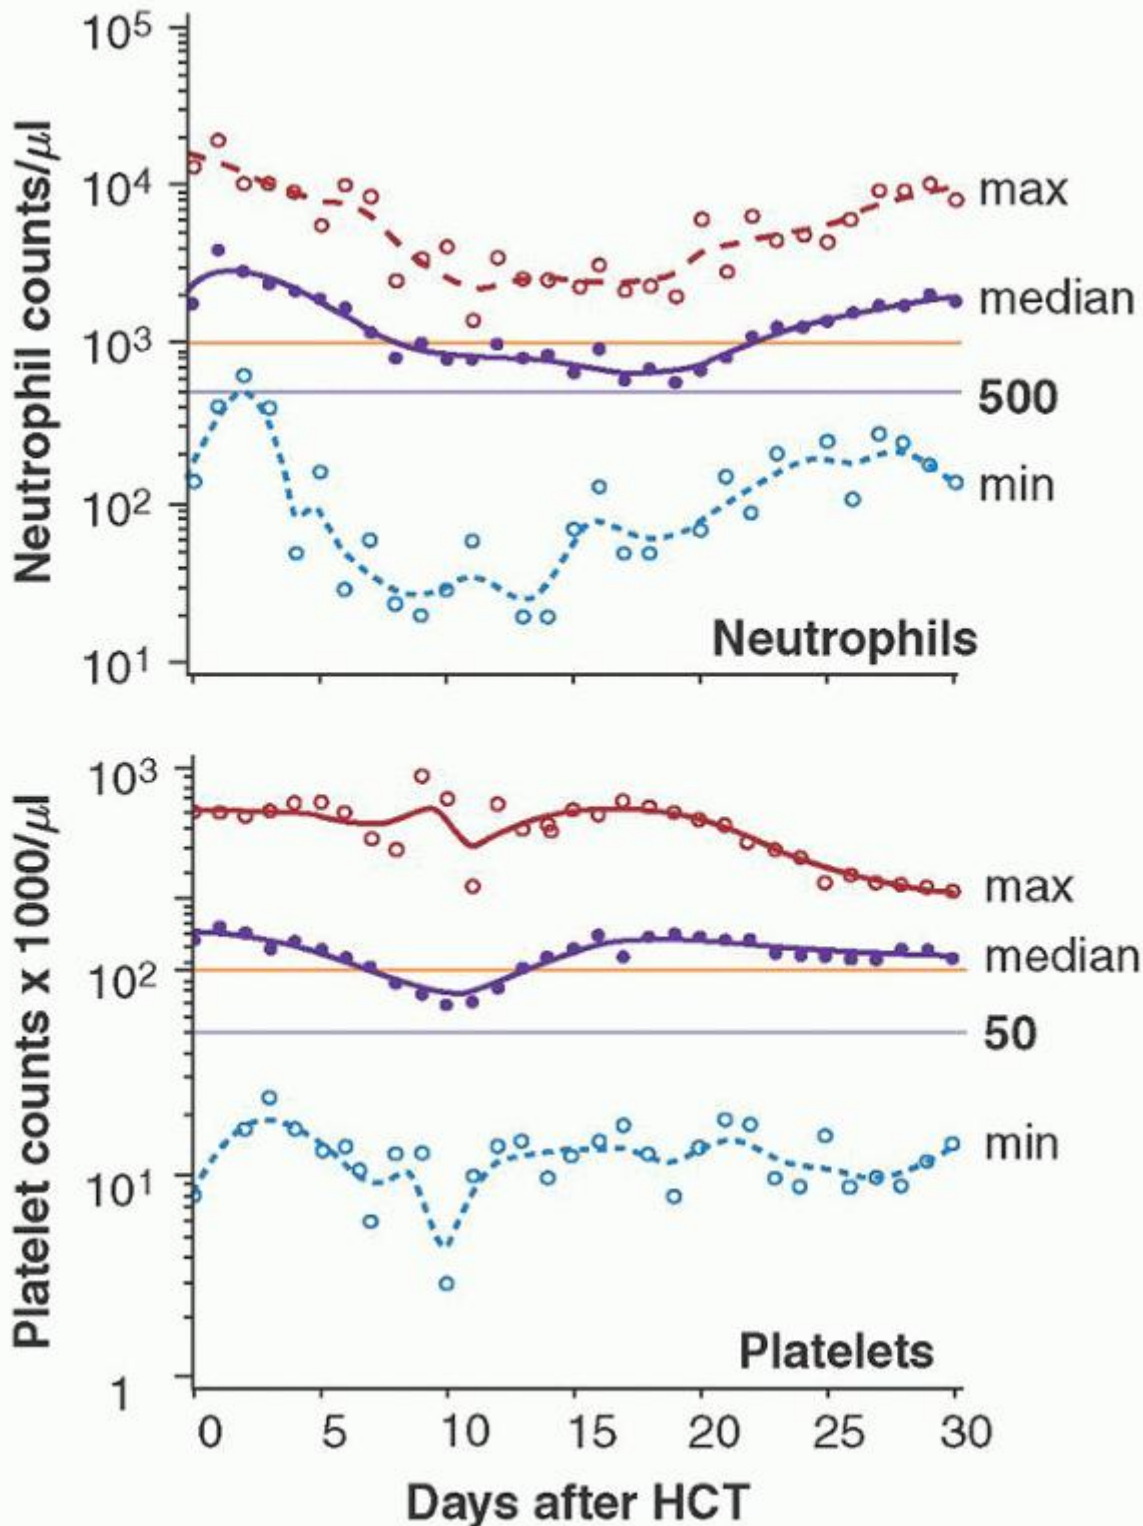

FIGURE 102.5. Engraftment after nonmyeloablative hematopoietic cell transplantation (HCT). Engraftment profile showing neutrophil and platelet changes after HCT. Graphs show the median (black lines) and range (broken lines) of neutrophil and platelet counts of all 45 patients on day 0 through 30. Circles represent the minimum and maximum values on each day. Min, minimum; max, maximum. (From McSweeney PA, Niederwieser D, Shizuru JA, et al. Hematopoietic cell transplantation in older patients with hematologic malignancies: replacing high-dose cytotoxic therapy with graft-versus-tumor effects. *Blood* 2001;97:3390-3400. Copyright American Society of Hematology, used with permission.)

Early studies of nonmyeloablative transplantation focused on patients with donors who were HLA-identical siblings because the risk of graft rejection and GVHD was considered less compared to other types of donors. Risk factors for graft rejection after conditioning with TBI 200 cGy alone were no prior intensive chemotherapy and a diagnosis of CML.¹⁷² When fludarabine was added to low-dose TBI, the incidence of graft rejection decreased. Nonmyeloablative conditioning regimens have also been effective for transplantation from alternative sources including unrelated donors and umbilical cord blood.^{175, 176, 177}

The allogeneic HSC graft can induce GVL/GVT effects. The effectiveness of the GVT effect can be best observed in the responses patients have had with the minimally myelosuppressive regimens (Fig. 102.6).^{172, 178, 179} In patients not otherwise eligible for a myeloablative conditioning regimen, sustained responses have been noted with AML, the chronic leukemias, lymphoma, and myeloma. A minimally myelosuppressive conditioning regimen may be appropriate for indolent hematologic malignancies including CML, chronic lymphocytic leukemia, agnogenic myeloid metaplasia, and low grade lymphomas.^{172, 180, 181, 182} In those diseases in which some cyto-reduction may be necessary, a reduced intensity regimen may be of more benefit. Another strategy is to use a cycle of chemotherapy or high-dose cytotoxic therapy and autologous transplantation to debulk the disease or induce a clinical remission followed by allogeneic nonmyeloablative transplantation.^{183, 184} The objective of this tandem approach is to consolidate the remission with a GVT reaction. The assessment of the patient, the disease type, and the disease status are required to determine the optimal approach. In retrospective comparisons

P.2168

of patient populations after myeloablative and nonmyeloablative conditioning regimens, no difference in overall survival was observed.^{185, 186, 187} However, relapse rates were higher in patient groups which had received a nonmyeloablative conditioning regimen.

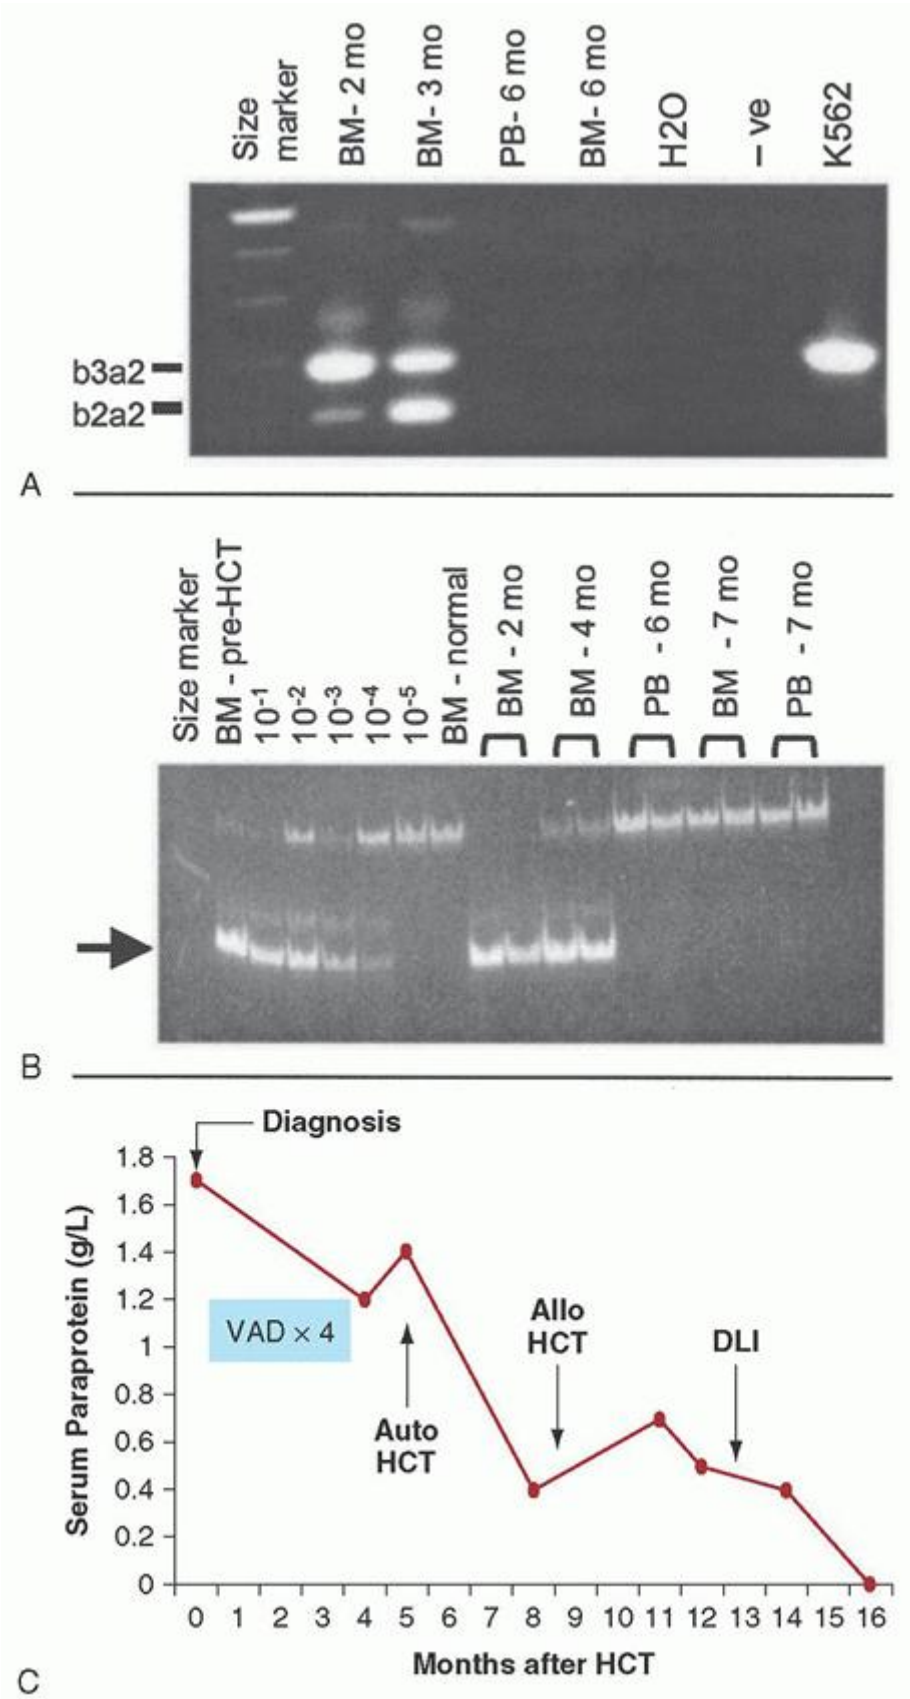

FIGURE 102.6. Complete disease responses after HCT. A: Example of molecular remission of chronic myelogenous leukemia (CML) induced by nonmyeloablative hematopoietic cell transplantation (HCT) without donor lymphoid infusion,

as documented by failure of reverse transcription-polymerase chain reaction (PCR) to detect BCR-ABL transcripts. The lane described “-ve” is negative control of normal bone marrow (BM). K562 is a positive control for BCR-ABL. B: Example of molecular remission of chronic lymphocytic leukemia (CLL) induced by HCT without donor lymphocyte infusion as documented by PCR to detect a tumor-specific immunoglobulin heavy-chain gene arrangement (arrow). Each posttransplantation sample was amplified in duplicate. The lanes designated 10^{-1} to 10^{-5} show a dilution series of the patient's pretransplantation sample (more than 90% tumor cells) into normal bone marrow. C: Example of complete remission of multiple myeloma after allogeneic HCT. The patient was initially treated with four cycles of vincristine, adriamycin, and dexamethasone. High-dose cytoreduction with melphalan 200 mg/m^2 and autologous transplantation was performed 3 months before allogeneic HCT. Donor lymphocyte infusion was given 4 months after HCT because of persistent tumor. After complete remission was achieved, trace levels of serum monoclonal paraprotein were detected by immunofixation intermittently in follow-up testing. DLI, donor lymphocyte infusions. (From McSweeney PA, Niederwieser D, Shizuru JA, et al. Hematopoietic cell transplantation in older patients with hematologic malignancies: replacing high-dose cytotoxic therapy with graft-versus-tumor effects. *Blood* 2001;97:3390-3400. Copyright American Society of Hematology, used with permission.)

GVHD and infections are the major reasons for transplant-related treatment failure after nonmyeloablative transplantation. Since these patients, in general, have been older and at higher risk of poor outcome based on preexisting complications at baseline, nonmyeloablative transplantation has been well tolerated compared to what could have been expected after myeloablative conditioning. The day 100 and year 1 treatment-related mortality has been reported as 3% and 16%, respectively, but significantly less than after myeloablative conditioning.¹⁸⁸ Earlier clinical trials of nonmyeloablative conditioning regimens had given short courses of immunosuppressive therapy or early administration of donor lymphocyte infusions (DLI). GVHD tended to develop later, with many cases developing at 3 to 6 months after transplantation.¹⁸⁹ The cumulative incidence of acute grade II-IV GVHD was less after a nonmyeloablative than a myeloablative conditioning regimen (64% versus 85%, $p = 0.001$). There was no difference in the incidence of chronic GVHD. GVHD developed in many patients as late as 6 to 12 months after nonmyeloablative conditioning and HCT. The incidence of acute GVHD decreased when GVHD prophylaxis was administered for a longer period after HCT.¹⁹⁰ Acute GVHD did not have a significant impact on the risk of progression but had an association with increased risk of nonrelapse mortality. Chronic GVHD was associated with a decreased risk of relapse or progression ($P = 0.006$) and an increased probability of progression-free survival ($P = 0.003$).¹⁷⁸ Strategies for the optimal management of GVHD are required so that complications are reduced but do not prevent an effective GVT response.

In the presence of a major ABO incompatibility, delayed development of donor red cell chimerism resulting in an increased need for red blood cell products has been reported.¹³⁶ Withdrawal of cyclosporine may induce a graft-mediated immune reaction against recipient isohemagglutinin-producing cells, thus resulting in a decrease in isohemagglutinin levels and improvement in donor red blood cell chimerism. The onset of CMV disease may be delayed after nonmyeloablative transplantation.^{191, 192} Patients after nonmyeloablative conditioning with a minimally myelosuppressive regimen can generally be managed in the outpatient setting.

ENGRAFTMENT

Stable engraftment of a hematopoietic cell graft requires the circulation, homing, and growth of HSC. The number of CD34^+ cells that are required to ensure prompt recovery of neutrophil and platelet counts is 2.5 to $5.0 \times 10^6/\text{kg}$. In addition, adequate suppression of the host immune system is required to prevent graft rejection after allogeneic HCT. To achieve adequate immunosuppression, conditioning regimens may be myeloablative or nonmyeloablative. Donor T cells are important to prevent graft rejection, even with the concomitant administration of substantial numbers of CD34^+ cells.¹⁹³ Although infrequently observed in humans, a single stem cell may substantially reconstitute hematopoiesis (clonal dominance) and demonstrates the considerable proliferative potential of a normal HSC.^{194, 195} In many clinical trials of HCT, engraftment has generally been defined as the achievement of a peripheral blood neutrophil count greater than $0.5 \times 10^9/\text{L}$ and evidence of donor chimerism if engraftment is being assessed after allogeneic HCT. The rate of engraftment is dependent upon the number of HSC (CD34^+ cell content), purging strategies for autologous grafts, use of growth factors, and the use of methotrexate for GVHD prophylaxis.^{61, 196, 197} Graft failure may result from either an infusion of inadequate numbers of HSC, drug toxicity, infection (CMV), or graft rejection (after allogeneic transplantation). Relapse also needs to be considered in a patient with decreasing peripheral blood counts.

Graft rejection is infrequent (<1% incidence) after HCT from HLA-matched siblings and was more common after HLA-mismatched related or unrelated HLA-matched donors (2% to 6%).¹⁹⁸ Luznik et al. reported a rejection rate of 13% after reduced intensity conditioning and HCT from an HLA-haploidentical donor.⁹⁸ All but 1 patient experienced recovery of autologous hematopoiesis after rejection in this study. As grafts are rejected, peripheral blood counts may drop, and

chimerism studies demonstrate the loss of donor cells in the peripheral blood and marrow. Factors that influence the risk of graft rejection include T-cell depletion of the hematopoietic cell graft, increased HLA disparity, the intensity of the conditioning regimen and posttransplant immunosuppression, pretransplant sensitization of the host against donor alloantigens, and the number of HSC in the graft.^{98, 198, 199, 200, 201} Previous chemotherapy has been associated with a reduced risk of graft rejection after nonmyeloablative conditioning.²⁰² T cell engraftment kinetics were also improved in patients with higher steady state concentrations of the active mycophenolate mofetil (MMF) metabolite (achieved with three times daily dosing instead of twice daily) without increased risk of relapse, albeit with a modest increase in the rate of CMV reactivation.²⁰³ Clinically, hematopoietic growth factors have not been demonstrated to be effective in preventing graft rejection. Historically, the occurrence of graft rejection after a myeloablative conditioning regimen and an allogeneic HCT had been almost always fatal. Strategies utilizing noncytotoxic immunosuppressive conditioning regimens and HCT may salvage patients after rejection of the first graft.²⁰⁴ Aggressive medical management during the prolonged neutropenic period is required to prevent death from infection after transplantation of the second hematopoietic cell graft. Although the rates of rejection have been higher in the studies of nonmyeloablative HCT for hematologic malignancy (2% to 7%), graft rejection has not been associated with a significant morbidity or mortality because the duration of the pancytopenic period before autologous recovery has in general been short.^{172, 205} When rejection occurs after reduced intensity conditioning, salvage HCT using a conditioning regimen of fludarabine and TBI (300 or 400 cGy) resulted in an engraftment rate of 87%.²⁰⁶ A different donor was used for salvage HCT in 63% of the cases. Nonrelapse mortality at 2 years was 24%. The estimated survivals at 2 and 4 years were 49% and 42%, respectively. Graft rejection can be successfully overcome by salvage HCT from the same or different donor with a reduced intensity conditioning regimen consisting of fludarabine and low-dose TBI.

REGIMEN-RELATED TOXICITIES

The severity of regimen-related toxicities is related to the intensity of the myeloablative therapy, the type of cytotoxic therapy, the medical condition of the patient before transplantation, and the presence of posttransplant factors, including the use of methotrexate, calcineurin inhibitors, and amphotericin B. Reduced intensity conditioning regimens may decrease the severity of certain regimen-related toxicities.^{188, 207, 208, 209, 210}

Oral mucositis occurs in more than 90% of patients after myeloablative conditioning, and most require pain relief with a continuous intravenous narcotic drug. Improvement occurs temporally, with marrow recovery approximately 2 to 3 weeks after transplantation. The severity of the oral mucositis depends on the intensity of myeloablative therapy and the use of methotrexate. Severe mucositis may result in upper airway obstruction or aspiration pneumonitis. A blinded randomized placebo control study of the recombinant human keratinocyte growth factor (palifermin) in patients receiving TBI plus high-dose chemotherapy followed by autologous stem cell rescue demonstrated a 35% reduction in severe mucositis and a 6-day reduction in the median time to

P.2169

resolution of severe mucositis.²¹¹ Furthermore, palifermin was associated with decreased opioid and total parenteral nutrition use. The role of palifermin in other types of HCT recipients has not been established. Gastroenteritis induced by chemotherapy and irradiation results in nausea, vomiting, and diarrhea, all of which may persist for up to 2 to 3 weeks after transplantation. Central lines are placed prior to transplant for administration of fluids, drugs, and hyperalimentation during the period of therapy-induced mucositis and gastroenteritis.

Renal dysfunction is common after HCT.^{212, 213} Some factors associated with the development of severe renal failure requiring dialysis were hyperbilirubinemia, significant fluid retention after transplant, amphotericin B administration, and pretransplant serum creatinine levels greater than 0.7 mg/dl. Renal dysfunction (as indicated by a doubling of the baseline serum creatinine) was most strongly associated with the use of amphotericin B administration and SOS of the liver.²¹³ In this study, calcineurin inhibitors, GVHD, sepsis, TBI, and CY were not found to be significant contributors to severe renal failure. Calcineurin inhibitors cause transient renal dysfunction that is generally reversible with aggressive hydration and eventual discontinuation of the drugs. Renal complications were decreased after HCT with a nonmyeloablative conditioning regimen.²⁰⁸

Lung and liver are the two organs that limit further escalation of the intensity of myeloablative therapy. Idiopathic interstitial pneumonitis occurs in 8% to 18% of patients after myeloablative conditioning and marrow transplantation.^{214, 215, 216} Clinical manifestations include dyspnea, nonproductive cough, hypoxemia, and diffuse pulmonary infiltrates. This toxicity is most likely due to TBI, but preparative regimens containing high doses of chemotherapeutic agents such as CY, BU, and carmustine also contribute directly to toxicity in the lungs. Pulmonary veno-occlusive disease (VOD) is important

to consider in patients with diffuse pulmonary infiltrates, since there may be a favorable response to corticosteroids.^{217, 218} Treatment for idiopathic interstitial pneumonitis consists of supplemental oxygen and ventilatory support. Survival is poor (3%) for patients requiring intubation and mechanical ventilation for greater than 24 hours.²¹⁹ Pulmonary complications are reduced after nonmyeloablative conditioning regimens.^{207, 209}

SOS (formerly known as veno-occlusive disease, or VOD) of the liver is an event characterized by damage to vascular endothelial cells and to hepatocytes in zone 3 of the liver acinus and is the most frequent cause of hyperbilirubinemia within 20 days following HCT.²²⁰ Historically, the overall incidence of SOS was 53%, and 15% of patients had severe disease. The incidence of SOS has decreased in more recent years because of the reduced intensities of conditioning regimens and better selection of patients for myeloablative regimens. Risk factors for the development of severe SOS are pretransplant hepatitis with elevated serum levels of hepatocellular enzymes, the intensity of the conditioning regimen (TBI greater than 13 Gy), or the use of busulfan. Targeting strategies may have reduced the incidence of severe SOS in patients conditioned with busulfan. Patients receiving ursodeoxycholic acid after HCT had significantly lower rates of severe hyperbilirubinemia and elevated alanine aminotransferase levels, although the rates of SOS were similar compared to controls.²²¹ Furthermore, the rates of severe GVHD were less and mortality was significantly improved at 1-year posttransplant in the ursodeoxycholic acid group. For the treatment of SOS, responses to the administration of tissue plasminogen activator have been reported.^{222, 223} However, the risk of bleeding must be weighed against the potential benefit of this agent. Responses were also observed in patients treated with defibrotide which is a single-stranded polydeoxyribonucleotide with fibrinolytic and antithrombotic activity.²²⁴ No randomized clinical trials of defibrotide for treatment of SOS have been conducted. However, in a randomized clinical trial of prophylactic therapy, administration of defibrotide to pediatric patients undergoing HCT demonstrated decreased rates of SOS at day 30 when compared to controls.²²⁵

Increasingly recognized as an important clinical problem are the delayed complications other than chronic GVHD after HCT (Chapter 106). Long-term risks associated with myeloablative conditioning include secondary malignancies, sterility, increased bone loss, delayed development in pediatric patients, neurocognitive changes, hypothyroidism, and cataracts.^{226, 227, 228, 229, 230, 231, 232} After autologous HCT there is an increased risk of myelodysplastic syndrome.^{233, 234} Use of immunosuppression for chronic GVHD treatment was associated with an increased incidence of squamous cell cancer of the skin and oral cavity in allogeneic transplant recipients.²³⁵ Risk factors for defective spermatogenesis are older age at transplantation and presence of chronic GVHD.²³⁶ Rapid bone loss after transplantation can be partially corrected with the administration of bisphosphonate drugs.^{237, 238} Children may experience delays in growth and development particularly after exposure to TBI-based conditioning regimens which may be improved with growth hormone therapy.²³⁹ Neurocognitive changes observed early after HCT largely recover at 1 year²⁴⁰; however, full recovery after HCT, especially psychological recovery, may be a 3- to 5-year process. Recovery might be accelerated by more effective interventions to increase work-related capabilities, improve social support, and manage depression.^{241, 242}

GRAFT-VERSUS-HOST DISEASE

GVHD is mediated by genetically disparate lymphocytes after transfer to an immunologically compromised recipient incapable of rejecting the donor graft (Chapter 105).²⁴³ In the initial stages of GVHD, donor T cells recognize disparate histocompatibility antigens on host cells. Two primary classes of MHC exist. HLA class I antigens have a broad distribution and are expressed on all cells. HLA class II antigens are expressed on antigen-presenting cells, including macrophages, dendritic cells, B cells, and activated T cells. The mHC are genetic polymorphisms of endogenous cellular proteins that are presented to T cells as small peptides bound within the hypervariable grooves of MHC proteins. Some mHC which have been identified in humans as being associated with GVHD are HA-1 and the DBY (male-specific mHA gene).^{244, 245} The presence of multiple disparate mHC between the recipient and donor was associated with an increased mortality.²⁴⁶ Single disparities of mHC may not be sufficient to result in a significantly increased risk of GVHD.²⁴⁷

The skin, liver, and gastrointestinal tract are the primary organs damaged by the GVH reaction. The cells which are targeted in the affected organs by the GVH reaction are primarily epithelial stem cells and their progeny.²⁴⁸ In the liver, the epithelium of the small interlobular and marginal bile ducts is damaged by the GVH reaction. In tissues involved with GVHD, a lymphoid infiltrate is present and cell death occurs by apoptosis. In lymph nodes there is an absence of germinal centers which lasts for many months after HCT. Abnormal CD4:CD8 ratios can be found both in the lymph node as well as in the peripheral blood. The induction and release of signaling cytokines might be important in the development and severity of GVHD.²⁴⁹ The IL-10 pathway may play an important role in controlling the severity of acute GVHD.^{250, 251} Plasma biomarkers for acute GVHD include IL-2-receptor-alpha, TNF-receptor-1, IL-8, and hepatocyte growth factor.²⁵² Regenerating islet-derived 3 α (REG3 α), secreted by Paneth cells, is a plasma biomarker for severe acute GVHD of the

gastrointestinal tract.²⁵³ In a multivariate analysis, stages 2 to 4 GVHD of the gastrointestinal tract, severe histologic damage, and high levels of REG3 alpha at GVHD diagnosis independently predicted nonrelapse mortality at 1 year.

GVHD has been traditionally classified into two different phases. Acute and chronic GVHD were defined as occurring before or after 3 months, respectively. However with increasing adoption

P.2170

of nonmyeloablative conditioning regimens in which engraftment of donor T cells occurs more gradually, the distinctions between these two phases of GVHD has blurred.^{189, 254} Findings consistent with either diagnosis often occur concomitantly.

Acute

Clinical Evaluation

Acute GVHD involves three organ systems primarily—the skin, the gastrointestinal tract, and the liver. A maculopapular rash which can involve the palms and soles is often present and can be pruritic or painful. Bullae and epidermal separation may occur in severe cases and resembles toxic epidermal necrolysis. GVHD can also involve any part of the gastrointestinal tract. Symptoms and signs include nausea, vomiting, crampy abdominal pain, diarrhea, intestinal bleeding, and ileus. Lesions in the mouth may also occur. Patients may also present with persistent anorexia, nausea, and vomiting, and require endoscopy to evaluate the gastrointestinal tract for GVHD.^{255, 256, 257} Permanent scarring with loss of mucosal regeneration may occur in very severe GVHD of the gastrointestinal tract.²⁵⁸ Cholestatic jaundice is common in liver GVHD but hepatic failure due solely to GVHD of the liver is unusual unless the GVHD is long-standing. A biopsy of these organs may be required to confirm the diagnosis of GVHD and to distinguish it from other posttransplant complications.

The major determinant for the development of acute GVHD is the degree of HLA match. The increased incidence of acute GVHD in HLA-matched unrelated donor transplants is likely attributable to increased disparity in mHC antigens or unrecognized disparities of the phenotypically matched major histocompatibility loci. Other factors influencing the rates of acute GVHD include sex mismatch with the donor, parity of female donors, TBI dose, and acute GVHD prophylaxis regimen.^{259, 260, 261} In peripheral blood HSC transplantation, the CD34-positive cell dose has been reported as an independent risk factor for acute GVHD.²⁶²

To facilitate the study and prognostication of acute GVHD, a clinical staging and grading system (Glucksberg) was developed and then updated in 1995 (Chapter 105).^{50, 263, 264} Grade I or very limited acute GVHD has a favorable prognosis and does not require treatment. Therapy is usually required for grade II GVHD since it is moderately severe and usually affects multiple organs. Since patients with anorexia, nausea, and vomiting with positive biopsies for GVHD from the upper gastrointestinal tract usually require therapy, this was included as grade II. Grades III-IV GVHD are severe, affect multiple organs, and are associated with a decreased patient survival.²⁵⁹ An acute GVHD severity index was also developed, grouping patients with patterns of organ involvement associated with similar risks of treatment-related mortality and treatment failure.²⁶⁵ In a prospective evaluation of the two classifications, the performance was similar in explaining the variability in survival by acute GVHD grade.²⁶⁶ An acute GVHD activity index has also been developed.²⁶⁷ The activity index considers serum bilirubin, oral intake, treatment with prednisone, as well as performance, and may predict nonrelapse mortality better than either of the more commonly used clinical grading schema.

FIGURE 102.7. Kaplan-Meier estimate of acute graft-versus-host disease (GVHD). The combination of tacrolimus and methotrexate was compared to cyclosporine and methotrexate as GVHD prophylaxis after a myeloablative conditioning regimen followed by hematopoietic cell transplantation (HCT) from an human leukocyte antigen (HLA)-matched unrelated donor. There was less acute GVHD in the tacrolimus group at 100 days after HCT than the cyclosporine group (56% vs. 74%, respectively, $P = 0.0002$). (From Nash RA, Antin JH, Karanes C, et al. Phase 3 study comparing methotrexate and tacrolimus with methotrexate and cyclosporine for prophylaxis of acute graft-versus-host disease after marrow transplantation from unrelated donors. *Blood* 2000;96:2062-2068. Copyright American Society of Hematology, used with permission.)

Prevention

The two major approaches to the prevention of acute GVHD after allogeneic marrow transplantation are pharmacologic immunosuppression and T-cell depletion. Agents for pharmacologic immunosuppression are generally more effective when used in combination. Methotrexate in combination with either cyclosporine or tacrolimus (both calcineurin inhibitors) are the pharmacologic agents used most commonly by transplant centers. In randomized controlled studies, the combination of tacrolimus and methotrexate was associated with a lower incidence of acute GVHD compared to cyclosporine and methotrexate, but there was no difference in the incidence of chronic GVHD or survival between the two groups (Fig. 102.7).^{268, 269} These agents may have significant adverse effects and therefore patients must be monitored closely. Methotrexate delays, but does not prevent, hematopoietic engraftment. Methotrexate also potentiates the mucositis associated with myeloablative conditioning regimens. Nephrotoxicity and neurotoxicity are complications associated with the administration of cyclosporine and tacrolimus.

Other immunosuppressive agents including corticosteroids and MMF have been studied in combination with cyclosporine. The addition of prophylactic corticosteroids to the combination of cyclosporine and methotrexate or to cyclosporine alone had only limited if any benefit, and in one study a paradoxical increase in chronic GVHD was observed in the corticosteroid arm.^{270, 271, 272} MMF, a reversible inhibitor of inosine monophosphate dehydrogenase, has been successfully used in combination with cyclosporine for prevention of both GVHD and graft rejection after nonmyeloablative conditioning. The use of MMF instead of methotrexate in standard prophylaxis regimens after myeloablative conditioning regimens has been demonstrated to result in similar rates of acute GVHD, less mucositis, and faster neutrophil engraftment.^{273, 274}

Alternative methods of GVHD prophylaxis include ex vivo T cell depletion of the hematopoietic cell graft, in vivo T cell depletion and posttransplant cyclophosphamide. Strategies for ex vivo T cell depletion include the use of monoclonal antibodies which

are specific for T cells, selective agglutination to soybean lectin, and counter flow centrifugation elutriation. Although reduction in acute and chronic GVHD has been observed with transplantation of T cell-depleted marrow, there was an associated increase in graft rejection, infections, posttransplant lymphoproliferative disorders, and relapse. A randomized controlled trial did not demonstrate any survival benefits for ex vivo T cell depletion compared to standard pharmacologic immunosuppression for acute GVHD prevention after HCT from HLA-matched unrelated donors.²⁷⁵ In vivo T cell depletion with pretransplant ATG and alemtuzumab was also effective for reducing the risks of severe acute and chronic GVHD after reduced intensity conditioning.²⁷⁶ However, relapse rates were higher and overall survival was significantly decreased compared to the T cell replete group in the study. Relapses were not increased with in vivo T cell depletion if patients were conditioned with myeloablative regimens.

Posttransplant cyclophosphamide reduced the risks of both acute and chronic GVHD but until more experience has been obtained, it is not known if this approach will improve overall survival.^{97, 98}

Treatment

The most common agents used to treat acute GVHD have been corticosteroids and ATG. In many marrow transplant centers the administration of corticosteroids (methylprednisolone or prednisone-equivalent dose of 2 mg/kg/day) had been the standard initial treatment for acute GVHD.^{277, 278} In a retrospective analysis, it was observed that initial treatment with a lower dose of corticosteroids (methylprednisolone dose of 1 mg/kg/day) may be as effective as the higher dose. However, this needs to be confirmed in a prospective study.²⁷⁹ Higher doses of methylprednisolone (10 mg/kg/day) did not improve outcomes.²⁸⁰ Because complete remission of GVHD is seen in only 40% to 50% of the cases after initial or primary treatment, other immunosuppressive agents have been investigated in combination with prednisone. When a CD5-specific immunotoxin was added to prednisone for primary treatment, GVHD manifestations were more effectively controlled only during the first 5 weeks after start of treatment when compared to prednisone alone.²⁸¹ Similarly, no long-term benefit was observed when ATG was added to prednisone.²⁸² In a study of daclizumab in combination with prednisone as primary therapy, survival was significantly decreased compared to prednisone alone.²⁸³ This suggested that caution must be used with approaches that intensify immunosuppression for primary treatment of acute GVHD. In a randomized clinical trial of primary treatment for gastrointestinal GVHD, a short course of prednisone in combination with either placebo or beclomethasone dipropionate (BDP), an oral topical agent with limited systemic absorption, was evaluated.²⁸⁴ The use of BDP was associated with better control of upper gastrointestinal GVHD and improved survival at 200 days and 1 year posttransplantation. For steroid-refractory GVHD, immunosuppressive agents which have been studied include ATG, daclizumab, rapamycin, MMF, ABX-CBL (CD147-specific mAb), and pentostatin among others. Outcomes at 6 to 12 months after salvage therapy for steroid-resistant GVHD have been poor with a high transplant-related mortality.^{285, 286, 287, 288, 289, 290} There are no standard effective therapies for steroid-refractory GVHD which can be recommended.^{291, 292} Psoralen and ultraviolet A therapy for the skin may permit a decrease in systemic immunosuppression.²⁹³ The massive secretory diarrhea of acute GVHD has been controlled in some cases with a somatostatin analog, octreotide acetate.²⁹⁴

Chronic

Clinical Evaluation

Chronic GVHD is a syndrome that may develop as early as 50 to 60 days or as late as 400 days after transplantation. The incidence of chronic GVHD is dependent on the degree of disparity in the MHC antigens. It was observed in 33% of HLA-identical sibling transplants, 49% of HLA-nonidentical related transplants, and 64% of HLA-matched unrelated transplants.²⁹⁵ A prior history of acute GVHD is a significant risk factor for the development of chronic GVHD. Other risk factors for chronic GVHD are older age, female donor if male recipient, DLI, and use of peripheral blood stem cells.^{296, 297, 298} Corticosteroid use for GVHD prophylaxis may also increase the risk of the development of chronic GVHD.^{270, 272}

Clinical features of chronic GVHD are skin lesions which may initially resemble lichen planus and may progress to generalized scleroderma, keratoconjunctivitis, oral mucositis, esophageal and vaginal strictures, intestinal abnormalities, chronic liver disease, pulmonary insufficiency secondary to bronchiolitis obliterans (BO), and a wasting syndrome.²⁹⁹ If generalized scleroderma occurs, it may lead to joint contractures and debility. Elevations in alkaline phosphatase and serum bilirubin are often the first indication of hepatic involvement with chronic GVHD. Bile duct damage has a similar histopathology as that seen in primary biliary cirrhosis. Liver biopsies are often helpful in establishing a diagnosis. BO affects the small airways of the lung and may occur at less than 150 days (40%) or more than 150 days (60%) following HCT.³⁰⁰ If serial pulmonary function tests show an evolving obstructive pattern, further testing is required including a high-

resolution computed tomography scan to evaluate for the presence of BO. Keratoconjunctivitis sicca is a common but irreversible complication that is managed with frequent eye drops and tear duct ligation.

Screening studies and clinical manifestations of chronic GVHD are used in a clinical classification of chronic GVHD. Based on a retrospective clinical and pathologic review from 1980, a staging system was developed in which chronic GVHD was classified into limited and extensive. Extensive disease was associated with more frequent infections.²⁹⁹ The utilization of this original classification system was difficult because many patients were not easily classifiable by strict organ criteria and thus other significant prognostic factors have since been identified. Poor prognostic factors were extensive skin involvement, thrombocytopenia, and progressive-type onset.^{301, 302} In 2005, the NIH consensus criteria were developed to standardize the criteria for the diagnosis of chronic GVHD.³⁰³ A clinical scoring system (0 to 3) described the extent and severity of chronic GVHD for each organ or site at any given time, taking functional impairment into account. A global assessment of chronic GVHD severity (i.e., mild, moderate, or severe) was then calculated based on the number of organs or sites involved and the degree of involvement in the affected organs. Diagnosis of chronic GVHD required at least 1 clinical sign or manifestation of chronic GVHD confirmed by biopsy or other relevant test and the exclusion of other possible diagnoses for those clinical symptoms considered to be chronic GVHD. Subtypes of late GVHD (>100 days) were recognized, including late onset acute GVHD, classical chronic GVHD, and an overlap syndrome (clinical symptoms of both acute and chronic GVHD).

Prevention

Several strategies to prevent the development of chronic GVHD have been pursued but none have made a significant impact on long-term overall survival. Prolonged administration (24-month course vs. 6-month course) of cyclosporine demonstrated no significant differences between the groups in the incidence of chronic GVHD, transplant-related survival, or overall survival.³⁰⁴ T cell depletion was associated with lower rates of chronic GVHD in HLA-matched sibling transplants, but not in the unrelated donor setting. No improvement in overall survival was associated with T cell depletion.³⁰⁵ Inclusion of alemtuzumab or ATG in the conditioning regimen was associated with a reduction in chronic GVHD.^{276, 306, 307}

P.2172

Treatment

Extensive chronic GVHD that is left untreated has a poor prognosis. In general, based on the NIH consensus criteria, topical or local therapy is recommended for mild chronic GVHD, and systemic immunosuppression for moderate or severe chronic GVHD. In an original report of chronic GVHD, only 2 of 13 patients survived and there was the development of significant morbidity.²⁹⁹ Prednisone given for 9 to 12 months reversed many of the signs and symptoms of disease. The mortality in the group treated with prednisone was 21%.³⁰⁸ Patient survival was worse with the combination of azathioprine and prednisone compared to prednisone alone.³⁰² The combination of cyclosporine and prednisone was first used in patients with high-risk chronic GVHD who had a platelet count less than 100,000. The results of this study appeared promising compared to historical controls.³⁰⁹ There was a trend toward improved survival and decreased morbidity. In contrast, a randomized study of combination therapy versus prednisone alone for standard-risk chronic GVHD suggested that more intense immunosuppression did not improve survival.³¹⁰ A report of a randomized clinical trial in 2009 comparing MMF plus prednisone to prednisone only as primary treatment for chronic GVHD did not show any benefit.³¹¹ Standard practice for primary treatment of patients with moderate-severe chronic GVHD remains systemic immunosuppression with prednisone. There is no evidence that additional immunosuppression is beneficial. In practice, patients with extensive chronic GVHD are treated for a period of 9 to 12 months. At the end of this period, a reevaluation is done and, if there is no evidence of active chronic GVHD, the immunosuppressive agents are tapered. Other therapies which have been reported to have some limited efficacy for treatment of chronic GVHD are extracorporeal photopheresis for skin and oral GVHD and ursodeoxycholic acid treatment for GVHD of the liver.^{312, 313, 314} There is insufficient data to make strong recommendations regarding treatment of steroid-refractory chronic GVHD.

By 3 to 5 years after initiation of therapy, many patients have inactive chronic GVHD and immunosuppressive therapy has been discontinued (Fig. 102.8).⁹⁰ Approximately 75% of patients treated for extensive chronic GVHD will survive with Karnofsky scores of greater than 80%. The major cause of excess mortality in patients with clinically extensive chronic GVHD is infections.

GRAFT-VERSUS-TUMOR EFFECT

Allogeneic immune surveillance or GVT reaction for malignancy contributes significantly to the therapeutic effectiveness of HCT. The term GVT refers to the GVL effect, the graft-versus-myeloma effect, as well as the effects on solid tumors by the graft. The first clinical report of a GVT effect after allogeneic marrow transplantation was published in 1979.³¹⁵ It was observed that patients who developed GVHD had a lower risk of relapse after transplantation. In 1990, Kolb and colleagues successfully treated 3 patients with CML who relapsed after marrow transplantation with DLI from the original HLA-identical sibling marrow donor.³¹⁶ In a subsequent report evaluating DLI in 135 patients with relapsed disease, complete remissions were achieved in 72% of CML patients and 29% of patients with AML.³¹⁷ No responses were observed in patients with acute lymphoblastic leukemia. Chemotherapy to induce remission before DLI was a more effective strategy for long-term disease control for some patients with acute leukemia. GVHD and myelosuppression developed in 41% and 34% of patients, respectively, after DLI. Fourteen patients (10%) died from complications related to GVHD or myelosuppression. Another large study of 140 patients with relapsed malignancy after marrow transplantation confirmed the effectiveness and risks of DLI after relapse.³¹⁸ Notably in both studies, GVHD after DLI correlated with disease response. The durability of the responses was confirmed with longer follow-up of patients who had achieved complete remission after DLI.³¹⁹

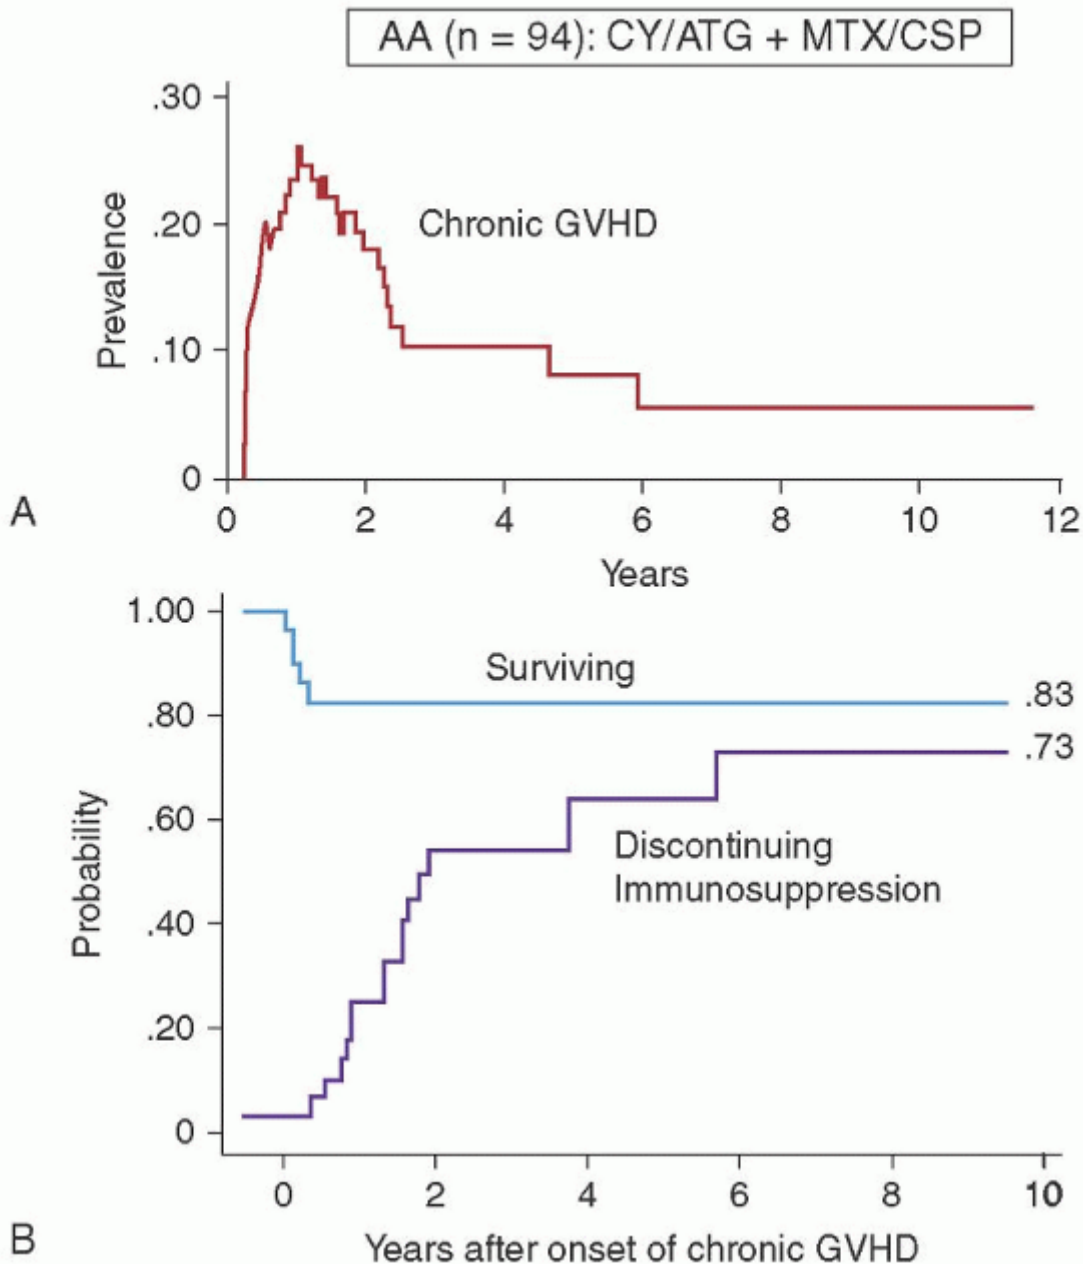

FIGURE 102.8. A: Prevalence of chronic graft versus host disease (GVHD) after allogeneic marrow transplantation from human leukocyte antigen (HLA)-identical sibling for aplastic anemia. The prevalence curve accounts for the time of onset of chronic GVHD and the time of its resolution in response to therapy. B: Probability of survival among the 29 patients with chronic GVHD (83%) and probability of discontinuing immunosuppression given for chronic GVHD (73%). (Modified from Storb R, Blume KG, O'Donnell MR, et al. Cyclophosphamide and antithymocyte globulin to condition patients with aplastic anemia for allogeneic marrow transplantations: the experience in four centers. *Biol Blood Marrow Transplant* 2001;7:39-44. Used with permission.)

The number of CD3-positive cells infused (or DLI dose) is an important parameter in determining clinical response and risk for development of GVHD.³²⁰ Patients with CML had a lower risk of GVHD, and the efficacy of treatment was maintained with a strategy of escalating the dose of donor lymphocytes based on response of disease and development of GVHD.³²¹ Comparable results with DLI from unrelated donors have also been demonstrated.³²² The response, severity of GVHD, and the degree of myelosuppression were similar to that observed after DLI from HLA-matched sibling donors.

After nonmyeloablative conditioning and allogeneic HCT, the GVT effect is the main contributor to the disease response. Disease responses have been observed in both myeloid and lymphoid hematologic malignancies. Since the establishment of a GVT effect may not be achieved for 2 to 3 months after HCT, malignant disease needs to be controlled before HCT. Several retrospective studies have now shown comparable overall survival after either myeloablative or nonmyeloablative conditioning and HCT.^{185, 186, 187, 323} However, all these studies showed relapse was higher and transplant-related mortality was lower after a nonmyeloablative conditioning regimen. In a randomized clinical trial of reduced intensity conditioning with TBI (800 cGy) and fludarabine compared to TBI (1,200 cGy) and cyclophosphamide in patients with AML in first remission, there were no differences in transplant outcomes including relapse and nonrelapse mortality except for increased severity of oral mucositis in the TBI (1,200 cGy) group.¹⁵¹

Although patients may have an excellent response to allogeneic HCT, severe GVHD may occur. Separation of GVHD from GVT

P.2173

effects may be possible because of disparate hematopoiesis-associated mHC molecules or tumor-restricted antigens on malignant cells.³²⁴ These tissue or tumor-restricted antigens could serve as targets for T cell immunotherapy to enhance GVT activity without inducing GVHD. Peptides identified as minor histocompatibility molecules have been isolated and sequenced.^{325, 326, 327, 328, 329, 330} Cytotoxic T lymphocytes (CTL) clones specific for recipient mHC antigens have been generated *ex vivo*.³³¹ These were infused into 7 patients who had relapsed after HCT. Pulmonary toxicity was seen in three patients and in one it was severe. The CTL circulated for 21 days, and five patients had complete but transient remissions. The contribution of natural killer (NK) cells to the antitumor effect after allogeneic HCT has also been investigated.³³² For AML, a disease with sensitivity to NK-mediated activity, NK cells from unrelated donors encoding the activating killer-cell immunoglobulin-like receptor KIR2DS1 was associated with improved relapse-free survival in an HLA-C-dependent manner. These studies may help to explain the mechanisms associated with a GVT effect after allogeneic HCT, and in the future this information might be helpful for improving outcomes.

IMMUNE RECONSTITUTION

After myeloablative therapy and autologous or allogeneic transplant, both humoral and cellular immunity are impaired for months to years. After autologous HCT, NK cells in the peripheral blood recover by 1 month and B cells and CD8+ T cells recover by 3 to 6 months after HCT. However, CD4+ T cells are not restored to normal levels until 1 to 2 years after HCT.^{333, 334} After allogeneic transplantation, recovery of the immune system from the donor graft occurs in phases over a period of 1 to 2 years in patients who do not develop GVHD. There are significant delays in recovery of the immune system if GVHD develops.

The first phase of recovery is the increase in neutrophil counts which occurs 2 to 3 weeks after transplantation. Although the function of neutrophils is largely intact, impaired chemotaxis persists for a period up to 4 months.³³⁵ Monocyte numbers in the peripheral blood return to normal within 3 to 4 weeks after transplantation. Monocyte counts in the peripheral blood were inversely correlated with infection rates between days 100 and 365.³³⁶ Macrophages in the liver and lung have been shown to be of donor type by day 80. NK cells and other cell types capable of antibody-dependent cytotoxicity have recovered to normal levels by 30 days after transplantation. The recovery of the donor-derived immune system is important in the understanding of the GVT effect and complications after HCT, including graft rejection, GVHD, and infections.

B Cells

There are defects in serum immunoglobulin production initially after the transplant. Serum antibody responses to different antigens, including ϕ X174, keyhole limpet hemocyanin, pneumococcal antigen, and meningococcal antigen are lower than normal.^{337, 338, 339} The defect in antibody production occurs in both T cell-dependent and T cell-independent systems. B lymphocytes respond to mitogenic stimulation including staphylococcal aureus and cross-linked anti-IgM antibodies after 2 months. By 3 months after transplantation, B lymphocytes with surface immunoglobulin have recovered to normal levels. Persistent deficiencies in B lymphopoiesis have been described in association with GVHD (acute or chronic) or its treatment.³⁴⁰ The number of B cell precursors in the marrow was not related to CD34 cell dose, type of transplant, donor age, or recipient age.

Serum IgG and IgM have typically achieved normal levels 1 year after transplantation in the absence of chronic GVHD.³³⁷ Serum IgA may remain low for a period of 2 years. If serum IgG levels are below 400 g/L, patients are generally treated with intravenous immunoglobulin.

T Cells

Reconstitution with donor T cells is poor initially in all recipients and remains defective in patients with chronic GVHD. Because of the faster recovery of CD8 positive T cells, a reversed CD4:CD8 ratio with low levels of CD4-positive cells has been demonstrated and persists in patients with chronic GVHD. In vivo cellular immunity, determined by skin testing to the recall antigens Candida, mumps, trichophyton, and the neo-antigen dinitrochlorobenzene, is diminished, but may be prolonged if chronic GVHD develops.³⁴¹ In in vitro assays, donor T cells from patients have a decreased proliferation to mitogenic stimulus with phytohemagglutinin (PHA) and CD3-specific antibody. After 3 months the addition of exogenous IL-2 can normalize the proliferative response to PHA stimulation.^{342, 343} By 6 months the response to PHA stimulation has normalized without the requirement for exogenous IL-2. T cell immunity to herpes simplex virus (HSV) can be detected by day 40.³⁴⁴ CTL function against varicella-zoster virus (VZV) and CMV is acquired later (≥ 3 months). Acquisition of T cell immunity to herpes virus may be delayed by prophylaxis of viral infections with anti-viral agents or GVHD treatment.^{345, 346}

Immunity early after myeloablative conditioning and allogeneic transplantation is restored by the adoptive transfer of mature T cells and may establish cellular immunity to infectious agents such as the herpes viruses.^{96, 346, 347, 348} Vaccination protocols may also improve the pathogen-specific cellular immunity. An inactivated varicella vaccine given before, and during the first 90 days after, transplantation significantly reduced the risk for the development of varicella-zoster infections.³⁴⁹ CD4 T cell proliferation in response to the VZV was greater in patients who received the vaccine. Immune function after HCT may also be improved with the use of a peripheral blood stem cell graft. There were higher lymphocyte subset counts after HCT, and the rate of definite infections was significantly decreased compared to marrow.³⁵⁰ T cell-depleted HCT or therapy for active GVHD has been observed to delay the recovery of cellular immunity, thus resulting in an increased risk of infections. The thymus contributes to late immune reconstitution.

T cell recovery is improved in younger patients compared to older patients, an effect attributable to the improved thymic function in the former group. Increased thymic output (i.e., high TREC levels) was associated with an increased number of naive T cells and broader T cell repertoires, while low TREC levels correlated with the presence of chronic GVHD and severe opportunistic infections.^{351, 352} Thymic rebound correlated with the capacity to respond to vaccinations.³⁵³ Measures to enhance thymic output after transplantation, especially in older patients, may enhance immune reconstitution and decrease the risk of infections.

Chapter 103

Hematopoietic Stem Cell Transplantation for Nonmalignant Disorders

Jacob R. Garcia

Mark C. Walters

INTRODUCTION

Hematopoietic stem cell transplantation (HSCT) has expanded significantly over the past several decades as a consequence of broader utilization in the treatment of malignant and premalignant conditions such as acute leukemia and myelodysplastic syndrome, respectively.^{1, 2} A parallel wider application also has evolved for nonmalignant disorders, such as hemoglobinopathies, primary immunodeficiency disorders (PIDs), inborn errors of metabolism, marrow failure syndromes, and other acquired and hereditary hematologic disorders, particularly among pediatric recipients.^{3, 4, 5, 6} Although supportive care for many of these conditions also has improved over this same period of time, long-term toxicity and morbidity of nontransplant interventions (e.g., chronic blood transfusions and iron overload) have a negative impact on the quality of life and can also cause early mortality.⁷ Thus, HSCT for nonmalignant disorders represents an alternative curative option for many patients who might otherwise succumb to complications of the underlying condition. In this chapter, we delineate and describe representative hereditary hematologic diseases for which HSCT is an option, review outcomes after HSCT in patients with these disorders, and outline the long-term effects of the therapy.

CONDITIONS SUITABLE FOR HEMATOPOIETIC STEM CELL TRANSPLANTATION

A broad array of hereditary and acquired nonmalignant disorders derives from selected hematopoietic cell lineages, which by virtue of their origin in the hematopoietic stem cell, also are theoretically amenable to cure by successful HSCT. Rather than attempt to catalog all these disorders, three broad categories of disorders have been selected to illustrate how and when to apply this therapeutic intervention.

The first of these are the PIDs, which classically are illustrated by the child with severe combined immunodeficiency syndrome (SCIDS) where there is absent B- and T-lymphocyte function. In these individuals, life-threatening infections occur in the first months of life and portend early mortality.⁸ Because there is no immunologic barrier to donor engraftment, marrow from an HLA-identical sibling can be infused in the absence of any pre-transplant immunosuppressive therapy. Thus, these were among the first cases in which the proof-of-principle of HSCT was demonstrated.

The next group of disorders are the hereditary bone marrow failure syndromes, of which Fanconi anemia (FA) is a prototypic example. Fanconi anemia is caused by a heterogeneous collection of defects in genes that encode proteins involved in DNA repair.⁹ This deficiency is associated with a variable phenotype that includes progressive aplastic anemia, musculoskeletal and other congenital defects, and cancer predisposition (particularly to myelodysplastic syndrome, acute myelogenous leukemia, and carcinoma of the skin and oropharynx).¹⁰ Although the hematologic manifestations of this condition are eliminated after successful HSCT, donor selection, modulation of the conditioning regimen, and the possibility of malignant transformation in the marrow together make this a challenging disease to treat by HSCT.

Finally, the broad category of hemoglobin disorders is discussed.¹¹ These disorders differ from the others because the immune and hematopoietic systems are intact before HSCT, and a proliferative marrow develops as a consequence of chronic anemia and ineffective erythropoiesis. Thus, the conditioning regimen before HSCT for the hemoglobin disorders typically requires a combination of ablative and immunosuppressive activities. In addition, there is a marked variability of clinical phenotype in sickle cell disease, which affects the decision making about when and in whom to consider this aggressive therapy.

Together, these broad examples of nonmalignant conditions illustrate the variety of clinical and genetic parameters one must consider in selecting appropriate transplantation candidates and regimens. These considerations are highlighted in the sections that follow.

HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR PRIMARY IMMUNODEFICIENCY DISORDERS

PIDs classically are associated with significant morbidity and early mortality caused by life-threatening infections in the first months and years of life. Before the availability of HSCT, these infections invariably caused death in the vast majority of affected children. SCIDS is the most widely recognized manifestation of a PID. SCIDS is a genetically heterogeneous group of over 20 mutations in 13 genes identified to date that result in the common phenotype of impaired T-cell production and/or function (Table 103.1). These mutations in varied target genes lead to impaired immunity as a consequence of absent T-cell function, but often defects in B-cell and natural killer (NK) cell number or function occur in parallel, as many of the genes affect all three lineages. However, the level of B- and NK-cell activity is highly variable. In rare cases, autoimmune phenomena are observed in these patients.¹³ This is particularly noteworthy in children with Omenn syndrome, which is caused by mutations in genes that participate in rearrangements of T-cell receptors and VDJ regions of immunoglobulins. Mutations in these genes elicit a phenotype that mimics graft-versus-host-disease as a consequence of the expansion of T-cell clones that are reactive to self-antigens. There is also reduced peripheral and central tolerance in these patients, which contributes to the observed phenotype.

Preparative Regimen

The first transplant for SCIDS using an HLA-matched sibling bone marrow donor was performed in 1968.¹⁴ In this case, no preparative regimen was administered to prevent graft rejection due to the absence of an immunologic barrier to engraftment. Thus, donor hematopoietic stem cells simply were infused and successful immune reconstitution followed. However, fatal graft-versus-host disease (GVHD) often occurred in donor/recipient settings in which there was a major HLA disparity. By testing transplantation in animal models of SCIDS, it was determined that by using the technique of donor T-cell depletion, it was possible to eliminate GVHD after HLA-mismatched HSCT, if thorough T-cell depletion was accomplished.^{15, 16} In addition,

P.2177

after successful HSCT in the mouse, there was durable engraftment of the donor cells with restored host immunity. However, even in the earliest clinical reports of HSCT after T-cell depleted HLA-haploidentical HSCT for SCIDS, B-cell engraftment was quite poor, as most patients required long-term immunoglobulin replacement after HSCT.

TABLE 103.1 MOLECULAR CAUSES OF SEVERE COMBINED IMMUNODEFICIENCY

Gene Defect	Defective Protein, Function, Features	Percentage of SCID ^a Cases	Lymphocyte Profile		
			T ^b	B	NK
<i>IL2RG</i> (X-linked)	Common γ -chain (γ_c) of receptors for IL-2, -4, -7, -9, -15, and -21	45-50 (only males)	-	+	-
<i>ADA</i>	Adenosine deaminase enzyme	16	-	+	-
<i>IL7R</i>	α -Chain of IL-7 receptor	9	-	+	+
<i>JAK3</i>	Janus kinase 3, activated by γ_c	6	-	+	-
<i>RAG1, RAG2</i>	Recombinase activating genes required for T- and B-cell antigen receptor gene rearrangement	5	-	-	+
<i>DCLRE1C</i>	Part of T- and B-cell antigen receptor gene	<5	-	-	+

(Artemis)	rearrangement complex, also required for DNA repair				
<i>TCRD, TCRE, CD3 δ, ε, and ζ chains of the T-cell receptor complex, TCRZ</i>	required for T-cell development	Rare	-	+	+
<i>CD45</i>	Protein tyrosine phosphatase receptor (PTPRC), required for T- and B-cell activation by antigen	Rare	-	+	+/low
<i>LCK</i>	Lymphocyte tyrosine kinase p56lck, required for T-cell development and activation	Rare	-	+	+
<i>PNP</i>	Purine nucleoside phosphorylase enzyme; deficiency also causes neurologic impairment	Rare	Low	Low	+/low
<i>LIG4</i>	DNA ligase IV required for antigen receptor gene rejoining	Rare	-	+	+
<i>DNAPKCS</i>	DNA protein kinase catalytic subunit, required for T- and B-cell antigen receptor rearrangement, and DNA repair	Rare	-	-	+
<i>NHEJ1</i> (Cernunnos)	Nonhomologous end joining of DNA; deficiency also causes microcephaly and radiation sensitivity	Rare	-	-	+
<i>AK2</i>	Adenylate kinase 2; deficiency causes reticular dysgenesis with granulocytopenia, lymphocytopenia, and deafness	Rare	-	-	-
<i>FOXN1</i>	Forkhead box N1, required for thymus and hair follicle development (ortholog of nude mouse)	Rare	-	+	+
<i>STAT5a</i>	Signal transducer and activator of transcription 5, phosphorylated after cytokine receptor engagement; deficiency also causes growth-hormone-resistant growth failure	Rare	-	+	-
<i>CORO1A</i>	Coronin-1A, protein mediating lymphocyte migration and T-cell emigration from the thymus	Rare	-	+	+
Currently unknown	Unknown defects, including SCID and congenital anomalies; SCID with multiple bowel atresias	~10	-	+/-	+/-

^a Based on Buckley, 18 Puck²⁵ and Lindegren et al.¹²

^b Some patients have substantial numbers of maternally derived T-cells at time of diagnosis; autologous T-cells are shown.

Adapted from Puck JM. The case for newborn screening for severe combined immunodeficiency and related disorders. *Ann N Y Acad Sci* 2011;1246:108-117.

Epub 2012 Jan 13.

In a cohort of 161 patients treated by HSCT at a single U.S. institution, Railey et al. reported the results in individuals with SCIDS who received no pre-transplant chemotherapy or GVHD prophylaxis.¹⁷ Notably, only 16 (10%) of these patients had HLA-identical sibling donors, and thus most received T-cell depleted HLA-haploidentical marrow. In this clinical series, it

P.2178

was observed that survival was highest among those patients who were transplanted before 3.5 months of age (94% compared to 70%, P = 0.002). Of those who died, the majority (76%) experienced progressive viral infections that predated HSCT. There were very few deaths related to GVHD or infections that were acquired after HSCT. Thus, this series

suggested that no chemotherapeutic preparation is necessary in patients with SCIDS who are treated by HSCT shortly after birth. However, many patients require regular immunoglobulin (IVIG) infusions after successful HSCT for SCIDS due to absent engraftment of donor B-cells, particularly in the absence of a conditioning regimen before HLA-haploidentical related donor HSCT in recipients with B-cell positive SCIDS.^{18, 19}

Long-term follow-up of patients showed mixed results regarding the stability of long-term donor T-cell engraftment after HLA-haploidentical HSCT in the absence of a conditioning regimen before HSCT. With up to 25 years follow-up in a report by Buckley, 11 of 19 patients had no evidence of decreased T-cell function or diminished T-cell repertoire diversity. However, as noted above, most patients lacked donor B-cell engraftment and thus received long-term replacement immunoglobulin therapy.⁸ In another series that included survivors with up to 16 years follow-up, 35% of the patients had low T-cell antigen receptor excision circle (TREC) levels and a limited T-cell repertoire as evidenced by oligoclonality that was demonstrated in 27.5% of patients.²⁰ Based upon these observations, it has been suggested that the use of an ablative conditioning regimen before HSCT may be required to ensure long-term T-cell engraftment in the setting of HLA-haploidentical donors.

Whether improved T-cell engraftment translates into improved survival remains in question, however. Patel et al. retrospectively reviewed a series of 22 patients with SCIDS who were treated by HSCT at a single institution.²¹ In this series, no statistical difference in overall survival was with respect to whether a preparative regimen was administered regardless of donor type. In addition, experience from a large European cohort treated between 1968 and 2005 showed that chemotherapeutic preparation did not improve overall survival in patients with SCIDS.²² These authors argued that a conventional ablative chemotherapeutic preparation does not improve survival in patients with SCIDS, particularly in those who undergo HSCT in the first 31/2 months of life. Unfortunately, proceeding directly to HSCT early in life is not always feasible, as affected individuals often are not identified in the first several months of life or before they have developed serious infections. Thus, the decision of whether to use a conditioning regimen should hinge on several salient clinical features, including the patient's age, the donor, and the baseline immunologic function with regard to resistance to donor engraftment. Also, recipients with SCIDS who have a T-/B+ lymphocyte profile appear to have better outcomes than recipients who lack B-cells.²³ The advent of pilot newborn screening programs by TREC screening from blood spots has the potential to mitigate the limitation of patient age.^{24, 25, 26}

Reduced Intensity Conditioning

To date, optimization of a conditioning regimen that might be safely applied in all patients with SCIDS has been elusive. In an attempt to reduce transplant-related morbidity and mortality, reduced intensity conditioning regimens that are not ablative and contain a diverse array of immunosuppressive agents such as fludarabine, busulfan (BU), etoposide, cyclophosphamide (CY), and low-dose radiation have been tested.^{27, 28, 29} Current data suggest that reduced intensity regimens are most appropriate in recipients with T-cell deficiency syndromes and in unrelated donor HSCT.^{30, 31} However, graft rejection associated with inadequate suppression of residual host immune function remains a concern, particularly in patients with T- and NK-cell function at baseline. Ultimately, the selection of a preparative regimen and its intensity will vary according to the level of retained immunity in the recipient, and with the degree of HLA matching in donor hematopoietic cells.

Donor Source

HLA-identical marrow HSCT has yielded very good results in SCIDS, with approximately 70% to 80% of patients surviving long-term³² (Fig. 103.1). Because most patients lack a HLA-ID sibling donor, alternative donor sources have been explored in clinical trials. Roifman et al. reviewed transplant outcomes after HLA-mismatched related donor HSCT compared to HLA-matched unrelated donor HSCT for SCIDS.³³ They reported that survival was superior in those receiving HLA-matched unrelated marrow. Specifically, patients who received a HLA-matched unrelated HSCT had better engraftment and immune reconstitution. They concluded that HLA-matched unrelated marrow transplantation is superior to HLA-mismatched related donor HSCT and should be considered as the first choice when a related HLA-identical donor is unavailable. In other patient series noted above, excellent results were observed after T-cell depleted HLA-haploidentical HSCT. Thus, the optimal donor source for HSCT remains a point of controversy.

More recently, the application of umbilical cord blood transplantation (UCBT) has been explored in SCIDS. Fernandes et al. recently compared results after HLA-mismatched related donor and unrelated donor UCBT in patients with SCIDS.³⁴ There were 175 HLA-mismatched donor HSCT recipients and 74 UCBT recipients in this retrospective cohort of patients with SCIDS or Omenn syndrome. The median follow-up was 58 and 83 months in each group, respectively. Most UCBT recipients received a myeloablative preparative regimen, whereas a larger fraction of the related donor recipients did not. UCBT recipients were more likely to have complete donor chimerism and faster lymphocyte recovery independent of the

preparative regimen. T-cell engraftment was equivalent in the two groups, and immunoglobulin replacement was discontinued earlier after transplantation in the UCBT group. There was a statistically insignificant higher incidence of grade II–IV acute GVHD and statistically significant rate of chronic GVHD after UCBT. However, the 5-year overall survival rates were equivalent. Other data suggest that B-cell engraftment may be better after UCBT.³⁵ Although a randomized, prospective trial has not been performed, these data indicate that UCB appears to represent a suitable alternative donor source.

Late Effects and Future Directions

There are limited series of long-term follow-up after HSCT for SCIDS in which the follow-up period exceeds 10 years.^{20, 21, 36} In several of these series, loss of T-cell diversity and autoimmune disorders was observed late after HSCT, although follow-up through 25 years after HSCT suggests improvement in the T-cell repertoire.³⁷ In addition, patients with adenosine deaminase deficiency in particular have experienced a high incidence of central nervous system abnormalities that include motor dysfunction, sensorineural hearing loss, and cognitive deficits that contribute to emotional and behavioral difficulties.²⁰ In addition, chronic infection by human papilloma virus also has been reported.²⁰ It is unclear which, if any of these, is related to pre-transplant conditioning and GVHD prophylaxis or to the underlying genetic defect. Finally, for those who lack a transplant donor, gene therapy is an alternative therapy for some patients, although development of this technology is ongoing.³⁸ A consensus group has discussed plans for future multicenter studies in North America, both retrospective and prospective, focused on collecting data from newborn screening and natural history sources.³⁹ The importance of collaboration in developing new protocols for these rare disorders

P.2179

was illustrated best by recent data showing that long-term mortality rates for both SCIDS and non-SCIDS patients with a PID are higher than their age- and gender-matched controls in the general population.⁴⁰

Overall survival after hematopoietic stem cell transplantation (HSCT) for severe combined immunodeficiency syndrome (SCIDS), according to donor stem cell source, degree of HLA matching, and the year of HSCT. Adapted from Antoine C, Muller S, Cant A, et al. Long-term survival and transplantation of haemopoietic stem cells for immunodeficiencies: report of the European experience 1968-99. *Lancet* 2003;361(9357):553-560. Epub 2003 Feb 25.

HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR FANCONI ANEMIA

Fanconi anemia is the most common hereditary cause of bone marrow failure. The genetic defect responsible for these findings has been characterized in 15 complementation groups, termed FANCA genes, most of which are autosomal and recessive (Table 103.2).^{41, 42} The most common mutations occur in FANCA, FANCC, FANCG, and FANCD2 genes. These gene products participate in a signal transduction pathway involved in DNA repair, called the FA/BRCA pathway (Fig. 103.2).⁴³ Thus, its diagnosis is confirmed by a chromosome fragility test that when positive, should be followed by an attempt to define the complementation group by DNA testing.

The most common hematologic manifestation is progressive marrow aplasia that causes cytopenias in the blood, which typically occur in the first or second decade of life.⁴⁴ Erythrocyte macrocytosis and elevated fetal hemoglobin often are present. In some cases, the diagnosis of FA will not be established until after the patient has developed myelodysplastic syndrome or AML. Some patients never develop pancytopenia but do experience an increased risk of malignancy. Based upon studies of a cohort of FA patients at the NCI, the risks of developing MDS and AML by age 50 are estimated to be 40% and 10%, respectively.^{45, 46} The overall survival and cancer-free survival in this cohort is shown in Figure 103.3 with a median overall survival of 33 years in those with FA.

Because of poor survival, HSCT was developed as a therapeutic measure to restore normal hematopoiesis and reduce or eliminate the risk of hematologic malignancy. There were several important

observations generated in the early clinical trials. The first was that high-dose alkylating chemotherapeutic drugs at doses administered for severe aplastic anemia and gamma irradiation caused severe toxicity including mucositis and hemorrhagic cystitis as a consequence of the sensitivity to DNA damage in all tissues.^{47, 48} Second, the risk of acute GVHD was increased in comparison to other indications for HSCT, presumably also as a consequence of impaired DNA repair and an extended duration of tissue injury eliciting an allogeneic reaction by donor T-cells.⁴⁹ The initial reports by Gluckman and her colleagues in 1984 showed that a reduced-dose regimen of CY (20 to 40 mg/kg) and a single fraction of total body irradiation or thoracoabdominal irradiation (400 to 450 cGy) effectively modulated the toxicity and was sufficient to ensure engraftment after HLA-ID sibling bone marrow transplantation with a long-term survival rate of 58.5%, although the rates of acute (55%) and chronic (70%) GVHD were quite elevated.⁵⁰ However, an updated experience of this regimen in 35 patients was reported in 2007, and included antithymocyte globulin (ATG) in the conditioning regimen.⁵¹ These results showed a probability of survival of 89% at 10 years, with the incidence of acute and chronic GVHD at 23% and 12%, respectively.

FIGURE 103.3. Survival, cancer-free survival, and survival free of marrow failure in a cohort of patients with bone marrow failure syndromes from the National Cancer Institute. The probabilities of overall survival (A), survival free of cancer (B) and survival free of bone marrow failure (C) are depicted in the 3 panels among patients with Fanconi Anemia, Dyskeratosis Congenita, Diamond-Blackfan Anemia, and Schwachman-Diamond Syndrome. From Alter BP, Giri N, Savage

SA, et al. Malignancies and survival patterns in the National Cancer Institute inherited bone marrow failure syndromes cohort study. *Br J Haematol* 2010;150(2):179-188. Epub 2010 May 29.

Several other notable improvements have occurred in the 25 years since these initial results after HSCT for Fanconi anemia were reported. The elimination of irradiation from the conditioning regimen has been associated with better results. In a series from Saudi Arabia, the replacement of thoracoabdominal irradiation by a combination of CY with ATG generated better results after HLA-ID sibling bone marrow transplantation (overall

P.2181

survival 96.9% versus 72.5%, $P = 0.013$).⁵² Alternatively, the use of CY alone at a reduced dose of 60 mg/kg by investigators in Brazil generated an overall survival and event-free survival 93% and 88%, respectively, with acute and chronic GVHD occurring in 71% and 28.5% of recipients after HLA-ID sibling transplantation.⁵³ Thus, in patients who have a HLA-ID sibling donor and who have not yet progressed to MDS or AML, the results of the reduced intensity conditioning regimens are excellent. In addition, by eliminating radiation from the conditioning regimen, the risk of developing a malignancy after transplantation also should be lowered.

Another important discovery was the benefit of fludarabine in the conditioning regimen, which effectively reduces the rate of graft rejection, in particular after alternate donor HSCT, without contributing significantly to toxicity.^{54, 55} The application of unrelated donor HSCT to Fanconi anemia is vital to expanding this treatment modality, as most individuals with FA lack a sibling donor. Initial trials of unrelated donor HSCT in which the same regimen of low-dose CY and irradiation was used were plagued by high rates of graft rejection, organ toxicity, and GVHD, with overall survival in the 30% to 40% range.^{56, 57} The escalation of the dose of radiation to 600cGy and the addition of ATG did little to improve overall survival.⁵⁸ However, in a retrospective analysis of the effect of fludarabine in the conditioning regimen, a significant impact was noted.⁵⁹ The probability of neutrophil and platelet recovery after HSCT improved from 69% to 89% and from 23% to 74%, respectively, and this translated in a lower transplant-related mortality (47% compared to 81%). The 3-year overall survival was 52% in those who received a fludarabine-containing regimen compared to 13% in those who did not (Fig. 103.4).

Another contributor to the positive effect of fludarabine on transplant outcome might be related to a condition of T-cell mosaicism that develops in some patients with FA. This condition is characterized by having two populations of host T-cells, one of which is sensitive to clastogenic/mutagenic agents and another that is resistant as a consequence of a reversion of the FA mutation.⁶⁰ McMillan et al. showed that T-cell mosaicism was a risk factor for graft rejection, presumably as a consequence of the reduced conditioning intensity used in FA not being sufficiently intensive to eradicate all the host T-cells.⁵⁸ Of interest, fludarabine mitigates this risk, as the incidence of graft rejection was not increased among those who had T-cell mosaicism and who received fludarabine.⁵⁹

There is growing consensus that marrow from an unrelated donor should undergo T-cell depletion to reduce the risk of GVHD. A benefit after T-cell depletion of donor marrow has been observed after HLA-ID sibling and after unrelated HSCT.^{55, 60, 61} In the retrospective analysis noted above, the incidence of acute GVHD decreased from 71% to 21% in the T-cell depleted group and was decreased further to 16% if fludarabine and T-cell depletion were utilized together. In parallel, umbilical cord blood also has been tested in FA as a source of HSC because it naturally contains fewer T-cells and is associated with a lower risk of GVHD after HSCT. Of note, the first successful report of UCB transplantation in 1989 was conducted in a patient with FA and who survives free of disease more than 20 years later.⁶² A retrospective review of 93 cases of FA treated by unrelated donor UCB transplantation showed acute and chronic GVHD rates of 32.5% and 16%, respectively, confirming a benefit.⁶³ Unfortunately, this benefit was balanced by high rate of graft rejection, with an overall survival rate of 40%. For this reason, the selection of UCB as a source for HSCT is generally assigned a lower priority in patients with FA.

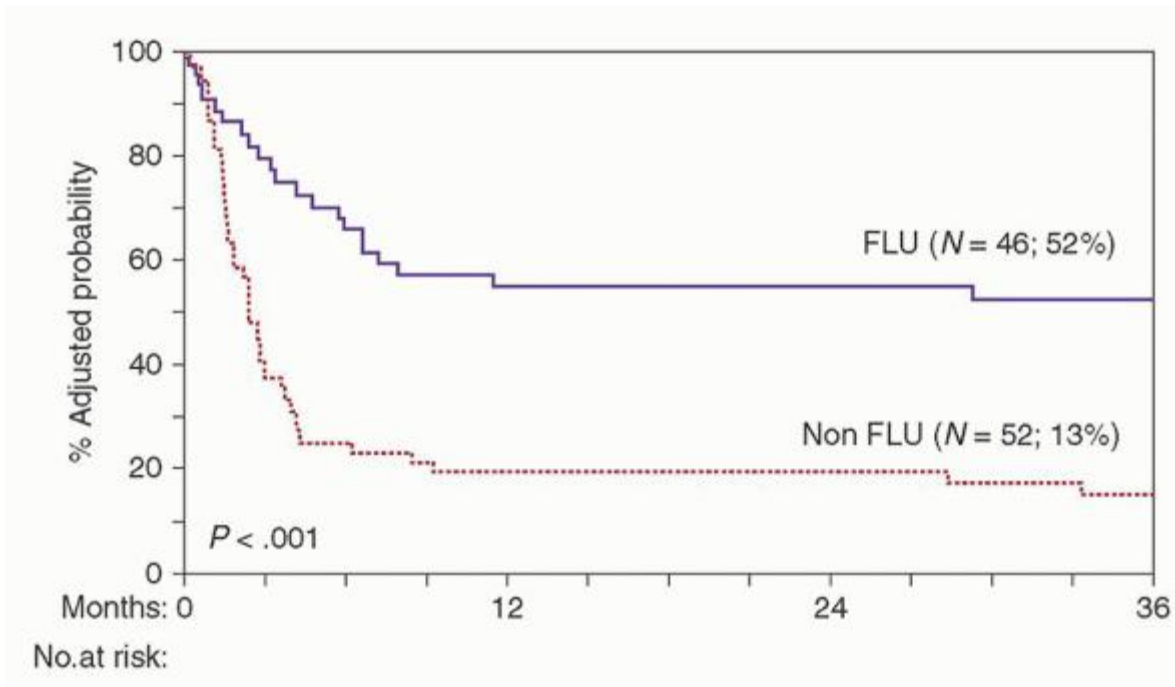

FIGURE 103.4. Effect of fludarabine administered before hematopoietic stem cell transplantation (HSCT) in patients with Fanconi anemia. From Wagner JE, Eapen M, MacMillan ML, et al. Unrelated donor bone marrow transplantation for the treatment of Fanconi anemia. *Blood* 2007;109(5):2256-2262. Epub 2006 Oct 14.

Late Effects in Fanconi Anemia Patients

The most important late complication after HSCT for FA is the development of cancer.⁶⁴ The most common forms include squamous cell carcinomas of the head and neck, carcinoma of the esophagus, and gynecologic squamous cell carcinoma. Exposure to radiation increases this risk, thus its elimination from conditioning regimens is an important advance. Survivors of successful transplantation still experience an increased risk of developing a malignancy. The risk is increased fourfold in those who receive transplantation compared to those who do not, and the cumulative incidence of a secondary cancer is 40% during the 15 to 20 years after HSCT.⁶⁵ In addition, the time to developing a secondary cancer is shortened on average by 16 years, for which the development of GVHD is a key risk factor.^{56, 66} Together, these factors must be considered carefully when making a decision about when to proceed to an alternate donor transplantation, particularly because some patients with marrow aplasia can be managed for extended periods of time by the administration of androgens and judicious use of transfusions without significant risk of progressing to MDS/AML.

Hematopoietic Stem Cell Transplantation for Hemoglobin Disorders

Together, thalassemia and sickle cell disease account for the most common hereditary disorders worldwide with broad distribution in regions of the world where malaria is endemic. However, the majority of transplantations performed for these disorders have been conducted in developed nations, which means that very few of those affected globally are ever considered for transplantation.

P.2182

The first case report of successful transplantation for thalassemia occurred 30 years ago and has been followed by several thousand children with thalassemia who have been treated successfully.^{67, 68} The first reports of successful transplantation for sickle cell disease occurred somewhat later, and because of the variable clinical course many children experience, far fewer individuals with sickle cell disease have been treated by HSCT.^{69, 70} Nonetheless, outcomes after HLA-ID sibling donor bone marrow transplantation for the hemoglobin disorders are excellent. The broader application of HSCT is limited by the risks of HSCT, which must be balanced by complications inherent to the underlying disease, for which significant progress in supportive care has occurred.

With the institution of universal newborn screening programs in the United States and elsewhere, now it is possible to identify patients with hemoglobin disorders shortly after birth and to institute comprehensive preventive care.⁷¹ As a consequence, the majority of children with SCD survive to adolescence and nearly all children with thalassemia major

survive into the third decade of life.^{72, 73} Still, the most severely affected patients with sickle cell disease experience significant morbidity and life-limiting complications that include stroke, acute chest syndrome, painful episodes, and with regular RBC transfusions, the development of iron overload.⁷⁴ However, in most children with sickle cell disease, supportive care measures are safe and mitigate the risk of life-threatening events. For these reasons, very few children with sickle cell anemia are treated by HSCT.⁷⁵ Unfortunately, the outlook for adults with sickle cell anemia has not changed substantially since the 1980s, when a median survival in males of 42 years, and in females, of 48 years was observed in the Cooperative Study of Sickle Cell Disease (CSSCD).⁷⁶ As a consequence, although most children with sickle cell disease survive to age 20, the outlook for young adults remains unsatisfactory.^{77, 78} Thus, decisions about HSCT for sickle cell anemia are often driven by an individual's outlook in the long term and by donor availability. In the child with thalassemia major where the genotype more reliably predicts the phenotype of the disease, families today are more likely to pursue HSCT in childhood if there is a suitable donor.

Hematopoietic Stem Cell Transplantation for Thalassemia

Pioneering studies that span several decades were performed by the transplant team in Pesaro led by Lucarelli.⁶⁸ Using a backbone combination of BU and CY before transplantation and a standard combination of methotrexate (MTX) and cyclosporine (CSP) to prevent GVHD, the majority of children were cured after a HLA-ID sibling bone marrow transplantation. However, the likelihood of cure was highest in those recipients who had good-risk features, defined as having no hepatomegaly, no evidence of portal fibrosis by liver biopsy, and by having adhered to a regular program of iron chelation therapy. Alternatively, children who had one (risk class 2) and two or more prognostic features (risk class 3) fared worse. Class 3 patients experienced a thalassemia-free survival probability of 50% and 30% had graft rejection with thalassemia recurrence (Fig. 103.5).⁷⁹ The improved outcomes that followed this initial report occurred by targeting good-risk young patients for transplantation promptly when there was an HLA-ID sibling donor, and by modulating the conditioning regimen in high-risk recipients to improve the safety profile. The latter also served to deliver sufficient pre-grafting immunosuppression necessary for ensuring the stable engraftment of donor cells.

FIGURE 103.5. Probabilities of event-free survival after HLA-ID sibling BMT for thalassemia according to risk category. From Lucarelli G, Galimberti M, Polchi P, et al. Bone marrow transplantation in patients with thalassemia. *N Engl J Med* 1990;322(7):417-421.

Initially, attempts to reduce the toxicity of transplantation in high-risk features focused on modifications to the BU/CY backbone. In particular, it was possible to reduce the incidence of regimen-related toxicity by reducing the dose of CY. Unfortunately, this was accompanied by a higher incidence of graft rejection, so that the overall thalassemia-free survival

rate did not improve after modifying the CY dose.⁸⁰ In response, a greater emphasis was placed on the role of immunosuppressive therapy before transplantation as a strategy for reducing graft rejection. Thus, Protocol 26 was established, which employed a combination of HU, azathioprine, and hypertransfusion with intensive iron chelation therapy that was administered 6 weeks before transplantation to modulate the proliferative erythron and induce an immunosuppressive effect.⁸¹ This was followed by a backbone of BU/CY with CY dosing that ranged from 120 to 160 mg/kg. This combination of changes resulted in a substantially improved outcome with an event-free probability of 85% and rejection incidence of 8% in class 3 recipients (Fig. 103.6). Thus, it was possible to modify the transplantation regimen in such a way as to generate outcomes that appeared indistinguishable from those in children with good-risk features. The importance of this modification was illustrated in a different fashion by results from a separate patient series from the Center for International Blood and Marrow Transplant Research (CIBMTR) registry. This retrospective analysis reported outcomes after HLA-ID sibling bone marrow transplantation from non-Italian centers. Using a modified risk categorization based upon patient age and liver size, outcomes were outstanding among recipients who had good-risk features.⁸² However, the use

P.2183

of the BU/CY conditioning backbone was associated with a far inferior outcome in this high-risk category of patients older than 7 years who had hepatomegaly, where the thalassemia-free survival probability was 50% (Fig. 103.7). This observation strengthened the conclusion that high-risk patients require a modified conditioning regimen for reasons of safety and efficacy.

FIGURE 103.6. Outcomes after HLA-ID sibling BMT for thalassemia in Class 3 patients. From Sodani P, Gaziev D, Polchi P, et al. New approach for bone marrow transplantation in patients with class 3 thalassemia aged younger than 17 years. *Blood* 2004;104(4):1201-1203. Epub 2004 Mar 25.

As most individuals with thalassemia major lack a sibling donor, the development of unrelated donor transplantation and alternative sources of hematopoietic stem cells has been pursued to broaden the availability of HSCT. An early report from the Pesaro team showed that the use of HLA-mismatched related donors was associated with an inferior outcome, and in particular, a high rate of graft rejection.⁸³ Thus, it became apparent that additional modification of the conditioning regimen would be needed to ensure engraftment across a MHC barrier and that selecting donors with optimal HLA

matching also was necessary. In one series, the BU/CY backbone was augmented by thiotepa to intensify the pre-grafting immunoablation. Among 32 patients, most of whom had class 2 or 3 risk features, the thalassemia-free probability was 66% and graft rejection occurred in 13% of the cases.⁸⁴ Of interest, 22 of 32 recipients shared at least one extended HLA haplotype with the donor. Of these, 19 survived and 17 survived free of thalassemia after transplantation. Thus, the importance of donor selection was suggested by these data. The unrelated donor HSCT outcomes were updated 5 years later and included the replacement of fludarabine for CY which accompanied thiotepa and BU in the conditioning regimen.⁸⁵ This combination was associated with reduced toxicity and lower transplant-related mortality (reduced from 25% to 13.3%) and a thalassemia-free survival rate of 71%. Most recently, the team from Pavia, Italy reported its experience with the use of treosulfan, a myeloablative drug that has a reduced toxicity profile when compared to BU. Using a combination of treosulfan, fludarabine, thiotepa, and ATG, 60 patients treated between 2005 and 2009 experienced 93% survival and 84% event-free survival probabilities after HLA-ID sibling (N = 20) or unrelated donor bone marrow transplantation (N = 40).⁸⁶ Twenty-one of the patients had Lucarelli class 2 or 3 features and 12 were adults. Thus, incremental progress in unrelated donor transplantation shows the potential for outcomes that appear indistinguishable from those after HLA-ID sibling HSCT.

Disease-free survival probabilities after HLA-ID sibling hematopoietic stem cell transplantation (HSCT) based upon pre-transplantation features among non-Italian thalassemics from the CIBMTR registry. From Sabloff M, Chandy M, Wang Z, et al. HLA-matched sibling bone marrow transplantation for beta-thalassemia major. *Blood* 2011;117(5):1745-1750. Epub 2010 Dec 2.

P.2184

Hematopoietic Stem Cell Transplantation for Sickle Cell Disease

The application of HSCT for sickle cell disease has developed more slowly than in thalassemia, in part due to the heterogeneous phenotype of sickling syndromes and also from a lack of suitable donors. However, several patient series were conducted in the mid- to late-1990s in the United States and Europe and demonstrated very similar outcomes.^{87, 88, 89} The aim of these clinical trials was to identify children who were at risk for early mortality or extensive morbidity, but to treat by HSCT before organ damage had occurred that might increase the risk of transplant-related complications. Thus, patients were deemed eligible if they had a stroke and were receiving regular RBC transfusion therapy to prevent another stroke, if they had recurrent painful episodes, or if there were recurrent episodes of acute chest syndrome. The current eligibility criteria are shown in Table 103.3.

Following these eligibility requirements, myeloablative conditioning regimens with a backbone of BU 14 to 16 mg/kg and CY 200 mg/kg were used, with or without ATG. Post-transplantation immunosuppression consisted of CSP and MTX in

most cases. The results of transplantation showed a disease-free survival of approximately 80% to 85%. A total of 5% to 10% of patients died of complications related to transplantation, with GVHD and its treatment as the leading cause of death.

In the Belgian series, many patients with symptomatic sickle cell disease were children of parents from Africa who were studying abroad in Europe.⁷⁰ It was reasoned that because supportive care was limited in their country of origin, the possibility of cure by HSCT was a reasonable justification for pursuing this therapy. The initial small series of patients reported in 1988 was later expanded to include 50 patients, and this was the earliest clinical trial to suggest that having the diagnosis of sickle cell anemia in and of itself was sufficient justification for bone marrow transplantation.⁸⁸ Of the 50 patients reported, 5 (10%) had graft rejection accompanied by recurrent sickle cell anemia and 86% survive free of sickle cell anemia. Of interest, some of the patients with graft rejection had persistent elevation of fetal hemoglobin levels despite having no evidence of donor cells in the marrow. This phenomenon of persistent fetal hemoglobin expression was associated with resolution of sickle-related complications.⁹⁰ Although in these cases, the fetal hemoglobin elevation was not durable and eventually levels declined, a long-lived elevation of fetal hemoglobin of host origin in thalassemia was observed in a more recent report.⁹¹

TABLE 103.3 INDICATIONS FOR HCT FOR SICKLE CELL DISEASE

Patients with sickle cell disease (HbSS or HbS β^0 -thalassemia)

One or more of the following complications:

Stroke or CNS event lasting longer than 24 hours

Recurrent acute chest syndrome

Recurrent vaso-occlusive painful episodes or recurrent priapism

Impaired neuropsychological function with abnormal cerebral MRI and angiography

Other indications under consideration:

Elevated cerebral arterial velocity by transcranial doppler

Pulmonary hypertension

Silent cerebral infarction

CNS, central nervous system; HCT, hematopoietic cell transplantation; MRI, magnetic resonance imaging.

An international study of BMT for sickle cell disease led by investigators in the United States was conducted between 1991 and 2000 and enrolled 59 patients from the United States, South America, and Europe.^{87, 92} Early in the course of the study, a high rate of neurologic complications was observed, including intracranial hemorrhage.^{93, 94} These events occurred in the setting of CSP administration, hypertension, and in some cases, thrombocytopenia or elevated hemoglobin levels as a consequence of hypertransfusion. These events also were observed in the European patient series. In response to observing these events, a standard approach for preventing neurologic complications was instituted and it included the strict control of hypertension, administration of anticonvulsant prophylaxis during CSP use, RBC transfusion support to maintain the hemoglobin between 9 and 11 gm/l to avoid hyperviscosity, and to keep the platelet level $>50,000/\text{mm}^3$. After the institution of these preventive measures, there were no further episodes of intracranial hemorrhage in the international study, although seizures still occurred in approximately 20% of recipients.⁹⁵

The largest single patient series of HSCT for sickle cell disease was reported in France and included 87 patients who received HLA-ID bone marrow or in 12 cases, umbilical cord blood grafts between 1988 and 2004.⁸⁹ Initially, patients were prepared for transplantation with a BU/CY backbone alone, but after the initial 12 patients were treated, rabbit ATG was added to the conditioning regimen. The overall cumulative incidence of graft rejection was 7%; however, the rejection rate was significantly lower after the addition of rabbit ATG to the conditioning regimen (Fig. 103.8). In addition, the level of mixed donor-host hematopoietic chimerism was analyzed with regard to the effect of ATG, and it was measured in 77 of the patients. A higher level of persistent host hematopoiesis was observed in those who received ATG. A larger fraction transplant recipients had full chimerism noted at 12 and 24 months after transplantation after receiving BU/CY alone. However, the development of mixed chimerism was not associated with sickle-related events after HSCT, although 2 patients with only 20% donor cells had moderate anemia (8.5 to 9 gm/dl) and did not require RBC transfusions.

FIGURE 103.8. The effect of rabbit antithymocyte globulin (ATG) on the cumulative incidence of graft rejection after sibling hematopoietic stem cell transplantation (HSCT) for sickle cell anemia. From Bernaudin F, Socie G, Kuentz M, et al. Long-term results of related myeloablative stem-cell transplantation to cure sickle cell disease. *Blood* 2007;110(7):2749-2756. Epub 2007 Jul 4.

P.2185

The development of stable donor chimerism has been observed after transplantation for thalassemia and sickle cell disease, and has been studied most extensively in the thalassemia cohort from Pesaro.^{96, 97, 98} The cause of the phenomenon is uncertain, and it is associated with oligoclonal skewing of the T-cell repertoire, which is not associated with impaired immune function.⁹⁹ In the RBC lineage, there is a natural enrichment of donor cells in the blood, as a consequence of ineffective erythropoiesis and longer RBC survival in donor erythrocytes. Most important, even when there is a minority of donor cells, the patients who develop stable mixed chimerism do not experience symptoms of the underlying hemoglobinopathy and thus survive disease-free.

These observations in part became the basis for exploring if a reduced intensity or nonmyeloablative conditioning regimen might be sufficient to establish mixed chimerism and thereby generate an alternative safer means of transplantation for these disorders. Initial clinical trials tested a minimal toxicity regimen of fludarabine with a single fraction of total body irradiation (TBI, 200 cGy) in patients with hemoglobinopathies.¹⁰⁰ The results showed that only transient donor chimerism was achieved in most patients, and that donor chimerism was lost when the intensity of the post-grafting immune suppression was tapered and discontinued. The addition of rabbit ATG to a backbone of fludarabine and TBI did not improve the outcome.¹⁰¹ There has been better success with the application of reduced intensity regimens that require hospitalization and cause cytopenias, but still retain a favorable toxicity profile. The use of alemtuzumab, an anti-CD52 antibody, in combination with melphalan and fludarabine in the conditioning regimen has generated better results and

most patients achieve full donor chimerism after HSCT. In one series, 12 of 16 patients with nonmalignant disorders survived with donor engraftment after receiving this conditioning regimen.¹⁰² In a more recent trial at the National Institutes of Health, adult recipients with severe sickle anemia who were judged too ill to receive a standard myeloablative preparative regimen received a nonmyeloablative combination of fludarabine, campath, and 300cGy of TBI before HLA-ID sibling mobilized peripheral blood stem cell transplantation. Sirolimus as a single agent was administered for post-grafting immunosuppression.¹⁰³ To date, 23 patients have been treated in the trial, and all 23 survive, and 20 survive with mixed chimerism sufficient to eliminate sickle-related clinical features including an improved reticulocyte count, LDH, and serum bilirubin after HSCT (Fig. 103.9). Although many of the recipients appear to require long-term immunosuppression with sirolimus to stabilize engraftment, this is a promising approach in older patients.

As in Fanconi anemia, umbilical cord blood might also have benefits in HSCT for hemoglobin disorders due to the lower risk of GVHD. In addition, finding suitably HLA-matched donors in underrepresented ethnic groups in the unrelated marrow donor registry still presents challenges.¹⁰⁴ Unlike marrow-derived hematopoietic stem cells, UCB units are immediately available upon request and are not affected by donor scheduling or health for procurement. Because of the lower GVHD risk, a greater degree of HLA disparity is acceptable when selecting a UCB unit, which effectively expands the pool of possible donors for patients.¹⁰⁵ Unfortunately, there are several limitations of cord blood units, including small volume, relatively low stem cell number, variable collection methods, and viability after cryopreservation. The nucleated and CD34+ cell dose are the major factors that affect outcome.¹⁰⁶ Thus the role of UCB transplantation for hemoglobin disorders is still evolving. Locatelli et al. reported the outcome after HLA-ID sibling cord blood transplantation for patients with SCD and thalassemia.¹⁰⁷ A total of 44 patients was included in the series (median age 5 years, range 1 to 20) and the patients had thalassemia (n = 33) or SCD (n = 11). The majority of children (n = 40) received CSP alone or CSP / MTX as GVHD prophylaxis and their median total nucleated cell dose was $4.0 \times 10^7/\text{kg}$ (range 1.2 to $10 \times 10^7/\text{kg}$). Eighty-two percent of patients were alive and disease-free with a median follow-up of 2 years (range 4 to 76 months), and only 4 (9%) had grade II acute GVHD. The two-year event-free survival probabilities were 79% and 90% for patients with thalassemia and SCD, respectively. Results were best in patients who did not receive MTX to prevent GVHD and also in those patients who received an additional immunosuppressive drug such as thiotepa or fludarabine with the BU/CY backbone.

In an attempt to extend these encouraging results observed after sibling donor UCB transplantation, the applicability of unrelated donor UCB transplantation was explored. Recently, a prospective investigation of unrelated donor HSCT for severe sickle cell disease reported the results after UCB transplantation.¹⁰⁸ In this phase II trial, eight children who met study criteria for severe SCD underwent unrelated-donor cord blood transplantation. They received alemtuzumab, fludarabine, and melphalan as their preparative regimen and either CSP or tacrolimus in addition to mycophenolate mofetil as GVHD prophylaxis. All patients had either 6 of 6 (n = 1) or 5 of 6 HLA matching based on low-/intermediate-resolution typing of HLA-A, -B, and -DRB1. Because of excessive graft rejection rates in the cord blood cohort, that arm of the trial was closed. Similarly, results after unrelated donor UCB transplantation in patients with thalassemia major are inferior to those with related marrow donors. Ruggeri et al. reported results of the CIBMTR data registry that included a cohort of 35 thalassemia patients who underwent either matched or mismatched UCB transplantation.¹⁰⁹ Despite acceptable HLA matching, disease-free survival and overall survival for patients in this report were 21% and 62%, respectively. Of these patients, 20 had graft failure that was fatal in 5. A larger cell dose ($>5 \times 10^7/\text{kg}$) was associated with lower risk of graft failure, indicating that perhaps survival could be improved through the use of multiple cord blood units or ex vivo expansion.

LATE EFFECTS

Assessment of Disease-free Survival

Disease-free survival after HSCT for hemoglobin disorders is defined as freedom from transfusions and iron loading in thalassemia, and in addition among those with sickle cell disease, freedom from sickle-related complications. However, the iron that accumulates as a consequence of RBC transfusions before and after HSCT is not eliminated after successful HSCT to any appreciable extent. Left untreated, iron overload causes significant morbidity and mortality with progressive liver disease and even cirrhosis after transplantation.¹¹⁰ A prospective analysis of annual liver biopsies in thalassemics not treated by iron chelation and in whom thalassemia was cured by HSCT demonstrated that iron overload and hepatitis C virus infection were independent risk factors for progressive liver fibrosis. Patients who had an active hepatitis C infection and also had very high levels of hepatic iron had an 80% risk of developing progressive hepatic fibrosis 10 to 12 years after successful transplantation.¹¹¹ Conversely, patients with a liver iron level less than 16 mg iron/gm liver dry weight and who were also free of evidence of active hepatitis C virus infection, showed no signs of progressive hepatic fibrosis.

Phlebotomy is safe, inexpensive, and highly efficient, and therefore it is the treatment of choice of transfusion iron overload after HSCT. With this approach, excess iron can be completely mobilized from the body without any significant

side effects. Following completion of the phlebotomy program, significant improvement in liver function was observed, particularly in patients infected with hepatitis C virus.¹¹¹ It is possible to reverse severe hepatic fibrosis and even early cirrhosis.¹¹² Patients with early cardiac involvement characterized by left ventricular diastolic dysfunction

P.2186

and impaired left ventricular contractility demonstrated regression of subclinical cardiac disease after phlebotomy.¹¹³

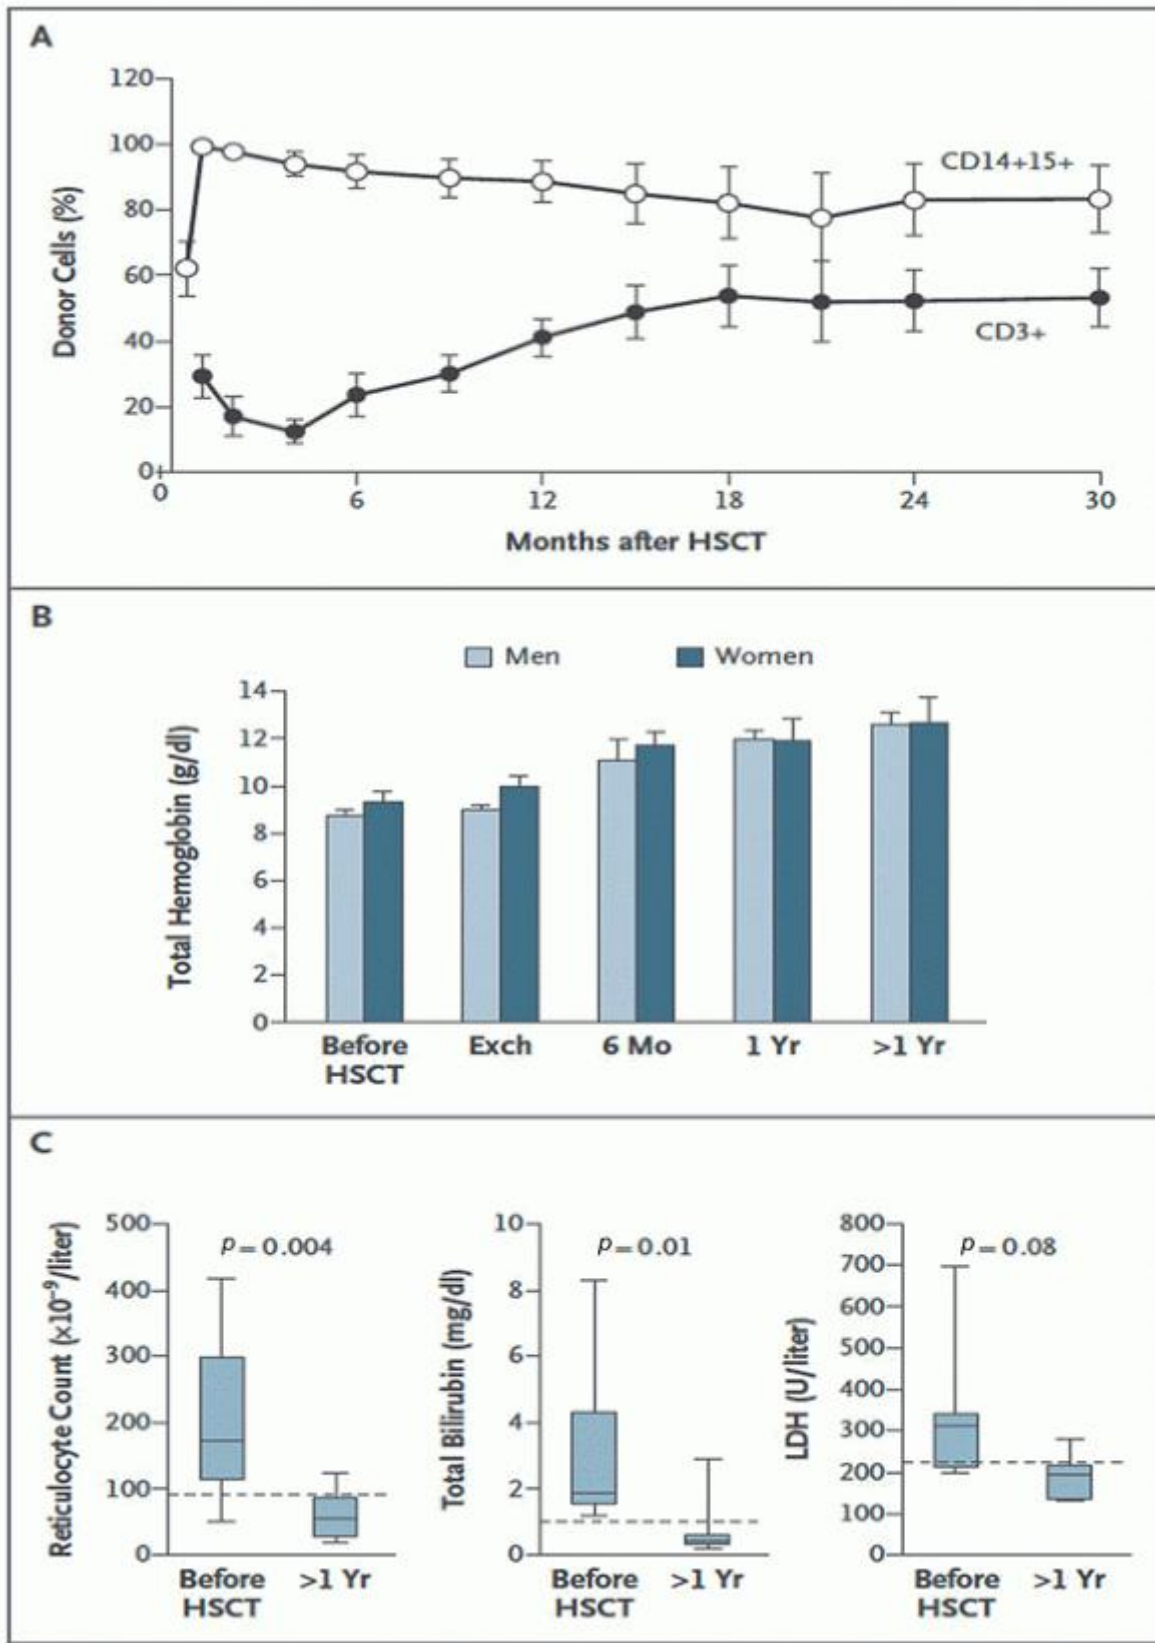

FIGURE 103.9. Effect of donor chimerism on sickle cell disease expression after nonmyeloablative hematopoietic stem cell transplantation (HSCT) from HLA-ID siblings in adult recipients with severe sickle cell disease. In panel A, the percentage of donor myeloid and T-cells in the blood over time is shown. In Panel B, the change in the hemoglobin level

over time in males and female transplant recipients is shown. In panel C, the reticulocyte count, total serum bilirubin and LDH levels before and after transplantation are shown. From Hsieh MM, Kang EM, Fitzhugh CD, et al. Allogeneic hematopoietic stem-cell transplantation for sickle cell disease. *N Engl J Med* 2009;361(24):2309-2317. Epub 2009 Dec 17.

After successful HSCT for sickle cell disease, patients with stable engraftment of donor cells do not experience sickle-related clinical complications, even if there is stable mixed donor-host hematopoietic chimerism.^{89, 97} In addition, investigators have reported improvements in splenic function and osteonecrosis.^{114, 115} Patients treated by HSCT also had stabilization of the underlying cerebrovascular disease.⁹⁵ Of 55 patients who were enrolled in the multicenter study, 46 underwent cerebral MRI performed a median of 25.4 months after transplantation. Of 59 patients, 29 had stroke or other significant central nervous system disease as an indication for transplantation and 28 survived after BMT. Surviving patients with stroke who also had stable engraftment of donor cells (n = 25) experienced no subsequent stroke events after BMT. However, patients who had graft rejection after BMT were not protected from stroke. One patient with graft rejection experienced a second stroke when the Hb S fraction reached 60% after BMT and another patient with graft rejection had a subarachnoid hemorrhage after BMT. In total, 28 of 29 (97%) of patients with stroke survived after transplantation, and 26 of 29 (90%) survived stroke-free after HSCT. Evidence of silent cerebral infarction before transplantation was found in 10 patients, and of these, all 8 who had MRI studies performed after HSCT had stable or improved appearance. There were no clinical strokes after HSCT in this group. No documented central nervous system disease before transplantation was found in 16 patients. MRI appearance was normal in all 10 patients in this group and P.2187

none had stroke. Together, these observations suggest that there is stabilization of cerebral vasculopathy after hematopoietic cell transplantation. These data also suggest that in those with silent cerebral infarction who are at risk of developing stroke, there is protection from disease progression and a first stroke. The French group reported a similar experience.⁸⁹ Among the 36 patients with a history of stroke before hematopoietic cell transplantation, 2 had a recurrent stroke. With a median follow-up of 6 years, the risk of recurrent stroke was 5.6%, which is a significantly lower rate of second stroke observed in sickle cell disease patients who are treated by regular transfusion therapy after a first stroke.

LONG-TERM TOXICITIES OF CONDITIONING

The incidence of secondary solid tumors in thalassemia and sickle cell disease after transplantation is less than 10/100,000 patient-years, a rate that does not appear different compared to patients who receive supportive care treatment for β thalassemia.¹¹⁶ These findings also are consistent with data reported by the CIBMTR; patients with nonmalignant disorders treated by HSCT had an incidence of secondary malignancies that was not significantly increased compared to the normal population.¹¹⁷

Gonadotropin and sex hormone levels confirm the toxic effect of BU on gonadal function after HSCT. In addition, hypogonadism is the most common endocrine disorder in medically treated patients with thalassemia major, affecting approximately half the patients.^{118, 119} In a study involving 68 children with thalassemia after HSCT, 32% reached an advanced or complete puberty spontaneously (34% of girls and 63% of boys), despite clinical and hormonal evidence of gonadal impairment in most cases.¹¹⁰ In this group, iron overload and the conditioning regimen were the major factors influencing endocrine function. In the cooperative study of HSCT for SCD follow-up gonadal function studies were performed in patients who were 21.6 (range, 16.1 to 28.5 years) and 21.7 (range, 14.1 to 27.8 years) years of age in males and females, respectively.⁹⁵ Among those evaluated, the luteinizing hormone (LH) and follicle stimulating hormone (FSH) levels were normal in 9 males and less than normal in 4 after transplantation. However, only 3 of 13 had normal testosterone levels, consistent with hypogonadotropic hypogonadism in most of the pubertal males. In contrast, 8 of 14 females had increased gonadotropin levels and/or below normal estradiol levels, a finding consistent with primary ovarian failure in the majority of post-pubertal females. Only 4 of 14 females had normal estradiol levels. However, one female had a successful pregnancy 13 years after BMT and another female with graft rejection gave birth to a healthy baby following preimplantation genetic diagnosis 14 years after BMT, although she had experienced 2 previous spontaneous abortions several years earlier. Among 6 evaluable pre-pubertal girls in the Belgian cohort, 5 had primary amenorrhea with elevated serum LH and FSH.⁸⁸ Two post-pubertal females developed secondary amenorrhea. Testicular function was also adversely affected in 4 of 6 evaluable boys who demonstrated decreased testosterone and elevated FSH levels. In the French series, 7 post-pubertal females, aged 13 to 22 years, developed amenorrhea after hematopoietic cell transplantation with decreased serum estradiol and elevated LH and FSH levels and received hormone replacement therapy.⁸⁹ It is anticipated that many, if not most, of the females will require hormonal replacement therapy after HSCT. The development of reduced intensity conditioning regimens is anticipated to reduce the late effect of gonadal toxicity.

Eggelston et al. reported growth outcomes in children who were enrolled in a multicenter investigation of HSCT for SCD.¹²¹ The baseline height and weight and growth velocities after HSCT were compared to children who were treated by HU and who were enrolled in the CSSCD, previous investigations of SCD during which prospective height and weight measurements were documented.^{122, 123} It was determined that growth after HSCT was not impaired, except in older males, where data from the CSSCD showed a more rapid height and weight velocity after age 11.6 and 12.1 years, respectively. However, males grew 0.67 cm/year faster after HSCT compared to males in the HU group before treatment with HU was initiated. Thus, the data showed that conventional myeloablative HCT generally had no adverse effect on height or weight gain in young children. However, diminished growth may occur in patients who undergo HSCT at or near the growth spurt. This study emphasized the importance of treating children early in the course of their disease to minimize toxicity.

CONCLUSION

HSCT for nonmalignant disorders can be life-saving when applied early in life of children who inherit a fatal condition such as SCIDS. In other disorders, early mortality caused by marrow failure or a predisposition to acute leukemia, as occurs in Fanconi anemia, similarly can be life-saving, but as applied over a longer time period. In the setting of hemoglobin disorders, the decision making about HSCT is more nuanced, and often families and their physicians must make decisions based upon long-term projections of mortality and the quality of life. Common to all these disorders, however, is a strict requirement for optimizing donor selection to avoid GVHD, a complication that offers no benefit in these disorders, and an understanding of conditioning regimens that are best tailored to minimize short- and long-term toxicities but still ensure engraftment of donor cells. It is these considerations and the development of improved methods of HSCT that remain the focus of ongoing clinical investigation and which are very likely to improve future outcomes for these disorders.

INTRODUCTION

The curative potential of allogeneic hematopoietic stem cell transplantation (HCT) in hematologic malignancies is well established,¹ and currently acute myelogenous leukemia (AML) is the most common indication for HCT, accounting for approximately more than one-third of adult HCT.² As the donor pool expands to include more unrelated and HLA-mismatched donors and umbilical cord blood (CB), and as treatment-associated morbidity and mortality rates decline with improvements in HLA matching, antimicrobial therapy, and management of graft-versus-host disease (GVHD), it has become increasingly feasible to offer this modality of treatment.³

HCT is offered either to increase the chance of cure in a disease that may have a low chance of cure with nontransplant approach (AML in first complete remission [CR1] with high-risk cytogenetics) or to cure an otherwise incurable disease (myelodysplastic syndrome [MDS], AML beyond CR1). Given the inherent risks of HCT, the risk-benefit ratio depends on the natural history of the disease versus the non-relapse mortality or transplant-related mortality due to the procedure itself. Although randomized control trials have been done, an ideal study of "intent to transplant analyses" is lacking in most disease types. With the advances in human leukocyte antigen (HLA) typing and supportive care, the non-relapse mortality after transplant continues to improve. The emergence of reduced-intensity conditioning (RIC) in deference to myeloablative conditioning (MST) broadens the applicability of this modality to patients who formerly would have been excluded from HCT because of advanced age or co-morbid conditions.^{4, 5, 6, 7} Here we discuss the indications, benefits, and risks of HCT in patients with hematologic malignancies.

Chronic myelogenous (or myeloid) leukemia (CML) was a model disease to cure with HCT in the pre-tyrosine-kinase inhibitors (TKI) era. The introduction of TKIs led to a paradigm shift. Current indications of HCT are outlined in the National Cancer Center Network (NCCN) guidelines and addressed in Chapter 81. Consideration of HCT is recommended at 3 months post-TKI therapy if there is a >10% increase in BCR-ABL transcript as measured by quantitative PCR (QPCR) using the International Scale, or if conventional cytogenetics shows less than a partial cytogenetic response. Loss of cytogenetic response, molecular progression, or evolution of new mutations associated with TKI resistance should prompt a transplant evaluation. HCT consideration is often delayed based on response to second generation TKIs. Patients presenting in accelerated phase (AP) or blast crisis (BC) should be considered for earlier HCT.

Acute Myeloid Leukemia

In the United States, approximately 25% of AML patients younger than 70 years undergo an HCT. Median age at transplantation is 45 years; 75% of HCT recipients are younger than 55 years.^{2, 8, 9, 10, 11} The increasing need for HCT in adults with AML requires that all patients and their siblings undergo HLA typing early after diagnosis to determine if a matched related donor (MRD) is available and to allow for the possibility of unrelated donor (URD), haploidentical donor or umbilical cord blood (CB) searches.

Rationale of Hematopoietic Stem Cell Transplantation in First Complete Remission

Transplants should preferentially be performed on time and not reserved for relapsed disease or complete remission 2 (CR2) in high-risk patients. Although several reports of successful HCT in CR2 with a curative potential of 25% to 30% have been reported, such data are highly selective and should not influence a decision against earlier HCT, especially at experienced transplant centers. Moreover, the risk of relapse after URD HCT is higher for patients with unfavorable cytogenetics, irrespective of whether the transplant is performed in CR1 or CR2. Since the probability of achieving CR2 after chemotherapy in this group of patients is low, early HCT provides the optimal approach.^{9, 10, 12, 13}

Indications of Hematopoietic Stem Cell Transplantation in Acute Myeloid Leukemia First Complete Remission

Several clinical features at presentation are associated with particularly poor outcome for AML patients. Age over 60 years, hyperleukocytosis, secondary AML (after antecedent myelodysplasia), or treatment-related myeloid neoplasm and, in some series, two induction cycles rather than one to attain CR1 are clinical factors that portend a worse outcome. As a result, many investigators proceed to offer HCT to such individuals.^{9, 12, 13}

Cytogenetics, however, remains the most robust prognostic marker for risk stratification of AML at the time of diagnosis as well as in selection of post-remission treatments. On the basis of specific structural and numerical cytogenetic abnormalities, AML patients are divided into favorable, intermediate, and adverse risk groups (Chapter 75). A notable exception is the favorable cytogenetic risk group, in which HCT did not further improve outcome.

In recent years, a variety of novel molecular markers including mutations in the FLT3 (FMS-like tyrosine kinase) gene, the NPM1 (nucleophosmin) gene, and the CCAAT/enhancer binding protein alpha (CEBPA) gene have refined the risk stratification of intermediate-risk AML. Several investigators have used combinations of molecular markers to improve the patient's risk assessment in cytogenetically normal AML.⁸

The most challenging group of patients with de novo AML falls within the intermediate-risk category.^{8, 12} Intermediate-risk patients who achieve CR1 after chemotherapy have a 50% probability of disease recurrence without HCT, and the probability that CR2 can be attained is low. With advances in the molecular classification of AML such as NPM1, FLT3-internal tandem duplication (ITD), CEBPA, and KIT, the indications for HCT can now be extended to approximately 40% of patients with AML with no chromosomal abnormalities.^{9, 10, 11, 12, 13} In a recent meta-analysis by Koreth et al.¹⁴ for the transplant period 1982 to 2006, a significant overall survival benefit was reported for patients with poor-risk and intermediate-risk AML who received HCT in CR1. NPM1 positivity has been considered a good-risk feature. More recently, it has been shown that only the subgroup with wild type isocitrate dehydrogenase 1 and 2 (IDH1/IDH2) along with NPM1 mutations are expected to do well.¹⁵ Thus, the prognostic impact

P.2190

of known well validated mutations continues to evolve as new mutations are identified and the interactions of these mutations are understood.

Donor Source and Outcome in Acute Myeloid Leukemia First Complete Remission

Importantly, the outcome of transplantation appears to be comparable for recipients of URD vs. MRD transplant. With improvements in transplant procedures including better donor selection (with high-resolution HLA- typing), excellent

supportive care, and pre-emptive therapy in high-risk patients, we anticipate that outcomes will continue to improve.^{3, 16, 17, 18, 19, 20, 21}

The results of 4 comparative studies together with meta-analyses of cord blood transplant (CBT) vs. URD transplant, the results of CBT appear to be as promising as those of matched URD transplant in adults with hematologic malignances.^{10, 12, 20, 22} In the absence of an HLA-matched donor, both CBT and haploidentical-stem cell transplantation (SCT) strategies (center dependent) are suitable options to treat high-risk patients. An upcoming blood and marrow transplant (BMT)-clinical trials network (CTN) study (BMT-CTN 1101; clinicaltrials.gov NCT01597778) will compare haploidentical-SCT with CBT.

Effect of Consolidation Therapy Pre-stem Cell Transplantation in Acute Myeloid Leukemia First Complete Remission

Relapse is the major cause of treatment failure after HCT in patients with AML^{10, 23}; new approaches to prevent disease recurrence are being explored. A question of practical importance is whether patients undergoing transplantation in CR1 will benefit from post-remission chemotherapy prior to transplantation. There are no prospective studies demonstrating that any form of post-remission chemotherapy further reduces the risk of post-transplant relapse. However, results from two retrospective registry analyses suggest no benefit from adding further consolidation chemotherapy prior to HCT; in both studies (transplant period 1980 to mid-1990s), most patients were young and received full-intensity conditioning MRD HCT.^{9, 12, 14, 24} The role of post-remission consolidation chemotherapy prior to RIC HCT in HR AML has not been adequately addressed.^{13, 25} In a recently published CIBMTR study, relapse occurred in 37% to 40%, and was higher in patients receiving RIC regimens. These findings highlight the importance of the depth of remission pre-SCT, especially in recipients in the RIC group.¹⁸ The efficacy of current chemotherapeutic regimens to achieve minimal residual disease negativity needs to be balanced against the risk of increasing co-morbidities prior to HCT.

Given the expanding use of RIC conditioning and the argument that treatment intensity may be important for cyto-reduction prior to SCT, assessing the impact of pre-transplant consolidation therapy in AML CR1 on outcomes post RIC HCT is an important clinical question that remains unanswered. There is an ongoing CIBMTR analysis to determine if consolidation chemotherapy prior to RIC regimen for AML CR1 improves survival and relapse risk after RIC HCT.

Allo- vs. Auto-Stem Cell Transplantation vs. Chemotherapy in First Complete Remission

A recent summary of several clinical trials comparing HCT with alternative therapies for patients with AML CR1 showed benefits of HCT over alternative therapies.^{8, 9, 13, 26} Studies showed lower relapse rates for allograft recipients compared with those who received auto-SCT or further chemotherapy. None of the studies demonstrated an advantage for any of the alternative modalities (auto-SCT or further chemotherapy) as compared with HCT.

Full Myeloablative vs. Reduced-intensity Conditioning Regimen for Acute Myeloid Leukemia First Complete Remission

Conditioning regimens prior to HCT serve two purposes. One is the suppression of host immunity to allow for donor cell engraftment, and the other is the ablation of underlying malignancy. Ideally both these tasks need to be accomplished with minimal extramedullary toxicity. Conditioning regimens can be broadly classified as myeloablative (MST), RIC, and non myeloablative (NMA), based on the intensity of conditioning. MST regimens cause irreversible cytopenia and hence stem cell support is necessary. RIC regimens cause profound cytopenia and should be given with stem cells but cytopenia may not be irreversible. NMA regimens can theoretically be given without stem cell support.

MST HCTs are associated with decreased relapse but with increased transplant-related mortality (TRM). We now know that myeloablation is not as critical for engraftment as is immunosuppression. Reduced-intensity immunosuppressive approaches such as antithymocyte globulin (ATG), alemtuzumab, rituximab, and others can be used for transplant conditioning. There is a balance between reducing TRM by reducing intensity, and risking more relapse as the regimen is weakened.^{6, 27}

No study to date has shown superiority of RIC to MST in AML^{4, 27, 28, 29, 30}; we recommend reserving RIC (but not truly NMA) for patients thought to be ineligible for the more intense MST regimen. The importance of disease control at the time of transplant, especially for those patients undergoing the RIC condition, appears to have paramount importance when evaluating outcomes. In Martino's large-scale retrospective analysis of AML patients undergoing SCT, those patients transplanted in CR1 had similar rates of relapse (MST: 27% vs. RIC: 32%).³¹ A prospective study randomizing patients to MST or RIC HCT regimens based solely on age of < or >50 years for AML patients in CR1 revealed similar non relapse mortality of 19% for MST and 20% for RIC with equivalent relapse and survival.³² These data suggest that MST conditioning may not be needed for those AML patients in CR1 at the time of HCT. Ongoing prospective randomized clinical trials (BMT-CTN 0901; clinicaltrials.gov NCT01339910) will answer this question more definitively.

Hematopoietic Stem Cell Transplantation for Patients Not in Remission and Beyond First Complete Remission

HCT for AML was first tested in patients with recurrent or relapsed refractory disease three decades ago. The transplant outcome for patients with induction failure or resistant relapse AML or for those with extramedullary disease treated with standard dose chemotherapy remains quite poor. Although the results are less than satisfactory, there is still a role for HCT for patients with advanced AML.

Difficulties in Achieving Complete Remission 2 Pre-stem Cell Transplantation

More recently, the investigators from City of Hope National Medical Center (COHNMC) reported their extended experience with 71 patients with refractory AML who were treated with HCT during a period of 22 years with 82% receiving grafts from MRD. The median age of these patients was 37 years (range 2 to 62 years) and the median follow-up was 1 year. Three-year disease-free survival (DFS) was 29% with a relapse rate of 54%. Cytogenetic data were available on 51 of the patients treated at COHNMC. Three patients had favorable, 27 intermediate, and 21 unfavorable cytogenetics. Those patients with favorable or

P.2191

intermediate cytogenetics had DFS of 44% vs. only 18% in those with unfavorable cytogenetic features.³³

A score to predict transplantation success was developed in a retrospective survey of 1,673 patients who underwent a MST HCT for AML in relapse. In patients with low score the 3-year overall survival (OS) was 42% and those with a very high score had a dismal prognosis with only 6% alive at 3 years. The high score refers to the same group of patients in whom attempts to reinduce second remission are likely to fail. Patients with a short CR1, poor cytogenetics, and/or circulating blasts present a major clinical challenge.^{34, 35}

Sequential Chemotherapy Followed by Reduced-intensity Conditioning Hematopoietic Stem Cell Transplantation

An interesting strategy of sequential cytoreductive chemotherapy, immediately followed by RIC and prophylactic donor lymphocyte infusion (DLI) in refractory and early relapse patients, was evaluated.³⁶ This German protocol known as the FLAMSA (fludarabine, Ara-C, amsacrine)-RIC approach was reported in a prospective multicenter study involving 103 patients. The median survival of 16.4 months and the 4-year estimated OS of 32% were promising.³⁶ This approach requires an HLA-matched donor available just when relapse is diagnosed. Therefore, for AML patients in CR1 even if HCT is not scheduled, a search for a donor should be initiated to enable sequential transplantation in case of early relapse.

Persistent Cytogenetic Abnormalities Pre-stem Cell Transplantation

Risk stratification is important to identify patients with AML who might benefit from HCT in CR1. An MD Anderson Cancer Center (MDACC) study analyzed 150 patients with AML and diagnostic cytogenetic abnormalities who underwent MST HCT while in CR1 to evaluate the prognostic impact of persistent cytogenetic abnormalities at HCT.³⁷ Three risk groups were identified. Patients with favorable/intermediate cytogenetics at diagnosis (n = 49) and patients with unfavorable cytogenetics at diagnosis but without a persistent abnormal clone at HCT (n = 83) had a similar 3-year leukemia-free survival of 58% to 60% despite the higher 3-year relapse incidence in the latter group (32.3%, versus 16.8% in the former group). A third group of patients with unfavorable cytogenetics at diagnosis and a persistent abnormal clone at HCT (n = 15) had the worst prognosis, with a 3-year relapse rate of 57.5% and 3-year leukemia-free survival of only 29.2%. These data suggest that patients with AML and unfavorable cytogenetics at diagnosis and a persistent abnormal clone at HCT are at very high risk for relapse after HCT.^{37, 38} These patients should be considered for clinical trials designed to optimize conditioning regimens (e.g., clofarabine-based regimen, see below) and/or to use preemptive strategies (e.g., chemotherapy [azacitidine], DLI, early withdrawal of immunosuppression if no GVHD, etc.) in the post-transplant setting, aimed at decreasing relapses.

Acute Myeloid Leukemia Complete Remission 2 and Beyond

Although the results of HCT in CR1 indicate an overall improved outcome compared with chemotherapy, many patients do not undergo transplantation while in CR1 based on either non-severe disease symptoms and/or on the patient desire, or mainly due to physician/patient preferences.

The currently available data suggest that patients with AML with untreated first relapse can expect an outcome following MST HCT similar to that of those patients proceeding to transplantation during CR2.¹⁰ Studies evaluating patients who receive an HCT in second or subsequent relapse, or third or later remissions following standard therapy, have demonstrated very few long-term survivors.

Relapse Prevention and Management of Relapses after Hematopoietic Stem Cell Transplantation

Monitoring of Relapse

Although HCT can be curative, even in advanced disease, treatment failure is commonly manifested by relapse of disease, for which treatment is successful in only a minority of patients.²³ Detection of minimal residual disease in post-transplant surveillance is felt to be a necessary component of any strategy.^{39, 40} Past strategies for relapse prevention have focused on the use of DLI with variable success. Peritransplantation intervention and maintenance therapies (e.g., azacitidine) are under current investigation.^{41, 42}

Traditionally, the detection of impending relapse in the post-transplant period had been based on donor chimerism analysis (e.g., poor donor chimerism has been associated with increased risk of relapse), but the lack of specificity remains a problem. In AML, the development of post-transplant minimal residual disease strategies is more complex because of the genetic heterogeneity of these disorders. Nevertheless, for some genetic subtypes, for example, reciprocal translocations or NPM1-mutated AML, minimal residual disease monitoring in the post-transplant period has already been realized.^{39, 43, 44, 45}

Walter et al.²⁴ investigated 99 AML patients receiving MST HCT CR1 by 10-color flow cytometry before transplantation. minimal residual disease-positive patients had lower 2-year estimates of survival (30.2% versus 76.6%) and higher 2-year estimates of relapse (64.9% versus 17.6%), compared with minimal residual disease-negative patients. After adjustment for other prognostically relevant parameters, a positive minimal residual disease status pre-HCT was significantly associated with increased overall mortality and relapse relative to minimal residual disease-negative HCT. Kebriaei et al.⁴⁶ found a trend toward improved outcomes in 68 patients in cytogenetic remission compared with those with residual cytogenetic abnormalities at the time of HCT.

In the conservative treatment setting of AML, many minimal residual disease studies confirmed the potential of real-time PCR to predict the relapse risk in patients with reciprocal rearrangements. Some studies investigated the potential of molecular minimal residual disease monitoring for patients with reciprocal rearrangements also in the post-transplant period.^{39, 43, 47}

Novel Conditioning Regimen

Incorporating novel agents in the conditioning regimen with potent antileukemic activity is a strategy that is currently under investigation.⁴⁸ Clofarabine is a novel nucleoside analog that has potent antileukemic activity. It has shown efficacy in refractory disease as well as upfront scenarios. Geyer et al.⁴⁹ combined total-body irradiation (TBI) with clofarabine and cytarabine for HCT in pediatric patients with refractory or multiply relapsed leukemia in a phase I/II study. The early results show the probability of a 1-year progression-free survival of 57.4%. Andersson et al.⁵⁰ reported on a clofarabine/fludarabine/busulfan-based RIC regimen for advanced MDS and AML in 42 patients, which included children. In this high-risk patient population, 20 patients are alive at median survival of 23 months, which is an encouraging early result and warrants further studies.

Targeted immunotherapy post-SCT: One of the strategies for the prevention of relapse of AML/MDS post-SCT is to use targeted immunotherapy as part of the conditioning regimen such as the employment of vaccines, and DLI. Additionally, natural killer cells

P.2192

could be transferred for the treatment of leukemia relapse both during and after SCT.^{23, 51, 52}

Post-transplant Therapy

The posttransplant therapeutic approach has been limited to TKI in patients with BCR-ABL1-positive leukemia. However, other strategies, including the use of interleukins, monoclonal antibodies, immunomodulatory agents (bortezomib), DNA methyltransferase inhibitors, and histone deacetylase inhibitors, are currently being explored in AML.³⁹ The goal of these approaches is to treat minimal residual disease while minimizing adverse side effects and avoiding the impediment of donor cell engraftment. The use of hypomethylating agents (e.g., azacitidine) in patients with AML/MDS has drawn increased interest because of their demonstrated efficacy and relatively acceptable toxicity profile.^{41, 42, 53}

As our ability to monitor minimal residual disease post-HCT improves, along with identification of actionable molecular mutations, it will allow for the development of clinical trials aimed at prevention of relapse in a targeted fashion. Therapeutic interventions will be needed not only to prevent relapse but allow for simultaneous favorable modulation of the GVHD-graft versus tumor (GVT) balance.

Relapse after HCT for AML carries a very poor prognosis. Second HCT, although curative, is not an appropriate treatment option for a large number of relapsing patients (only 2% to 20% patients receive a second HCT), and efforts to increase the number of patients who may benefit from a second HCT are ongoing.²³

Incorporating Novel Agents

The development of novel agents is expected to gather momentum as new actionable mutations are identified. A mutation in FLT3 is well known to be a poor prognostic marker in newly diagnosed and relapsed AML. Specific inhibitors of FLT3 such as sorafenib, lestaurtinib (CEP-701), and quizartinib (AC220) have been studied in relapsed or refractory AML.^{10, 39, 54} FLT3 inhibitors need to be investigated post-SCT in patients with FLT3 + AML to prevent relapse, a most common cause of transplant failure.⁵⁵

Hypomethylating agents are active in high-risk MDS, and to a lesser degree in highly proliferative AML. 5-Azacitidine was shown in one study to prolong survival in elderly AML patients with low proliferative disease (expected disease course after HCT), and hence has drawn attention as an agent that may control low proliferative relapses after HCT.⁵³

Summary

The initial approach for patients should be determined by cytogenetic risk factors, molecular markers, availability of a donor/ stem cell source, and response to induction chemotherapy. Patients with cytogenetic features associated with a good prognosis who achieve a CR with induction followed by consolidation chemotherapy should be observed without immediate transplantation, although HLA typing of these patients and their siblings is warranted at diagnosis. Patients with intermediate or poor markers who achieve a CR with induction/consolidation chemotherapy should undergo an HCT procedure early during CR1 if a histocompatible donor is available or any other stem cell source is available with low risk for transplant procedure. For those patients who do not enter a CR or who relapse after standard therapy, an HCT should be performed sooner rather than later. The transplant approach should be individualized for all patients based on remission status, performance status, and coexisting medical problems, i.e., MST vs. RIC regimens.

The treatment outcome of patients who have suffered a relapse of AML following HCT remains poor. Additional chemotherapy and second transplants are associated with exceptionally high morbidity and mortality and have generally resulted in short remissions. Chemotherapy followed by second non-myeloablative stem cell transplant (NST) HCT or DLI is a reasonable option for patients with late relapse after HCT. Relapse remains a major cause of transplant failure. We believe that the outcome of AML will be further improved by an innovative approach to reducing relapse risk, and that enrollment in clinical trials is the way to go and should be encouraged for all HCT recipients.

Myelodysplastic Syndrome

MDS is primarily a disease of older patients, with a median age at diagnosis in the eighth decade of life. Despite new therapeutic interventions, HCT remains the only curative option for this disease, with long-term survival probabilities ranging from 25% to 70%.^{56, 57, 58, 59} There is a significant selection bias for HCT as illustrated by the age difference between the average MDS patients and those who ultimately receive a transplant.

Rationale of Hematopoietic Stem Cell Transplantation in Myelodysplastic Syndrome

MDS originates in hematopoietic stem or precursor cells, and a logical approach is, therefore, to replace the clonal MDS cells by healthy donor cells via HCT procedure. Successful HCT requires that the infused cells from the healthy donor establish themselves (engraft), and that the malignant cells of the patient's disease are eliminated by graft-versus-tumor (GVT) effects.

Over the past decade the approach to treating MDS has undergone major changes, at least in part related to the Food and Drug Administration (FDA) approval of several drugs for MDS and the development of new concepts for HCT. The drug therapy has improved the prognosis of patients with MDS, with 35% to 65% of patients achieving clinically relevant hematologic responses which may last from a few months (for high-risk MDS) to several years (predominantly for low-risk diseases). Concurrently, the emphasis with HCT has shifted from high-dose therapy, aimed at maximum tumor cell kill, to low- or reduced-intensity conditioning, relying heavily on donor cell-mediated immune effects to eradicate the disease (GVT effect). This GVT effect eliminates residual cells of the patient's disease via recognition of minor histocompatibility antigens.

Patient Selection for Hematopoietic Stem Cell Transplantation

Since age is a major factor determining the decision about HCT, many patients younger than 60 years of age are likely to be considered for transplantation sooner and more often than older patients.⁶⁰ Kuendgen et al. recently presented

registry data that included 232 patients less than 50 years of age and 2,496 patients more than 50 years of age, where approximately 42% of the younger patients underwent transplantation compared to only 8% of the older patients.⁶¹

The International Prognostic Scoring System (IPSS) and World Health Organization prognostic score (WPSS) (discussed in the MDS chapter) are generally thought to identify patients in whom HCT should be considered sooner rather than later.⁶² In a retrospective registry-based analysis, Cutler and collaborators showed that upfront transplantation was associated with a greater number of added life years for intermediate-2 and high-risk IPSS patients.⁶³ Delaying HCT offered the longest life expectancy in patients in IPSS categories low and intermediate-1. In the MDACC experience in 89 MDS patients who underwent HCT from 2002 to 2008, the 3-year OS rates were 79%, 49%, and 27%, respectively, for patients with WPSS low-intermediate-, high-, and very-high-risk categories, respectively.⁵⁶

P.2193

The European Group for Blood and Marrow Transplantation (EBMT) analyzed the post-transplant outcome of 692 patients with MDS according to their cytogenetic status. The overall survival and relapse rates were 47% and 34% for good-risk, 40% and 35% for intermediate-risk, and 31% and 57% for high-risk cytogenetics.⁶⁴ A recent analysis showed that patients with secondary MDS had a post-transplant prognosis comparable to patients with de novo MDS once the data were adjusted for cytogenetic risk. In a small series of 47 patients with high-risk MDS, the 3-year OS was better in patients who received HCT than in those who did not (71% v 31%).⁶⁵

Novel genetic factors are being studied to determine possible predictors of transplant outcomes.⁵⁶ A significant correlation between HLA-DR15 and tumor necrosis factor (TNF) polymorphisms at position 308 among patients with MDS has been observed. The TNF-308 AG genotype conferred an increased risk of TRM compared to the GG genotype. Conversely, the TNF-863 AA genotype was correlated with decreased overall mortality and TRM compared with the CC genotype.⁶⁶

Timing of Hematopoietic Stem Cell Transplantation

Determining the optimal timing of HCT for MDS has proven difficult, although all available data indicate that patients transplanted at an early stage of their disease have superior outcomes. Al-Ali et al.⁶⁷ observed that HCT outcome was best if SCT was performed between 6 and 12 months after diagnosis, the negative effect of later HCT being possibly related to frequent blood transfusion, longer duration of pancytopenia, and disease progression while waiting for HCT. If SCT is delayed, for example because of a lengthy search for an unrelated donor, bridging treatment with hypomethylating agents may delay progression to AML.⁶⁸

It is expected that incorporation of newer prognostic tools such as flow cytometry or molecular markers will improve our ability to select patients for transplantation at an earlier time period.^{69, 70} Newer risk models and individual risk factors (such as co-morbidities) will hopefully identify covariates that are likely to affect outcomes across non-transplant and HCT therapies.^{59, 71, 72, 73, 74}

Pre-transplant Disease Status

In an attempt to improve chances for post-SCT success, patients with a high marrow myeloblast count, (e.g., >5-10%), typically will receive pre-SCT therapy with a hypomethylating agent or with more classical induction-type chemotherapy.^{56, 58, 68} The clinical impression is that pre-SCT therapy may select chemosensitive patients since it appears that patients who do respond to such therapy have a superior outcome, and patients who fail to respond have a poorer outcome than do untreated patients.⁷⁵

The CR status at the time of transplant may impact relapse and TRM rates favorably; however, CR in chemotherapy-treated patients with MDS is infrequent. Warlick et al.⁷⁶ studied 84 patients undergoing HCT, and observed a 1-year cumulative incidence of relapse of 18% in patients in CR compared to 35% for those transplanted with active disease. In a retrospective analysis of 49 MDS/AML patients treated with T cell-depleted grafts, the 2-year cumulative incidences of TRM were 23%, 38%, and 40%, respectively, dependent upon response status prior to HCT (responsive disease, untreated, and refractory).⁷⁷ Oran et al. also documented the benefit of minimal tumor burden at HCT in patients with high-risk MDS/AML undergoing RIC HCT. CR at SCT was associated with day-100 and 2-year TRM rates of 0% and 20%, respectively. Estimates of 2-year OS were 66% for those in CR, 40% for patients with active disease without circulating blasts, and 23% for patients with circulating blasts.⁷⁸

Nakai et al.⁷⁹ compared the outcomes of 283 adult patients with MDS (n = 215) or secondary AML (n = 68) who received (n = 188) or did not receive (n = 95) induction chemotherapy prior to HLA-identical sibling donor HCT, and showed no difference in survival rates between the two groups, with 5-year OS rates of 54% and 57%, respectively. Similarly, Scott and collaborators in Seattle failed to demonstrate a clear survival advantage for a cohort of patients studied retrospectively that received induction chemotherapy pre-transplant, although the risk of relapse was somewhat reduced.⁸⁰

In the absence of controlled data, the decision to use pre-SCT induction therapy should be made on an individual basis. The treatment strategy should also take into account the fact that promising novel drugs are becoming available, although it is unclear if this approach will change long-term outcomes.

CURRENT OUTCOME DATA

An analysis by Warlick et al.⁷⁶ showed a 1-year OS of 48%, a cumulative relapse incidence of 23%, and a DFS of 38%. The EBMT registry analyzed results in a cohort of 374 patients with <5% myeloblasts who received HCT from HLA-matched donors after various conditioning regimens.⁸¹ At 4 years, DFS was 48%, the relapse incidence 15%, and deaths not related to relapse 37%. The risk of relapse was increased after RIC compared to MST conditioning (HR 2.8), but overall survival did not differ significantly. Patients transplanted from URD had a lower relapse risk (HR 0.6), but a higher risk of non-relapse mortality (NRM) (HR 1.4), and OS did not differ significantly between related and unrelated HCT. T cell depletion of the transplanted cells resulted in higher NRM. Younger patients and patients transplanted within 12 months of diagnosis had superior outcomes.

The Fred Hutchinson Cancer Research Center (FHCRC) published results in 257 patients transplanted for secondary MDS. At 5 years, 19% of patients with tAML were surviving in remission, compared with 25% of patients with refractory anemia with excess blasts (RAEB), and 41% of patients with refractory anemia/refractory anemia with ringed sideroblasts (RA/RARS). Two-thirds of patients developed acute GVHD grades II–IV and 57% developed chronic GVHD. After adjusting for karyotype, there were no significant differences in outcome between the cohort with secondary MDS and the cohort of 339 patients with de novo MDS. The probability of relapse and DFS correlated significantly with disease stage ($P < 0.001$) and cytogenetics ($P < 0.001$). As in many other studies, patients transplanted from unrelated donors (n = 122) had a lower risk of relapse ($P = 0.003$) and superior DFS ($P = 0.02$) compared to patients transplanted from related donors.⁵⁸ These results were confirmed in principle in a more recent analysis of CIBMTR data.⁸² These studies emphasize the importance of cytogenetics on HCT outcome.

Martino et al.⁸³ analyzed HCT results in an EBMT cohort of 215 patients with MDS conditioned with RIC and 621 patients who received MST conditioning and were transplanted from HLA-matched related donors. For the MST and RIC cohorts, NRM at 3 years was 32 versus 22%, OS was 45% versus 41%, and DFS 41% versus 33%. Lack of remission before HCT ($P = 0.001$), poor-risk cytogenetics ($P = 0.03$), transformation to AML, and older age were risk factors for inferior DFS.

A British trial⁸⁴ evaluated the results in 75 patients conditioned with an alemtuzumab-based RIC regimen and transplanted from unrelated donors. After 3 years transplant-related mortality (TRM), DFS, and OS for patients with refractory cytopenia with multilineage dysplasia (RCMD) were 24%, 55%, and 59%, respectively; the corresponding numbers for patients with RAEB (1 and 2) were 44%, 18%, and 18%, respectively. HLA-mismatch negatively affected all endpoints, as did disease status at HCT and patient co-morbidities.

Strategies to Improve Transplant Outcome after Hematopoietic Stem Cell Transplantation

Pre-transplant Use of Hypomethylating Agents

Field et al.⁸⁵ presented data in 54 consecutive patients with MDS or chronic myelomonocytic leukemia (CMML) who underwent HCT from HLA-matched donors. Thirty patients had received azacitidine for one to seven (median 4) cycles, and 24 patients had not received azacitidine. At 1 year after HCT with conditioning involving high-dose busulfan and fludarabine, 47% of azacitidine-treated patients were alive, compared with 60% of patients not given azacitidine, but relapses were 20% and 32%, respectively. The authors concluded that outcome was consistent with a trend toward a lower incidence of relapse in azacitidine-treated patients.

In a study by De Padua Silva et al.⁸⁶ 17 patients with MDS underwent HCT after having received decitabine. At 1 year, 11 patients were alive, whereas six had died: four from disease progression, one from GVHD, and one with septicemia.

Lubbert et al.⁸⁷ presented data on 15 similarly treated patients who then underwent HCT following RIC regimen. At the time of reporting, 6 patients were alive in remission, whereas four had died from progressive disease and five from transplant-related complications while in remission.

FHCRC recently reviewed results in 68 patients who underwent HCT for MDS or AML transformed from MDS (tAML). Thirty-five patients had received cytarabine prior to SCT followed by either an MST (40%) or RIC (60%) regimen, and 33 patients had undergone induction-type chemotherapy followed by SCT with MST conditioning. The 1-year overall survival was 57% in the cytarabine group, and 36% in the group given induction chemotherapy. Although the risk of post-SCT relapse and NRM was lower in the cytarabine group, none of the differences were statistically significant.⁸⁸

Hypomethylating Agents Post-transplantation

Post-SCT relapse has remained a major cause of failure, particularly in high-risk MDS. Earlier studies had shown that intensification of the transplant conditioning regimen reduced the relapse frequency, though the associated increase in NRM may prohibit such use. It may be advantageous to allow for recovery from the conditioning-related effects, and then administer additional agents. As most of the post-transplant relapses occur within the first 1 to 2 years, addition of hypomethylating agents may have immunomodulatory effects that could potentially increase the GVT response.⁶⁸

In a phase I dose-finding study, de Lima et al.⁵³ at the MDACC started azacitidine at 6 to 7 weeks after HCT and determined that a dose of 32 mg/m² given for 5 consecutive days was well tolerated. Forty-five patients with high-risk MDS/AML were treated and 1-year RFS was 58%. In addition, the authors noted that the incidence of chronic GVHD was lower in 5-azacitidine-treated patients than in historical controls. This observation was confirmed in a study at Washington University, which emphasized, in addition, that the beneficial effect on GVHD did not compromise the GVT effect.⁸⁹

Similarly, Platzbecker et al.⁴¹ reported a prospective study of patients receiving HCT for MDS and AML. If the donor chimerism fell below 80%, patients were offered treatment with 5-azacitidine. This event occurred in 25 of 59 screened patients at a median of 169 days, and azacitidine was initiated at 75 mg/m²/day for 7 days. Sixteen patients responded with an increase in donor chimerism or stabilization at 80%. Eleven patients were given additional 1 to 11 (median 4) cycles of azacitidine. Hematologic relapse eventually occurred in 13 patients (65%), but was delayed to days 56 to 558 (median 231). Therefore, preemptive azacitidine treatment may be effective in delaying hematologic relapse.

Other Post-stem Cell Transplantation Interventions

DLI may improve transplant outcomes in high-risk MDS by decreasing relapse rates. Kolb et al.⁹⁰ investigated escalating doses of DLI to treat a subset of patients with high-risk MDS (n = 67) or patients with secondary AML (n = 90) after RIC HCT. Relapse appeared less likely in patients given DLI. Another approach under investigation by several groups is the use of vaccines against leukemia-specific antigens such as Wilms tumor gene 1 (WT1) and proteinase-3-derived PR1 peptide (or the use of antigen-specific cytotoxic T-lymphocytes). Peptide-based vaccination has been shown to elicit immunologic T cell and clinical responses in myeloid leukemia.^{51, 52}

Relapse after Hematopoietic Stem Cell Transplantation

Post-SCT relapse remains a challenging problem, particularly in patients prepared for HCT with RIC regimens.^{23, 57, 60} Multiparameter flow cytometry has been used effectively to show that aberrancy of marrow blasts pre-SCT can influence outcome after SCT.⁶⁹ However, the definition of minimal residual disease in patients with MDS has not been clarified.³⁹

The infusion of donor lymphocytes in patients with relapse has shown only limited efficacy, as has withdrawal of immunosuppressive therapy (IST).^{23, 58} Early administration of hypomethylating agents may be more effective.^{23, 41, 53, 89} The prophylactic use of drugs such as hypomethylating agents or small molecule inhibitors that are coming into use in patients with high-risk disease may be even more effective. Intensive chemotherapy has generally been disappointing, and second allo-SCT in adults has yielded low-success rates.^{23, 91}

Summary

HCT continues to be the only curative option for MDS. Since the majority of patients with this disease are often older and frail, treatment-related mortality and morbidity remain major obstacles to be overcome. The development of reduced toxicity regimens has allowed HCT to be offered to older patients and those with clinically relevant co-morbid conditions.

Post-transplant relapse and GVHD remain problems requiring further research in this area. Ongoing studies are exploring the incorporation of novel agents (used in non-transplant therapy) during the peri-transplant period.

Acute Lymphoblastic Leukemia

HCT is a potentially curative therapeutic modality for acute lymphocytic leukemia (ALL). Unlike the dramatic advances made in the treatment of childhood ALL with 5-year survival at more than 80%, therapeutic progress for adult ALL has been relatively slow, with long-term survival being achieved in only about 30% to 40% of patients.^{92, 93}

As modern induction regimens can obtain CR rates in up to 80% to 90% of patients, the major barrier to improved results in the treatment of ALL in adults remains the high relapse rates in patients with CR1. Among the various post-remission therapies, HCT remains the single most effective modality for consolidation and prevention of relapse.

Among 3,113 patients \geq 20 years of age receiving HLA-matched sibling HCT for ALL between 2000 to 2009, the 3-year survival probabilities were 51%, 34%, and 21% for patients with early, intermediate, and advanced disease, respectively. Corresponding probabilities among the 3,086 recipients of unrelated donor HCT

P.2195

were 45%, 33%, and 16% (Center for International Blood and Marrow Transplant Research, CIBMTR, 2011).²

Major predictors of HCT outcome in ALL are remission state at time of transplantation and age.⁹⁴ Defining prognostic markers to help determine the optimal use and timing of HCT in the treatment algorithm of patients with ALL is critical. This part of the chapter describes the recent studies and current practice patterns concerning the who, when, and how of HCT in the management of adult ALL.

Indications of Hematopoietic Stem Cell Transplantation

Generally accepted prognostic indicators including age, WBC count, immunophenotype, certain high-risk cytogenetics, and treatment response during induction therapy remain classic prognostic features. OS ranges from 34% to 57% for patients less than 30 years compared with only 15% to 17% for patients greater than 50 years. Generally, a WBC count greater than 30,000/ul or 50,000/ul for B-lineage ALL and greater than 100,000/ul for T-lineage ALL predict for poor prognosis. T-lineage ALL also appears to have better outcomes than B-lineage ALL, while among T-lineage ALL, patients with cortical T ALL appeared to have the best outcomes.⁹³

The achievement of CR and time to CR after induction therapy also carries significant prognostic implications, with patients who require more than 4 weeks achieving a CR having a lower likelihood of being cured. Specific cytogenetic abnormalities also have a major impact on prognosis. The presence of the Philadelphia (Ph) chromosome and t(4;11)(q21;q23) have been associated with inferior survival in multiple large series. Additionally, the presence of the t(8;14)(q24.1;q32) complex karyotype defined as \geq 5 chromosomal abnormalities, or low hypodiploidy/near triploidy, were noted to have poor survival in the analysis of patients treated in the UKALL XII/ECOG 2993 trial.^{95, 96}

Despite documented improvements in the long-term survival of adult patients with certain phenotypes of ALL, the results have not been as good as those achieved in children. Several large studies have shown that CR can now be achieved in 80% to 90% of newly diagnosed adult patients under the age of 60 years. With modern intensive chemotherapy, approximately 30% of adult patients can achieve a cure of the disease. For patients with poor-risk features (discussed above), HCT is the therapy most likely to lead to long-term DFS. For those patients who relapse, HCT offers the only chance for long-term disease control.

For patients with high-risk features, there is general agreement that allo-HCT in CR1 is a potentially curative option; however, there is no consensus on early transplant for standard-risk patients.^{92, 97} Minimal residual disease evaluation and monitoring is developing as an important prognostic factor and could guide physicians in determining which patients, especially those with standard risk, might require transplant.⁹⁸ On the basis of the Medical research Council and Eastern Cooperative Oncology Group (MRC/ECOG) data, it is worth considering HCT for standard-risk patients in CR1, as the relapse rate is high and the prospects of achieving CR2 are uncertain.^{99, 100}

Philadelphia Chromosome-Positive (Ph+) Acute Lymphoblastic Leukemia

Historically, patients with Ph+ ALL have had a poor prognosis with long-term DFS rates of 10% to 20%.¹⁰¹ In the pre-imatinib era, HCT from a related or unrelated donor was widely used for consolidation, with 30% to 65% long-term survival for patients receiving HCT in CR1. Beyond first remission, HCT was curative in only a small fraction of patients with DFS ranging from 5% to 17%.^{92, 93, 100}

In the post-TKI era, the incorporation of imatinib into standard ALL therapy has resulted in significantly improved remission induction rates, as well as improved depth of remissions, enabling more HCT performed in CR1. Indeed, in a report from the MRC/ECOG group, the rate of HCT was found to be improved with the addition of imatinib (28% in the pre-imatinib era, compared with 44% for patients receiving any imatinib on protocol).¹⁰² With the use of an imatinib

induction combined with a MST HCT, 3-year OS rates of between 50% and 65% have been reported.¹⁰³ In recent years, there has been increasing use of second-generation tyrosine kinase inhibitors together with chemotherapy in the frontline therapy for patients with Ph+ ALL. Results have been encouraging with high CR rates (more HCT eligible patients) and encouraging DFS, albeit with relatively short follow-up. The data on HCT in patients treated with second-line agents, however, remains very limited.¹⁰³

Reduced-intensity vs. Myeloablative Regimen in Tyrosine-Kinase Inhibitor era

The key challenges in the treatment of Ph+ ALL are the selection of appropriate pre-transplantation therapy, the minimization of transplantation toxicity, the use of TKIs after transplantation, and the appropriate use of and response to BCR-ABL monitoring.

Where imatinib-based induction was combined with MST HCT, the 3-year OS rate in the UKALL12/E2993 protocol was 59%.⁹⁹ Successive German Multi-Centre ALL (GMALL) studies in Ph+ ALL also revealed that excellent outcomes can be achieved with MST HCT when an imatinib-based induction is used; OS at 3 years was 72%.¹⁰⁴ A recent Japanese Adult Leukemia Study Group also reports a 3-year OS probability of 65% after imatinib-based induction and MST HCT.¹⁰⁵

In recent data from the Seattle group, the subgroup of Ph+ patients receiving an HCT following a Fludarabine (Flu)/TBI non-myeloablative allogeneic stem cell transplantation (NST) regimen had an impressive 3-year OS of 62%, up to 73% in the group without minimal residual disease at transplant, and a relapse rate of 32% when done in CR1, thus demonstrating that GVT contributes to the excellent outcomes in this patient population.¹⁰⁶ Importantly, it may be feasible to achieve CR following a milder induction regimen consisting of TKI combined with steroid therapy only, followed by RIC or NST HCT consolidation in the older patient population who are ineligible for intensive induction.

In summary, HCT approaches appear promising, offering DFS rates in Ph+ ALL that appear higher than could be obtained with chemotherapy and imatinib alone. A comparative study of EBMT registry reports of the outcome of MST versus RIC HCT in patients with ALL confirms this impression.¹⁰⁷ In a multivariate analysis, the type of conditioning regimen was not significantly associated with outcome.

Patients with Poor Donor Options

TKIs such as imatinib, dasatinib, and nilotinib are now standard therapy for Ph+ patients and the resultant increase in initial remission rates has allowed greater eligibility for HCT.

It is hard to be exactly sure if the risk of TRM balances against the increased risk of relapse. Haploidentical HCT often results in a very high TRM. However, recently the group at Johns Hopkins developed a novel approach of haploidentical transplantation using unmodified haploidentical marrow followed by the use of post-transplantation cyclophosphamide to eliminate alloreactive T-cells, with encouraging preliminary results in patients with hematologic malignancies.¹⁰⁸ CBT in adults has a higher TRM than matched-unrelated donor (MUD) HCT. However, where the donor is not fully matched, CB is arguably a better option. A recent report from Japan documented 8 adults with Ph+ ALL who, after a median of 26 months of follow-up, had an estimated 3-year OS

P.2196

of 100% and a leukemia-free survival of 85%.¹⁰⁹ In a recent report from the University College London group of 50 patients receiving mismatched-URD grafts after RIC for a variety of disorders, including acute leukemias, there was no difference in 3-year OS (53% vs 49%, $P = 0.44$) between fully matched and mismatched-URD, even though the mismatch occurred at the antigenic level in 40 cases.¹¹⁰

The advent of these new alternative sources of stem cell transplants have allowed increased accessibility of HCT to patients without matched adult donors. The results from the limited studies discussed above have demonstrated the feasibility of such transplants. However, more studies will be necessary in order to determine the optimal timing and use of these novel approaches, and until then these should be performed in experienced centers and ideally in the context of a well-designed clinical trial, if available.

Post-transplant Tyrosine-Kinase Inhibitor

A very important and as yet unanswered question concerns whether TKIs should be administered after HCT and under what circumstances.

A Programa para el Estudio de la Terapéutica en Hemopatía Maligna (PETHEMA) study reported that imatinib was poorly tolerated after MST HCT; only 62% of patients were able to start at a median of 3.9 months after HCT, and many patients required discontinuation or a significant dose reduction.¹¹¹ In an ongoing GMALL study for which preliminary results have

been reported, patients were randomized after HCT to either upfront imatinib beginning at 3 months after HCT wherever possible, or imatinib started only upon any BCR-ABL reappearance.¹⁰³ This study also reported poor tolerance of imatinib when given early after HCT. In contrast, most patients who started imatinib after the detection of BCR-ABL had a prompt suppression of BCR-ABL in response to the drug, and no difference in outcome between the groups. A small, nonrandomized, single-center study from the University of Minnesota showed a trend toward improved outcome in patients who could be treated with imatinib in the pre- and post-transplantation period after TBI-based MST regimen.¹¹² Similarly, Ram et al.¹⁰⁶ reported that imatinib given for a median duration of 11.5 months after RIC with fludarabine and 2 Gy of TBI (which was relatively well tolerated after transplantation, with only 3 of 18 patients needing to stop the drug) was associated with significantly reduced mortality on univariate analysis, although the effect on relapse was not statistically significant.

There is insufficient evidence to conclude that TKI should be given to all patients after HCT. However, outside of a clinical trial, careful consideration should be given on a patient-by-patient basis as to whether and when to start TKI.

Philadelphia-Negative (Ph-) Acute Lymphoblastic Leukemia

Stem Cell Transplantation in First Complete Remission for HR Patients

HCT in CR1 from related or unrelated donors is generally accepted as the most effective available therapy for patients with Ph- ALL.^{92, 93, 94}

For standard-risk patients, earlier studies did not show a benefit for HCT. In the LALA87 trial, for example, standard-risk patients had no significant benefit from being assigned to the HCT arm, with a 10-year OS of 49% as compared to 43% in the chemotherapy arm.¹¹³ Two recent studies have, however, suggested that HCT may benefit standard-risk patients. Standard-risk patients in the MRC/ECOG trial with a donor had a statistically significant benefit in OS to having a sibling donor and receiving an HCT, with a 5-year overall OS in the donor group of 62% compared to 52% for patients with no donors ($P = 0.02$).⁹⁹ A recent study from the HOVON Cooperative Group allocated standard- and high-risk patients with a matched sibling donor to HCT and those without to auto-SCT. Interestingly, in this study, the differences in OS were again more pronounced in the standard-risk group (5-year OS 69% vs. 49%) than in the high-risk group.¹¹⁴

In the more recent meta-analyses by Ram et al.¹¹⁵ and Pidala et al.,¹¹⁶ the survival benefits for HCT were more pronounced in the standard-risk arms.

Relapse and Refractory Diseases

Transplantation in Complete Remission 2

Patients with ALL refractory to primary chemotherapy or who relapse have extremely poor prognoses; HCT is the only curative option if they can achieve remission pre-transplantation.

In patients with refractory disease or who relapse following initial chemotherapy, the CR rates to salvage therapy range from 40% to 45% and the OS is usually less than 10%.^{92, 93, 94} The 609 adults with relapsed ALL who were previously treated on the MRC UKALL12/ECOG2993 had a 5-year survival rate of 7%. Importantly, in the subgroup analysis based on treatment strategy, 5-year survival following HCT ranged from 15% to 23% depending on donor type (15% for autograft, 16% for URD, 23% for MRD), and was significantly better than chemotherapy (4%) ($P < 0.05$).⁹⁹

Oriol et al.¹¹⁷ reported on the outcome of 263 adults with relapsed ALL, all of whom were previously treated on four consecutive PETHEMA trials with similar induction therapies. Forty-five percent of patients achieved a second remission, with better outcome noted in the group who then proceeded to HCT. The best outcome was noted for patients younger than 30 years with a long first remission duration transplanted in CR2, with OS 38% at 5 years. In an analysis of 421 patients previously treated with the LALA-94 trial who had disease relapse, 44% of patients achieved a CR2, but the 5-year OS was again significantly better in the subset able to receive HCT (25% vs. 7% for the whole group).¹¹⁸

The results from these trials demonstrate that in patients in CR2, HCT offers a better chance for long-term survival as compared to chemotherapy alone.

Marks et al.¹¹⁹ recently demonstrated that the relative risk of relapse is significantly higher for patients with Ph- ALL in CR2 compared to CR1, particularly for those patients whose duration of CR1 was less than 1 year. Outcomes for patients with active disease are dismal and this contributes to the argument that perhaps all patients should be transplanted in CR1, as CR2 is frequently not achievable.

Active Disease Pre-stem Cell Transplantation

Given the high risks associated with salvage chemotherapy, some argue that for patients with an available donor, low to moderate tumor burden, and disease features suggestive of a highly aggressive course, reinduction chemotherapy may be omitted in preference for immediate HCT. In one of the largest retrospective reviews specifically addressing this issue, Terwey et al.¹²⁰ were able to show a 5-year OS rate of 47% in 19 patients with relapsed or refractory disease who received an HCT without prior reinduction chemotherapy, a result that was superior to the group that had received prior reinduction chemotherapy (5-year OS = 18%). Further prospective data are necessary before any recommendations can be made, and currently, management decisions regarding reinduction chemotherapy versus upfront transplant in early relapse will have to be individualized depending on the patient, their disease behavior, and the availability of donors.

P.2197

Importance of Minimal Residual Disease

In addition to age and cytogenetics at diagnosis, the most important prognostic factor, and a direct reflection of sensitivity to chemotherapy, is the achievement of CR (minimal residual disease negativity).

The developments of molecular techniques both to diagnose and monitor small amounts of ALL cells have been utilized to determine the risk of relapse in patients undergoing either standard therapy or HCT.⁹⁸

The role of minimal residual disease quantitation to evaluate treatment response and predict relapse is evolving in adult populations with exploration of flow cytometry and RT-PCR techniques. Several studies have indicated that testing for minimal residual disease both pre- and post-transplant for patients with ALL may also be useful. In general, these studies show that relapse was higher in patients who showed a positive assay before SCT or within the first year after HCT, compared to those who showed no PCR positivity.⁹⁸

Presence of minimal residual disease is associated with adverse outcomes even in patients otherwise considered at standard risk, and these patients may benefit from early allo-HCT in CR1. Data support an minimal residual disease level of (0.01%) or greater as the current determinant of high risk for disease relapse.⁹⁸

Management of Relapse after Hematopoietic Stem Cell Transplantation

Once patients with ALL relapse after HCT, the prognosis is extremely poor. Similarly to the approach in patients with AML and CML, manipulation of the antitumor effect mediated by the donor graft is often employed as a treatment strategy.^{23, 121} Unfortunately, in patients with ALL, this therapy has not been as effective as it has been for patients with CML.¹²²

Overall, few patients who relapse after HCT are long-term survivors. In a series of 130 patients who relapsed after HCT for treatment of ALL, 94 patients underwent salvage therapy. Relapse more than a year after SCT and isolated extra-medullary relapses were associated with a higher probability of subsequent remission. However, of the 52 patients who achieved a remission, only three became long-term survivors.¹²³ DLIs and second HCT are also considered in patients who relapse late after SCT.^{19, 124, 125} In a series of 15 patients who relapsed after SCT, a second HCT was associated with TRM of 36% at day 100, and only 8% had long-term DFS.¹²⁵

DLIs rarely produce long-term DFS in ALL. In a report from Europe, 40 patients with ALL received DLI as treatment for relapse and of 29 evaluable patients, only one achieved CR. Therefore, DLI as a sole therapy appears to have low potential for contributing to a remission and long-term control of disease in patients with relapsed ALL, and, if considered, should be a component of a chemotherapy-based treatment program (e.g., chemo-DLI or chemo-second SCT options).¹²⁰ Studies focused on developing antigen-specific T cell immunotherapy for ALL may help augment the GVL activity of donor T cells.

Summary

HCT is an effective post-remission therapy in patients with ALL, and HCT adult CR1 from related or unrelated donors is generally accepted as the most effective available therapy for patients with ALL. Increased advances in RIC preparative regimens and alternative donors have increased the accessibility of HCT. A risk-adapted paradigm, using minimal residual disease analysis, may help in the selection of patients at highest risk for relapse, who may benefit most from HCT.

A recently published American Society for Blood and Marrow Transplantation (ASBMT) evidence-based review reports: (1) MST HCT is an appropriate treatment for adult (<35 years) ALL in CR1 for all disease risk groups; and (2) RIC may produce similar outcomes to MST. Treatment recommendations unchanged or strengthened by new evidence include: (1) HCT is recommended over chemotherapy for ALL in CR2 or greater; (2) HCT is superior to auto-SCT; and (3) there are similar survival outcomes after related and unrelated HCT. New treatment recommendations based on new evidence include: (1) in the absence of a suitable allogeneic donor, auto-SCT may be an appropriate therapy, but results in a high relapse rate;

(2) it is appropriate to consider CBT for patients with no HLA well-matched donor; and (3) imatinib therapy before and/or after SCT (for Ph+ ALL) yields significantly superior survival outcomes.¹²²

Lymphoid Malignancies

Over the past decade, the number of HCTs performed for lymphoma continues to rise and lymphoma is a common indication for consideration of HCT. HCT in lymphoma is often indicated in patients with recurrent disease relapse, failure after auto-SCT, or massive bone marrow involvement on presentation. Primary refractory disease or disease relapse following immune-chemotherapy are usually incurable with chemotherapy alone. Despite recent advancements in immune-chemotherapy, a significant proportion of patients succumb to disease relapse. The curative potential of graft-versus-lymphoma (GVL) effect has been demonstrated in several lymphoma histologies. The response to DLI further strengthens the argument that the GVL effect exists in both Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL). The timing of transplantation needs to be redefined in this modern era of maintenance and targeted therapies. There is a great interest in considering HCT earlier under certain circumstances. RIC or NST HCT is gaining popularity among lymphoma patients needing HCT and is being increasingly performed as it can be offered to older patients with less toxicity and yet with the benefits of the GVL effect. In this part of the chapter we will discuss the role of HCT in patients with various lymphomas.^{126, 126, 127, 128, 129}

Follicular Lymphoma

The optimal timing of HCT in FL is yet unclear.¹³⁰ A prospective study comparing auto-SCT and HCT was closed early due to poor accrual.¹³¹ Retrospective analyses of large registry data support the use of HCT which is associated with lower relapse rate and longer DFS.

The GELTAMO group has reported the outcome in 37 FL patients who underwent an MRD using melphalan and fludarabine conditioning. The majority of patients had chemosensitive disease and 40% were in CR at the time of HCT. After median follow-up of 52 months, the 4-year DFS for patients with PD, PR, or CR at transplantation were 29%, 48%, and 64%, respectively; whereas the 4-year cumulative incidences of NRM were 71%, 33%, and 26%, respectively.¹³² A B cell lymphoma-specific NST regimen—fludarabine, cyclophosphamide, and rituximab (FCR)—is reportedly safe and effective and this regimen resulted in a TRM of 10%, with 85% patients alive without disease at 8 years. In the updated 12-year follow-up analysis, the OS and progression-free survival (PFS) were 78% and 72%, respectively.^{133, 134}

Favorable outcomes were also reported by the Cancer and Leukemia Group B 109901 trial in 16 patients with relapsed chemosensitive FL using an NST regimen consisting of fludarabine and cyclophosphamide (FC). This study reported a 3-year EFS and OS of 75% and 81%, respectively. Compared with studies employing NST regimens (such as FC or FCR), there is no evidence that the more substantial RIC regimens (fludarabine and melphalan or busulfan) provide any advantage in disease control in patients with chemosensitive disease.¹³⁵

A tandem auto- followed by allo-HCT approach for aggressive disease in 27 patients demonstrated an OS and PFS of 96% at

P.2198

3 years. These results are encouraging, albeit in a highly selected group of patients, but this approach is worth considering in patients with advanced disease.¹³⁶ Non-ablative or RIC HCT is feasible and safe to perform after prior auto-HCT failure.¹³⁷

T cell depletion allografts among 82 patients were evaluated recently. The NRM was 15% with a very favorable 4-year PFS of 76%.¹³⁸ In the United Kingdom (UK), alemtuzumab was incorporated in the conditioning regimen with fludarabine and melphalan. The NRM with this regimen was only 11% with a 3-year OS of 73%.¹³⁹

The experience of HCT for patients with FL is summarized in Table 104.1.

There are no randomized controlled data available to support allografting in chemosensitive FL patients in first remission. Limited single institution data are available for HCT in a small subset of high-risk FL patients with primary refractory disease. Such high-risk FL patients with primary refractory disease could be considered for an HCT within the context of a clinical trial.

Auto-Stem Cell Transplantation vs. Reduced-intensity Conditioning Hematopoietic Stem Cell Transplantation for Relapsed Follicular Lymphoma

A commonly encountered question is whether to offer auto- or RIC HCT to patients with FL relapsing after multiple lines of prior therapies. An adequately powered prospective trial comparing these two options is lacking. Unfortunately, the very

important BMT-CTN trial comparing auto-SCT to RIC HCT in FL was closed early because of poor accrual. While acknowledging the scarcity of good quality clinical trial data, it appears that the TRM rate with FCR RIC allo-HCT is relatively low, with much lower risk of disease relapse and no risk of sMDS/ AML, when compared against auto-SCT. Considering these facts, it is appropriate to offer RIC allo-HCT for selected FL patients when curative intent is pursued. While the timing remains controversial, we consider this option mainly in patients who have progressed after 2-3 lines of prior therapies (including at least one with anthracyclines and/or fludarabine), provided that the disease remains chemosensitive and patients are not candidates for clinical trials. Auto-SCT could be considered for patients who are medically unfit for RIC HCT or those without an adult or alternative donor, with the understanding that a cure may not be achievable.^{133, 140}

Summary

It is important to obtain a good remission status prior to HCT. Intensified therapies to improve disease control prior to SCT are needed to make HCT an eligible option. Various strategies are being investigated to improve outcome in patients with refractory disease and to prevent relapses after SCT, including incorporating novel agents into the conditioning regimen to increase effectiveness without increasing toxicity, and enhancing GVL effects through tumor-specific immunization or post-transplantation immunomodulation (e.g., DLI with or without rituximab).^{141, 142}

TABLE 104.1 OVERALL SURVIVAL OF PATIENTS FOLLOWING HCT FOR FOLLICULAR LYMPHOMA

Author/Year	N	Conditioning Regimen	Type	PFS	OS	NRM
Hari (2008)	208	Variable	RIC n = 88	3 y 67%	3 y 71%	28%
			MST n = 120	3 y 55%	3 y 62%	25%

Thomson (2010)	82	Flu/Mel/Alemtuzumab	RIC	4 y 76%	4 y 76%	15%
Shea (2011)	16	FC	RIC	3 y 75%	3 y 81%	9%
Khoury (2012)	73	FCR	RIC	72%	78%	10%

Bu, busulfan; C(y), cyclophosphamide; Flu, fludarabine; Mel, melphalan; MST, myeloablative; RIC, reduced-intensity conditioning; PFS, progression-free survival; OS, overall survival; NRM, non-relapse mortality; FC, fludarabine, cyclophosphamide; FCR, fludarabine, cyclophosphamide, and rituximab.

Chronic Lymphocytic Leukemia

Poor-risk patients, defined as resistant to purine analog therapy, 17p deletion, TP53 mutations, responding to salvage therapy, are considered for early HCT.

HCT in CLL dates back to 1992; initial data reported the outcome on 26 patients who underwent MST HCT for refractory CLL. The high NRM (50%) with this regimen was disappointing. Long-term PFS can be achieved in 30% to 60% of transplanted patients by RIC HCT.¹⁴³ In the CLL3X trial of the German CLL Study Group (GCLLSG), 90 patients underwent HCT with an FC-based regimen. In this study, patients with purine analog resistance had similar PFS as patients without purine analog refractoriness. Patients with uncontrolled disease at the time of transplant affected outcome adversely. The negative impact of del 17p was overcome by HCT.^{139, 144} In an analysis of 46 patients receiving RIC HCT for advanced CLL as reported by Brown et al., the 2 year OS and PFS were 54% and 34%, respectively. The number of prior regimens was inversely proportional to patient outcome.^{139, 145}

As with FL, the FCR RIC regimen was applied to patients with CLL. Following HCT, about half of the patients required immune manipulation including therapy with DLI, again suggesting a GVT effect.^{139, 146} The potential curative role of HCT in patients with 17p deletion was noted in 44 patients with this chromosomal abnormality. In this study, the 3-year PFS and OS were 37% and 44%, respectively. The vast majority (89%) of the patients in this study had received RIC.^{139, 147} In the study by the Seattle Consortium, a 5-year PFS of 39% was reported with very few late events despite a high proportion

(87%) of patients with fludarabine refractoriness.¹³⁹ The vast majority (89%) of the patients in this study had received RIC. In older registry data the NRM rates were up to 44% following MST HCT for CLL; whereas more recent data obtained with RIC uniformly show a NRM between 15% and 25% and the latest studies using FCR RIC HCT show around 10%.^{139, 148, 149}

The experience of all-SCT for patients with CLL is summarized in Table 104.2.

The EBMT consensus on indications for HCT in CLL includes eligible patients with previously treated, poor-risk CLL, that is, purine analog refractoriness, early relapse after purine analog combination therapy, and CLL with p53 lesion requiring P.2199

treatment. These consensus guidelines were based on evidence of grade II or less. As mentioned earlier, evidence is increasing that RIC HCT can mitigate the adverse prognostic impact of purine analog refractoriness and del 17p- as long as CLL has not become generally resistant to salvage treatment.¹⁵⁰

TABLE 104.2 OVERALL SURVIVAL OF PATIENTS UNDERGOING HCT FOR CHRONIC LYMPHOCYTIC LEUKEMIA

Author/Year	N	Conditioning Regimen	Type	PFS	OS	NRM
Brown (2006)	46	Flu/Bu	RIC	2 y 34%	2 y 54%	17%
Schetelig (2008)	44	Flu-Bu/Flu-Mel/Flu-Cy	RIC or MST	3 y 37%	3 y 44%	32%
Sorrer (200)8	82	Flu-TBI/TBI	RIC	5 y 39%	5 y 50%	36%
Dregger (2010)	90	FC	RIC	4 y 42%	4 y 62%	23%
Khoury (2011)	86	FCR	RIC	5 y 68%	5 y 51%	17%
Toze (2012)	49	Flu/Bu Cy/TBI Flu/Cy	RIC or MST	10 y 22%	5 y 55%	36%

Bu, Busulfan; Cy, Cyclophosphamide; Flu, fludarabine; Mel, Melphalan; MST, myeloablative; RIC, reduced-intensity conditioning; TBI, total-body irradiation; PFS, progression-free survival; OS, overall survival; NRM, non-relapse mortality; FC, fludarabine, cyclophosphamide; FCR, fludarabine, cyclophosphamide, and rituximab.

The addition of novel treatment modalities and emerging clinical data, though they may not result in cures, should be incorporated into HCT. To date, HCT is the only treatment with the potential of providing long-term disease control in this condition. In addition to the disease risk, patient-related risk factors, such as age and co-morbidity, have to be considered when the decision about HCT is made. Prospective data is available on RIC HCT patients rather than MST regimens, which are mainly derived from registry data. Given the safety, efficacy, and age at which this disease manifests, RIC is possibly superior despite the lack of randomized data.¹⁵¹

Transformed Lymphoma

There is a paucity of literature on the treatment of TL, and therefore deciding on the optimal evidence-based treatment is a challenge. The most specific publications report on auto-SCT showed encouraging results. However, these series are highly selected groups of patients, and unfortunately, the majority of patients with transformed lymphoma (TL) are likely to be too old, with poor performance status, or to have had an insufficient response to reinduction chemotherapy, making them ineligible for SCT. Non-HCT treatment options are limited by a high relapse rate and short DFS. HCT is safer than ever before and it is possible that novel immunomodulatory RIC might provide a high cure rate in this otherwise fatal lymphoid malignancy.

Consideration of Early Allogeneic Stem Cell Transplantation in Transformed Lymphoma

With increasing use of RIC regimens, many older patients are able to receive HCT as curative intent. The hypothesis that RIC transplants could be used to deliver an effective GVL effect is true. Indeed, the typical delayed regression of malignant disease, long after any effect from the preparative regimen has passed, is proof of principle that RIC HCT exerts strong and curative alloresponses against the recipient's malignancy.

Given the high relapse rate seen even after auto-SCT, and the potential benefit of a GVL after HCT, many more eligible patients with NHL including TL are receiving upfront HCT.^{152, 153} Historically, the limitation of HCT has been TRM. In order to offer the curative HCT treatment option to most patients, safer regimens with acceptable GVHD associated morbidity and TRM are preferred (discussed above in FL).

Novel Hematopoietic Stem Cell Transplantation Approaches for Transformed Lymphoma

For patients in whom a nonablative transplant is preferred, radioimmunotherapy can be employed to provide cytoreduction to safely induce disease control while minimizing nonhematologic toxicity. The HCT could maintain the remissions via the GVL effect, and reconstitute hematopoiesis. Using this approach, 16 patients with relapsed CD20+ lymphoma, of which 15 patients were chemotherapy resistant, underwent therapy with 0.4 mCi/kg Y-90 ibritumomab tiuxetan followed by fludarabine and 2 Gy TBI conditioning regimen and matched HCT. At day 28, seven of 16 patients demonstrated responses.¹⁵⁴ Khouri et al. reported a feasibility study using escalated doses of 90Y-ibritumomab tiuxetan prior to FCR HCT in 7 patients with relapsed B cell NHL. Though longer follow-up on outcome and toxicities are needed, it is clear that such approaches need to be urgently considered for TL to make many more TL patients eligible for a curative HCT option.

Summary

There is an almost universal consensus that chemosensitivity and disease control before HCT is important to prevent early relapse, which is a major cause of treatment failure in TL. Incorporating novel radio-immunotherapy as part of the RIC regimen might be a very attractive option to prevent early relapse before GVL takes over disease control.¹⁵⁵ Tandem auto followed by HCT needs to be explored in selected patients with early good results in a small series.

In this era, a stem cell source can be found for virtually all patients who have an indication to receive HCT. RIC haploidentical-related donor or CBT have emerged as alternatives to fill the gap for those patients who do not have MRD or URD, and the outcome of these types of transplantations are expected to be better than chemotherapy alone or even better than auto-SCT for selected high-risk, heavily pretreated TL. The individual transplant center experience choosing URD, CBT, and haploidentical transplantation should also be taken into consideration.

Diffuse Large B cell Lymphoma

Allo-SCT has been used as treatment of high-risk first relapse, refractory disease, and in patients who have relapsed after auto-HCT.¹⁵⁶ In high-risk large cell lymphoma patients (double-hit,

P.2200

triple-hit, failure after auto) HCT should be offered early with a potential survival benefit. For relapsed disease, Lazarus et al. retrospectively analyzed the outcomes of diffuse large B-cell lymphoma (DLBCL) patients undergoing first autologous (n = 837) or HLA-identical sibling allo-HCT using MST conditioning (n = 79) reported to the CIBMTR between 1995 and 2003. The allo-HCT group had more patients with an intermediate-high or high IPI score, extranodal involvement, B symptoms, more prior chemotherapy regimens, and more resistant disease. Allo-HCT was associated with a higher TRM and treatment failure. Auto-HCT was associated with superior OS. Despite having several adverse risk features, patients in the allo-HCT group had a similar risk of relapse. The high TRM rate of MST allo-HCT (45% at 5 years) greatly limited the potential benefit of this approach.¹⁵⁷

Given the high TRM associated with MST conditioning, the use of RIC regimens has increased for HCT in DLBCL. RIC regimens rely more on the GVT effect and less on the intensity of the chemotherapy to eradicate lymphoma. They are in general better tolerated and can be used for older patients or for patients with co-morbidities. The French Society of Bone Marrow Transplant reported the collective experience on 68 patients undergoing RIC HCT for DLBCL. Prior to transplant, 47% of the patients were in remission and 79% had received a prior auto-SCT. The donor was an HLA-identical sibling in 82% of the cases. With a median follow-up of 49 months, the estimated 2-year OS rate was 49%, the PFS rate was 44%, and cumulative incidence of relapse was 41%. The 1-year cumulative incidence of NRM was 23%.¹⁵⁸

Bacher et al. analyzed the outcomes (registry data) of 396 adults who received HCT for DLBCL following MST conditioning (n = 165), RIC (n = 143), or non-MST conditioning (n = 88) regimens between 2000 and 2009.¹⁵⁹ Significant baseline differences between the cohorts included the following: RIC and NST recipients were older (54% and 58% >50 years vs. 39% for MST conditioning), and they were more likely to have received prior auto-SCT (36% and 51% vs 18%), prior radiation, and more prior chemotherapy regimens (55% and 70% vs. 44% with >3 regimens) than those recipients with MST conditioning. The TRM rate at 5 years was significantly higher in MST conditioning recipients (56%) than in the RIC (47%) and NST conditioning (36%) recipients. Lymphoma relapse/progression at 5 years was significantly lower in the MST conditioning group (26%) than in the RIC (38%) and NST conditioning (40%) groups, but the respective 5-year PFS rates (18%, 15%, and 25%) and OS rates (18%, 20%, and 26%) did not differ significantly. Others have shown similar survival rates with TBI and fludarabine conditioning regimens.^{128, 160}

The experience of all-SCT for patients with DLBCL is summarized in Table 104.3. HCT can induce long-term PFS regardless of the intensity of conditioning, with a lower incidence of TRM with the RIC and NST conditioning regimens. The risk of relapse or progression is concordantly higher in the RIC and NST conditioning recipients so that survival does not differ significantly among conditioning regimens. However, the use of RIC or NST conditioning allowed older and sicker patients to proceed to transplant with a lower TRM. HCT has also been used as a salvage strategy with encouraging results for patients who failed a previous auto-HCT. In a retrospective analysis by the EBMT registry that included 101 patients, approximately two-thirds received a RIC regimen and 70% had an identical sibling donor. Outcomes at 3 years were encouraging, with a NRM of 28%, a relapse rate of 30%, a PFS rate of 41%, and an OS rate of 54%. With a NRM that can be considered acceptable in this heavily-pretreated population, HCT led to a long-term survival in this poor-risk group.¹⁶¹ Patients with a long remission after auto-SCT and with sensitive disease at allo-HCT appear to be the best candidates for this approach.

TABLE 104.3 OVERALL SURVIVAL OF PATIENTS FOLLOWING HCT FOR DIFFUSE LARGE B CELL LYMPHOMA

Author/Year	N	Conditioning Regimen	Type	PFS	OS	NRM
Rezvani (2008)	31	Flu/TBI Non-MST	3 y 35%	3 y 45%	25%	
Sirrent (2008)	68	Flu	RIC	2 y 44%	2 y 49%	23%
Thomson (2009)	48	Flu/Mel/ Alemtuzumab	RIC	4 y 48%	4 y 47%	32%
VanKemper (2011)	101	variable RIC	= 64			
			MST = 37	3 y 42%	3 y 54%	28%

Flu, fludarabine; Mel, melphalan; MST, myeloablative; TBI, total-body irradiation; PFS, progression-free survival; OS, overall survival; NRM, non-relapse mortality.

Summary

At this time it is not clear which conditioning intensity to use in HCT for DLBCL. MST conditioning carries a higher mortality with a lower risk of relapse and may still be the preferred option for younger patients without co-morbidities and for those considered to be at high risk for relapse (not in CR at transplant). RIC and NST conditioning regimens may be preferred for older patients or for those with multiple comorbid conditions and with a lower risk of relapse. HCT is effective salvage strategy in patients who have failed a previous auto-SCT for DLBCL.

Mantle Cell Lymphoma

Despite improvements in outcome with chemotherapy, mantle cell lymphoma (MCL) is not considered curable with this approach. Strategies including more intense multiagent chemotherapy as induction followed by consolidation with auto-HCT have demonstrated higher response rates (RR), improved PFS, and the possibility of improved OS. However, even with this aggressive approach, relapse frequently occurs, with the worst outcomes in those with the highest mantle cell international prognostic index (MIPI) scores. Once relapse occurs after auto-HCT, survival can be limited, especially for those transplanted beyond first complete or partial remission or with relapses within 1 year of transplant. HCT is felt to be the only therapeutic strategy with curative potential. Most MCL patients are older and are typically excluded from this approach. The advent of RIC regimens has allowed this treatment to be administered safely to older patients, allowing its use in a greater number of patients.

P.2201

Improved Outcome after HCT in Heavily Pretreated Patients

The emerging role of RIC regimens has created a paradigm shift by reducing TRM, and therefore offering more individuals the option of HCT in MCL. We reported a 5-year survival rate of 70% with an NRM of 12.5%, albeit in a highly selected group receiving HCT.¹⁶² In the era of improved supportive care and decreasing TRM, RIC HCT should be offered for otherwise fit patients who have relapsed following high-dose chemotherapy. The group at MDACC published the most encouraging long-term results of NST in 35 patients with relapsed MCL. Six-year OS was 53%; DFS was 46%. No patients had grade 3 to 4 acute GVHD. This study suggests RIC HCT could be offered up front to a selected group of patients.¹⁶³

Maris et al. published the results on 33 patients with relapsed MCL undergoing NST (related or unrelated donor) HCT. At 2 years, the OS was 65% and PFS was 60%.¹⁶⁴

The British Society for Blood and Marrow Transplantation (BSBMT) published the results of a retrospective analysis of 70 heavily-pretreated patients with relapsed/refractory MCL who received RIC allo-HCT with or without alemtuzumab.^{164, 165} In this heterogeneous group, the 1-year NRM was 18%, the cumulative risk of relapse at 5 years was 65%, the 5-year OS rate was 37%, and the 5-year PFS rate was 14%. Twenty-seven patients received DLI; all but 1 had received alemtuzumab as part of the conditioning regimen. The 3-year OS rate for patients who received DLI for relapse was 79%, indicating a powerful GVL effect.

Le Gouill et al. reported a multicenter retrospective analysis of 70 heavily-pretreated patients with MCL who received RIC allo-HCT in 12 centers in France and Germany.¹⁶⁶ A previous auto-HCT had failed in 47 patients. The 2-year EFS and OS rates were 50% and 53%, respectively, and the 2-year TRM was 32%. This study showed that RIC allo-HCT is effective not only in patients with chemosensitive disease regardless of the number of prior lines of therapy, but also as salvage therapy for those patients in whom auto-HCT had failed.

The experience of all-HCT for patients with MCL is summarized in Table 104.4. Based on the presented data, HCT appears to be effective for relapsed and refractory MCL and the only approach associated with long-term survival.¹⁶⁷ However, toxicity is a limiting factor, and some patients may be unable to tolerate this therapy. Early referral for HCT is certainly warranted, especially in patients with elevated Ki-67 levels who do poorly with conventional chemotherapy and auto-HCT.

Early discussion of transplantation is warranted since the safety and tolerability of RIC HCT has allowed older and heavily pre-treated patients to benefit from this promising therapy.

Management of Relapses after HCT

One interesting approach to this disease state is DLI (with or without prior chemotherapy). Some of the earliest reports of HCT for MCL included patients who relapsed and were shown to respond to DLI. Since that time, additional studies have paid specific attention to this phenomenon and reported responses to DLI in their relapsed patients, particularly the studies which included alemtuzumab as part of the pre-transplant conditioning. The report by Cook et al. included 36 relapses after RIC HCT, 32 of whom were further evaluable. The 3-year OS among patients who received DLI for treatment of relapse was 60% (with no deaths reported after approximately 15 months) compared to 0% for those who did not receive DLI for relapse.¹⁶⁵

TABLE 104.4 CONDITIONING REGIMEN AND SURVIVAL OF PATIENTS UNDERGOING HCT FOR MANTLE CELL LYMPHOMA

Author/Year	N	Conditioning Regimen	Type	PFS	OS	NRM
Moris (2004)	33	Flu/TBI	RIC	2 y 60%	2 y 65%	24%
Tam (2009)	35	FC/FCR	RIC	6 y 46%	6 y 53%	9%
Cook (2010)	70	Flu/Mel, Flu/Bu, BEAM ± anti-CD52	RIC	5 y 14%	5 y 37%	21%

A, Cytarabine; anti CD52, alemtuzumab; B, BCNU; Bu, Busulfan; C(y), Cyclophosphamide; E, Etoposide; Flu, fludarabine; Mel, Melphalan; RIC, reduced-intensity conditioning; TBI, Total-body Irradiation ; PFS, progression-free survival; OS, overall survival; NRM, non-relapse mortality; FC, fludarabine, cyclophosphamide; FCR, fludarabine, cyclophosphamide, and rituximab.

The data for post-HCT relapse show that the disease is potentially salvageable with a re-challenge with antilymphoma chemotherapy with or without immunomodulation (e.g., DLI). Since the data available for HCT are relatively limited, it should come as no surprise that the data for management of relapsed MCL after HCT are even less robust. Since it remains a relatively unknown issue, such patients are probably best treated in the context of a clinical trial.

Summary

Most studies highlight that HCT is often not used in first remission, instead implementing it for relapsed or refractory disease. Reserving HCT until later in the natural history of MCL means patients receiving this therapy often have a disease biology that is more refractory to conventional therapy. The majority of the published literature on HCT for MCL in the past 10 years has focused on RIC HCT. The success with RIC HCT seems to improve when this approach is used for patients with disease that is still chemosensitive. It should still be noted that data also do show that heavilypretreated patients or patients with active disease can still potentially benefit from RIC HCT. Another facet of these studies that raises some additional questions is the use of further adoptive immunotherapeutic strategies (administration of rituximab with the

conditioning regimen) to augment the response to RIC HCT, and these studies did have some of the highest rates of OS and PFS.¹⁶⁸

Peripheral and Cutaneous T-cell Lymphoma

HCT Concept and Indications in peripheral T-cell lymphoma (PTCL)

PTCL are a rare heterogeneous group of lymphomas with a worse prognosis compared with B cell lymphoma. Auto-SCT is offered for patients whether in CR1 or at the time of relapsed disease with chemosensitivity. Auto-SCT has been shown to achieve a promising early response, but median PFS ranged from less than 100 days to about a few months. HCT is an option for patients who relapse after auto-SCT but who are chemosensitive. HCT provides a GVT effect with potential survival benefit despite the high NRM associated with HCT. All published cases

P.2202

after HCT following MST or RIC regimens showed a decreased relapse rate and increased overall- and PFS when compared to published data of conventional therapies. Patients who relapsed after HCT have been shown to achieve remissions again after DLI (with or without prior chemotherapy), which strongly supports the existence of a GVL effect. RIC regimens may lead to decreased TRM rates and improved results. Therefore, RIC-based HCT seems to represent a promising treatment approach, especially when combined with post-transplant therapies with DLI. As GVHD frequently occurs in the skin, the major manifestation site of mycosis fungoides/cutaneous T-cell lymphoma (MF/CTCL), this phenomenon may also contribute to the efficacy of HCT in this disease entity.¹⁶⁹

Outcome Data after HCT

In a retrospective study of 77 patients, at a median follow-up of 43 months, the 5-year OS and PFS were 57% and 53%, respectively, and NRM was 34% at 5 years.¹⁷⁰ RIC regimen was used in 17 patients as reported by Corradini et al.; 8 patients had previous auto-SCT and 16 patients underwent related donor transplant. The estimated 3-year survival was 81% with a NRM of 6% at 2 years.¹⁷¹

Shustov et al.¹⁷² published data using the Seattle NST regimen with fludarabine and 2 Gy TBI on 17 patients. Of these, 6 patients relapsed after prior auto-SCT. At a median follow-up of 3.3 years, the 3-year OS and PFS were 59% and 53%, respectively, with 19% 3-year probability of NRM.

In a retrospective review on 34 patients receiving HCT for PTCL, the 2-year OS was 61%, 2 of the 3 patients receiving DLI demonstrated response supporting a GVL effect.¹⁷³ A recently published retrospective study from EBMT centers, which is the first large multicenter analysis of HCT in CTCL patients, showed a PFS of 42% at 1 year and 34% at 3 years. The current PFS at the last published follow-up was 52% in patients who received NST and 29% in patients who received MST HCT. Estimated OS rate was 66% at 1 year and 53% at 3 years.¹⁷⁴ These noncontrolled results are promising and challenge the outcomes known so far after conventional treatment options. Nevertheless, a controlled study to confirm the role of HCT in CTCL patients is needed.

The long-term outcome on 52 patients undergoing HCT was reported by Dodero et al. Patients received related or alternative donor transplants including haplo-transplants. At a median follow-up of 67 months, 52% were alive. The cumulative incidence of NRM at 5 years was 12%. Refractory disease and age over 45 years were negative prognostic features.¹⁷⁵ An HCT is particularly successful in patients with nodal disease and less so in those with extranodal disease. The experience of all-SCT for patients with PTCL is summarized in Table 104.5.

TABLE 104.5 SURVIVAL OF PATIENTS FOLLOWING HCT PERIPHERAL T-CELL LYMPHOMA

Author/Year	N	Conditioning Regimen	Type	PFS	OS	NRM

progression-free survival; OS, overall survival; NRM, non-relapse mortality.

Auto vs. Hematopoietic Stem Cell Transplantation

In a recent meta-analysis comparing auto- vs. HCT in patients with MF/SS, 20 patients received HCT and 19 underwent auto-HCT. OS rates at 1 and 5 years were 68% and 23% in the auto-HCT, and 85% and 80%, respectively, in the HCT group. The most common cause of death in the HCT group was GVHD.¹⁷⁶

Currently, ongoing Italian and German trials are comparing auto-HCT vs. HCT after first line induction therapy.

Summary

Despite the lack of randomized studies in recommending HCT for this disease, our experience has been that responses with conventional therapies are short-lived, and long-term remissions in carefully chosen patients can be achieved with HCT. HCT has been demonstrated to achieve long-term remissions in many cases; and conditioning regimens with reduced intensity and therefore with less toxicity might be superior to MST conditioning, and represent an option for the elderly, who represent the majority of patients.

Hodgkin Lymphoma

Auto-HCT is offered for patients who relapse after initial chemotherapy. This approach has a 40% to 50% 5-year survival rate.¹⁷⁷ For patients who relapse after auto-HCT, prompt consideration of RIC HCT is important. Referral to a transplant center for coordination of donor search and discussions of salvage regimens may improve outcomes.

The earlier CIBMTR results reported a 3-year OS of 21% in patients undergoing HCT for relapse after auto-HCT.¹⁷⁸

The EBMT group compared various conditioning regimens and reported on outcomes of patients undergoing MST or RIC HCT.¹⁷⁹ Of the 168 patients who underwent HCT, 89 patients received RIC allo-HCT. The NRM was significantly lower in the RIC group: at 1 year 23% vs. 46% in the MST arm. In this patient population, 61% had prior auto-HCT. Robinson et al. reported the results on 285 patients who underwent RIC HCT in HL. At 12 months, the NRM was 20% and 3-year OS was 56%.¹⁸⁰

In a retrospective study by Sarina et al., based on donor availability status, 185 patients were analyzed, among whom 66% had an available donor and 85% underwent HCT using a RIC approach.¹⁸¹ In patients who had an available donor, the 2-year OS was 66% compared with 42% without a donor.

In a study of 90 patients with relapsed HL, related, unrelated, or haploidentical donors were used with a non-MST conditioning regimen. The 2-year OS was 53% for matched donors and 58% for unrelated and haploidentical donors.¹⁸² Interestingly, in this study, the NRM was lower in the haplo-transplants as

P.2203

compared with HLA-matched recipients. Reducing the number of donor T-cells may decrease the risk and severity of GVHD. Alemtuzumab (anti-CD52) with fludarabine and melphalan was used as a conditioning regimen for relapsed HL. In a series of 67 patients as reported by Peggs et al.¹⁸³ were treated with or without alemtuzumab. The 3-year PFS was higher in patients with T cell depletion, at 43% compared with 25%. This was, however, counteracted by increased DLI use. The experience of all-HCT for patients with HL is summarized in Table 104.6.

Responses after the use of DLI in relapsed HL patients have been reported. This suggests the role of graft versus HL activity. In a similar patient population as reported earlier, in patients undergoing T-cell depletion more frequent use of DLI was noted. Of the 16 patients that underwent DLI, 56% of patients experienced a response that led to a 4-year survival of 56%.¹⁸⁴

Newer treatments are being considered in a maintenance setting following auto-HCT. Until we have further data from these clinical trials, HCT is considered for patients who relapse after auto-HCT. Current data does not favor a particular donor pool. Depending on various studies, in patients with chemosensitive disease RIC HCT results in OS of 40-66% with NRM rates between 20% and 30%. More importantly, outcomes with related vs. alternative donors do not appear to be different.^{126, 185}

Relapse after Reduced-intensity Conditioning Hematopoietic Stem Cell Transplantation

As shown above, there are proportions of patients with relapsed/refractory HL who achieve a lasting cure with RIC allo-HCT, although many patients unfortunately suffer relapses. To better counsel patients in this situation and to evaluate specific management strategies in this setting, Ram et al. described 101 patients with lymphoma who had relapses after

RIC and HCT.¹⁸⁶ This group included 26 patients with relapsed/refractory HL, 50% (13 patients with HL) of whom had prior auto-HCT. HL patients tended to relapse later than those with other lymphoma histologies (6.3 months vs. 3.4 months for indolent NHL and 1.3 months for aggressive NHL). Relapse occurred much sooner in the HL group with prior auto-HCT (median 4.6 months) compared with patients who did not have prior auto-HCT (median 12 months). The estimated 3-year OS after relapse in HL patients was 47%. Patients with HL, despite a longer time to initial relapse relative to indolent NHL, were shown to have the greatest risk of PD even after response to initial therapy for post RIC allo-HCT relapse.

Thus, further strategies to achieve lasting remission following RIC HCT are needed. One potential option that has been evaluated includes brentuximab vedotin, which was shown by Gopal et al., in a multicenter series of 25 patients with HL recurring following allo-HCT, to yield a 50% response rate in evaluable patients.¹⁸⁷ This if followed by DLI at response would be the best available strategy for responding patients. Nevertheless, despite interest in this area, improved strategies are still needed for management of post-HCT relapse.

TABLE 104.6 SURVIVAL OF PATIENTS FOLLOWING HCT FOR HODGKIN LYMPHOMA

Author/Year	N	Conditioning Regimen	Type	PFS	OS	NRM

BEAM BCNU, etoposide, cytarabine, melphalan; Cy, cyclophosphamide; HCT, hematopoietic stem cell transplantation; Mel, melphalan; MST, myeloablative; RIC, reduced-intensity conditioning; TBI, total-body irradiation; PFS, progression-free survival; OS, overall survival; NRM, nonrelapse mortality.

Myelofibrosis

Myelofibrosis is a heterogeneous disease for which long-term, effective medical therapeutic options are currently limited. There is only one curative treatment in myelofibrosis patients using HCT. As myelofibrosis is primarily a disease of the elderly, this has historically been a rare indication of HCT. However, with the advent of RIC regimens, the applicability of this approach has been broadened to include a larger proportion of myelofibrosis patients.^{188, 189, 190, 191, 192, 193, 194}

Janus kinase (JAK)2-inhibitor therapies have been developed for patients with myelofibrosis. Clinical trials have shown that these agents have considerable therapeutic potential in myelofibrosis patients, thus offering an additional treatment option as a potential alternative or integration of JAK inhibitors during the HCT process.

Allo-Outcome and Hematopoietic Stem Cell Transplantation Indications

In a recent study from the United Kingdom, 51 patients with primary myelofibrosis (24%, 33%, and 43% with Dupriez low-, intermediate-, and high-risk disease) received mostly related MST or RIC HCT. The 3-year OS was 44% for MST and 31% for RIC HCT; the corresponding relapse rates were 15% and 46%, nonrelapse mortality rates were 41% and 32%, and extensive chronic GVHD rates were 30% and 35%.¹⁹⁵

A higher 5-year DFS (51%) was reported from another RIC allo-HCT study in which relapse was predicted by high-risk disease and prior splenectomy.¹⁹⁶ A history of splenectomy did not affect outcomes in the recent study from the Center for International Blood and Marrow Transplant Research (CIBMTR).¹⁹⁷

More recent results from FHCRC in more than 100 patients with myelofibrosis, aged 18 to 70 years, show a 7-year actuarial survival of 61% for HLA-matched related and unrelated transplants. NRM at 5 years was 34%, but, as we all know, NRM does not equate with treatment-related mortality. Many patients who underwent HCT had life expectancies of <5 years, based on disease severity, and a 5-year mortality of that magnitude would have been expected even without HCT.¹⁹²

European Leukemia Net suggests that patients with transfusion dependence or unfavorable cytogenetics should be considered for HCT, reflecting the inclusion of these factors in the dynamic international prognostic scoring system (DIPSS).¹⁹⁸

P.2204

A number of important non-disease-related factors, such as age, donor type, and comorbidities, also have a major influence on the outcome following HCT, and these have to be carefully integrated into the decision to proceed to HCT.¹⁹⁹,
200, 201, 202, 203

In summary, on the basis of the available data the risk of HCT is currently not justified in patients with myelofibrosis with low- or intermediate 1-risk disease patients. There are no convincing data that transplant-related mortality and morbidity in myelofibrosis have been favorably altered by the use of RIC transplantation when TRM, relapse, and cGVHD rates remain high. Therefore, if HCT is indicated because of high- or intermediate 2-risk disease, the use of MST HCT is preferred in all eligible patients, considering its association with a lower risk of relapse compared with RIC transplantation. It is reasonable to offer RIC transplantation for older patients (ineligible for MST regimen)²⁰⁴ with high- or intermediate 2-risk disease, especially if a matched donor is available.²⁰⁵ Utilization of umbilical cord blood units or a haploidentical source must still be considered as experimental for myelofibrosis and an experimental option for myelofibrosis transplant candidates lacking a suitable MRD or URD.

In the event of blastic transformation of Myelofibrosis, where the median survival is only 2 to 7 months, HCT, if eligible, may offer a chance of long-term survival, with some encouraging results in a small series.

Role for Splenectomy and JAK-2 Inhibitor Therapy Pre-hematopoietic Stem Cell Transplantation

The splenomegaly itself may lead to sequestration of donor cells after HCT, and may cause delayed engraftment or graft failure. Indeed, some reports have shown faster engraftment in splenectomized patients, which may allow hematopoietic recovery without increased rate of the GVHD, characterized by significantly faster recovery of neutrophil and platelet counts.¹⁸⁸

A vast majority of myelofibrosis patients referred for consideration of HCT have bulky splenomegaly. Its attraction as a tumor debulking strategy is often upheld in clinical practice and the question still remains if there is a subgroup of patients who will benefit from splenectomy pre-HCT. Data reports decreased transfusion requirements and enhanced neutrophil recovery in patients undergoing HCT, favoring pre-transplant splenectomy.²⁰⁶

In contrast, a recent study reported a higher rate of relapse at 3 years in those who underwent splenectomy, 51% versus no splenectomy 20%; $P = 0.005$.¹⁹⁶ A retrospective CIBMTR study did not suggest an effect of prior splenectomy on either graft failure rates or DFS.¹⁹⁷ It is important to note that successful engraftment can still occur despite the presence of even massive splenomegaly. Ciurea et al.²⁰⁷ recently described a cohort of patients ($n = 10$) with splenomegaly, five of whom were defined as extensive with a longitudinal spleen diameter >30 cm, undergoing RIC HCT. All patients engrafted and had a progressive reduction in spleen size, occurring as marrow fibrosis resolved.

There is currently limited data to support the need for splenectomy before transplantation. An alternative to surgical splenectomy is the use of cytoreductive therapy or JAK inhibitors (that produce rapid spleen shrinkage, improvement of constitutional symptoms in the immediate pre-transplantation setting, and decreasing inflammatory cytokine with additional theoretical benefits, discussed below).²⁰⁸ JAK2 inhibitors lead to a marked reduction in levels of inflammatory cytokines in patients with myelofibrosis and might play a role in reducing the rates of GVHD post-HCT.

Monitoring Post-transplantation and Treatment of Relapse

Several studies have assessed whether the presence of JAK2 V617F can be used as a marker of minimal residual disease after HCT in order to institute preemptive immunotherapy prior to overt relapse.^{209, 210, 211, 212, 213} One study used a sensitive reverse transcription (RT)-PCR detection method to monitor and quantify JAK2 V617F levels following 22 RIC HCT procedures for 21 JAK2 V617F positive myelofibrosis patients. Patients became JAK2 V617F negative in 17 of 22 cases (78%) after a median of 89 days following HCT. Of the 5 patients who remained PCR-positive, 4 fulfilled the criteria for CR, demonstrating the utility of this technique as a marker for minimal residual disease and hence depth of remission achieved. In one of these cases, residual JAK2 positivity was eliminated following DLI.²⁰⁹ A subsequent study demonstrated that achievement of JAK2 V617F negativity after HCT for myelofibrosis was significantly associated with decreased incidence of relapse. Patients who achieved PCR negativity 6 months following HCT had a relapse risk of 5% compared with 35% in those who remained PCR-positive.²¹⁰

The timing of DLI, whether as a preemptive or salvage approach, post-HCT is less clear in myelofibrosis than other diseases. Kroger et al.²¹⁴ initially reported the use of both salvage and preemptive DLI (triggered by JAK2 V617F persistence on sequential monitoring) in 17 patients, with a median time from transplant to relapse of 269 days (127 to 1,570). DLI was used preemptively in 8 patients and as salvage in 9. Grade II–IV GVHD occurred in 3 patients (18%) in the salvage cohort. Encouragingly, the overall complete molecular response rate was 68% (100% in the preemptive group versus 44% in the salvage group), confirming the efficacy of this approach.

Little evidence is available to help delineate the role of post-HCT chemotherapy or second HCT in relapsed-myelofibrosis. A recent retrospective study reported on the use of DLI +/- second HCT for relapsed patients (morphologic relapse [n = 24] and molecular relapse [n = 6]). A total of 17 patients underwent a second RIC HCT at a median time of 17 months (11 to 77) post-initial transplant. Outcome data was encouraging; a total of 16 engrafted and responses identified in 12 evaluable patients, demonstrating the feasibility of a second HCT in this group.²¹⁵ However, the toxicity of a second HCT should not be underestimated, particularly given the median age of this patient population.

Hematopoietic Stem Cell Transplantation in HIV patients

Before the highly active antiretroviral therapy (HAART) was available, initial attempts to treat HIV-infected patients with allo-HCT led to extremely poor outcomes.²¹⁶ After HAART became widely available, several case reports suggested a potential benefit of HCT in this patient population. HCT in patients with malignancy and HIV infection has particular challenges, including the risk of opportunistic infection before and after transplantation, the high frequency of other concomitant viral infections, the potential impact of HIV in bone marrow environment and immune reconstitution post-transplant, and the potential for complex interactions between HAART, high-dose therapy, and immunosuppressive agents.

The CIBMTR retrospectively evaluated the results of allo-HCT in 23 HIV-infected patients undergoing transplant between 1987 and 2003, including patients receiving transplantation prior to the advent of HAART.²¹⁷ The indications for transplant included primarily malignant conditions, with lymphoma being the most common, followed by acute leukemia. With a median follow-up of 6 months, 30% of the patients were alive at 2 years; the primary causes of death were organ toxicity and infection. Despite initial mortality due to organ damage and infection, several patients achieved long-lasting remission. The BMT-CTN is conducting a prospective multicenter trial (BMT-CTN 0903; clinicaltrials.gov NCT01410344), enrolling patients with HIV infection and malignancy or bone marrow failure to assess the day-100 mortality after allo-HHCT. This trial will also study OS, PFS, and the impact of HCT on HIV reservoirs.

P.2205

Summary

The challenge to the transplant community is to make transplantation safer and to decrease the incidence and morbidity of GVHD without compromising the GVT effect. This dream will be realized as our understanding of transplant immunology increases. The role of HCT in the diseases discussed in this chapter will continue to evolve as transplantation becomes safer. On the other hand, advances in non-transplant genomic-driven targeted therapy, and advances in response assessment using minimal residual disease will continue to shape the future of HCT in hematologic malignancies. The use of targeted therapy post-HCT is inevitable. The impact of these agents on immunologic parameters will need to be assessed. Both transplant and non-transplant specialists will need to collaborate in an integrated team approach to advance this field and improve patient outcomes.

Chapter 105

Graft-Versus-Host Disease and Graft-Versus-Tumor Response

Joseph Pidala

Frederick L. Locke

Claudio Anasetti

INTRODUCTION

Graft-versus-host disease (GVHD) is the most common treatment complication following hematopoietic stem cell transplantation (HSCT) from an allogeneic donor, and it is a major cause of recipient morbidity and mortality. GVHD results from the recognition of recipient tissue antigens by immune competent T cells transplanted with the graft. There is an acute form of GVHD with a rapid onset, usually early after transplantation, and a chronic form of GVHD with late onset. These two GVHD syndromes are largely distinct in pathogenesis, clinical manifestations, prevention, and treatment, and therefore are presented separately in this chapter. Donor cells in the graft also produce an immune response against targets in the recipient malignant cells, through a reaction that contributes substantially to the antitumor activity of allogeneic HSCT. Such a graft-versus-tumor (GVT) response is presented in the third section of this chapter.

ACUTE GRAFT-VERSUS-HOST DISEASE

Pathophysiology

The requisites for the development of GVHD were recognized over 50 years ago by Billingham: (1) the inclusion of immune competent cells in the graft, (2) the inability of the recipient to reject the graft, and (3) the presence of recipient tissue antigens foreign to the donor. Animal model studies, primarily in rodents, led to a three-step model of GVHD pathophysiology that simplifies the complex immune interactions by placing emphasis on cellular interactions and cytokines: (1) host antigen-presenting cell (APC) activation, (2) donor T-cell activation, and (3) pathogenic effector cells and inflammatory mediators produce the disease.^{1, 2} GVHD biology is extremely complex involving intracellular signaling, soluble mediators, and cellular interactions. Positive and negative signals exist at multiple levels including the cell surface, signaling protein networks, transcription promoters, mRNA, and posttranslational modification. In addition to histocompatibility antigen disparities between donor and recipients, genetic polymorphisms at any of these immune

checkpoints may promote or prevent GVHD. The interaction of immune cells, visceral organ tissue, cytokine, and chemokine signals, cellular trafficking into and out of lymphoid and visceral organs is similarly complex. Recent attempts to rein in these numerous, continuous, and interrelated processes led Paczesny and Reddy to create a comprehensive model of GVHD pathophysiology based on the framework of normal immune system interactions. It is the expected behavior of donor immune cells to cause pathophysiology within the host that harbors unrecognized antigens which are treated as foreign by the donor cells. Put more simply, acute GVHD arises when donor T cells react in a physiologically appropriate way against recipient proteins recognized as foreign. However, the signaling events, intracellular pathways, and immune cell trafficking are extremely complex and remain to a large degree incompletely understood. This proposed nonlinear model consists of four interrelated elements to describe the role of immune system recognition and activation at the genetic, cellular, and cytokine level: triggers, sensors, mediators, and effectors of GVHD (Table 105.1).³

Critical to acute GVHD onset is the degree of genetic variability between donor and host, the level and site of tissue damage set forth by the conditioning regimen, the ability of host or donor cells to present antigen, the cellular and cytokine mediators of response, and the nature and degree of the immune effector activity.

Triggers

Human leukocyte antigens (HLAs) are encoded by the major histocompatibility gene complex (MHC) on chromosome 6p and function as major histocompatibility antigens in transplantation. The natural function of HLA is to present antigenic peptides to specific T cells. Exogenous and endogenous proteins present within human cells are continually broken down into peptides. HLA molecules on professional APCs bind those peptides within their groove and present them from the cell surface to the T-cell receptors on T lymphocytes. Inasmuch as the human genome includes greater than 10^7 polymorphic sequences, there is great likelihood that donor and recipient differ for one or more of the proteins that are presented as HLA:peptide complexes to T cells. These polymorphic proteins function as minor histocompatibility antigens (mHAs) in transplantation. Autoreactive T-cell recognition of "self" peptides in the thymus leads to negative selection (death), so that the probability of an individual developing autoimmunity is minimized. After transplantation, this delicate balance of self and nonself is perturbed. Donor and recipient may differ for HLA molecules or mHA. Each peripheral T cell harbors a unique T-cell antigen receptor; therefore, the human repertoire for recognition of foreign antigens is enormous. Donor and recipient HLA mismatching plays a critical role in the development of GVHD, because each type of HLA presents a unique repertoire of antigenic peptides. When recipient cells are mismatched at an HLA locus, the donor T cells have not undergone thymic deletion to avoid recognizing those HLA:peptide complexes. Therefore, the degree of HLA disparity directly increases the probability and severity of acute GVHD following transplantation.^{4, 5} For umbilical cord blood donors a greater degree of HLA mismatch is tolerated presumably due to the small number of T cells within the cord blood ($\sim 10^4$ per kg recipient weight) as compared to adult donor blood ($\sim 10^8$) or marrow ($\sim 10^7$).

mHA are polymorphic proteins genetically encoded anywhere outside HLA. Host mHA proteins are presented as HLA:peptide complexes to donor T cells and elicit an immune response even when presented via a matched HLA molecule. mHA mismatches are only partially characterized for the ability to affect acute GVHD. Some mHA have broad tissue expression such as the male-associated H-Y antigen.⁶ Alternatively, HA-1 and HA-2, for example, have their expression restricted to hematopoietic cells, including leukemia, and immune cells.⁷ It is this variability of tissue mHA expression that may allow for tailoring therapy toward hematopoietic-restricted mHA to promote GVT response without GVHD. Efforts to prevent GVHD would have to target immune responses against the ubiquitously expressed mHA.^{6, 8, 9}

Other triggers of GVHD include molecules that activate the innate immune system. Pre-transplant radiation or chemotherapy damages host cells and enteric microbes that contain damage-associated molecular patterns (DAMPs) or pathogen-associated molecular patterns (PAMPs), respectively. DAMPs such as proteases

P.2207

or ions released from damaged epithelial cells and PAMPs such as lipopolysaccharide within common bacteria, can activate Toll-like receptors setting off a cascade of immune events characterized by proinflammatory cytokine secretion.¹⁰ To a large degree these processes are responsible for initiation of the "cytokine storm" described as critical in earlier models of acute GVHD.¹¹

TABLE 105.1 ACUTE GRAFT-VERSUS-HOST DISEASE PATHOPHYSIOLOGY: TRIGGERS, SENSORS, MEDIATORS, AND EFFECTORS

Key Elements	Physiologic Role	Aberrant Process in Graft-versus-Host Disease
---------------------	-------------------------	--

Triggers

HLA molecules	Present antigen to T cells	Mismatches in HLA molecules from donor to host lead to recognition of the cell as foreign by T cells.
mHA	Normal variability of protein within genome	mHA are recognized as foreign by MHC:T-cell interactions.
DAMPs and PAMPs	Common organic patterns originating from damaged cells or pathogens triggering innate immunity	DAMP release after cell death due to conditioning therapy or PAMP presence via pathogens triggers innate immunity and cytokine cascade.

Sensors

Antigen presenting cells	Present antigens to effectors	Present exogenous and endogenous protein sequences to T cells via direct, indirect, or cross presentation.
--------------------------	-------------------------------	--

Mediators

CD4 T helper subsets	Skew effector responses to the appropriate degree	Effects of T-cell subsets on graft-versus-host disease incompletely understood.
Regulatory T cells	T-cell subset which acts to prevent untoward autoimmunity	Donor regulatory T cells play a role in reducing graft-versus-host disease.
Inhibitory signals	Signals provided in concert with antigen presentation to decrease the immune response	
Co-stimulatory signals	Signals provided by professional antigen presenting cells to initiate immune response	

Effectors

Activated CD4 and CD8 T cells	Lead to killing or neutralization of foreign cells or debris via IFN γ , perforin, or granzyme secretion	Donor cells act to damage host cells and organs leading to manifestations of graft-versus-host disease.
-------------------------------	---	---

HLA, human leukocyte antigen; DAMPs, damage-associated molecular patterns; mHA, minor histocompatibility antigen; MHC, major histocompatibility complex; PAMPs, pathogen-associated molecular patterns.

Adapted from Paczesny S, Hanauer D, Sun Y, Reddy P. New perspectives on the biology of acute GVHD. Bone Marrow Transplant 2010;45:1-11.

Sensors

Sensors of GVHD refer to the cells and processes that recognize the mHA or HLA mismatches as foreign, thereby setting the immune response in motion. Antigens are presented by host professional APC such as dendritic cells, macrophages, or Langerhans cells. Host dendritic cells may be primed for antigen presentation via the cytokine storm accompanying the conditioning therapy. The nature of antigen presentation interactions includes direct presentation, which mimics physiologic APC-T-cell interactions. Specifically, direct presentation consists of host APC presenting endogenous (cytosolic) host peptide to donor CD8 T cells, and exogenous (extracellular, endocytosed peptide, processed in lysosomes) antigens are presented to donor CD4 T-cells. Indirect presentation specifies exogenous antigen presented from donor APC to donor CD4 cells. Cross-presentation refers to exogenous antigen (derived from host cells) presented to donor T cells from donor APC. Over time APC change from primarily host origin to donor origin. It is likely that direct presentation by host APC is

predominant during early stages of acute GVHD, whereas indirect or cross-presentation by donor APC is predominant in chronic GVHD. APC-T-cell interaction involves not only interaction between HLA plus cognate antigen with T cell receptor (TCR), but co-stimulatory and inhibitory signals at the immune synapse, secondary signals from cell subsets, and paracrine or autocrine mediators. APC provide necessary co-stimulatory signals directly when activating T cells, such as CD28, CD40, and ICOS as well as inhibitory signals such as CTLA-4 and PD-1. Manipulation of these signals via antibody interference or small molecule blockade of downstream signaling events remains a field ripe for modulation of GVHD. Exogenous cell types critical to inhibition of APC include regulatory T cells, gamma-delta T cells in the GI tract, natural killer (NK) cells, and host NKT cells. T-cell response is an adaptive immune response which is often triggered by the innate immune response. As described, Toll-like receptors are sensors of the DAMP and PAMP release precipitated by the condition regimen. These Toll-like receptor interactions lead to release of proinflammatory cytokines such as tumor necrosis factor alpha (TNF α) and interleukin (IL)-6 which contribute to the inflammatory milieu surrounding T-cell-mediated GVHD damage.

Mediators

GVHD is primarily mediated by donor T cells, and differing subsets that have normal physiologic activities outside the framework of transplant, act at different capacities to induce or inhibit GVHD development. Most animal models point to the relevance of naive T cells, rather than memory T cells, in the induction of GVHD. The process of homeostatic proliferation in the lymphoablated host causes brisk clonal expansion of the transferred donor T cells and plays an important role for the initiation of acute GVHD. Donor regulatory T cells (Treg) repress the GVHD responses. Treg are CD4 T cells that express the FOXP3 transcription factor, high levels of the alpha chain of the IL-2 receptor, but no IL-7 receptor and function as a natural suppressor to maintain peripheral tolerance. These donor-derived regulatory T cells inhibit the activation and proliferation of donor T cells implicated in the pathogenesis of acute GVHD and may spare the GVT effect.¹² Recent data show that low-dose IL-2 expands regulatory T cells in vivo and may be effective therapy for established GVHD,¹³ whereas anti-IL-2 receptor antibodies, tested before Treg importance and biology were recognized, appear to accelerate GVHD.¹⁴

Additional CD4 T-cell subsets are critical. It is Th1 cells, characterized by IL-2 and interferon gamma (IFN γ) secretion, which

P.2208

are the likely main T-cell mediators of acute GVHD. Th2 T cells have been linked to protection against acute GVHD. Th17 CD4 cells secrete IL-17 and function distinctly from Th1 cells in a manner that is not yet fully characterized in the context of human GVHD. Murine transplant models provide evidence that Th17 can cause GVHD.^{15, 16} T-cell trafficking is another important step in GVHD pathogenesis. Differential expression of chemokines on GVHD target organs and draining lymph nodes mediate differential trafficking of T-cell subsets expressing different chemokine receptors. An initial report indicated that a CCR5 inhibitor can prevent GVHD in gut and liver.¹⁷

Effectors

The effectors of acute GVHD are the cytolytic cellular elements and inflammatory cytokines. Activated CD4 and CD8 cytotoxic T lymphocytes are the primary effectors of GVHD. Upon interaction with their cognate HLA:peptide they act to lyse or cause apoptosis of target cells via secretion of perforin and granzyme or binding of FAS, respectively. IFN γ and TNF α are both critical to the inflammatory process of GVHD. Inflammatory cytokines induce and amplify cellular damage.

EPIDEMIOLOGY

The major source of treatment-related morbidity and mortality is GVHD. The incidence of clinically relevant (grade II to IV) acute GVHD ranges from 35% to 80%, with a higher incidence reported for recipients of unrelated donors compared to matched related donors.^{18, 19} The day 100 incidence of severe acute GVHD (grades III-IV) occurs in approximately 15%, but may be as high as 35% depending upon risk factors such as HLA disparity.⁵

RISK FACTORS

Risk factors for the development of acute GVHD include T-replete transplant, recipient and donor HLA disparity, female donor for a male recipient, donor and recipient age, hematopoietic stem cell source (peripheral blood progenitor cells [PBPCs] > marrow > cord blood), graft cellular composition (worse with higher T-cell and CD34 cell numbers), higher conditioning intensity, diagnosis (worse with chronic myeloid leukemia), and immune response gene polymorphisms.^{20, 21} Predictive factors are of great interest to stratify patients prior to development of serious morbidity or mortality and to focus prevention upon the proper biological parameters.

HLA matching is critical to prevent acute GVHD. A single allele mismatch at HLA-A, HLA-B, HLA-C, or HLA-DRB1 increases the likelihood of acute GVHD development, and mismatch for multiple alleles compound the risk.^{5, 22}

Female donor for a male recipient and donor parity are risk factors for the development of acute GVHD. The increased risk for male recipients of female as opposed to male donors is attributed to the recognition of H-Y mHAs by female donor T cells.^{23, 24} During pregnancy, female donors develop an immune response to the paternal mHAs of the fetus and mount a secondary, augmented T-cell alloimmune response against the same mHAs if expressed in the recipient.²⁵

Increasing donor age is associated with increased risk for the development of severe acute and chronic GVHD, and worse mortality.²⁶ Age of the recipient is also important with higher rates of acute GVHD in older compared to younger cohorts.^{20, 27}

The rate of chronic GVHD in patients receiving PBPC grafts is higher compared to bone marrow; however, the association of PBPC with acute GVHD is not clearly established.^{28, 32} Unrelated cord blood transplant is associated with a low rate of acute GVHD when compared to transplant with similarly HLA mismatched adult donors.^{33, 34} Multiple factors may contribute to this effect; however, the low number of T cells in the graft and T-cell naive likely play a protective role.

The conditioning regimen used affects the incidence of acute GVHD. With high-dose intensity conditioning the incidence of acute GVHD is higher. For example, increasing doses of radiation can double the incidence of acute GVHD.³⁵ Several large retrospective studies showed that reduced intensity regimens lead to reduced rates of grade II-IV acute GVHD when compared to higher intensity regimens.^{36, 37} Animal models suggest the correlation of the incidence of GVHD with intensity may be due to increased damage to host tissue and amplified release of cytokines followed by activation of APC.³⁸ In addition, higher intensity regimens decrease the fraction of recipient T cells that persist after the regimen, leading to a lower barrier to donor engraftment and greater homeostatic re-population by donor T cells, which is associated with worse acute GVHD.^{39, 40}

The cellular composition of the graft is linked to the incidence of GVHD. Despite the link between chronic GVHD and CD34 cell dose, conflicting studies outline the importance of CD34 cell dose on acute GVHD.^{41, 42} The preponderance of evidence suggests that there is no correlation between CD34 cell dose and the incidence of acute GVHD, whether the progenitor source is marrow or PBPC,^{43, 44, 45} although one study, looking at patients given cyclosporine as a prophylactic agent, revealed a positive association of CD34 dose with acute GVHD.⁴⁶

Genetic polymorphisms of immune response genes are associated with an increased incidence of acute GVHD. Single nucleotide polymorphisms (SNPs) can alter cytokine binding domains, thereby altering affinity in a functional or nonfunctional way. Particular SNPs in genes coding IL-10, IL-6, IL-2, HPSE, CTLA-4, and MTHFR have all been identified as increasing the risk of clinically relevant or severe acute GVHD, likely via increased level or activity of these cytokines or receptors.⁴⁷

Cytokine biomarkers correlate with the presence of acute GVHD and provide prognostic information independent of the severity of GVHD. Although not widely in diagnostic use, the panel which includes IL-2-receptor-alpha, TNF-receptor-1, IL-8, and hepatocyte growth factor, can confirm the diagnosis at the onset of clinical symptoms.⁴⁸ An expanded 6 biomarker panel which also includes elafin, a skin-specific marker, and regenerating islet-derived 3- α , a gastrointestinal (GI) tract-specific marker was shown to predict response rate at day 28 after onset and survival at day 180 after onset, for patients with acute GVHD. This panel was predictive at 3 time points; onset, 2 weeks, and 4 weeks into therapy. Future clinical trials will determine if such stratification into high and low risks groups will lead to improved outcomes by capitalizing on the opportunity for early intervention.⁴⁹

PROGNOSIS

Acute GVHD response rates to high-dose steroid therapy are in the range of 50%, and achievement of response to steroids is the most important predictor of outcomes. Durable responses of a month or longer can be expected in about 30% and partial responses (PRs) in 20%. Lower intestinal acute GVHD has been linked to worse response rates compared to patients without lower intestinal manifestations.

CLINICAL MANIFESTATIONS OF ACUTE GRAFT-VERSUS-HOST DISEASE

The most common sites of involvement are skin, GI tract, and liver. Additional organ sites may be involved and clinicians should maintain a high degree of suspicion for acute GVHD as a

P.2209

cause for any unexplained abnormalities in eyes, buccal mucosa, and lung. A biopsy of the presumptive site should be

attempted whenever possible to confirm diagnosis, although histological manifestations can overlap with many inflammatory conditions confounding histological results. A pathologist familiar with acute GVHD is preferable, and appropriate immunohistochemical stains should be employed to rule out viral infection, particularly of the GI tract.

The onset and natural history of acute GVHD is variable depending on organ site, nature, and severity of disease. A hyperacute form, occurring in the first 14 days after transplant,⁵⁰ is characterized by early onset of typical signs and symptoms, with a preponderance of patients, 90%, exhibiting skin involvement. In addition a higher percentage of patients are likely to experience stage III-IV disease (88% vs. 66%).^{51, 52}

Most cases of acute GVHD manifest within the first 100 days following transplant. With the use of modern prophylaxis regimens including cyclosporine or tacrolimus, the onset is typically 20 to 25 days after cell infusion. With T-cell depletion, average onset is typically at 30 days, although it can be delayed several months as T cells reconstitute.⁵³ NIH consensus criteria for chronic GVHD includes classification of acute GVHD occurring after day 100 (late-onset acute GVHD) and for patients manifesting signs and symptoms of both acute GVHD and chronic GVHD (overlap subtype of chronic GVHD).⁵⁴ The severity of acute GVHD can easily be quantified using Keystone consensus grading criteria (Table 105.2).

Skin

Skin is the most commonly involved site of acute GVHD, being present 80% of the time at onset. A maculopapular rash is characteristic and may be described as a painful or pruritic sunburn. Characteristically involved sites include the back of the neck, palms, soles, dorsal surfaces of the extremities, and ears, although the rash can spread quickly to include the entire body. Although many cases are mild, severe manifestations can include bullous lesions and a clinical picture consistent with toxic epidermal necrolysis. Careful full-body examination allows for staging of acute GVHD by the Keystone consensus criteria. This scale is based upon percentage of body surface area (BSA) involvement. For example, when acute GVHD is confined to the skin and involves <50% of BSA, it is classified as grade I acute GVHD. Such a degree of involvement may require no more than topical steroids and frequent monitoring of symptoms (see "Primary and Secondary Therapy of Acute Graft-versus-host Disease" below). A biopsy of the skin can help to solidify the diagnosis, however, treatment is usually based on the clinical diagnosis.⁵⁵

TABLE 105.2 KEYSTONE CONSENSUS CRITERIA STAGING AND GRADING OF ACUTE GRAFT-VERSUS-HOST DISEASE

	Skin	Liver	Gut
Stage			
1	Rash on <25% of skin	Bilirubin 2-3 mg/dl	Diarrhea >500 ml/d or persistent nausea
2	Rash on 25-50% of skin	Bilirubin 3-6 mg/dl	Diarrhea >1000 ml/d
3	Rash on >50% of skin	Bilirubin 6-15 mg/dl	Diarrhea >1500 ml/d
4	Generalized erythroderma with bullous formation	Bilirubin >15 mg/dl	Severe abdominal pain with or without ileus
Grade			
I	Stage 1-2	None	None
II	Stage 3 or	Stage 1 or	Stage 1
III		Stage 2-3 or	Stage 2-4
IV	Stage 4 or	Stage 4	
Functional Grading			
	Skin	Liver	Gut
I	Rash on <50% of skin		
II	Rash on <50% of skin or	Bilirubin 2-3 mg/dl or	Diarrhea >500 ml/d or persistent nausea

III-IV Generalized erythroderma with bullous formation or Bilirubin >3 mg/dl Diarrhea >1000 ml/d

Criteria for grading given as minimum degree of organ involvement required to confer that grade.

Grade IV may also involve lesser organ involvement but with extreme decrease in performance status. From Przepiorka D, Weisdorf D, Martin P, et al. 1994 consensus conference on acute GVHD grading. *Bone Marrow Transplant* 1995;15:825-828.

Hepatic

Liver acute GVHD is typically characterized by involvement of the bile duct epithelium, resulting in cholestasis. Bilirubin and alkaline phosphatase elevation, accompanied by cholestatic jaundice are the typical manifestations. Direct hepatocyte damage is rare, absent a more chronic fibrosis, although transaminitis often occurs. Hyperbilirubinemia must be distinguished from other common post-transplant complications such as toxicity from preparative chemotherapeutics, sinusoidal obstructive syndrome (also called hepatic veno-occlusive disease), and occasionally fulminant viral hepatitis. Sinusoidal obstructive syndrome is characterized by hyperbilirubinemia, portal hypertension, and weight gain due to third spacing of fluids. Portal hypertension is part of the clinical picture of sinusoidal obstructive syndrome, and not a manifestation of acute GVHD in patients without underlying liver disease. Doppler assessment of portal hypertension, measurement of the hepatic vein occlusive pressure, and if necessary histological examination, are critical in resolving the differential diagnosis. A transjugular liver biopsy is preferable to transcutaneous biopsy, as portal pressures can be measured. Acute GVHD produces cholestatic hepatitis, with histology showing frequent acidophilic bodies evolving to bile duct exocytosis and disruption. As the disease progresses beyond day 100 post-transplant, portal fibrosis is seen with increasing bile duct dropout.⁵⁶ This is in contrast to sinusoidal obstructive syndrome, which is characterized by occluded hepatic venules, sinusoidal fibrosis, and hepatocyte necrosis.⁵⁷

P.2210

Gastrointestinal Tract

Anorexia, nausea, and vomiting are the most common symptoms of GI acute GVHD, but diarrhea, abdominal pain, and hemorrhage are symptoms of serious lower-tract disease. Almost any site along the tract can be involved. Unexplained GI symptoms such as mouth ulcers or ileus can be caused by acute GVHD. Endoscopy with biopsies of the upper and/or lower tract should be obtained for persistent symptoms, inasmuch as histology provides critical information. The differential diagnosis of uppertract GVHD includes herpes simplex, cytomegalovirus, or candida esophagitis, stomach ulcer, and peptic gastritis or duodenitis. The differential diagnosis of lower tract disease includes enteritis from *C. difficile*, cytomegalovirus, Norfolk viruses, cryptosporidium, giardia, or enteric pathogens such as *Salmonella*, and side effects of irradiation or medications including cytotoxic chemotherapy, tacrolimus, and mycophenolate mofetil among others. Radiologic findings by computed tomography (CT) scan can include thickening of the esophageal, small, or large bowel wall; adjacent vasa recta engorgement; mesenteric fat stranding; or mucosal enhancement.⁵⁸ Radiologic modalities should not be relied upon for confirmation of diagnosis. Upper or lower endoscopy affords both a visual examination of the mucosa which may exhibit edema, erythema, ulceration, and mucosal sloughing, as well as the opportunity to obtain tissue for histology. Classic microscopic findings include epithelial crypt apoptotic bodies and lymphocytic infiltration. Involved mucosa can be noncontinuous and a lack of findings or a low degree of severity at one level does not rule out other areas or degrees of involvement.⁵⁹

Lung

Lung complications following allogeneic transplant can be of cardiac, infectious, vascular, or immune nature. Infections and pulmonary embolism should always be entertained in the differential diagnosis of a transplant patient with shortness of breath, hypoxia, or new infiltrate. Volume overload and cardiogenic pulmonary edema is another mechanism of respiratory distress. Immune-mediated processes should be entertained when infectious work-up is negative, or CT scanning is not consistent with infectious processes. Diffuse alveolar hemorrhage has long been recognized as a post-transplant complication and occurs in approximately 10% of patients, with myeloablative regimens associated with a higher incidence. Patients manifest with dyspnea (92%) accompanied with mild to severe bleeding into the alveoli, although hemoptysis is seen in a minority (15%) of cases. Fever can be a presenting symptom (67%) and diagnosis is typically made following bronchoscopy. Patients often require ventilatory support and mortality rates can reach 70%.^{60, 61}

Lung wedge resection or video-assisted thoracoscopic biopsy should be entertained for patients where an organism is not identified and diagnostic uncertainty remains. Bronchiolitis obliterans with organizing pneumonia (BOOP) is seen in up to 2% of patients during the post-transplant period. Although not considered a manifestation of GVHD,⁶² biopsy-proven BOOP occurs at a median of 108 days after transplant and can display a wide range of severity and reversibility. It is typically a restrictive lung disease with radiographic findings showing peripheral patchy consolidation, ground glass infiltrates, and nodular opacities. BOOP after transplant is associated with GVHD and steroid therapy affords a chance for improvement.^{63, 64}

PREVENTION

A half century ago, Storb and collaborators determined that the immunosuppressive agent methotrexate could mitigate or prevent the onset of acute GVHD, when applied shortly after transplantation. Although oral and liver toxicity can be severe and preclude up to 40% of patients from receiving a full course of therapy, methotrexate remains widely in use, now typically in combination with a calcineurin inhibitor.²⁷ Calcineurin inhibitors act to inhibit IL-2 mediated T-cell expansion. Cyclosporine, the first calcineurin inhibitor, was found to be synergistic with methotrexate, leading to a reduction in severe (grade III/IV) acute GVHD when utilized in HLA-matched sibling allografts and to a lesser degree with unrelated donor allografts.^{65, 66} Subsequent development of the calcineurin inhibitor, tacrolimus, included two phase III head-to-head comparisons of methotrexate/cyclosporine and methotrexate/tacrolimus.^{67, 68} The combination of methotrexate/tacrolimus reduced the incidence of grade II-IV acute GVHD for both matched sibling donors (31.9% vs. 44.4%; $P = 0.01$) and unrelated donor transplants (56% vs. 76%, $P = 0.0002$), but it did not prevent chronic GVHD or improve survival. This lack of survival advantage propagated the use of both combination regimens at the discretion of individual transplant centers.

Attempts at further decreasing the incidence of acute GVHD have included the addition of agents to a calcineurin inhibitor with or without methotrexate. Mycophenolate mofetil is a prodrug of mycophenolic acid, an inhibitor of de novo synthesis of purines in lymphocytes required for lymphocyte proliferation. Mycophenolate mofetil has been examined in combination with cyclosporine or tacrolimus. Single-center randomized studies of mycophenolate mofetil suggest greater safety but not greater efficacy over methotrexate. One study was stopped early as cyclosporine/mycophenolate mofetil showed a clear advantage over cyclosporine/methotrexate in regard to decreased mucositis (21% vs. 65%, $P = 0.008$) and faster neutrophil engraftment (11 days vs. 18 days, $P < 0.001$) but without a difference in the incidence of acute GVHD.⁶⁹ A second single-center study revealed that mycophenolate mofetil decreased severe mucositis, use of parenteral nutrition, and promoted early hospital discharge, however, mycophenolate mofetil was associated with higher rates of severe (grade III-IV) acute GVHD (19% vs. 4%, $p = 0.03$), which was predominantly seen with unrelated donors.⁷⁰

Sirolimus is an mTOR inhibitor that has complex immunomodulatory properties affecting T cells and APC. The drug requires therapeutic monitoring and is affected by inhibitors or inducers of CYP3A4. Sirolimus is associated with the risk of endothelial damage such as in sinusoidal obstructive syndrome.^{71, 72, 73} Initially shown to be safe in combination with tacrolimus and methotrexate,⁷⁴ sirolimus has now been tested in several phase II studies in combination with tacrolimus and the two agents likely synergize to reduce acute GVHD rates.^{75, 76} In particular, sirolimus supports regulatory T-cell reconstitution post-transplant, which are protective against acute GVHD after transplantation.⁷⁷

Bortezomib is a proteasome inhibitor that has activity against multiple myeloma via nuclear factor kappa B inhibition and other mechanisms. A phase I/II trial showed that bortezomib could be added to tacrolimus and methotrexate as acute GVHD prophylaxis. This regimen is promising as the 180 cumulative incidence of grade II-IV acute GVHD was 13%.⁷⁸

The chemokine receptor CCR5 plays a role in alloreactivity via effects on lymphocyte migration, and has shown promise in an early phase study. Blockade using the CCR5 antagonist, maraviroc, in combination with tacrolimus and methotrexate as acute GVHD prophylaxis led to inhibition of lymphocyte trafficking, without attenuating T-cell function or impairing stem cell function *in vitro*.¹⁷

Special circumstances surrounding the selection of acute GVHD prophylaxis include HLA-incompatible related donors, unrelated donors, or cord blood. For cord blood transplants, cyclosporine has been the drug primarily utilized as a prophylaxis backbone.⁷⁹ For HLA mismatched donor transplants, a calcineurin inhibitor/methotrexate-based regimen is generally

P.2211

inadequate for GVHD prophylaxis. Triple combination regimens, ATG, and other methods of T-cell depletion have been shown effective in prevention of acute GVHD for mismatched donor transplants.^{71, 80}

As T cells are the primary effectors of acute GVHD, methods of depleting T cells from the graft or in vivo, following transplant have succeeded in reducing rates and the severity of acute GVHD. An ex vivo method of soybean agglutination and E-rosetting was performed⁸¹ to achieve T-cell depletion from allografts, resulting in high rejection rates, presumably due to rejection by residual recipient T cells.^{82, 83} When combined with more immunosuppressive conditioning regimens this complication is ameliorated, yet even so T-cell depletion has not proven to increase overall survival following transplant, considering increased likelihood for relapse and higher infection rates.⁸⁴ Similarly, the anti-CD52 monoclonal antibody, alemtuzumab, has been utilized ex vivo to deplete T cells, resulting in low incidence of grade II/IV GVHD (12%), but a concerning rate of graft failure (15%).⁸⁵ CD34+ cell isolation has been studied and shown to result in extremely low rates of severe acute GVHD in high-risk patients.⁸⁶

In vivo alemtuzumab has been utilized in combination with several different regimens, both with and without a calcineurin inhibitor, with acceptable rejection rates and low incidence of GVHD.⁸⁷ The use of alemtuzumab is associated with increased infectious complications.⁸⁸

Antithymocyte globulin (ATG) refers to polyclonal antibodies against thymus tissue. When used for as prophylaxis or treatment for patients with acute GVHD it leads to depletion of T lymphocytes. It may cause an acute cytokine release syndrome that may include fever, hypotension, and may progress to shock, and delayed "serum sickness." Infectious complications include Epstein-Barr virus re-activation and associated post-transplant lymphoproliferative disorder, and human herpes virus-6 reactivation and associated encephalitis.^{89, 90}

Another agent used to reduce T-cell numbers following transplant is cyclophosphamide, which is a potent immunosuppressive agent, yet spares stem cells. This strategy can result in low rates of severe acute GVHD, even when used as a single prophylactic agent.⁹¹

PRIMARY AND SECONDARY THERAPY OF ACUTE GRAFT-VERSUS-HOST DISEASE

Primary therapy for acute GVHD consists of high-dose steroids (the equivalent of 1 to 2 mg/kg/day of prednisone, with a taper initiated as soon as patients have a major decrease in GVHD signs or symptoms). This standard is based upon historical empirical evidence and randomized controlled data which suggest no advantage to prednisone-equivalent steroid doses of >2.5 mg/kg/day and no disadvantage for 1 mg/kg/day for grade II acute GVHD.⁹²

Standardized consensus response criteria for acute GVHD clinical trials are defined as a complete response, with resolution of all signs and symptoms of disease and normalization of laboratory values, and a very good partial response (VGPR), which allows for residual nonbullous erythematous rash on <25% of BSA, occasional nausea or vomiting, and a reduction of bilirubin to <25% of baseline at enrollment.⁹³ The definition of VGPR (Table 105.3) allows for confounding variables that clinicians must recognize while monitoring for resolution of acute GVHD such as residual GI and hepatic toxicities from conditioning or prophylactic medicines and the recognition of erythema or darkening skin as resolving skin lesions. Prolonged high-dose steroid use leads to a significant degree of morbidity and mortality, and the tapering of these drugs must take precedence once symptomatology and abnormal laboratory data recede.

TABLE 105.3 CONSENSUS TERMINOLOGY DESCRIBING VERY GOOD PARTIAL RESPONSE FOR ACUTE GRAFT-VERSUS-HOST DISEASE

Skin	No rash, or residual erythematous rash involving <25% of the body surface, without bullae (residual faint erythema and hyperpigmentation do not count)
Liver	Total serum bilirubin concentration <2 mg/dl or <25% of baseline at enrollment
Gut	Tolerating food or enteral feeding Predominantly formed stools No overt gastrointestinal bleeding or abdominal cramping No more than occasional nausea and vomiting

From Endpoints for Clinical Trials Testing Treatment of Acute Graft-Versus-Host Disease: A Consensus Document. from Martin PJ, Bachier CR, Klingemann HG, et al. Endpoints for clinical trials testing treatment of acute graft-versus-host disease: a joint statement. *Biol Blood Marrow Transplant* 2009;15:777-784.

The largest studies to date have not been consistent in identifying predictors of response. Risk factors to steroid therapy are not uniform,^{94, 96} although lack of response to primary therapy is clearly a predictor of decreased survival.

Unfortunately complete response (CR) rates to high-dose steroid monotherapy are as low as 20% to 50% of patients, although patients may tolerate steroid taper following a PR. Few data exist to inform the rate of steroid taper. Continuation of the taper must be conducted with frequent monitoring of GVHD parameters to prevent a flareup of symptoms.

Several agents have been added to steroids in comparative studies; at this time no evidence supports the use of these in combination, beyond a well-designed clinical trial for primary acute GVHD therapy. A recent randomized, phase II multicenter trial evaluated four agents, each in combination with glucocorticoids, as initial therapy for acute GVHD. Of the four agents (etanercept, mycophenolate mofetil, denileukin diftitox, and pentostatin) used individually in combination with steroids, the mycophenolate mofetil and steroid combination provided the most encouraging 28-day CR rate,⁹⁷ however, this was not confirmed in a subsequent phase III trial.

For patients unresponsive and unable to tolerate a steroid taper, consideration of second-line therapy in addition to steroids should be made at an interval appropriate to the severity of symptoms. For patients without a significant decrease in symptoms or laboratory parameters, within 3 to 5 days an additional agent is typically added. No particular agent has been shown to be superior to another as therapy for steroid-refractory patients as data on comparative effectiveness of salvage agents is sparse, thereby limiting conclusions and application to clinical practice. Combination therapy has not been systematically studied to date, and it remains uncertain if combinations of drugs will be of benefit for steroid-refractory GVHD patients. Some practitioners utilize differential subset response rates from differing agents to inform selection of agents.

ATG has been studied as second-line therapy with variable overall response rates (ORR) in the range of 30% to 56%. CR was more likely for manifestations in the skin than in other sites.⁹⁸ Other antibodies that have been studied but have yet to prove of benefit over alternatives for use as second-line therapy for steroid-refractory acute GVHD include anti-CD147, expressed on activated T and B lymphocytes as well as APC, anti-CD3 antibodies (OKT3, visilizumab), anti-CD5-ricin conjugated antibodies, and anti-CD52 (alemtuzumab), expressed on most hematopoietic cells.

P.2212

Anti-CD25 antibodies (daclizumab, enlimomab, basiliximab) against the IL-2 alpha receptor subunit act to block T-cell proliferation and signaling, but also may block or deplete regulatory T cells. These agents have led to ORRs of 40% to 67%⁹⁹ and response rates are greater in skin compared to other organs, whereas infectious complications due to concomitant glucocorticoids remain a prominent cause of mortality.¹⁰⁰ Denileukin diftitox (Ontak) is recombinant IL-2 fused to diphtheria toxin and has demonstrated some activity in acute GVHD in phase I trials.^{101, 102}

Antibodies against TNF α (infliximab and etanercept) have shown promise in retrospective single institution series with an ORR of 50% to 67%. At least one series showed intestinal involvement predicted for response, although this was not supported in the other series.^{103, 104, 105}

Mycophenolate mofetil has been studied for glucocorticoid refractory GVHD in several reports.^{106, 107} ORRs with mycophenolate mofetil are in the range of 31% to 67%, and dose-limiting cytopenias must be taken into account. Sirolimus has been studied as an agent for refractory acute GVHD in several retrospective series and one safety study. Adverse effects have included hyperlipidemia and cytopenias. Thrombotic microangiopathy has been observed in up to 35% of patients when used in combination with calcineurin inhibitors. Pentostatin, a nucleoside analogue, has shown activity in refractory GVHD.

Extracorporeal photochemotherapy utilizes 8-methoxypsoralen and exposes peripheral blood cells to UV-A light extracorporeally. It is believed this alters APC activation and promotes Th2 polarization. This therapy is relatively well tolerated and has been associated with an ORR of 67% to 75%. Best response is typically seen after 2 months of therapy; lesser responses seen in patients with GI involvement and patients with higher-grade disease.

SUPPORTIVE CARE

For prophylaxis, there should be appropriate minimization of exposure to precipitating agents such as the sun. Patients with active acute GVHD, there should be special attention paid to the immunocompromised state of the patient. Understanding of the hospital and community bacterial resistance patterns is essential to select appropriate prophylactic antibiotics. Patients on high-dose steroids are at high risk for contraction of fungal pneumonia and appropriate coverage with antifungal medication is warranted. It was recently shown in a large randomized trial that the antifungal agent posaconazole was superior to fluconazole at preventing invasive aspergillus when used as prophylaxis in patients with

GVHD requiring high-dose steroid, combination immunosuppressive therapy, or ATG.¹⁰⁸ A comparison of transplant outcomes between the time period of 1993 to 1997 and 2003 to 2007 at a large single center, revealed significant reduction in mortality. Although this change is due to many factors including the advent of reduced intensity regimens, decreased infection related deaths, and decreased severe GVHD, improved supportive care plays a key role.¹⁰⁹

CONCLUSION

Acute GVHD remains a significant source of morbidity and mortality after allogeneic transplant. The advent of improved prophylactic regimens has led to decreases in the rates and severity, although the most effective primary therapy remains steroids. Future directions should focus on genetic risk factors for the development of disease, ways to predict which patients will not respond to steroids as primary therapy, and agents or cellular therapies that will prevent the development or stop the progression of acute GVHD.

CHRONIC GRAFT-VERSUS-HOST DISEASE

Introduction

Major efforts in basic, translational, and clinical research in chronic GVHD are underway, and promise to improve outcomes of affected patients. The following sections review major progress in our understanding of the pathobiology, clinical advances in the management of the syndrome, and remaining challenges for future research.

Biology

Although there is uncertainty in the mechanisms at work in human chronic GVHD pathogenesis, pre-clinical models have suggested several areas for ongoing investigation and potential avenues for novel therapeutic approaches.

CD4 T-cell Subsets

Allied clinical observations suggest the role of alloreactive donor T cells: peripheral blood mobilized stem cell products, which contain greater donor T cells compared to bone marrow harvested stem cells, impose a greater risk for chronic GVHD and prolonged duration of immune suppression.¹¹⁰ Ex vivo T-cell depletion strategies,^{111, 112} as well as in vivo strategies such as antithymocyte globulin,¹¹³ ATG-Fresenius,¹¹³ or alemtuzumab, are associated with decreased risk of chronic GVHD.^{114, 115} Ongoing investigation aims to discern the relationship between regulatory T cells and chronic GVHD. Early clinical evidence suggests an inverse relationship between regulatory T-cell numbers and the risk of chronic GVHD.¹¹⁶ In a randomized trial comparing sirolimus/tacrolimus versus methotrexate/tacrolimus, sirolimus-treated patients had selective recovery of functional regulatory T cells, and significant reduction in NIH moderate-severe chronic GVHD.⁷⁷ Taken together, current evidence suggests that selective immune modulation may favorably affect chronic GVHD pathogenesis.

Loss of Central Tolerance

Negative selection of autoreactive T cells naturally constitutes a major mechanism of immune tolerance. Immature T cells are positively selected first in the thymic cortex through recognition of class I or class II MHC. In the thymic medulla, T cells engage marrow-derived APCs bearing self-antigens. Strongly self-reactive T cells suffer negative selection through apoptosis. Thus, in normal immunity, naive T cells are educated in the thymus, and autoreactive cells are deleted. Dysregulation of central tolerance due to thymic epithelial damage, which may result from transplantation conditioning therapy or prior GVHD, constitutes a major hypothesis for development of chronic GVHD after allogeneic HSCT. A murine model of thymic dysfunction largely recapitulates a chronic GVHD phenotype. Here, lethally irradiated C3H/HeN recipients receive T-cell-depleted bone marrow from MHN-mismatched B6 mice deficient in MHC class II antigens (B6 H2-Ab1^{-/-}).¹¹⁷ Thus, thymic negative selection is compromised by lack of MHC class II in thymic dendritic cells. The resulting phenotype includes sclerodermatous (Scl) skin changes, weight loss, bile duct loss, mononuclear cell infiltration of the salivary glands, and mortality. Evidence of impaired thymic negative selection has not been observed in other murine models. The clinical relevance of these findings has also been challenged, as thymic function declines with age and may not be relevant to development of GVHD in adult recipients of HSCT. Experimental models have suggested benefit of keratinocyte growth factor to prevent thymic injury, however, this strategy was not successful in human clinical investigation.¹¹⁸

P.2213

Altered B-cell Homeostasis

Several major basic and clinical observations support the role of loss of B-cell tolerance and altered B-cell homeostasis following transplantation in chronic GVHD pathogenesis. B cells have multiple functions, including antibody production, immune regulation, antigen presentation, and cytokine production, which all may have relevance to chronic GVHD pathogenesis.¹¹⁹ A major murine chronic GVHD model, the systemic lupus erythematosus (SLE)-chronic GVHD model, supports the coordination of CD4 T and B cells for antigen presentation and antibody production responsible for the chronic GVHD phenotype. In this model, involving parent-into-F1 combinations, both class I and class II MHC mismatched immune cells are adoptively transferred into nonirradiated mice, resulting in autoantibody production and immune-complex glomerulonephritis. In this model, B cells present antigen to CD4 T cells, leading to activation and production of Th2 cytokines including IL-4 and IL-10. These cytokines activate B cells, which produce autoantibodies. Further antigen reprocessing and presentation leads to activation of other CD4 T cells, and epitope spreading. Despite differences between this model and human chronic GVHD, it supports the role of B cells in chronic GVHD pathogenesis. B-cell stimulatory signals, including B-cell-activating factor (BAFF), have a key role in B-cell reconstitution and homeostasis after transplant. In such models, B-cell survival is dependent on B-cell receptor and BAFF signaling, and B-cell homeostasis is dependent on soluble BAFF concentration. BAFF levels, as well as the balance of autoreactive B cells and competing naive B cells determine the fate of autoreactive B cells.^{120, 121}

Beyond these basic findings, multiple lines of human clinical evidence support this hypothesis: first, autoantibodies have been detected in patients with chronic GVHD. After sex mismatched HSCT, alloantibodies directed against the Y chromosome-associated mHAs, or H-Y antibodies, have been detected and correlate with the occurrence of chronic GVHD.^{122, 123} In the setting of cutaneous sclerosis of chronic GVHD, activating antiplatelet-derived growth factor receptor (PDGFR) antibodies have been detected. As well, reduced levels of immature B cells in patients with chronic GVHD support altered B-cell homeostasis.¹²⁴ It is important to note that investigators have demonstrated aberrant B-cell homeostasis and elevated BAFF levels in human HSCT recipients with chronic GVHD. A consolidative model suggests that, in patients who develop chronic GVHD, high BAFF levels and decreased numbers of naive B cells (high BAFF/B-cell ratio) support alloreactive pre- and post-germinal center CD27+ B cells that contribute to chronic GVHD development.¹²⁵ Additionally, recipient BAFF SNP has association with chronic GVHD phenotypic presentation.¹²⁶ This mounting basic and clinical evidence has informed allied clinical investigation: multiple clinical trials have demonstrated activity of the anti-CD20 monoclonal antibody, rituximab, in the treatment of chronic GVHD which has failed standard glucocorticoid therapy,^{127, 129} and there is interest in the incorporation of B-cell-depleting agents in both prevention and primary therapy of chronic GVHD.

Profibrotic Pathways

Clinical and basic evidence suggest that profibrotic pathways play a role in chronic GVHD development. In particular the coordination of Th2 CD4 cells, TGF- β and IL-13, and potentially stimulatory anti-PDGFR antibodies, effect fibroblast production of collagen and lead to fibrosis. One major murine model, the Scl-chronic GVHD model, has provided mechanistic insight into fibrotic chronic GVHD phenotypes. In this model, B10.D2 (H-2^d) into BALB/c (H-2^d), donor immune cells (bone marrow and splenocytes) are adoptively transferred into sublethally irradiated mice that are matched at MHC, but mismatched for mHAs. With full donor lymphoid chimerism, chronic GVHD is mediated by donor immune cells. The resulting phenotype includes fibrosis in multiple organs (skin, GI tract, liver, lung, and parotid salivary gland), mononuclear cell infiltration and collagen deposition, and mortality. In this model, inflammatory signals lead to activation of donor and host APC, recruiting CD4 T cells, which in turn produce TGF- β and IL-13. These signals drive fibroblast collagen synthesis and resultant fibrosis. The specific role of TGF-beta has been supported by amelioration of chronic GVHD manifestations after neutralization of this cytokine in murine models, and the clinical observation of an inverse relationship between TGF-beta signaling in CD4 and CD8 cells and the risk of chronic GVHD.¹³⁰ In the setting of cutaneous sclerosis of chronic GVHD, activating anti-PDGFR antibodies have been detected, and agents with activity against this receptor kinase such as imatinib have demonstrated activity in this condition.¹³¹

Diagnosis of Chronic Graft-versus-Host Disease

Chronic GVHD occurs in the majority of patients at risk, up to 60% to 80% of those who survive more than 100 days after transplantation.^{132, 133} The reported incidence of chronic GVHD in the published literature is dependent upon classification of the syndrome, patient and transplantation characteristics, pharmacologic GVHD prophylaxis utilized, and the use of further in vivo or ex vivo T-cell-depleting agents. Accurate recognition and management of the syndrome is important, as it is a major source of late HSCT-related morbidity and mortality,^{134, 135} an important determinant of overall health, functional ability, and quality of life,^{132, 133, 136, 138} as well as prolonged immune suppressive therapy after HSCT.¹³⁹

The syndrome is characterized by diverse manifestations, and has several parallels to human autoimmune and inflammatory disorders, such as systemic lupus erythematosus, Sjogren's disease, systemic sclerosis, and inflammatory

bowel disorders, among others. The most commonly occurring manifestations arise in the skin, eyes, mouth, and liver. Common skin manifestations include pigmentation changes, lichen planuslike changes, poikiloderma, as well as more advanced cutaneous and subcutaneous sclerosis. Note that cutaneous erythema is a manifestation shared by acute GVHD and overlap subtype of chronic GVHD (when present together with other diagnostic findings of chronic GVHD). Oral findings include lichen planuslike changes, hyperkeratotic plaques, or decreased oral range of motion. Patients can suffer from oral and ocular sicca symptoms, including dry mouth and dry or gritty eyes. Hepatic involvement with chronic GVHD results in a cholestatic pattern of elevated alkaline phosphatase and bilirubin. In the GI tract, diagnostic chronic GVHD features include esophageal web, stricture, or concentric rings on endoscopic or radiographic study. Other manifestations such as anorexia, nausea/vomiting, and diarrhea are shared between acute and overlap subtype of chronic GVHD. Bronchiolitis obliterans is a less common manifestation of chronic GVHD. Bronchiolitis obliterans represents a diagnostic manifestation of chronic GVHD, and is characterized by clinical symptoms (e.g., cough, dyspnea) and respiratory physiologic abnormalities (forced expiratory volume in 1 second [FEV1]/forced vital capacity ratio <0.7, FEV1 <75% predicted value, evidence of air trapping or bronchiectasis on CT scan, residual volume of >120%, presence of another chronic GVHD manifestation, and absence of infectious etiology). Tissue biopsy is not required for diagnosis.

Given the importance of the syndrome, a major challenge for clinicians remains to recognize chronic GVHD accurately, and distinguish it from competing syndromes, such as acute GVHD (i.e., sole presence of acute GVHD manifestations), other medical conditions, infectious etiology, or adverse effects from medications (e.g., hepatic function abnormalities due to medications such

P.2214

as azole antifungals). Once the syndrome is recognized, it should be classified appropriately, and severity assessed; these data together provide both prognostic information, as well as indications for topical or systemic therapy.

CLASSIFICATION AND SEVERITY GRADING

Major changes in the classification and severity grading of the syndrome have been suggested by the NIH Chronic GVHD Consensus Conference. Among these proposed changes, the previously accepted division between acute and chronic GVHD according to the landmark of 100 days post-HSCT was eliminated. The guidelines propose definition of chronic GVHD according to diagnostic manifestations of the syndrome, rather than the time of onset following HSCT.

Accordingly, manifestations of acute GVHD occurring before day 100 are defined as acute GVHD, and sole acute GVHD manifestations occurring after day 100 are considered persistent, recurrent, or late acute GVHD based on the prior occurrence of acute GVHD. Classic chronic GVHD is defined based on the definitive manifestations of the syndrome in the absence of concurrent acute GVHD manifestations. Diagnosis of chronic GVHD requires the presence of at least one diagnostic clinical sign of chronic GVHD or the presence of at least one distinctive manifestation confirmed by biopsy or allied diagnostic test. The concurrent presentation of both chronic GVHD and acute GVHD manifestations defines the overlap subtype of chronic GVHD. Readers are directed to Filipovich et al. for comprehensive coverage of chronic GVHD diagnosis and severity grading criteria.⁵⁴ Although prior retrospective studies reported after the NIH Consensus failed to support the importance of the overlap subtype of chronic GVHD consistently, prospective data from the Chronic GVHD Consortium demonstrates that patients with overlap have greater symptom burden, worse quality of life, impaired function, and significantly inferior survival compared to classic chronic GVHD cases.¹⁴⁰

In addition, consensus guidelines for chronic GVHD severity grading were proposed to replace the previously accepted scheme based on limited versus extensive involvement. In the prior severity grading scheme, limited involvement included only localized skin involvement or hepatic dysfunction, whereas extensive chronic GVHD was defined by the presence of generalized skin involvement or the presence of aggressive chronic hepatitis, bridging necrosis or cirrhosis in liver biopsy, or involvement of other target organs such as the eye, mouth, or lung. Rather, chronic GVHD severity according to the NIH Chronic GVHD Consensus is scored according to objective criteria for each organ involved, with attention to the functional implications of the degree of involvement, such as degree of weight loss in GI scoring, or frequency of artificial tear use or more aggressive interventions needed for therapy of ocular sicca manifestations.

The individual organ scores are then summarized for an overall global severity score of mild, moderate, or severe. A global severity score of mild encompasses no more than 2 organs, with severity of 1 each; moderate global severity indicates any organ site with a score of 2 (or lung score of 1), or involvement of 3 or more organ sites; finally, the severe category results from either any individual organ site score of 3, or a lung score of 2.⁵⁴ Data from the Chronic GVHD Consortium validates the importance of the proposed NIH Consensus severity criteria: global severity scores at cohort study

enrollment were associated with nonrelapse mortality ($P < .0001$) and survival ($P < 0.0001$); 2-year overall survival was 62% (severe), 86% (moderate), and 97% (mild) (Fig 105.1).¹⁴¹

FIGURE 105.1. Survival outcomes per NIH chronic GVHD overall severity. From Arai S, Jagasia M, Storer B, et al. Global and organ-specific chronic graft-versus-host disease severity according to the 2005 NIH consensus criteria. *Blood* 2011;118(15):4242-4249.

Clinical Predictors of Chronic Graft-versus-Host Disease Development

Clinical predictors for the development of chronic GVHD may facilitate identification of patients at risk, and could potentially provide a rationale for risk-adapted strategies for prevention of the syndrome. The most consistently reported risk factors for development of chronic GVHD have included increasing age of the donor or recipient, donor/recipient HLA disparity and donor relation, male recipients of allografts from alloimmunized female donors, prior occurrence of acute GVHD, and the use of peripheral blood mobilized stem cells versus bone marrow.^{110, 142, 143, 144} However, it should be noted that these analyses have utilized the historical definition for chronic GVHD, rather than the proposed NIH Consensus criteria for diagnosis and classification of chronic GVHD. These potential limitations are highlighted by the fact that a recent analysis did not demonstrate that these traditional risk factors for chronic GVHD development had association with severity of chronic GVHD.¹⁴¹

PROGNOSTIC VARIABLES

Previously reported prognostic variables include extensive involvement versus limited progressive onset of chronic GVHD from acute GVHD, platelet count less than 100,000/ μ l at chronic GVHD diagnosis, impaired performance status, and failure to respond to therapy.^{134, 145, 146, 147} In a recent large Center for International Blood and Marrow Transplant Research analysis, investigators examined prognostic factors to develop a chronic GVHD risk score in a sample of 5,343 chronic GVHD-affected patients. In this analysis, 10 variables were significantly associated in multivariate analysis with overall survival and nonrelapse mortality: age, prior acute GVHD, time from transplantation to chronic GVHD, donor type, disease status at transplantation, GVHD prophylaxis, gender mismatch, serum bilirubin, Karnofsky performance status, and platelet count. From these data, six risk groups were identified based on the number of risk factors present. Nonrelapse mortality at 5 years ranged from 5% in the lowest risk group to 72% in those with greatest risk. Similarly, 5-year overall survival ranged from 91% in the lowest risk group down to 4% in the greatest risk group ($P < 0.01$).¹⁴⁸ Moving forward, predictive variables for long-term outcome need to be examined based on current transplantation practices and in the setting of the revised diagnostic and severity grading criteria. Analyses performed to date from the Chronic

P.2215

GVHD Consortium support both the NIH overall severity,¹⁴¹ and the overlap subtype of chronic GVHD¹⁴⁰ as significant determinants of overall survival and nonrelapse mortality.

PREVENTION OF CHRONIC GRAFT-VERSUS-HOST DISEASE

Successive advances in pharmacologic prophylaxis strategies for acute GVHD prevention have led to more effective reduction in grade II-IV and grade III/IV acute GVHD. Inasmuch as severe acute GVHD, especially that refractory to standard first-line steroid therapy, results in significant mortality, these approaches represent major breakthroughs in reduction of early transplant-associated complications and mortality. However, these benefits in acute GVHD prevention have largely not resulted in reduction in chronic GVHD. Randomized phase III trials in matched sibling and unrelated donor HSCT supported the superiority of tacrolimus/methotrexate over cyclosporine (cyclosporine)/methotrexate for prevention of acute GVHD, but did not result in reduction of the incidence of chronic GVHD.^{67, 68} Similarly, single-center phase II trials examining the combination of sirolimus/tacrolimus,¹⁴⁹ as well as a comparative trial of mycophenolate mofetil/tacrolimus versus methotrexate/tacrolimus⁷⁰ have not shown major benefit in chronic GVHD prevention when methotrexate is replaced with alternative agents.

The optimal duration of immune suppression administration is not known, however, and chronic GVHD can often arise during or after discontinuation of immune suppression. Thus, several investigators have explored whether prolonged administration of immune suppression may reduce the risk for chronic GVHD. Some reports indicated decreased risk with prolonged administration of cyclosporine,^{150, 151} however, prospective trials have not consistently demonstrated a benefit. In a randomized trial of allogeneic related or unrelated marrow transplant recipients, the hazard for chronic GVHD did not significantly differ between 6 and 24 months of cyclosporine administration after transplantation.¹⁵² Others have demonstrated in peripheral blood stem cell grafts from matched related donors reduced incidence of chronic GVHD in those treated with 12 versus 6 months of cyclosporine after transplantation.¹⁵³ In the setting of nonmyeloablative conditioning, retrospective analysis did not demonstrate significant differences in extensive chronic GVHD between three tapering schedules.¹⁵⁴ Emerging data from a randomized trial comparing sirolimus/tacrolimus and methotrexate/tacrolimus suggests that prolonged administration of sirolimus through 1 year after transplantation may be associated with reduction in NIH moderate-severe chronic GVHD, however, further follow-up is needed.⁷⁷ Based on the rationale that alloreactive T cells are responsible for chronic GVHD development, investigators have pursued both in vivo and ex vivo strategies for T-cell depletion. Memorial Sloan Kettering Cancer Center published a phase II trial of ex vivo T-cell depletion employing CD34 enrichment by the Miltenyi device in 35 unrelated donor transplants.¹¹² The median CD3+ cell dose was 1.52×10^3 /kg. With no pharmacologic prophylaxis, the incidence of chronic GVHD was only 29%. Epstein-Barr virus-associated post-transplant lymphoproliferative disease occurred in 9% of the cases. With intense conditioning, the relapse incidence was low, 6% at 4 years, despite a largely advanced disease cohort. In addition, the BMT CTN 0303 trial confirmed the efficacy of this protocol in HLA-matched sibling donor transplantation ($n = 44$) for acute myeloid leukemia in first or second complete remission.¹¹¹ T-cell-depleted allografts contained a median CD3+ dose of 6.6×10^3 /kg. Without pharmacologic prophylaxis, extensive chronic GVHD was 6.8% (0% to 14.4%) at 24 months. With median follow-up of 34 months, the 36-month leukemia-free survival was 58%. These results demonstrate that subtotal depletion of donor T cells provides protection against chronic GVHD.

Investigators from Johns Hopkins have pioneered GVHD prophylaxis with post-transplant high-dose cyclophosphamide (50 mg/kg/d on days +3 and +4) based on its selective activity against alloactivated donor T cells.⁹¹ In a recent phase I/II Bayesian design trial ($n = 117$) including HLA-matched related or unrelated donors, T replete marrow was transplanted following myeloablative doses of busulfan and cyclophosphamide. With sole post-transplant cyclophosphamide prophylaxis, chronic GVHD incidence was only 10% with median follow-up of 26 months. These data suggest that targeting alloreactive donor T cells may reduce chronic GVHD risk and facilitate transplantation tolerance. Investigators from MD Anderson Cancer Center reported a higher risk for chronic GVHD using post-transplant cyclophosphamide prophylaxis after peripheral blood stem cell transplantation rather than bone marrow, however. In vivo strategies for T-cell depletion, including antilymphocyte antibodies such as ATG or alemtuzumab, have promise to reduce risk for chronic GVHD as well. Long-term follow-up from a randomized phase III trial comparing ATG-Fresenius versus placebo alongside cyclosporine/methotrexate standard prophylaxis demonstrated cumulative incidence of extensive chronic GVHD after 3 years of 12% in the ATG-Fresenius group versus 45% in the control group ($P < 0.0001$), with comparable incidence of primary disease relapse and nonrelapse mortality. The hazard ratio for receiving immunosuppressive therapy was 0.31 after ATG-Fresenius ($P < 0.0001$), and the 3-year probability of survival free of immune suppression was 53% and 17% in the ATG-Fresenius versus control.¹¹³

Finally, based on preclinical insights supporting the role of B cells in chronic GVHD pathogenesis, as well as activity of anti-CD20 therapy in steroid-refractory chronic GVHD, investigators have presented results of a single-center phase II trial of rituximab for chronic GVHD prevention.¹⁵⁵ There is also great interest in disruption of B-cell stimulatory signals (e.g., BAFF) after HSCT for prevention of chronic GVHD.

CHRONIC GRAFT-VERSUS-HOST DISEASE TREATMENT

Systemic immune suppressive therapy is generally required to control extensive chronic GVHD, or rather moderate to severe manifestations per the NIH Consensus severity grading. Those who have limited or mild chronic GVHD can often be treated with topical agents, such as artificial tears for ocular sicca; steroid mouth rinses for troublesome mouth symptoms such as dryness, sensitivity, or pain; topical steroid creams for mild cutaneous manifestations; or vaginal estrogen for vaginal dryness and atrophy. In total, the diverse manifestations of the syndrome require a tailored and multidisciplinary approach.

For those requiring systemic therapy, accepted standard primary therapy for chronic GVHD includes 1 mg/kg/day or greater of prednisone or equivalent with or without a calcineurin inhibitor.^{132, 156} A randomized trial comparing prednisone versus prednisone plus cyclosporine for primary therapy of extensive chronic GVHD did not detect significant differences in chronic GVHD control, transplant-related mortality, or overall survival, but showed less prednisone side effects in the combination arm.¹⁵⁶ Based on the limited durable response rates observed with standard primary therapy, several studies have been performed to determine whether combined therapy (i.e., steroids + additional systemic immune suppressive agent) improves response. The addition of other systemic immune suppressive agents has not provided benefit, as evidenced by trials employing azathioprine, thalidomide, hydroxychloroquine, or mycophenolate mofetil.^{157, 158, 159, 160}

Based on major published primary chronic GVHD therapy trials,^{156, 157, 158, 159, 160, 161} the following summarizes current evidence. Complete response rate assessed at 6 to 9 months following steroid-based therapy (either 1 mg/kg of prednisone alone or this in combination with additional agents such as azathioprine, thalidomide,

P.2216

hydroxychloroquine, or mycophenolate mofetil) includes a range of reported values from 16% to 37%. In the study by Sullivan et al., 9-month complete response rate to prednisone was 33%, prednisone + azathioprine 37%, and prednisone alone among high-risk cases 16%.¹⁵⁷ Arora et al. reported 6-month complete response rate of 17% in prednisone + thalidomide and cyclosporine, and 28% for prednisone and cyclosporine alone.¹⁵⁸ In a more recent trial comparing activity of prednisone versus prednisone and mycophenolate mofetil, Martin et al. reported a 6-month complete response rate of only 23%.¹⁶⁰ Finally, Gilman et al. reported CR rates at 9 months of 38% and 33%, respectively, for hydroxychloroquine + prednisone versus prednisone alone. Thus, available randomized trials suggest an average complete response rate at 6 to 9 months of 27%.

ORR (total of CR + PR) has been reported as the following. Sullivan et al., reported ORR of 62% among prednisone-treated patients, 64% for prednisone with azathioprine, and only 32% for prednisone-treated patients with thrombocytopenia.¹⁵⁷ Arora et al. reported ORR of 84% at 6 months for prednisone-treated patients and 88% for those treated with prednisone and thalidomide.¹⁵⁸ Martin et al. reported an ORR of 62% at 6 months for patients treated with prednisone + mycophenolate mofetil or prednisone + placebo.^{160, 162} Gilman et al. reported ORR at 9 months of 39% and 46% for hydroxychloroquine + prednisone versus prednisone alone.¹⁵⁹ Thus, published randomized trials support an average ORR at 6 to 9 months of 60%. Note that Martin et al. demonstrated that ORR at 6 months of therapy was significantly associated with the ultimate risk for treatment failure, defined as initiation of secondary systemic GVHD treatment, nonrelapse death, or development of bronchiolitis obliterans. The cumulative incidence of treatment failure was 37% versus 63% in those with overall response versus not, $P = 0.01$.¹⁶² Ongoing clinical trials aim to study targeted therapeutic approaches for specific chronic GVHD phenotypes [e.g., imatinib or rituximab for treatment of cutaneous sclerosis (NCT01309997) and fluticasone, azithromycin, and montelukast for treatment of bronchiolitis obliterans (NCT01307462)].

Based on limited response to primary therapy, many will go on to require additional immune-suppressive agents for chronic GVHD control. Steroid-refractory chronic GVHD has most commonly been defined as either progressive manifestations despite 1 month, or rather incomplete response despite 2 months of 1 to 2 mg/kg of prednisone or equivalent.¹³² Multiple immune-suppressive agents, including pharmacologic agents such as mycophenolate mofetil, sirolimus, pentostatin, tacrolimus, and thalidomide, monoclonal antibodies including rituximab, and strategies such as extracorporeal photopheresis have demonstrated moderate activity in this setting, both ameliorating objective chronic

GVHD manifestations, as well as facilitating decrease in systemic steroids.¹³² Their activity is incomplete, however, and many with steroid-refractory chronic GVHD will require multiple agents to achieve disease control.

Note that chronic GVHD is associated with prolonged immune suppressive therapy after HSCT. In an analysis of 751 patients with chronic GVHD, the cumulative incidence of discontinuation of immune suppression at 7 years following chronic GVHD diagnosis was 50%; nonrelapse mortality was 24%, and relapse was 19%. On multivariable analysis, several factors were associated with decreased likelihood of discontinuation of immune suppression: peripheral blood stem cells, female donor: male recipient, number of chronic GVHD sites involved, bilirubin > 2 mg/dl at diagnosis, HLA mismatch, and year of transplantation.¹³⁹

ASSESSMENT OF THERAPEUTIC RESPONSE

The established method for response determination in the majority of chronic GVHD therapy trials has been that of clinician-determined response. This method relies on the clinician's integration of dynamic chronic GVHD manifestations for a summary response categorization. CR indicates complete resolution of all chronic GVHD manifestations; PR signifies reduction in disease activity at response assessment compared to pre-treatment levels, but without complete resolution; stable disease indicates no response and no progression; and progressive disease indicates progressive chronic GVHD manifestations from baseline to response assessment.

Following the NIH Consensus Conference for Chronic GVHD, several additional means of response assessment in chronic GVHD therapeutic trials have been proposed. These include change in overall NIH severity categories, proposed NIH response criteria, 0-4 and 0-10 ordinal scales that rely on clinician assessment, organ-specific tools such as the Vienna skin scale, as well as patient-determined change in chronic GVHD activity, chronic GVHD-associated symptom burden, functional limitations, and change in quality of life. A national Chronic GVHD Consortium is currently assessing these competing measures of disease activity and their relationship to longer-reaching outcomes indicating clinical benefit, such as survival, discontinuation of immune suppression, and patient-reported benefit. One analysis recently reported demonstrates limited agreement between clinician-determined response and that calculated by the proposed NIH Consensus response criteria (Fig. 105.2)¹⁶³; thus, response rates reported in the literature need to be interpreted with attention to the response metric utilized.

SUPPORTIVE CARE

Patients with chronic GVHD require careful supportive care and infectious prophylaxis. Given the immune dysfunction associated both with chronic GVHD as well as the immune-suppressive agents used to treat it, they are at increased risk for morbidity and mortality from infectious complications. Prophylactic antimicrobials should be utilized to prevent *Pneumocystis jirovecii*, encapsulated bacterial infections such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*, and *Varicella zoster*.¹⁶⁴ Systematic monitoring and pre-emptive therapy for cytomegalovirus reactivation is also important. The routine use of antifungal agents as prophylaxis beyond 75 days after transplantation has not been proven to be effective in preventing invasive fungal infections; however, many administer these agents for prophylaxis, particularly in those patients on prolonged courses of glucocorticoids. The use of intravenous immunoglobulin following HSCT has not been proven to be of benefit.¹⁶⁵ Other important components of supportive care include vaccination once appropriate after transplantation, skin care, oral cavity health and symptom control, management of ocular sicca symptoms, supportive care for vulvovaginal manifestations of GVHD, physical therapy for musculoskeletal impairment, prevention and management of osteopenia and osteoporosis, management of fatigue, and psychosocial support. A comprehensive review of appropriate, evidence-based ancillary care has been published.¹⁶⁴

CONCLUSION

In summary, investigation into chronic GVHD pathogenesis, diagnosis and classification, and therapy offers promise for improved patient outcomes. Insights into chronic GVHD biology will provide novel strategies for prevention and therapy. Validation of the proposed NIH Consensus diagnostic and severity classification criteria, as well as determination of best-response criteria will move the state of chronic GVHD clinical trials forward. Novel preventive and therapeutic strategies based on detailed understanding of chronic GVHD pathogenesis will advance the field.

GRAFT-VERSUS-TUMOR RESPONSE

Evidence for Graft versus Tumor in Animals and Humans

Multiple lines of evidence point to a powerful immune response of donor immune cells against tumor cells after allogeneic HSCT. Initial proof of principle for an allogeneic GVT effect was established in rodents.^{166, 167} Single-center and registry studies found an inverse correlation between acute and chronic GVHD and relapse of malignancy after human marrow transplantation (Fig. 105.3).^{168, 169} The probability of relapse was higher after twin compared to HLA-identical sibling transplants, pointing to disparate mHA as the target of the GVT effect. Similarly high was the probability of relapse after a T-depleted allogeneic transplant, pointing to mature donor T cells as GVT effectors. There was protection from relapse after a T-replete allogeneic HSCT in patients without history of GVHD, indicating that GVHD is not required for the GVT effect. Lower relapse rates, however, were in patients who had experienced acute GVHD, and the lowest in those with chronic GVHD. As shown in Figure 105.3, the GVT effect in allogeneic recipients with GVHD did account for about half of the total antitumor activity of the transplant procedure, thus GVT was as effective as the high-dose chemoradiotherapy administered before the transplant. Allogeneic HSCT after safer, low-intensity conditioning regimens, are also associated with durable responses in some malignancies.¹⁷⁰ As immune-suppressive therapy to prevent or treat GVHD also affects GVT responses, spontaneous remissions have been observed after stopping immune suppression in a variety of hematologic malignancies that had relapsed after allogeneic HSCT.¹⁷¹ Direct evidence for a GVT effect was provided by infusion of donor lymphocytes for sole treatment of relapse after allogeneic HSCT (Table 105.4).¹⁷² Response to donor lymphocyte infusions occurs after allogeneic transplants but not twin transplants, as disparate histocompatibility antigens are the GVT targets, and require stable donor engraftment, although it does not help

P.2218

patients who have rejected the graft. Donor lymphocytes are most effective in patients who have received a T-depleted graft, in those who have not already experienced GVHD, in chronic more than acute leukemia, and in patients with minimal tumor burden.¹⁷³

FIGURE 105.3. Actuarial probability of relapse after bone marrow transplantation for early leukemia according to type of graft and development of graft-versus-host disease (GVHD). AGVHD, acute GVHD; CGVHD, chronic GVHD. From Horowitz MM, Gale RP, Sondel PM, et al. Graft-versus-leukemia reactions after bone marrow transplantation. *Blood* 1990;75:555-562.

TABLE 105.4 EVIDENCE FOR A GRAFT-VERSUS-TUMOR RESPONSE

1. Allogeneic but not syngeneic marrow transplants can cure mice with leukemia.
2. Allogeneic marrow transplants are more effective than twin transplants in preventing leukemia relapse in humans.
3. Patients with graft-versus-host disease are more likely to be cured from leukemia than those without graft-versus-host disease.
4. Spontaneous remissions occur after stopping immune suppression in patient with relapsed malignancy after allogeneic marrow transplantation.
5. Donor lymphocyte infusions induce remission in patient with relapsed malignancy after allogeneic marrow transplantation.

T-cell-mediated Graft versus Tumor

Infusions of isolated CD4 or CD8 donor T cells for treatment of relapse have demonstrated that each of these cell types can mediate GVT.^{174, 175} The predominant GVT targets are mHA expressed in the recipient's malignant cells. As discussed under the "ACUTE GRAFT-VERSUS-HOST DISEASE" section, mHAs can be expressed ubiquitously (including, e.g., skin and leukemia) and are therefore targets for both GVHD and GVT (i.e., the H-Y associated male antigens), or their expression can be restricted to one or more hematopoietic lineages so they are targets for GVT but not GVHD (e.g., HA-1 and HA-2 antigens). Little is known about most mHAs, because diversity assessment of the human genome predicts over 107 polymorphisms that can function as mHAs in transplantation. A variety of genetic techniques have sped up the discovery of functional mHAs, and investigators hope to find a relatively small number of dominant mHAs that can be targeted for prevention of GVHD and exploitation of GVT.¹⁷⁶ Weaker immune targets are a variety of tumor-associated antigens that by themselves are not sufficiently immunogenic to elicit a protecting immune response, but in conjunction with the adjuvant

effect of an allogeneic transplant can contribute to the GVT effect. These include the following: (1) tumor-specific antigens that result from the oncogenic mutations such as the Bcr/Abl tyrosine kinase in chronic myeloid leukemia, and the promyelocytic leukemia/retinoic acid receptor- α transcription factor in promyelocytic leukemia; (2) viral proteins, such as those from human papilloma virus in cervical cancer; (3) tissue-specific proteins, such as prostate-specific antigen in prostate cancer and proteinase-3 in myeloid leukemias; (4) germ-cell antigens, such as the melanoma-associated antigen (MAGE) family; (5) tumor-selective overexpressed self-proteins, such as WT1 in Wilms tumor or acute myeloid leukemia. Proteinase-3-derived PR1 peptide and WT1 are the best characterized tumor-associated antigens in patients after allogeneic HSCT.^{177, 178} Initial attempts have been made to amplify tumor immunity after allogeneic HSCT by vaccines.¹⁷⁹

Natural Killer-cell-mediated Graft versus Tumor

As disparate HLA molecules are strong GVHD targets, one may expect that they would also be GVT targets for T cells. In contrast, most studies have failed to detect a GVT effect of HLA mismatch in T-replete transplants.^{180, 181} One hypothesis is that GVHD is so forceful after T-replete transplants from HLA-incompatible donors, that the required immune suppression may dissipate any possible appearance of GVT. Most HLA-incompatible transplants are performed nowadays with ex vivo or in vivo T-cell depletion. Early recovery of functional NK cells after T-depleted transplants from HLA-incompatible related donors has unveiled a powerful effect against myeloid leukemia without GVHD. NK-cell alloreactivity has been related to a reduced risk of leukemia relapse, no GVHD, and markedly improved survival in HLA disparate transplants.^{182, 183} For patients with acute myeloid leukemia in remission, the cumulative incidence of relapse was significantly lower after transplantation from NK alloreactive donors (3% vs. 47%; $P < 0.003$), and this translated into an improved event-free survival (67% vs. 18%; $P = 0.02$). For patients in relapse at the time of HSCT, donor NK-cell alloreactivity was not protective. Based on these data, donor NK alloreactivity against recipient cells has become a selection criterion for HLA-disparate donors when a T-depleted protocol is employed. To this purpose, high-resolution HLA-C typing is a good predictor of NK-cell alloreactivity, because the basis for NK allorecognition resides primarily in a bi-allelic system of inhibitory killer-cell Ig-like receptors (KIR) that silence NK effector function after recognition of their cognate ligands encoded by HLA-C alleles.¹⁸⁴ KIR2DL1 recognizes HLA-C molecules characterized by a Lys80 residue (i.e., HLA-Cw4), and KIR2DL2 and KIR2DL3 recognize HLA-C with an Asn80 residue (i.e., HLA-Cw3). Also, KIR3DL1 is the receptor for HLA-B alleles that include a Bw4 domain and the CD94/NKG2A heterodimer (encoded by the KLRD1/KLRC1 genes) is an inhibitory receptor for HLA-E. During development, HLA class I molecules select for a self-tolerant KIR repertoire so that every mature NK-cell expresses at least one inhibitory receptor for self-HLA. NK cells that express a KIR for the class I group absent on allogeneic targets, sense the missing expression of self-class I HLA and kill the allogeneic target ("missing self" model). The alternative "missing ligand" model has also been proposed to predict protection from relapse after HLA-matched sibling transplants.¹⁸⁵ When KIR ligand-matched donors possess anergic NK cells with an "extra" KIR for which neither donor nor recipient has an HLA ligand, upon transfer into the recipient, those NK-cells may regain competency and produce a GVT effect.¹⁸⁶ Activating KIRs regulate both NK- and T-cell functions. Unlike inhibitory KIRs, activating KIRs exhibit extensive population variation in gene number and content. Transplantation from donors carrying activating KIR genes is associated with improved control of leukemia relapse after unrelated donor transplantation.¹⁸⁷ Several biological models suggest that alloreactive NK-cells are responsible for favorable transplantation outcomes. Transfer of human alloreactive NK-cells into immune-deficient mice eradicated human myeloid leukemia.¹⁸³ KIR ligand mismatches correlate with the ability of donor NK-cell clones to kill recipient leukemic cells.¹⁸³ Alloreactive NK clones are detected in the recipients long after transplant.¹⁸⁸

Conclusions

HSCT from allogeneic donors provide powerful GVT effects, via innate and adaptive immunity. The most recent effects of these findings have been: (1) decreased reliance on the use of toxic and sometimes lethal conditioning regimens to control leukemia; (2) use of donor lymphocyte infusion for prevention or treatment of relapse; (3) development of tumor vaccines to amplify the immune response after T-replete transplants; (4) selection of NK alloreactive, HLA-incompatible donors to decrease relapse of myeloid leukemias after T-depleted transplants.^{189, 190} We anticipate that further understanding of the factors that regulate GVT will continue to shape the protocols for allogeneic HSCT.¹⁹¹

Chapter 106 Late Effects After Transplantation

INTRODUCTION

Allogeneic hematopoietic cell transplantation (HCT) provides curative therapy for a variety of diseases. Over the past several decades, significant advances have been made in the field of HCT, and now HCT has become an integral part of treatment modality for a variety of hematologic malignancies and nonmalignant diseases. Historically, the limitation of HCT has been transplant-related mortality (TRM). In order to offer the curative HCT treatment option to most patients, safer regimens with acceptable graft-versus-host-disease (GVHD)-associated morbidity and TRM are preferred. The development of less toxic pretransplant conditioning regimens, more effective prophylaxis of GVHD, improved infection control, and other advances in transplant technology have resulted in a rapidly growing number of transplant recipients surviving long-term free of the disease for which they were transplanted.^{1, 2}

Since its introduction in the early 1970s the number of patients who undergo HCT for a variety of malignant and nonmalignant disorders has increased steadily and, today, nearly 60,000 allogeneic HCT are performed worldwide annually,^{1, 3, 4, 5} a number that has been increasing yearly. With broadening indications, more options for HCT, and improvement in survival, by 2020 there may be up to half a million long-term survivors after allogeneic HCT worldwide.⁶ In this era, a stem cell source can be found for virtually all patients who have an indication to receive HCT. Since 2007, more allo-HCT procedures have been performed using alternative donor stem cell sources, such as volunteer unrelated donors (URD) or cord blood, than related donors.^{5, 7} Haploidentical-related donor or cord blood transplantations (CBT) have emerged as alternatives to fill the gap for those patients who do not have matched related donors or URD, and the outcome of these types of transplantations are expected to be better than chemotherapy alone or even better than autologous-SCT for selected indications. All these result in a steady increase in numbers of long-term survivors after HCT, creating an enlarging pool of children, youth, and mature adults at risk for long-term complications of HCT.

Many patients who recover from immediate posttransplant problems eventually regain health and return to normal activities of life. For those who survive 2 or more years post-HCT, the prospect for long-term survival is excellent (85% at 10 years after HCT). Yet, among long-term survivors, mortality rates are 4- to 9-fold higher than observed in an age-adjusted general population for at least 30 years after HCT, yielding an estimated 30% lower life expectancy compared with someone who has not been transplanted.⁸ The most common causes of excess death other than recurrent malignancy are chronic GVHD (cGVHD), infections, second malignancies, respiratory diseases, and cardiovascular diseases (CVDs).^{3, 6, 8, 9, 10}

cGVHD is a multisystem chronic alloimmune and autoimmune disorder that occurs later after HCT. It is characterized by immune dysregulation, decreased organ function, significant morbidity, and impaired survival. Approximately 10% to 30% of patients require continued immunosuppressive treatment because of cGVHD beyond 5 years after HCT.^{8, 11} Therefore, it is not surprising that cGVHD, corticosteroid, and other immunosuppressive therapies are major contributors to late complications after HCT.

With survivorship, a shift in survivorship care occurs from large transplant centers to community health care providers. As a result, many hematologists/oncologists and primary care physicians are assuming the post-HCT care of late effects. Preventive measures as well as early detection and treatment are important aspects to reducing morbidity and mortality. This chapter focuses on the essentials of diagnosis, screening, treatment, and long-term surveillance of survivors after HCT.

CARDIOVASCULAR EVENTS AND METABOLIC SYNDROME

CV causes are not only the leading contributor to mortality in the general population but also impact the health of long-term transplant survivors.¹² CV morbidity and mortality is typically latent in the early survivorship period because of the younger age and superior performance of transplant candidates. Nevertheless, there is growing data suggesting that traditional CV risk factors are elevated in long-term survivors, and that risk factor elevation is persistent and eventually results in premature CV events. CVD manifests as coronary artery disease/events, cerebrovascular disease/events, or peripheral vascular disease/events. Susceptible patients need to be identified early, and screened for modifiable risk factors with early intervention where possible.

Cardiovascular Events

Tichelli et al. were the first to show that CV events occurred prematurely in transplant survivors (median age 49 years), albeit at a long interval after transplantation, with the cumulative incidence of late CVD being 22% at 25 years (Fig. 106.1).¹³ Interestingly, allogeneic HCT recipients were significantly more likely to have arterial events than autologous transplant recipients. The Late Effects Working Group of the European Group for Blood and Marrow Transplantation (EBMT) found a cumulative CV event incidence of 6% at 15 years.⁹ In a matched cohort study of 1,491

P.2222

long-term survivors, transplant recipients experienced increased CV mortality (adjusted incidence rate difference, 3.6 per 1,000 person-years; 95% CI, 1.7 to 5.5) with increased cumulative incidence of ischemic heart disease, cardiomyopathy or heart failure, stroke, vascular diseases, and rhythm disorders.¹⁴

FIGURE 106.1. The cumulative incidence of cardiovascular events at 15 years, adjusted for age. (From Tichelli A, Bucher C, Rovo A, et al. Premature cardiovascular disease after allogeneic hematopoietic stem cell transplantation. *Blood* 2007;110:3463-3471.)

Disease Spectrum

Coronary artery disease and/or CV accidents are much more common than isolated peripheral artery disease. In a case control study of 63 patients with late CV disease, 44 subjects had coronary artery disease, and 19 had cerebrovascular diseases. Thirty-four of these 63 patients with CVD died, 31% of them from a CV event.¹⁵ Furthermore, CVD may contribute to chronic ill health seen in long-term survivors. The magnitude of chronic illness in a study of 1,022 HCT survivors was 59% at 10 years after HCT and increased in comparison to their sibling controls.¹⁶

Cardiovascular Risk Factors

Traditional CV risk factors include male gender, family history, dyslipidemia, diabetes mellitus, obesity, hypertension, chronic kidney disease (CKD), and smoking. In addition, transplant survivors have unique risk factors such as exposure to ionizing radiation, immunosuppressant use (including steroids), and endocrinopathies.

CV risk factors generally increase with age and it is difficult to attribute the emergence of new CV risk factors to the transplant process itself without a good control population. A clear increase in the incidence of diabetes and hypertension was seen in a study of 1,022 HCT survivors, with the incidence of CVD being 3-fold that of their sibling controls.¹⁶ In a cross-sectional study, HCT survivors had a 2.2-fold increase in the prevalence of metabolic syndrome, a clustering of CV risk factors characterized by abdominal obesity, dyslipidemia, hypertension, and elevated fasting glucose, compared to age- and gender-matched controls.¹⁷ In a long-term study (17.5 years median) of 44 pairs of recipients and their respective donors after HCT, recipients were more likely to have hypertension ($P = 0.015$), dyslipidemia ($P = 0.002$), lower glomerular filtration rates (GFRs) ($P < 0.0001$) and reduced thyroid function ($P = 0.002$).¹⁸ The occurrence of dyslipidemia is a function of age and immunosuppressive treatment. Dyslipidemia appears to play a central role in the elevated CVD risk after HCT.¹⁹ De novo dyslipidemias may even impact a pediatric population.²⁰

Pathobiology

The factors leading to persistent elevation of CV risk in HCT survivors long after cessation of immunosuppression remain unclear. Residual effects from radiation, endocrine dysfunction (including steroid exposure, hypogonadism, hypothyroidism, and growth hormone deficiency), and endothelial damage have been implicated.

Chest irradiation is a validated cause of CV mortality. Extrapolating from the CV impact of chest irradiation in nontransplant populations with malignancy, it is reasonable to suspect that the use of total body irradiation (TBI) in transplant conditioning contributes to increased CVD risk, but this remains to be proven in a well-controlled study. Pretransplant chest radiation exposure was associated with a 9.5-fold higher risk of CVD.¹⁵

Hypothyroidism is a frequent late effect in transplant survivors and is related to conditioning with TBI and prolonged cGVHD.²¹ Hypothyroidism may affect ~30% to 40% of survivors, is often subclinical in presentation, and is strongly linked to dyslipidemias. Gonadal dysfunction will occur in the majority of transplant survivors and is linked to conditioning intensity and recipient age. Endocrinopathy and metabolic syndrome are strongly associated with gonadal dysfunction.²² In males, metabolic syndrome and low androgen levels are strongly correlated,²³ and in females, estrogens are necessary for maintenance of CV health.^{24, 25} In a series of 109 long-term allogeneic HCT survivors, CV risk factors were significantly elevated in males but not in females who were all recipients of hormonal supplementation.²⁶ Relative growth hormone deficiency may be a factor in adult and pediatric transplant survivors. Growth hormone deficiency in adults leads to insulin resistance and is characterized by dyslipidemias and hypertension.²⁷ Pediatric survivors of cancer treatment and HCT are particularly sensitive to the metabolic consequences of impaired growth hormone secretion.^{22, 28}

Leptin is an adipokine responsible for regulating food intake and energy metabolism. Hyperleptinemia has been implicated as the pathobiologic link between transplant and metabolic syndrome.^{29, 30} Vascular endothelium may be the target of damage by radiation exposure and by alloreactivity (e.g., GVHD). Radiation has a dose-dependent impact on vasculature and endothelium in animal models. In a rodent model, TBI with 10 Gy injured coronary microvasculature, and altered endothelial physiology and myocardial mechanics.³¹ Host endothelial cells are a target of alloreactive donor cytotoxic T lymphocytes, and chronic skin GVHD is characterized by the progressive loss of microvessels.³² cGVHD is also characterized by elevations in von Willebrand factor,¹⁸ which may be released by endothelial injury. Chronic hypomagnesemia is common early after transplantation³³ and is known to induce insulin resistance, diabetes, and metabolic syndrome. However, its precise impact on CV risk, if any, requires confirmation.

Management of Cardiovascular Risk

Since the burden of CV risk in transplant survivors has been poorly defined till now and CV events occur late, management of CV risk has often been a low priority. In a recent cross-sectional study of 86 adult survivors at a median of 3 years from HCT, 25% of cases with hypertension, 17% with abnormal glucose metabolism, and 60% with dyslipidemia were

untreated.¹⁷ Current guidelines suggest a central role for transplantation centers in counseling primary health providers on screening and prevention.³⁴

The management focus should be on modifiable CV risk factors: lifestyle (diet, smoking, and activity), obesity, diabetes, dyslipidemias, hypertension, hypothyroidism, hypogonadism, and other endocrinopathy. Dyslipidemias may be the most important driver of CV risk and are susceptible to therapy.²⁶ The management of CV risk in transplant survivors is an evolving effort, but expert guidelines are now available.^{6, 12, 19} Table 106.1 summarizes the approach to the hyperlipidemia in long-term survivors after HCT.

SECONDARY MALIGNANCIES

The risk of second malignancies as an important late effect after HCT was first recognized in the early 1990s. As the age and life expectancy of survivors continue to rise, second malignancies are expected to become an increasingly common complication.³

Secondary malignancies following HCT are commonly categorized into one of three histologic types: leukemia, lymphoma, and solid tumors.³⁵ However, these disorders have distinctive chronology. Secondary leukemia generally occurs at a median of 6.7 months after auto-SCT, lymphoma at a median of 2.5 months, while the median time to development of solid tumors lies between 5 and 6 years.³

Risk of Second Malignancies and Risk Factors

Based on large retrospective analyses, the cumulative incidence of solid tumors following HCT ranges between 1.2% and 1.6% at 5 years, 2.2% and 6.1% at 10 years, and from 3.8% to 14.9% at 15 years post-HCT.^{36, 37, 38, 39} The incidence rate does not plateau; rather, there is a steady increase over time.³⁹ Second cancers are

P.2223

a very important contributor to late nonrelapse mortality (NRM) in patients who survive more than 2 to 5 years posttransplantation, accounting for 5% to 10% of such deaths.^{8, 40, 41} And, in a recent study of 28,874 HCT survivors, the incidence of new solid tumors was double that of an age- and gender-matched general population.³⁹ The risk increased over time, reaching 3-fold among patients followed for 15 years or more after transplantation.

TABLE 106.1 APPROACH TO LIPID MANAGEMENT IN HCT PATIENTS

Evaluation

Obtain fasting lipid profile prior to transplantation

Evaluate CVD Risk

1. If patient has CVD or CVD risk equivalent, then manage as high-risk with appropriate therapy to reach LDL goal
 - a. Option to consider allogeneic HCT patients age 40 or older as high-risk
2. Otherwise, calculate 10-y risk with online risk assessment tool (www.nhlbi.nih.gov) and manage LDL per ATP-III Guidelines

Monitor lipid profiles after HCT

1. Check lipid profile within 4 wk after HCT then at least every 3 mo for patients on IST
2. For patients at treatment goal on stable therapy every 6-12 mo as indicated, or after significant change in IST regimen in patients with dyslipidemia
3. If patients develop significant dyslipidemia after HCT compared to baseline, consider secondary causes of dyslipidemia (IST, diabetes, hypothyroidism)
4. Even patients without dyslipidemia should have lipids monitored every 1-2 y after allogeneic HCT, given increased CV risk

Management

If patient has high CVD risk (>20% 10-y risk), treat dyslipidemia with appropriate agent(s) to meet

LDL goal, but monitor clinically if on IST or renal dysfunction

In patients with low (<10%) or moderate CVD risk (10-20%), consider drug treatment based upon severity of dyslipidemia, estimated prognosis post-HCT, and risks of lipid drug therapy (if on long-term IST for GVHD)

1. Patients with low CVD risk that develop moderate secondary dyslipidemia on IST can be managed conservatively, if IST will be tapered off
2. Patients with low to moderate CVD risk that develop severe hypertriglyceridemia (>500 mg/dl) should be treated to prevent pancreatitis

Consider referral to a lipid specialist for the following:

1. Severe dyslipidemia (total cholesterol > 300 or LDL > 180, triglycerides > 500-1,000)
2. Patients with dyslipidemia refractory to treatment and not meeting goals
3. Patients with intolerance or contraindications to lipid lowering therapy
4. Patients requiring combination lipid therapy, particularly in setting of IST
5. Patients needing individualized CV risk assessment due to strong family history of premature CVD or other factors

ATP-III, adult treatment panel-III; CV, cardiovascular; CVD, cardiovascular disease; GVHD, graft-versus-host-disease; HCT, hematopoietic cell transplant; IST, immunosuppression therapy; LDL, low density lipoprotein.

Pathobiology

The process of malignant transformation of secondary solid tumors after HCT is not well understood but multiple factors have been implicated.⁴² These include exposure to TBI, primary disease, male sex, and pretransplantation therapy. The risk of developing a nonsquamous cell cancer (SCC) is associated with younger age at transplantation and the use of radiation in the conditioning regimen. Radiation is also a known significant risk factor for the development of several other solid tumors, particularly cancers of the breast, thyroid, brain, central nervous system, bone and connective tissue, and melanoma; and screening is available for some of these tumors.^{10, 42} For the majority of these sites, risks are greater among those who survived 5 or more years after initial radiotherapy, in keeping with the latent period typical for radiation-related solid cancers.^{8, 10, 40, 43}

cGVHD and immunosuppressive therapy (IST) are associated with SCC of the skin and mucosa.^{43, 44, 45} A particularly high-risk was observed in the 1 to 4 year interval after HCT, which remained elevated among long-term survivors. Duration of IST, and particularly prolonged exposure to azathioprine, has been associated with development of SCC.⁴⁶

Several oncogenic types of human papillomavirus (HPV) have been implicated in the etiology of SCC of the female genital tract and head and neck, and may play a role in HCT-associated SCC.^{46, 47} Certainly, some inherited genetic polymorphisms have been reported to increase the risk of malignancies in patients who received alkylating agents either as pretransplant chemotherapy or as part of the conditioning regimen.⁴⁸

Types of Secondary Solid Cancers

In a 2009 registry data study, 189 new cancers were found in 28,874 HCT recipients who underwent long-term follow-up.³⁹ The average age at HCT was 27 years, and 67% received TBI as part of their conditioning regimen. The findings demonstrated that the risk of developing a nonSCC was dependent on the age at exposure to conditioning radiation. The relative risk of nonSCC for patients irradiated at ages <30 years was 9-fold that of nonirradiated patients, while the comparable risk for older patients was 1.1. cGVHD and male gender were the main determinants for the risk of SCC. The oral cavity, salivary glands, liver (prior hepatitis C exposure), skin, brain, breast, thyroid, and bone/connective tissue were the sites with a significant increase in secondary malignancy. These data indicate that HCT survivors, particularly those irradiated at young ages, face increased risks of solid cancers, supporting strategies to promote lifelong surveillance among these patients.

The risks of secondary solid cancers in HCT survivors who have not received irradiation are not well understood and deserve further study, because radiation-free conditioning regimens are being more frequently utilized. When

chemotherapy alone is used for conditioning, the rates of solid tumors are still increased, as evidenced by a report examining solid tumor incidence in survivors who underwent high-dose busulfan-cyclophosphamide conditioning. In this study of 4,318 patients who received HCT for AML and CML, the cumulative incidence of solid tumors at 5 and 10 years after HCT was 0.6% and 1.2% for AML, and 0.9% and 2.4% for CML patients. The recipients had invasive solid cancers at a rate that was 1.4 times higher than expected in the general population.⁴⁹ Sites with a significant increase in secondary malignancy included the oral cavity, esophagus, lung, soft tissue, and brain. cGVHD was found to be an independent risk factor for all solid cancers. Recipients of HCT using busulfan-cyclophosphamide conditioning are thus similar to TBI in the risk for developing solid cancers.

Diagnosis, Screening, and Prevention

Since there is no plateau in the incidence curve of new malignancies, consensus guidelines call for lifelong surveillance, and early diagnosis and treatment.⁵⁰ Recommendations include the following: A. Recognition that radiation exposure and photosensitization by transplant medications increases the risk of skin malignancy, suggesting that survivors should protect against UV skin exposure by appropriate clothing or high-SPF sunscreen. B. Survivors should be reminded of the risks of secondary malignancies annually. Routine self-screening by breast and skin examination is to be encouraged, as is avoidance of high-risk behaviors, particularly all forms of tobacco use and unprotected UV exposure. C. Annual health screening should include symptom review for secondary malignancies. Screening mammography is recommended earlier than age 40 years for women exposed to radiation. Mucocutaneous involvement by GVHD increases the

P.2224

risk of malignant sequelae, and annual specialist examination (dermatologic, gynecologic, dental, or ENT) may be required.

Management

Successful management of second malignancies requires recognition of the special attributes of transplant survivors and close collaboration between the transplant center and the primary physician. Impaired hematopoietic reserve may be evident years after HCT and may manifest as prolonged myelosuppression after standard doses of cytotoxic agents or XRT. cGVHD management will often be a great challenge to treatment. Secondary SCC is biologically more aggressive, with frequent invasion beyond free surgical resection margins and metastasis to draining lymph nodes. Support should be provided for psychologic vulnerability in survivors facing a new diagnosis of malignancy.

LATE PULMONARY COMPLICATIONS

Lung injury is a frequent contributor to post-HCT morbidity and mortality.^{11, 51, 52} Pulmonary injury can be delayed, and the cumulative incidence of chronic pulmonary dysfunction in long-term HCT survivors ranges from 30% to 60%, depending on donor source and elapsed time from transplantation.^{11, 51} Bronchiolitis obliterans syndrome (BOS) is the most frequent and potentially lethal noninfectious pulmonary complication. BOS is now considered one of the diagnostic criteria for defining cGVHD by the NIH consensus report.^{52, 53} It is characterized by an insidious onset, high morbidity and mortality, and is typically accompanied by other manifestations of cGVHD. Much knowledge of BOS has been borrowed from the field of lung transplantation, in which BOS impacts more than half of the long-term survivors and is the major contributor to morbidity and mortality.⁵⁴

Pathophysiology

Airway narrowing in BOS is mostly in the small airways, the terminal and respiratory bronchioles, with an internal diameter <2 mm. These small airways can be considered parallel high-resistance conduits which account for the vast majority of the total airway volume and the cross-sectional area. Small airway damage must be extensive and 45% of the terminal bronchioles need to be lost before impacting the forced expiratory volume 1 (FEV1) or FEV1/FVC ratio. Furthermore, small airway obstruction may have less effect on lung mechanics than on ventilation distribution.^{55, 56}

Prevalence, Clinical Presentation, and Diagnosis

Recent prevalence estimates suggest that BOS is often underdiagnosed and that 14% of all long-term survivors with cGVHD may develop BOS. BOS is difficult to diagnose, may already be severe by the time the patient complains of symptoms, and is not easy to reverse.

Clinically, patients present with dyspnea on exertion, decreased exercise tolerance, or nonproductive cough, with their degree of symptomatology paralleling their degree of obstruction on pulmonary function testing (PFT). BOS usually occurs within the first 2 years, but may develop as late as 5 years after allo-HCT. Reliance upon symptoms for diagnosis can be

dangerous, because once symptoms are apparent the extent of airflow obstruction may not only be significant (FEV1 < 40% predicted), but the process may be irreversible. With routine screening spirometry, BOS is often diagnosed on the basis of new airflow obstruction even before the patient is symptomatic.

BOS is diagnosed by demonstration of a fixed airflow obstruction that is defined as: (1) decreased 1-second FEV1 <75% of predicted, and evidence of airway obstruction as demonstrated by FEV1/forced vital capacity ratio of <0.7 on PFT; (2) signs of air trapping by PFT as shown by residual volume >120% of predicted, or evidence of air trapping on computed tomography or lung biopsy; (3) absence of acute respiratory infection; and (4) another manifestation of cGVHD in an additional organ system if no histologic evidence of BOS can be demonstrated.^{52, 55}

Early identification strategies, borrowed from the field of lung transplantation, utilize serial testing of the extent of FEV1 decline from pretransplantation baseline. Early onset of BOS can have worse outcomes than late-onset BOS, suggesting that these are two distinct clinical entities that may warrant different treatment approaches.^{52, 55} There is growing awareness that patients with BOS have high mortality rates regardless of therapy, suggesting the need for early identification, preemptive treatment, and novel approaches.⁵⁷

Prophylaxis of Chronic Graft-versus-host-disease and Bronchiolitis Obliterans Syndrome

cGVHD can be a significant complication of HCT impacting up to 80% of patients receiving alternative donor grafts. cGVHD is independently associated with late pulmonary complications and BOS is strongly associated with cGVHD.^{11, 57} It has been reported that the administration of antithymocyte globulin (ATG) during the conditioning regimen or early after transplant, in addition to the conventional GVHD prophylaxis, can reduce the incidence and the severity of subsequent cGVHD.^{56, 58} The magnitude of reduction is ~ 20% or greater for both aGVHD grade II-IV and cGVHD.⁵¹ In comparison to those who did not receive ATG, the incidence of cGVHD was reduced from 60% to 37% (P = 0.05), and extensive cGVHD reduced from 41% to 15% (P = 0.01). Significantly, the cumulative incidence of chronic lung dysfunction was reduced from 51% to 19% (P = 0.005). Further incentive for using ATG has been found in the conclusions of prospective randomized trials with ATG, which suggest that prevention of cGVHD is possible without significantly interfering with the graft-versus-malignancy effect and may result in wider use of ATG.

Management of Bronchiolitis Obliterans Syndrome

Systemic Glucocorticoids

The mainstay of therapy has been systemic IST including high-dose corticosteroids, CSA, azathioprine, and ATG with the intent of general control of cGVHD. Sullivan et al.⁵⁹ first described in 1981 use of prednisone along with azathioprine in a series of 52 patients with cGVHD as effective therapy. Since then, systemic high-dose corticosteroids have been thought to be the most efficacious treatment in cGVHD. Ratjen et al.⁶⁰ showed improvement in FEV1 with 7 of 9 patients in the pediatric population after HCT with clinical stability following treatment with high-dose methylprednisolone for BOS. Despite the unfavorable side-effect profile and the absence of strong evidence, systemic glucocorticoids remain the recommended first-line therapy (dosage varies from 0.1 to 1 mg/kg/day—depending on severity) for patients diagnosed with BOS (Table 106.2).

Inhaled Corticosteroids

Inhaled corticosteroids may optimize local delivery while abrogating the risks of systemic corticosteroids in the treatment of BOS. Bashoura et al.⁶¹ used fluticasone-propionate in patients with BOS after HCT and reported stabilization or improvement in FEV1 after 3 to 6 months of treatment in 16 of 17 patients. Similarly, Bergeron et al.⁶² reported improvement in symptoms as well as in FEV1 at 3 to 6 months posttherapy using a combination of budesonide and formoterol. This strategy has yet to be evaluated in a prospective

P.2225

randomized controlled manner, but the potential to deliver high doses of steroid therapy in the inhaled modality is a promising method of improving treatment without the systemic risks.

TABLE 106.2 AVAILABLE THERAPEUTIC OPTIONS FOR BOS AFTER ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION (HCT)

Agent	Mechanism of Action
Systemic corticosteroids	Systemic immunosuppression

Inhaled corticosteroids	Localized antiinflammatory
Calcineurin inhibitors	Systemic immunosuppression
Mycophenolate mofetil	Inhibits fibroblast proliferation
mTOR inhibitors (e.g., sirolimus)	Inhibits fibroblast proliferation
Azithromycin	Macrolide antibiotic Impairs neutrophilic inflammation ? prokinetic GI properties leading to reduction of GERD
Montelukast	Leukotriene receptor antagonist Reduces bronchoconstriction, eosinophilic and neutrophilic recruitment
Extracorporeal photopheresis	Mechanism not understood Involvement of regulatory T cells
Imatinib	Antifibrinogenic
Rituximab	Inhibits B cell proliferation (Anti-CD20 antibody)
Inhaled cyclosporine	Local immunosuppressant therapy
Etanercept	TNF- α blockade
Bortezomib	Proteasome inhibitor Inhibits TGF- β 1
Combination therapy	

BOS, Bronchiolitis obliterans syndrome; GERD, gastroesophageal reflux disease; GI, gastrointestinal; mTOR, mammalian target of rapamycin; TGF- α , transforming growth factor- α ; TNF- β 1, tumor necrosis factors.

Systemic Immunosuppression Therapy

Other immunosuppressive agents such as calcineurin inhibitors (cyclosporine and tacrolimus), mammalian target of rapamycin inhibitors (sirolimus and everolimus), as well as mycophenolate mofetil have also been shown to be efficacious in treatment of BOS in patients who undergo lung transplant.⁵⁵

Azithromycin

Azithromycin, a macrolide antibiotic, has been shown to modulate cytokine production and impair neutrophil function. Several small studies in the lung transplant literature have shown that chronic therapy with azithromycin can improve FEV1 or slow progression of BOS.^{63, 64, 65} The largest study reported to date has been by Vos et al.,⁶⁶ whose cohort of 107 lung transplant recipients with BOS were evaluated on long-term azithromycin therapy. Forty percent of patients were responsive to treatment, and these patients were reported to have improved OS compared with those who did not respond to macrolide therapy. The same authors have also published data that prophylactic azithromycin thrice weekly for 2 years after transplantation may prevent BOS by improving FEV1 as well as BOS-free survival in the same cohort.⁶⁷ Khalid et al.⁶⁸ reported significant clinical improvement in FEV1 and forced vital capacity in 7 of 8 patients with BOS after allo-HCT using azithromycin 500 mg daily for 3 days followed by 250 mg three times weekly for a minimum of 12 weeks.

Given its ease of administration and favorable side-effect profile, it is being increasingly used as upfront therapy for BOS and is recommended as adjunctive therapy in addition to corticosteroids and additional IST.

Novel Combination Therapy

Norman et al.⁶⁹ have reported a small case series (n = 8) of BOS after HCT using combination therapy with fluticasone, azithromycin, and montelukast (FAM). Their results suggest that combination therapy may spare some patients from systemic steroids and is being investigated in a prospective phase II trial. A list of other therapeutic agents available in clinical practice is summarized in Table 106.2.

Lung Transplantation

Although data is limited, lung transplantation upon failure of medical therapy is also an option, with several cases reported in the literature after HCT for patients who are thought to have achieved a cure for their hematologic malignancy but have severe BOS.^{70, 71, 72} Currently, there are no defined criteria for the appropriate timing for referral to a lung transplant, but those who have remained in remission for years without significant comorbidities or other long-term complications from HCT may be good candidates for consideration.

INFECTION AND IMMUNE RECONSTITUTION

Infection remains an immense challenge in long-term survivors, especially in patients requiring prolonged IST for cGVHD. Infection in survivors, even in the absence of cGVHD, is over 20 times greater than reported in the general population. About 20% of patients remain on IST beyond 3 years post-HCT, with a higher incidence in older patients receiving HCT.^{8, 11} There is an elevated risk of bacterial, fungal, and viral infections occurring even years after HCT, although this plateaus after 2 years.⁷³ Infections remain a significant contributor to morbidity, rehospitalization and NRM in 5-year survivors.^{50, 74, 75, 76, 77}

Immune reconstitution of the B and T cell repertoire from the donor can be insufficient, and long-term survivors still have an increased risk of infectious diseases.^{8, 78, 79} cGVHD and the use of systemic IST for cGVHD are the main risk factor of long-term poor immune reconstitution after HCT.⁸⁰ Immune status should be monitored periodically,³⁴ especially in those with recurrent severe infections.

Bacterial Infection

Bacterial infections such as pneumococcal infection can be lethal, especially in patients with cGVHD. Fortunately there are effective preventive options such as antibiotic prophylaxis and vaccinations.^{34, 76} Prolonged antibiotic prophylaxis is generally recommended for preventing infection by encapsulated organisms among patients with active cGVHD on systemic IST. Oral penicillin is generally preferred, but consideration of susceptibility patterns may warrant other options such as second-generation cephalosporins, macrolides, or fluoroquinolones. However, because of the risks of resistance, vaccinations should always be initiated if available. Several guidelines have been published^{34, 76, 81}; our current vaccination schedule is summarized in Table 106.3.

The optimal timing of vaccination is also important³⁴; the guidelines recommend not postponing vaccinations with nonlive vaccines in patients with ongoing active cGVHD.⁸² Checking antibody titers is useful in monitoring the success of vaccination in such patients. Live vaccines are generally avoided in subjects

P.2226

with ongoing IST. Another investigational approach to hasten the recovery of immunity is to boost donors prior to graft collection to enhance immune recovery in the eventual recipients.

TABLE 106.3 ROUTINE VACCINATIONS RECOMMENDED FOR HCT RECIPIENTS

Vaccine	Recommendation after HCT	Time Post-HCT to Initiate Vaccine (mo)	Number of Doses	Improved by Donor Vaccination
Pneumococcal conjugate (PCV)	Yes	3-6 ^b	3-4 ^b	Yes, may be considered when recipient is at high-risk for GVHD
Tetanus, diphtheria, Acellular Pertussis ^c	Yes Tetanus-Diphtheria	6-12	3 ^d	Tetanus: likely Diphtheria: likely Pertussis: Unknown
<i>Haemophilus influenzae</i> conjugate	Yes	6-12	3	Yes
Meningococcal conjugate		6-12	1	Unknown
Inactivated polio		6-12	3	Unknown

Recombinant hepatitis B	6-12	3	Likele ^e
Inactivated influenza	Yearly	4-6	1-2 ^f
Measles, mumps and rubella ^g	24	1-2 ^h	Unknown

GVHD, graft-versus-host disease; HCT, hematopoietic cell transplant.

^a A uniform specific interval between doses cannot be recommended, because various intervals have been used in studies. As a general guideline, a minimum of 1 month between doses may be reasonable.

^b If immunization is started early, consider evaluating for antibody levels and if they are low, revaccinate. Following the primary series of 3 PCV doses, a dose of the *23-valent polysaccharide pneumococcal vaccine* (PPSV23) to broaden the immune response might be given. For patients with chronic GVHD (cGVHD) who are likely to respond poorly to PPSV23, a fourth dose of the PCV should be considered instead of PPSV23.

^c DTaP is preferred; however, if only Tdap is available (e.g., because DTaP is not licensed for adults), administer Tdap. Acellular pertussis vaccine is preferred, but the whole-cell pertussis vaccine should be used if it is the only pertussis vaccine available.

^d See text for consideration of an additional dose(s) of Tdap for older children and adults.

^e Significant improvement of recipient response to hepatitis B vaccine posttransplant can be expected only if the donor receives more than 1 hepatitis vaccine dose prior to donation.

^f For children <9 years of age, 2 doses are recommended yearly between transplant and 9 years of age.

^g Measles, mumps, and rubella vaccines are usually given together as a combination vaccine. In females with pregnancy potential, vaccination with rubella vaccine either as a single or a combination vaccine is indicated.

^h In children, 2 doses are favored.

Fungal Infection

Late fungal infection is associated with cGVHD and systemic IST with *Aspergillus* spp. being the most common pathogen.^{76, 83, 84} There is very limited evidence to demonstrate clinical benefit of antifungals in the setting of cGVHD; however, antifungal prophylaxis especially against *Aspergillus* is usually recommended for patients with severe cGVHD.⁸⁵ Iron overload, a frequent finding after HCT, has shown a possible association with fungal infections and this represents a potential therapeutic target.^{86, 87, 88, 89} Iron overload is an established risk factor for infections in patients with myelodysplastic syndromes.⁹⁰ Iron chelation or phlebotomy could not only reverse transfusional overload, but might mitigate the risk of fungal infection.

Viral Infection

Viral infections, including CMV, varicella zoster virus (VZV), and influenza are responsible for late hospitalization, morbidity, and mortality in HCT survivors and are frequently associated with cGVHD.^{73, 77} While most CMV reactivations occur early, recent developments in transplant techniques such as preemptive CMV treatment strategies, cord blood, mismatched-related or URD HCT, and reduced-intensity conditioning have led to the emergence of late CMV reactivation and infection. CMV seropositive recipients of CMV seronegative grafts are at particular risk for prolonged reactivation.

Acyclovir prophylaxis to prevent VZV reactivation is nontoxic, effective, and routinely recommended for at least the first year after HCT.^{91, 92} Longer duration acyclovir prophylaxis beyond 1 year should be considered in patients with cGVHD or

systemic IST. Vaccination against VZV requires administration of an attenuated virus, and early reports are promising.^{93, 94} However, live vaccines should be administered no earlier than 24 months after HCT; there may be differences in the safety profiles of different vaccine brands and, as yet, no VZV vaccine has been approved for HCT recipients.

There is considerable high-level evidence that annual influenza vaccination is beneficial to HCT recipients.^{34, 76, 81} After HCT, the first dose is often insufficient in producing satisfactory antibody titers, but a booster dose can improve the immune response.^{95, 96, 97, 98} However, even with two doses of vaccine the most vulnerable HCT recipients, i.e., those who have a shorter transplant-tovaccination interval and active GVHD, might fail to be protected.⁹⁵ Consequently, attention must also be paid to other proven measures, such as exploiting herd immunity by vaccinating household members and avoiding symptomatic contacts.

BONE MINERAL DENSITY LOSS AND AVASCULAR OSTEONECROSIS

Bone Mineral Density Loss

Definitions

Bone mineral density (BMD) loss is usually determined by dual-energy x-ray absorptiometry (DEXA). Scores in adults are compared to the mean BMD of a gender-matched younger adult population at peak density to generate the T-score. A T-score between -1.5 and -2.5 defines reduced bone mass or "osteopenia," while a T-score less than -2.5 defines "osteoporosis." For pediatric populations an age-matched score, the Z-score, is used. BMD loss alone does not predict fracture, and osteoporosis may be diagnosed independently in the presence of fragility fractures.

P.2227

Bone Loss Risk

Accelerated BMD loss is observed in the vast majority of HCT survivors. In a representative series of 78 long-term survivors, 73% had BMD loss, 42% with osteopenia.⁹⁹ In terms of clinical sequelae, the 3-year cumulative incidence of fractures was 8% in a series of 146 transplant recipients, predominantly in childhood recipients.¹⁰⁰ For unclear reasons, and in contrast to their lower vulnerability to other transplant complications, children experience greater BMD loss than adults.^{100, 101} However, this susceptibility does not extend into young adulthood and the incidence of osteoporotic fracture rates is not increased in younger adults, arguing against the routine use of bisphosphonates in this population.⁹⁹

Trabecular bone is particularly vulnerable. The spine and hip contain 50% to 75% trabecular bone and are most at risk for fracture after HCT. The magnitude of BMD loss is greater in the femoral neck¹⁰² compared with the spine, and tends to be more difficult to reverse.^{103, 104} BMD loss is extremely rapid in the first 4 months of transplant. The BMD loss between baseline and day 100 DEXA scans is equivalent to the aging of bones by 7 to 10 years for auto-SCT and 13 to 17 years for allo-HCT recipients.¹⁰⁵ Recovery of BMD occurs first in the lumbar spine, followed by slower recovery in the femoral neck: BMD nadir at month 6 for the spine and at month 24 for total body and femoral neck.¹⁰⁴ Partial or complete recovery of BMD is possible with improvement of bone turnover, but with variable kinetics.¹⁰⁶

BMD loss has also been noted after autologous HCT.¹⁰⁷ However, the risk factors are different: lymphoma was associated with greater bone loss after autologous HCT than myeloma, whereas higher steroid dose was the most significant risk factor after allogeneic HCT.¹⁰⁸

Pathobiology

BMD loss results from reduced bone formation and accelerated resorption, with increased markers of bone turnover being a consistent feature.¹⁰⁹ Corticosteroid exposure plays a major role; 50% of nontransplant patients will develop osteoporosis after 6 months of steroid exposure.¹¹⁰ Studies have shown that transplant recipients have abnormally low vitamin D.^{111, 112} In addition, HCT recipients have unique pathologic influences on BMD loss. The most important and reversible condition is hypogonadism, which is a prominent feature of myeloablative conditioning regimens and disproportionately impacts females. Immunosuppressive medications, particularly cumulative steroid exposure, are widely accepted as an important risk factor. cGVHD either directly (via inflammatory cytokine release) or indirectly (via steroid usage) is a notable risk factor.⁹⁹

The role of inflammatory mediators is not well understood, but emerging information implicates osteoprotegerin (OPG):Rank-L interaction, arguably the most critical mediator of bone remodeling.¹¹³ Serum levels of OPG, the antagonist of the osteoclast differentiation factor Rank-L, are increased in transplant recipients.¹¹⁴ Increased insulin resistance may also be contributory.¹¹² Multivariable risk models explain only 11% to 30% of the variation in transplant-related BMD

change, suggesting that poorly characterized risk factors, likely inflammatory cytokines, play a dominant role in the pathobiology.¹⁰⁵ Additionally, the rapidity of BMD loss sustained after HCT could potentially increase fracture risk independently by inducing microarchitectural changes even when BMD loss is reversed.

Management of Post-hematopoietic Cell Transplantation Bone Loss

It is recommended that HCT recipients undergo evaluation to include BMD by DEXA starting shortly before and after transplantation, calcium/vitamin D supplementation, and sex hormone levels with possible hormonal supplementation. There should be a low threshold to consider bisphosphonate therapy (e.g., annual Reclast) for patients at significant progressive risk, such as long-term steroids.¹¹⁵ The Fracture Risk Assessment Tool (FRAX; www.shef.ac.uk/FRAX/) is an algorithm commonly used to predict the 10-year risk of fracture and guide therapeutic intervention, but is not yet validated in HCT recipients.

Standard prophylactic measures for osteoporosis prevention as applicable to aging are far less effective in the HCT population.¹¹⁶ Calcium with or without calcitonin is ineffective in preventing a decline in BMD.¹¹⁷ Nevertheless, simple calcium and vitamin D supplementation is necessary in transplant recipients because of impaired gastrointestinal (GI) absorption. A minimum of 400-600 IU vitamin D per day appears to be required to achieve optimal serum 25-hydroxy D concentrations following HCT.¹¹² Current guidelines call for adequate daily calcium intake (at least 1,200 mg daily) plus vitamin D (1,000 IU per day, and higher if serum 25-hydroxy vitamin D levels are <30 ng/ml), regular weight bearing activity, and avoidance of smoking or excess alcohol.^{118, 119}

Hormone replacement therapy (HRT) is now standard for all females who are at risk.¹²⁰ In a prospective study for children at particular risk, 28 girls with a median age of 10 years with sex hormone deficiency after HCT were followed longitudinally. At their first evaluation, performed at a median of 3.8 years after HCT, BMD increased significantly from -2.7 ± 1.1 (Z-score) to -2.3 ± 1.2 after HRT administration, with 24 of 28 patients showing a good response.¹²¹

Antiresorptive therapy should be an individualized decision based upon the clinical status, T-score, fracture risk (FRAX score), tolerability, and risks. Bisphosphonates, the primary option, have been shown to be beneficial in improving BMD in the specific setting of HCT; however, the benefits need to be balanced against the risks, particularly of osteonecrosis.¹²² Bisphosphonates have been proven to be superior in a nonrandomized trial comparing zoledronate and risedronate to calcium + vitamin D ± HRT.¹²³ Benefits are lost after stopping therapy with bisphosphonates.¹²⁴ Most experts advocate a drug holiday after 3 to 5 years of continuous bisphosphonates with stable BMD.¹²² Second line therapies include calcitonin, raloxifene and human recombinant parathyroid hormone, but experience is limited. PTH is contraindicated in children with open growth plates, recipients of TBI, and those with renal dysfunction. Denosumab, which sequesters RANK-L, is yet to be formally evaluated in HCT recipients.

Avascular Necrosis of Bones After Hematopoietic Cell Transplantation

Avascular osteonecrosis (AVN) is a painful and debilitating bone complication distinct from BMD loss, with a different pathobiology but an important risk factor in common (prolonged steroid exposure). AVN is caused by focal bone necrosis and seen in 4% to 19% of allogeneic HCT survivors.^{122, 125, 126} Early osteonecrotic changes in hips and knees have been seen in the transplant population with a frequency up to 43% by magnetic resonance imaging (MRI) screening. In the same study, 15% of patients had coexistent loss of BMD.¹²⁷

AVN may occur at a median of 2 years, but may be detected as early as 6 months and as late as 10 years after HCT. Pathogenetic factors are poorly understood, but involve local vascular damage leading to ischemia, ineffective repair due to metabolic factors, and mechanical stresses.¹²⁸ Risk factors for AVN include GVHD therapy with steroids¹²⁹ and calcineurin inhibitors, an underlying diagnosis of acute lymphoblastic leukemia (probably also steroid-related), older age, female gender, and the use of TBI in conditioning.

AVN most commonly destroys the femoral heads and presents with severe pain. Knees, shoulder and other joints may be involved and multiple joint involvement is common. Diagnosis is made by MRI, which is not only more sensitive but allows estimation of the extent of involvement. The Association of Research Circulation Osseus (ARCO) classification is typically used for staging (Table 106.4).¹³⁰

TABLE 106.4 ASSOCIATION OF RESEARCH CIRCULATION OSSEUS (ARCO) STAGING SYSTEM FOR OSTEONECROSIS

Stage	Radiologic Findings	Subclassification
--------------	----------------------------	--------------------------

0	All diagnostic studies normal, diagnosis by histology only	
I	Plain radiographs and CT normal; MRI positive and biopsy positive	Extent: A (<15%), B (15-30%), C (>30%) Location: 1 (medial third), 2 (median third), 3 (lateral third)
II	Radiographs positive	Extent/location as above
III	Subchondral fracture (crescent sign)	Extent/location as above
IV	Flattening of femoral head	Depression of femoral head: A (<2 mm), B (2-4 mm), C (>4 mm)
V	Flattening of femoral head, osteoarthritic joint space, and acetabular changes	Depression as above
VI	Joint destruction	

CT, computed tomography; MRI, magnetic resonance imaging.

Management requires a multidisciplinary approach with early orthopedic surgeon involvement, physical and occupational therapy, plus attention to pain control. Treatment decisions are individualized based upon the joint location, staging, expected longevity, a continued need for immunosuppression, comorbidities, and age. Although sometimes prescribed, there is no evidence that statins or bisphosphonates are helpful for prevention or treatment of AVN in HCT. Conservative management aims to preserve native joint function for as long as possible with analgesics and by minimizing impact to the joint. Surgical options are joint preserving (such as core decompression, vascularized fibular grafts, osteotomy) versus joint replacement. Nonoperative management is limited in scope, with satisfactory clinical results reported in 63.5% of hips in 24 studies of core decompression versus 22.7% of hips in 21 studies of nonoperative management.¹³¹ Typically, for early symptomatic AVN involving <15% or asymptomatic lesions involving >30% of the femoral head, conservative management and core decompression are appropriate. Larger lesions, even if asymptomatic, or ARCO stage > II lesions warrant more aggressive approaches.¹²² A recent series of 122 total hip arthroplasty procedures for AVN in nontransplant recipients demonstrated durability, with 89% joint survival rate at 15 years.¹³²

OCULAR COMPLICATIONS IN LONG-TERM SURVIVORS AFTER HEMATOPOIETIC CELL TRANSPLANTATION

In a series of 620 allogeneic HCT recipients, major ocular complications occurred in 13% of patients. The most frequent complications were cGVHD, xerophthalmia without cGVHD, corneal ulcers, cataract, glaucoma, cytomegalovirus retinitis, fungal endophthalmitis, and acquisition of allergic conjunctivitis from atopic donors.¹³³ Of these, cGVHD and cataracts are the most frequent late complications. Management should always include regular ophthalmologic evaluations, with prompt referral for symptoms.

Ocular Graft-versus-host-disease

Ocular cGVHD often affects the lacrimal glands, the conjunctiva, the lids (including meibomian glands), and the cornea, but can also involve other parts of the eye such as the sclera. The typical presentation is that of keratoconjunctivitis sicca. In a series of 248 evaluable patients from the EBMT, the actuarial probability of developing dry eyes was 21% ± 3% at 15 years, and is strongly associated with systemic cGVHD (RR 3.5; CI, 1.9 to 6.9), female patients (5.6; CI, 1.6 to 18.8), age older than 20 years (3.1; CI, 1.6 to 5.6), single-dose irradiation for preparation to HCT (3.8; CI, 1.3 to 11.3), and methotrexate for prevention of GVHD (3.6; CI, 1.05 to 12.8).¹³⁴ There are no pathognomonic diagnostic features of ocular GVHD and evidence levels for diagnosis and treatment are generally low.¹³⁵ Therapeutic goals are to reduce inflammation and dryness in order to relieve symptoms and maintain functional ocular integrity. Therapy is individualized based upon the patient's overall condition, systemic IST, symptoms, ocular surface integrity, and inflammatory activity. Artificial tears are the first line of treatment. Topical immunosuppression, for example, with steroid¹³⁶ or cyclosporine eye drops,^{137, 138, 139} reduces inflammation and dryness in ocular GVHD and improves symptoms in the majority of cases. Autologous serum eye drops are also effective.^{140, 141} Gas-permeable scleral lens for management of severe keratoconjunctivitis sicca may be necessary for severe cases refractory to conventional treatment.^{142, 143} Plugs for occlusion of the lacrimal drainage system and punctal cauterization¹⁴⁴ are usually reserved for resistant cases. Further clinical trials are necessary to elucidate risk factors for eye manifestation, complications, and visual loss, and to evaluate staging criteria and diagnostic and therapeutic measures for ocular cGVHD.

Premature Cataract Development after Hematopoietic Cell Transplantation

The risk of premature cataract was as high as 23% in pediatric HCT recipients.¹⁴⁵ Risk factors include steroids¹⁴⁶ and radiation.¹⁴⁷ The impact of TBI on the risk of cataract formation can now be quantified¹⁴⁸ and may support studies of lens shielding in susceptible populations. Aggressive management of dry eyes is an important adjunct to cataract surgery.¹⁴⁹

ENDOCRINE AND SEXUAL DYSFUNCTIONS IN LONG-TERM SURVIVORS

Diabetes Mellitus after Hematopoietic Cell Transplantation

Adjusting for age, sex, race, and body mass index, survivors of allogeneic HCT are 3.6 times more likely to report diabetes than their sibling controls.¹⁵⁰ The actual prevalence of diabetes depends on the age of the transplant population and ranges from 3.3% to 15%.¹⁵¹ Risk factors include cGVHD,²⁰ TBI,¹⁵² and a cumulative prednisone dose of >0.25 mg/kg/day.¹⁵³ There are no specific guidelines for screening; however, it is prudent to screen high-risk patients periodically because diabetes may be asymptomatic. Euglycemic survivors with a history of steroid-induced

P.2229

diabetes remain at higher risk for the future development of diabetes and should undergo aggressive screening (every 3 to 6 months).¹⁵⁴ Screening for diabetes is similar to that in the nontransplant population, with the exception that HbA1c is an unreliable marker in anemic or transfused recipients. Beyond lifestyle changes, therapy is usually based on insulin because traditional oral hypoglycemic agents are often contraindicated (Table 106.5).

Male Hypogonadism and Sexual Dysfunction

Male hypogonadism is common in survivors of malignancies but susceptible to neglect. Manifestations are low testosterone, reduced libido, impaired spermatogenesis and erectile dysfunction. Testosterone-producing Leydig cells are less damaged than the sperm-producing Sertoli cells in transplant survivors, resulting in mild elevation of luteinizing hormone compared to greater elevations in follicle-stimulating hormone.¹⁵⁵ Impaired spermatogenesis is common, with recovery seen in only 50% to 90% of nonirradiated and about 20% of irradiated survivors.¹⁵⁶ Younger men receiving reduced-intensity HCT are more likely to recover spermatogenesis.¹⁵⁷ Both organic¹⁵⁸ and psychological¹⁵⁹ factors are responsible for erectile dysfunction and reduced libido.

The goals of therapy are to restore fertility if desired, improve libido and sexual function, and reduce bone loss. Since azoospermia is common, often the only options to preserve male fertility are semen banking and/or testicular tissue cryopreservation prior to transplantation.¹⁶⁰ A low morning total testosterone level with reduced libido¹⁶¹ or bone mass¹⁶² may be indications for supplementation. Testosterone dose should be titrated to achieve a mid-normal range while monitoring prostate-specific-antigen and hematocrit.

Thyroid Disorders in Long-term Survivors

The thyroid gland is frequently damaged in transplant survivors. TSH elevations, initially subclinical, are found in up to 17% of survivors and are dependent upon the dose of TBI.¹⁶³ In a long-term study of pediatric transplant recipients, approximately 30% eventually developed thyroid abnormalities; hypothyroidism was much more frequent than hyperthyroidism or thyroiditis.¹⁶⁴ Risk factors for hypothyroidism include age less than 10 years at transplant, conditioning intensity (particularly TBI), and cGVHD.^{21, 164, 165}

In a study of 791 pediatric transplant recipients, thyroid tumors occurred at a median of 9.9 (4.5-22.3) years after HCT and included 13 with papillary carcinoma and 5 with benign adenomas.¹⁶⁴ Radiation exposure underlies most cases,^{164, 165} but age less than 20 years, female sex, cGVHD, and family history are also factors.¹⁶⁶ Thyroid nodules need evaluation by ultrasound and biopsy. Excellent outcomes are observed with total thyroidectomy and iodine ablation. Patients with elevated TSH who are symptomatic should be considered for early replacement therapy to improve quality of life (QOL) (even in patients with subclinical hypothyroidism).

HCT, hematopoietic cell transplantation.

Adrenal Insufficiency

Even short-term supraphysiologic doses (equivalent to prednisone of >7.5 mg/day) of steroids are known to suppress the hypothalamic-pituitary-adrenal (HPA) axis, and adrenal insufficiency may last for up to 9 months. Glucocorticoid-induced adrenal insufficiency is highly prevalent (and often overlooked) in HCT survivors. In one series, 19 of 20 allogeneic HCT long-term survivors had abnormalities on ACTH stimulation.¹⁶⁷ Adrenal insufficiency may be clinically overt or diagnosable by ACTH challenge. Alternate day or early morning steroid administration minimizes HPA axis suppression and early replacement in symptomatic patients is a key step in management.

Pituitary Dysfunction

Pituitary complications are predominantly pediatric and manifest as growth failure, central hypogonadism, and central hypothyroidism. Irradiation, male gender, and young age at BMT are the most important factors for growth impairment, and 40 out of 141 children failed to achieve normal adult height.^{168, 169} Regular screening for growth and replacement in needed patients is essential in pediatric HCT survivors.

CHRONIC KIDNEY DISEASES: MONITORING AND MANAGEMENT GUIDELINES

Epidemiology and Prevalence

Estimates of the cumulative incidence of CKD in HCT survivors vary from 13% to 66% for adults and 62% in children, with variation attributable at least in part to the lack of a uniform disease definition.^{170, 171} The initial insult may occur pretransplant or evolve from acute kidney injury early after HCT, but is often delayed as much as 10 years posttransplant. CKD is independently associated with an increased risk of NRM; and progression to end-stage renal disease (ESRD) that requires dialysis is associated with a near 90% mortality.^{170, 171}

There are 3 separate clinical entities that are distinguishable after HCT (Fig. 106.2): thrombotic microangiopathy (TMA), nephrotic syndrome, and idiopathic or GVHD-related CKD. Acute deteriorations in renal function will occur in the majority of patients in the first few months after HCT. This acute kidney injury may persist and eventually contribute to the later development of CKD. Careful monitoring of blood pressure, renal function, and proteinuria is mandatory, especially in older patients and those with preexisting renal impairment. Renal function should be evaluated before HCT and monitoring should occur at least every 3 to 6 months in these patients. Renal biopsies are indicated in patients with proteinuria and persistent or progressive rises in serum creatinine to determine etiology and prevent the progression to ESRD.

Definition of Chronic Kidney Disease

CKD is defined by an elevation in serum creatinine, or a decreased GFR ($\text{GFR} < 60 \text{ ml/min/1.73 m}^2$), for 3 or more months. Kidney damage is further described in terms of structural or functional abnormalities in morphology, imaging, or composition of the blood or urine, such as proteinuria (a ratio of greater than 300 mg of albumin per gram of creatinine on spot urine testing).¹⁷⁰

P.2230

FIGURE 106.2. Types of CKD in long-term survivors of HCT: Sites of action of different renal insults with consequent clinicobiologic syndromes of kidney injury. CKD, chronic kidney disease; CNI, calcineurin inhibitor; GVHD, graft-versus-host-disease; HCT, hematopoietic cell transplant; TBI, total body irradiation; T-I nephropathy, tubulointerstitial nephropathy; TMA, thrombotic microangiopathy.

Spectrum of Kidney Disease

There are 3 major risk factors contributing to the pathogenesis of kidney injury after HCT: the underlying malignancy and previous therapies, transplant-related treatments, and complications and immunobiology of transplantation (GVHD). The spectrum of renal disease after HCT ranges from vascular (hypertension, TMA), to glomerular (albuminuria, nephrotic glomerulopathies), to tubulointerstitial abnormalities, which may all result in the reduction of GFR (Fig. 106.2). However, since it is not currently feasible to evaluate these components independently in clinical practice, it is common to group the disorders into three distinct clinical syndromes: TMA, nephrotic syndrome, and idiopathic or GVHD-related CKD.

Evaluation and Follow-up Guidelines of Patients with Chronic Kidney Diseases

Screening recommendations for patients beyond 6 months following HCT were developed by a consensus panel formed by CIBMTR, EBMT, and ASBMT⁵⁰ and are briefly summarized in Table 106.6: 1. Hypertension should be investigated at every clinic visit and at least annually and managed aggressively. 2. Renal function should be evaluated at day 90 to 100 and then 6 and 12 months after transplantation for all patients, and yearly thereafter at a minimum for those with early renal insufficiency. Screening should include assessment of urine albumin and protein, serum BUN, and creatinine. Of note, serum creatinine is not an accurate measure of kidney function. Serum creatinine level and related estimating equations are dependent on muscle mass and are influenced by age, race, gender, and weight. 3. Ultrasonography should be used to exclude obstructive uropathy, especially in patients with acute or chronic kidney injury. 4. Renal biopsy is warranted to diagnose etiology of persistent AKI or CKD and nephrotic range proteinuria.

Long-term Implications, Surveillance, Prevention, and Management

The final consequences of CKD are independent of the underlying kidney disorder and include the possibility of progression to ESRD and complications from renal dysfunction such as metabolic, electrolyte, endocrine, bone and mineral abnormalities, hypertension, proteinuria, anemia, and contribution to CV risk.

Management guidelines include:

- Avoidance of nephrotoxic drugs (NSAIDs, calcineurin inhibitors, contrast media, aminoglycosides, chemotherapy), renal
P.2231

dose adjustment, and drug level monitoring. While options are limited for substitution of calcineurin inhibitors, agents such as sirolimus are well tolerated.

TABLE 106.6 EVALUATION OF CHRONIC KIDNEY DISEASE (CKD) IN HEMATOPOIETIC CELL TRANSPLANTATION (HCT) SURVIVORS

Evaluation	Treatment
Specific diagnosis (type of kidney disease):	Therapy based on the specific diagnosis:
-A thorough search for “reversible causes” of kidney disease should be conducted (pathology and noninvasive work-up)	-GVHD -TMA -CNI -Viral infection
-Early referral to a nephrologist	-Other causes (GN, obstruction, etc.)
-Disease severity is assessed by the level of kidney function (stage of CKD)	Measures to prevent and treat complications of decreased kidney function: Hypertension Water and electrolytes imbalance Anemia Mineral metabolism Malnutrition
-Estimation of disease progression	
-Assessment of complications (related to the level of kidney function)	
-Assessment of comorbid conditions and risk factors for CKD (initiation/progression):	Medication dosage adjustments at each visit Detect drug interactions
Poor glycemic control in diabetes	Management of comorbid conditions and measures to slow loss of kidney function
Uncontrolled hypertension	
Higher level of proteinuria	
Drug toxicity	Preparation for renal replacement therapy (dialysis or transplantation)
Urinary tract infections	
Other (urinary stones/obstruction, autoimmune diseases, systemic infections, smoking)	
Evaluation of the risk for development of cardiovascular disease	Measures to prevent and treat cardiovascular disease
CKD, chronic kidney disease; CNI, calcineurin inhibitors; GVHD, graft-versus-host-disease; GN, glomerulonephritis; TMA, thrombotic microangiopathy.	

- Nephrotic Syndrome-Steroids, in addition to calcineurin inhibitors, can reverse minimal change or membranous nephropathy.¹⁷² Rituximab has also shown benefits, by directly killing dysregulated B-lymphocytes which have been associated with membranous nephropathy.^{173, 174} Membranous nephropathy is a clinical entity that is more refractory to immunosuppression, with only 27% of patients achieving remission, compared to 90% for minimal change disease.¹⁷⁵
- TMA management-TMA is often confirmed by pathologic changes on kidney biopsy and may not produce clinically significant microangiopathic hemolysis. Deficiency in ADAMTS13 is uncommon, unlike nontransplant TTP, and plasma exchange produces inconsistent results.¹⁷⁶ Calcineurin inhibitors (cyclosporine and tacrolimus) and sirolimus often warrant discontinuation, but management may be complicated by the presence of GVHD. Sometimes, continued immunosuppressive treatment of GVHD while attempting to reduce endothelial injury by aggressive hypertensive therapy may be preferable.¹⁷⁷ A small case series showed that 4 of 5 patients with TMA after HCT responded to treatment directed against cGVHD with rituximab.¹⁷⁸ In another report of 12 patients with early TTP after transplant, 50% of patients responded to defibrotide.¹⁷⁹
- Management of hypertension-Treatment of hypertension is usually indicated unless the severity is mild or the condition is temporary, such as an elevation in tacrolimus levels. Consideration should be given to early referral to a nephrologist.

Angiotensin-converting enzyme inhibitors (ACEI) and angiotensin receptor blockers (ARBs) are useful agents in CKD. In a rodent model of radiation-induced hemolytic-uremic syndrome (HUS) the use of these agents reduced azotemia, hypertension, and proteinuria, and led to long-term preservation of renal function.¹⁸⁰ In a randomized controlled trial, captopril demonstrated a trend toward improving the 1 year GFR and serum creatinine level.¹⁸¹ ACEI and ARBs also produce indirect protective effects by reducing posttransplant inflammatory markers.¹⁸²
- ESRD and renal transplantation- It may be impossible to stall the progression to ESRD. Standard therapies include peritoneal and/or hemodialysis, but survival in HCT recipients is particularly poor.¹⁷¹ Renal transplantation remains a therapeutic option for selected patients, with the additional advantage that those who received a kidney allograft from their original stem cell donor required minimal immunosuppression.^{183, 184}

GASTROINTESTINAL AND LIVER PROBLEMS

GI and hepatobiliary problems in HCT survivors are usually sequelae of GVHD, adverse medication effects, and infections.

Esophageal Symptoms (Heartburn, Dysphagia, and Painful Swallowing)

Gastroesophageal reflux disease is a common finding and may be exacerbated by GVHD and the dyspepsia associated with steroids. Involvement of the esophagus by cGVHD may lead to chronic dysmotility and reflux, necessitating prolonged proton pump inhibitor therapy. Rarely, esophagitis may be due to fungal or viral infection or to a retained pill. Therapy for strictures includes IST (for cGVHD) and careful endoscopic dilation to avoid progressive luminal narrowing.

Upper Gastrointestinal Symptoms (Anorexia, Nausea, Vomiting, and Satiety)

Causes include cGVHD, infections, and adverse drug effects. Upper GI GVHD can manifest in isolation, without other systemic manifestations of cGVHD.^{53, 185} GVHD must be distinguished from reactivation of herpesvirus (HSV, CMV, VZV) in susceptible individuals who have had antiviral prophylaxis and viral surveillance discontinued. Occasionally enteric viruses (e.g., rotavirus and norovirus) and parasites (*Giardia lamblia*, cryptosporidia) can present with anorexia and nausea with minimal diarrhea.^{186, 187}

Lower Gastrointestinal Symptoms (Diarrhea and Abdominal Pain)

cGVHD involving the lower GI tract is far less common than its acute counterpart. When this occurs, it may be a manifestation of delayed or recurrent acute GVHD, sequelae from gut injury in the early posttransplant period, infections, or common GI disorders. Subacute intestinal obstruction episodes may occur in those with a history of severe GVHD, with or without focal inflammation.¹⁸⁸ Treatment is either symptomatic with opioids or with topical or systemic IST or 5-aminosalicylic acid.

Chronic Liver Diseases in Long-term Survivors after Hematopoietic Cell Transplantation

Chronic liver dysfunction may be due to viral infection, GVHD, drug toxicity, biliary obstruction, iron overload, nodular regenerative hyperplasia, focal nodular hyperplasia, fatty liver (NASH, secondary to metabolic syndrome), cirrhosis, or recurrent malignancy.^{88, 89}

Cirrhosis may be related to chronic hepatitis C and is rising in frequency in patients transplanted before the 1990s. Viral replication and fibrosis may be accelerated by immunosuppression, injury by GVHD, and hemosiderosis.^{89, 189, 190} Long-term HCT survivors have a significantly elevated risk of developing a new solid malignancy, and there is direct evidence for an increased incidence of hepatocellular carcinoma.^{36, 37} Survivors with a history of hepatitis B or C infection, obesity, and diabetes are particularly vulnerable and should be offered annual screening for hepatocellular carcinoma.¹⁹¹

Pancreatic and Biliary Disease

Exocrine pancreatic insufficiency is an uncommon finding in HCT survivors and presents with chronic diarrhea and malabsorption.^{192, 193, 194} Potential causes include repeated episodes of pancreatitis, immunosuppressive agent toxicity, passage of a stone or sludge, damage by recurrent GVHD, viral infection, and hemosiderosis.^{88, 195} Screening involves measurement of serum trypsinogen, fecal elastase-1, and chymotrypsin levels, but imaging is required for evaluation of pancreatic atrophy.^{89, 194} Therapy is specific to the underlying cause and oral pancreatic enzyme supplementation may be of partial benefit.

HCT survivors have an increased risk of gallstones, and biliary sludge is found by ultrasound in approximately 70%¹⁹⁶ and at autopsy in 100% of HCT survivors.¹⁹⁷ This is thought to be related to immunosuppressive medications.

IRON OVERLOAD IN LONG-TERM SURVIVORS

Pathobiology

Transfusional iron overload is common in benign and malignant hematologic conditions and is often present prior to transplant. Iron overload can occur after as few as 20 units of PRBC

P.2232

transfusions, impacts 30% to 60% of allotransplant recipients, and is liable to be overlooked.^{88, 198} Not only is nontransferrin bound iron deposited into the liver, heart, pancreas, cartilage, and endocrine tissues, but it may lead to the formation of reactive oxygen species.^{199, 200} While the liver is capable of accumulating a substantial amount of iron, the most significant sequelae are not hepatic, but cardiac and endocrine.⁸⁹

Clinical Presentation and Diagnosis

Iron overload may masquerade as liver GVHD. Iron overload was the sole pathologic finding in one-third of cases with liver function test (LFT) abnormalities which underwent biopsy²⁰¹ and phlebotomy may normalize abnormal LFTs.²⁰²

Serum ferritin is the best screening test. Levels higher than 200 µg/L in women and 300 µg/L in men are generally considered elevated, but are not very reliable because of frequent confounding conditions in the transplant setting. It is important to distinguish iron overload from other causes of elevated ferritin such as systemic inflammation (GVH, infections), metabolic syndrome, hepatitis, and alcoholism.⁸⁸ Liver iron concentration is the gold standard for diagnosis, but biopsy has been supplanted by T2 quantitative MRI. Mutational analysis for hereditary forms of hemochromatosis is helpful in diagnosing selected cases where the transfusion burden is not great.

Prognostic Importance

There is growing data on the adverse impact of iron overload, particularly when severe, on transplant outcomes.^{88, 89, 203, 204, 205, 206} The impact of moderate degrees of iron overload on transplant outcomes remains debatable because excessive transfusions are a surrogate for a complicated clinical course.

Management

While more research is necessary to assess the role of iron overload in HCT survivors, clearly there is much to be gained from prevention even prior to transplant.^{88, 207, 208, 209, 210} After the cessation of transfusions, the rate of spontaneous iron unloading is unsatisfactory.²⁰⁶ Therapeutic options include phlebotomy and iron chelation; however, there are no randomized trials. Phlebotomy, sometimes supported by erythropoiesis stimulating agents and folic acid, is effective, relatively nontoxic, and inexpensive. Frequent phlebotomy is limited only by anemia, leading to considerations of iron chelation as an option. Iron chelation by deferoxamine, deferiprone, and deferasirox have all been shown to reduce iron overload in the transplant setting, and one retrospective study showed a significant reduction in relapse for iron-overloaded patients treated with deferoxamine.²¹¹ With this exception, no study has shown significant clinical benefit for iron chelating agents and prospective trials are required to demonstrate their safety and optimize their administration in transplant survivors.

FEMALE LONG-TERM SURVIVORS AND RELATED ISSUES

Given the complexities involved with the evaluation and management of this patient population, it is important for close collaboration between the obstetrician/gynecologist and the hematologist/oncologist.²¹² Preventive gynecologic care is critical to manage cGVHD of the genital tract, which can be a cause of significant morbidity. Other issues relevant to women of reproductive-age include HPV-related cervical dysplasia, contraception, infertility, pregnancy issues, sexual health, and hypogonadism.

Vulvovaginal Graft-versus-host disease

The incidence of female genital GVHD ranges between 25% and 49% of allo-HCT survivors.^{213, 214} Genital GVHD manifests in the vulva (68%), or the vulva and vagina concomitantly (26%).²¹² Vulvovaginal cGVHD typically starts in the first year posttransplant but vaginal GVHD may present in a delayed fashion, after several years following HCT.^{215, 216} Late manifestations include vaginal synechiae, stenosis, and hematocolpos. Severe vaginal GVHD is strongly associated with sclerotic skin cGVHD,²¹⁶ but may be isolated in 27% of cases.²¹³ Genital cGVHD has been classified into grade I (mild), grade II (moderate), and grade III (severe).^{213, 214, 216}

Management is complicated by symptom underreporting, empiric therapies directed at infectious or menopausal etiologies without gynecologic examination, or severe illness interfering with gynecology referral.²¹⁷ Treatment of only vulvar disease does not prevent development of vaginal GVHD. In one series, 63% of patients required surgery for vaginal GVHD despite aggressive treatment of vulvar cGVHD,²¹³ whereas others instituting regular monitoring avoided surgery.²¹⁴ The key to successful management is early recognition of genital GVHD and early implementation of topical immunosuppressive and estrogen therapy with concomitant use of dilators, if needed.^{214, 216, 218} Surgery is necessary for severe resistant cases.

Human Papillomavirus-related Secondary Cancer and Other Diseases

The clinical manifestations of HPV infection include genital warts (condylomata acuminata), cervical, vaginal, vulvar, or anal intraepithelial neoplasia, and anogenital SCC. Cervical SCC in long-term allo-HCT survivors is reported to have a 13-fold increased risk compared to the general population,³⁶ and escalates to 18-fold higher if the patient is older than 34 years. Over 40% of female long-term survivors in another study had abnormal cervical cytology, with 20% having high-grade cervical dysplasia.⁴⁷ Lower genital tract dysplasia and anogenital condyloma, other manifestations of HPV infection, are also prevalent. These manifestations are strongly associated with prolonged systemic or local IST and likely represent reactivation of existing HPV infection, rather than acquisition of new infection. Loss of protective immunity explains why the resulting HPV-related disease is more prevalent and more rapidly progressive, as is observed in other immunocompromised populations.²¹⁹

Current guidelines recommend annual screening after HCT.²¹⁸ Screening for cervical dysplasia is by cytology testing with reflex HPV testing. Colposcopy is reserved for cytology testing documenting atypical squamous cells of undetermined significance (ASC-US) coupled with concurrent positive testing for high-risk HPV types, atypical squamous cells suggestive of a high-grade lesion, low-grade squamous intraepithelial lesions, high-grade squamous intraepithelial lesions, or cancer. Women with ASC-US on cytology specimens a year apart are considered to have persistent abnormalities and should also undergo colposcopy.

Guidelines for vaccinating against HPV infections after allo-HCT have been proposed, although immune response may be suboptimal.^{46, 220} Vaccination in the year after transplantation could theoretically mitigate reactivation of HPV disease, if an immune response is generated.

Infertility and Sexual Health

Most women undergoing transplantation are in their reproductive years and are extremely susceptible to ovarian insufficiency or failure. Manifestations are amenorrhea, reduced libido, vaginal changes, and menopausal symptoms. Puberty may still occur spontaneously in up to 60% of prepubertal transplanted

P.2233

females,¹⁵⁵ whereas postpubertal myeloablative transplants result in ovarian failure in >90% of women, with delayed recovery occurring in 29%.^{221, 222} For those whose menses return months or years after transplant, transient ovarian failure is common in the first year after treatment and liable to terminate in premature menopause.^{25, 223, 224, 225}

The likelihood of permanent ovarian failure and infertility is affected by age, pubertal status, conditioning intensity, radiation dose, and location.^{222, 226, 227} The risk of premature ovarian insufficiency related to TBI increases with age.²²⁸ Radiation doses of 6 Gy are sufficient to cause irreversible ovarian injury in most patients treated after age 40, while two

to three times this dose is required to precipitate ovarian failure in irradiated children.²²⁹ In contrast, the incidence of ovarian failure is greatly reduced (<40%) by utilizing reduced-intensity conditioning.²³⁰ Apart from ovarian failure, fertility is also affected by uterine damage from radiation²²⁸ and dyspareunia related to vulvo-vaginal GVHD.²¹⁶

Successful pregnancies are uncommon. The largest series with 19,412 allogeneic and 17,950 autologous transplants documented only 312 pregnancies in 232 (0.6%) of patients or their partners.²³¹ Moreover, pregnancies in transplant survivors are complicated by an increased risk of low birth weight, preterm delivery, and cesarean section delivery. Additional concerns include intrauterine growth restriction, abnormal placentation, and uterine rupture.^{232, 233} Patients with decreased uterine volume after TBI are at increased risk for spontaneous abortion, even with the use of donor oocytes and in vitro fertilization.²²⁸ The risk of spontaneous abortion is unclear, with conflicting data.^{218, 228, 231, 234} All conceptions in transplant survivors are high risk.

Sexual dysfunction is common in women and lags behind their male counterparts. 80% of female transplant survivors reported sexual dysfunction (in contrast to 46% of men). Female sexual dysfunction persists even when other measures of physical and emotional well-being return to normal.²³⁵ Contributing factors include fatigue, medications, endocrinopathy, genital GVHD, and psychological causes. The goals of therapy are to restore fertility if desired, improve sexual function and libido, and reduce bone loss. Women should be advised to avoid pregnancy using a reliable method of birth control while they receive transplant-related medications, and should be assessed for engraftment disease status and ovarian function. Amenorrhea after menses have returned should prompt a pregnancy test, since fertility can recover in some patients.²³⁶

Options to preserve fertility after myeloablative HCT, when time permits, include preconditioning embryo, oocyte, or ovarian tissue cryopreservation for subsequent in vitro fertilization.^{160, 218, 231} HRT is successful in treating menopausal symptoms²³⁷ and in developing secondary sexual characteristics. However, HRT has little effect on sexual desire or dissatisfaction.²¹² The optimum duration of HRT is undefined, but cessation at the normal age for menopause should be considered. For menopausal symptom control in those with contraindications to HRT, placebo-controlled trials suggest a benefit from SSRIs.²³⁸

QUALITY OF LIFE AND SOCIAL CHANGES IN LONG-TERM SURVIVORS

HCT survivors have undergone the most intense form of anticancer therapy. The prevalence of severe late complications in transplant survivors, even when a cure is achieved, emphasizes a necessity to also focus on QOL issues. HCT often reduces the overall health-related quality of life (HRQOL) of survivors, which is a result of decrements across all dimensions, including a significant symptom burden.²³⁹ Discordance between the anticipated and the actual diminution of QOL after transplant may be a cause of significant dissatisfaction in survivors^{240, 241} and may be mitigated by careful pretransplant counseling. HRQOL includes physical, cognitive, emotional, and social functioning, as well as well-being components. Comparison of transplant QOL studies has been imprecise because of subjective designs, lack of standardized methodologies, differences in time points, overreliance on cross-sectional rather than prospective/longitudinal studies, lack of well-defined control groups, and population heterogeneity.²⁴²

Health-related Quality of Life Studies

A study of 2,800 pooled transplant survivors found that QOL declines immediately after transplantation,²⁴³ with recovery over the next 1 year. More than half of transplant survivors return to work in 1 year.^{244, 245, 246} Physical recovery precedes that of fatigue, dyspnea, or sleep patterns²⁴⁷ and of psychological or work recovery.²⁴⁸ 19% recovered on all outcomes at 1 year and 63% by 5 years. Among survivors without recurrent malignancy, 84% returned to full-time work by 5 years. Beyond 5 years, most survivors are disease free with an excellent performance status, preserved physical and psychological health, and excellent HRQOL.²⁴⁹ Pretransplant factors impacting long-term QOL were studied in a registry cohort of 662 survivors at a median of 6.6 years posttransplant.²⁵⁰ Surviving adversity can alter life-perceptions, and several transplant survivors report positive experiences related to psychological and interpersonal growth.^{249, 250, 251, 252} Posttraumatic growth is well documented in cancer medicine and studies are now beginning to also focus on the positive impact of transplant on QOL.²⁵³

Psychological and Cognitive Issues

Both autologous and allogeneic HCT survivors report a high prevalence of psychiatric symptoms²⁴⁰ and 5% of survivors meet diagnostic criteria for posttraumatic stress disorder.²⁵⁴ Psychological stressors include the fear of relapse and the inability to return to pretransplant performance level. Interestingly, the extent of psychological and cognitive decline appears to be similar for leukemia patients treated either with chemotherapy or HCT.^{255, 256}

Depression affects about one-third of posttransplant survivors. cGVHD, inferior social support, and female gender were significant factors for depression.²⁵⁷ A significant generalized decline in neurocognitive performance has been observed as early as 80 days after HCT.²⁴⁸ Although neurocognitive function improved from 1 to 5 years after HCT, deficits remained for more than 40% of survivors.²⁵⁸ Impairments in attention, concentration, reaction time, reasoning, and problem solving were observed to last up to 8 years posttransplant and were directly correlated to the dose of TBI.²⁵⁹ Inflammatory cytokines, such as TNF- α , have been implicated as putative factors for cognitive decline.²⁶⁰

Interventions to Improve Quality of Life

Psychosocial screening is routinely performed pretransplant but has not been adequately studied posttransplant. Consensus guidelines recommend additional periodic screening at 6 months and annually after transplant, by one of several simple screening instruments.⁵⁰ Screens are available for distress, depression, and posttraumatic stress disorder.^{261, 262} Fatigue that is not related to depression or underlying medical reasons may respond to an exercise program.²⁶³ Behavioral intervention, pharmacologic therapy, and exercise may help depression.

CONCLUSION

A better understanding of the pathogenesis of late effects will allow for more effective screening to identify patients at risk prior to the allo-HCT procedure and allow more effective monitoring to

P.2234

detect early evolution of the late effects after allo-HCT. This may, in turn, allow for improved therapeutic decision making while evaluating patients for HCT, and early institution of treatments directed at preventing and treating late effects in patients at risk after allo-HCT. We also recommend early referral or discussion with a transplant center for enrollment of patients in available late effect studies and for management guidelines.
