Chapter 53

Inherited Coagulation Disorders

Jerry S. Powell

George M. Rodgers

Inherited disorders of coagulation result from the deficiency or functional abnormality of one of the plasma proteins involved in providing normal coagulation.¹ There are other proteins that regulate the kinetics of coagulation, and abnormalities in one of these proteins usually result in increased risk of thrombosis; these proteins will not be covered in this chapter. If von Willebrand disease (vWD) is included, the inherited coagulation abnormalities (Table 53.1) are common; for example, vWD may affect up to 1% of the population. The other inherited coagulation disorders occur less often.

Since the purpose of the coagulation cascade is to rapidly produce fibrin to form a clot, the clinical manifestation of any deficiency or functional abnormality in any coagulation protein will be similar, i.e., clinical bleeding, with greater bleeding associated with more severe deficiency. Therefore, the manifestations and complications of clinical bleeding will be described in this chapter in the section on hemophilia A. A recent review of treatment of hemophilia A has been published with proposed algorithms for therapy.²

TABLE 53.1 INHERITED DISORDERS OF COAGULATION

X-linked recessive traits

Hemophilia A

Hemophilia B (i.e., CRM⁺ and CRM⁻ variants; hemophilia B_m, B Leyden, etc.)

Autosomal recessive traits

Factor XI deficiency

Prothrombin deficiency

Factor V deficiency

Factor VII deficiency

Factor X deficiency (i.e., Prower variant, Stuart variant, Friuli variant, others)

Afibrinogenemia

Hypofibrinogenemia

Factor XII deficiency

Factor XIII deficiency

Autosomal dominant traits

von Willebrand disease

Dysfibrinogenemias

Combined abnormalities

Associated with factor VIII deficiency (i.e., factor V deficiency, hemophilia B, factor XI deficiency, factor VII deficiency, von Willebrand disease, dysfibrinogenemias, platelet dysfunction)

Involving vitamin K-dependent factors (i.e., factors II, VII, IX, and X; factors IX and XII; others)

Miscellaneous

Prekallikrein deficiency

High-molecular-weight kininogen deficiency

Deficiency of physiologic inhibitors (i.e., α_2 -antiplasmin, abnormal α_1 -antitrypsin [antithrombin Pittsburgh])

CRM, cross-reacting material.

NOMENCLATURE

Historically, the best known inherited coagulation disorder is hemophilia, which dramatically manifested itself in the royal families of Europe in the 20th century, following a spontaneous mutation that apparently arose in Queen Victoria in

England. The international Roman numeral designations for these disorders are summarized in Table 18.1. Like abnormal hemoglobins, qualitatively abnormal fibrinogens are designated by the name of the city in which they were first discovered, as in fibrinogen Paris.

PRINCIPLES OF PATHOPHYSIOLOGY

With the exception of fibrinogen and prothrombin, the coagulation factors are trace proteins. Clinical laboratory measurements of their activity depend on bioassays, which detect both quantitative absence of a specific factor and a qualitative functional abnormality in a factor that is present in normal amounts. Further laboratory testing is required to determine the actual concentration of the protein, usually by enzyme-linked immunoabsorbent assay (ELISA) methodology. Thus, for example, in hemophilia A, the bioassay measures factor VIII coagulant activity (factor VIIIc) and refers to the functional property of the factor VIII molecule that corrects the coagulation defect of patients with hemophilia A. The amount of protein measures the amount of antigen by ELISA and is referred to as factor VIII_{Ag} (Table 53.2). Many hemophilia treatment centers currently proceed to determine the genotype for individual persons with inherited coagulation disorders; such analysis is helpful to predict the severity of the clinical phenotype, to predict the risk of inhibitor development, and to aid in family counseling.

Most qualitative abnormalities in coagulation factors result in loss of function of the protein in the coagulation cascade. However, some mutations produce qualitative abnormalities that result in “gain of function.” Such factors are called abnormal or aberrant factors to distinguish them. The most clearly defined disorders of this type are the dysfibrinogenemias, in which the abnormal fibrinogen typically is not completely nonfunctional, but may also inhibit the function of normal fibrinogen. Other disorders characterized by aberrant coagulation factors include the B_m variant of hemophilia B and some of the variants of prothrombin deficiency. Aberrant procoagulant proteins also may be synthesized in acquired deficiencies of the vitamin K-dependent factors (see Chapter 54). An example of a “gain of function” mutation for factor IX was described recently, factor IX Padua, in which a leucine was substituted for arginine at position 338 (R338L) and, despite a normal concentration of factor IX protein in plasma, the factor IX clotting activity was eight times normal, resulting in clinically significant thrombosis.³

P.1144

TABLE 53.2 NOMENCLATURE FOR FACTOR VIII AND VON WILLEBRAND FACTOR

Definition	International Nomenclature
Protein lacking or aberrant in hemophilia A	Factor VIII
Functional property of factor VIII that is deficient in hemophilia A and measured using coagulation assays	Factor VIIIc
Antigenic property of factor VIII that is measured by immunoassays in which homologous antibodies are used	Factor VIII _{Ag}
Protein required for normal platelet adhesion that is aberrant or deficient in von Willebrand disease	von Willebrand factor (vWF)
Antigenic property of vWF that is measured by immunoassays in which heterologous antibodies are used	vWF antigen (vWF _{Ag})
Property of vWF required for platelet agglutination by ristocetin	Ristocetin cofactor activity (vWF:RCo)

Note: This table is based on recommendations of the International Committee on Thrombosis and Haemostasis.

Recommended abbreviations for von Willebrand factor and its activities. *Thromb Haemost* 2001;86:712.

HEMOPHILIA A

Hemophilia A refers to the inherited coagulation disorder characterized by deficiency of function of the coagulation protein called factor VIII. Except for vWD, it is the most common inherited coagulation disorder, and is X-linked. As the most common bleeding disorder, historians assume that it is the severe and often fatal hemorrhagic diathesis that affected the male children of certain families and that was well recognized in antiquity, as noted in the writings of Rabbi Simon ben Gamaliel (2nd century A.D.) in the Talmud, and those of Maimonides, the Hebrew physician and philosopher, and Albucasis, the Arab (twelfth century).⁴ Complete monographs have reviewed the early literature.⁵ However, the bleeding disorder that occurred in males throughout the royal families of Europe due to a mutation that arose with Queen Victoria, long assumed to be the more common hemophilia A, turned out, after extensive medical forensic investigation, to be hemophilia B.⁶

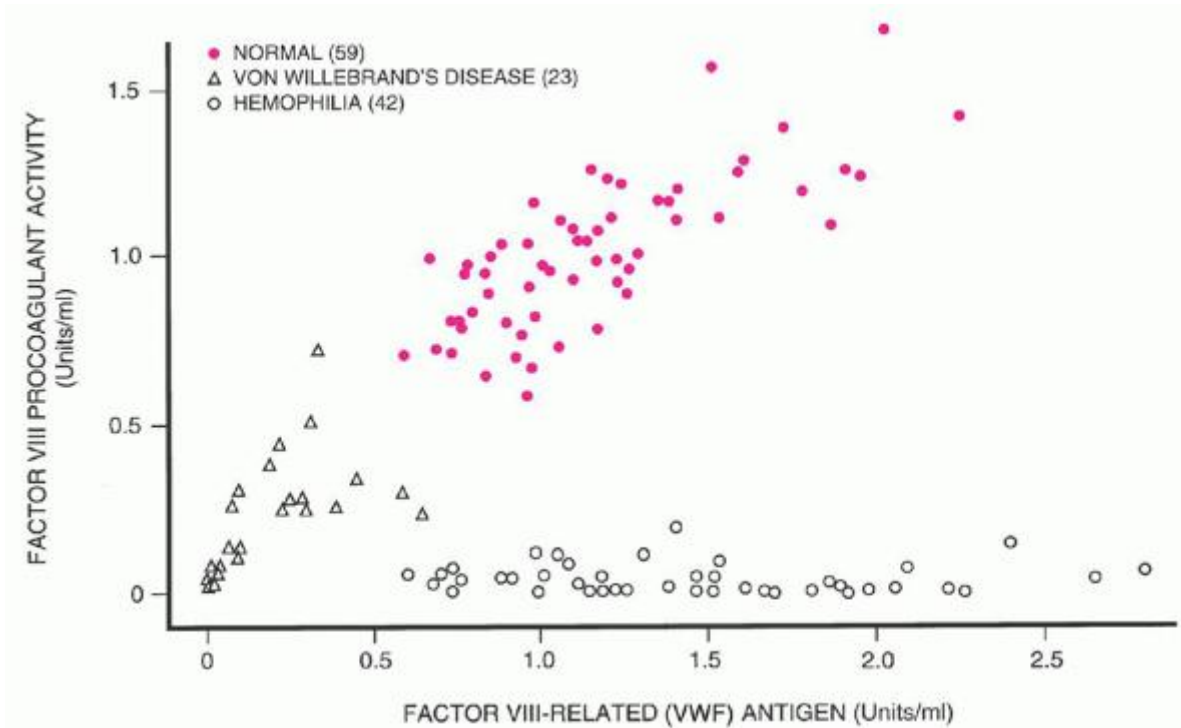

FIGURE 53.1. The relationship of factor VIII procoagulant activity and factor VIII-related antigen (von Willebrand factor [vWF]) in the plasma of normal subjects and patients with hemophilia or von Willebrand disease. (From Hoyer LW. The factor VIII complex: structure and function. *Blood* 1981;58:1-13, with permission.)

Pathophysiology

The hemostatic abnormality in hemophilia A (factor VIII deficiency, classic hemophilia) is a deficiency or functional abnormality of the plasma protein factor VIII. It normally circulates in the plasma bound to a much larger molecule, vWF. The half-life of factor VIII in the absence of vWF is much shorter, as seen in individuals with the vWF Normandy mutation, resulting in loss of the protein sequences for the binding interaction site between factor VIII and vWF, and causing low levels of factor VIII and clinical bleeding that appears similar to the bleeding seen in patients with hemophilia A. The production of vWF is coded by an autosomal gene, and this protein is qualitatively normal and is present in normal or increased amounts in patients with hemophilia A (Fig. 53.1).^{7, 8} The function of the coagulation protein factor VIII is to serve (when activated) as a cofactor for the serine protease enzyme factor IX, and accelerate the reaction as part of the coagulation cascade. No other function for factor VIII has been clearly characterized.

Incidence

Hemophilia A has been recognized in all areas of the world and in all ethnic groups. Estimates of its incidence approximate 1 in 5,000 males, or 1 in 10,000 persons.^{9, 10} A population-based study of the southeastern United States by the Centers for Disease Control and Prevention found that 11 cases per 100,000 persons had hemophilia A and that the prevalence was similar among different racial groups.¹¹ This same survey estimated that in 1994, there were 13,320 cases of hemophilia A in the United States.¹¹

Genetics

Hemophilia A is a classic example of an X-linked recessive trait. In such a disorder, the defective gene is located on the X chromosome¹²; the factor VIII gene maps to Xq28, on the distal end of the long arm of the X chromosome. In males who lack a normal allele, the defect is manifested by clinical hemophilia (Fig. 53.2; generation I, number 1). The affected male does not transmit the disorder to his sons (generation II, numbers 4 and 5) because

P.1145

his Y chromosome is normal. However, all of his daughters are obligate carriers of the trait because they inherit his X chromosome (generation II, numbers 2 and 3). Most of these women are unaffected clinically because of the presence of a normal allele from the mother. The female carrier transmits the disorder to half of her sons (generation III, numbers 6 and 7) and the carrier state to half of her daughters (generation III, numbers 8 and 9). Due to Lyonization of the X chromosome, if the normal factor VIII allele is inactivated more often by chance, then some of the carrier females may have clinical bleeding. The severity of their bleeding depends on their factor VIII activity level; and, rarely, a woman can have very low factor VIII activity and present with symptoms of moderate or even severe hemophilia.

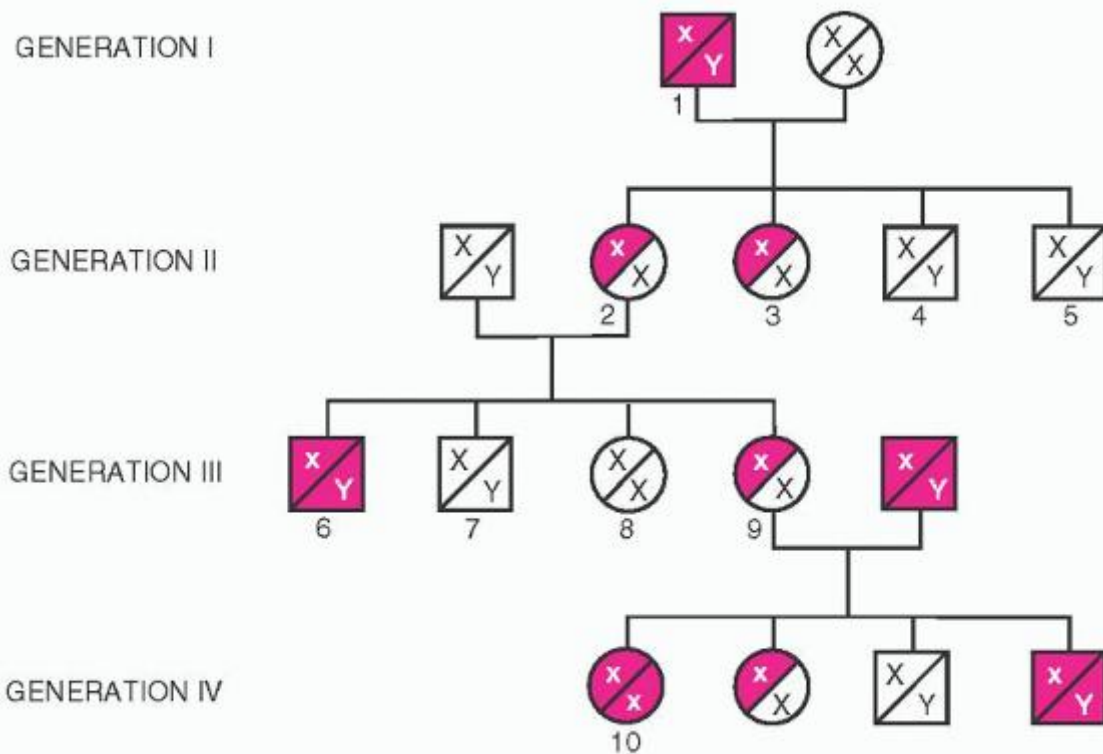

FIGURE 53.2. The inheritance of hemophilia A and hemophilia B. The pedigree is hypothetical. Squares indicate male; circles indicate female; fully shaded squares or circles indicate affected members; half-shaded circles indicate carriers. X, normal X chromosome; x, abnormal X chromosome.

The severity of bleeding varies in different kindreds, and closely depends on the particular genetic defect. Since the same gene defect is present in the kindred, each of the affected males will have very similar clinical phenotypes.¹³ As expected, hemophilia A has been observed several times in twins.¹⁴ Occasionally, however, the coinheritance of other genetic defects can influence the clinical symptoms of hemophilia A patients. An example is the coinheritance of the factor V Leiden mutation (discussed in Chapter 55) with hemophilia A. These patients have a milder clinical phenotype than expected for the same molecular defect in factor VIII.¹⁵ The coinheritance of the factor V Leiden mutation or other prothrombotic risk factors in children with severe hemophilia A may delay the first symptomatic bleeding event.¹⁶

Intriguing, and yet to be fully explained, is the fact that in over a third of families with hemophilia A, there is no evidence or history of abnormal bleeding in other members of the family.^{17, 18} This percentage is consistent with the Haldane hypothesis, which predicted that maintenance of a consistent frequency of a genetic disorder in the population would require that approximately onethird of cases result from spontaneous mutation. In other instances, neonatal deaths or

the passage of the trait through a succession of female carriers may explain the negative family history. For practical purposes, therefore, a negative family history is of little value in excluding the possibility of hemophilia A. Mutations that cause hemophilia A originate in males at least threefold more often than in females.¹⁹ The large size of the factor VIII gene (186 kb), the presence of hot spots (e.g., CpG dinucleotides), and the fact that the X chromosome is unpaired in males may predispose for the factor VIII gene to undergo spontaneous mutation.^{20, 21, 22, 23}

Nearly 3,000 individuals with hemophilia have had their factor VIII genes analyzed; this genetic information is collected in the Hemophilia A Mutation Database (HADB, formerly the Hemophilia A Mutation, Structure, Test and Resource Site [HAMSTeRS] database).²¹ The genetic defects of hemophilia A encompass deletions, insertions, and mutations throughout the factor VIII gene.²⁴ Point mutations involving CpG dinucleotides are especially common. Approximately 5% of patients with hemophilia A have large (>50 nucleotides) deletions in the factor VIII gene.²⁵

Approximately 45% of severe hemophilia A cases result from a major inversion of a section of the tip of the long arm of the X chromosome, one breakpoint of which is situated within intron 22 of the factor VIII gene.²⁶ This common inversion is associated with severe hemophilia A, and a higher incidence of inhibitor formation. It is presumed that in the absence of homologous X chromosome pairing during male meiosis, an intrachromosomal recombination event occurs on the single X chromosome, resulting in this inversion. This event typically occurs in the father of the mother of a child with severe hemophilia A, and often leads to relief of guilt feelings in the mother, as the genetic mutation is not "her fault." Another common inversion (intron 1) accounts for 5% of patients with severe factor VIII deficiency.²⁷ Thus, two inversions of the factor VIII gene are seen in nearly one-half of all severely affected patients with hemophilia A. In contrast, point mutations are most likely found in patients with mild to moderate hemophilia A.²⁸ The first case of hemophilia A caused by unequal homologous Alu/Alu recombination has been reported.²⁹ Because there are ~50 Alu repeats in the factor VIII gene, it is possible that many cases of hemophilia may result from this mechanism.²⁹ More than 95% of hemophilia A patients have mutations detected.^{22, 30, 31} Approximately 2% of hemophilia A patients have no detectable mutations in the coding region of the factor VIII gene.³² These results indicate that a substantial number of families with severe hemophilia A can undergo accurate gene tracking and carrier analysis. The intron 1 and 22 inversions responsible for 50% of severe hemophilia A cases can be sought using long and inverse polymerase chain reaction (PCR) techniques. Various algorithmic approaches to rapid laboratory genetic testing have been described,^{30, 33, 34} and a recent method of performing linkage analysis of hemophilia A in families in whom mutations could not be identified has been reported.³⁵

There is a strong association between genetic mutations that lead to absence of large portions of the factor VIII protein and the development of antibodies to therapeutic factor VIII infusions. These antibodies generally develop within the first 50 infusions of factor VIII, as expected when the immune system detects a protein to which it has not been exposed previously.

Variants

Hemophilia A with autosomal dominant transmission has been reported; however, it is important to distinguish these "variant hemophilia A patients" with negative X-linked transmission from patients with variant vWD (type 2N, vWD Normandy), an autosomal vWD subtype caused by defective factor VIII binding to vWF and with a clinical picture similar to hemophilia A.³⁶

Carrier Detection

Despite the high rate of spontaneous de novo mutations in hemophilia A, detection of females who are carriers is important. When the family history of a patient suggests risk for being a carrier, then coagulation-based assays are performed, followed by DNA testing. The daughter of a man with hemophilia is an obligate carrier, whether she has symptomatic bleeding or not. Similarly, if a female has two sons with hemophilia, then she is likely a carrier; if she has one son with hemophilia and a family history of hemophilia, then she is likely a carrier; but if she has one son with hemophilia and a negative family history, then the odds are approximately 67% that she is a carrier. A number of specialized laboratories perform molecular testing for the factor VIII gene. It is most efficient and less expensive if the DNA of the relative with hemophilia is available to identify the specific genetic mutation in that kindred; then only that specific mutation is evaluated in the potential carrier.³⁷

P.1146

Coagulation-based Assays

Coagulation-based assays may be useful in confirming or excluding the carrier state, although they have limitations. The regularity with which the abnormal factor VIII gene is suppressed by the normal allele in female carriers of hemophilia varies because of the phenomenon of random X chromosome inactivation (the Lyon hypothesis). Thus, although the mean concentration of factor VIIIc in the plasma of heterozygous female carriers is ~50% of that in normal women,^{13, 38} observed values scatter widely around this mean and often overlap with those found in the normal population. This is a result, in part, of the large error of assay methods and the wide range of factor VIIIc levels in normal subjects.

Although the demonstration of low levels of factor VIIIc by means of the usual assay methods strongly suggests the presence of the carrier state, the converse statement cannot be made with equal certainty—that is, the presence of normal levels of factor VIIIc does not reliably exclude the carrier state.³⁹ Furthermore, pregnancy and hormonal medications may increase the levels of factor VIIIc in female carriers.⁴⁰ Normal women and carriers with blood types A, B, or AB have higher levels of factor VIIIc and vWF_{Ag} than those with blood type O.⁴¹

The use of immunoassays for vWF has improved carrier detection in hemophilia A.⁴² These methods allow measurement of levels of vWF, which are normal⁴³ or increased in carriers of the disorder, despite mild but variable deficiencies of factor VIIIc. Results obtained when a bioassay and an immunoassay are performed on the same sample, and the ratio of VIIIc to vWF is computed, differentiate between the carrier population and the normal population with minimal overlap.⁴⁴ This ratio normally ranges from 0.74 to 2.20 and was found to be from 0.18 to 0.90 in obligatory carriers. The overall detection rate ranged from 72% to 94% in such obligatory carriers⁴⁶ and from 48% to 51% in women without hemophilic sons or fathers.⁴² In the latter group (possible carriers), 50% would be predicted to be carriers. Abnormally low ratios of VIIIc:vWF (false positives) have been encountered in an occasional normal subject,^{43, 45} which may be attributable to nonspecific variables such as stress.⁴⁶ Pregnancy and the use of oral contraceptives, blood type,⁴¹ or contamination of plasma samples with thrombin⁴⁶ or other proteolytic enzymes may produce falsely high ratios (false negatives) in documented obligatory carriers. Linear discriminant analysis⁴⁷ has been recommended for the expression and analysis of such laboratory data. The carrier detection rates using standardized assays with discriminant analysis exceed 90%.⁴⁸

DNA-based Assays

Molecular analyses of the factor VIII gene identify mutations in 97% of hemophilia A patients. Based on the frequency of the intron 22 inversion, severe hemophilia A patients should be initially screened for this defect. Inversion-negative patients and those with mild or moderate hemophilia A should have systematic sequencing of the factor VIII promoter, exons, and splice junctions performed. Such an approach has been reported to identify mutations in 97% of hemophilia A patients.³⁰

DNA-based assays have been adapted for prenatal diagnosis,⁴⁹ and for pre-implantation genetic diagnosis in association with in vitro fertilization. One commonly used method is to obtain chorionic villi samples during the eleventh to twelfth gestational week and perform direct genotype testing.⁵⁰ Alternatively, genetic linkage analysis of polymorphisms can be performed. The subject of genetic counseling in hemophilia has been reviewed.⁵¹

Hemophilia in the Female

Hemophilia has been well documented in human females.^{44, 52} The most common form is that seen in a minority of heterozygous carriers, discussed previously, in whom X chromosome inactivation may occur at an unusually early stage of embryogenesis, resulting in unusually low levels of factor VIII.

A second cause of female hemophilia is a mating between an affected male and a carrier female (Fig. 53.2; generation IV, number 10).⁵³ One-half of the female offspring of such a match would inherit two abnormal X chromosomes, one from the father and one from the mother. Such homozygous female hemophilia was once thought to be lethal and to inhibit the development of the embryo. That this is not true was first suggested by the successful experimental production of hemophilia in female dogs. Homozygous hemophilia is now well authenticated in several women^{53, 54} and resembles the disorder seen in affected males in all respects.

Clinical Manifestations of Hemophilia

Prior to effective replacement therapy, the life expectancy for a child born with severe hemophilia was less than 20 years. These boys would die from exsanguinating hemorrhage after a trivial traumatic injury, from spontaneous internal bleeding or from spontaneous intracranial hemorrhage. It is dramatic that a boy born today with severe hemophilia A can expect to have a normal life expectancy.

However, the most characteristic bleeding manifestations in hemophilia are spontaneous bleeding in weight-bearing joints, leading to severe hemarthrosis. The frequency and severity of these joint bleeds are related to the functional activity level of factor VIII in plasma^{8, 55} (Table 53.3). Three categories of severity have been defined by a consensus

committee on the basis of FVIII activity levels (Table 53.3).⁵⁶ Severe hemophilia (factor VIII level <1 IU/dl) is manifested clinically by repeated and severe hemarthroses, resulting almost invariably in crippling arthropathy in the absence of replacement therapy; such severe cases often are called classic hemophilia. Moderate hemophilia (factor VIII level of 1 to 5 IU/dl) is associated with less frequent and less severe hemarthroses and seldom results in serious orthopedic disability. In mild hemophilia (factor VIII level of 6 to 40 IU/dl), hemarthroses and other spontaneous bleeding manifestations may be absent altogether, although serious bleeding may follow surgical procedures or traumatic injury.⁵⁷ As indicated in Table 53.3, most patients with hemophilia A have severe disease. However, one epidemiologic survey reported variable differences in the incidence of severity between individual states within the United States; for example, 13% of hemophilia cases were of moderate

P.1147

severity in Massachusetts, whereas 35% of cases in Georgia were classified as moderate severity.¹¹

TABLE 53.3 PREVALENCE AND SEVERITY OF HEMOPHILIA A AND HEMOPHILIA B IN THE UNITED STATES

Factor VIII or IX Level (IU/dl)	Clinical Picture ^a	Incidence (%) ^b	
		Hemophilia A	Hemophilia B
<1	Severe, spontaneous bleeding	70	50
1-5	Moderate bleeding with minimal trauma or surgery	15	30
6-40	Mild bleeding with major trauma or surgery	15	20

^a The criteria for classifying hemophilia severity are taken from White GC, Rosendaal F, Aledort M, et al. Definitions in hemophilia. *Thromb Haemost* 2001;85:560.

^b Incidence figures are for the United States in 1989 and were provided by the National Hemophilia Foundation (Courtesy of Kathleen F. Cortes, PhD).

From Rodgers GM. Common clinical bleeding disorders. In: Boldt DH, ed. *Update on hemostasis: contemporary management in internal medicine*. New York: Churchill Livingstone, 1990:75-120, with permission.

Hemarthrosis

Hemarthrosis is the most common manifestation of the inherited coagulation disorders (Fig. 53.3). Joint bleeding and the consequent damage to weight-bearing joints remain the most common debilitating symptom in severe hemophilia.

Pathophysiology

Bleeding presumably originates from the synovial vessels and develops spontaneously or as the result of imperceptible or trivial trauma. Spontaneous joint bleeding in the absence of identifiable mild trauma is unusual in patients with moderate hemophilia and very rare in patients with mild hemophilia. Hemorrhage occurs into the joint cavity or into the diaphysis or epiphysis of the bone. In the acute stage, the synovial space is distended with blood. Muscular spasm further increases the intrasynovial pressure. Hemorrhage into the periarticular structures is a common complicating feature that occurs most often around small joints. The inflammatory response to joint bleeding is highly variable and not well studied. However, in many patients permanent joint damage, detectable by MRI, appears to occur after only one or two minor bleeds into a single joint.⁵⁸

The joint may regain normal function after the first few episodes of hemarthrosis. More often, however, the absorption of intraarticular blood is incomplete, and the acute bleeding leads to chronic inflammation of the synovial membrane with the development of long-term damage to the joint. Sometimes, the joint remains swollen, tender, and painful for months, and in this setting may often suffer episodes of rebleeding. Such a joint is often termed a “target joint,” and should be treated aggressively with physical therapy and appropriate factor replacement to interrupt the vicious cycle of

inflammation, swollen synovium, and recurrent bleeding. Release of inflammatory cell proteolytic enzymes initiates destruction of cartilage and bone.⁵⁹

Acute hemarthroses almost invariably recur from time to time. With each recurrence, the synovium becomes progressively more thickened and vascular; folds and villi, which predispose to synovial injury during even minimal activity, may form. Proliferating synovium often fills and distends the joint, which remains swollen and enlarged in the absence of bleeding or pain (chronic proliferative synovitis).⁶⁰ Together with the weakening of the periarticular supporting structures, this process predisposes the joint to recurrent episodes of bleeding. Repeated episodes of hemarthrosis, with the associated subchondral and synovial ischemia, result in progressive loss of hyaline cartilage, particularly at the margins of the joint. Large punched-out areas of destruction are sometimes produced by subchondral hemorrhages and, in the cancellous structure of the bone, cavitation may be caused by intraosseous hemorrhage. Through disuse, diffuse demineralization of the involved bones also may occur. Subperiosteal hemorrhages are not common.

FIGURE 53.3. Hemophilic arthropathy. This figure illustrates the sequelae of recurrent joint bleeding.

The terminal stage of hemarthrosis is called chronic hemophilic arthropathy.⁶¹ It is manifested by fibrous or bony ankylosis of larger joints; complete destruction may take place in the smaller articulations because of the weaker joint structure and the thinner cortices of the smaller bones. Other permanent sequelae of hemarthrosis include atrophy and proliferation of bone, roughening of the articular surfaces with lipping and osteophyte formation, bone necrosis and cyst formation, stunted growth as the result of interference with the nutrition of the bone, and accelerated development and overgrowth of the epiphyses caused by excessive blood flow (Figs. 53.3 and 53.4). Chronic hemophilic arthropathy is less common now because of widespread use of prophylactic replacement therapy and improved availability of factor replacement therapy. Magnetic resonance imaging is superior to standard radiography for assessment of early arthropathy.⁶² A scoring system for magnetic resonance joint evaluation has been reported⁶² (Table 53.4).

It should be emphasized that with modern prophylactic therapy of regular factor infusions to maintain the plasma factor concentration above 1% of normal, boys are now reaching adolescence and young adulthood with essentially normally functioning joints. However, such a program of regular infusions with currently available factor therapies requires intensive medical and family support.

Clinical Presentation

Most persons with severe hemophilia report a characteristic warm, tingling sensation before the onset of symptoms of joint bleeding and hemarthrosis; this is called the aura. The earliest definite symptom is pain, which in the acute form may be excruciating. Physical examination reveals muscle spasm and limited motion of the affected joint. If therapy is not initiated immediately, typically within approximately 30 minutes, then the joint may progress so that it is warm and grossly distended and discolored,

P.1148

but external evidence of bleeding may be minimal or absent in chronically damaged large joints because of thickening of the articular capsule. Generally, only one joint is involved at a time, although bleeding may develop simultaneously in two or more joints. The weight-bearing joints are most commonly affected and the knees are the joints most often severely affected. However, because of the success of total knee and total hip replacement surgeries, the ankles are the most commonly affected joints that lead to chronic problems that interfere with quality of life for persons with severe hemophilia.

FIGURE 53.4. Elbow and knee joints in a patient with hemophilia A. Thickening of synovium with deposition of calcium is shown in (A) and (A1); increased intercondylar notch is shown in (B); increased density and decreased interarticular space are shown in (A), (B), and (C); and lipping along the borders of the joint surfaces is shown in (C).

Score Abnormalities on Imaging

- O None
- I Minimal hemosiderin
- II Large amount of hemosiderin and cartilaginous erosion
- III Cartilage destruction, bone erosion, subchondral cysts
- IV Osteoarthritis with or without ankylosis

Subcutaneous and Intramuscular Hematomas

Large ecchymoses and subcutaneous and intramuscular hematomas were common in hemophilia A prior to the use of regular infusion therapy, reflecting the substantial amounts of time patients had factor levels less than 1% of normal. With modern treatment protocols designed to keep plasma levels above 1% of normal, and immediate home infusion when a bleeding episode occurs, the frequency of large soft tissue bleeds has decreased dramatically. Such hemorrhages, when not treated promptly, characteristically spread within fascial spaces and dissect deeper structures (see Fig. 45.2). Subcutaneous bleeding may be extensive. When not treated promptly with factor infusion, the bleeding continues; and at the site of origin, the tissue is hard, indurated, raised, and purplish black. From this center, the hemorrhage extends in all directions, with each successive concentric extension less deeply colored. The point of origin of the hemorrhage may be absorbed entirely while the margin is still progressing. Intramuscular and subcutaneous hematomas may produce leukocytosis, fever, and severe pain in the absence of significant discoloration of the overlying skin.

Hematomas may produce serious consequences from the compression of vital structures. Bleeding into the tongue, throat, or neck may develop spontaneously and is especially dangerous because it may compromise the airway with surprising rapidity.⁶³ Gangrene may result from pressure on arteries; and the development of compartment syndrome and, if not promptly treated, ischemic contractures are common sequelae of hemorrhage into the calves or forearms. Peripheral nerve lesions of varying severity are common complications of untreated hemorrhage into joints or muscles. Hemophilic cysts are discussed in the section Special Aspects of Treatment.

Psoas and Retroperitoneal Hematomas

Spontaneous hemorrhage into internal fascial spaces and muscles of the abdomen is common in severe hemophilia A,⁶⁴ reflecting plasma factor levels less than 1% of normal. Bleeding into or around the iliopsoas muscle produces pain of progressively increasing severity and tenderness; when it occurs on the right side, it may closely simulate acute appendicitis. Femoral nerve involvement may be partial or complete, with the development of pain on the anterior surface of the thigh. The psoas sign is positive, and the hip is held in partial flexion. Paresthesias, partial or complete anesthesia, and, ultimately, weakness or paralysis of the thigh extensors with eventual muscular atrophy may ensue. Retroperitoneal hemorrhage and intraperitoneal hemorrhage also are common. Computed tomography may be helpful in the diagnosis of these hematomas.⁶⁴ Prompt factor infusion is critical to normalize coagulation and should be continued until the hematoma has resolved completely, as any residual hematoma is at higher risk for rebleeding and pseudocyst formation.

Gastrointestinal and Genitourinary Bleeding

Hemorrhage from the mouth, gums, lips, frenulum, and tongue is common and often serious. The eruption and shedding of deciduous teeth usually occur without abnormal bleeding, but may occasionally be accompanied by hemorrhage that lasts for days or weeks if not treated. Epistaxis occurs in many patients and may be of exsanguinating proportions.

Hematemesis, melena, or both are not uncommon. The source of the bleeding is usually the upper gastrointestinal tract. In most patients in whom bleeding is persistent or recurrent, it originates from a structural lesion, most commonly a peptic ulcer or gastritis. Hemorrhage may be accompanied by abdominal pain, distention, increased peristalsis, fever, and leukocytosis. Intramural bleeding into the intestinal wall may result in intussusception or obstruction.

Hematuria is more common than gastrointestinal bleeding, but it is less often the result of a demonstrable pathologic condition in the genitourinary tract. The bleeding may arise in the bladder or in one or both kidneys and may persist for

days or weeks.⁶⁵ When clots form, ureteral colic may develop. Typically, the hematuria resolves after factor infusion, but if persistent, then a short course of prednisone may prove helpful to shorten the course of hematuria.⁶⁶

Traumatic Bleeding

Patients with coagulation disorders seldom bleed abnormally from small cuts such as razor nicks, reflecting the normal function of platelets, as measured by platelet function tests. All laboratory assays of platelet function are normal in patients with severe hemophilia A. After larger injuries, however, hemorrhage out of proportion to the extent of the injury is characteristic. The bleeding reflects both increased acute bleeding rates beyond what is expected after the trauma, and persistent bleeding as slow continuous oozing occurs for days, weeks, or months. Such traumatic bleeding may be massive and life-threatening unless coagulation replacement therapy is provided by immediate factor infusion.

Delayed bleeding is common. Thus, although hemostasis after an injury or a minor surgical procedure may appear to be adequate, hemorrhage, often of sudden onset and serious proportions, may develop several hours or even days later. This phenomenon apparently occurs because the processes of primary hemostasis are only temporarily effective. Delayed bleeding may occur in patients with mild hemophilia and is a significant hazard after minor surgical procedures, particularly those performed on an outpatient basis, such as tooth extraction and tonsillectomy.

Venipuncture, if skillfully performed, is without danger for the person with severe hemophilia, primarily because of the elasticity of the venous walls. If venipuncture is traumatic, digital pressure on the puncture site or a pressure dressing may prevent further complications. Subcutaneous, intracutaneous, and small intramuscular injections seldom produce hematomas if firm finger pressure is maintained for at least 5 minutes. Large intramuscular injections should be avoided. Vaccination using intramuscular injections is acceptable with minimal increase in bleeding risks.

Other Clinical Aspects

Infants usually are asymptomatic because they are insulated from trauma.⁶⁷ However, trauma during birth or afterwards may trigger

P.1149

life-threatening bleeding. Infants of women who are known carriers may be at risk during delivery, and instrumentation during vaginal delivery should be avoided. Currently, the usual standard of care is to avoid testing the infant in utero due to the risks inherent in current techniques available to test the fetus, and to allow normal vaginal delivery with back-up Caesarean section available if any difficulties arise during birth. Typically, hematomas are seen first when children become active, and hemarthroses seldom develop until they begin to walk. Occasionally, evidence of the disorder is not seen until patients reach teenage years or young adult life. Spontaneous hemorrhage may be cyclic in nature. Petechiae, which are characteristic of disorders of platelets and blood vessels, are rare in patients with hemophilia but have been noted in severely affected patients during an exacerbation of bleeding. Hemorrhage from the umbilical cord or stump is unusual, but prolonged bleeding after circumcision is common and brought hemophilia to the attention of the ancient Hebrews. Pulmonary and pleural bleeding are uncommon, although mediastinal and pleural shadows have been noted radiographically and presumably originate from fresh or old hematomas. Intraocular hemorrhage is uncommon, but bleeding into the orbit and conjunctiva occurs often. Spontaneous rupture of the spleen has been reported. Intracranial bleeding is discussed in the section Special Aspects of Treatment. The website for the National Hemophilia Foundation is www.hemophilia.org and contains useful information and links to more detailed information on this bleeding disorder.

Course and Prognosis

In recent years, the prognosis in severe hemophilia has improved dramatically. With modern therapy using regular factor infusions to maintain adequate plasma factor concentrations to prevent nearly all spontaneous bleeding episodes, a person born with severe hemophilia A can expect to live an essentially normal lifespan. No other genetic disease has made such dramatic progress in the past 50 years. It is not yet clear whether hemophilia protects older hemophilia patients from thromboembolic disorders,⁶⁸ atherosclerosis,⁶⁹ or cardiovascular diseases. Despite the lack of stringent prospective clinical studies for this emerging problem of aging patients with severe hemophilia and other medical problems, reviews of current practice and expert opinion on how to treat aging patients with severe hemophilia have been published.^{70, 71, 72, 73}

TABLE 53.5 LABORATORY FINDINGS IN COMMON INHERITED COAGULATION DISORDERS

Disorder	Partial Thromboplastin	Prothrombin Time	Thrombin Time	Ancillary Tests
-----------------	-----------------------------------	-----------------------------	--------------------------	------------------------

	Time (PTT)			
	A	N	N	
Hemophilia A	A	N	N	vWF antigen and activities are normal or increased, ratio VIIIc:vWF is low.
Hemophilia B ^a	A	N ^a	N	—
von Willebrand disease ^{a, b}	A or N	N	N	vWF antigen and VIIIc are usually low, ratio VIIIc:vWF is variable; ristocetin-induced platelet aggregation and ristocetin cofactor activity are usually diminished.
Afibrinogenemia	A	A	A	Platelet function may be abnormal.
Dysfibrinogenemia ^a	vA	vA	A ^{c, d}	Hypofibrinogenemia, ^e reptilase time is prolonged, ^a fibrin(ogen) degradation products levels are increased. ^a
Hypoprothrombinemia ^a	A	A	N	Two-stage assay is abnormal. ^f
Factor V deficiency	A	A	N	—
Factor VII deficiency ^a	N	A	N	Stypven (Russell viper venom) time is normal.
Factor X deficiency ^a	A	A	N	Stypven time is abnormal.
Factor XI deficiency	A	N	N	—
Factor XII deficiency	A	N	N	—
Factor XIII deficiency	N	N	N	Clot solubility tests are abnormal.

A, abnormal; N, normal; v, variable; vWF, von Willebrand factor.

Certain PTT reagents may not detect mild deficiency of factors VIII, IX, and XI.

^a Findings are significantly different in some variants.

^b Coagulation abnormalities are caused by deficiency of factor VIIIc.

^c Patient's plasma may inhibit normal coagulation.

^d Abnormality may be corrected by increasing calcium concentration and may be magnified by diluting the thrombin solution.

^e Abnormality varies depending on technique.

^fResults of one-stage techniques may be uninterpretable.

Laboratory Diagnosis

The activity of the various coagulation factors is expressed in terms of units, defined as the activity present in 1 ml of fresh plasma from normal donors. The concentration of all coagulation factors in normal pooled plasma is thus 1 IU/ml or 100 IU/dl, or 100% activity. It should be noted that the activity levels in blood bank plasma are somewhat lower, approximately 80 IU/dl because of the dilution with anticoagulant.

Routine clinical laboratory tests (noncoagulation) are normal in patients with hemophilia A. The presence or absence of anemia or of signs of blood regeneration depends on the severity and frequency of bleeding, as in any individual patient. Neutrophilia may accompany severe hemorrhage, and the destruction of red blood cells in the hematoma may be reflected in elevated LDH, AST, or bilirubin. As in other instances of posthemorrhagic anemia, the bone marrow reflects the response to blood loss.

Screening Tests of Hemostasis and Coagulation

The partial thromboplastin time (PTT) usually is prolonged in patients with hemophilia A (Table 53.5). The biochemical conditions for most laboratory assays of PTT are set so that the PTT is abnormal if the factor VIII level is <25% of normal; however, some PTT reagents are insensitive to mild factor VIII deficiency.⁷⁴ Therefore, in most situations the abnormality of the PTT can be

P.1150

normalized by mixing the patient's plasma with normal plasma in a ratio of 1:1; and this test, called a mixing study, is routinely used to detect whether neutralizing factor VIII antibodies are present. The platelet count usually is normal, but may be elevated in the stress reaction to hemorrhage.

Factor VIIIc Assays

Assay of factor VIII is a simple technique, but requires trained and experienced technicians, as the results are sensitive to errors in laboratory technique, or to errors in proper handling of the blood specimen. In clinical practice, if the laboratory results do not seem to fit the clinical picture, then most clinicians will repeat the laboratory test, and/or discuss the results with the laboratory personnel. Two-stage methods,⁷⁵ one-stage methods,⁷⁶ and micromethods⁷⁷ are suitable for diagnosis. The one-stage techniques are used most widely because they are simple to perform. They require either a supply of plasma from a known individual with severe hemophilia, which is available commercially, or artificial substrate plasma. Two-stage assays detect approximately 20% more factor VIII than do one-stage methods,⁷⁸ and they are less subject to variables⁷⁹ such as fluctuations attributable to contaminating traces of thrombin or other proteolytic enzymes.

The World Health Organization makes international standards, but many laboratories purchase commercial secondary standards that are calibrated to the international standard. Under most circumstances, a pool of citrated plasma carefully collected from normal subjects and frozen in individual laboratories also serves as an acceptable standard.

The factor VIII assay has a large potential for error, even in expert hands. Therefore, when borderline values are obtained, the assay should always be repeated. Extensive studies of the many variables of the factor VIII assay have been reported.^{80, 81, 82, 83}

In the clinical setting of delivery of a boy with a question of hemophilia A, assays for both factor VIII and vWF may be carried out with reasonable accuracy on material obtained by fetoscopy—that is, mixtures of blood and amniotic fluid⁸⁴ or unmixed fetal blood.⁸⁵

The availability of a new recombinant form of factor VIII (B domain-deleted factor VIII, Xyntha) raised concerns about accurate laboratory monitoring of patients receiving this product.⁸⁶ Chromogenic substrate assays or typical one-stage PTT assays using physiologic phospholipids are needed to quantitate factor VIII levels accurately in patients receiving B domain-deleted factor VIII.⁸⁷ Alternatively, a standard one-stage PTT assay using B domain-deleted factor VIII as the assay

standard would be appropriate. The use of concentrate standards (rather than plasma standards) diluted in factor VIII-deficient plasma has been proposed as a solution to resolve discordant results using different assay methods.⁸⁸

Analysis of appropriate methods for laboratory assays of factor VIII activity levels after therapeutic infusions of the newer factor VIII products with extended half-life will be an important part of the small phase III clinical trials initiated in 2012.⁸⁹ The Scientific Subcommittee on Standards of the International Society of Thrombosis and Haemostasis is involved in defining appropriate standards for these new products.

Factor VIII Ag (cAg) Assays

Highly specific but complicated assays using immunoradiometric methods and ELISA techniques⁹⁰ are available to measure factor VIII Ag (VIII Ag). The latter methods use liquid- and solid-phase principles and both natural factor VIII antibodies and monoclonal antibodies. The results of both of these techniques demonstrate the absence of factor VIII Ag in most severely affected hemophiliacs and correlate well with factor VIIIc measurements in most cases. Results are more variable when mild hemophiliacs are tested. In most series, ~10% of patients have detectable levels of factor VIII Ag and a low VIIIc-to-VIII Ag ratio (the CRM-positive variant). Immunoassays for vWF are discussed in the section Laboratory Diagnosis.

Differential Diagnosis

The diagnosis of hemophilia A is seldom difficult, especially in the severely affected patient with repeated and often serious hemorrhagic manifestations, including such characteristic signs as hemarthrosis. Typically the PTT is abnormal and leads to specific assays for clotting factor activity and mixing studies to rule out neutralizing inhibitors of coagulation activity. Hemarthrosis with significant orthopedic disability is rare in patients with coagulation disorders other than hemophilia A or B.

In patients with mild forms of the disorder, however, failure to recognize the existence of the disease or to make the correct diagnosis is more likely. Such patients rarely have a history of spontaneous bleeding, and the family history tends to be vague or negative. A history of abnormal bleeding after minor trauma may be difficult to establish due to variability in bleeding. Occasionally, mild hemophilia A may present with a normal PTT when the factor VIII activity assay result is greater than 25%; thus a normal PTT may be misleading. It must be emphasized that individuals with mild hemophilia are still at risk for hazardous hemorrhage after trauma or during surgical procedures.^{91, 92} A survey of hemophilia carriers found that mild reduction in factor VIII or IX levels (41 to 60 IU/dl) was associated with excessive bleeding.⁹³ A normal PTT value, therefore, cannot be relied on to exclude the possibility of hemophilia. In the mildly affected patient, specific factor assays must be performed to confirm or exclude the diagnosis of hemophilia.

The results of screening tests (Table 53.5) usually are sufficient to exclude the possibility of acquired hemorrhagic disorders associated with serious bleeding. Such disorders are seldom associated with a prolonged PTT and a normal prothrombin time (PT), a combination that strongly suggests an inherited disorder or an inhibitor. Among the inherited disorders characterized by this combination of findings (hemophilia A, hemophilia B, and deficiencies of factors XI, XII, prekallikrein, and high-molecularweight kininogen [HMWK]), deficiency of the latter three factors can be readily excluded because their deficiency is not associated with excessive clinical bleeding. Factor XI deficiency in males may mimic mild hemophilia, and hemophilia B is clinically identical to hemophilia A. Both factor XI deficiency and hemophilia B must be distinguished from hemophilia A in the laboratory using specific factor activity assays. The best way to accomplish this goal in evaluating patients with an isolated prolonged PTT is by performing specific assays of these three factors in the order of their statistical frequency—that is, VIII, IX, and XI. A PTT mixing study should also be performed to exclude an inhibitor. A definitive diagnosis is of great importance because specific products are used to treat each of these disorders.

Severe vWD in males may be indistinguishable from mild hemophilia A. Confirmatory tests for vWD are needed to make this distinction. Patients with the uncommon type 2N vWD may also be clinically indistinguishable from patients with hemophilia A. This diagnosis is important to establish, because therapeutic infusions of recombinant factor VIII (r-FVIII) would be ineffective due to the shortened half-life of factor VIII resulting from the absence of effective binding to von Willebrand protein. An X-linked family history of bleeding supports a diagnosis of hemophilia A in these patients, and an autosomal recessive family history of bleeding supports a diagnosis of type 2N vWD. Statistically, one would expect a rare family that might carry both genetic disorders; clearly that situation may be problematic to resolve without additional genetic testing.

Bleeding manifestations in hemophilia may simulate a variety of conditions. However, serious confusion results only when the

correct diagnosis has not been considered and appropriate laboratory studies have not been ordered. Thus, a deep hematoma may be mistaken for a suppurative condition, and surgical drainage may be attempted. Bleeding into a small joint may produce a clinical and radiologic picture suggestive of sarcoma; when larger joints are involved, findings simulate tuberculosis, arthritis, or Perthes disease. Bleeding elsewhere may suggest local causes such as kidney tumor, pulmonary disease, or peptic ulcer. For example, blood clots due to hemophilia bleeding in the renal collection system might appear as masses on a CT scan and be confused with cancer, leading potentially to inappropriate invasive procedures to obtain tissue for cancer diagnosis.

Intra-abdominal bleeding raises particularly serious diagnostic and therapeutic problems in the patient with hemophilia, even when the hemophilia condition has been accurately diagnosed. Thus, hemorrhage into the psoas, when on the right side, may simulate acute appendicitis so closely that, in the opinion of many experienced clinicians, there is no reliable clinical means to differentiate between the two diagnoses. A retroperitoneal hematoma may be mistaken for an appendiceal abscess. Intraperitoneal hemorrhage and bleeding into and around other viscera may simulate perforating peptic ulcer, bowel obstruction, or virtually any acute intra-abdominal condition. Computed tomography scanning and sonography may be particularly helpful in differentiating between intra-abdominal conditions that require surgical intervention and retroperitoneal and psoas hemorrhages. In any case, early therapeutic infusion of factor VIII will prevent further bleeding and carries no additional risk for the individual with hemophilia. Therefore, when there is a question and further diagnostic tests are planned, factor VIII should be administered first and promptly before the diagnostic tests are performed.

HEMOPHILIA B

Hemophilia B was recognized as a separate disorder from hemophilia A in 1947.⁹⁴ Hemophilia B (Christmas disease, factor IX deficiency) was established as different from hemophilia A by Aggeler et al. in 1952.^{95, 96} Hemophilia A is approximately 5 times more common than hemophilia B.¹⁸ A 1994 survey estimated that there were 3,640 cases of hemophilia B in the United States.¹¹ As expected, it appears that the severity of hemophilia B is a consequence of the plasma factor IX concentration, and that for any particular plasma concentration, the clinical severity is similar for hemophilia A and B. However, in contrast with hemophilia A, most of the genetic causes of hemophilia B are not large deletions or inversions; therefore in many patients there is some antigenic protein, and often some low level of function of the mutated protein. Consequently, the clinical phenotype is often less severe. As with hemophilia A, hemophilia B is classified as severe, moderate, or mild based on the percentage of functional factor IX in coagulation activity assays. In addition, because of the presence of low levels of factor IX protein in more patients with hemophilia B, there are fewer persons with hemophilia B that develop neutralizing inhibitors (approximately 3% versus more than 25% in hemophilia A).

Historically, when plasma from patients with hemophilia B was tested against autologous antibodies, three distinct groups were defined: A cross-reactive material (CRM)-positive variant, the most common form; a CRM-negative variant; and a third form of the disorder in which antibody neutralization was variable in extent and was approximately proportional to coagulant factor IX activity (the CRM-reduced variant).⁹⁷ These distinctions are only of historical interest now.

In a disorder called hemophilia B Leyden,⁹⁸ the clinical manifestations tend to diminish during puberty in association with a rise in the factor IX level from as low as 1 IU/dl in childhood to levels of 20 IU/dl or more in adult life. The Leyden variant is characterized as CRM-negative at birth but becomes CRM-positive or CRM-reduced with advancing age.⁹⁸ The genetic basis for factor IX Leyden is that mutations occur in the factor IX gene promoter region; this region contains an androgen response element that, with age, stimulates factor IX gene transcription and protein synthesis.⁹⁹

In another variant of hemophilia B, the PT is prolonged when performed with ox brain thromboplastin.¹⁰⁰ This disorder has been called hemophilia B_m and is characterized by the presence in the plasma of CRM that neutralizes both autologous and heterologous antibodies to factor IX.¹⁰¹ The degree of abnormality of the ox brain PT is proportional to the plasma level of CRM in both affected males and carrier females. This variant results from mutations in the carboxy terminus of the factor IX molecule, resulting in a factor IX molecule that interacts abnormally with ox brain thromboplastin.

Numerous factor IX mutations have been recognized.^{22, 102} Factor IX purified from the plasma of affected members of one kindred did not fragment normally when activated in vitro (hemophilia B Chapel Hill).¹⁰¹ The molecular defect was found to be a substitution of histidine for arginine at position 145, a defect that inhibits cleavage by factor XIa.¹⁰³ Studies of factor IX obtained from another family¹⁰⁴ revealed biochemical abnormalities identical to those characteristic of the descarboxy analog of this factor that is found in vitamin K deficiency or produced by coumarin drugs. Such molecules lack Ca²⁺-binding sites and do not undergo conformational changes induced by Ca²⁺. Another report concerns a unique variant with deficient Ca²⁺ binding and an abnormally high-molecular-weight (factor IX Zutphen).¹⁰⁵

Genetics

Hemophilia B is inherited as an X-linked recessive trait, but the locus on the X chromosome of the gene controlling factor IX production is remote from that involved with factor VIII biosynthesis.¹⁰⁶ Factor IX levels <10% have been documented in a few women, including some with chromosomal abnormalities.^{107, 108, 109} Ten useful polymorphisms have been described that are associated with the factor IX gene.⁴⁹ An updated listing of mutations is available at www.kcl.ac.uk/ip/petergreen/haemBdatabase.html. Unlike hemophilia A, the spontaneous mutation rate is low,¹⁷ and most patients with hemophilia B have positive family histories.

Factor IX defects may be severe, moderate, or mild. Severe defects result from large gene deletions, nonsense mutations, and inversions; these defects are associated with absence of factor IX protein. Milder gene defects such as splice-site or missense mutations result in a dysfunctional protein with some residual activity. Missense mutations account for ~80% of mutations in severe hemophilia B patients.^{22, 110, 111, 112}

Detection of Carriers

Detection of heterozygous carriers of hemophilia B involves the same principles and limitations as described for hemophilia A. Carrier detection based on coagulation assay alone usually is more reliable than is the case with hemophilia A.¹¹³ Thus, in one series of 45 obligatory carriers, the mean factor IX level in the plasma was 33 IU/dl; 40 from the group had levels <50 IU/dl, and 10 had levels <25 IU/dl. As a consequence of these low levels of factor IX, abnormal hemorrhage is not uncommon in carriers of hemophilia B.

Results of immunoassays of factor IX and the ratio of factor IX-related antigen to coagulant factor IX levels in the carrier population overlap with the normal population to a considerable degree, particularly in the CRM-positive variants.^{114, 115} Such studies provide a lower overall detection rate among obligatory carriers of hemophilia B than is the case with hemophilia A.^{114, 115} Levels of factor IX-related antigen obtained by immunoassay

P.1152

are significantly increased by the use of oral contraceptives. The use of DNA probes¹¹⁶ and monoclonal immunoassays¹¹⁷ provide highly accurate methods for determining carrier status. Rapid carrier testing using allele-specific microarray methods has been described. This method permits detection of a majority of common factor IX mutations in a single assay.¹¹⁸ Prenatal diagnosis of hemophilia B has been successful in the CRM-negative variants.¹¹⁹ Modern methods for prenatal diagnosis use genetic testing and are quite reliable.^{120, 121} Determination of carrier status is based on several factors, including pedigree analysis, factor IX assay results, and genotype.¹²²

Clinical Features

Severely affected patients (those with factor IX activity levels <1 IU/dl) are less common than in hemophilia A (Table 53.3), but the clinical manifestations of the two disorders are identical for the same activity levels of the coagulation factors. Specific factor assays are necessary to distinguish between hemophilia A and hemophilia B. Mild factor IX deficiency should always be considered in the differential diagnosis of patients with coagulation-type bleeding and normal routine coagulation test results (PT, PTT).¹²³ Many PTT reagents do not detect mild factor IX deficiency (factor IX levels of 20% to 30%).⁷⁴

Laboratory Diagnosis

The laboratory diagnosis of hemophilia B involves the same approach and methods as those described for the recognition of hemophilia A (Table 53.5). The screening tests reveal similar abnormalities in the two disorders, except that the PT is abnormal in the B_m variant when either ox brain or Thrombotest is used as the thromboplastin.

Hemophilia A may be easily distinguished from hemophilia B by a specific factor assay. One-stage and two-stage assays for factor IX use the same principles as those discussed for factor VIIIc. Sensitive immunoassay methods for factor IX have been developed.¹²⁴

VON WILLEBRAND DISEASE

The historical confusion that has surrounded the pathogenesis of vWD is apparent from the many names that have been applied to this disorder. These designations include angiohemophilia, vascular hemophilia, pseudohemophilia, constitutional thrombopathy, and idiopathic prolonged bleeding time. von Willebrand first recognized the disorder in a 1926 study of the inhabitants of the Åland Islands.¹²⁵ Three cardinal manifestations of this bleeding disorder are mucocutaneous hemorrhage rather than hemarthrosis and deep-muscle bleeds; autosomal dominant inheritance, rather than sex-linked as seen in hemophilia A; and prolonged bleeding time. Evaluation of one large kindred revealed variable

severity of bleeding symptoms, with some obligate heterozygote carriers being asymptomatic. von Willebrand thought that the hemostatic defect resulted from combined defects in platelet function and vascular endothelium. The discovery that plasma from normal volunteers or patients with hemophilia A corrected the hemostatic defect of vWD suggested that a plasma protein distinct from factor VIII caused vWD. In 1972, von Willebrand factor (vWF) was purified. Genetic variants were correlated with various vWF structural abnormalities, and demonstration of the heterogeneous nature of vWD was furthered by development of vWF multimer analysis by gel electrophoresis.¹²⁶ In its most common form (type 1), the disorder is characterized by mild mucocutaneous hemorrhage, which is attributable to deficiency of both vWF and factor VIIIc. The disorder is not homogeneous, however, in part because of the multiple physiologic functions played by vWF. The recognition of a number of variants, together with the demonstration of multiple genetic patterns, suggested that vWD is very heterogeneous. However, all forms of vWD can be traced to insufficient amounts of vWF or defective function of this protein. Recent reviews of this area have been published,^{127, 128} and a consensus document on vWD sponsored by the National Institutes of Health reviewed all aspects of the disorder.^{129, 130}

Incidence

Epidemiologic studies indicate that vWD is the most common bleeding disorder, affecting about 1% of the population.¹³¹ The high incidence of the disease is not limited to certain ethnic groups^{131, 132}; however, only a fraction of people come to medical attention because of bleeding symptoms. This may be because of either the relatively mild nature of the disease in many affected individuals, or a lack of recognition by patients of excessive bleeding in response to either physiologic challenge (e.g., heavy menstrual bleeding) or trauma.

Nomenclature

The identification of numerous variants of vWD has led to attempts to simplify classification of this disorder. An updated classification system has been proposed (Table 53.6).¹²⁸ Quantitative defects are divided into partial deficiency (type 1) and severe deficiency with virtually complete absence of vWF (type 3). The qualitative defects (type 2) are divided into four categories according to the nature of the defect of vWF function. Type 2A refers to variants with impaired interaction between vWF and platelets, resulting from a deficiency of intermediate- and high-molecular-weight multimers of vWF. Type 2B refers to variants in which vWF exhibits increased affinity for its receptor, platelet GPIIb. Paradoxically, bleeding in these patients develops as a result of clearance of larger vWF multimers and platelets from the circulation. Type 2M refers to variants with defective interaction between vWF and the platelet GPIIb receptor that is not due to deficiency of high-molecular-weight multimers of vWF from plasma, but rather results from defects within the GPIIb-binding domain of vWF. Finally, variants of vWD in which decreased affinity of vWF for factor VIII results in depressed plasma factor VIII levels are classified as type 2N.¹²⁸ Thus, six major categories of vWD are defined, each having distinct pathophysiology.

TABLE 53.6 REVISED CLASSIFICATION OF VON WILLEBRAND DISEASE

Revised Type	Features
1	Partial deficiency of vWF
2	Qualitative vWF defects
2A	vWF variants with loss of high-molecular-weight multimers and decreased vWF-dependent platelet adhesion
2B	vWF variants with loss of high-molecular-weight multimers caused by increased affinity for platelet glycoprotein IIb
2M	vWF variants with decreased vWF-dependent platelet adhesion not associated with the loss of high-molecular-weight multimers
2N	vWF variants with decreased binding affinity for factor VIII
3	Severe deficiency of vWF

vWF, von Willebrand factor.

Data from Sadler JE, Budde U, Eikenboom JC, et al. Update on the pathophysiology and classification of von Willebrand disease: a report of the Subcommittee on von Willebrand Factor. *J Thromb Haemost* 2006;4:2103-2114.

P.1153

Genetics

A gene on chromosome 12 codes for the synthesis of the vWF macromolecule. The genetic message is composed of 52 exons covering a span of 158 kb.^{132, 133} The vWF gene encodes for a protein with multiple copies of homologous motifs, including three "A," three "B," two "C," and four "D" motifs (see Fig. 53.5). These motifs in turn encode protein domains that subserve the various functions of vWF. The A1 domain contains binding sites for platelet GPIb, ristocetin, and collagen,^{134, 135} the A2 domain contains a protease-sensitive domain that may have a role in regulating vWF function,¹³⁶ the A3 domain contains a second collagen-binding domain,¹³⁵ the C1 domain has an RGD sequence capable of interacting with platelet glycoprotein IIb/IIIa, and the D' and D3 domains contain a factor VIII-binding sequence.¹³⁵

vWD appears to be inherited by multiple genetic mechanisms (Table 53.7). The most common form of the disorder (type 1 vWD) accounts for ~70% of all cases of vWD. Diagnostic criteria for type 1 vWD have been proposed,¹²⁸ including a history of bleeding symptoms, a positive family history of bleeding symptoms, and bleeding that is attributable to quantitatively low vWF levels. Population screening suggests that the prevalence of vWD may be as high as 1% of the population, but only a minority of these patients subsequently present with clinically significant bleeding.¹³⁷ vWD is inherited as an incompletely dominant autosomal trait with variable penetrance, even among members within a single kindred. Because of variable penetrance and expression of vWD, only ~33% of children may be affected. Figure 53.6 illustrates one of the original pedigrees described by von Willebrand.

Twin studies demonstrated that ~60% of the variation in vWF level and ~50% of the variation in factor VIII level is attributable to genetic factors.¹³⁸ Genetic loci outside of the vWF gene contribute to variation of vWF level. Individuals with blood group O have vWF levels that are on average 30% lower than those of people with blood group A, B, or AB,¹³⁹ and it is likely that carbohydrate groups attached to vWF play a subtle role in clearance of vWF from plasma.^{140, 141} In addition, variation in expression of levels of other hemostatically active proteins, such as variation in the level of platelet adhesion receptors, may modulate the severity of symptoms conferred by vWF deficiency.¹⁴² vWF levels are under hormonal and other controls, which further complicates disease expression. Variation in levels of as much as 20% has been reported with menstrual cycle, with levels lowest in the early follicular phase (before day 7 of the cycle); and levels increase with age, rising ~15% for each decade increase in age.¹⁴³ As will be discussed later, the criteria for diagnosing quantitative vWD deficiency, and the specificity of historic bleeding, have introduced controversy in what constitutes type 1 vWD and have led to the potential for the new diagnostic entity of "low vWF".^{137, 144}

Mild to moderate quantitative deficiency of vWF characterizes patients with type 1 vWD, whereas virtual absence of vWF characterizes type 3 disease. Two large studies of families with a diagnosis of type 1 vWD and genetic evaluation of patients with type 3 disease have begun to shed light on the genetics of quantitative vWF deficiency.

Very low vWF levels in the range of 5 to 20 IU/dl tend to be highly inheritable and are frequently associated with "dominant negative"-acting mutations. Mutations in these patients with type 1 vWD appear to be different than those with type 3 disease, such that type 1 disease is not simply explained by being heterozygous for a type 3 allele. Genetic defects associated with these more severe type 1 phenotypes encode amino acid changes that in turn lead to defects in protein expression. Mechanisms responsible for decreased plasma vWF level include reduced secretion related to impaired intracellular transport of vWF subunits, increased clearance from the circulation, or accelerated catabolism as a result of increased susceptibility to degradation by ADAMTS13. Changes that were most likely to cause a "dominant negative" mechanism

P.1154

are often missense mutations that change the number of cysteine residues in the vWF protein. Although such changes probably affect vWF synthesis and trafficking in the cell, at least one common mutation (Tyr1584Cys) also results in enhanced degradation by ADAMTS13.^{145, 146} One non-cysteine-related mutation is seen in vWD Vicenza. In these patients, a mutation encoding for Arg1205His results in accelerated clearance of plasma vWF, with levels of vWF in the range of 15 IU/dl. With DDAVP stimulation, timed plasma sampling revealed that the released vWF had a circulation half-life that was approximately one-sixth of normal.¹⁴⁷ Several other similar mutations have recently also been described.¹⁴⁸

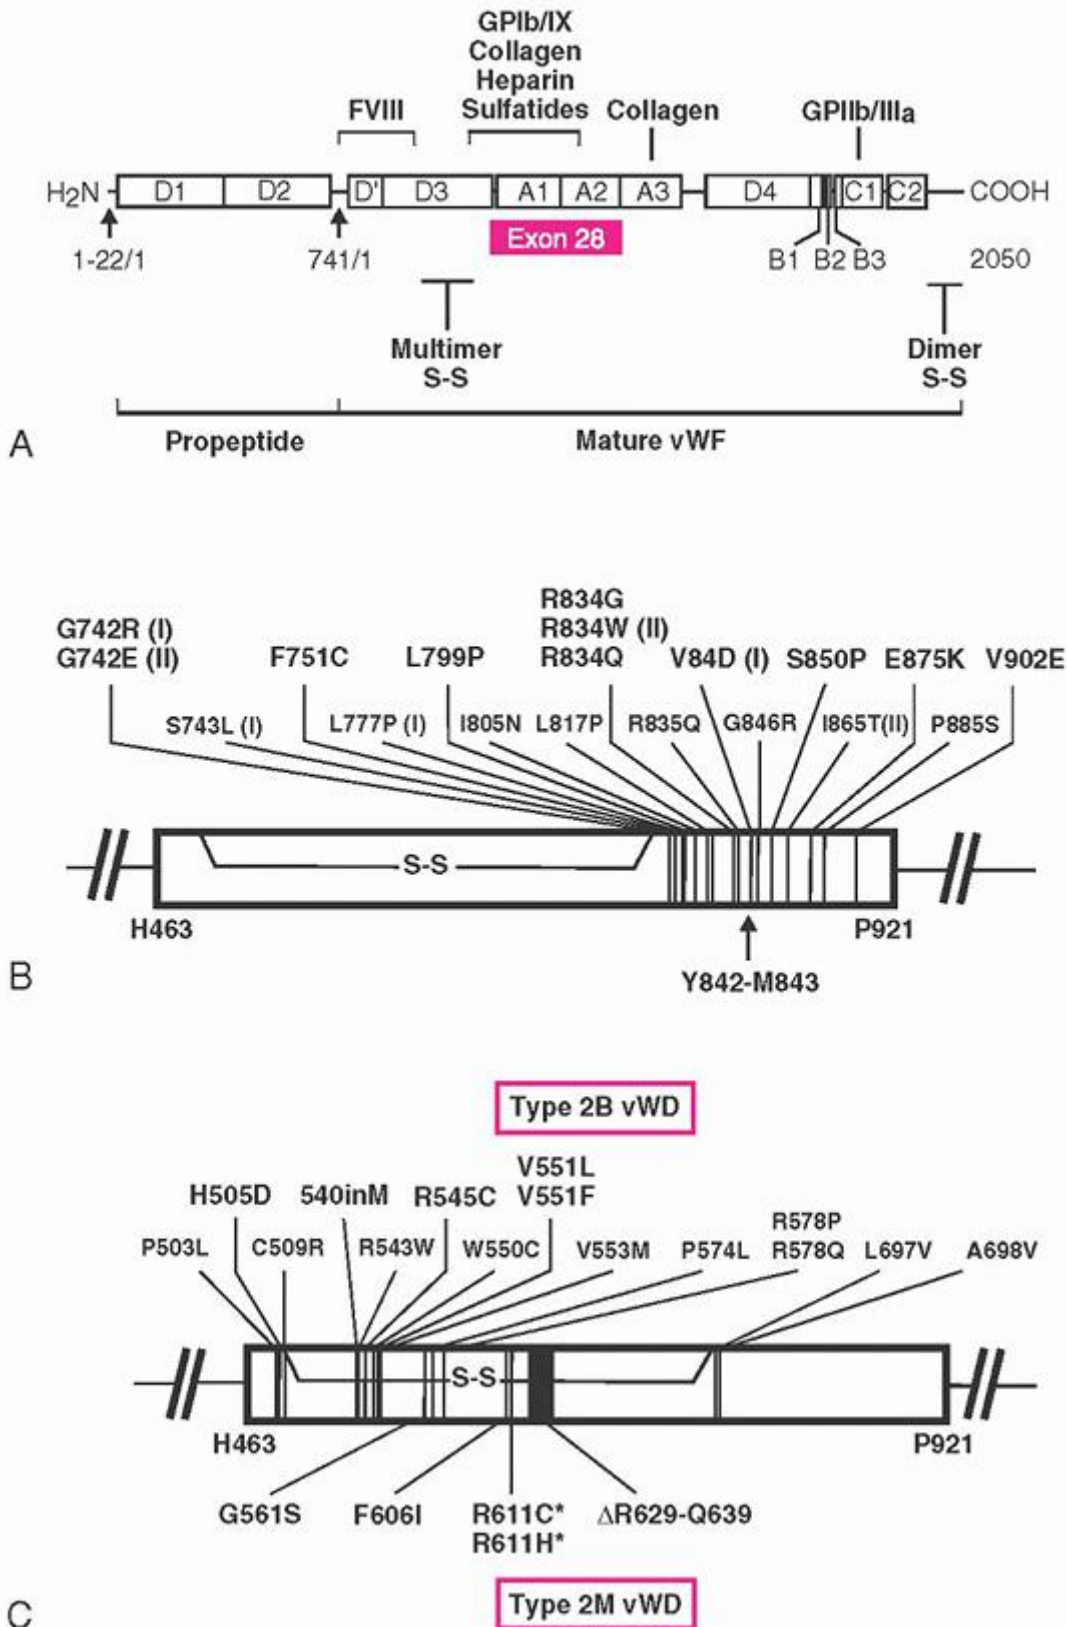

FIGURE 53.5. A: Structure and functional domains of von Willebrand factor (vWF). The open rectangles indicate domains of pre-pro-vWF. The first 22 amino acids of pre-pro-vWF are the signal sequence. The left arrow identifies the site of

cleavage of the signal peptide, resulting in pre-vWF monomers. Pro-vWF monomers form dimers, and the vWF propeptide (vWAgII) is cleaved from mature vWF (right arrow indicates cleavage site). Dimer S-S and multimer S-S indicate locations of disulfide bonds that covalently link monomeric vWF into dimers and dimeric vWF into multimers, respectively. The red rectangle identifies exon 28, which encodes the A1 and A2 domains of mature vWF. Functional domains are identified above the open rectangles. The factor VIII binding site is located in the D'and D3 domains in the amino-terminal 272 amino acids of mature vWF. The A domains of vWF contain the binding site for the platelet glycoprotein (gp) Ib/IX complex, as well as binding sites for heparin, collagen, and sulfatides. The gpIIb/IIIa complex binding site of activated platelets is located at the carboxy-terminal portion of the C1 domain and contains the Arg-Gly-Asp sequence. The numbers below the open rectangles indicate amino acid numbers: Signal peptide, 22 amino acids; propeptide (vWA-gII), 741 amino acids; mature vWF, 2,050 amino acids. B: Mutations associated with type 2A von Willebrand disease (vWD). The open rectangle represents vWF exon 28 encoding domains A1 and A2. The arrow indicates the site of proteolysis seen in type 2A vWD. Mutations are identified using the single-letter code for amino acids. I and II identify group I and group II missense mutations that result in impaired synthesis of vWF or increased sensitivity to proteolysis in plasma, respectively. The disulfide bridge shown represents the boundary of the Cys 509-Cys 695 loop in the A1 domain. Type 2A vWD mutations associated with defective vWF multimerization are not shown in this figure; these latter mutations occur in the propeptide (vWAgII) D1 and D2 domains. C: Mutations associated with types 2B and 2M vWD. The large open rectangle represents exon 28, which encodes domains A1 and A2 of vWF. The mutations responsible for type 2B vWD are shown above the rectangle. Most type 2B mutations lie between residues 540 and 578 of mature vWF. The mutations responsible for type 2M vWD are shown below the rectangle. Asterisks identify mutations that reduce the platelet-dependent function of vWF and vWF multimeric size. δ indicates deletion of an amino acid sequence. TABLE 53.7 FEATURES OF COMMON VARIANTS OF VON WILLEBRAND DISEASE

Features	Type 1	Type 2A	Type 2B	Type 3	Platelet Type
Inheritance	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal recessive	Autosomal dominant
Factor VIIIc in plasma	Normal or reduced	Normal or reduced	Normal or reduced	Markedly reduced	Normal or reduced
vWF antigen	Normal or reduced	Normal or reduced	Normal or reduced; increased affinity for platelets	Markedly reduced	Normal or reduced; increased affinity for platelets
Ristocetin cofactor activity	Normal or reduced	Reduced	Normal or reduced	Markedly reduced	Reduced or normal
vWF multimeric analysis	Normal (plasma and platelets)	Absence of large and intermediate-sized multimers in plasma	Absence of large multimers from plasma; normal in platelets	Small or absent multimers in plasma and platelets	Reduction in large multimers caused by "consumption" by platelets
Ristocetin-induced platelet aggregation	Normal or diminished	Diminished	Increased aggregation at low ristocetin concentrations	Markedly diminished	Hyperaggregation with patient's platelets, normal plasma, and low concentration of ristocetin

vWF in platelets	Normal or reduced	Normal or absence of large and intermediatesized multimers	Normal	Absent	Normal
Ancillary findings	DDAVP usually produces significant increase in plasma VIIIc and vWF	DDAVP produces rise in factor VIIIc, but functional vWF increase is variable and may be of short duration	Variable response to DDAVP, with intravascular platelet aggregation and thrombocytopenia in some cases; ristocetin-induced platelet aggregation enhanced in presence of patient's plasma; cryoprecipitate does not aggregate platelets in vitro unless ristocetin is added	Response to DDAVP lacking; endothelial vWF absent and	Transfusion of vWF or DDAVP may produce intravascular platelet aggregation and thrombocytopenia; cryoprecipitate produces in vitro platelet aggregation

DDAVP, 1-deamino-8-d-arginine vasopressin; vWF, von Willebrand factor.

At higher levels of vWF, linkage of the vWF level to the vWF gene is found less often. The recent European type 1 vWF cohort study demonstrated this observation. Almost all families with vWF levels <30 IU/dl showed linkage to the vWF gene, but the proportion fell to only 51% with vWF levels >30 IU/dl.⁹⁸ These data were corroborated in the Canadian study.¹⁴⁶

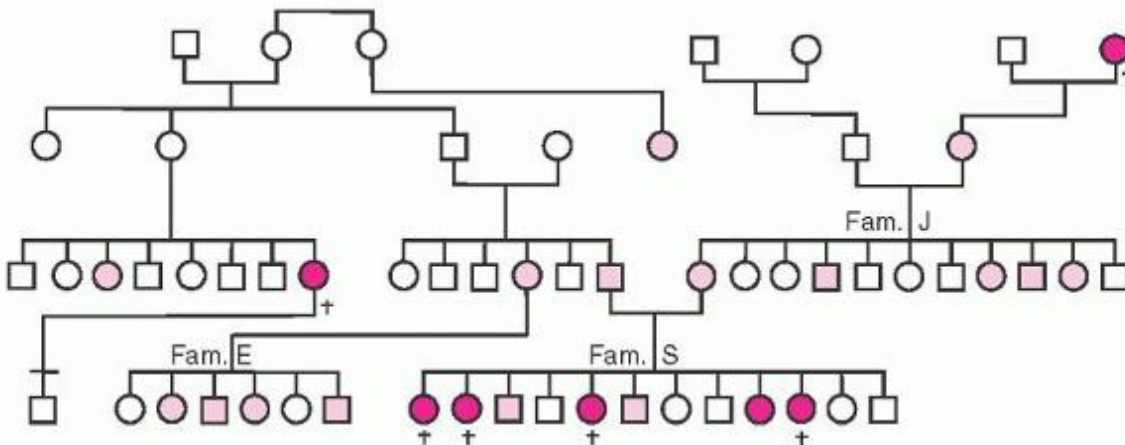

FIGURE 53.6. Pedigree of patients described by von Willebrand. Three families are emphasized: S, E, and J. Clinical details of bleeding events in these families have been reported. Open circles indicate female nonbleeders, open squares indicate male nonbleeders. Shaded circles and squares indicate female and male bleeders, respectively. Solid symbols indicate family members who experienced severe bleeding, and crosses indicate family members who experienced hemorrhagic deaths. (Modified from von Willebrand EA. Über hereditäre pseudohämophilie. Acta Med Scand 1931;76:521-550, with permission of the publisher.)

Complete absence of vWF is responsible for the most extreme form of vWD, and this is classified as type 3 vWD.¹²⁸ As one might predict, a large variety of genetic abnormalities scattered throughout the vWF gene have been reported in families with type 3 vWD. These have included large gene deletions, small gene deletions, frame-shift mutations, splice-site mutations, nonsense mutations, and point mutations.¹⁴⁹

Type 2 vWD is characterized by production of a qualitatively defective protein, and the genetics of these variant forms is more straightforward than that of type 1 vWD. In families affected by types 2B and 2M, as well as in the majority of families with type 2A vWD, inheritance is autosomal dominant. Rare cases of type 2A disease are transmitted in an autosomal recessive fashion, as are most cases of type 2N disease. vWF gene sequencing studies combined with vWF

mutation-expression analysis has revealed that single missense point mutations underlie the majority of type 2 disorders.¹²⁸ Type 3 vWD is also inherited as a recessive trait and occurs when both copies of the vWF gene are defective. In type 3 disease, gene abnormalities include large or partial gene deletions, disruption of orderly messenger RNA transcription (frame-shift mutation, splice site, or nonsense mutation), and missense mutation. For patients with recessively inherited vWD phenotypes (type 2N, type 3, or some rare type 2A), genetic analysis may reveal either homozygous or compound heterozygous gene abnormalities. Members of the International Society of Thrombosis and Hemostasis maintain a database of vWD mutations (www.vwf.group.shef.ac.uk).

Pathophysiology

The basic defect in vWD is a deficiency or abnormality of vWF function. vWF is synthesized in endothelial cells and
P.1155

megakaryocytes.¹³⁴ The primary transcription product is 2,813 amino acids in length and undergoes extensive further processing, including dimerization and polymerization, to form very-large-molecular-weight “multimers”.¹³⁴ Multimerization and intracellular trafficking of vWF through the endoplasmic reticulum and Golgi apparatus and into storage granules is directed by the vWF propeptide (vWFpp). vWFpp is cleaved off the “mature subunit” after multimer assembly. Large vWF multimers, which may exceed 20 million daltons in size, are stored in endothelial cells in Weibel-Palade bodies and in platelet α -granules.

The majority of circulating vWF is present in plasma, with a concentration of ~ 10 $\mu\text{g/ml}$. The circulating half-life of plasma vWF is ~ 8 to 12 hours. Approximately 15% of circulating vWF is present intracellularly within platelets. Ultralarge multimers released from endothelial cells into the plasma are further degraded to smaller multimers through the activity of a “vWF cleaving protease”.¹³⁶ The cDNA sequence identified this protein to be the thirteenth member of the ADAMTS family (a disintegrinlike and metalloproteinase with thrombospondin type 1 motifs, ADAMTS13).^{150, 151} vWF is cleaved between tyrosine 1605 and methionine 1606 located in the A2 domain.¹⁵² High shear stress and tethering of vWF by platelets most likely enhance exposure of the cleavage site.¹⁵³ The physiologic importance of enzymatic degradation of vWF after release is demonstrated clinically by the association of an inherited form of thrombotic microangiopathy (Schulman-Upshaw syndrome) with congenital absence of the protein due to defects of the ADAMTS13 gene,¹⁵⁰ and the observation of plasma deficiency of the protein with presence of autoantibody in most patients with sporadic thrombotic thrombocytopenic purpura.¹⁵⁴ Endothelial cell stores of vWF can be released therapeutically with administration of desmopressin.¹⁵⁵

vWF is required for normal platelet adhesion (see Chapter 17), and also acts as a carrier of factor VIII in the plasma. When vWF is deficient or aberrant, both factor VIII deficiency and abnormalities in the early steps of primary hemostasis result. vWD is thus manifested as a multifaceted hemostatic defect. Both abnormalities— factor VIII deficiency and abnormal primary hemostasis—give rise to characteristic and distinct laboratory abnormalities, and both defects contribute to the bleeding tendency.

Abnormalities of Primary Hemostasis

Convincing evidence exists that the platelets, although intrinsically normal, do not adhere to subendothelium normally in the setting of deficient or defective vWF.¹⁵⁶ This abnormality is well demonstrated by methods that measure platelet adhesion to subendothelial surfaces under flow conditions (the Baumgartner technique). The physiologic stimulus for interaction of vWF with platelets is not completely defined, but tethering of vWF on exposed subendothelial cell matrix or shear stress may cause vWF to undergo conformational change. Results of experimental studies suggest that in the absence of vWF, platelet adhesion to collagen in a flowing stream of blood may be particularly deficient at high rates of shear, when only a short time is available for formation of a platelet-collagen bond.¹⁵⁷ Deficient platelet plug formation has been observed directly in experimental wounds.¹⁵⁸ In vitro, the interaction of vWF with the platelet GPIb receptor can be induced by addition of the antibiotic ristocetin, by the snake venom protein botrocetin, or by subjecting platelets to high shear stress in the presence of vWF. For the effective support of platelet adhesion, vWF is multimerized into long chains (strings), which can exceed 2 μm in length. Plasma vWF demonstrates a spectrum of sizes; however, the longest vWF multimers are the most efficient at supporting platelet adhesion.¹³⁴

Abnormalities of Secondary Hemostasis

A second function of vWF is as a molecular chaperone for factor VIII, increasing the plasma half-life of factor VIII approximately fivefold.¹⁵⁹ This effect may occur through protection of factor VIII from activated protein C-mediated degradation.¹⁶⁰ Furthermore, the binding of vWF to subendothelium at sites of vascular injury could serve to co-localize

factor VIII, where it can participate in its role in the regulation of hemostasis on the activated platelet membrane.¹³⁴ It is generally thought that whereas vWF is synthesized in endothelial cells and megakaryocytes, factor VIII is synthesized by hepatocytes. When the drug desmopressin (DDAVP, 1-deamino-8-D-arginine vasopressin) is administered to normal subjects or individuals with mild quantitative deficiency of vWF or factor VIII, levels of both molecules rise. Studies of hemophilia patients and patients with type 3 vWD on replacement therapies suggest that both vWF and factor VIII must be endogenously synthesized in order for there to be coordinated release after DDAVP. The cell responsible for that coordinated synthesis remains controversial.

Response to Transfusion

When blood products containing the vWF-factor VIII complex are infused into patients with hemophilia A, peak levels of factor VIIIc are present immediately after the infusion; this activity then declines rapidly, with an overall half-life of 8 to 10 hours (Fig. 53.7). Twenty-four hours later, factor VIIIc activity is minimal. This response is highly predictable and is discussed in a later section concerning replacement therapy for hemophilia A. In most patients with vWD, the infusion of normal vWF-factor VIII complex produces an initial rise in factor VIIIc that is predicted from the preinfusion level and the amount of factor infused. This is followed by a sustained but variable rise in factor VIIIc activity that reaches a plateau about 24 hours later and may persist for 48 to 72 hours. This phenomenon is highly variable and irregular; in some patients, a rapid initial fall of factor VIIIc is followed by a secondary rise in activity. This disproportionate response to transfused factor VIII has been called the secondary transfusion response, a feature that is apparently unique to vWD. Various hypotheses have been advanced to explain the disproportionate response to transfusion described above. The leading hypothesis is that the infused vWF results in stimulation of increased factor VIII release into the plasma with the attachment of the newly released factor VIII onto infused vWF.¹⁶¹

FIGURE 53.7. The phenomenon of new factor VIII synthesis in patients with von Willebrand disease (vWD) who receive plasma transfusion. Open circles indicate changes in the plasma factor VIII levels of a patient with vWD after infusion of plasma from a patient with severe hemophilia A. A significant and sustained increase in the factor VIII levels of the recipient was observed even though no active factor VIII was present in the infused plasma. Solid circles indicate effects of infusing plasma from a patient with vWD into a patient with severe hemophilia A. The factor VIII level in the infused plasma was 15% of normal. Note the slight and transitory effects. (From Shulman NR, Cowan DH, Libre EP, et al. The physiologic basis for therapy of classic hemophilia (factor VIII deficiency) and related disorders. *Ann Intern Med*

1967;67:856-882, with permission.)

P.1156

Transfusions of blood products containing vWF shorten the bleeding time to a variable degree in patients with vWD. This corrective effect seldom persists for more than a few hours, even after massive transfusions that raise vWF to high levels. The correction of the bleeding time apparently requires the large molecular forms of vWF that are present in cryoprecipitate and select intermediate-purity factor VIII concentrates,¹⁶² but that are completely absent from monoclonally purified or recombinant concentrates of factor VIII.¹⁶³ Failure of the skin template bleeding time of patients with vWD to show sustained correction with appropriate replacement therapy has been noted, and does not necessarily predict defective surgical hemostasis. This apparent paradox may be a result of sensitivity of the bleeding time test to platelet α -granule vWF, which is not replenished during vWF replacement therapies.¹⁶⁴

Clinical Manifestations

The bleeding manifestations in vWD are heterogeneous but consistent with the dual roles of vWF in supporting both primary and secondary hemostasis. Thus, in the mild forms of vWD, the clinical picture is dominated by cutaneous and mucosal bleeding, which appears to be mainly the result of disordered primary hemostasis. In the most severe forms of the disorder, in which factor VIII levels are low, hemarthroses and dissecting intramuscular hematomas may develop. As in mild classic hemophilia, serious hemorrhage resulting from traumatic injuries or after surgical procedures is a significant hazard in severe vWD. Petechiae are rare, but hematoma formation and the extent of bruising are excessive compared with the inciting trauma.

The bleeding manifestations in the usual patient with type 1 vWD are mild, however, and many patients are virtually asymptomatic. The disorder may be symptomatic at any age, but it is not always recognized. Easy bruising is common in vWD, but it is not specific. Mucosal bleeding is particularly common. Childhood epistaxis, a life-long history of easy bruising, bleeding with dental extraction, heavy menstrual bleeding or anemia attributed to excessive menstrual blood losses, or postpartum hemorrhage are all included in the spectrum of vWD symptomatology. Systemic bleeding disorders are often not considered in women with menorrhagia,¹⁶⁵ but clinical studies reveal that the prevalence of vWD is significant in individuals who present with this complaint.¹⁶⁶ Angiodysplasia of various vascular beds, particularly those in the gut, has been demonstrated in some patients with vWD and may be an important contributory factor in chronic gastrointestinal bleeding.¹⁶⁷ In type 1 vWD, symptoms usually become milder during pregnancy or with estrogen therapy, when the vWF and factor VIIIc levels rise significantly.⁴⁰ The disorder may also decrease in severity with advancing age. Bleeding manifestations tend to be more prominent in patients with more severe quantitative deficiency and in patients with qualitative (type 2) defects.

While eliciting the history of bleeding, one should bear in mind that women are often inaccurate assessors of whether their menstrual flow is normal or excessive. Supplemental questioning regarding the frequency of changes of menstrual protection, and questions regarding a history of iron deficiency anemia and transfusion, may be informative. Retrospective studies of women with vWD show that abnormal bleeding can often be traced to menarche.¹⁶⁸ Family history also may provide important clues to a diagnosis. The physician should specifically seek a history of the response to hemostatic challenge, such as dental extraction, tonsillectomy, surgical procedures, menstruation, peripartum hemorrhage, and transfusion. A model questionnaire with a scoring system has been published.¹⁶⁹ Coexistent conditions or drug effects can strongly influence the severity of bleeding symptoms. Risk of hemorrhage may increase in patients with concomitant liver disease, uremia, gastrointestinal ulcer, or angiodysplasia. Excessive bleeding in response to challenge with aspirin may also point toward a bleeding disorder, but this history is not specific for vWD. Valproic acid use can result in lower vWF activity levels, as may hypothyroidism and valvular heart disease. Conversely, oral contraception frequently ameliorates menorrhagia.¹²⁷

Laboratory Diagnosis

Criteria for the laboratory diagnosis of vWD are imperfect. One goal of applying a series of laboratory evaluations is to exclude other causes of bleeding. When specifically considering vWD, the laboratory evaluation may be complicated. Even with the more elaborate confirmatory tests now available, the diagnosis of this disorder may be difficult and may require repeated observations over a period of time. Both vWF and factor VIII are "acute-phase reactants," increasing with stress, trauma, estrogen therapy, or pregnancy, such that levels may fluctuate from time to time. Evaluation of a patient at a time remote from acute infection, pregnancy, or strenuous activity is preferable. However, pregnancy and acute-phase reaction are unlikely to obscure diagnosis in patients with more severe quantitative deficiency or qualitative defects.

Diagnosis of vWD is complicated, because of both the breadth of vWF functions and the spectrum of disorders that constitutes vWD. Consequently, a battery of studies should be considered to evaluate a patient conclusively for vWD.¹³⁴ Screening tests such as bleeding time, Platelet Function Analyzer-100 (PFA-100), and PTT lack sensitivity; specific tests such as those for vWF antigen, vWF activity, and factor VIII level are preferred. Correlating the values of these various quantitative assays with each other, or obtaining qualitative tests such as vWF multimer analysis or lowdose ristocetin-induced platelet aggregation, may provide important clues toward a diagnosis of type 2 vWD (Table 53.7).

Bleeding Time and Platelet Function Analyzer-100

The template bleeding time, the Ivy bleeding time, or technical modifications thereof may be useful in detecting the abnormality characteristic of vWD. However, the bleeding time may be normal in many patients with vWD.¹⁷⁰ Consequently, the bleeding time adds to the diagnosis of vWD if it is prolonged, but otherwise may have little clinical utility in the diagnosis and management of patients with vWD. The bleeding time may not improve following replacement therapy with vWF, and monitoring is generally not recommended,¹⁷¹ because surgical bleeding can generally be prevented by replacement of plasma vWF.

Standardization issues, inconvenience, and residual scarring of patients are some of the issues that have fostered development of in vitro tests to replace the bleeding time. The PFA-100 evaluates platelet adhesion and aggregation to collagen in a whole-blood assay under high shear conditions.¹⁷² Citrate-anticoagulated whole blood is aspirated through an aperture in a collagen-coated membrane, and the device measures the time from first flow until flow ceases as the "closure time." PFA-100 closure times are sensitive to multiple factors, including vWF function, platelet count, platelet function, and hematocrit. Initial studies using the PFA-100 in patients with diagnosed vWD indicated that the assay was sensitive to most forms of vWD. However, when the closure time test was applied in clinical settings where patients were referred for evaluation of bleeding symptoms, the sensitivity of the PFA-100 for diagnosis of vWD ranged from 62% to 80%, with specificity ranging from 84% to 89%.^{173, 174} In addition, the closure time may remain normal in acquired vWD despite a very reduced plasma vWF level, because the platelet vWF level may remain normal. The PFA-100 closure time may also be normal in patients with type 2N vWD, in which the major defect is low factor VIII levels. As with the bleeding time, correction of plasma vWF level in the absence of concomitant correction of the platelet vWF may be insufficient to correct the closure time, so this test may not be very helpful for perioperative monitoring of patients on replacement therapy.^{175, 176}

P.1157

Partial Thromboplastin Time and Factor VIIIc Assay

Among the simple screening tests (Table 53.5), the PTT may be abnormal, reflecting reduced levels of factor VIIIc. Plasma levels of factor VIIIc vary greatly in this disorder and range from as low as 3 IU/dl in patients with type 3 vWD to normal levels in patients with mild type 1 vWD. Because factor VIIIc deficiency is often mild in patients with vWD, a diagnosis of vWD may be missed by the routine screening PTT. Consequently, a specific assay is required to reliably detect factor VIIIc deficiency in patients with vWD.

von Willebrand Factor Immunoassay

The immunoassay of vWF is a quantitative measure of vWF protein that is one of the most sensitive methods available for the diagnosis of vWD.¹⁷⁷ A variety of methods have been used, all of which depend on antibodies specific to vWF. The electroimmunodiffusion method of Laurell was initially widely used because it was simple to perform, but ELISA or automated assays using related methodologies have now largely replaced this technique. Average levels of vWF antigen (vWF:Ag) obtained by different laboratories will vary, but a level of ~45 to 50 IU/dl is the lower limit of normal reported by many laboratories. The ratio of factor VIII to vWF also varies by laboratory but normally ranges from ~0.7 to 2.2 (Fig. 53.1). Plasma levels of vWF:Ag are regulated to some extent by carbohydrate residues attached to the protein; ~25% lower vWF antigenic levels have been noted in patients with blood type O compared to patients with other blood types.¹³⁹ The contribution of blood group O is more marked in patients with mild quantitative vWF deficiency, where the low vWF level is less likely to be related to abnormalities of the vWF gene.^{145, 146} Whether these patients actually have vWD type I is subject to debate, and the role of blood group in the diagnosis of vWF deficiency remains to be resolved.¹²⁸ Patients with type 2 vWD may have normal vWF:Ag levels, emphasizing the need to use more than just a vWF antigen assay to evaluate a patient for vWD.

von Willebrand Factor Functional Assays

vWF has multiple functions, and assays have been devised to specifically evaluate many of these. The function most often clinically assessed is its ability to interact with platelets. An assay that evaluates the ability of vWF to interact with collagen has also been proposed as a functional assay. The relevance of collagen-binding activity analysis is questioned for routine screening, and collagen-binding activity assay has not gained widespread acceptance in the United States.¹⁷⁸ Finally, vWF binding of factor VIII can be assessed in special circumstances when questioning whether mild factor VIII deficiency is due to failure of vWF chaperone function. vWF functional assay generally correlates well with vWF:Ag in patients with quantitative disorders of vWF. Observing a discrepancy between vWF function and vWF:Ag provides a useful clue for qualitative defects, provided that the testing laboratory uses the same control plasma for determining both assays.¹⁷⁹

Ristocetin Cofactor Activity and Ristocetin-induced Platelet Aggregation

The assay for ristocetin cofactor activity (vWF:RCo) is a quantitative technique for estimating the ability of vWF in patient plasma to bind target platelets that are specially prepared or preserved for use in the assay.¹⁸⁰ Ristocetin induces an activated conformation of vWF such that it will then bind platelets via the platelet GPIb receptor, mimicking the in vivo sequence of events that allows interaction between subendothelial tissue-bound vWF and platelets. Quantitation of vWF:RCo is held to be the single most sensitive and specific assay for vWD by multiple authorities.^{181, 182, 183} vWF:RCo activity is adversely affected by loss of the larger-molecular-weight vWF multimers. The discrepancy between vWF:RCo and vWF:Ag that is observed in qualitative defects characterized by loss of both the intermediate- and higher-molecular-weight multimers (such as type 2A vWD) is thought to result from this. Ristocetin cofactor activity is also generally utilized to follow a vWD patient's response to therapeutic interventions. However, obtaining typical ristocetin cofactor activity is a time-consuming procedure, and assay standardization remains somewhat problematic. Automation of the vWF:RCo assay has resulted in a clinically more available, but less sensitive technique, which requires modification to detect levels below ~10 to 20 IU/dl. Simpler ELISA-based methods using monoclonal antibody to the GPIb-binding domain of vWF have been explored for estimating vWF activity.¹⁸⁴ Unfortunately, commercial functional epitope assays have not performed sufficiently well to allow them to replace vWF:RCo assay,^{185, 186} and these assays do not measure the increased functionality of the larger vWF multimers directly.

Ristocetin-induced platelet aggregation (RIPA) is a distinct test from ristocetin cofactor activity. RIPA is a qualitative test that involves evaluating the rate or extent of agglutination of patient-derived platelet-rich plasma in response to the addition of the antibiotic ristocetin. The concentration of vWF and platelets present in the test plasma, as well as the amount of ristocetin added, affect RIPA. The assay is relatively insensitive to mild deficiency of vWF, but decreased aggregation response is observed in both more severe deficiency and in patients with Bernard-Soulier syndrome (in which platelets are missing the GPIb receptor). Titrating down the amount of ristocetin added in the assay may be of specific interest in defining variants of vWD in which there are "gain of function" mutations (type 2B and platelet-type [pseudo] vWD). These two conditions are characterized by increased sensitivity of patient vWF or platelets to the effect of ristocetin.¹²⁸ However, insensitivity of patient samples to low-dose ristocetin aggregation is seen in occasional patients with type 2B vWD in whom there is marked reduction in the amount of high- and intermediate-molecular-weight multimers, and genetic analysis may be required to distinguish some cases of type 2B from type 2A vWD. In addition, low-dose ristocetin aggregation of patient-derived platelet-rich plasma cannot differentiate type 2B vWD from the rarer platelet-type (pseudo) vWD, and mixing studies using patient plasma and donor platelets have been devised to help make that distinction at the phenotypic level.¹⁸⁷

von Willebrand Collagen-binding Activity

vWF contains collagen-binding sites in both the A1 and A3 domains of the vWF protein, and collagen-binding activity (vWF:CB) may be an important function that allows vWF to adhere to platelets at sites of vascular injury. Like ristocetin cofactor activity, vWF:CB is dependent on multimer size, with the larger multimers binding collagen more avidly. The assay is generally done in an ELISA format, in which type I and/or type III collagen is plated into microtiter wells, and the amount of vWF captured is assayed.¹⁸⁸ vWF:CB correlates well with vWF:Ag in normal individuals and those with quantitative deficiency of vWF, and discrepant results are indicative of vWD subtypes that are characterized by deficiency of larger vWF multimers. A single case of vWD characterized by mutation of the vWF A3 domain with isolated loss of collagen-binding function despite the presence of a normal multimer distribution has been described.¹⁸⁹ Although some studies suggest that vWF:CB testing complements assays of vWF:Ag and vWF:RCo in distinguishing type 1 vWD from type 2A and 2B variants, the role of vWF:CB testing in routine clinical practice remains to be determined.^{127, 178, 190}

Assay of von Willebrand Factor's Ability to Bind Factor VIII

Factor VIII binding by vWF (vWF:FVIII) can be measured in a few reference coagulation laboratories, and is indicated for the evaluation of patients suspected of having factor VIII deficiency on the basis of defective vWF chaperone function (type 2N vWD).¹⁹¹ In this ELISA format assay, ELISA plate wells are coated with antibody to vWF in order to capture vWF from patient plasma. After washing patient-derived factor VIII from the well, the ability of patient-derived vWF to capture r-FVIII is assessed using a chromogenic or immunoassay for factor VIII, and the quantity of patient-derived vWF:Ag in the well is quantified by standard ELISA technique. The calculated ratio of captured r-FVIII to vWF:Ag is expected to be in the normal range when testing plasma from a patient with hemophilia A, whereas it will be abnormally low in the rare cases of type 2N vWD.¹⁹²

Multimeric Analysis of von Willebrand Factor

Normal vWF in plasma consists of a complex series of multimers, ranging in size from about 500 to 20,000 kDa. vWD initially diagnosed by abnormal assays for factor VIIIc, vWF antigen, or ristocetin cofactor activity should be further characterized by multimeric analysis. In this test, the spectrum of vWF molecular sizes of the patient's vWF is assessed by size-based separation of vWF multimers via agarose gel electrophoresis, and vWF multimers are imaged by immunologic methods coupled to autoradiography or other detection methods.¹⁹³ Multimer analysis is characterized as either "low-resolution" (which differentiates the largest multimer forms from the intermediate and smaller forms), or "high-resolution" (which resolves each multimer band into three to five satellite bands), which inform on the activity of ADAMTS13 on plasma vWF. Multimer analysis will confirm the presence of the entire spectrum of vWF multimers in normal individuals and those with type 1 vWD, and allows identification of the loss of intermediate- or high-molecular-weight multimers of vWF as is characteristic of the type 2A and type 2B qualitative defects.¹⁹³ Unfortunately, the distinction between type 2A and type 2B vWD is not always possible using multimer analysis alone, necessitating further testing. Multimeric analysis is a very labor-intensive test and is usually performed only in coagulation reference laboratories. The multimeric composition of plasma from normal subjects and patients with vWD is shown in Figure 53.8. This methodology has been reviewed.¹⁹⁴

Genetic Testing in von Willebrand Disease

Direct mutational analysis by vWF gene sequencing, allele-specific PCR, or restriction enzyme analysis is useful in confirming a diagnosis of type 2 variant vWD.¹⁹⁵ The functional domain structure of the vWF gene results in clustering of the various type 2 vWD defects in limited areas of the vWF sequence.¹²⁸ vWF exon 28 encodes for the A1 loop of vWF responsible for the interaction of vWF with platelet GPIb, and vWD variants characterized by defects of this interaction (types 2B and 2M) are encoded by genetic mutations clustered in this exon.¹⁹⁶ Exon 28 also encodes the A2 domain, which contains the ADAMTS13-sensitive bond tyrosine1605-methionine 1606. Mutations that increase the susceptibility of this bond to cleavage by ADAMTS13 underlie a high fraction of type 2A vWD (previously classified as 2A, subtype 2). Less commonly, type 2A vWD results from a defect of the multimerization process. The carboxy terminus of the vWF peptide (encoded by exons 51 to 52) is involved in initial vWF dimer formation in the rough endoplasmic reticulum. The vWFpp (encoded by exons 3 to 17) directs further multimerization via cross-linkage of the amino-terminal D' and D3 of the mature vWF protein (encoded by exons 18 to 28). As one might expect, type 2A vWD on the basis of failure of multimerization (previously classified as 2A, subtype 1) has been attributed to genetic abnormalities in each of these regions of the genome. Mutations responsible for defective interaction of vWF with factor VIII (type 2N vWD) are predominantly clustered in exons 18 to 20, which encode for the factor VIII-binding domain of vWF; however, rare cases have been attributed to mutations in exons 24 and 25. An online database of defects found in vWD patients can be accessed at www.vwf.group.shef.ac.uk. Figure 53.5 shows the location of these various genetic abnormalities schematically. Rapid, complete vWF gene sequencing has been reported.¹⁹⁷

FIGURE 53.8. Multimeric composition of von Willebrand factor from normal plasma and that from types I, IIA, IIB, IIC, IID, and IIE von Willebrand disease (vWD), as well as from a type IIC heterozygote (IIC^h). Using the revised classification scheme, these types would correspond to 1, 2A, 2B, 2A, 2A, and 2A, respectively. The three brackets include the smallest normal oligomers, with arrows pointing to the central predominant band in each. In type 1 vWD, the relative concentration of large multimers varies. (From Zimmerman TS, Ruggeri ZM. von Willebrand disease. *Hum Pathol* 1987;18:140-152, with permission.)

Genetics of Type 1 and Type 3 vWD

Mild to moderate quantitative deficiency of vWF characterizes patients with type 1 vWD, whereas virtual absence of vWF characterizes type 3 disease. Genetic analysis is not generally required to make these diagnoses, but may provide useful additional information concerning pathogenesis of a patient's condition, responsiveness to DDAVP, or risk for alloantibody formation. In distinction from type 2 vWD, genetic defects underlying quantitative vWF deficiency are distributed throughout the vWF gene, complicating evaluation. In addition, for families with patients who demonstrate normal multimer structure and higher vWF levels, the chances of finding linkage to the vWF gene are reduced,^{145, 146} and family members are usually asymptomatic.¹³⁷ Type 3 patients with large gene deletions are particularly prone to develop anti-vWF alloantibodies after treatment with vWF-containing concentrates.

Type 1 von Willebrand Disease and "Low von Willebrand Factor"

Patients with bleeding attributed to decreased production of qualitatively normal vWF are classified as having type 1 vWD. Most patients with vWD (70% to 80%) fall into this category.¹³⁴ The majority of patients have a mildly symptomatic disorder, but bleeding may increase with physical trauma, surgery, or during menstruation. vWF levels are low, with concordant reduction of vWF:Ag and vWF:RCo (and vWF:CB, if that is measured). Factor VIII levels are generally equal to or higher than vWF levels, and all vWF multimers should be present if that analysis is performed as part of the patient evaluation. The diagnosis of type 1 vWD may be simpler in an individual with mucosal bleeding symptoms, a strong family history of similar symptoms, and quantitative vWF level (vWF:Ag and/or vWF:RCo) <30 IU/dl. Although not required for a diagnosis of type 1 vWD, the probability of finding linkage of the phenotype to the vWF gene in such an individual would be high, such that both therapeutic choices and genetic counseling would be straightforward.

P.1159

Unfortunately, many factors make the diagnosis of type 1 vWD difficult.¹⁴⁴ Mild bleeding symptoms are common in hemostatically normal people (see Chapter 45). In addition, the relative risk of bleeding for individuals with only modest reductions in vWF level appears to be minimal. Finally, because of the strong influence of blood group on vWF levels, there is a high prevalence of blood group O among individuals with mildly depressed vWF levels. These observations have led to the recent proposal of the concept of "low vWF".^{137, 144} The term "low vWF" could be applied to patients with vWF levels below the normal reference range but above some lower limit. A recently convened "expert group" brought together by the National Heart, Lung and Blood Institute is considering this proposal.¹²⁹ Studies of families of patients with a diagnosis of type 1 vWD suggest that linkage to the vWF gene is less often seen when the vWF level rises above 30 IU/dl,

suggesting that this might be a candidate for the lower limit of the "low vWF" category.^{145, 198} Empiric therapy to raise vWF levels in patients with "low vWF" at times of hemostatic challenge would be reasonable for patients with a history of bleeding, but the genetic counseling issues would clearly be different.¹⁴⁴

On the other hand, two population-based studies have shown that "low vWF" causes increased bleeding.^{199, 200} These latter studies would suggest that abnormally low ristocetin cofactor activity, and not the presence of a mutation, should primarily be used to identify bleeders.

Type 3 von Willebrand Disease

Type 3 vWD is the most severe form of vWD, because it results from complete failure of vWF synthesis. This bleeding disorder is generally diagnosed during infancy. Hematoma formation is common, epistaxis may be life-threatening, and hemarthrosis may occur as a result of the low factor VIII levels that are seen in this condition. Plasma from patients with type 3 vWD contains virtually no detectable vWF, and vWF is not present in either platelets or endothelial cells. Factor VIII level is generally in the range of 1 to 10 IU/dl, similar to that seen in moderate to mild hemophilia A. Multimeric analysis of the little vWF present yields variable results, in some cases revealing only small multimers.¹⁹³ Type 3 vWD is rare, with an estimated frequency of 1 in a million people.²⁰¹ Genetic analysis reveals either homozygous or compound (double) heterozygous defects of the vWF gene, with gene deletions, frame-shift mutations, missense mutations, or nonsense mutations. Careful laboratory evaluation of the parents of patients with type 3 disease may reveal mild quantitative deficiency of vWF. In a review of 117 obligate heterozygotes, the mean plasma vWF level was 45 IU/dl, with a range from 5 to 130 IU/dl.¹⁴⁴ Parents are frequently asymptomatic, consistent with the impression that type 3 disease is inherited as a recessive trait. Consanguinity is common in kindreds with this variant. In some patients with type 3 vWD, large gene deletions have been identified on one or both vWF alleles.^{128, 202} Such patients are at increased risk of developing inhibitory alloantibodies to vWF after transfusion therapy.²⁰²

Because these patients lack vWF in their endothelial cells and platelets, there is no rise in vWF level in response to DDAVP. For replacement therapy, these patients require vWF-containing concentrates. This is usually provided in the form of specific intermediate-purity factor VIII concentrates that have been documented to contain intact vWF.¹⁵⁵ Because these patients possess a normal factor VIII gene but are missing the vWF chaperone, posttransfusion factor VIII recovery and survival may be longer in a patient with type 3 vWD than in a patient with hemophilia A, owing to endogenous factor VIII production. Although life-threatening bleeds require immediate replacement of both vWF and factor VIII, replacement with vWF alone may be sufficient if therapy is begun 12 to 24 hours before elective surgery.²⁰³

Qualitative Defects of von Willebrand Factor

Several subsets of patients with vWD differ substantially from those with the common quantitative deficiency states (Table 53.6).¹²⁸ Classified as type 2 variants, these qualitative defects of vWF are less common, but they may represent up to 20% to 25% of cases of vWD. Type 2 forms of vWD are suspected when the severity of the patient's symptoms seems in excess of the observed vWF and factor VIII levels, when there is discordant reduction between vWF antigen and vWF functional activity or factor VIII assay, or when there is concomitant vWF deficiency and thrombocytopenia. Discrimination between qualitatively normal and abnormal vWF can be difficult; however, when the ratio of vWF:RCo to vWF:Ag or vWF:CB to vWF:Ag is found to be <0.6, dysfunctional vWF should be considered. The sensitivity and specificity of such ratio screening depends to a large extent on the expertise and precision of the laboratory performing the assays, but the predictive value of ratios decreases when the level of vWF antigen is <20 IU/dl. Examining the structure of patient vWF may provide further definition of the nature of the qualitative defect. This can be demonstrated by vWF multimer analysis. If required, further information is provided by supplemental studies of vWF function, or via genetic analysis of the vWF gene (Fig. 53.5).^{126, 128, 193} Type 2 defects were initially classified using a Roman numeral system, but further understanding of the genetics of vWD led to the consolidation and reclassification into types 2A, 2B, 2M, and 2N,¹²⁸ based on the nature of the vWF functional defect. In addition to the well-defined variants described in this chapter, other forms of vWD continue to be described.

Type 2A von Willebrand Disease

vWD with defective interaction of vWF with platelets due to deficiency of intermediate- and high-molecular-weight forms of vWF is classified as type 2A vWD.¹²⁸ This form of the disorder is generally inherited as an autosomal dominant trait,²⁰⁴ and it accounts for the majority of patients with type 2 defects. Levels of factor VIIIc and vWF:Ag in the plasma may be normal or reduced. The vWF activity as assayed by either vWF:RCo or vWF:CB is significantly lower than vWF:Ag because of the absence of the larger multimers (which are more potent in their ability to interact with platelet GPIb and collagen). Analysis of vWF multimers reveals a relative reduction in intermediate- and high-molecularweight species.¹²⁷ Protein studies followed by genetic analysis of the basis of type 2A vWD revealed multiple mechanisms for the generation of this

disorder.^{205, 206, 207} In some patients, there is failure to synthesize full-length multimers (type 2A, subgroup 1). Mutations associated with impaired vWF multimerization have been localized to the vWFpp (formerly called type IIC), the region of the mature vWF protein associated with the amino terminus area of multimer formation (formerly called type IIE), and the carboxy terminus region that is involved in initial dimer formation (formerly called type IID). Subtle abnormalities uncovered by high-resolution multimer analysis or genetic evaluation can be used to distinguish these subtypes of type 2A vWD. The spectrum of multimers released into plasma after DDAVP administration would not be expected to improve significantly in these patients whose defects prevent normal multimer assembly.

A second group of type 2A patients has been described in whom there is excessive catabolism of fully multimerized vWF after vWF is released into the plasma. These patients demonstrate mutations in exon 28, encoding the A1 and A2 regions of vWF. These mutations allow increased proteolysis of multimerized vWF by ADAMTS13. Again, high-resolution multimer gel studies may be informative by demonstrating increased "satellite" band intensity, which accumulates as a result of excessive ADAMTS13 activity. Because intracellular vWF is protected from cleavage by ADAMTS13, these patients may demonstrate very transient

P.1160

improvement in both vWF:RCo and multimer spectrum after DDAVP administration.

Inheritance of type 2A vWD is generally autosomal dominant, with the majority of cases caused by mutations clustered in the region of exon 28, which encodes the vWF A2 homologous repeat (Fig. 53.5).¹²⁸ Rare recessive forms of type 2A vWD have been reported with some multimerization defects (formerly called types IIC and IID).

Because of the underlying structural abnormality of the vWF produced in these patients, neither stress nor pregnancy significantly increases the functional amount of vWF protein in the plasma. As noted above, the administration of DDAVP does not result in a significant rise in vWF:RCo in patients with type 2A vWD, in which the underlying mechanism is defective multimerization or transport, but a very short-lived correction may be observed in patients with mutations associated with increased vWF cleavage by ADAMTS13.

Type 2B von Willebrand Disease

Type 2B vWD is a paradoxical bleeding disorder, characterized by increased interaction of patient vWF with platelets which is demonstrated in vitro in the presence of low doses of ristocetin. Increased in vivo interaction of the larger multimers of type 2B vWF with platelets is thought to result from mutations that either allow increased access of platelets to the A1 loop of vWF or that stabilize that interaction.¹²⁷ This may in turn allow increased generation of vWF-platelet complexes, which are subsequently cleared from circulation, resulting in thrombocytopenia.

This bleeding disorder is characterized by deficient vWF function attributable to mild reduction of vWF:Ag, a somewhat more marked deficiency of vWF:RCo activity (and vWF:CB, if measured). Multimeric analysis reveals a deficiency of the highest-molecular-weight vWF multimers. Measurements of factor VIIIc are variable. Many patients with the type 2B variant have mild persistent thrombocytopenia.²⁰⁸ The platelet count may fall further during physiologic stresses, pregnancy, in association with surgical procedures, or after the administration of DDAVP.²⁰⁹

Additional laboratory evaluation is required to support a diagnosis of type 2B vWD. In most cases, multimeric analysis reveals absence of higher-molecular-weight forms of plasma vWF, but distinction of type 2B from type 2A vWD is not possible by multimeric analysis alone. To show the distinct "gain in function" in type 2B disease, RIPA studies are done to reveal enhanced interaction of patient vWF and platelets with low doses of the drug. Finally, to differentiate the more common type 2B vWD from the rare platelet-type (pseudo) vWD, one should prove that the defect resides in vWF. This is done either through performing mixing studies of patient plasma with donor platelets¹⁸⁷ or by analysis of the patient's vWF gene.

Type 2B vWD is inherited as an autosomal dominant trait. A small cluster of mutations within the portion of vWF exon 28 that encodes the vWF A1 domain that interacts with platelet GPIb accounts for all the cases of type 2B vWD that have been reported (Fig. 53.5).¹²⁸

Recent studies evaluating a large number of patients with type 2B vWD mutations revealed diversity in laboratory findings.²¹⁰ Not all patients had reduced vWF:RCo activity or abnormal multimeric analysis, and not all patients had thrombocytopenia.²¹⁰ Type 2B patients with normal multimers did not develop thrombocytopenia.

Type 2M von Willebrand Disease

The type 2M vWD variant is defined by diminished platelet-dependent vWF function that is not attributed to deficiency of vWF multimers.¹²⁸ Thus, these patients have an initial laboratory profile that in many ways is similar to that of patients with type 2A vWD, revealing variable deficiency of vWF:Ag but disproportionately decreased interaction of vWF with platelets in the presence of ristocetin as measured by vWF:RCO assay. Factor VIII level is proportionate to the vWF:Ag, and the platelet counts are normal. What differentiates type 2M vWD from the type 2A patients is that the vWF multimeric analysis is normal (and, if measured, the vWF:CB is usually similar to the vWF:Ag). Type 2M vWD is inherited as an autosomal dominant trait, and, when investigated, mutations have been found in the region of exon 28 that encodes the A1 domain of vWF. Unlike the type 2B mutations, 2M mutations cause impairment of the binding of vWF to the GP1b receptor and have been shown to be localized to an alternative area in the A1 domain (Fig. 53.5).¹⁹⁶

One case classified as a type 2M defect was described in which the vWF interaction with collagen was defective. In that case, a mutation in the A3 domain that contributes to the interaction of vWF with collagen was found.¹⁸⁹

Type 2N von Willebrand Disease

Mutations affecting the association of vWF with factor VIII can result in “autosomal hemophilia” in which factor VIII levels are significantly reduced relative to vWF.¹²⁸ Affected patients have factor VIII levels in the range of 5 to 30 IU/dl, attributed to mutations at the factor VIII-binding site near the amino terminus of the vWF subunit.²¹¹ Indeed, genetic studies indicate that the majority of mutations underlying type 2N vWD involve vWF exons 18, 19, and 20, which encode the bulk of the factor VIII-binding domain of vWF. The other functions of vWF in patients with type 2N vWD are qualitatively normal, and thus vWF laboratory parameters (vWF:Ag, ristocetin cofactor activity, etc.) are usually normal (unless there is coinheritance of type 1 vWD). This variant was originally named vWD Normandy but has been renamed type 2N vWD in the revised classification.¹²⁸ The factor VIII-binding defect in these patients is inherited in an autosomal recessive manner, and thus affected patients must inherit 2N alleles from each of their two parents, or inherit type 1 vWD from one parent while inheriting a 2N allele from the other. Patients with factor VIII deficiency and a bleeding disorder that is not clearly transmitted as an X-linked disorder or who demonstrate an unexpectedly short in vivo survival of infused factor VIII should be evaluated for type 2N vWD.²¹² Diagnosis requires performance of an assay that assesses the interaction of factor VIII with vWF,^{191, 192} or genetic studies of the vWF gene. A survey of almost 400 unrelated patients with either hemophilia A or type 1 vWD indicated a prevalence of type 2N vWD in these patient populations of 3% and 1.5%, respectively.²¹³ Consideration of this diagnosis is important because both therapy and genetic counseling are distinct from that of mild hemophilia A.

Platelet-type (Pseudo) von Willebrand Disease

Platelet-type (pseudo) vWD resembles type 2B vWD in most respects, except that the basis for platelet-type vWD is a structural defect in platelet GP1b²¹⁴ rather than a defect of vWF (thus platelet-type [pseudo] vWD is a form of platelet dysfunction). However, as with type 2B vWD, a genetic defect results in increased interaction between GP1b and vWF. Phenotypically, platelet-type (pseudo) vWD is manifested by mild thrombocytopenia, a prolonged bleeding time, and variable deficiency of plasma vWF and factor VIIIc. The reductions in plasma vWF and factor VIIIc may be a result of the attachment of these proteins to platelets that are subsequently removed from the circulation. This “consumption” of vWF and platelets results in preferential loss of high-molecular-weight multimers from patient plasma.²¹⁴ In vitro platelet aggregation studies reveal platelet agglutination at unusually low concentrations of ristocetin. Spontaneous intravascular platelet clumping may also occur. Platelet-type (pseudo) vWF is inherited as an autosomal dominant trait in most families.^{214, 215}

P.1161

Distinction of platelet-type vWD from type 2B vWD is based on showing that the enhanced interaction of platelets with vWF is either platelet-based or resides in the plasma phase (type 2B vWD).²¹⁶ This can sometimes be demonstrated through low-dose ristocetin-based agglutination assays using mixtures of normal donor and patient samples, or genetic analysis can be used. To date, all cases of platelet-type vWD have been traced to genetic variations of platelet GPIb α .²¹⁷ These include missense mutations that alter the amino acid sequence from Gly233 to Met 239. This region of the protein adopts a β -sheet conformation after interaction with vWF, and these mutations may function to stabilize this conformation.²¹⁸ In addition, a 27-bp gene deletion that encodes for deletion of proline 421 through serine 429 has been shown to underlie platelet-type vWD in one kindred. Thus, genetic analysis of the GPIb α gene could confirm a diagnosis of platelet-type vWD in cases in which phenotypic studies were unsuccessful.

CLINICAL DISORDERS OF THE FIBRINOGEN MOLECULE

The clinical disorders of fibrinogen are complex, and depending on the types of mutation may present with bleeding or with thrombotic symptoms, or both. These disorders can be divided based on whether the defect is predominantly a quantitative or qualitative abnormality of the fibrinogen molecule.^{219, 220} Quantitative abnormalities are disorders associated with the complete absence of fibrinogen (afibrinogenemia) or with low levels of fibrinogen (hypofibrinogenemia). Qualitative abnormalities are disorders resulting from synthesis of an abnormal fibrinogen molecule (dysfibrinogenemia) with altered functional properties.^{219, 220, 221, 222} Dysfibrinogenemia may be asymptomatic and identified only through laboratory studies, or it may be associated with either hemorrhagic or thrombotic consequences.

Fibrinogen is a 340-kDa plasma protein that circulates at a concentration of 1.5 to 3.5 mg/ml. It is a symmetric disulfidelinked dimer with a central E domain linked via "coiled coil" peptide chains to outer D domains.²²³ Each half-molecule consists of a set of three different peptide chains, termed A α , B β , and γ , which are linked at their amino termini by disulfide bonds to form the E domain. The D domains are formed by disulfide linkages near the carboxy termini of the peptides. Fibrinogen is synthesized in hepatocytes²²⁴ by coordinated expression of three separate genes on chromosome 4.²²⁵ The rate-limiting step in fibrinogen synthesis is transcription of the B β gene. Fibrinogen is an acute-phase reactant, and levels may rise considerably with inflammation. The circulation half-life of plasma fibrinogen is ~4 days. Fibrinogen participates in multiple physiologic processes, including fibrin clot formation mediated by the enzymatic activities of thrombin and factor XIIIa, and cohesion of activated platelets through interaction with the GP IIb/IIIa receptor. Fibrinogen also acts as a plasma carrier for factor XIII. Fibrinogen physiology has been reviewed.²²³

The congenital disorders of fibrinogen associated with afibrinogenemia and hypofibrinogenemia are reviewed in the next section, followed by a discussion of the dysfibrinogenemias. Afibrinogenemia is a very uncommon condition. The first case was described in 1920 (reviewed in Ref. 226), and ~300 cases have been reported since then (see database at isth.org). Congenital hypofibrinogenemia was first reported in 1935 (reviewed in Ref. 227), and at least 40 cases have been reported in the literature. However, it is likely that many of the cases of hypofibrinogenemia were actually cases of dysfibrinogenemia with a reduced level of circulating clottable fibrinogen. Congenital disorders of fibrinogen are rare, and, in practice, most commonly observed disorders are acquired as a result of liver disease or consumptive processes.

Pathogenesis of Quantitative Fibrinogen Disorders

In congenital afibrinogenemia and hypofibrinogenemia, defects in synthesis, secretion, or intracellular processing of the final gene product result in deficiency of plasma fibrinogen.²²⁸ When newly synthesized fibrinogen is not secreted, the protein may accumulate in the rough endoplasmic reticulum of hepatocytes or other cells, resulting in amyloid-like accumulations.²²⁹ In both afibrinogenemia and hypofibrinogenemia, the fibrinolytic system and other coagulation pathways are completely normal. Similarly, there is no evidence of blood coagulation activation, which could cause consumption, or degradation of the fibrinogen molecule. The fibrinogen gene locus is located on chromosome 4; it contains three distinct genes that encode for the A α , B β , and γ peptide chains that compose the fibrinogen molecule.²³⁰ The inheritance pattern of afibrinogenemia is autosomal recessive in nature,²²⁷ and many reported cases are the result of consanguineous relationships between asymptomatic parents with symptomatic homozygote offspring. The molecular basis for quantitative fibrinogen disorders has been reviewed.²³¹ Genetic defects are scattered throughout the three fibrinogen genes that code for the three polypeptide chains—A α , B β , and γ . Multiple genetic defects have been reported, including deletions, point mutations, missense mutations, and uniparental isodisomy.²³¹ Deletion of an 11-kb region of the fibrinogen α gene appears to be a recurrent finding in unrelated families from both Europe and the United States.²³² A database of genetic defects that have been identified in patients with congenital fibrinogen abnormalities is accessible at www.geht.org/databaseang/fibrinogen. An unexpectedly large number of individuals with congenital fibrinogen disorders have been described in southern Iran.²³³

Afibrinogenemia

Inherited afibrinogenemia is a rare autosomal recessive disorder, with an estimated frequency of 1 in a million individuals.²³² It is somewhat of an anomaly that patients who are afibrinogenemic have little hemorrhage, despite the fact that their blood cannot clot normally. This may in part be due to the presence of functional vWF, which allows platelet adhesion and aggregation, with the formation of loose thrombi even in the absence of fibrinogen.²³⁴ A similar phenotype was recently described for afibrinogenemic mice created by gene-targeted knockout.²³⁵ In patients with afibrinogenemia, life-threatening hemorrhages do occur, but in many situations the bleeding is not as severe as is seen in hemophilia. The diagnosis is often made early in infancy, when prolonged umbilical stump bleeding occurs.²³⁶ A major cause of death is intracranial hemorrhage during infancy or childhood.²³⁷ The clinical manifestations include mucosal membrane bleeding, such as epistaxis, menorrhagia, or gastrointestinal hemorrhage. A review of the cases entered into

the North American Rare Bleeding Disorder Registry indicated that most bleeding events were triggered by trauma, with only 20% to 30% occurring spontaneously.²³⁸

Increased incidence of first-trimester abortion, placental abruption, and postpartum hemorrhage have been observed in patients with afibrinogenemia.²³⁹ Fetuses of female afibrinogenemic patients rarely reach full term unless replacement therapy is given.²⁴⁰ Although 20% of afibrinogenemic patients are affected with hemarthrosis, the severity is generally less than that seen in patients with hemophilia. Replacement therapy for patients with afibrinogenemia is available,^{241, 242} although there may be some concern with increased risk of thrombosis during therapy. Transgenic afibrinogenemic mice demonstrate abundant thrombus formation in a vascular injury model.²³⁴ The basis for this is not well understood, but may be in part related to the fact that fibrinogen has non-substrate-binding sites for thrombin that

P.1162

could potentially modulate thrombin availability to activate platelets.²⁴³ Patients with congenital hypofibrinogenemia do not typically have any spontaneous bleeding unless the fibrinogen level is <50 mg/dl. These patients may actually have hypodysfibrinogenemia, which is discussed in a later section of this chapter.

Laboratory Diagnosis

Screening coagulation tests from afibrinogenemic and hypofibrinogenemic patients typically show a marked prolongation of all tests where the endpoint is the appearance of fibrin clot, as severe fibrinogen deficiency renders plasma nonclottable. These tests include the PT, PTT, thrombin clotting time, and reptilase time. These test abnormalities, when due to functional deficiency of clottable fibrinogen, are usually corrected when patient plasma is mixed with normal plasma.²⁴⁴ A diagnosis of afibrinogenemia depends on the specific finding of undetectable fibrinogen antigen in the plasma of these patients. Platelet fibrinogen is also absent. Mild thrombocytopenia has been reported in some afibrinogenemic patients, but typically the platelet count is usually not lower than 100,000/ μ l.²⁴⁵ The bleeding time is prolonged in approximately one-third of patients with afibrinogenemia, presumably caused by the failure of platelets to aggregate in the absence of plasma or platelet fibrinogen. These abnormalities are correctable by infusion of plasma,²⁴⁶ or more recently therapeutic concentrates of fibrinogen.^{241, 242} Furthermore, afibrinogenemic patients who undergo hypersensitivity reaction skin testing do not typically show an induration response to allergens. They show only erythema because the later phases of the hypersensitivity reaction depend on the deposition of subcutaneous fibrin.²⁴⁷

Differential Diagnosis and Therapy of Afibrinogenemia

Congenital quantitative defects in fibrinogen must be carefully distinguished from acquired quantitative defects in the fibrinogen molecule, which are often seen in the setting of liver disease or disseminated intravascular coagulation. Acquired hypofibrinogenemia has been reported after therapy with L-asparaginase, which impairs hepatic synthesis of fibrinogen,²⁴⁸ and in patients with aplastic anemia treated with antithymocyte globulin and corticosteroids.²⁴⁹ In the absence of purified fibrinogen concentrates, cryoprecipitate administration is used for replacement therapy for patients with severe afibrinogenemia. Prophylactic therapy is recommended only for pregnant patients, or patients with a history of central nervous system (CNS) hemorrhage.²³⁶ Replacement therapy is indicated for any episode of acute active bleeding, preoperatively, and in pregnant patients. Fibrinogen levels between 50 and 100 mg/dl are usually adequate for normal hemostasis.²³⁶ Levels >100 mg/dl are recommended for maintenance during pregnancy, based on empiric clinical observations.²³⁶ Weekly infusions are recommended, but one should be aware that fibrinogen requirements may rise significantly around the time of parturition, and that levels as high as 150 mg/ml may be helpful to avert abruption.²⁵⁰ Each bag of cryoprecipitate contains ~250 mg of fibrinogen, and one bag of cryoprecipitate typically raises plasma fibrinogen levels of an adult by ~10 mg/dl; thus 5 to 10 bags of cryoprecipitate are usually sufficient in the average adult patient. Because the fractional catabolic rate of fibrinogen is 25% per day, acute-care patients should receive one-third of their loading dose daily for as long as fibrinogen support is desired.^{241, 242, 251} There are plasma concentrates of fibrinogen now available that may provide advantages over the use of cryoprecipitate.^{252, 253} Measurement of plasma fibrinogen levels after infusion is recommended to confirm that a patient has obtained the desired therapeutic effect. The complications of replacement therapy in afibrinogenemia include allergic reactions, development of antifibrinogen antibodies, and anaphylaxis.²⁵⁴ Thromboembolic complications following cryoprecipitate infusions include deep venous thrombosis and pulmonary emboli; the risk of these complications may be increased when an inhibitor of fibrinolysis or oral contraceptive therapy is also administered.^{255, 256} Low-molecular-weight heparin in combination with fibrinogen replacement has been used to avoid these thromboembolic complications.²⁵⁷ Antifibrinolytics alone may be sufficient to prevent bleeding from mucosal sites, but caution should be exercised in patients with a personal or family history of thrombosis.

Dysfibrinogenemia

The first reported case of dysfibrinogenemia mediated by a qualitatively abnormal fibrinogen molecule occurred in 1965, and since that time >300 families have been reported with this disorder.^{220, 221, 222} The molecular genetic basis of fibrinogen dysfunction has been fairly well established in many families that have been studied. However, uncertainty persists concerning the linkage of genetic defects of fibrinogen and the disease phenotype expressed by patients, as environmental factors and other concomitant genetic abnormalities may be influencing disease manifestations.²⁵⁸ There is an intriguing report of an increased association of dysfibrinogenemia with chronic thromboembolic pulmonary hypertension.²⁵⁹ A database containing an updated list of the genetic defects associated with dysfibrinogenemia is accessible at http://site.geht.org/site/Pratiques-Professionnelles/Base-de-donnees-Fibrinogene/Database-English-Version/Fibrinogen-variants-Database-_79_.html.

Molecular Basis of Dysfibrinogenemia

The reported abnormalities in the fibrinogen molecule include defects in each of the major steps of fibrin formation and stabilization. The conversion of fibrinogen to an insoluble fibrin clot requires that the molecule first be cleaved by thrombin between arginine 16 and glycine 17 of the A α chain to release fibrinopeptide A, and between arginine 14 and valine 15 of the B β chain to release fibrinopeptide B. This produces a fibrin monomer capable of undergoing the second step, fibrin polymerization. Once these molecules polymerize, they are stabilized by the action of factor XIIIa. Fibrinogen also supports the hemostatic process through interaction with platelets during platelet cohesion (aggregation). Finally, during the process of wound healing and tissue remodeling, the fibrin clot undergoes fibrinolysis by concerted activities of plasminogen and plasminogen activators. Fibrinogen dysfunction may affect any of these various steps of fibrin clot formation, platelet interaction, or lysis. It is therefore expected that the dysfibrinogenemias can be associated with abnormal clinical bleeding, thrombotic tendency, disorders of wound healing, or no clinically apparent disease. Domain location of a mutation does not necessarily predict the associated disease phenotype. Defects of fibrinopeptide release have been associated with both hemorrhagic and thrombotic complications. Similarly, disruption of D-D interactions have been associated with both bleeding and thrombosis. Patients who have heterozygous dysfibrinogenemia typically have ~50% of normal fibrinogen levels, which should be adequate for hemostasis. Clottable fibrinogen protein measurements may not be a reliable indicator of plasma fibrinogen concentration, because functionally abnormal molecules are not always incorporated into the clot. An abnormal fibrinogen may inhibit the conversion of normal fibrinogen to fibrin, so the tendency for many of these patients to bleed is higher than one would suspect. Hypodysfibrinogenemia occurs when an abnormality of the fibrinogen molecule results in decreased secretion or increased clearance of the protein. More than 20 families have been reported with hypodysfibrinogenemia. Autosomal amyloidosis has been attributed to genetic disorders of fibrinogen, as well as to genetic disorders of several other proteins (including transthyretin, gelsolin, apolipoprotein A, and lysozyme).

P.1163

Hereditary renal amyloid disease has been associated with genetic defects of the A α chain, and renal amyloid has recurred in renal transplants. Hepatic amyloid disease has also been attributed to abnormalities of fibrinogen.^{230, 260}

Dysfibrinogenemia is typically inherited as an autosomal dominant trait with high levels of penetrance. Most of these patients are heterozygotes, but a few homozygotes and some rare compound heterozygotes have been reported in the literature. Approximately 40% of dysfibrinogenemic patients are asymptomatic, and 45% to 50% have a bleeding disorder.²⁶¹ The remaining 10% to 15% have either a thrombotic disorder (venous or arterial) or both bleeding and thrombotic tendencies. The bleeding associated with dysfibrinogenemia is generally mild and includes soft tissue hemorrhage, easy bruising, and menorrhagia. Although intraoperative and postoperative bleeding have been reported, most bleeding is not life-threatening.

There are only a few families in which a thrombotic tendency can be unambiguously associated with dysfibrinogenemia, and criteria for making this association have been proposed. These criteria include a demonstrated molecular defect, thrombosis at an early age or in multiple family members, presence of no other predisposing factor for thrombosis, strong association between the fibrinogen defect and thrombus complications within a family, and association of the same molecular defect with thrombosis in another, unrelated kindred.²⁶² The true prevalence of thrombosis among patients with dysfibrinogenemia is unknown. Studies indicate a distinct thrombotic tendency in individuals with dysfibrinogenemia related to defects in the α -C domain of the A α chain of fibrinogen, especially if new cysteine residues are encoded that can become disulfide-linked to albumin. In contrast, dysfibrinogenemic patients with defective cross-linking experience primarily defective wound healing.

Laboratory Diagnosis of Dysfibrinogenemia

The thrombin clotting time remains a sensitive screening test for dysfibrinogenemias,²⁴⁴ and the PT appears to be more sensitive than the PTT to the effects of dysfibrinogenemia. In some cases, clot formation may be absent. Reptilase is a snake venom enzyme that differs from thrombin in that it cleaves only fibrinopeptide A of fibrinogen. The reptilase time is often more prolonged than the thrombin clotting time, especially in patients who have defective fibrinopeptide A release. Some dysfibrinogenemias exhibit a very short thrombin clotting time, and these patients may have thrombotic complications. The fibrinogen concentration can be either low or normal in these patients. Most patients with dysfibrinogenemia have a significant discrepancy between the level of clottable fibrinogen and that detected by immunologic methods. Criteria for diagnosing dysfibrinogenemias using ratios of immunologic and functional fibrinogen assays have been reported,²⁶³ but the sensitivity and specificity of these criteria are not well characterized. The euglobulin clot lysis time is a crude measure of fibrinolytic potential, and may be helpful in detecting abnormal fibrinogens that show increased susceptibility to fibrinolysis. For example, with fibrinogen St. Louis,²⁶⁴ the euglobulin clot lysis time is shortened, and fibrinogen degradation products are elevated in the plasma. Laboratory testing for fibrinogen abnormalities has been reviewed.²⁶⁵

The diagnosis of inherited dysfibrinogenemia must be distinguished from hypofibrinogenemia, which is either acquired or congenital in nature. Acquired dysfibrinogenemia occurs typically in the setting of severe liver disease,²⁶⁶ and the suspicion can be readily investigated by evaluation of liver function tests. Acquired dysfibrinogenemias are also associated with malignancies that produce an abnormal fibrinogen molecule, such as some hepatomas (see Chapter 54), multiple myeloma,²⁶⁷ and renal cell carcinoma,²⁶⁸ as well as autoimmune disorders. An algorithm has been proposed for the orderly evaluation of patients in whom dysfibrinogenemia is a consideration.²⁴⁴

Acquired inhibitors to fibrin formation that interfere with fibrinogen-to-fibrin conversion may also be confused with dysfibrinogenemia. These acquired inhibitors include heparin-like molecules, elevated levels of fibrin split products, and antibodies at concentrations such as may occur in macroglobulinemia, multiple myeloma, or other disorders that interfere with fibrin polymerization.²⁶⁹ Acquired antibodies against the fibrinogen molecule are quite rare but have been reported in association with a variety of diseases.^{270 271}

Therapy

The majority of patients with dysfibrinogenemia do not require any specific therapy. Any bleeding complications that develop can be managed with transfusion of either plasma or cryoprecipitate. The role of the newer fibrinogen concentrates in treating patients with dysfibrinogenemia has not been clarified through appropriate clinical trials yet. Antifibrinolytic drugs have been used in some patients but should be especially avoided in patients who have thrombotic tendencies. Patients who have repeated venous thrombotic episodes may actually require long-term antithrombotic therapy. A patient with life-threatening thrombophilic manifestations was successfully managed with plasma exchange prior to surgery,²⁷² but one wonders whether simple anticoagulation therapy would have been sufficient to provide a satisfactory outcome. In women with dysfibrinogenemia, recurrent miscarriages may be prevented using prophylactic cryoprecipitate, and successful pregnancy outcomes in such cases have been reported.²³⁶

FACTOR XIII DEFICIENCY

The initial hemostatic plug is not sufficient to prevent blood loss unless it is stabilized by the action of plasma factor XIII (fibrin stabilizing factor). A complex set of reactions among thrombin, fibrin, and plasma factor XIII is necessary for clot stabilization (see Chapter 18). When fibrin begins to polymerize after thrombin cleaves the fibrinopeptides, a complex forms between thrombin and fibrin, which promotes the conversion of factor XIII to factor XIIIa. Fibrin is the main catalytic substrate for factor XIIIa.²⁷³ Factor XIIIa transforms the unstable, noncovalently associated fibrin clot to a stable covalently cross-linked set of fibrin fibers that are mechanically stronger, more rigid, and more elastic. A cross-linked fibrin clot is more resistant to mechanical as well as enzymatic degradation by plasmin than uncross-linked fibrin because α_2 -plasmin inhibitor is also cross-linked to fibrin to inhibit plasmin activity. Factor XIIIa is a transglutaminase that catalyzes the formation of intermolecular γ -glutamyl- ϵ -lysyl covalent (isopeptide) bonds between the γ chains and α chains of fibrin strands within the clot. Cross-linkage of γ -chain Gln 398 and Lys 406 residues appears to occur earlier, with α -chain linkages between Gln 328 and 366 with Lys 508, 556, and 562 occurring more slowly.²⁷³ In addition, several other plasma and extracellular matrix proteins are linked to the fibrin clot through the action of factor XIII. Cross-linking of thrombin-activatable fibrinolysis inhibitor into fibrin clots further increases the resistance of the clot to plasmin degradation.²⁷³ Cross-linkage of fibrin to adhesive proteins such as vWF, fibronectin, thrombospondin, and vitronectin may improve adhesion to vessel walls and may play a role in cell migration during wound healing. In fact, fibronectin is the second most abundant material in the fibrin clot, accounting for 4% of the total protein.²⁷⁴

The importance of factor XIII function in normal health is emphasized by the clinical scenarios characteristic of inherited and acquired deficiency of factor XIII. In the following section, the pathogenesis, molecular genetics, clinical laboratory, diagnostic, and therapeutic elements of the diagnosis and treatment of factor XIII deficiency are discussed.

P.1164

Pathogenesis

In 1944, Robbins postulated that a deficiency of fibrin-stabilizing factor, which later became known as factor XIII, would produce a serious bleeding disorder.²⁷⁵ However, it was not until the first case of factor XIII deficiency was described in 1960 that the severe nature of this bleeding disorder was recognized.²⁷⁶ During the last five decades, >200 cases of congenital factor XIII deficiency have been reported in the literature.²⁷⁷ It is estimated that ~1 person in every 1 million to 5 million people has factor XIII deficiency. The disorder is inherited as an autosomal recessive trait.^{236, 277}

The factor XIII molecule is present in both plasma and in blood platelets and monocytes. The plasma concentration of factor XIII is 14 to 28 µg/ml. Approximately half that concentration circulates within blood platelets. Tissue-based factor XIII resides in monocyte/macrophages. Structurally, platelet and monocyte factor XIII consists of only A dimers, present within the cytoplasm of both platelets and megakaryocytes. The plasma factor XIII molecular complex is a heterotetramer, containing two of each of the A and B subunits. The A subunit mediates factor XIII function, containing an activation peptide, calcium-binding site, and enzymatic domain with an active site sulfhydryl residue that is characteristic of this class of enzymes.²⁷⁸ The three-dimensional structure for the A subunit has been determined by x-ray crystallography.²⁷³ The majority of the A subunit in circulation is derived from cells of marrow origin.²⁷⁹ The B subunit of plasma factor XIII is synthesized in the liver and probably associates with the A subunit in the plasma phase after release from the hepatocyte. The B subunit appears to promote stabilization of the A subunit in plasma and may play an important role in regulating both the localization of the A subunit to the fibrin clot and thrombin-dependent activation of the protein. Two distinct forms of factor XIII deficiency have been described, based on whether the A and B subunits are absent or present.²⁷³ In type I deficiency there is absence of the B subunit, with resultant decreased concentration of the A subunit in plasma, but platelet A subunit content is maintained. In type II deficiency, the A subunit is absent and the B subunit is present.

Molecular Genetics

Since the protein was initially described in human serum in 1944, both the A and B subunits have been purified, and cDNA sequence and gene structure have been established.²⁷³ The A subunit is encoded on chromosome 6, containing 15 exons and spanning a region of 160 kb. A common genetic polymorphism of the A subunit has been described that results in Val34 replacement by Leu just three amino acid residues from the site of cleavage of the activation peptide. This polymorphism may influence factor XIII activation and has been investigated in reference to risk for myocardial infarction.²⁸⁰ The B subunit is encoded by chromosome 1.²⁸¹ Because the mode of inheritance of factor XIII deficiency is autosomal recessive in nature, only homozygotes or compound heterozygotes are clinically symptomatic. The homozygotes reported in the literature are often children of consanguineous marriages.²⁸²

In the cases reported to date, factor XIII deficiency is more frequently attributed to mutation of the gene encoding the A subunit, confirming the functional importance of this subunit. To date, over 70 mutations have been described.²⁷⁷ The majority of defects observed are "point mutations" resulting in stop codons, missense errors, or frame-shifts and small deletions. Inherited deficiency of the factor XIII A chain is not restricted to any specific ethnic group.²⁸³

Factor XIII B chain deficiency is a very rare autosomal recessive disorder, with very few reported cases in the literature.²⁸⁴ One unique patient displayed a complete absence of the B chain and a shortened half-life of the A chain. Interestingly, this B chain-deficient patient had many of the same symptoms as an A chain-deficient patient. The ability of the B chain to promote A chain binding to the fibrinogen molecule may account for this clinical finding.²⁸⁵ Only ~5 mutations have been reported in the B chain gene.²⁷⁷

Clinical Aspects

Clinically affected factor XIII-deficient patients typically have plasma levels that are <1% of normal,²⁷³ with bleeding attributed to accelerated fibrin clot degradation. The bleeding phenotype in patients with inherited factor XIII deficiency is unusually severe. Abnormal bleeding manifests shortly after birth, when bleeding from the healthy umbilical cord remnant occurs.²⁸⁶ This has been a prominent feature, reported in up to 80% of cases,²⁸² but this complication was observed in only 22% of the 34 cases reported to the North American Rare Bleeding Disorders Registry.²³⁸ Umbilical stump bleeding is an uncommon presentation for other congenital bleeding disorders. Rebleeding at circumcision is also

common. Other bleeding manifestations in these patients include soft tissue hemorrhage, hemarthrosis, hematomas, and the development of large pseudocysts.²⁸⁶ The most life-threatening complication of factor XIII deficiency is spontaneous intracranial hemorrhage. Intracranial hemorrhage is more prevalent in factor XIII deficiency than in other inherited bleeding disorders. Approximately 25% of factor XIII-deficient patients experience intracranial hemorrhage.²⁸⁷ Bleeding is usually spontaneous, and prevention of intracranial hemorrhage forms the basis for the recommendation of prophylactic therapy of factor XIII-deficient patients. Surgery in these patients is often complicated by abnormal wound healing and excessive postoperative bleeding, which can occur either immediately or later. Delayed bleeding may occur several days after surgery or tissue injury, and patients may experience cycles of repetitive bleeding that span weeks to months. Poor wound healing is reported in ~20% of patients with factor XIII deficiency. The affected males in some families also have oligospermia, resulting in infertility. Furthermore, infertility in affected females results from spontaneous abortions. Females with this deficiency cannot carry a pregnancy to term unless plasma factor XIII levels are maintained at levels that prevent bleeding.²⁸⁸ The manifestations of factor XIII deficiency vary greatly among patients and may not necessarily present as bleeding symptoms. It has been hypothesized that heterogeneity of genetic defects underlying the deficient state accounts for the clinical variability in disease expression.²⁸⁹ Factor XIII-deficient mice display a similar phenotype to the human condition.²⁹⁰

Differential Diagnosis

Congenital or acquired factor XIII deficiency must be considered when a patient has a major bleeding disorder and all of the initial screening laboratory tests are normal, including PT, PTT, and platelet count. Bleeding can occur spontaneously or after major surgery. It remains imperative in the adult to exclude both inherited and acquired factor XIII deficiency, because patients can develop antibodies to factor XIII that interfere with fibrin stabilization. Specific antibodies to factor XIII were reported in patients taking isoniazid, phenytoin, procainamide, penicillin, and valproic acid.²⁷³ Factor XIII antibodies also occur in association with autoimmune disease, in patients with monoclonal gammopathy, or as an idiopathic occurrence. Acquired factor XIII deficiency has been reported in Henoch-Schönlein purpura, liver disease, Crohn disease, and ulcerative colitis.²⁷³

Laboratory Diagnosis

The PT and PTT assays are normal (Table 53.5). The solubility of a fibrin clot in 5M urea or 1% monochloroacetic acid (clot stability assay) is the most useful screening test for factor XIII deficiency.

P.1165

In these conditions, clots formed in the absence of factor XIII activity dissolve within 60 minutes.²⁷³ In contrast, normal clots covalently modified by factor XIIIa remain insoluble for at least 24 hours. This is a qualitative assay, and as little as 5% of the normal factor XIII activity level can render a clot insoluble in urea. Unfortunately, clot stability testing is not well standardized. If clot solubility is found, a mixing study with normal plasma is recommended to exclude factor XIII inhibitor. Deficiency of α_2 -antiplasmin may also cause a bleeding disorder with normal coagulation screening studies and increased urea clot solubility; a specific assay for α_2 -antiplasmin should be considered, to exclude this possibility.²⁹¹ Quantitative measurements of factor XIII activity can also be done, and these tests are useful to confirm factor XIII deficiency that is suspected based on an abnormal qualitative clot solubility assay. Specialized laboratories may measure either ammonia production (an end product of the factor XIIIa reaction)²⁹² or the incorporation of fluorescent or radioactive amines (such as dansylcadaverine) into proteins such as casein.²⁹³ However, the most sensitive and specific measurement of factor XIIIa activity remains the functional assay measuring the stability of a covalently cross-linked fibrin clot.²⁹⁴ Finally, immunologic based assays that detect factor XIII antigen are available, such as ELISAs specific for either the A or B subunits of factor XIII.²⁷³ Results of immunologic assays correlate with factor XIII activity assays, but immunologic assays are not widely available.

PROTHROMBIN DEFICIENCY

Inherited prothrombin deficiency is an exceedingly rare, autosomal recessive bleeding disorder, with a frequency of <1 in 1 million.²⁹⁵ To date, <40 mutations have been identified from <100 reported cases (Ref. 296, isth.org database). As with some of the other factor deficiencies, the frequency of prothrombin deficiency is greater in countries where consanguineous marriages occur. Phenotypically, prothrombin deficiency is classified as either hypoprothrombinemia (type I), distinguished by reduced prothrombin activity and reduced prothrombin antigen, or dysprothrombinemia (type II), distinguished by reduced prothrombin activity but normal prothrombin antigen.

Pathophysiology

Similar to deficiencies of the other vitamin K-dependent coagulation factors, prothrombin deficiencies result from mutant prothrombins that are either CRM-negative (hypoprothrombinemia) or CRM-positive (dysprothrombinemia). The CRM-negative form may be more common, is a product of missense, nonsense, insertion, or deletion mutations, and is characterized by a true deficiency of prothrombin, with a strong correlation between functional assays and immunoassays. The CRM-positive form is a product of missense mutations and is characterized by antigenically competent prothrombin, usually in quantities much greater than the associated functional activity.

By convention, these mutant prothrombins have been named according to the proband's origin, e.g., prothrombin Cardeza.²⁹⁷ The prevalence of prothrombin deficiency in Puerto Ricans led to the recent description of several unrelated families of Puerto Rican ancestry having a common mutation, prothrombin Puerto Rico I, with characteristics of both hypoprothrombinemia and dysprothrombinemia.²⁹⁸ Dysprothrombins with amino acid substitutions at or near the factor Xa cleavage sites inhibit activation to thrombin.^{299, 300} Amino acid substitutions elsewhere in prothrombin can affect the function determined by that region, including the catalytic domain (Quick II,³⁰¹ Molise, Perijé³⁰²), and fibrinogen-binding (Quick I³⁰³). Figure 53.9 summarizes some of these mutant prothrombins and their concomitant functional abnormalities.

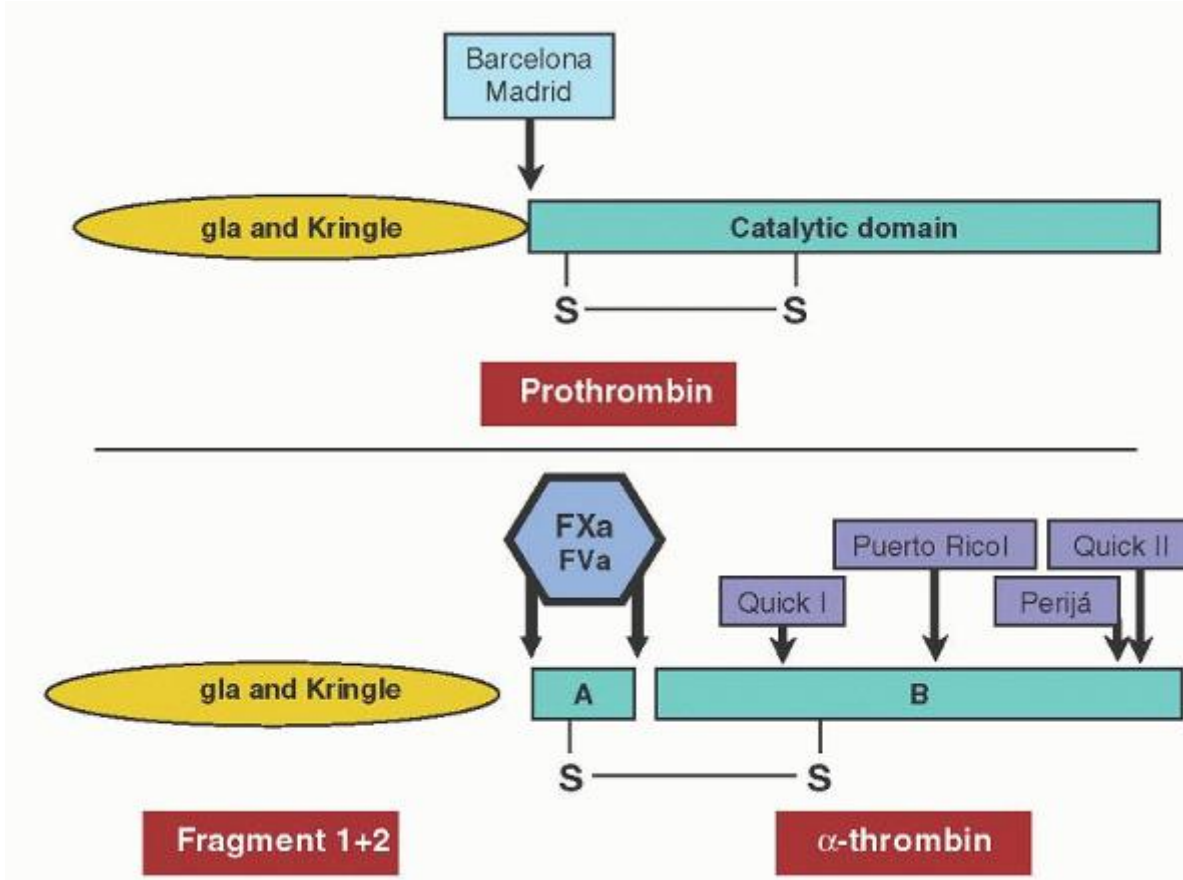

FIGURE 53.9. Schematic representation of prothrombin activation by prothrombinase (i.e., factors Xa, Va, and a negatively charged phospholipid surface) and sites of certain prothrombin mutations leading to inherited prothrombin deficiency. The fragment 1 + 2 domain contains γ -carboxyglutamic acid (gla) residues responsible for Ca^{2+} -dependent binding of prothrombin to cellular membranes. Prothrombins Barcelona and Madrid have a mutation at the factor Xa cleavage site (Arg271Cys), preventing activation to thrombin. The remaining depicted mutations are within the catalytic site/regulatory elements of α -thrombin. Prothrombin Quick I results in decreased proteolytic activity toward fibrinogen, as well as reduced abilities to release fibrinopeptide A, aggregate platelets, and stimulate the release of prostacyclin from human endothelial cells; prothrombins Perijé and Quick II result in decreased proteolytic activity due to alterations within the primary binding pocket; and prothrombin Puerto Rico I results in decreased activation to thrombin, possibly due to the removal of a salt bridge linking the A and B chains of thrombin.

Clinical Features

Epistaxis, menorrhagia, and posttraumatic bleeding are the most common complaints. Hemarthroses and muscle hematomas have also been reported.²⁹⁵ The extent of prothrombin deficiency does not necessarily correlate with clinical

bleeding. Although hemostasis can be maintained by prothrombin levels >25% of normal, significant bleeding is usually seen when prothrombin levels are <2% of normal.³⁰⁴ Of the severe prothrombin deficiency patients reported to the Rare Bleeding Disorders Registry, 20% experienced intracranial bleeding.²³⁸ Prothrombin-deficient heterozygotes have 40% to 60% of normal prothrombin activity; compound heterozygotes and homozygotes usually have <10% of normal prothrombin activity.³⁰⁵ As of yet, no human cases of total prothrombin deficiency have been reported. Based on studies with knockout mice, such a complete deficiency is thought to be incompatible with life, leading to a loss of vascular integrity, arrested development, and tissue necrosis, ultimately resulting in embryonic or neonatal lethality.³⁰⁶ This effect is thought to result from a developmental activity of thrombin on yolk sac vasculature. The genetic elimination of prothrombin in an adult mouse model was also not compatible with survival.³⁰⁷

Laboratory Diagnosis

A summary of laboratory findings in prothrombin deficiency is included in Table 53.5. Prothrombin deficiency is associated with normal thrombin times but prolonged PT and aPTT, which can be corrected in mixing studies. Specific factor assays for prothrombin are used in diagnosis. Acquired prothrombin deficiency, caused by either vitamin K deficiency or an antiprothrombin antibody associated with antiphospholipid antibodies, should be considered before making the diagnosis of inherited prothrombin deficiency. Fresh-frozen plasma (FFP) and prothrombin complex concentrates (PCCs) are used to treat prothrombin deficiency, as outlined later, in Table 53.8.

P.1166

TABLE 53.8 REPLACEMENT THERAPY IN OTHER INHERITED COAGULATION DISORDERS

Disorder	Therapeutic Product	Loading Dose	Maintenance Dose
von Willebrand disease	Humate-P ^a	40-60 IU/kg	40-50 IU/kg every 12-24 h for up to 7 d
	Cryoprecipitate ^b	Not required	1 bag/10 kg daily
Fibrinogen deficiency	Cryoprecipitate	1-2 bags/10 kg	1 bag/10 kg every other d
	Purified fibrinogen ^c	50-100 mg/kg	20 mg/kg every other d
Prothrombin deficiency	Fresh-frozen plasma ^d	15 ml/kg	5-10 ml/kg daily
Dysprothrombinemia	Purified prothrombin complex ^e	20 IU/kg	10 IU/kg daily
Factor V deficiency	Fresh-frozen plasma	20 ml/kg	10 ml/kg every 12-24 h
Factor VII deficiency	Fresh-frozen plasma ^d	20 ml/kg	5 ml/kg every 6-24 h
	Purified prothrombin complex ^e	30 IU/kg	10-20 IU/kg every 6-24 h
Factor X deficiency	Fresh-frozen plasma ^d	15-20 ml/kg	5-10 ml/kg daily
	Purified prothrombin complex ^e	15 IU/kg	10 IU/kg daily
Factor XI deficiency	Fresh-frozen plasma ^d	15-20 ml/kg	5 ml/kg every 12-24 h
Factor XIII deficiency	Fresh-frozen plasma ^f	5 ml/kg every 1-	Not usually required
		2 wk	

Note: The replacement therapy regimens suggested in this table are for major bleeding or surgical prophylaxis. Patients with minor bleeding may require lower dosages of these replacement products. Confirmation of hemostatic levels of the appropriate coagulation factor being replaced should be done, with dosage adjustments performed as needed.

^a Labeled in ristocetin cofactor units. Alphanate and Wilate can also be used to treat von Willebrand

disease.

^b Recommended only if purified factor replacement therapy is not available.

^c Not routinely available in the United States.

^d Plasma after removal of cryoprecipitate is satisfactory.

^e Prothrombin complex concentrates are thrombogenic and should be used only for major bleeding or major surgery. Antifibrinolytic drugs (ϵ -aminocaproic acid, tranexamic acid) should not be used in conjunction with prothrombin complex concentrates.

^f A factor XIII concentrate is now available in the United States. See text for details.

FACTOR V DEFICIENCY

Inherited factor V deficiency, also known as labile factor deficiency, proaccelerin deficiency, and parahemophilia, is a rare autosomal recessive bleeding disorder first described by Owren,³⁰⁸ with an estimated frequency of 1 in 1 million.²⁹⁵ To date, >100 mutations have been identified from >200 reported cases,^{309, 310, 311} and a database at isth.org lists >120 factor V mutations. As with some of the other factor deficiencies, the frequency of factor V deficiency is greater in countries where consanguineous marriages occur.²⁹⁵ Phenotypically, factor V deficiency is classified as either type I, distinguished by reduced factor V activity and reduced factor V antigen, or type II, distinguished by reduced factor V activity but normal factor V antigen.

Pathophysiology

The majority of factor V deficiencies result from a failure to either synthesize or secrete factor V. The mutants responsible for these deficiencies are CRM-negative (type I); CRM-positive factor V mutations (type II) have also been detected.³¹² The CRM-negative form is a product of missense, nonsense, insertion, or deletion mutations and is characterized by a true deficiency of factor V, with a strong correlation between functional assays and immunoassays. Factor V New Brunswick, a CRM-positive form, is caused by a missense mutation and is characterized by antigenically competent factor V with reduced activity, most likely due to reduced stability of factor Va.^{313, 314}

By convention, many of these mutant factor Vs have been named according to the proband's origin, e.g., factor V Stanford³¹⁵ and factor V Ogden.³¹⁶ Factor V Quebec is associated with a moderate reduction in plasma factor V levels and a severe reduction in platelet factor V, but also other α -granule proteins, including multimerin (a factor V carrier molecule within platelets), and is thus more properly considered a platelet disorder.³¹⁷ Approximately 20% of the circulating pool of factor V is contained within platelets. This platelet pool of factor V and low levels of tissue factor pathway inhibitor seen in factor V deficient patients may explain the milder bleeding phenotype in this bleeding disorder.³¹⁰

Clinical Features

Epistaxis, menorrhagia, and posttraumatic bleeding are the most common complaints. Trauma-induced hemarthroses and muscle hematomas have also been reported.²⁹⁵ Gastrointestinal or CNS bleeding is observed very rarely. Although neonatal bleeding has seldom been observed, factor V deficiency has been associated with other congenital abnormalities.³¹⁸ Hemostasis can be maintained by factor V levels >10% to 20% of normal, but moderately severe bleeding

is usually seen when factor V levels are <10% of normal. Factor V-deficient heterozygotes have 40% to 60% of normal factor V activity; compound heterozygotes and homozygotes usually have <10% of normal factor V activity. Bleeding symptoms may correlate better with platelet factor V content rather than the plasma factor V level.³¹⁷

A genetic model of factor V deficiency utilizing factor V-knockout mice underscores the importance of factor V in not only hemostasis but development, as fetal loss in utero is markedly increased.³¹⁹ Based on these knockout-mouse studies, complete factor V deficiency is apparently incompatible with life, but <0.1% of normal factor V activity is sufficient to rescue completely deficient mice.³²⁰ As of yet, no human cases of total factor V deficiency have been reported, and even patients with a homozygous or compound heterozygous factor V deficiency usually have some residual factor V activity.

Laboratory Diagnosis

A summary of laboratory findings in factor V deficiency is included in Table 53.5. Factor V deficiency is associated with P.1167

normal thrombin times but prolonged PT and aPTT, which can be corrected in mixing studies. A PT-based factor V assay or an ELISA can be used to verify quantitative reductions in factor V. Good results have been obtained using aged oxalated or ethylenediaminetetraacetic acid plasma as a factor V-deficient substrate,³²¹ as well as artificially depleted substrate plasmas. Acquired factor V deficiency, caused by liver disease, disseminated intravascular coagulation, or antibodies to factor V, should be excluded before making the diagnosis of inherited factor V deficiency. Upon confirmation of factor V deficiency, however, a specific assay for factor VIII should also be performed to rule out the rare combined factor V/factor VIII deficiency,³²² treatment of which entails a different replacement therapy. Currently, FFP is used to treat factor V deficiency, as outlined later, in Table 53.8.

FACTOR VII DEFICIENCY

Factor VII deficiency was first described in 1951 by Alexander et al. under the name serum prothrombin conversion accelerator (SPCA) deficiency. Approximately 200 cases of true factor VII deficiency have been reported, and the population prevalence is estimated to be 1 in 500,000,²⁹⁵ making it the most common of the “rare bleeding disorders.” Also known as stable factor or proconvertin deficiency, the condition is inherited as an autosomal recessive trait that produces severe deficiency in the homozygote and mild deficiency, usually without clinical manifestations, in the heterozygote. As in other rare bleeding disorders, it is more common in cultures where consanguineous marriage is practiced.

Pathophysiology

Factor VII is secreted as a single-chain proenzyme glycoprotein of ~50 kDa by hepatocytes. Factor VII has the shortest plasma half-life of all coagulation factors (~5 hours), and its plasma concentration is very low, ~500 ng/ml.³²³ Factor VIIa is detectable in trace amounts in normal plasma,³²⁴ and sensitive assays indicate that ~1% of circulating factor VII is in the activated form.³²⁴ The circulating half-life of activated factor VIIa is approximately 2.5 hours.³²⁵ Tissue factor increases the rate of activation of factor VII significantly,³²⁴ and current theory is that coagulation is initiated in the presence of tissue factor that is exposed at sites of vascular injury or contributed by blood monocytes.³²⁶

The factor VII gene includes nine exons and spans 128 kb on chromosome 13.³²⁷ It is located just upstream of the factor X gene. In a mouse knockout model in which factor VII is completely lacking, fatal hemorrhage occurs perinatally.³²⁸ In humans, factor VII deficiency occurs as a recessive trait resulting from homozygous or compound heterozygous mutations. Many mutations of the factor VII gene have been reported, with >200 mutations listed in 2012 in a database at isth.org. Most reported genetic defects are single-base substitutions, including missense, splice-site, and nonsense mutations. Most mutations affect only a few patients, but one mutation (Ala242Val) was detected in 23 “apparently” unrelated Jews in Israel.³²⁹ More extended haplotype testing suggests a “founder effect”.³²⁹ Although Dubin-Johnson syndrome is associated with factor VII deficiency,³³⁰ the genetic defect underlying that syndrome is located on chromosome 10, and the association of Dubin-Johnson syndrome and factor VII deficiency may simply reflect a high consanguinity rate in one population.²⁹¹ Combined deficiency of factor VII along with the other vitamin K-dependent coagulation proteins or as a deficiency with a single other coagulation protein has been reported in rare families (see below).

Clinical Features

Only severe factor VII deficiency is associated with hemorrhagic symptoms, and heterozygous carriers are asymptomatic. Factor VII levels do not completely correlate with the severity of symptoms, and this may in part reflect heterogeneity in the molecular basis of factor VII deficiency or the tissue factor-containing reagents used to quantify the factor VII activity

level in patients.³³¹ However, patients with levels of >10 to 15 IU/dl rarely manifest bleeding.³³² Patients with levels between 5 and 10 IU/dl tend to have milder symptoms, such as epistaxis, gingival bleeding, or genitourinary and gastrointestinal bleeding. Patients with levels <1 IU/dl may have symptoms similar to patients with hemophilia A or hemophilia B, with spontaneous joint and deepmuscle bleeding, but some patients with factor VII levels of <1 IU/dl have been asymptomatic. Bleeding into the CNS is particularly common, being observed in 15% to 60% of patients with factor VII levels <2 IU/dl.³³³ CNS bleeds often present during the neonatal period, and the risk of recurrence is high enough that prophylaxis with factor replacement therapy should be considered in patients who present with this complication.³³⁴ The severity of bleeding after trauma or surgical procedures varies to a surprising degree in this disorder, with oral and urogenital cavity procedures being particularly troublesome, possibly reflecting the high local fibrinolytic activity in these regions of the body. Prior clinical bleeding symptoms are an important prognostic factor predicting surgical bleeding complications in patients with factor VII deficiency.

Some reports indicate that patients with factor VII deficiency may also be more prone to various thromboembolic manifestations.³³⁵ The explanation for this phenomenon is unknown, but thrombophilic markers have been observed in most of these cases.³³⁶

Laboratory Diagnosis

In factor VII deficiency, normal results are obtained with coagulation tests that bypass the extrinsic pathway of coagulation and factor VII (Table 53.5), that is, the PTT, thrombin time, and, if tested, the Stypven (Russell viper venom) time. Thus, a diagnosis of factor VII deficiency is suspected in a patient with a life-long history of bleeding when there is an isolated prolonged PT and normal PTT. The PT will correct on 1:1 mixing of patient plasma with normal plasma, but a diagnosis of factor VII deficiency requires a specific factor VII assay for confirmation. Use of human thromboplastin in the PT assay is recommended. A factor VII mutation (factor VII Padua) has been described in African-American patients who are asymptomatic; this defect results in low factor VII activity levels when rabbit brain thromboplastin is used, but normal factor VII activity when human thromboplastin is used.³³⁷ Confirmation of low factor VII antigen level can be obtained by ELISA assay. Levels of factor VII in heterozygous carriers overlap the normal range. Before making a diagnosis of factor VII deficiency, one should exclude causes for acquired abnormalities such as vitamin K deficiency, liver disease, or warfarin therapy. Also, rare conditions such as combined deficiency of all vitamin K-dependent factors, and combined factor VII and factor X deficiency should be considered. Autoantibody directed to factor VII occurs, but few case reports have been published.

Phenotypically, patients have been characterized by evaluating plasma levels of factor VII antigen (or CRM). CRM-negative patients have low factor VII antigen as a result of the lack of synthesis or increased factor clearance, whereas CRM-positive patients produce factor VII that is detected antigenically but is structurally abnormal and with deficient function. CRM-reduced individuals presumably represent a combination of these two entities. Further complexity of the factor VII-deficient phenotype is introduced because of insensitivity of some factor VII activity assays to low levels of factor VII or from variability in assays that is introduced by the use of varying animal sources of tissue thromboplastin.

Treatment of factor VII deficiency with recombinant human factor VIIa, plasma, or PCCs is discussed later in this chapter. Although the necessity for correcting factor VII deficiency has

P.1168

been questioned,³³⁸ patients who have factor VII deficiency and a history of excessive clinical bleeding should be given replacement therapy before surgery. Numerous clinical reviews confirm that the patient's clinical bleeding history is the best predictive parameter of bleeding risk.³³⁹ It has been reported that patients with factor VII deficiency who have factor VII levels >10% when assayed using human thromboplastin reagents have minimal bleeding symptoms.

FACTOR X DEFICIENCY

Inherited factor X deficiency, first described in the Prower³⁴⁰ and Stuart³⁴¹ kindreds, is a rare autosomal recessive bleeding disorder with an estimated frequency of 1 in 1 million.²⁹⁵ Factor X deficiency represents ~10% of all rare bleeding disorders. To date, >100 mutations have been identified,^{342, 343, 344} with the majority being missense mutations.³⁴⁵ As with some of the other factor deficiencies, the frequency of factor X deficiency is greater in countries where consanguineous marriages occur.²⁹⁵ Phenotypically, factor X deficiency is classified as either type I, distinguished by reduced factor X activity and reduced factor X antigen, or type II, distinguished by reduced factor X activity but normal factor X antigen.

Pathophysiology

The CRM-negative form is a product of missense, insertion, or deletion mutations, and is characterized by a true deficiency of factor X, with a strong correlation between functional assays and immunoassays. The CRM-reduced and -positive forms are products of missense mutations and are characterized by low to normal levels of antigenically competent factor X but with disproportionately reduced factor X activity. Deletion mutations result in premature termination and thus the loss of the factor X catalytic domain, whereas missense mutations may affect not only the catalytic domain, but phospholipid binding, activation, secretion, or even synthesis of factor X. By convention, these mutant factor Xs have been named according to the proband's origin, e.g., factor X San Antonio I,³⁴⁶ factor X Friuli,³⁴⁷ and factor X St. Louis II.³⁴⁸

Clinical Features

The symptoms of factor X deficiency tend to be the most severe of the inherited coagulation deficiencies. Epistaxis, menorrhagia, and posttraumatic bleeding are common complaints, and hemarthroses and hematomas have been reported in two-thirds of factor X-deficient patients.²⁹⁵ Umbilical stump, gastrointestinal, and CNS bleeding are also frequently observed. Heterozygotes generally appear asymptomatic, as hemostasis can be maintained by factor X levels >10% of normal. On the other hand, compound heterozygotes and homozygotes with factor X levels <1% of normal suffer from severe bleeding. Experiments utilizing factor X-knockout mice resulted in either neonatal death or postnatal death, caused by intraabdominal or intracranial bleeding.³⁴⁹

Laboratory Diagnosis

A summary of laboratory findings in factor X deficiency is included in Table 53.5. Factor X deficiency is associated with normal thrombin times but prolonged PT, aPTT, and often Stypven (Russell viper venom) time, particularly among the CRM-negative variants. Unfortunately, factor X-deficiency variants have been described with isolated prolonged PT or aPTT values.^{350, 351} Upon ruling out other inherited bleeding disorders, a factor X-specific assay can be used to verify factor X deficiency. Acquired factor X deficiency, caused by liver disease, warfarin therapy, amyloidosis,³⁵² or antibodies to factor X, should be excluded before making the diagnosis of inherited factor X deficiency. Currently, FFP or PCCs are used to treat factor X deficiency, as outlined in Table 53.8.

FACTOR XI DEFICIENCY

Factor XI deficiency (plasma thromboplastin antecedent deficiency) was first recognized by Rosenthal et al. in 1953³⁵³ and was called hemophilia C. Factor XI deficiency is transmitted as an incompletely recessive autosomal trait manifested either as a major defect in homozygous patients with factor XI levels <20 IU/dl or as a minor defect in heterozygous patients with levels ranging from 30 to 65 IU/dl.³⁵⁴ The incidence of this disorder varies widely, with estimates of frequency in the general population being 1 in 1 million persons. A particularly high frequency of the disorder exists in people of Jewish extraction,^{354, 355, 356} with an estimated gene frequency of 5% to 11% in Ashkenazi Jews.³⁵⁷ Up to 0.3% of this population is homozygous for factor XI deficiency.³⁵⁷

Factor XI deficiency has been reported to result from three major types of mutations: Type I mutations result in disruption of splicing; type II mutations result in a stop codon and nonfunctional molecule; and type III mutations result in amino acid substitutions and a dysfunctional molecule.³⁵⁸ Patients with type II mutations have the greatest bleeding tendency.³⁵⁹ Type II and III mutations are most common in Ashkenazi Jews. The type II mutation is also common in Iraqi Jews,³⁶⁰ who may represent the ancient gene pool of Jews.³⁶¹

A more recent classification scheme for factor XI-deficiency cases that are CRM-negative includes three mechanistic categories: (a) Mutations that reduce or prevent polypeptide synthesis, (b) mutations resulting in polypeptides that fail to form intracellular dimers, and (c) mutations resulting in polypeptides that form dimers that are not secreted.³⁶² Mechanism (c) may account for some kindreds with apparent autosomal dominant factor XI deficiency.³⁶³ In general, most factor XI mutations result in decreased factor XI protein proportionate to factor XI clotting activity. Over 100 factor XI mutations have been reported^{364, 365} (database at isth.org).

Clinical Features

The clinical manifestations of factor XI deficiency are extremely variable and generally milder than those of hemophilia A or B.^{355, 364, 366} As a rule, spontaneous bleeding is rare, and hemorrhage usually occurs only after trauma or a surgical procedure. The extent of factor XI deficiency may not correlate with bleeding.^{355, 364, 366} Hemarthrosis is uncommon, but delayed bleeding is a particularly treacherous feature in some patients,^{353, 367, 368} especially for surgical procedures involving tissues rich in fibrinolytic activity.²³⁶ Mild factor XI deficiency may be associated with Noonan syndrome³⁶⁹ and Gaucher disease.³⁷⁰ Hemorrhagic manifestations may be absent in certain patients,³⁷¹ especially in those with type I mutations. Approximately one-half of heterozygous factor XI-deficient patients have a bleeding tendency.³⁷² Factor XI

deficiency should be considered in female patients with menorrhagia.³⁷³ In one study of women with menorrhagia, the prevalence of factor XI deficiency was 4%.¹⁶⁸

Laboratory Diagnosis

In the homozygous form of factor XI deficiency,³⁷⁴ the PTT is prolonged. In most of these patients, factor XI levels in the plasma are in the range of 3 to 15 IU/dl. In people with the mild form of the disorder, the PTT often is normal because most PTT reagents are insensitive to mild factor XI deficiency.^{74, 236} Abnormalities in the plasma of such mildly affected patients may be removed by freezing. Specific factor assays are used to diagnose

P.1169

factor XI deficiency. The bleeding time and thrombin time are normal. Factor XI deficiency has also been reported in combination with inherited factor IX deficiency (type VI familial multiple factor deficiency).³⁷⁶ Treatment of factor XI deficiency is discussed later in this chapter in the section "Plasma".

FACTOR XII DEFICIENCY

Factor XII deficiency was discovered by Ratnoff and Colopy during routine preoperative coagulation studies on John Hageman, an adult who had no evidence or history of abnormal bleeding.^{376, 377, 378} The disorder, subsequently named Hageman factor deficiency, is inherited as an autosomal recessive trait. Factor XII deficiency has been identified in 1.5% to 3.0% of a healthy blood donor population.³⁷⁹

Pathophysiology

The plasma of most patients with factor XII deficiency does not contain material that reacts with antibodies to this factor. Radioimmunoassays with heterologous antibodies have demonstrated antigenic material identical to normal factor XII in only 2 of 42³⁸⁰ and 2 of 31³⁸¹ separate kindreds. One large study of 31 factor XII-deficient kindreds identified most mutations in the serine protease domain.³⁸¹

Clinical Features

Factor XII deficiency usually is not associated with hemorrhagic manifestations.^{376, 382} It is noteworthy that myocardial infarction and thrombophlebitis have been observed in patients with severe factor XII deficiency,³⁸³ and that Hageman died of thromboembolic complications.³⁸⁴ It was originally thought that factor XII deficiency might actually predispose to thrombosis, possibly as the result of deficient activation of fibrinolysis.³⁸⁵ However, more recent surveys indicate that factor XII deficiency is not associated with an excessive risk of thrombosis^{68, 386, 387}; thrombotic events in factor XII-deficient patients may be explained by the presence of other prothrombotic gene defects in these patients.³⁸⁸

In vitro experiments suggest that factor XII has a central role in the initiation of the intrinsic pathway of coagulation and mediates a variety of other processes such as fibrinolysis, complement activation, inflammation, and chemotaxis.^{382, 389} The physiologic importance of these factor XII-mediated phenomena remains obscure, because patients with even severe deficiency of this proenzyme reveal no evidence of deficiency or aberrance of host defenses.

The discrepancy between in vitro evidence of grossly abnormal blood coagulation and the absence of hemorrhagic manifestations in factor XII deficiency poses a fundamental question regarding the role of the intrinsic coagulation pathway in hemostasis and the significance of laboratory measurements of coagulation. Alternative mechanisms for initiation of coagulation are discussed in Chapter 18.

Results of an animal model of arterial thrombosis have again raised the question of whether factor XII has a role in thrombosis.³⁹⁰ When factor XII-deficient mice were exposed to arterial vascular injury, defective platelet-rich thrombosis was observed, a defect that was corrected by administration of exogenous factor XII.³⁹⁰ Results from a mouse stroke model indicate that factor XII deficiency protects affected mice from ischemic brain injury.³⁹¹ Although a large body of clinical evidence suggests that factor XII is not important for hemostasis, the animal model data suggest that factor XII is important for pathologic (arterial) thrombosis, perhaps by factor XII_a-mediated factor XI activation.³⁹²

Laboratory Diagnosis

Factor XII-deficient patients typically present with a negative history of clinical bleeding and an isolated, prolonged PTT that corrects with mixing with normal plasma. The coagulant effects of contact activation are diminished or absent in plasma from subjects with factor XII deficiency.³⁹³ Normal levels of factor XII range from 50 to 150 IU/dl. As with factor XI, accurate assays of factor XII depend on a source of deficient substrate plasma. Laboratory demonstration of the heterozygous state is difficult. The mean level of factor XII in the plasma of carriers is ~50% of normal, but observed values

are distributed in a bimodal manner, an observation interpreted as suggesting the presence of multiple abnormal alleles.³⁹⁴

PREKALLIKREIN DEFICIENCY

An additional abnormality of the intrinsic pathway of coagulation was defined and named Fletcher factor deficiency by Hathaway in 1965.³⁹⁵ In 1972, Wuepper et al. established that Fletcher factor was identical to plasma prekallikrein, a protein that had been studied for many years in terms of its role in inflammation.³⁹⁶ The convergence of these two avenues of research demonstrated that prekallikrein, in addition to its role in inflammation and chemotaxis, is essential for the optimal activation and fragmentation of factor XII in the early steps of coagulation.³⁸⁹

Pathophysiology

Prekallikrein deficiency apparently is inherited as an autosomal recessive trait,³⁹⁵ although genetic information is scanty. ~80 cases have been reported.³⁹⁷ Heterozygotes with ~50% of normal plasma levels of prekallikrein can be identified. The disorder is associated with the absence of antigenically competent prekallikrein in most cases.³⁹⁸

Clinical Features

Prekallikrein deficiency, like factor XII deficiency, is not associated with abnormal bleeding. Studies of affected patients revealed variable deficiencies in stress-induced fibrinolysis, chemotaxis, immediate and delayed inflammatory responses, and responses to preformed permeability-enhancing activity.³⁹⁹ These abnormalities are not associated with any apparent deleterious effects. Most patients with prekallikrein deficiency are of African ancestry.⁴⁰⁰ Prekallikrein deficiency is not associated with an excessive risk of thrombosis.⁶⁸

Laboratory Diagnosis

Prekallikrein deficiency is associated with a moderate prolongation of the PTT. The PT and thrombin time are normal. The time required for release of vascular plasminogen activators in vivo after venous occlusion is prolonged.⁴⁰¹ The disorder is characterized by abnormally slow contact activation. Thus, the PTT may be normalized by prolonged incubation (10 to 15 minutes) of plasma with particulate activators.^{395, 402} This phenomenon appears to result from autoactivation of factor XII.⁴⁰³ Specific assays for prekallikrein are based on traditional coagulation techniques and chromogenic substrate assays.⁴⁰⁴

HIGH-MOLECULAR-WEIGHT KININOGEN DEFICIENCY

A unique inherited coagulation abnormality associated with deficiencies of kinin formation and fibrinolysis was described in three unrelated kindreds in 1975. The disorder received the names

P.1170

of the affected families (Fitzgerald trait,⁴⁰⁵ Williams trait,⁴⁰⁶ Flaujeac trait, and Fujiwara trait⁴⁰⁷) and has subsequently been found to be the result of deficiency of HMWK. Patients with this disorder are asymptomatic. The data suggest that HMWK functions in its nonactivated form as a cofactor, binding prekallikrein and factor XI to anionic surfaces, accelerating their activation by surface-bound factor XIIIa (see Chapter 18).

Pathophysiology

Deficiency of HMWK appears to be inherited as an autosomal recessive trait.³⁶⁶ Mildly affected heterozygotes have been identified in some families. Detailed biochemical studies of five kindreds revealed considerable heterogeneity.^{406, 408} Thus, HMWK levels in the plasma ranged from nil⁴⁰⁶ to 50 IU/dl.⁴⁰⁵ With the exception of the Fitzgerald kindred, associated deficiencies in low-molecular-weight kininogen have been demonstrated in all families. Variable deficiency of prekallikrein also was present in the Williams, Fitzgerald, and Fujiwara kindreds; prekallikrein levels were normal in the Flaujeac kindred. Immunologic studies revealed the absence of kininogen antigen in the homozygotes and 50% of normal levels in the heterozygotes.⁴⁰⁹ The associated prekallikrein deficiency also apparently is of the CRM-negative type.⁴⁰⁹ The absence of the stabilizing effects of HMWK may lead to accelerated degradation and deficiency of prekallikrein in this disorder.⁴⁰⁹ HMWK deficiency is not associated with excessive clinical bleeding or thrombosis. There is limited information on the genetic basis for HMWK deficiency.^{410, 411, 412}

Laboratory Diagnosis

Deficiency of HMWK is manifested by an isolated, prolonged PTT. The PTT assay results are abnormal whether particulate or soluble contact activators are used, and values are not normalized by prolonged incubation of the plasma with particulate activators.

MISCELLANEOUS INHERITED COAGULATION DISORDERS

Combined Defects

Of unusual interest are reports concerning the presence of combined deficiencies of two or more coagulation factors. Deficiency of factors V and VIII, and combined deficiency of various vitamin K-dependent factors appear to be the most common combined deficiency disorders.⁴¹³ Several other combined coagulation defects have been described (Table 53.1).

Deficiency of Factors V and VIII

Combined deficiency of factors V and VIII, reported in <200 patients, is inherited as an autosomal recessive trait.⁴¹⁴ This combined defect manifests clinically with mild mucosal and cutaneous bleeding. Severe posttraumatic and postsurgical bleeding is common (e.g., after tooth extractions).⁴¹⁴ Hemarthrosis is rare. Laboratory findings in homozygous patients include a prolonged PTT and PT and levels of factor VIIIc and Vc that average 15 IU/dl. Levels of factor VIIIa (VIIIa) and VAg are low and are proportional to those obtained by coagulation measurements.⁴¹⁵

Linkage analysis of combined factor V and VIII deficiency to chromosome 18q excluded all known hemostasis proteins, suggesting that the basis for the disease is a defect affecting a process common to the biosynthesis of factors V and VIII. Indeed, subsequent studies by two groups identified the genetic basis for most patients with the disorder as mutations in the endoplasmic reticulum-Golgi intermediate compartment protein 53 (also known as lectin mannose-binding type 1 [LMAN1]). Other patients with this combined defect have mutations in another protein termed multiple coagulation factor deficiency-2 (MCFD2).^{416, 417, 418} LMAN1 and MCFD2 form a complex that acts as a receptor (chaperone) or cargo receptor for transport of several secreted proteins, including factors V and VIII.^{417, 419} Still other patients with combined factors V and VIII deficiency have been identified⁴¹⁷ who appear to have unique mutations.

Combined Deficiency of Factors II, VII, IX, and X

Combined deficiency of factors II, VII, IX, and X is an autosomal recessive coagulation disorder that has been identified in only a small number of patients.^{238, 413, 420, 421} In addition to affecting levels of the vitamin K-dependent factors, skeletal abnormalities may also be seen, resulting from effects on bone Gla proteins.⁴²² Levels of the vitamin K-dependent proteins range from <12% to 50% of normal; thus, clinical bleeding manifestations may vary widely. Both the PT and PTT are prolonged. Measurement of serum warfarin levels may be necessary to exclude surreptitious anticoagulant use. Mutations in the γ -glutamyl carboxylase gene have been identified in a few patients with this disorder,^{423, 424, 425} and another group has identified a second gene locus (vitamin K epoxide reductase complex, subunit 1 [VKORC1]) causing this defect.⁴²⁶ Some patients have clinical improvement and correction of the coagulopathy with vitamin K therapy.^{420, 424}

ABNORMALITIES OF PROTEASE INHIBITORS

Rare abnormalities of three plasma antiproteases, which are associated with bleeding, are described in this section. Other, more numerous abnormalities of the components of the antiprotease system and the fibrinolytic enzyme system that may be associated with thrombosis are discussed in Chapter 55.

 α_2 -Antiplasmin Deficiency

Severe bleeding, including hemarthrosis, was associated with deficiency of α_2 -antiplasmin in several kindreds.^{427, 428, 429, 430, 431} This disorder appears to be inherited as an autosomal recessive trait, in which heterozygotes have detectable deficiencies of this antiprotease but only mild bleeding. CRM-positive and CRM-negative forms have been identified.⁴³⁰ A report published in 2008 identified 15 cases; seven cases had genetic abnormalities defined.⁴³²

Most cases had mutations in exon 10, which is the location of the active site, and the plasminogen-binding site.^{431, 432} Bleeding presumably is the result of premature lysis of hemostatically important fibrin plugs caused by unregulated plasmin activity. The laboratory findings are variable. Hypofibrinogenemia and increased clot solubility in urea have been reported. Fibrinogen degradation product levels and platelet counts were normal in most cases.⁴³⁰ When assayed qualitatively by fluorometric or photochromogenic techniques, α_2 -antiplasmin levels usually are <10 IU/dl. Treatment of bleeding episodes with tranexamic acid and other antifibrinolytic agents may be helpful.

Plasminogen Activator Inhibitor-1 Deficiency

Deficiency of plasminogen activator inhibitor (PAI)-1 is associated with a moderate bleeding disorder.⁴³³ Only ~10 to 20 families have been reported.⁴³⁴ One study investigated a large kindred with multiple family members who were homozygous for this disorder.⁴³⁵ Homozygous patients, but not heterozygous patients, exhibited clinical bleeding.⁴³⁵ The null gene mutation responsible for PAI-1 deficiency was identified in this kindred.⁴³⁵ Other cases have been described.⁴³⁶ The basis of the bleeding is similar to that described for α_2 -antiplasmin deficiency: Excessive plasmin activity, caused in this case by excessive activation of plasminogen.

P.1171

Laboratory screening studies are typically normal, but the euglobulin clot lysis time is shortened. It is recommended that measurement of PAI-1 antigen and activity in both serum and plasma be done to screen for PAI-1 deficiency.⁴³⁵ The in vitro activities and clinical relevance of PAI-1 have been reviewed.⁴³⁷

α_1 -Antitrypsin Pittsburgh

A life-long hemorrhagic diathesis in a 14-year-old boy was associated with a unique qualitatively abnormal form of α_1 -antitrypsin (antithrombin III Pittsburgh).^{438, 439} This disorder is the result of the substitution of a single amino acid (arginine for methionine at position 358 in the α_1 -antitrypsin molecule).⁴³⁹ This site corresponds to the P1 residue or “bait” amino acid of the molecule, and the substitution produced a mutation of α_1 -antitrypsin, a weak antiprotease with little affinity for thrombin, into a potent antithrombin that impaired blood coagulation to a significant degree. The mutant molecule also is a potent inhibitor of factor XIa, factor XIIa, and kallikrein, a property lacking in the normal molecule.⁴⁴⁰ The plasma concentration of the abnormal molecule increased after trauma, possibly as the result of an acute-phase response. The patient ultimately died of bleeding. A second family was reported with the disorder; it is inherited in an autosomal dominant manner.⁴⁴¹ Other amino acid substitutions at position 358 have been produced artificially by genetic engineering.⁴⁴²

TREATMENT OF INHERITED COAGULATION DISORDERS

The principal treatment for the inherited coagulation disorders is replacement therapy—that is, the intravenous administration of the required factor in the form of blood products derived from normal people or animals, or recombinant coagulation proteins.⁴⁴³ Estrogens may be useful in treating female patients with vWD.⁴⁴⁴ Topical hemostatics (thrombin) may be temporarily effective in small injuries or nose bleeds, and certain other treatments such as DDAVP and inhibitors of fibrinolysis are useful adjunctive therapy under specific circumstances such as dental surgery.⁴⁴⁵

Replacement Therapy

The objective of replacement therapy is to obtain a concentration of the required factor at the bleeding site such that coagulation may become hemostatically effective. The pharmacokinetic (PK) properties of the various coagulation factors (Table 53.9) and clinical assessment of the severity of the hemorrhagic risk are important considerations in determining appropriate doses and duration for therapy. Replacement products are dosed on the basis of actual body weight (Tables 53.8 and 53.10) or plasma volume. This latter method may be more precise in patients who do not have a normal plasma volume because of bleeding. In one such method, blood volume is considered to be 7% of body weight; plasma volume is then calculated using the patient's hematocrit. Next, the therapeutic objective is assessed (e.g., the desired incremental increase in factor VIII level). For example, if a patient with severe hemophilia A (<1% factor VIII) has a plasma volume of 3,000 ml and requires major surgery, the target factor VIII level should be 100% of normal. Infusion of 3,000 IU of factor VIII would result in a calculated peak factor VIII level of 1 IU/ml (100% of normal). Peak factor levels should be monitored to determine whether the expected response was achieved, and then further dosage adjustments can be calculated if necessary. Subsequent doses are scheduled according to the predicted half-life of the factor, with laboratory tests to verify actual levels when appropriate. Case reports and clinical experience detailing management of hemophilia A during surgery have been published.^{446, 447, 448, 449, 450}

TABLE 53.9 BIODYNAMIC PROPERTIES OF COAGULATION FACTORS OF CONCERN IN REPLACEMENT THERAPY

Disorder	Hemostatic Level (IU/dl) ^a		Biologic Half-life (h)
	*	+	
Hemophilia A (factor VIII deficiency)	25-30		12
Hemophilia B (factor IX deficiency)	20-60		20-24
Fibrinogen deficiency	100 mg/dl	>100 mg/dl	77-106
Prothrombin deficiency	40-50		72-96
Factor V deficiency	10-30	12	15-36
Factor VII deficiency	10-20	25	4-7
Factor X deficiency	10-40	56	32-48

Factor XI deficiency	20-30	26	40-80
Factor XIII deficiency	10	31	280
von Willebrand disease	20-50		20-40

^aPatients undergoing major surgery or experiencing major bleeding should receive dosages to achieve higher factor levels; for example, patients with hemophilia A should have replacement such that factor VIII levels approach 100% of normal. For patients with factor XIII deficiency and major trauma, plasma factor XIII levels of at least 25% should be achieved.

*Data in this table are taken from Teruya J, Ramsey G. Blood components for hemostasis. Lab Med 2001;32:31-35.

[†]Data taken from Peyvandi F, Palla R, Menegatti M, et al. Coagulation factor activity and clinical bleeding severity in rare bleeding disorders: results from the European Network of Rare Bleeding Disorders. J Thromb Haemost 2012;10:615-621.

Hemostatic Levels

The hemostatic level may be defined as the lowest plasma concentration of a given coagulation factor that is required for normal hemostasis (Table 53.9). This value was determined by purely empiric means—that is, by measurement of the blood levels of the deficient factor at which bleeding appeared to stop in patients with one of the inherited coagulation disorders during the course of replacement therapy. Such estimates obviously may be inaccurate. In patients with hemophilia A, the hemostatic level of factor VIIIc is ~25 to 30 IU/dl; in those with hemophilia B, values range from 20 to 60 IU/dl. However, for patients with major trauma or those undergoing surgery, higher plasma levels of these coagulation proteins should be achieved (i.e., 100% for factors VIII or IX; 25% to 50% for factor XIII).

In Vivo Recovery and Survival of Infused Coagulation Factors

When a coagulation factor is infused intravenously into a recipient who is deficient in that factor, the levels present in the circulation after intravascular mixing usually are significantly lower than those that would be expected from mere dilution in the recipient's plasma. That this initial in vivo recovery of infused coagulation factors (Table 53.9) is <100% presumably is the result of loss of these proteins from the intravascular space. The adsorption of coagulation factors by platelets and various cell and vascular surfaces may also be involved. The initial recovery of infused coagulation factors is difficult to quantify and ranges from nearly 100% for factor XI to as low as 30% for factor IX. Typically, because the range of in vivo recovery in a population is so variable, clinicians will determine the in vivo recovery for each individual by laboratory testing of blood samples drawn 10 to 20 (peak level) minutes after the therapeutic infusion.

P.1172

TABLE 53.10 REPLACEMENT THERAPY IN HEMOPHILIA A AND HEMOPHILIA B

Disorder	Therapeutic Product	Minor Bleeding (i.e., Uncomplicated Hemarthroses; Hematomas in Noncritical Areas; Hematuria; Dressing Changes; ^a Arthrocentesis; ^a Removal of Sutures and Drains ^a)		Major Bleeding (Hematomas in Critical Locations; Traumatic Injuries; Multiple Tooth Extractions; Major Surgical Procedures)	
		Loading Dose	Maintenance Dose	Loading Dose	Maintenance Dose
Hemophilia A (factor VIII deficiency)	Cryoprecipitate ^b	Not required	1.25-1.75 bags/10 kg every 12 h for 1-3 d	3.5 bags/10 kg	1.75 bags/10 kg every 8 h for 1-2 d; every 12 h thereafter
	Purified factor	Not	10-15 IU/kg every 12 h	30-40	30-40 IU/kg every 12

	VIII ^c	required	for 2-4 d	IU/kg	h
Hemophilia B Prothrombin (factor IX deficiency)	complex ^{b, c}	20-30 IU/kg	15 IU/kg every 24 h for 2-4 d	40-60 IU/kg	20-25 IU/kg every 24 h
		Purified factor IX ^{c, d}	20-30 IU/kg	15 IU/kg every 24 h for 2-4 d	60-70 IU/kg

Note: Because weight-based calculations may not correctly predict plasma volumes in bleeding patients, confirmation of the hemostatic level of the coagulation factor being replaced should always be performed for patients with major bleeding indications, with appropriate dosage adjustments performed based on these results.

^a Single dose of 15 IU/kg or equivalent amounts of concentrated product usually are sufficient.

^b Recommended only if purified factor replacement therapy is not available. Antifibrinolytic therapy should not be used with prothrombin complex concentrates.

^c Initial in vivo recovery of active factor varies somewhat depending on preparation.

^d Recombinant factor IX may require higher doses.

After in vivo mixing is complete, the activity of most coagulation factors in the plasma declines in a biphasic manner—that is, an initial rapid loss of activity is followed by a more gradual decline (Fig. 53.10).⁴⁵¹ The first or rapid phase presumably is the result of diffusion into extravascular pools. This diffusion half-life ranges from minutes for factor VII to several hours for factor VIII. In general, it is the rapidity of this first phase, together with the initial in vivo recovery of the particular factor, that determines the necessity for and the size of the preliminary or loading dose of therapeutic product.

The second or slow phase of the survival curve presumably is the result of degradation and reflects the true biologic half-life of the infused factor (Table 53.9; Fig. 53.10). This parameter, together with the hemostatic level for the factor of concern, is the main determinant of the frequency of administration and the size of the maintenance dose of therapeutic product. For example, ~80% of factor VIII infused is initially recovered in the circulation; its initial (diffusion) and subsequent (biologic) half-lives are ~6 and 12 hours, respectively.⁴⁵² Thus, in the treatment of patients with hemophilia A, doses are administered every 8 to 12 hours. In patients with hemophilia B, the initial recovery of factor IX is 50% or less; its initial and subsequent half-lives are ~3 and 24 hours, respectively.⁴⁵³ Hence, larger doses are required initially, but dosing is usually once a day to maintain adequate hemostasis. After a large loading dose or after several courses of therapeutic product have been administered, the survival curves of infused coagulation factors become nearly monophasic, presumably because extravascular spaces and the other mechanisms that remove infused coagulation factors from the circulation are saturated. New factor VIII and factor IX products currently in small phase III clinical trials have extended half-lives, so it will be important during these clinical trials to determine the appropriate initial dosing and dosing intervals for each of the new products.^{89, 454, 455}

FIGURE 53.10. Biodynamics of factor VIII. A hypothetical survival curve obtained in a patient with severe hemophilia A after transfusion of sufficient factor VIII to increase the plasma factor VIIIc level to 100 IU/dl is shown. $T_{1/2}$, half-life.

Products

Before 1960, plasma was the only agent generally available for the treatment of the inherited coagulation disorders. Tremendous progress has been made in treating congenital coagulation disorders, primarily through development of effective therapeutic products. It should be noted that the life expectancy of a boy born in 1960 with severe hemophilia A was approximately 20 years, and now the life expectancy is essentially normal with modern therapeutic products and the comprehensive care of hemophilia treatment centers.⁴⁵⁶ Tables 53.11, Tables 53.12, Tables 53.13, Tables 53.14, Tables 53.15 and 53.16 summarize therapeutic choices available to treat certain inherited bleeding disorders.

Plasma

Although most current replacement therapies of coagulation factor deficiencies involve sterile purified concentrates or recombinant proteins, plasma therapy is still important in treating some deficient states such as factor XI deficiency. FFP is usually preferred for therapeutic purposes. For factor VIII and fibrinogen deficiencies, and vWD, the appropriate coagulation factors are concentrated in cryoprecipitate. Both the rate of administration and the total dose of plasma administered are limited by the possibility of acute or chronic circulatory overload. The volume expansion

P.1173

P.1174

resulting from even moderate doses of plasma also limits the blood levels of the missing coagulation factor that can be attained. As a consequence, therapy with plasma alone can be expected to increase the levels of a deficient factor no

more than 20 IU/dl above baseline values. When plasma is the only therapeutic agent available, plasmapheresis may be of adjunctive value.⁴⁵⁷ A sterile solvent-detergent-treated plasma preparation is available,⁴⁵⁸ but activity of certain coagulation proteases and inhibitors in this product is not equivalent to that of FFP.^{459, 460} Better preparations of solvent-detergent-treated plasma are available in Europe and are in clinical trials for the U.S. A British guideline for the use of FFP and cryoprecipitate has been published.⁴⁶¹

Purified or Concentrated Coagulation Factors

Cryoprecipitate

A major advance in the therapy of hemophilia A was the demonstration by Pool et al. that cold insoluble material obtained from plasma contains high concentrations of factor VIII and fibrinogen.⁴⁶² Cryoprecipitate, which for many years was discarded during clarification of plasma, is prepared by slowly thawing rapidly frozen plasma at 2-4°C, then harvesting the precipitate by centrifugation. Cryoprecipitate prepared from 200 ml of fresh plasma (1 unit) contains 50 to 120 units of factor VIII, ~250 mg of fibrinogen, and therapeutically useful amounts of factor XIII and vWF that are rich in high-molecular-weight multimers. Cryoprecipitation provides 7- to 20-fold purification of factor VIII with respect to plasma and can be carried out by means of a closed double-bag system, even in small blood banks without special equipment. With the widespread availability of modern therapeutic products to treat hemophilia A and vWD, cryoprecipitate is now used primarily to treat hypofibrinogenemia.

Purified Factor VIII

Among the many methods developed to purify factor VIII, several are suitable for the large-scale production of concentrates of the human protein for therapeutic use, and sufficiently robust to attain in vivo factor VIIIc levels as high as 100 IU/dl in hemophilic patients without significant expansion of the plasma volume. Most plasma-derived factor VIII concentrates contain vWF but lack the high-molecularweight vWF multimers found in cryoprecipitate or plasma.

Nearly all individuals with severe or moderate hemophilia require frequent therapeutic intravenous infusions and therefore,

P.1176

as the concentrated factor products became available in the late 1970s most patients learned how to administer these infusions themselves at home.

Unfortunately, before the mid-1980s, the risk of viral transmission accompanied the use of these concentrated preparations, because they were prepared from large plasma pools and specific virucidal treatment was not used. The risk of virus transmission has been greatly diminished by serologic testing of the plasma for viruses and by sterilization of the concentrate by solvent-detergent treatment and/or heat sterilization.⁴⁶³ High-potency preparations of factor VIII can be obtained by affinity chromatography using monoclonal antibodies. Therapeutic products of r-FVIII, activated factor VII, and factor IX are available for clinical use.⁴⁶⁴ The initial (first-generation) r-FVIII products contain human albumin. Second-generation products eliminated albumin, but human and/or animal protein components are utilized in the manufacturing process. Third-generation products have removed all exogenous human and animal proteins from the manufacturing process. Other recombinant factor products are in development or in clinical trials in 2013, including products with extended half-life for factors VIII, IX, and VII.

Although modern production methods have reduced the risk of transmitting lipid-enveloped viruses (e.g., human immunodeficiency virus [HIV] and hepatitis B and C), transmission of non-lipid-enveloped viruses, such as hepatitis A and parvovirus B19, has been reported with sterilized plasma-derived products.^{465, 466, 467} Tables 53.11, 53.13, and 53.14 summarize information on currently available products used to treat hemophilia A and hemophilia B.

Prothrombin Complex Concentrates, Factor IX, and Factor VII (VIIa)

The vitamin K-dependent factors (prothrombin; factors VII, IX, and X; and proteins C and S) are avidly absorbed by aluminum hydroxide or barium sulfate and can be readily concentrated by elution therefrom. This simple procedure is the starting point for several methods of preparing therapeutically useful concentrates of these proteins⁴⁶⁸ (Table 53.15).

Concentrates of vitamin K-dependent coagulation factors contain small but significant amounts of activated coagulation factors that may be thrombogenic when administered in large doses or for extended periods of time. The thrombogenicity of such concentrates varies from preparation to preparation and from lot to lot and has been variously attributed to thrombin, factor VIIa,³²⁷ factor Xa,⁴⁶⁹ factor IXa,⁴⁷⁰ and coagulant phospholipids.⁴⁷¹ Attention has been directed to the serious and even fatal thromboembolic complications of these products, including disseminated intravascular coagulation.^{469, 472} Such complications are particularly common in infants and in patients with liver disease,⁴⁷³ as discussed in Chapter 54. The availability of monoclonally purified and recombinant factor IX products has led to decreased use of PCCs in the treatment of hemophilia B.^{474, 475, 476} PCCs are now used primarily to treat patients with inhibitors to factor VIII, a condition in which the presence of thrombogenic proteins is clinically useful.^{477, 478, 479} PCCs are also useful in treating deficiencies of prothrombin and factors VII and X. PCCs also are used for reversal of the anticoagulation effects of warfarin or the new oral anticoagulants when bleeding occurs, although their usefulness with the latter is controversial.^{480, 481}

P.1177

When treating hemophilia B with replacement factor IX products, it should be noted that factor IX distributes to both intravascular and extravascular compartments. Consequently, loading doses required to achieve 100% of the normal plasma factor IX level are usually 1.5 to 2.0 times greater than those calculated from the patient's plasma volume. Thus, when purified factor IX products are used, twice the calculated amount of factor IX should be given for the initial dose. On the other hand, PCCs are thrombogenic, and when these products are used to treat patients with hemophilia B, the dosage should be reduced below that given when the purified products are used.

Recombinant factor VIIa is being used primarily for treatment of bleeding episodes in patients with hemophilia with inhibitors,⁴⁸² but also in patients with bleeding due to refractory thrombocytopenia, platelet dysfunction, factor VII deficiency (discussed in the section Factor VII Deficiency), or severe liver disease (discussed in Chapter 54).

Detailed summaries of prior and current coagulation factor products have been published recently.^{2, 483, 484} A summary of the biologic properties of the new factor products in clinical trials in 2013 has also been published.⁴⁸⁵

Adjunctive Therapies

A congener of vasopressin, DDAVP, was originally developed for the treatment of diabetes insipidus. Its extrarenal actions stimulate vascular endothelial cells to release several proteins, including vWF in amounts sufficient to raise the plasma levels of this protein and associated factor VIII two to five times (Fig. 53.11).⁴⁸⁶ This effect is therapeutically useful in most patients with type 1 vWD⁴⁸⁷ and in some patients with mild hemophilia A,⁴⁸⁸ and it is particularly useful because the biohazards of blood products are avoided. Excellent responses were obtained in the prevention of bleeding after minor surgical procedures, such as tooth extractions, and in some major surgical procedures.^{489, 490} It has been noted that young boys with mild to moderate hemophilia A have a lower response rate to DDAVP; the response rate of these patients improves later in life, and nonresponder children are candidates for retesting when they are older.⁴⁹¹

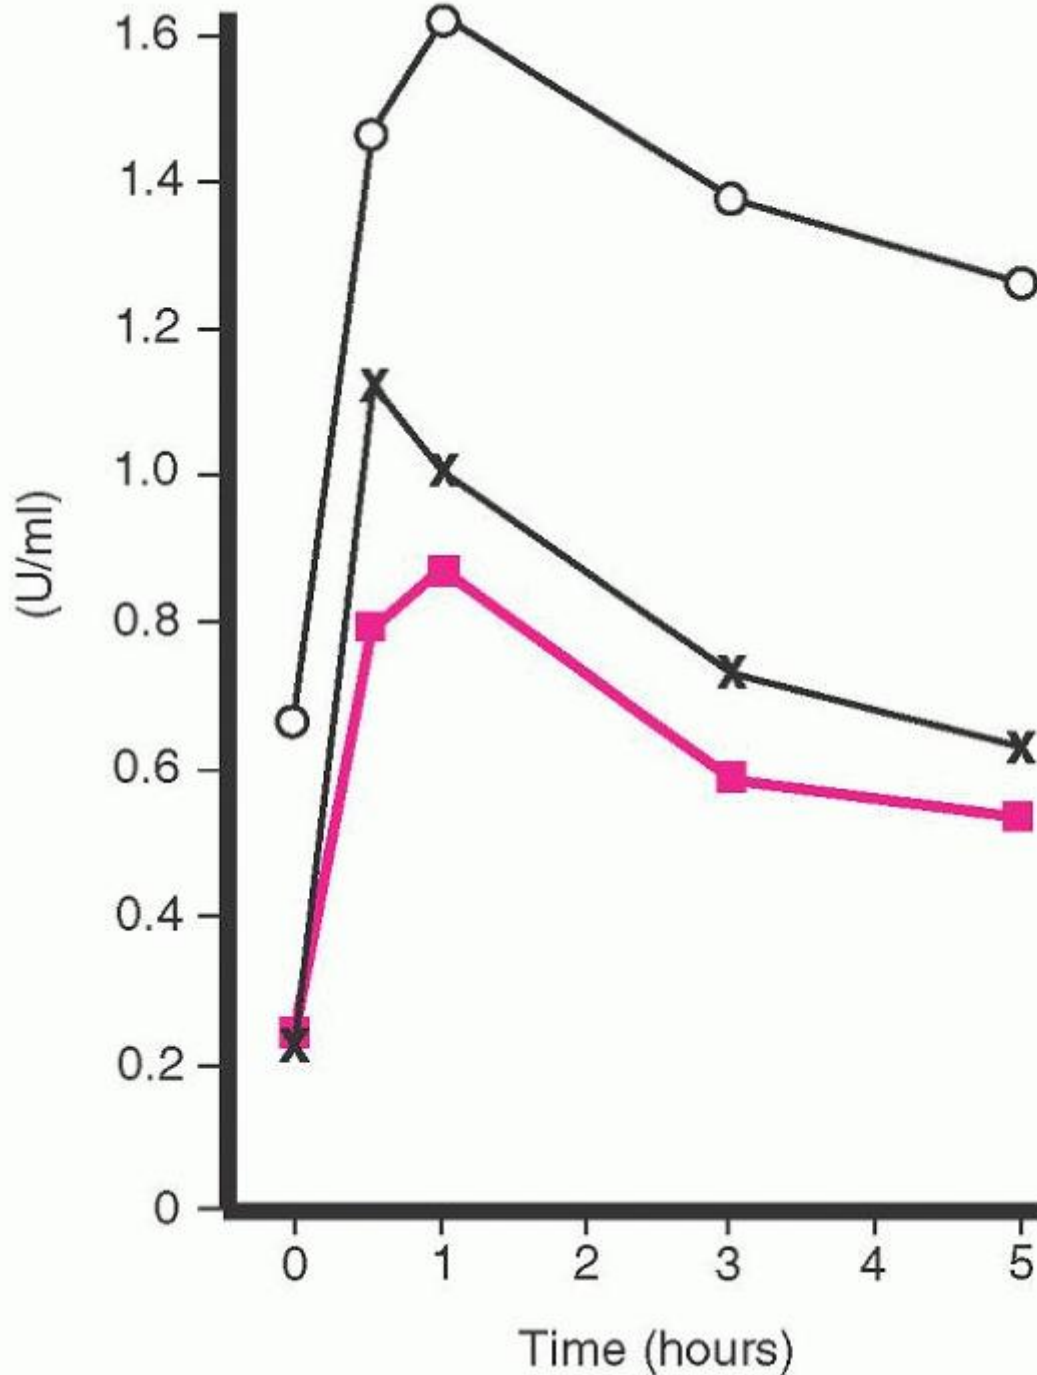

FIGURE 53.11. The response to desmopressin infusion ($0.3 \mu\text{g}/\text{kg}$ body weight) in a hemophilic patient. Open circles indicate von Willebrand factor antigen, solid boxes indicate factor VIIIc activity, and crosses indicate factor VIIIc antigen. (From de la Fuente B, Kasper CK, Rickles FR, et al. Response of patients with mild and moderate hemophilia A and von Willebrand disease to treatment with desmopressin. *Ann Intern Med* 1985;103:6-14, with permission.)

The vWF released in response to DDAVP is rich in high-molecular-weight multimers⁴⁹² that increase adhesion and spreading of platelets at injury sites. This effect may explain the therapeutic efficacy of the drug in several disorders of platelet function, including uremia.⁴⁹³

DDAVP has also been reported to be clinically useful in patients with hemophilia B.⁴⁹⁴ Although factor IX levels are minimally increased by DDAVP, the improved PTT values in hemophilia B patients given DDAVP associated with increases

in factor VIII and vWF activity probably account for drug efficacy. Another group found DDAVP useful in hemophilia B patients when combined with antifibrinolytic therapy.⁴⁹⁵

DDAVP also induces the release of endothelial cell-derived plasminogen activators and has produced exaggerated fibrinolytic phenomena in several rare cases. For this reason, it is sometimes given with ϵ -aminocaproic acid (EACA) or other fibrinolytic enzyme inhibitors. Compared to vasopressin, DDAVP is markedly less potent as a pressor agent, but does retain significant antidiuretic activity. Neither effect has proved to be a major problem in its therapeutic use, but most experienced clinicians use caution when treating patients with hypertension or congestive heart failure. Reports of hyponatremia and seizures in children less than 2 years of age have led to cautious use of DDAVP in this population. Serum sodium should be monitored in adults who receive more than 3 or 4 sequential doses of DDAVP because of the side effect of hyponatremia, and in these patients water restriction is advised. DDAVP should not be administered more than once a day, and repeated doses of DDAVP may produce progressively diminishing amounts of vWF (tachyphylaxis), presumably because of exhaustion of stored vWF. DDAVP is available in a formulation for parenteral use or by the nasal spray Stimate.^{490, 496} DDAVP can be given parenterally (0.3 μ g/kg, up to a maximal dose of 20 to 24 μ g).⁴⁹⁷ Physicians should be aware that two DDAVP nasal sprays are available, and that only the nasal spray with the higher DDAVP concentration (Stimate, 1.5 mg/ml) is effective in treating vWD. DDAVP should be used cautiously in older patients with vascular disease because of the potential risk of drug-induced thrombosis.^{497, 498, 499}

Increasing use of DDAVP has revealed certain limitations of this hemostatic drug. One report in adult patients indicated that ~20% of patients experienced toxicity with DDAVP, including nausea and headache, and symptomatic hyponatremia was seen in ~5% of patients.⁴⁹⁶ These side effects may be minimized with water restriction. Limitations of DDAVP in the pediatric population have been summarized.⁵⁰⁰

Inhibitors of fibrinolysis, such as EACA or tranexamic acid, may diminish bleeding from mucosal membranes where the concentrations of fibrinolytic enzymes are high, in patients with inherited coagulation disorders: For example, with bleeding in the mouth, tongue, tonsils, and pharynx, and with bleeding associated with operative dental procedures.⁵⁰¹ These drugs act to protect labile hemostatic plugs from fibrinolytic degradation. The use of EACA alone has been effective in the treatment of patients with mild hemophilia A (plasma levels of factor VIII >5 IU/dl)⁵⁰² and those with other mild inherited coagulation disorders such as vWD or factor XI deficiency. Some clinicians have used EACA as an adjunct to single-dose⁵⁰³ or various other factor replacement regimens. EACA should be administered in oral doses (pills or syrup) of 6 g every 6 hours to adults and 100 mg/kg every 6 hours to children, for 3 to 4 days after tooth extraction. Doses of as little as 1 g every 6 hours may be as effective in most adult patients. The drug can be given intravenously (1 g/hour) for patients who cannot swallow. Hematuria or abnormal renal function is a contraindication to the use of this drug because of the hazard of intrarenal or ureteral obstruction by blood clots.⁵⁰⁴ EACA also should not be given to patients with disseminated intravascular coagulation or active hepatitis, or to patients receiving PCCs, although an EACA mouthwash can be used with these latter drugs.^{501, 505}

P.1178

Tranexamic acid is now available; the recommended adult dosage is two 650 mg tablets orally three times daily. These drugs may be teratogenic and should be used with caution in pregnant women.

MAJOR AND MINOR BLEEDING

General treatment guidelines for patients, including newborns with hemophilia and other bleeding disorders, have been published.^{73, 505, 506} Additional detailed guidelines are available on the National Hemophilia Foundation's website, www.hemophilia.org, under Medical and Scientific Advisory Council (MASAC) recommendations.

For purposes of replacement therapy, the various bleeding manifestations commonly encountered in the inherited coagulation disorders are often divided subjectively into major and minor bleeding. Manifestations falling into the minor category include bleeding associated with uncomplicated hemarthrosis, symptomatic hematomas in noncritical areas, and minor traumatic injuries, as well as such therapeutic procedures as minor dental procedures, arthrocentesis, and dressing changes. Small cuts and scratches, removal of stitches or drains, superficial ecchymoses, and small hematomas may require no replacement therapy.

Major bleeding is by definition life-threatening and includes hematomas in critical locations and bleeding resulting from traumatic injuries, particularly those in which external blood loss is significant. Major bleeding occurs in surgical procedures, including tonsillectomy and the extraction of molar teeth. In the treatment of major bleeding, general guidelines recommend that the in vivo levels of the missing factor should be maintained above 60% to 80% to provide effective hemostasis until bleeding has stopped and appropriate healing has occurred so that there is no risk of

rebleeding. In bleeding of a particularly critical nature, such as intracranial hemorrhage, or for the prevention of excessive bleeding during neurosurgery, factor levels should be maintained at 100% of normal.

Hemophilia A Minor Bleeding

DDAVP is effective in the treatment of minor bleeding manifestations in individuals with hemophilia A with baseline factor VIIIc levels >5 IU/dl, if patients have been previously demonstrated to respond to DDAVP with therapeutic levels of factor VIIIc after administration of DDAVP.^{489, 490} Side effects are more prominent if the total dose exceeds 24 µg. Both parenteral and intranasal administration produce significant increases in factor VIIIc and vWF.⁵⁰⁷ Repeated doses of DDAVP at approximately daily intervals may produce useful increments of factor VIII in many patients. At least 24 hours should elapse before repeat administration of the drug in order for the endothelial cell stores of vWF to be replenished. Patients should be tested before surgery for their response to DDAVP by documenting adequate hemostatic levels of factor VIII levels 30 to 60 minutes after treatment, to ensure that the drug will be effective in appropriate responders. Only small amounts of factor VIII are produced by DDAVP in persons with severe hemophilia, and the use of this drug in patients with factor VIII levels <5 IU/dl is seldom useful and therefore is not recommended, even for minor bleeding manifestations. EACA (6 g orally every 6 hours) or tranexamic acid (25 mg/kg orally every 6 to 8 hours) has been administered together with DDAVP in an attempt to minimize fibrinolysis.⁵⁰¹ For maximal effectiveness, antifibrinolytic drugs should be started 24 hours prior to surgical procedures.

Although effective in minor bleeding, plasma or cryoprecipitate is not currently recommended for use in the treatment of patients with hemophilia A. Factor VIII concentrates are widely available and are the most useful therapeutic products. The regimens summarized in Table 53.10 illustrate one approach to treating hemophilia A. For some minor bleeding manifestations, treatment for a minimum of 3 days is required, but in most cases, a single dose of 10 to 15 IU/kg of factor VIII is usually sufficient.⁵⁰⁸ In the treatment of minor bleeding, loading doses are not required, and laboratory monitoring of in vivo factor VIII levels is unnecessary. The minor bleeding treatment regimens summarized in Table 53.10 typically result in peak factor VIII levels of ~30%. Occasionally, if the minor bleeding episode is not treated promptly and bleeding is prolonged, then a hematoma may form, and often additional doses of factor products at higher doses are needed to prevent continued bleeding around the hematoma and potential pseudocyst formation. It is generally recommended in such cases of delayed treatment that full (100%) doses be administered to maintain adequate hemostatic levels until the hematoma is completely resolved.

Hemophilia A Major Bleeding

To treat major bleeding in patients with hemophilia A, sufficient factor VIII must be given often enough to ensure that the blood level does not fall to <30 to 50 IU/dl for any length of time. Most experienced clinicians target trough levels of more than 50% IU/dl until bleeding has stopped and substantial healing has taken place. Maintenance doses usually are administered every 8 to 12 hours. Regimens of continuous infusion of factor VIII are being used with increasing frequency during hospitalization, and have been shown to save total factor use by as much as 30%.^{509, 510, 511, 512, 513} The administration of 2 IU/kg/hour of factor VIII produces a mean factor VIIIc level in the plasma of ~50 IU/dl and appears to be more cost-effective than twice-daily intravenous bolus treatments.⁵¹⁴ Continuous infusion also has the advantage of maintaining a consistent, therapeutic factor level. It is important to note that the treatment of postsurgical or major traumatic hemorrhage in patients with mild hemophilia A requires nearly as much therapeutic product as is needed for the severely affected patient. Many authors recommend treatment for 10 to 14 days after major surgical procedures, whereas others administer the full doses indicated in Table 53.10 for 10 days and continue half-doses for longer periods as healing continues and the patient is undergoing increasingly active physical therapy, especially after major orthopedic surgeries.

Determination in the laboratory of the in vivo levels of factor VIIIc is recommended during the treatment of patients with major hemorrhage. Incidents of unexpected subtherapeutic responses to infused factor VIII have been reported.⁵¹⁵ The use of the PTT to guide factor VIII replacement therapy is not recommended, because the results of these tests may be normal at levels of factor VIII that do not provide adequate hemostasis.⁷⁴

von Willebrand Disease

In a disease as heterogeneous as vWD, decisions about treatment begin with accurate diagnosis (including vWD subtype) and complete evaluation. Fortunately, in many patients with vWD, bleeding manifestations are mild, and replacement therapy is seldom required. Unlike the situation in hemophilia, in which there is a close correlation between factor levels and clinical outcome, treatment decisions are more complicated in vWD because it is unclear which measurement (vWF, factor VIII, or platelet function) correlates best with the severity of bleeding or clinical outcome.¹²⁷ Many experts recommend following vWF:RCo and factor VIII levels,⁵¹⁶ but little information exists about the level of vWF:RCo that is

critical for control of mucosal bleeding or the prevention of surgical bleeding. Bleeding times may not normalize, but a normal bleeding time is not required for a satisfactory response, and monitoring of bleeding time is not recommended.¹⁵⁵ Therapeutic goals include resolution of active bleeding and prevention of excessive bleeding in response to invasive procedures or trauma.

P.1179

Unlike the situation with hemophilia A or B, chronic prophylaxis therapy is rarely required, but should be considered in patients with type 3 vWD who have recurrent gastrointestinal or joint hemorrhage.

The spectrum of therapeutic interventions in vWD includes desmopressin (DDAVP), concentrate infusion, and adjunctive therapy with medications that modulate bleeding symptoms by affecting either menstrual pattern or fibrinolysis. Dosing recommendations in vWD are empiric. In the case of a patient with major surgery or trauma, one recommendation is that clinicians attempt to bring the vWF (and factor VIII) level to near 100 IU/dl, and maintain it >40 to 50 IU/dl for the first 3 to 5 days, after which one recommended goal is to maintain the factor VIII level at >40 IU/dl for a total of 7 to 10 days or until healing is completed.¹⁵⁵ In surgical settings, monitoring of factor levels seems prudent, but monitoring of the bleeding time is discouraged, as surgeries have been done successfully in patients with type 3 vWD in the face of only partial correction of bleeding time.¹⁵⁵

DDAVP is the mainstay of treatment for patients with mild forms of type 1 vWD.¹⁵⁵ The dosage, route of administration, and contraindications described under the discussion of hemophilia A also apply to the use of the drug in vWD. vWF and factor VIII levels generally increase by two- to fourfold over baseline. Because responsiveness to therapy between patients is variable, a test dose given at the time of diagnosis or before elective surgery is advised. Obtaining both vWF:RCo and factor VIII levels 1 hour after DDAVP administration is recommended in order to confirm a patient's responsiveness. It may also be informative to obtain a second sample between 2 and 4 hours after DDAVP to confirm that vWF has the expected 8- to 10-hour half-life after release.¹⁴⁷ Concerns regarding tachyphylaxis, hyponatremia, and rare thrombotic complications are similar to those when treating patients with hemophilia A. Note that whereas patients with type 1 vWD are likely to have a satisfactory response, patients with non-type 1 vWD respond poorly or unpredictably to DDAVP. Type 3 patients have essentially no endogenous vWF synthesis, and are DDAVP-nonresponsive. In one large series of patients with type 2B vWD, the platelet count fell from an average of 86,000 to 60,000/ μ l after administration of this drug.²¹⁰ Because thrombocytopenia may worsen after administration of DDAVP to patients with type 2B vWD and the platelet-type form of the disorder, patients with these variants should not be treated routinely with DDAVP.¹⁵⁵ However, some authors report good-responder type 2B vWD patients who received DDAVP.⁵¹⁷ Response in type 2A vWD is variable and may be of shorter duration than in type 1 patients, because of increased vWF proteolysis. Similarly, factor VIII levels may rise in response to DDAVP in patients with type 2N vWD, but because of the deficient factor VIII-stabilizing activity of vWF in this variant, levels of factor VIII then fall at an accelerated rate.⁵¹⁸ Because of interindividual variability, a documented therapeutic response to DDAVP should be obtained before surgical prophylaxis with the drug, to ensure adequate hemostasis postoperatively. It is recommended that this DDAVP trial be performed at the time of diagnosis of vWD.

Transfusion therapy with plasma-derived products is the therapy of choice in DDAVP-unresponsive patients who require factor support. In order to treat both the factor VIII deficiency and the defect in primary hemostasis seen in patients with severe vWD, it is generally necessary to give a product with factor VIII activity that also contains high-molecular-weight multimers of vWF. The concentrations of vWF and factor VIII in FFP are insufficient for appropriate therapy. Cryoprecipitate contains ~80 to 100 units/bag, 5 to 10 times the concentration of these factors compared to plasma. Cryoprecipitate has a small residual risk of viral transmission and is not currently suited for virus-inactivation therapy; consequently, pathogen-inactivated, intermediate-purity factor VIII concentrates with demonstrated preservation of vWF multimers are the preferred replacement product. At the time of this writing, three commercial plasma-derived products were licensed in the United States for this indication (Humate-P, manufactured by CSL Behring and known as Haemate-P in Europe; Wilate, manufactured by Octapharma; and Alphanate SD/HT, manufactured by Grifols) (Table 53.12). Several other commercial products have been developed and are currently licensed in other countries. A Canadian multicenter study confirmed "excellent" or "good" outcomes in 97% of patients treated with Humate-P, with a median recovery of 1.23 IU/kg per IU/kg infused.⁵¹⁹ Similarly, Alphanate was shown to ultimately control all bleeding episodes in one large multicenter trial.⁵²⁰ Alphanate is currently not licensed for treatment of vWD; it is labeled only in factor VIII units, but vWF:RCo has been reported to be ~50% lower than the labeled factor VIII content.⁵²⁰ A PK clinical trial compared Wilate vs Humate-P and found similar PK parameters for the two products; however, Wilate achieved a 1:1 ratio for vWF:factor VIII, suggesting simpler dosing of Wilate.⁵²¹ A chromatographically purified vWF concentrate with minimal factor VIII (Wifactin) has been evaluated in type 3 vWD. After infusion, factor VIII levels rise slowly and peak ~6 to 8 hours later. These data

imply that if type 3 patients are to be pretreated for surgery with a pure vWF-containing concentrate, either concomitant factor VIII will need to be administered, or the surgery should be scheduled for 6 to 8 hours after the vWF administration.^{155, 203} Very-high-purity plasma-derived factor VIII concentrates and r-FVIII concentrates are essentially devoid of vWF, and they should not be used to treat vWD.

Suggested doses and target factor levels for treatment of vWD patients have been published.^{129, 522} Recommended doses in ristocetin cofactor units are similar to factor VIII doses, because both have similar in vivo recovery (~2 IU/dl rise in plasma concentration for each IU/kg of factor administered). Monitoring response to therapy with both factor VIII and vWF:RCo is appropriate. Although vWF levels can be expected to fall between doses of vWF-containing concentrate, which has a half-life of 8 to 10 hours, factor VIII levels may continue to rise in response to the patient's endogenous factor VIII production. Avoidance of unusually high factor VIII levels is suggested in order to minimize venous thrombotic risk.⁵²³

Platelets are estimated to contain ~15% of the total body vWF. Some authors suggest using platelet transfusion in patients with severe vWD who exhibit bleeding despite plasma factor VIII concentrate therapy.¹⁵⁵ Thrombocytopenia may be exacerbated by the administration of normal exogenous vWF in platelet-type (pseudo) vWD,⁵²⁴ but not in type 2B vWD. Patients with platelet-type vWD should receive platelet transfusions for significant bleeding or surgery.

Adjunctive therapy for vWD patients with menorrhagia usually takes the form of oral contraception or other hormonal intervention.¹⁵⁵ Antifibrinolytic therapy and DDAVP have also found a role in control of menorrhagia^{501, 525} and oral bleeding. Doses of intranasal DDAVP administered every 12 to 24 hours for up to 3 days, or ε-aminocaproic acid up to 5 g three times per day, or tranexamic acid, have been reported to be useful in control of menorrhagia,¹²⁷ but toxicity profiles should also be considered. Failure of medical therapy may lead to surgical approaches, such as endometrial resection or even hysterectomy.

Pregnancy is a special situation for patients with vWD. vWF levels generally improve in patients with type 1 vWD as pregnancy proceeds, but improvement is less likely in type 2A vWD, and thrombocytopenia may actually worsen in patients with type 2B and platelet-type (pseudo) vWD variants. Current information indicates that the patient's factor VIIIc at delivery predicts the risk of bleeding, with a factor VIII level <50% of normal at term being associated with excessive bleeding.⁵²⁶ If sufficient factor VIII levels are achieved, aggressive surgical hemostasis and efficient uterine contraction should prevent peripartum bleeding. Thus, factor levels should be determined before delivery. If sufficient

P.1180

factor VIII levels are not achieved before delivery and the patient is known to respond to DDAVP, this drug can be given to the mother immediately postpartum. If the patient does not respond to DDAVP, then vWF/factor VIII concentrate should be administered peripartum. Although endogenous vWF levels rise during pregnancy in patients with type 1 vWD, the vWF levels fall quickly after parturition, and patients should be advised to report late bleeding. DDAVP or replacement therapy may be useful to prevent late bleeding in patients with vWD. Finally, unlike type 1 vasopressin agonists, DDAVP has little or no oxytocic activity, and some authorities have advocated prophylactic use before invasive diagnostic or surgical interventions in pregnant vWD patients.¹⁵⁵

Alloantibodies to vWF develop in a minority of patients with type 3 vWD after replacement therapy. The risk appears to be highest in patients with large gene deletions. Administration of vWF-containing concentrates to these allosensitized patients has been associated with anaphylactic reactions. Alternative therapies that have been successful include high-dose r-FVIII administered by continuous infusion at doses of 700 to 900 IU/kg/day,¹²⁷ or recombinant factor VIIa. Patients with acquired vWD (see Chapter 54) have broader therapeutic options, because DDAVP and replacement therapy may have some efficacy, as would treatment of the underlying disease process.

Hemophilia B Treatment

Most of the guidelines for replacement therapy of patients with hemophilia A apply to the treatment of those with hemophilia B (Table 53.10). Because of the low initial in vivo recovery and the rapid initial disappearance of factor IX from the circulation, higher initial doses are recommended, even for the treatment of minor bleeding. In patients with hemophilia B, purified factor IX concentrates or recombinant factor IX products are recommended for the treatment of major or minor hemorrhage because of the thrombotic potential of PCCs^{469, 472} (Table 53.14). One disadvantage of recombinant factor IX compared to plasma-derived factor IX is a lower in vivo recovery of recombinant factor IX (~30% lower than predicted), perhaps related to different posttranslational modifications of the recombinant protein.⁵²⁷ Higher doses of recombinant factor IX need to be given routinely to achieve similar therapeutic levels, and monitoring factor IX levels with this product should be done routinely,⁵²⁸ especially in young children.⁵²⁹ These concerns about in vivo recovery do not seem to apply to the new extended half-life factor IX products in clinical trials in 2013.^{454, 455, 530}

An unusual complication of hemophilia B therapy is anaphylaxis. These patients typically have severe factor IX deficiency with complete gene deletions.^{531, 532} The anaphylaxis typically occurs with the first or second administration of factor IX, and essentially never with subsequent infusions if the initial doses are tolerated well. These patients rarely respond to immunetolerance induction, and should be treated with either PCCs or recombinant factor VIIa (see Chapter 54).

Gene Therapy for Hemophilia

Gene therapy for the inherited bleeding disorders is now promising, after many years of frustrating failures.^{533, 534, 535} A major success was recently published involving patients with severe factor IX deficiency.⁵³⁶ Six of six subjects with severe hemophilia B were treated with adeno-associated viral vector carrying a normal factor IX gene, and have had factor IX levels of 2% to 4% for many months. While this is encouraging, there need to be additional studies with more subjects to evaluate safety and efficacy of gene therapy in hemophilia.⁵³⁷ Work with the factor VIII gene for viral delivery is more complex because of its much larger size. Viral and nonviral constructs containing genes for factor VIII or factor IX have been used, as well as modified retrovirus, adenovirus, or adeno-associated virus vectors. Sustained partial correction of factor VIII or factor IX deficiency has been seen with gene transfer in animal models, and it is expected that with additional work, these encouraging results will be seen in patients also. A major focus of gene therapy research is to develop a gene delivery system that is efficient, safe, nonimmunogenic, and provides longterm gene expression.^{538, 539} The promise for gene therapy lies in the fact that if gene therapy could increase endogenous factor VIII or factor IX levels only from <1% to 1 to 2 IU/dl, this incremental change would dramatically alter the clinical course and treatment of patients with severe hemophilia. Significant questions about potential risks associated with gene therapy, including inflammatory responses, inhibitor development, oncogenesis, and germline mutations will need to be addressed as further clinical trials are undertaken.⁵⁴⁰

Factor VII Deficiency

Unlike in patients with severe hemophilia A or B, bleeding in a patient with factor VII deficiency undergoing surgery is variable, so multiple issues should be considered in the perioperative care of factor VII-deficient patients,^{541, 542, 543} including the individual patient's prior experiences and symptomatology: Patients with a history of hemarthrosis or CNS hemorrhage are at a higher risk for bleeding complications. The oral and urogenital tracts are areas of high local fibrinolytic activity. The minimum factor VII level required for surgical hemostasis is not known; patients with levels <3 IU/dl are at high risk for bleeding, whereas patients with levels of 15 to 25 IU/dl are less likely to develop bleeding complications associated with surgery. Finally, one should consider the logistics of therapy, because factor VII has a short half-life, possibly as short as 3.5 hours. Volume overload is likely, as plasma is commonly used as a source for factor replacement, and the safety profile of the various factor VII-containing products varies.

Traditionally, FFP, PCCs, or plasma-derived factor VII concentrate has been used for factor VII replacement therapy, and more recently, recombinant human activated factor VIIa (rFVIIa) has been the recommended product.^{544, 545, 546, 547, 548, 549, 550} In general, doses of between 15 and 30 µg/kg of rFVIIa were administered at intervals of 4 to 6 hours. The half-life of recombinant factor VIIa is between 2.5 and 3 hours, and the roles of continuous factor infusion and laboratory monitoring remain to be defined in treating factor VII-deficient patients.⁵⁵¹ Antibody to factor VII has developed in response to therapy in some individuals with congenital factor VII deficiency.⁵⁵¹ Although serious thrombotic events have been reported when rFVIIa has been used in an attempt to control bleeding in the setting of acquired coagulopathy,⁵⁵² only three reports of serious thrombotic complications were collected in a recent review of rFVIIa use to treat congenital factor VII deficiency. Furthermore, at least two of those three cases were managed using higher doses of rFVIIa than are recommended here. The risk of thrombosis should be considered when rFVIIa is being used, especially when treating a condition that itself is associated with thrombosis, such as orthopedic surgery.⁵⁵³

Although the half-life of factor VII is short, both factor VII and, more recently, rFVIIa infusions have been successful in chronic infusion prophylaxis programs to prevent spontaneous CNS and joint bleeding. Factor VIIa was administered every other day or twice weekly, suggesting that an additional mechanism of action independent of the short plasma half-life was operative in these cases.

Although it is no longer the "product of choice," plasma can be used for replacement therapy for factor VII in emergency situations when other products are not available. Plasma has the disadvantage of posing a large volume load and has potential for viral transmission. For patients treated with plasma, a loading dose of 15 to 20 ml/kg, followed by 4 to 6 ml/kg every 6 hours for 7 to 10 days has been recommended. Plasma exchange therapy has been used in some patients to avoid volume overload.⁵⁵⁴ PCCs

have been used, but they too are not the product of choice. PCCs carry some thrombotic risk, which may be associated with the generation of unnecessarily high levels of other activated vitamin K-dependent coagulation proteins.⁵⁵⁵ This is especially a problem with extended PCC use or use of PCCs in the setting of liver disease. Those products are not generally labeled with their factor IX content, but the factor VII content is usually available from the manufacturer. Recovery studies indicate that an administered factor VII dose of 1 IU/kg will raise the patient's plasma factor level by ~2 IU/dl. If it is available, the use of purified factor VII concentrate might decrease the thrombotic risk associated with the use of less-specific PCCs. A heat-treated intermediate-purity factor VII concentrate (manufactured by Immuno A.G.) had been used for treatment of acute bleeds, perioperative prophylaxis, and for prevention of recurrent CNS hemorrhage. Factor VII levels rose ~2.33 IU/dl for each IU/kg infused, and the factor VII half-life was ~6 hours. Despite the short half-life of factor VII, infusions as infrequent as once per week were successful in preventing recurrent intracranial bleeding.³³⁶ For replacement therapy in a surgical setting, factor-level monitoring is recommended, to ensure that perioperative factor levels are >25 IU/dl.

Factor XIII Deficiency Treatment

Therapy for congenital factor XIII deficiency is based on the principle that only a small quantity of factor XIII must be present in human plasma to promote normal hemostasis.⁵⁵⁶ The long half-life of factor XIII (estimated as being between 9 and 19 days in the literature⁵⁵⁷) makes prophylactic therapy both practical and highly advisable given the high frequency of intracranial hemorrhage.²⁸⁴ This long half-life may not be present in some situations in newborn infants with severe FXIII deficiency.⁵⁸⁸ FFP and factor concentrates have been used successfully to prevent factor XIII-associated bleeding, and these remain the treatment of choice. Pasteurized factor XIII concentrate that contained only the A subunit prepared from human placenta has been replaced by plasma-derived preparations that contain both A and B subunits.⁵⁵⁹ A plasma-derived factor XIII preparation is available (Corifact, CSL Behring, Table 53.16) to treat congenital factor XIII deficiency. Recommended dosing is 40 IU/kg every 4 weeks with dose adjustments based on achieving a trough level of 5% to 20%. Two other preparations that have been used therapeutically are Fibrogammin-P, which is licensed in several countries (but not the United States or Canada), and a factor XIII preparation from Bio Products Laboratory that has been used in the United Kingdom. Kinetic studies with Fibrogammin-P indicate a mean recovery of 65% and a plasma half-life of ~5 to 11 days.^{560, 561} A recombinant factor XIII concentrate composed of the A subunit has been developed and is currently undergoing clinical investigation.⁵⁶² Recommended dosing for factor XIII concentrate is 10 to 20 IU/kg body weight every 4 to 6 weeks for prophylaxis against unprovoked bleeding. It is strongly recommended that all patients with severe factor XIII deficiency be placed on life-long prophylaxis in order to prevent the devastating complication of intracranial hemorrhage. Prophylactic therapy of affected patients undergoing surgery may actually require more intensive replacement therapy. If concentrates are unavailable, patients can be given either FFP or cryoprecipitate.⁵⁶³ A typical plasma dose is 10 to 20 ml/kg body weight, every 4 to 6 weeks. Cryoprecipitate at a dose of 1 bag per 10 to 20 kg of body weight every 3 to 4 weeks is an alternative therapy that has the advantage of requiring transfusion of a smaller volume. It is recommended that factor XIII levels be kept between 25% and 50% of normal to achieve normal hemostasis following major trauma in these patients; doses of concentrate recommended are 35 IU/kg preoperatively, followed by 10 IU/kg/day for 5 more days. Affected patients with a history of spontaneous abortions can complete a normal pregnancy when they are managed with prophylactic FFP or factor XIII concentrates. Factor XIII levels fall during pregnancy, and replacement therapy is recommended every 21 days.⁵⁶⁴ Monitoring of factor XIII trough levels may also be helpful. Formation of antibody inhibitors to factor XIII after replacement therapy appears to be rare.

In acquired factor XIII deficiency, >50% of patients need aggressive therapy. The most useful therapy for patients who have acquired inhibitors to factor XIII remains plasma exchange with or without immunosuppression with cytotoxic drugs. In addition, infusions of platelets can be given with occasional success, because platelets contain large amounts of factor XIII. Alternatively, replacement therapy with a factor XIII concentrate can be considered.

Treatment Considerations for Miscellaneous Disorders

Therapeutic regimens recommended for the treatment of patients with any of the less common inherited coagulation disorders are summarized in Table 53.8.

The management of major bleeding caused by deficiencies of prothrombin and factor X has been facilitated by the availability of PCCs (Table 53.15). The majority of these plasma-derived products contain three factors (prothrombin, factor IX, and factor X), but four-factor concentrates are also available.⁴⁸¹ Factor IX content has generally been used to label the potency of these concentrates, but factor content of the other vitamin K-dependent factors relative to the factor IX content is often available, either in published reports⁴⁸¹ or from the manufacturer. The currently available PCC products are subjected to virus-attenuation steps to inactivate hepatitis B, hepatitis C, and HIV. However, the thrombogenicity of

these products remains a concern,^{469, 472} and concomitant use of antifibrinolytics may increase that risk. In the absence of a specific factor concentrate, plasma transfusion may also be used to replace vitamin K-dependent coagulation factors.

There are few data on which to base recommendations on treating the rare bleeding disorders. It is estimated that 1 IU/kg of infused PCC will raise the prothrombin level by 1 IU/dl. Relatively low levels of prothrombin are required for normal hemostasis, and target values of 40 to 50 IU/dl are recommended for surgery. The half-life of prothrombin is ~72 hours, so infrequent postoperative infusions, every 2 to 3 days, is reasonable.⁵⁶⁵ Guidelines for the treatment of factor X deficiency vary. The biologic half-life of factor X is 20 to 40 hours. Calculation of the factor X dose is based on the empiric observation that for each 1 IU/kg infused, factor X levels rise ~1.5 IU/kg. Factor X levels varying from 5 IU/dl to as high as 40 IU/dl have been recommended for surgery; however, levels >20 IU/dl were suggested by the United Kingdom Haemophilia Centre Doctors' Organisation.²³⁶ Monitoring of the factor level achieved is prudent.

There are currently no factor V concentrates, so patients with factor V deficiency who require replacement therapy are treated with transfusions of plasma. Target levels of factor V recommended before surgery vary. The United Kingdom Haemophilia Centre Doctors' Organisation recommend target levels >15 IU/dl, whereas others have suggested levels of 25 to 30 IU/dl.²³⁶ The half-life of plasma factor V is reported to be 12 to 36 hours. In the United States, some blood collection organizations are moving away from production of FFP, toward production of plasma that is separated and frozen within 24 hours after collection (FP-24). Although factor V has been called "labile factor," levels of factor V in FP-24 are only modestly reduced compared to those in FFP.⁵⁶⁶ In addition, factor V appears to be relatively stable in "thawed plasma" held up to 5 days in transfusion service refrigerators at 0-4°C.⁵⁶⁷ Loading plasma doses of 20 ml/kg are often given, followed by maintenance infusions of 3 to 6 ml/kg every 12 hours. Cryoprecipitate does not contain sufficient factor V to be used as an alternative to plasma. If adequate factor V levels cannot be achieved by simple transfusion, exchange transfusion may be

P.1182

tried. Finally, in the setting of acquired factor V autoantibody, platelet transfusion has been used successfully. Similarly, platelet transfusion might hold some promise in treatment of a patient with congenital factor V with alloantibody.²³⁶

Patients with factor XI deficiency usually respond well to FFP. A solvent-detergent plasma preparation has been developed⁵⁶⁸ and may be the desired therapy not only for factor XI deficiency, but for other factor deficiencies for which sterile concentrates are not available. Unfortunately, some of the factor XI concentrates were shown to be thrombogenic in early clinical studies,²³⁶ and their clinical utility may be limited by this toxicity.

Cryoprecipitate is used in replacement therapy for afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia. When a sterile, nonthrombogenic fibrinogen concentrate becomes routinely available, it should replace cryoprecipitate for treating these latter disorders. Such a product is in clinical trial.²⁴¹ Fibrinogen replacement therapy has been reviewed.²⁴¹

SPECIAL ASPECTS OF TREATMENT

Hemarthrosis

All patients with hemarthrosis should receive adequate replacement therapy in order to prevent the development of permanent disability due to repeated bleeding into a joint. Pain usually is relieved promptly and is a reliable index of the therapeutic response. Supportive therapy follows the acronym of RICE: Rest through immobilization, ice to cool the inflammation and reduce the swelling, compression to reduce the swelling and bleeding, and elevation to reduce the swelling. The administration of analgesics that do not interfere with platelet function is appropriate to relieve the pain of bleeding into the joint.

Arthrocentesis usually is unnecessary if therapeutic infusion is accomplished early, but it may be of significant benefit when the joint is severely distended or when resolution of the hemarthrosis is delayed despite adequate replacement therapy.⁵⁶⁹ Large volumes of blood seldom can be aspirated, but even a small volume may relieve symptoms. If arthrocentesis is performed, it should be done immediately after the administration of a therapeutic dose of factor.

Early physiotherapy aimed at restoring the full range of motion of the affected joint should be instituted as soon as the acute stage of hemarthrosis has resolved. More energetic physiotherapeutic techniques should be carried out only in conjunction with an adequate course of replacement therapy. Various orthopedic devices (orthotics), such as braces and removable bivalve plaster casts, which provide additional support for chronically injured joints, have proved useful in reducing the frequency of recurrent hemarthrosis, particularly in the knee and ankle joints.⁵⁷⁰ For pain management of hemophilic arthropathy, nonsteroidal antiinflammatory agents may be helpful.⁵⁷¹ In particular, salsalate (Disalcid) or

choline magnesium trisalicylate (Trilisate) or the newer cyclo-oxygenase-2 inhibitors (Celebrex) may be useful in patients with bleeding disorders, because these drugs have antiinflammatory activity but do not impair platelet function.^{572, 573}

Regular infusions of factor concentrates may prevent or significantly delay progression of hemophilic arthropathy. A randomized clinical trial in boys demonstrated the markedly better results of a prophylaxis program versus episodic treatment on long-term joint function.⁵⁸ This study demonstrated a significant reduction in joint damage and other bleeding episodes in the prophylaxis group. Similar results would be expected in adult patients also, but have not yet been demonstrated in a rigorous clinical trial.

Prophylaxis therapy is regarded as optimal treatment for patients with severe hemophilia. One report compared two prophylaxis regimens for hemophilia A—standard prophylaxis (20 to 40 IU/kg every other day) vs. PK-tailored prophylaxis (20 to 80 IU/kg every third day). Annualized bleeding rates, factor consumption, and adverse events were similar.⁵⁷⁴

Reconstructive surgical procedures are available to improve the function of chronically damaged joints.^{61, 575, 576} Favorable results have been reported with total knee arthroplasty in several series.⁵⁷⁶ Long-term follow-up (>5 years) indicates adequately functioning prostheses and persistent pain relief in most patients. Synovectomy is effective in reducing the frequency of hemarthrosis that cannot be controlled by replacement therapy.⁵⁷⁷ Radioisotopic synovectomy is also effective therapy for hemophilic arthropathy.⁵⁷⁸ A review of the literature on radioisotopic synovectomy indicates that ~80% of patients benefit from the procedure,⁵⁷⁹ but an updated safety review identified two patients who subsequently developed acute lymphocytic leukemia.⁵⁸⁰ While not statistically significant, this report raises a safety question, and until more data and long-term follow-up is obtained, radioisotopic synovectomy should be considered carefully in the context of each patient's needs.

Hemophilic Cysts

Hemophilic cysts are very rare with modern treatment, but once were a serious complication that developed in patients with severe hemophilia A or B that had recurrent bleeding with inadequate treatment. Also known as hemophilic pseudotumors, such cysts are gradually expanding blood-filled loculations that apparently originate from hemorrhages into confined subperiosteal, tendinous, or fascial spaces. The osmotic pressure created by breakdown products of blood in such confined spaces may produce further influx of fluid; this, together with recurrent bleeding, explains the progressive increase in the size of the cyst and its ability to erode contiguous structures. Such cysts most commonly develop in the thigh and may destroy bone as well as the soft tissues as they increase in size. Hemophilic cysts are readily prevented, but difficult to treat. Although long-term replacement therapy combined with x-ray treatment has been successful in a few cases,⁵⁸¹ hemophilic pseudocysts may require radical surgical procedures such as extensive resections or amputations. Even with optimal supportive therapy, these procedures often are unsuccessful and may be complicated by infection. Surgical and nonsurgical approaches to manage pseudotumors have been reviewed.^{582, 583} The modern use of home prophylaxis has made pseudotumors an unusual complication of hemophilia, although they still occur in parts of the world that do not have access to prophylaxis treatment of hemophilia.

Intracranial Bleeding

Despite the widespread use of prophylaxis programs, hemorrhage, including intracranial hemorrhage, remains a leading cause of death among persons with hemophilia.⁵⁸⁴ After the neonatal period, intracranial hemorrhage affects 3% to 10% of hemophilia patients not receiving prophylaxis.⁵⁸⁵ An estimate of the incidence of intracranial hemorrhage placed the risk at 1 in 200 per year, proportional to the time spent with factor levels below 1 IU/dl.⁵⁸⁵ A mortality survey for hemophilia A for the years 1995 to 1998 found that hemorrhage was the listed cause of death for 22% of hemophilia A patients who died during that time period.¹¹ Approximately 50% of cases are associated with head injury⁵⁸⁶; the etiology is not apparent in 38% of cases (spontaneous cases).⁵⁸⁷ Bleeding may be subdural, epidural, or intracerebral. Subarachnoid bleeding occurs least commonly, but it carries the best prognosis. Hemorrhage also may develop in the spinal cord or spinal meninges. In cases associated with head trauma, the presence of a lucid interval and the absence of localizing neurologic signs at the time of presentation are commonly seen.⁵⁸⁷

Significant head injury must be treated early and intensively in patients with inherited coagulation disorders. Those with

P.1183

hemophilia A and B should immediately receive sufficient factor product to raise the plasma level of deficient factor to 100 IU/dl. Samples for essential coagulation studies should be drawn before administration of replacement therapy, but treatment should not be delayed while waiting for results of these studies. Radiologic procedures, such as computed tomography scanning, should be performed after the therapeutic product is administered. If it is performed expertly,

lumbar puncture usually can be carried out without serious risk, but many clinicians prefer to wait until replacement therapy has been given. In one series, replacement therapy given within 6 hours of head injury prevented any intracranial bleeding.⁵⁸⁸

In cases involving major cranial trauma, if neurologic signs or symptoms develop, or if intracranial bleeding is confirmed radiologically or otherwise, the administration of factor VIII or factor IX concentrates should continue on a schedule in doses sufficient to keep the nadir levels of the deficient factor >30 IU/dl. Treatment should be maintained for 10 to 14 days.⁵⁸⁷ Before the widespread use of factor VIII concentrates, the mortality rate after intracranial bleeding was greater than 70%.⁵⁸⁶ For treatment of patients who have suffered from an episode of spontaneous intracranial hemorrhage, most experts recommend prophylaxis therapy so that the factor level rarely is below 1 IU/dl, as the risk of recurrence is significantly higher in such patients. It is expected that the morbidity and mortality of intracranial bleeding will be reduced further with the increased use of the extended half-life factor products currently in phase 3 clinical trials.

Viral Transmission from Past Factor Concentrates: HIV and Hepatitis C

Acquired immunodeficiency syndrome (AIDS) was first recognized in 1978 and was found to be transmitted in blood products in the early 1980s,⁵⁸⁹ infecting approximately 70% of persons with severe hemophilia using factor concentrates prior to 1984. HIV transmission through factor concentrate was reduced to zero after 1985, through the development of factor concentrates including virucidal steps in the manufacturing process, the institution of stringent donor testing, and the availability of recombinant products. Improvements in therapy for HIV have allowed many persons with hemophilia to become long-term survivors, although there remain many seropositive patients who have not progressed to AIDS.

In the United States mortality survey of hemophilia A patients between 1995 and 1998, liver disease was listed as a cause of death in 15% of patients.⁵⁹⁰ It is estimated that approximately 90% of persons with severe hemophilia who used factor concentrates prior to 1984 were infected by the hepatitis C virus transmitted in the factor concentrate.⁵⁹¹ Nearly 20% of these individuals were able to eradicate the virus, thus becoming hepatitis C antibody positive, but hepatitis C virus negative. However, for other patients, the hepatitis C virus has progressed inexorably with many dying from chronic liver disease. Liver biopsies confirmed the presence of chronic active hepatitis in many patients.⁵⁹² The disorder is usually the result of persistent infection with the hepatitis C virus, but may be complicated in some individuals by coinfection with hepatitis B.^{593, 594} A prospective study of U.S. hemophilia patients found that 66% of the hepatitis C-infected hemophilia patients also had HIV infection,⁵⁹¹ and that coinfection was associated with a five- to sixfold increase in endstage liver disease. Modern manufacturing methods render factor concentrates free of hepatitis C virus and other lipid-enveloped viruses. No hepatitis C viral transmission has been connected with factor concentrates since 1986. Patients who are seronegative for the hepatitis A and B viruses should receive immunizations for these viruses. However, standard solvent-detergent-inactivated products may still transmit non-lipid-enveloped viruses such as parvovirus,⁵⁹⁵ hepatitis A,⁵⁹⁶ and other viruses.⁵⁹⁷ An unresolved issue is the transmission potential of the agent that causes Creutzfeldt-Jakob disease, but the manufacturers of plasmaderived factor concentrates have taken steps to reduce the risk of transmitting this agent also.^{598, 599, 600}

Antibodies to Coagulation Factors

A major problem with current therapeutic products in hemophilia A is the development of neutralizing antibodies (inhibitors) to factor VIII. This complication is less common in patients with hemophilia B and other inherited coagulation disorders. Such antibodies may seriously complicate the treatment of these patients (see Chapter 54).

Home Treatment Programs

In general, current recommended therapy of hemophilia is replacement therapy or prophylaxis treatment to prevent any spontaneous bleeding episodes, rather than treating bleeding episodes after they occur, termed "on demand." A prospective randomized clinical trial has demonstrated that joint damage is minimized if treatment is begun immediately after the onset of symptoms.⁵⁸ The availability of factor VIII concentrates that are stable in home refrigerators led to the development of various early home-care programs.⁶⁰¹ Parents and patients are trained to administer the product at the first sign of bleeding. Such programs have resulted in decreased bleeding episodes and improved preservation of joint function.^{602, 603} Typical prophylactic regimens are 25 to 40 IU/kg of factor VIII three times per week for hemophilia A, and 25 to 40 IU/kg of factor IX twice per week for hemophilia B. Such therapy usually maintains the trough factor level at or above 1% of normal. In older hemophilia patients with significant joint arthropathy, higher doses often are needed, while in younger patients with essentially normal joints, the lower factor doses are sufficient. A 30-year follow-up report confirmed the efficacy of prophylaxis.⁶⁰⁴ An economic analysis of prophylaxis found that although higher costs were associated with prophylaxis programs, the approach was justified on medical grounds.⁶⁰⁵ It is recommended that patients begin prophylaxis soon after the first joint bleed.⁶⁰⁶

In 2013 there were at least 3 new factor VIII products and 3 factor IX products with extended half-lives in clinical trials. There have been no safety issues demonstrated so far in this clinical trial experience. These new products should dramatically improve the treatment of patients with hemophilia by simplifying prophylaxis regimens.

Dental Care

Special attention should be given to preventive dental care in patients with coagulation disorders, so as to minimize the complications, expense, and hazards of operative dental procedures. The extraction of even a single tooth usually requires replacement therapy. Most authorities recommend that dental procedures in patients with inherited coagulation disorders be carried out under cover of replacement therapy and antifibrinolytic therapy.⁵⁰²

THE FUTURE IN HEMOPHILIA TREATMENT

After the devastating epidemics in the hemophilia community caused by HIV and hepatitis C, it was a major step forward to have available recombinant products for treatment of hemophilia in the early 1990s. Now, 20 years later, several new products are in clinical trials that promise major advances in hemophilia treatment. Factor VIII and factor IX have been available as recombinant proteins for nearly 20 years, but due to their relatively short

P.1184

half-lives, still require frequent intravenous infusions in order to maintain clotting factor concentrations in plasma to avoid the risk of spontaneous bleeding. The longer half-life factor VIII and factor IX products will change treatment paradigms. In addition, there are efforts to provide other coagulation proteins as recombinant therapeutic products. Finally, there are renewed efforts in gene therapy for hemophilia, with better and safer viral vectors.

Chapter 54

Acquired Coagulation Disorders

George M. Rodgers

Abnormalities in blood coagulation may complicate a large number of disorders (Table 54.1). In contrast to inherited disorders in which deficiency or abnormality of a single factor is characteristic, the acquired forms usually are associated with multiple coagulation abnormalities, and the disorder often is complicated by thrombocytopenia, deficient platelet function, and abnormal inhibitors of coagulation. Because of the compound nature of the hemostatic defect, the severity of bleeding often correlates poorly with the results of laboratory tests in patients with acquired coagulation disorders, and replacement therapy may be ineffective. With some notable exceptions, however, bleeding usually is less severe than in the inherited forms, and the clinical picture often is complicated by signs and symptoms of the underlying disease.

DEFICIENCIES OF VITAMIN K-DEPENDENT FACTORS

Prothrombin; factors VII, IX, and X; and proteins C and S are synthesized by the liver by a process that depends on vitamin K (see Chapter 18 and Fig. 54.1).^{1, 2} When stores of this vitamin are deficient or abnormal, hypofunctional analogs of these factors are synthesized, which inhibit normal coagulation. These descarboxy analogs of the vitamin K-dependent factors

do not bind to cellular phospholipid surfaces and, therefore, do not participate in cell-associated coagulation reactions. This may occur in disorders in which intake or absorption of vitamin K is deficient and in disorders that impair the biosynthetic capacity of the liver (Fig. 54.1). A similar coagulation abnormality may be produced by anticoagulant drugs such as coumarin and indanediones, which antagonize the action of vitamin K (see Chapter 55).

Vitamin K Deficiency Bleeding (Hemorrhagic Disease of the Newborn)

Hemorrhagic disease of the newborn is the result of vitamin K deficiency in the neonate; this phrase was first used more than 100 years ago.³ The preferred term is vitamin K deficiency bleeding (VKDB) in infancy as proposed by a consensus committee.⁴ Formerly a major cause of bleeding, this disorder is now uncommon because of the routine administration of vitamin K at birth⁵; however, it is still encountered in economically deprived populations.

Pathophysiology

The normal newborn has a moderate deficiency of the vitamin K-dependent coagulation factors. The plasma levels of these factors normally fall even further during the first 2 to 5 days of life, rise again when the infant is 7 to 14 days old, and attain normal adult levels later in life (see also Table 45.6). The deficiency of the vitamin K-dependent coagulation factors that is present at birth, as well as the slow rate at which adult levels are attained, presumably is the result of intrinsic "liver immaturity;" neither of these physiologic phenomena is affected by vitamin K administration.⁶ On the other hand, the diminution in levels of these factors that occurs at age 2 to 5 days is prevented by vitamin K administration because it is the result of a transitory physiologic deficiency of this vitamin. Factors that further diminish the amount of vitamin K available at this juncture and those that further impair the synthetic capacity of the liver predispose neonates to hemorrhagic disease of the newborn. These factors are (a) prematurity, (b) inadequate dietary intake, (c) delayed gut colonization by bacteria, (d) various obstetric and perinatal complications, and, possibly, (e) maternal deficiency of vitamin K.

Prematurity often has been associated with VKDB.⁷ Levels of the vitamin K-dependent factors at birth are approximately proportional to gestational age and birth weight.⁸ In premature infants, the physiologic immaturity of the liver is marked, and the response to vitamin K that is present is subnormal.

Most factors associated with deficient intake of vitamin K also delay the colonization of the gut by bacteria. These factors include delayed feeding, breast-feeding, vomiting, severe diarrhea, and antibiotics, including those present in maternal milk. Human milk and colostrum are poor sources of vitamin K,⁶ and reliance on breast milk as the sole source of nutrients in the neonatal period is an important factor in many cases of VKDB.⁵

Coumarin and indanedione drugs cross the placenta and may produce hemorrhagic disease in the newborn.⁹ Infants born of mothers who were taking diphenylhydantoin or other anticonvulsants, including barbiturates, or salicylates have developed a syndrome similar to VKDB.¹⁰ Treatment of the mother with vitamin K during the last trimester may prevent this complication.

Clinical Features and Laboratory Diagnosis

VKDB etiology is considered idiopathic (no cause other than breast-feeding) or secondary (malabsorption of vitamin K, liver

P.1187

disease, drugs).⁴ VKDB can also be classified in terms of age of onset: Early (onset <24 hours of age), classic (onset usually between 3 and 5 days), and late (onset on or after 8 days). Early VKDB is uncommon and usually results from placental transfer of maternal drugs that antagonize vitamin K in the newborn. Late VKDB occurs almost exclusively in breast-fed infants who may also have hepatobiliary disease.⁴

TABLE 54.1 ACQUIRED COAGULATION DISORDERS

Deficiencies of vitamin K-dependent coagulation factors

Hemorrhagic disease of the newborn (vitamin K deficiency bleeding)

Biliary obstruction (gallstone, strictures, fistulas)

Malabsorption of vitamin K (sprue, idiopathic steatorrhea, celiac disease, ulcerative colitis, regional enteritis, gastrocolic fistulas, *Ascaris* infestation)

Nutritional deficiency

Drugs

1. Pharmacologic antagonists of vitamin K (coumarins, indandiones, others)
2. Those that alter gut flora (broad-spectrum antibiotics, sulfonamides)
3. Miscellaneous (cholestyramine)

Liver disease (see Table 54.3)

Accelerated destruction of coagulation factors

Disseminated intravascular coagulation (see Table 54.4)

Fibrinolysis (liver disease, thrombolytic agents, tumors, after surgery)

Inhibitors of coagulation

Specific inhibitors (antibodies) (see Table 54.6)

Antiphospholipid-protein antibodies (see Table 54.7)

Miscellaneous (antithrombins, paraproteinemias)

Miscellaneous

After massive transfusion

After extracorporeal circulation

Drugs (antibiotics, antineoplastic agents, others)

Other disorders (polycythemia vera, congenital heart disease, amyloidosis, nephrotic syndrome, Sheehan syndrome, Gaucher disease, leukemia, others)

FIGURE 54.1. Etiologies of vitamin K deficiency. Sources of vitamin K include the diet and gut bacterial synthesis. Processes leading to vitamin K deficiency are indicated with a solid line ending in a squiggle.

Bleeding in classic VKDB is severe.³ The most common manifestations are melena, large cephalohematomas, and bleeding from the umbilical stump and after circumcision. Generalized ecchymoses, often without petechiae, intracranial bleeding, and large intramuscular hemorrhages also may develop.^{3, 6}

Laboratory diagnosis is relatively simple (Table 54.2), but physiologic differences in the results of various coagulation tests in normal neonates must be kept in mind (see Table 45.6). In infants with VKDB, the prothrombin time (PT) always is prolonged. The partial thromboplastin time (PTT) is also prolonged. Specific factor assays reveal deficiencies of prothrombin; factors VII, IX, and X; and proteins C and S. The presence of normal antigenic levels of the vitamin K-dependent factors may be demonstrated by immunoassays.¹¹ Factors V and VIII, as well as fibrinogen, are present in normal amounts. The consensus committee recommends diagnosing VKDB with a prolonged PT value, a normal fibrinogen level, and a normal platelet count.⁴

The clinician should not assume that bleeding in the neonate is invariably the result of vitamin K deficiency.⁴ In the differential diagnosis of VKDB, virtually all causes of bleeding, particularly thrombocytopenia (see Chapter 46) and disseminated intravascular coagulation (DIC) must be considered.¹² The inherited coagulation disorders (see Chapter 53) also may produce serious hemorrhage in the neonatal period, but significant prolongation of the PT is not found in the most common forms, for example, hemophilia A and hemophilia B. Umbilical bleeding and hemorrhage after circumcision are relatively less common in the inherited coagulation disorders than in VKDB.

Treatment

Vitamin K₁ (0.5 to 1.0 mg given intramuscularly) is dramatically effective in the treatment of VKDB¹³; the 0.5-mg dose appears to be more than adequate.¹⁴ Shortening of the PT may be expected within 6 hours, and normal neonatal levels of the vitamin K-dependent factors usually are attained within 24 hours of administration. An American Academy of Pediatrics consensus report has summarized recommendations of vitamin K therapy for prevention of early and late VKDB.¹⁵ Larger (2 mg) or repeated (every 4 to 8 hours) doses of vitamin K₁ may be required to counteract the effects of coumarin drugs in infants.⁶ The response in premature infants to vitamin K₁ usually is incomplete. The administration of

large doses of vitamin K may produce hemolysis, hyperbilirubinemia, and even kernicterus in the neonate. These complications appear to be associated more commonly with the synthetic derivatives than with vitamin K₁, but even the latter may be dangerous in large doses.⁶

In severe cases of VKDB, the transfusion of plasma may be helpful.⁶ Concentrates of vitamin K-dependent coagulation factors are effective but have led to thrombosis and intravascular coagulation in some infants, particularly in premature infants. This result has been attributed to immaturity of the hepatic clearance functions and physiologic deficiency of antithrombin.

Because VKDB is primarily a disease of breast-fed infants,¹⁶ VKDB can be prevented by the administration of vitamin K to the mother before delivery. Most authorities, however, recommend administering vitamin K₁ to the infant. This procedure is now routine in most nurseries. Many pediatricians also recommend the

P.1188

prophylactic administration of vitamin K₁ to infants 1 to 5 months of age, especially those who are breast-fed or who have a disorder that may impair vitamin K absorption.¹⁷ The usual dosage in such older infants is 50 to 100 µg daily or 1 mg monthly.

^a May reveal effects of acute bleeding or abnormality characteristic of underlying disease.

^b Results may differ from adult norms in normal neonates.

^c One-stage assays may yield aberrant results.

^d Hypofibrinogenemia may alter results.

^e The presence of immunoglobulin M rheumatoid factors in certain patients may lead to a false-positive result in latex-agglutination assays.

Most pediatricians would attribute the decrease in incidence of VKDB in recent years to the prophylactic administration of vitamin K. There is widespread consensus on continuing vitamin K prophylaxis to newborns.^{3, 15} A prospective population study in the United Kingdom found that with prophylaxis, VKDB in newborns is rare,¹⁸ whereas in developing countries, prophylaxis is not frequently used, and VKDB is common.

Other Causes of Vitamin K Deficiency

Obstruction of the biliary tract, either intrahepatic or extrahepatic, produces vitamin K deficiency because of the absence of bile salts in the gut. Complete obstruction may lead to severe coagulation abnormalities and bleeding within 2 to 4 weeks. This was a major obstacle to surgical procedures on the biliary tract before the discovery of vitamin K.

Most malabsorption syndromes and various other chronic gastrointestinal disorders also may give rise to vitamin K deficiency. Such disorders include celiac disease, sprue, gastrocolic fistulas, ulcerative colitis, regional enteritis, extensive gut resections, protracted diarrhea of any cause, *Ascaris* infestations, and cystic fibrosis. The last named disorder often is complicated by liver disease.¹¹ Severe abnormalities of coagulation and bleeding are less common in association with these disorders than with biliary obstruction, presumably because absorption of vitamin K is seldom completely deficient.

Because vitamin K normally is available from two independent sources (Fig. 54.1), neither nutritional deficiency nor gut sterilization alone produces deficiency of a degree that results in significant coagulation abnormalities. In normal adults, the daily oral intake of vitamin K must be reduced to 20 µg or less for several weeks to produce significant hypoprothrombinemia.¹ However, vitamin K deficiency is more common than is usually realized in hospitalized patients with poor or negligible oral food intake, especially if they are also taking antibiotics.^{19, 20} Significant coagulation abnormalities may arise with surprising rapidity

P.1189

in such patients, and when unsuspected, they may be confused with DIC or may first be revealed by serious, unexpected postoperative hemorrhage. Antimicrobial agents presumably impair vitamin K production by inhibiting the synthesis of menadiones by gut bacteria, but they may also directly affect carboxylation reactions.^{21, 22} Vitamin K deficiency also may result from use of drugs other than antimicrobial agents, such as cholestyramine,²³ which acts by binding bile salts, or mineral oil and other cathartics when used for protracted periods. Vitamin E may antagonize the metabolic action of vitamin K and potentiate the action of coumarins.⁶ When taken in large doses, this vitamin may prolong the PT.²⁴ Antibiotic therapy, poor diet, or any of the aforementioned disorders may predispose patients to coumarin toxicity (see Chapter 55).²⁵ Large doses of aspirin, as given to treat rheumatic disorders or in amounts associated with overdosage of the drug, may also induce vitamin K deficiency.²⁶

Treatment

In adults, the parenteral administration of 10 mg of vitamin K₁ abolishes coagulation abnormalities within 12 to 24 hours if they are the consequence of a deficiency of this vitamin. Failure of vitamin K to normalize the PT is evidence for the presence of a complicating process, such as liver disease or DIC, or super-warfarin ingestion.²⁷ The synthetic vitamin K₃ (menadiones) may be absorbed in the absence of bile salts and in various malabsorption syndromes. However, these congeners of vitamin K have a more transient effect than the natural forms of this vitamin and offer minimal therapeutic advantage in the usual case. Replacement therapy with fresh frozen plasma or prothrombin complex concentrates (PCCs) is effective in the treatment of emergent vitamin K deficiency.

Intravenous administration of vitamin K may produce hemolytic anemia in patients with inherited deficiencies of various red cell enzymes, and may be associated with a risk of anaphylaxis.²⁸ Malnourished patients receiving broad-spectrum antibiotic therapy should receive vitamin K prophylactically, 5 mg twice weekly, orally or subcutaneously.²⁹

Commercially available rodenticides (super-warfarins) that exhibit long-acting vitamin K antagonism have been associated with significant bleeding disorders when these compounds have been ingested by humans.²⁷ These drugs are chemically distinct from warfarin, are 100 times more potent than warfarin, and can induce vitamin K deficiency lasting for months. In 1995 alone, more than 13,000 people were exposed to these agents and treated.³⁰ Initial treatment of these patients may require up to 100 mg of vitamin K daily to normalize vitamin K metabolism.³⁰

LIVER DISEASE

Virtually every hemostatic function may be impaired in patients with severe hepatic disease (Table 54.3)^{31, 32, 33} as the result of failure of both the biosynthetic and clearance functions of the liver. The pathophysiology of some of these abnormalities is tied to thrombocytopenia (see Chapter 46), platelet dysfunction (see Chapter 52), intravascular coagulation and fibrinolysis, and the effects of products of fibrinogen catabolism on hemostasis (see below).

Pathophysiology

Thrombocytopenia

Patients with significant liver disease have portal hypertension, splenomegaly, and splenic sequestration of platelets, contributing to thrombocytopenia. The liver is also the major site of production of thrombopoietin, the principal humoral factor involved in megakaryocyte maturation and platelet formation (see Chapter 15). Recent studies have evaluated whether deficient levels of thrombopoietin occur in liver disease. Results indicate that thrombocytopenia in liver disease is not explained by deficient hepatic production of thrombopoietin.^{34, 35} However, there is a correlation between the extent of liver disease and platelet expression of the thrombopoietin receptor, c-Mpl,³⁵ and this reduced expression may contribute to thrombocytopenia. Additionally, increased thrombopoietin degradation by platelets sequestered in the spleen may also contribute to thrombocytopenia in these patients.³⁶

TABLE 54.3 ABNORMALITIES OF HEMOSTASIS AND COAGULATION IN LIVER DISEASE

Deficient biosynthesis

Of fibrinogen; prothrombin; coagulation factors V,³⁹ VII, IX, X, XI, XII, XIII; prekallikrein; high-molecular-weight kininogen

Of antiplasmins,⁵⁸ antithrombin,⁵⁷ proteins C and S

Aberrant biosynthesis

Of abnormal fibrinogen,^{41, 45} factor V

Of abnormal inhibitory analogs of prothrombin, factors VII, IX, and X⁴⁶

Deficient clearance

Of hemostatic “products” (e.g., fibrin monomers, fibrin[ogen] degradation products, platelet factor-3)

Of activated coagulation factors (IXa, Xa¹⁵⁸, XIa)

Inhibition of coagulation by products of fibrinogen degradation^{53, 54}

Loss or consumption of coagulation factors in ascitic fluid⁶⁸

Deficient or Aberrant Synthesis of Coagulation Factors

In patients with liver disease, all coagulation factors except factor VIII may be deficient as a consequence of synthetic failure of the hepatic cells. Failure of biosynthesis of coagulation factors often correlates with the severity of hypoalbuminemia, but exceptions to this rule are common. Deficiencies of prothrombin; factors VII, IX, and X; and proteins C and S result mainly from synthetic incompetence. For example, factor VII expression in liver biopsies from patients with liver disease decreases as the severity of hepatic dysfunction increases.³⁷ Impaired carboxylation of precursors may contribute to the defect.¹¹ Superimposed vitamin K deficiency may result from a poor diet or malabsorption caused by insufficient production of bile salts or by exocrine pancreatic insufficiency.³⁸ The failure of these coagulation abnormalities to respond to vitamin K administration provides good evidence of hepatic cell dysfunction.

P.1190

Factors V, XI, and XIII are synthesized by the liver but are not vitamin K-dependent³⁹; all of these factors may be deficient in patients with severe liver disease. Plasma levels of factor XII, prekallikrein (Fletcher factor), and high-molecular-weight

kininogen (Fitzgerald factor) also may be low in association with liver disease. Deficiencies of these latter three factors do not contribute to a bleeding diathesis.

Hypofibrinogenemia rarely may result from deficient hepatic biosynthesis^{39, 40} or may be the consequence of fibrinogenolysis or DIC, as discussed subsequently. In many patients with liver disease, prolongation of the thrombin time can be significant in the absence of hypofibrinogenemia or increased levels of fibrin(ogen) degradation products (FDPs).⁴¹ This apparently is the result of a qualitatively abnormal fibrinogen that is synthesized by the diseased hepatic cell. Such acquired dysfibrinogenemia has been reported in most forms of liver disease, ranging from mild acute hepatitis to acute hepatic necrosis and cirrhosis.⁴² Fibrin monomer polymerization is delayed,⁴³ and the abnormal fibrinogen molecule acts as an antithrombin.⁴¹ Additionally, this hepatic disease dysfibrinogen may have an abnormally high content of sialic acids⁴⁴ and may produce a structurally defective fibrin clot.⁴⁵ Acquired dysfibrinogenemia, abnormal inhibitors of fibrinolysis, and the presence within the plasma of descarboxy analogs of prothrombin⁴⁶ have been reported in patients with hepatomas.⁴⁷ Hepatoma-associated dysfibrinogens have also been noted to have an increased carbohydrate content.

Plasma levels of factor VIIIc usually are elevated in both parenchymal and cholestatic liver disease.⁴⁸ Studies in patients with cirrhosis indicate that elevated plasma factor VIII levels are not due to increased transcriptional activity of factor VIII in the liver, but instead likely result from increased liver synthesis of von Willebrand factor (vWF) and decreased levels of lipoprotein receptor-related protein. Both of these latter proteins regulate plasma factor VIII levels.⁴⁸

Fibrinogenolysis and Fibrinolysis

Endogenous plasminogen activators normally are removed from the circulation by the liver. In patients with severe liver disease, however, they may circulate for an abnormally long time and lead to the chronic or intermittent activation of the fibrinolytic enzyme system.^{49, 50} This process may be a contributory factor in the pathogenesis of hypofibrinogenemia in patients with liver disease. It also leads to the production of large amounts of FDP, which persist in the circulation for abnormally long periods because of deficient hepatic clearance, and may impair blood coagulation and platelet function.⁵¹ Such proteolytic activity also may produce a shift in the mean molecular weight of circulating fibrinogen from the normal species to a less reactive species of lower molecular weight,⁵² thereby contributing to the "antithrombins of liver disease."^{53, 54}

The incidence of hyperfibrinolysis was surveyed in patients with cirrhotic and noncirrhotic liver disorders.⁵⁵ Hyperfibrinolysis, as measured by a shortened euglobulin clot lysis time, was present in approximately 30% of cirrhotic patients but not present in noncirrhotic patients.⁵⁵ The role of thrombin-activatable fibrinolysis inhibitor deficiency in liver disease in contributing to hyperfibrinolysis has been studied; thrombin-activatable fibrinolysis inhibitor levels are reduced in liver disease, with lower levels seen in more severe liver disease.⁵⁶ However, there was no association of low thrombin-activatable fibrinolysis inhibitor levels with hyperfibrinolysis, even in cirrhotic patients. These studies suggest that hyperfibrinolysis is not common in liver disease, even in cirrhosis.^{55, 56}

Plasma levels of antithrombin,⁵⁷ antiplasmin,⁵⁸ and plasminogen⁵⁹ are subnormal in patients with liver disease. These abnormalities are of uncertain clinical importance.

Intravascular Coagulation

Severe liver disease theoretically predisposes individuals to the development of DIC because DIC is associated with deficient hepatic clearance of activated coagulation factors and other coagulant substances. The in vivo turnover rates of prothrombin,⁶⁰ fibrinogen,⁶¹ plasminogen,⁶⁰ and antithrombin⁵⁷ often are accelerated in patients with cirrhosis. Plasma levels of fibrinopeptide A are elevated in most patients with cirrhosis.⁶² All of these abnormalities may be normalized in some cases by the administration of heparin.⁶³ It has been hypothesized that accelerated catabolism of coagulation factors in these disorders is the result of DIC. The nature of the initiating process is unclear, but one suggestion is that DIC is activated by hypoperfusion of the congested portal bed.⁴⁰ Indirect evidence suggests that in severe liver disease, activators of coagulation, possibly endotoxin, may originate in the gut.

Low-grade DIC or localized intravascular coagulation indeed may occur in association with severe liver disease, but overt DIC is responsible only rarely for bleeding in the absence of other etiologic factors that trigger this process, for instance, sepsis, shock, and cancer.^{64, 65} This conclusion is supported by findings in patients with stable cirrhosis that demonstrated no increased levels of markers of activation of coagulation, such as prothrombin fragment 1+2, thrombin-antithrombin complex, and so forth.⁶⁶

Evidence for accelerated fibrinogen turnover in ascitic fluid suggests that the loss or consumption of coagulation factors in peritoneal fluid may be a contributory factor in the coagulopathy of chronic liver failure. Shunting of ascitic fluid into the venous circulation by means of LeVeen shunts consistently produces coagulation abnormalities consistent with DIC in

cirrhotic patients.⁶⁷ Although this phenomenon usually is attributed to intravascular coagulation, evidence shows that it may result in part from the presence of plasminogen activators and active plasmin⁶⁸ or collagen⁶⁹ in peritoneal fluid.

A transitory coagulation disorder that resembles intravascular coagulation with active fibrinolysis has been documented during liver transplantation procedures. Coagulation abnormalities disappear promptly if the graft is successful.⁷⁰ The complex coagulopathy seen with liver transplantation has been reviewed.⁷¹

Clinical Manifestations

In view of the numerous hemostatic abnormalities associated with severe liver disease, it is surprising that many patients do not bleed abnormally. Gastrointestinal hemorrhage is the most common bleeding manifestation, but it almost always originates from a local lesion, such as esophageal varices, peptic ulcer, or gastritis. The degree to which coagulation abnormalities contribute to such bleeding is uncertain. In one large series, gastrointestinal bleeding was not significantly more severe or protracted in patients with coagulation abnormalities than in those without them.⁷² In another study, serious hemorrhage occurred only in patients with prolonged PTs and significant factor IX deficiency.⁷³ Moderate generalized bleeding manifestations, such as recurrent ecchymoses and epistaxis, are not uncommon, and severe generalized bleeding may complicate surgical procedures, including biopsies, tooth extractions, and other minor procedures.

The above-mentioned paradox of the lack of bleeding in many patients with severe liver disease despite multiple hemostatic abnormalities has been explored.⁷⁴ An emerging concept is that coagulation in liver disease patients is "rebalanced" due to parallel reductions in both procoagulant and anticoagulant factors. Standard coagulation tests (such as the PT) do not measure major *in vivo* regulators of coagulation such as thrombomodulin and may not adequately reflect hemostasis in these patients.^{32, 74} This new paradigm has implications for managing the coagulopathy of liver disease.

P.1191

Laboratory Diagnosis

The laboratory findings in liver disease vary with the cause and severity of the underlying disorder and range from a slight prolongation of the PT in anicteric hepatitis to the findings summarized in Table 54.2, which are seen in severe decompensated cirrhosis. In cirrhosis, coagulation abnormalities correlate with the presence of portal hypertension and may be minimal in inactive cirrhosis; thrombocytopenia alone is common in association with portal hypertension. Acute fibrinogenolysis is significantly more common in patients with cirrhosis⁵⁵ than in those with acute hepatocellular disease, such as hepatitis, although elevations of FDP are consistently found in people with chronic aggressive hepatitis.⁴² Coagulation abnormalities are seldom marked in biliary cirrhosis, and some patients with this disorder have abnormally high levels of prothrombin and factors VII and X. Hemostatic abnormalities of any sort are rare in metastatic liver disease. In acute liver failure, the PT value has prognostic value and is indicative of the need for liver transplantation.⁷⁵ The spectrum of coagulation abnormalities in liver disease has been reviewed.³¹

Although screening tests of coagulation are almost invariably performed before liver biopsy, they apparently are of little value in predicting hemorrhage after this and other minor surgical procedures.^{32, 74, 76, 78} Similarly, the bleeding time test is of little clinical use in predicting bleeding.⁷⁹ Many physicians use the international normalized ratio (INR) as a substitute coagulation test for the PT.⁸⁰ When measured with a sensitive thromboplastin, the INR can quantitate vitamin K deficiency due to liver disease, but it should not be interpreted as in patients receiving warfarin.⁸⁰

Treatment

Not all patients with the coagulopathy of liver disease require hemostatic correction before procedures such as liver biopsy. A retrospective study looked at the PT ratio (patient PT/mean of reference range PT) and degree of thrombocytopenia to determine the necessity of plasma and platelet transfusion.⁸¹ In patients with platelet counts of 50,000/ μ l or greater, there was no increased bleeding with liver biopsy compared with patients with normal platelet counts. With regard to elevated PT values, if the PT ratio was <1.5, no increased bleeding was observed.⁸¹ Therefore, patients with moderate thrombocytopenia and mild liver disease coagulopathy do not need routine hemostatic correction with blood products. One exception to this recommendation is patients with a diagnosis of malignancy, who may have a higher bleeding risk, possibly due to chronic DIC and elevated FDP levels.⁸¹ On the other hand, a British guidelines committee on the use of plasma products suggests that "patients with liver disease and a PT more than 4 seconds longer than control are unlikely to benefit from FFP."⁸² This recommendation is based on expert opinion.

Elevated FDP levels may be a significant hemostasis risk factor in liver disease. High levels of FDP may impair platelet function and fibrin monomer polymerization. The thrombin time can screen for the latter defect. A prolonged thrombin time in a patient with a normal functional fibrinogen level and high FDP levels, who is not receiving heparin, may constitute a significant bleeding risk, especially in the setting of moderate thrombocytopenia.

Vitamin K₁, in a dose of 10 mg, produces some improvement in the coagulation abnormalities in approximately 30% of patients with liver disease,⁷³ but the PT often becomes prolonged again after an initially favorable response. Patients with severe liver disease have minimal or no response to vitamin K therapy.

Replacement therapy with fresh frozen plasma is indicated only in the presence of serious bleeding or before surgical procedures, and its effect is often disappointing in patients with liver disease.⁷³ Reasons for this may include the short in vivo half-life of factor VII, hypervolemia, the loss of transfused factors into ascitic fluid, and the fact that the in vivo recovery of transfused factor IX is significantly lower than that of other factors, even in the absence of liver disease. Concentrates of vitamin K-dependent coagulation factors (PCC) have been used in the replacement therapy of bleeding in patients with liver disease with variable success but, in several cases, have led to thromboembolic complications and DIC.⁸³ Thrombosis presumably develops because such concentrates contain trace amounts of activated coagulation factors, particularly factors IXa and Xa,^{83, 84} that normally are not cleared from the circulation by the diseased liver and because of antithrombin deficiency, which is commonly present. Newer PCCs are becoming available; these also contain proteins C and S in addition to the procoagulant vitamin K-dependent factors. These products have not been well studied in liver disease coagulopathy, but appear to be effective in reversing warfarin coagulopathy.⁸⁵ Fresh frozen plasma is the preferable treatment option, but the effects of even maximum doses (20 to 30 ml/kg of body weight) often are transitory. Cryoprecipitate is useful to maintain fibrinogen levels over 100 mg/dl. A controlled trial found that 1-desamino-8-darginine vasopressin (DDAVP) is not helpful in management of variceal bleeding in cirrhotic patients.⁸⁶

Recombinant factor VIIa (rVIIa) is a potential therapy for liver disease patients with significant coagulopathy. However, the drug is not indicated for use in variceal bleeding, partial hepatectomy, or liver transplantation.⁸⁷ Disadvantages of rVIIa include its high cost and risk of DIC and thromboembolic complications.

Even though heparin administration may normalize fibrinogen catabolism, little evidence is cited that it decreases the duration or severity of bleeding in patients with low-grade DIC and severe liver disease. However, heparin may be useful in conjunction with PCC therapy. In this setting, the addition of small amounts of normal plasma and heparin to vials of these thrombogenic concentrates inactivates activated proteases and minimizes the thrombotic risks of these concentrates.⁸⁸

Correction of thrombocytopenia may be difficult in patients with severe liver disease. One promising intervention is the use of synthetic thrombopoietins and thrombopoietin mimetic agents. Eltrombopag is approved to treat thrombocytopenia in chronic hepatitis C patients who receive interferon therapy.

For patients requiring liver biopsy who are deemed "high risk" from the hemostasis perspective, the transjugular approach should be considered.

DISSEMINATED INTRAVASCULAR COAGULATION

The syndrome of DIC (defibrination syndrome, consumption coagulopathy) has been one of the most intensively studied subjects in hematology. This large body of information has been summarized in many detailed reviews and monographs.^{89, 90, 91} A consensus definition of DIC has been proposed: "DIC is an acquired syndrome characterized by the intravascular activation of coagulation with loss of localization arising from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction."⁹⁰

Etiology and Incidence

DIC has been well documented in association with the disorders summarized in Table 54.4. Several retrospective studies suggest that DIC remains a relatively uncommon entity, but in one large general hospital, its overall incidence was 1 in 1,000 admissions.⁹² The most prevalent etiologic factor was infection,⁹² but in another study, more than 50% of cases were obstetric patients.⁹³ A Japanese study found that in a hospital population, 45% of DIC cases were associated with malignancy.⁹⁴ In many of the disorders listed in Table 54.4, DIC develops only in an occasional case. Thus, it is rare in heatstroke,⁹⁵ autoimmune disorders,⁹⁶ and hemolytic anemias.⁹⁷ DIC is present in most cases of venomous

P.1192

snakebite, which is probably one of the most common causes of the disorder worldwide.

TABLE 54.4 ETIOLOGIES OF DISSEMINATED INTRAVASCULAR COAGULATION**Obstetric complications**

Abruptio placentae,¹⁸⁸ septic abortion and chorioamnionitis, amniotic fluid embolism, intrauterine fetal death, miscellaneous (degenerating hydatidiform moles and leiomyomas, postpartum hemolytic-uremic syndrome, abdominal pregnancy, tetracycline-induced hepatorenal failure, fetomaternal blood passage, saline-¹⁹⁴ and urea-induced¹⁹⁵ abortions)

Infections

Viral (herpes, rubella, smallpox, acute hepatitis, Reye syndrome, cytomegalic inclusion disease, various epidemic hemorrhagic fevers, others)

Rickettsial (Rocky Mountain spotted fever, others)

Bacterial (meningococemia, septicemia, particularly that due to Gram-negative organisms, many others)

Mycotic (histoplasmosis, aspergillosis)

Protozoal (malaria, kala-azar, trypanosomiasis)

Neoplasms

Carcinomas⁹⁸ (prostate, pancreas, breast, lung, ovary, many others)

Miscellaneous (metastatic carcinoid, rhabdomyosarcoma, neuroblastoma, others)

Disorders of the hematopoietic system

Acute leukemia (promyelocytic²¹⁹, other types)

Intravascular hemolysis (transfusion of incompatible blood, paroxysmal nocturnal hemoglobinuria⁶⁰⁷, fresh-water submersion⁶⁰⁸)

Histiocytic medullary reticulosis

Vascular disorders

Malformation (giant hemangiomas [Kasabach-Merritt syndrome]²²⁵, aneurysms, coarctations of the aorta and other large vessels, Takayasu aortitis, large prosthetic arterial grafts,⁶⁰⁹ cyanotic congenital cardiac lesions)

Collagen-vascular disorders⁶¹⁰

Hypoxia and hypoperfusion, myocardial infarction, cardiac arrest,⁶¹¹ various forms of shock, hypothermia

Massive tissue injury

Large traumatic injuries and burns, extensive surgical intervention,⁶¹² extracorporeal circulation, fat embolism⁶¹³

Miscellaneous

Pathophysiology

Mechanisms by Which Disseminated Intravascular Coagulation Is Initiated

The pathophysiology of DIC is complex. The mechanisms that activate or “trigger” DIC act on processes that are involved in normal hemostasis, namely, the processes of platelet adhesion and aggregation and contact-activated (intrinsic) and tissue factor-activated (extrinsic) pathways of coagulation (Fig. 54.2). These mechanisms have in common the capacity, in terms of either the magnitude or the duration of the activating stimulus, to exceed normal compensatory processes. Thrombin is persistently generated, and fibrin is formed in the circulating blood. Fibrinogen, various other coagulation factors, and platelets are consumed. The fibrinolytic mechanism is activated, and large amounts of FDP are produced, which further impair hemostatic function. Bleeding, shock, and vascular occlusion commonly supervene and produce profound alterations in the function of various organ systems. Normal compensatory processes may become impaired, creating a self-perpetuating “vicious cycle.” The ultimate outcome is determined by a dynamic interplay between the various pathologic processes and compensatory mechanisms, in other words, fibrin deposition versus fibrinolysis; depletion versus repletion of coagulation factors and platelets; and production versus clearance of fibrin, FDPs, and other products of coagulation (Fig. 54.3). In most forms of DIC, the initiating factors are multiple and interrelated. For example, in meningococemia, endothelial cell injury may lead to expression of tissue factor and to collagen exposure; the latter then initiates platelet adhesion, aggregation, and thrombosis.

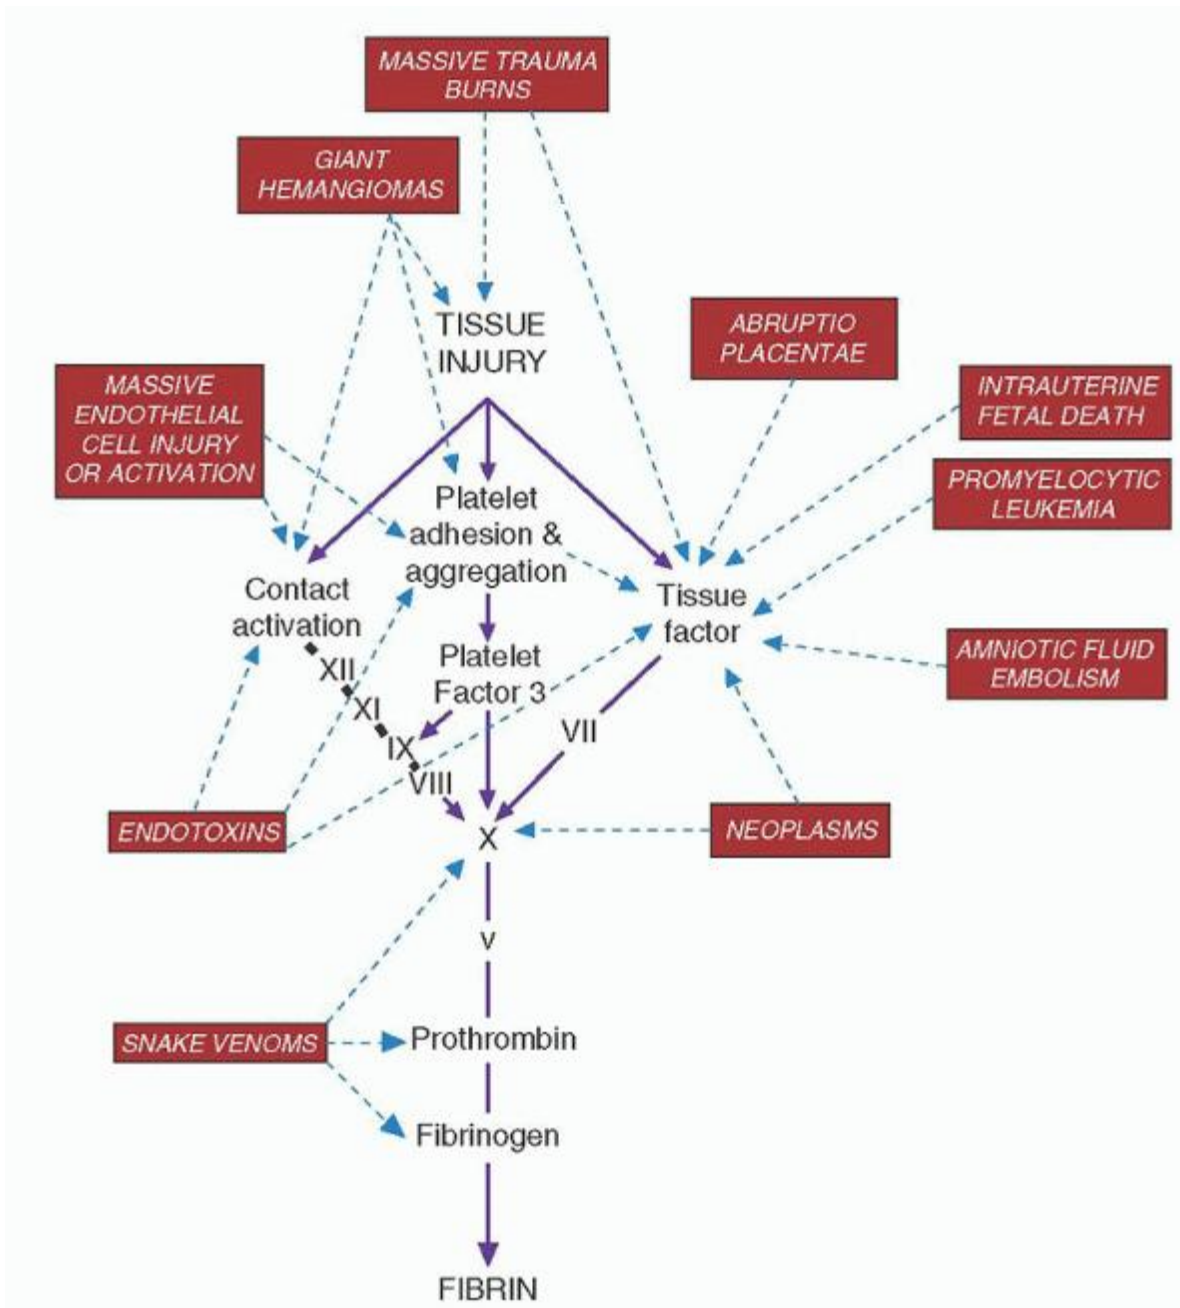

FIGURE 54.2. Initiating mechanisms of disseminated intravascular coagulation (DIC). The solid arrows indicate normal hemostatic pathways, and dotted arrows indicate pathways by which certain disorders associated with DIC initiate or promote the coagulopathy of DIC. Initiation of coagulation by expression of tissue factor activity is probably the most important mechanism triggering DIC.

Tissue Factor

The exposure of procoagulant tissue extracts to blood is a major contributory factor in most forms of DIC and is of major pathogenetic importance in cases associated with abruptio placentae, intrauterine fetal death, acute promyelocytic leukemia, amniotic fluid embolism, massive trauma, and various neoplasms.⁹⁸ The active component of such extracts is tissue factor (thromboplastin); that is, tissue factor interacts with factor VIIa to activate the extrinsic pathway of coagulation.

In abruptio placentae⁹⁹ decidual fragments, serum-containing activated coagulation factors, and other substances from the placental site enter the intervillous “maternal lake” and, hence, the venous circulation. This process is initiated by rupture of the basal decidual plate.

In amniotic fluid embolism, relatively weak thromboplastins that increase in potency with gestational age¹⁰⁰ and large P.1193

amounts of particulate matter enter the circulation suddenly. In intrauterine fetal death, thromboplastic substances from the dead fetus are slowly but continuously absorbed, producing a picture of chronic but progressive DIC.

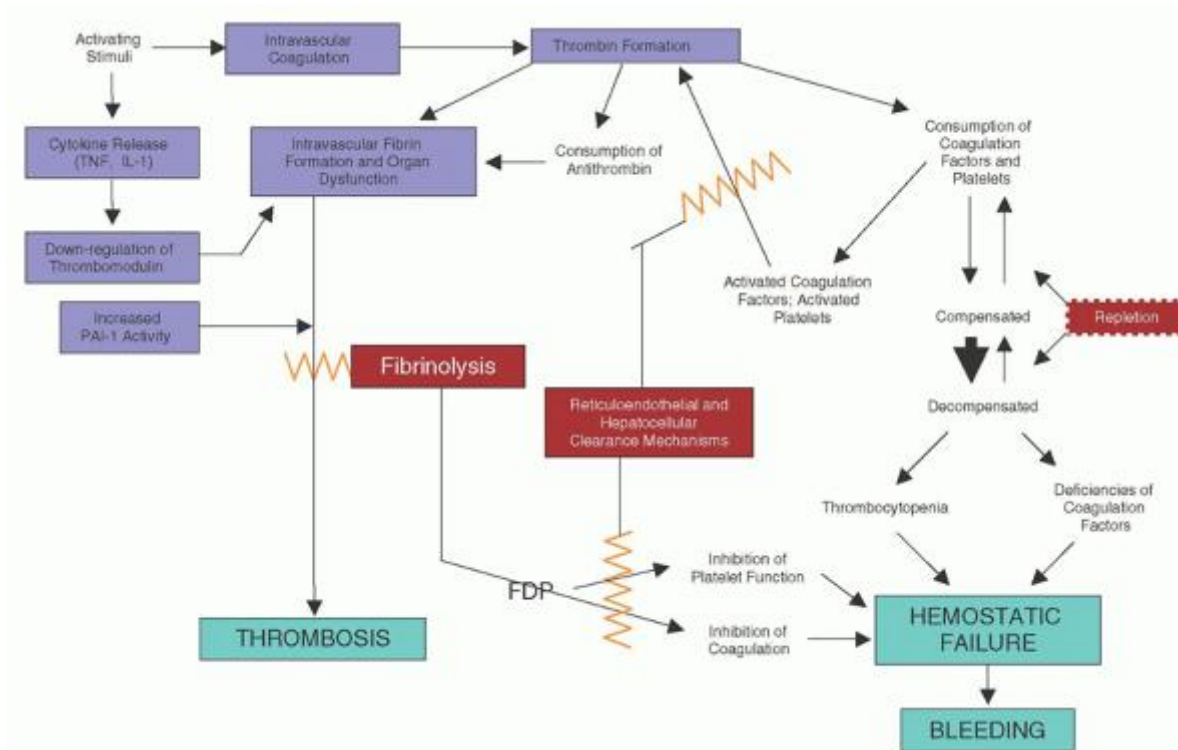

FIGURE 54.3. Pathophysiology of disseminated intravascular coagulation (DIC). The critical event in DIC is the generation of thrombin in an unregulated fashion. The clinical consequences of thrombin production depend on the rate of thrombin formation as well as underlying host factors (marrow reserve of platelet production, liver function). Patients with adequate compensatory responses (ability to enhance platelet or coagulation factor production, fibrinolysis, intact clearance mechanisms) may have minimal symptoms, whereas other patients with defective compensatory responses may bleed, thrombose, or both. Increased levels of cytokines occur (TNF, IL-1) that contribute to the proinflammatory state by down-regulating thrombomodulin activity; this leads to enhancement of intravascular fibrin formation and organ dysfunction. Major compensatory factors that influence clinical events are indicated in colored blocks. The zig-zag line indicates interruption of an adverse clinical event by a compensatory factor. FDP, fibrin(ogen) degradation product; IL-1, interleukin-1; PAI-1, plasminogen activator inhibitor-1; TNF, tumor necrosis factor.

In neoplasms, tumor microemboli and tumor “vesicles”¹⁰¹ are thought to enter the circulation and act as thromboplastins.^{98, 102} Tumor cell surface expression of tissue factor has been demonstrated.¹⁰³ Some neoplasms may secrete a factor X activator.¹⁰⁴

DIC in association with acute leukemia presumably results from the formation or release of tissue factor by leukemic cells.¹⁰⁵ Additional leukocyte enzymes such as elastase may contribute to DIC and fibrin(ogen)olysis by proteolysis of coagulation zymogens and fibrinogen.¹⁰⁶ Malignant promyelocytes, as seen in promyelocytic leukemia, express high levels of annexin II, a phospholipid-binding protein and receptor for plasminogen and tissue plasminogen activator.¹⁰⁷ This overexpression of annexin II results in enhanced plasmin production and increased fibrinolytic activity.¹⁰⁷ The granules of various “blast” forms contain tissue factor, with the promyelocyte containing particularly high concentrations.¹⁰⁵

In DIC associated with massive trauma,¹⁰⁸ major surgical procedures, or large burns, damaged tissue expressing tissue factor activity presumably is a major initiating factor. In such cases, additional abnormalities and complications are important contributory factors, such as “hypercoagulability,” azotemia, shock, intravascular hemolysis, massive transfusions of stored blood, septicemia, and hypoxia. Cerebral trauma of sufficient magnitude to produce significant brain destruction induces a brief episode of DIC, which, although transitory, may be significant in that it may perpetuate cerebral bleeding.¹⁰⁹

Monocyte-associated Procoagulants

It has been known for many years that monocytes and tissue macrophages may, when suitably activated, express substances capable of initiating blood coagulation.¹¹⁰ This phenomenon is thought to be of importance in inflammation and in tissue localization of infectious agents and tumors. It has become apparent that “recognition-coupled” responses of the monocyte-macrophage system¹¹¹ may be important in triggering DIC in association with meningococcemia¹¹² and other forms of septicemia, certain forms of leukemia, major transfusion reactions, and anaphylaxis. The best defined model of this process is the induction of tissue factor by monocytes exposed to endotoxin¹¹³ or immune complexes.¹¹⁴ Other substances that may induce monocyte procoagulant activity include anaphylatoxins¹¹⁵ and cytokines.¹¹⁶ Most of these substances induce the formation of monocyte coagulants only in the presence of T lymphocytes¹¹⁷ and the complement system.¹¹⁵ A prothrombinase-like activity¹¹⁸ and a specific activator of factor X¹¹⁹ also are formed by appropriately conditioned monocytes.

Vascular Endothelium

In addition to monocytes or macrophages, vascular endothelium can be induced to express tissue factor activity in the setting of experimental DIC.¹²⁰ Endothelium can also be down-regulated in

P.1194

terms of anticoagulant properties (e.g., thrombomodulin activity, fibrinolysis) by stimuli relevant in the pathogenesis of DIC (see Chapter 19). This altered endothelium is referred to as activated; properties of activated endothelium include conversion of the normally anticoagulant phenotype to a procoagulant phenotype, expression of adhesion molecules, production of inflammatory mediators, and production of vasoactive agents.¹²¹ Many of these pathologic events are amplified by endothelial cell protease-activated receptors (PARs) (see Chapter 19). Vascular endothelium may also promote coagulation by formation of thrombogenic microparticles, which express anionic phospholipid.¹²² Microparticles in DIC may also originate from platelets or granulocytes.¹²³ Thrombin generation caused by activation of factor XII in DIC appears to be less important than that initiated by tissue factor.¹²⁴ Contact activation, instead, appears critical in mediating DIC-associated hypotension.¹²⁵

Role of Cytokines

Although there are numerous etiologies for DIC (Table 54.4), a common pathway for activation of coagulation by these disorders is cytokine release.⁸⁹ Important mediators include endotoxin, interleukin-1 (IL-1), IL-6, IL-8, platelet activating factor, and tumor necrosis factor (TNF). TNF and IL-1 both increase monocyte and endothelial cell tissue factor activity and inhibit protein C activation. Elevated levels of IL-8 correlate with sepsis mortality and DIC.¹²⁶

Infections

DIC often accompanies septicemia as a result of bacteria that possess potent endotoxins. This correlation has led to the intensive study of the effects of endotoxin on the hemostatic mechanism. Purified endotoxin produces several effects that may lead to DIC, namely, activation of factor XII,¹²⁷ platelet aggregation, inhibition of fibrinolysis, leukocyte aggregation, direct endothelial injury,¹²⁸ cellular induction of tissue factor activity,¹²⁹ and impairment of compensatory clearance

functions. Many of these phenomena may be mediated by the interaction between endotoxin and monocytes, as discussed earlier.

Shock, Hypoperfusion, and Hypoxemia

Shock may favor the development of DIC by potentiating various activating stimuli that ordinarily would not exceed the capacity of compensatory processes and may perpetuate DIC after a transient activating stimulus has been dissipated. Hypoperfusion, even of normal vessels, acidosis, and hypoxemia produce hypercoagulability and favor intravascular platelet aggregation. Furthermore, splanchnic hypoperfusion impairs reticuloendothelial and hepatic clearance functions and is present in virtually all forms of shock. Shock also may impair hepatic synthesis of coagulation factors and thus contribute to the coagulation defect in DIC. Activated neutrophils may generate oxygen radicals and proteases to alter vascular permeability. Vascular injury may also occur with ischemia/reperfusion that elicits inflammatory responses.

DIC in association with giant hemangiomas (Kasabach-Merritt syndrome)¹³⁰ or with aneurysms of the aorta or other large vessels¹³¹ has been attributed to hypoperfusion and stasis in local vascular beds. In Kasabach-Merritt syndrome, large gaps in the endothelium that expose subendothelial collagen and other fibers, together with the induction of thromboplastic substances by poorly supported, recurrently injured vessels within the tumor, also may be important factors leading to the initiation of DIC.

Miscellaneous Activating Stimuli

Snake venoms contain enzymes that may trigger coagulation in unique ways. Such venoms may produce defibrination without affecting other coagulation factors, such as ancrod, an enzyme purified from the venom of the Malayan pit viper (*Agkistrodon rhodostoma*). Other venoms contain thrombinlike enzymes or substances that specifically activate factor X or prothrombin.¹³² Crude venoms also contain substances that act as thromboplastins and produce intravascular red cell hemolysis and massive vascular damage.¹³³ An inventory of the biochemical properties of snake venoms and their constituent enzymes has been summarized elsewhere.^{134, 135}

Consumption of Coagulation Factors and Impaired Anticoagulant Pathways

DIC constitutes a model of accelerated turnover of various coagulation factors, the levels of which at any time are determined by the size of the plasma pool and the differences between the rates at which they are being destroyed and replenished. Results of quantitative studies have demonstrated accelerated turnover rates for platelets, fibrinogen,¹³⁶ and prothrombin. Numerous factors complicate a simple kinetic approach. For example, the depletion of plasma fibrinogen induces a compensatory release of large amounts of fibrinogen into the circulation, possibly from the hepatic-lymphatic system, and also increases the rate of fibrinogen synthesis. Other complexities include impaired hepatic synthesis of coagulation factors and the phenomenon of postdepletion “rebound” and “overshoot.”¹³⁷

Generalizations based on the consumption of coagulation factors during *in vitro* coagulation are not always consistent with laboratory findings in patients with DIC. Plasma levels of factors that are normally consumed, such as fibrinogen, prothrombin, and factors V and XIII, often are reduced in severe DIC, but factors that normally are not consumed also may be deficient, such as factors VII, IX, and X. Prothrombin, which is consumed completely during coagulation *in vitro*, often is at a normal level in patients with DIC. Significant hypoprothrombinemia must reflect either massive and protracted activation of coagulation or complicating factors, because in animals, severe depletion of platelets, fibrinogen, and factors V and VIII results from activation of only 10% of plasma prothrombin.¹³⁸

Proteins other than coagulation factors may be depleted as a result of DIC; those of potential importance include antithrombin,¹³⁹ α_2 -antiplasmin,¹⁴⁰ and plasminogen.¹⁴¹ Plasminogen has great avidity for fibrin and may co-precipitate in fibrin thrombi. In experimental animals, depletion of tissue plasminogen activator, as well as plasminogen, can be produced by the protracted infusion of tissue factor.

Antithrombin is the principal inhibitor of thrombin activity; low levels of antithrombin in DIC result from consumption due to persistent neutralization of thrombin, degradation by elastase released from activated neutrophils, and decreased hepatic synthesis. Other natural anticoagulant pathways—the protein C pathway and tissue factor pathway inhibitor—are also diminished in DIC.¹⁴² Proinflammatory cytokines (TNF, IL-1) down-regulate endothelial cell thrombomodulin activity, resulting in decreased levels of activated protein C (APC). Low levels of APC not only fail to inhibit activation of coagulation (by inactivating factors V_a and VIII_a), but also contribute to failure to down-regulate inflammation. Thus, impairment of the protein C pathway in DIC contributes to the procoagulant and inflammatory phenotype seen in the disorder.

The numerous and diverse defense processes that are mediated by factor XIIa are activated in DIC, including the complement system and the kallikrein system. It has been suggested that the hypotensive effects of bradykinin may

explain the conspicuous presence of hypotension in patients with DIC triggered by activation of factor XII,¹⁴³ for example, that associated with endotoxemia.

Consumption of Platelets

In DIC, the platelet count often is depressed out of proportion to the severity of coagulation abnormalities. Thrombocytopenia may result from processes other than the consumption of platelets in

P.1195

thrombotic lesions. These processes include adhesion to denuded or damaged endothelial cell surfaces and intravascular aggregation with subsequent sequestration, which may be caused by endotoxin, antigen-antibody complexes, thrombin, particulate matter, and, possibly, fibrin-FDP complexes.

All of these agents initiate the platelet release reaction, which may produce a population of partially activated platelets that are depleted of storage nucleotides (acquired storage pool disease). Partially activated platelets may contribute to impairment of clearance functions. Epinephrine and serotonin are released from the platelets and may reach extremely high concentrations in hypoperfused vascular beds. This process may produce sustained constriction of the afferent renal arteriole and may predispose to cortical necrosis. Serotonin also may produce pulmonary and cerebral hypoperfusion.

A mouse model of DIC investigated the role of PARs in mediating the endothelial cell and platelet response to activation of coagulation. In this model of endotoxemia, activation of coagulation occurred, but knockout of PARs failed to improve survival or thrombocytopenia. Although this model may not be extrapolated to human DIC, the possibility is suggested that PARs may not mediate the DIC response, and that thrombocytopenia in DIC may result from mechanisms other than thrombin activation.¹⁴⁴

Intravascular Fibrin Formation

The formation of fibrin, in the form of small strands and "microclots", is the immediate result of DIC; the ultimate consequence of this process is determined by a balance between the rate of fibrin formation and the rate of its clearance from the circulation or lysis by the fibrinolytic enzyme system.

Erythrocytes are injured mechanically during passage through fibrin networks in the microcirculation. Such microangiopathic hemolysis leads to the production of schistocytes and microspherocytes. Erythrocyte damage in metastatic carcinoma appears to be caused mainly by fibrin strands that form around tumor cell emboli as a result of low-grade DIC.¹⁴⁵ It should be noted that red cell fragmentation is not seen in all patients with DIC.¹⁴⁶

Fibrinolysis

Fibrinolysis is present in virtually every patient with DIC, but it generally plays a homeostatic rather than a pathologic role. In the setting of DIC, this "secondary fibrinolysis" is an appropriate response to persistent thrombin generation. Fibrinolysis may be activated by several mechanisms. The major endogenous source of plasminogen activators is in the vascular endothelium of the microcirculation, and in DIC, such activators, especially tissue plasminogen activator, are apparently released as a result of thrombin formation and fibrin deposition on endothelial surfaces, endothelial injury, or hypoxia. Many of the thromboplastic substances that initiate DIC, such as tumor tissues and extracts of leukemic cells, also contain plasminogen activators. The release of plasminogen activators from platelets and leukocytes also may be significant. Finally, factor XIIa activates plasminogen by interacting with normal proactivators and the kinin system.¹⁴⁷

Fibrinolysis must be distinguished clearly from the process of fibrinogenolysis, in which fibrinogen and other coagulation factors are proteolytically destroyed in the circulation. Fibrinogenolysis may be an inappropriate response in DIC associated with amniotic fluid embolism,¹⁴⁸ heatstroke,⁹⁵ and, rarely, carcinoma. It is uncommon in other forms of DIC; when present, it is usually transitory and overshadowed by marked fibrinolysis. Disorders in which fibrinogenolysis arises in the absence of DIC (primary fibrinolysis) are discussed elsewhere in this chapter.

Following the initial enhanced fibrinolytic response to DIC, suppression of fibrinolysis occurs due to elevated levels of plasminogen activator inhibitor-1; this inhibition of fibrinolysis was associated with a poorer clinical outcome.¹⁴⁹

Fibrin(ogen) Degradation Products

The stepwise process by which fibrin is degraded proteolytically and the biologic effects of the various products of the process (FDPs) are discussed in Chapter 18. These protein fragments act as antithrombins,^{53, 54} inhibit fibrin polymerization, produce a structurally defective fibrin polymer,¹⁵⁰ and may impair platelet⁵¹ and reticuloendothelial

clearance functions. The presence of large amounts of FDP in the circulation is a major factor in the production of hemorrhage in many patients with DIC.

The infusion of large amounts of FDP (fragment D) into rabbits produces changes that resemble the posttraumatic respiratory distress syndrome in humans.¹⁵¹ This observation suggests that large amounts of FDP may directly damage the pulmonary vasculature, leading to respiratory distress syndrome, which has been reported in association with DIC and the use of thrombolytic agents.¹⁵² The smallest FDPs are peptides of 3,000 to 4,000 molecular weight that inhibit smooth muscle contractility, an effect that may explain the frequency of uterine inertia in abruptio placentae.¹⁵³

In DIC, a large amount of fibrin remains in a soluble state as a consequence of the formation of complexes between fibrin monomers, various FDPs, and fibrinogen. This solubility has been regarded as a final defense against vascular occlusion. In vitro, the complexes dissociate in the presence of alcohol or protamine sulfate to form gels or precipitates of various types (paracoagulation).

Impairment of Clearance Mechanisms

The numerous processes that normally remove procoagulant material from the circulation are of the utmost importance in DIC because of the presence of massive amounts of both activators and products of coagulation. Most of the products of intravascular coagulation (prothrombinase, platelet factor-3 activity, various types of FDPs and complexes thereof^{154, 155}), as well as various initiators of the process (tissue fragments, endotoxin, antigenantibody complexes, tissue factor, and red cell stroma), are removed from the circulation by the reticuloendothelial system¹⁵⁶ (Fig. 54.3). The Kupffer cells of the liver¹⁵⁷ and splenic macrophages are of particular importance. In certain forms of DIC, large amounts of relatively inert particulate matter (e.g., amniotic fluid embolism) place an additional burden on the reticuloendothelial system. The hepatic cells are of primary importance in the clearance of activated coagulation factors (IXa, Xa,¹⁵⁸ and XIa).

Investigators have suggested that various substances saturate and produce an "autoblockade" of reticuloendothelial and hepatic clearance functions in DIC in a manner comparable to that produced experimentally in the Schwartzman reaction.^{156, 159} This blockade may be an important pathophysiologic factor, particularly in perpetuating DIC after a transient activating stimulus. Shock and endotoxemia, both of which produce significant hepatic hypoperfusion, may contribute indirectly to autoblockade of clearance functions.

Chronic or "Compensated" Disseminated Intravascular Coagulation

Certain forms of DIC result from a weak or intermittent activating stimulus. In such patients, destruction and production of coagulation factors and platelets are balanced (Fig. 54.3). The pathophysiology of such chronic, subacute, or "compensated" DIC is fundamentally the same as that in the acute case. Nevertheless, the distinction is valuable because the clinical picture and laboratory findings in the chronic form are quite variable and may be diagnostically confusing.

Chronic DIC has been described in many patients with intrauterine fetal death or giant hemangiomas (Kasabach-Merritt syndrome) and in many cases of adenocarcinoma.⁹⁸ Other etiologic factors that may produce chronic DIC include various forms of vasculitis, acute leukemia, aneurysms, hemangiomatous transformation of the spleen, and renal allograft rejection.

In cancer patients, a virtually continuous spectrum of clinical and laboratory features has been described; these range

P.1196

from recurrent venous thrombosis or arterial embolism⁹⁸ with high levels of platelets and coagulation factors to acute DIC with severe hemorrhage.⁹⁸ The clinical and experimental evidence is incontrovertible that pregnancy, the best studied form of hypercoagulability, is associated with an increased propensity for the development of DIC.^{160, 161} Indeed, even normal pregnancy has been suggested as a form of low-grade "physiologic" DIC,¹⁶⁰ which, at term, becomes overt for a short time. Thus, transitory but significant elevations of FDP and corresponding diminution in fibrinogen levels are observed regularly during the first 4 hours after delivery.¹⁶⁰ This may be triggered, in part, by the release of tissue factor into the circulation.

Clinical Features

The major clinical features of DIC are bleeding, often of serious magnitude and abrupt onset; a variable element of shock that is often out of proportion to apparent blood loss; and symptoms of hypoperfusion of various vascular beds. Acute renal failure is common, and thromboembolic manifestations often are noted.¹⁶² Any of these features or signs and symptoms of the underlying disorder may predominate in a given case.

Evidence of major organ dysfunction is a common finding in patients with DIC, most often including signs, symptoms, and laboratory evidence of abnormal pulmonary, renal, hepatic, and central nervous system function. Although virtually all of these manifestations have been attributed to the underlying DIC, the clinical manifestations that have been described usually were the result of the underlying disorder. For example, one study observed that patients with DIC due to aortic aneurysm had laboratory features of DIC but minimal clinical manifestations. Patients with DIC due to obstetric disorders all had bleeding, but only 20% had organ dysfunction. In contrast, of patients with DIC due to sepsis, only 15% had bleeding, but 76% had organ failure.⁹⁴ These results suggest that marked heterogeneity exists in clinical manifestations of DIC, and that the etiology of DIC is a major predictor of clinical events.⁹⁴

In this section, the clinical manifestations and diagnosis of DIC are discussed in general terms. Various specific clinical features and details regarding treatment of the most common forms follow in a separate section.

Acute Disseminated Intravascular Coagulation

Bleeding manifestations of virtually every kind have been described, and they may evolve rapidly in the patient with acute DIC. Generalized ecchymoses, petechiae, and bleeding from previously intact venipuncture sites or around indwelling intravenous needles or catheters are noted in many patients. Large, spreading, hemorrhagic skin lesions often are superimposed on familiar exanths in patients with rickettsial and viral infections. "Geographic" acral cyanosis is a prominent feature in some patients. Large, sharply demarcated ecchymotic areas may result from thrombotic occlusion of dermal vessels and may progress to skin infarction. Such infarcts are particularly common in patients with purpura fulminans (Fig. 54.4) and are seen also in coumarin-induced skin necrosis and inherited homozygous deficiency of protein C (see Chapter 55). In patients with meningococcemia, cutaneous hemorrhage may be striking. Bleeding from apparently normal gingivae, epistaxis, gastrointestinal bleeding, pulmonary hemorrhage, and hematuria are common. In patients who develop DIC after surgical procedures, alarming hemorrhage may develop around drains and tracheostomies, and accumulations of blood may be concealed in serous cavities.

Chronic Disseminated Intravascular Coagulation

Superficial but extensive ecchymoses of the extremities, often without petechiae, may develop intermittently or may persist. Recurrent episodes of epistaxis or more serious internal mucosal bleeding may punctuate the course. Trousseau sign (recurrent migratory thrombophlebitis in association with cancer) in most instances is a manifestation of chronic DIC. More serious hemorrhagic manifestations may develop as the underlying disease progresses or may arise with dramatic suddenness after surgical procedures such as a prostatectomy. Acute DIC may be heralded by further thrombophlebitis or pulmonary emboli. In some patients, evidence of vascular obstruction (e.g., impairment of renal function, confusion, transitory neurologic syndromes, or repeated episodes of cerebral thrombosis) may develop with minimal bleeding.

FIGURE 54.4. Purpura fulminans in infection-associated disseminated intravascular coagulation. Early lesions (A) are circumscribed; progressive lesions (B) may become necrotic. (From Dudgeon DL, Kellogg DR, Gilchrist GS, et al. Purpura fulminans. *Arch Surg* 1971;103: 351-358; copyright 1971, American Medical Association.)

Laboratory Diagnosis

The laboratory findings in DIC are summarized in Table 54.2. Contrary to what is commonly assumed, they may be quite variable. The plasma fibrinogen level, PTT, PT, platelet count, and estimates of FDP or D-dimer are the cornerstones on which the diagnosis of DIC is based. These simple tests should always be performed first. Additional information may

confirm, but seldom refutes, the diagnosis of DIC if typical abnormalities are demonstrated by these tests. Laboratory data may change with remarkable rapidity in DIC, based on disease progression or therapy.

Laboratory data must be interpreted with caution. Levels of platelets and various coagulation factors, fibrinogen, and factor VIII, in particular, may be elevated in many of the conditions associated with DIC, including pregnancy. Thus, a fibrinogen level of 200 mg/dl, although within the normal range determined in

P.1197

healthy subjects, may represent a significant decrease in a patient whose baseline level was 800 mg/dl due to acute-phase changes.

The best test for diagnosing DIC is the D-dimer assay. The semiquantitative method is sensitive,¹⁶³ and D-dimer values >2,000 ng/ml have been reported to be consistent with DIC.¹⁶⁴ More sensitive, quantitative D-dimer assays are now available; one study reported that a sensitive D-dimer assay result <8.2 µg/ml optimized sensitivity and negative predictive value in patients with DIC.¹⁶⁵

A new test, measurement of the biphasic waveform in the PTT assay, has been reported to precede development of DIC and to predict DIC better than the D-dimer assay.¹⁶⁶ The biphasic waveform results from the formation of a precipitate on plasma recalcification; the precipitate contains very-low-density lipoprotein complexed with C-reactive protein. If confirmed in clinical outcome studies, this assay may be a useful addition to laboratory tests for DIC.

Basic Blood Examinations

In patients with DIC, routine hematologic tests may reveal evidence of acute bleeding, accelerated red cell destruction, or signs of the underlying disease. Examination of the blood smear reveals schistocytes in approximately 50% of cases,^{93, 146} but the degree of schistocytosis bears no necessary correlation with other facets of the disorder. More subtle evidence of intravascular hemolysis often is found, such as increased serum levels of lactic acid dehydrogenase and diminished haptoglobin levels. Rarely, massive intravascular hemolysis with hemoglobinemia and hemoglobinuria is noted.¹⁴⁴

Thrombocytopenia is an early and consistent sign of acute DIC, and the consideration of this diagnosis in the presence of a persistently normal platelet count is difficult. Platelet counts in the range of 50,000 to 100,000/µl are the usual finding, but thrombocytopenia may be severe.

Coagulation Defect

The PTT, PT, and thrombin time are prolonged in most patients with acute DIC. Early in the course of the disorder and in chronic DIC, the PTT may be normal or even shorter than normal, which may be the result of the procoagulant effects of activated coagulation factors or elevated factor VIII levels.

Occasionally, one can follow the process of DIC from its inception, and specific assays for various coagulation factors obtained at the time of diagnosis reveal a variable and rapidly changing picture. The plasma levels of fibrinogen and of factors V and XIII usually are significantly depressed; fibrinogen and factor V are the most consistently affected.¹⁶⁷ The level of factor X may be lower than that of other "stable" factors (factors VII, IX, and XI), which usually are present in normal amounts.¹⁶⁷ In many patients, particularly those with abruptio placentae, normal prothrombin levels are maintained,^{99, 167} but marked hypoprothrombinemia often is present in those with septic DIC.¹⁶⁸

The levels of factors VIII, IX, and XI as determined by onestage assays may fluctuate widely as the result of the presence of activated factors¹⁶⁹ such as thrombin and factor Xa.¹⁶² This problem is minimized in two-stage assays.¹⁶⁷ Levels of factor VIIIc often are normal or increased, particularly when assayed by twostage techniques.¹⁷⁰ In many patients, the levels of coagulation factors tend to "overshoot" after repletion. As a consequence of the inhibitory effects of FDPs, the thrombin time may be prolonged out of proportion to the reduction in the fibrinogen level.

Tests for Fibrinolysis: Fibrin Monomers, Fibrin(ogen) Degradation Products, and D-Dimer

In most patients with DIC, FDP levels as determined by quantitative methods, such as red cell hemagglutination inhibition or latex agglutination, are 25-µg fibrinogen "equivalents"/ml or higher.¹⁶⁷ All methods are most sensitive to large or "early" FDPs. These fragments, particularly fragment X, retain thrombin-binding sites or may form a complex with fibrinogen and consequently be removed during the preparation of serum for FDP tests. This phenomenon or the presence of only small FDPs may explain the normal levels of FDPs in some patients with otherwise typical DIC.

Fibrinopeptide A and certain fibrinogen fragments that are formed by the lysis of cross-linked fibrin, such as the DD-dimer and the DD-dimer-E complex, can be demonstrated by using special techniques. These latter FDPs provide direct evidence

of the action of thrombin on fibrinogen and provide a means of differentiating fibrin degradation products from fibrinogen degradation products.^{171, 172}

The simplicity, specificity, and sensitivity of the D-dimer test have led many laboratories to replace less sensitive or less convenient tests for DIC with the D-dimer test. Because false-positive results may be seen with FDP latex agglutination tests in patients with dysfibrinogenemia, the D-dimer test may be more specific in diagnosing DIC, especially in distinguishing the coagulopathy of liver disease from DIC.^{65, 163, 173} False-positive D-dimer latex agglutination tests may occur in patients with elevated levels of immunoglobulin M (IgM) (rheumatoid factor).

“Paracoagulation” techniques are simple to perform, but they are less specific than tests for FDPs. The results of the ethanol gelation test, in particular, often are negative in DIC. To the contrary, results of protamine gelation tests usually are positive,¹⁷⁴ but abnormal results are obtained in numerous other disorders, including many that commonly are associated with DIC.

Other Laboratory Findings

Plasma levels of fibrinopeptide A¹⁷⁵ and the rate of incorporation of ¹⁴C-labeled glycine ethyl ester into soluble “circulating fibrin”¹⁷⁶ are exceptionally sensitive indicators of DIC and may be abnormal even in patients with normal levels of FDP. Levels of antithrombin,¹⁷⁷ α_2 -antiplasmin, and proteins C and S may be diminished in some cases.

Other parameters of activation of coagulation and fibrinolysis have been studied in DIC, especially in sepsis. Thrombin-antithrombin III (TAT) complexes and plasmin- α_2 -antiplasmin (PAP) complexes are often elevated in sepsis-associated DIC. Assays such as TAT and PAP complexes may have prognostic significance in DIC, as may other coagulation parameters, including plasminogen activator inhibitor type-1, vWF antigen, and α_2 -antiplasmin.¹⁷⁸ In a primate model of Gram-negative sepsis, a number of molecular markers of coagulation were investigated for their use in monitoring DIC.¹⁷⁹ Markers such as soluble thrombomodulin and soluble fibrin monomer are useful in assessing the status of microvascular injury.

The clinical role of these assays in diagnosing or managing DIC patients at this time is uncertain. The best test for diagnosis and monitoring DIC appears to be a sensitive D-dimer assay; the PTT waveform analysis may also prove to be a useful test. The International Society on Thrombosis and Haemostasis (ISTH) has proposed clinical and laboratory criteria to better define the spectrum of DIC cases.^{90, 180}

Differential Diagnosis

The syndrome of DIC is seldom difficult to recognize. Problems arise when the diagnosis simply is not considered or in chronic forms, when the underlying coagulation disorder may be masked by features of the basic disease or by thromboembolic complications.¹⁸¹

Two disorders, however, produce laboratory abnormalities that resemble DIC: Severe liver disease, which is common, and primary fibrinogenolysis or “pathologic” fibrinolysis, which is rare (Table 54.2).

In patients with primary fibrinogenolysis, the following conditions may be evident: Hypofibrinogenemia; increased levels

P.1198

of FDP; abnormalities of the PTT, PT, and thrombin time; and deficiencies of factors V and VIIIc. The euglobulin lysis time is significantly and persistently shortened, often in association with plasminemia. However, the platelet count usually is normal, the D-dimer level should be normal or only minimally elevated, and protamine sulfate tests should be negative. Hypoprothrombinemia and deficiencies of stable coagulation factors VII, IX, X, and XI are rare. Thus, routine coagulation tests should be able to distinguish DIC from primary fibrinogenolysis.

In patients with liver disease, coagulation abnormalities and thrombocytopenia may originate from many pathologic processes (Table 54.3). Chronic or intermittent fibrinogenolysis with high levels of FDP is common, particularly in patients with cirrhosis. In such patients, the exclusion of the diagnosis of DIC may be difficult. Factor VIIIc levels usually are elevated when liver disease is severe, and the levels of factors VII and IX typically are low. A helpful test in discriminating between the coagulopathy of liver disease and DIC is the D-dimer test, the results of which should be abnormal in DIC but normal in liver disease (unless additional disorders coexist^{65, 173}).

DIC, particularly that associated with carcinoma, may be confused with various microangiopathic hemolytic anemias, such as thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome; in these disorders, the clinical picture may resemble that of DIC in many respects. High levels of FDP may be encountered in patients with microangiopathic hemolytic anemias, but significant coagulation abnormalities are not commonly present. Many other disorders may produce slight to moderate elevations of FDP: For example, pulmonary embolism and chronic renal disease with uremia.

Moderate thrombocytopenia is a common consequence of the use of extracorporeal circulatory devices, and coagulation abnormalities often are noted immediately after their use because of the presence of residual heparin. Heparin levels also may rise several hours later (the rebound phenomenon). In such patients, the presence of thrombocytopenia together with the effects of heparin may be confused with DIC; similar difficulties may arise after hemodialysis. Even the small amounts of heparin required to irrigate indwelling catheters, or to contaminate Hickman catheters, are a common cause of "pseudo-DIC."

Treatment

DIC always is the end result of a serious underlying disorder. Although the patient may benefit greatly from the replacement of depleted coagulation factors and platelets, correction of the syndrome depends on prompt and energetic treatment of the primary disorder. This—not the therapeutic measures described in this section—remains the cornerstone of therapy.

Anticoagulants

Heparin is a specific activator of the physiologic antithrombin system and thereby inhibits a number of proteolytic enzymes, including factors IXa and Xa and thrombin (see Chapter 55). The therapeutic efficacy of heparin is unquestionable in some animal models of DIC, but assessment of its effectiveness in humans has proved more difficult. In view of the complexity of DIC, inhibition of coagulation alters only one facet, albeit a fundamental one, of the pathophysiologic cycle. Recent appreciation of the role of anticoagulation and inflammatory pathways has led to consideration of novel therapies, including replacement of anticoagulant proteins such as antithrombin and APC.¹⁴²

In patients with chronic DIC, the results of heparin therapy usually are favorable and may be dramatic. In most patients, heparin would not be expected to alter ultimate mortality because of the nature of the underlying diseases; however, this drug typically does reduce the severity of bleeding and thromboembolic manifestations and produces parallel improvement in the abnormalities of laboratory test values. Elevated levels of D-dimer and FDPs drop rapidly, and accelerated fibrinolysis, if present, disappears after the administration of heparin, often before the coagulation defect has been alleviated. The response of the platelet count to heparin therapy for DIC is slow and often erratic.

In patients with acute DIC, particularly that associated with sepsis, the results of heparin therapy have been less encouraging.¹⁸² Most clinicians are reluctant to use heparin in patients with acute DIC. Because baseline PTT values are usually prolonged in acute DIC, heparin levels may be required to monitor therapy (see Chapter 55).

Replacement Therapy with Platelets and Coagulation Factors

Many patients with DIC ultimately receive large amounts of blood products, even though evidence is only anecdotal that they are necessary or therapeutically effective.¹⁸³ The major aim of replacement therapy with blood products in DIC is to replenish fibrinogen. This goal is best accomplished by the administration of cryoprecipitate, each unit of which contains approximately 250 mg of fibrinogen.¹⁸⁴ The amount of cryoprecipitate given should be sufficient to elevate the plasma fibrinogen level to at least 100 to 150 mg/dl. As a general guide, 3 g of fibrinogen can be expected to raise the plasma level of an adult patient approximately 100 mg/dl. Fibrinogen administration probably should be restricted to the occasional patient with hypofibrinogenemia and significant bleeding, in whom DIC is self-limited or has been controlled by heparin therapy (e.g., in intrauterine fetal death before surgical intervention). Sterile fibrinogen concentrates are not yet available for routine therapeutic use in the United States.

Patients with DIC, bleeding, and platelet counts $<50,000/\mu\text{l}$ should be considered for platelet transfusion. Due to the acquired storage pool defect seen with DIC, as well as FDP inhibition of platelet function, DIC patients may require a higher platelet count for adequate hemostasis than patients with thrombocytopenia in the absence of platelet dysfunction.

The availability of purified, sterile antithrombin concentrates has led to its investigation in treating DIC. As seen in most studies,¹⁸⁵ although antithrombin concentrates can normalize plasma levels of this protein in patients with DIC and improve hemostasis parameters, consistent clinical benefit in terms of survival is not evident. A large clinical trial demonstrated that high-dose antithrombin therapy in patients with sepsis had no effect on mortality.¹⁸⁶ A post hoc analysis of this clinical trial indicated that high-dose antithrombin therapy may be effective in improving survival in the subset of patients with severe sepsis and high risk of death, especially if concomitant heparin treatment is avoided.¹⁸⁷ Prospective studies will be important to confirm this subgroup analysis.

Other Therapeutic Measures

Treatment of shock should be immediate and vigorous in all patients with DIC. Packed erythrocytes should be given promptly if indicated. The indiscriminate use of ϵ -aminocaproic acid (EACA) and other antifibrinolytic drugs should be discouraged. Because of the potential risks, fibrinolytic enzyme inhibitors should be administered only to carefully selected patients, that is, those in whom DIC has resulted from a transitory stimulus or has been arrested by heparin administration and in whom fibrinogenolysis or inappropriate fibrinolysis, hypofibrinogenemia, and adequate renal function have been clearly documented. The therapeutic use of EACA in fibrinogenolysis and appropriate dosage schedules are discussed elsewhere in this chapter.

P.1199

Specific Features of Various Forms of Disseminated Intravascular Coagulation

Obstetric Disorders

Abruptio Placentae

DIC complicates abruptio placentae in approximately 10% of cases¹⁸⁸ in which fetal compromise occurs. Shock develops rapidly, but vaginal bleeding may be minimal or absent for a time and bears little relationship to the extent of abruption. Brisk external hemorrhage may originate from episiotomies and lacerations, and large amounts of blood may be concealed behind the placenta and within the wall of the uterus. Severe placental abruption associated with fetal death is often linked with DIC.¹⁸⁹

Hemorrhage is the major factor leading to shock and renal complications in abruptio placentae, and the most essential therapeutic measures are the vigorous treatment of blood loss and the prompt evacuation of the uterus. Extensive replacement therapy seldom is required. Often, fibrinogen replacement is given if immediate surgical treatment is necessary. Fibrinogen replacement may be most useful in patients with fetal death requiring cesarean delivery. If the coagulation defect and thrombocytopenia are severe or persist for an unusually long time, the administration of platelets, fibrinogen in the form of cryoprecipitate, and fresh frozen plasma¹⁹⁰ may reduce hemorrhage. Most obstetricians do not administer heparin because it may increase bleeding and because rapid spontaneous remission of DIC is usual when the uterus is evacuated.

Intrauterine Fetal Death

In the event of intrauterine fetal death, definite laboratory abnormalities are not seen until the dead fetus has been retained for ≥ 5 weeks¹⁸⁸; plasma levels of FDPs then begin to rise, and the platelet count and fibrinogen level gradually decline. Bleeding may be inconspicuous, but a progressive loss of renal function is not uncommon. In most women in whom delivery of the dead fetus is induced promptly according to usual obstetric practice, bleeding is not serious, even in the presence of low-grade DIC. Operative intervention is dangerous when hypofibrinogenemia is severe, and such patients should receive heparin until safe fibrinogen levels are restored.¹⁹¹ If immediate surgery is imperative, heparin administration should be followed by platelet replacement and enough fibrinogen, in the form of cryoprecipitate, to produce plasma fibrinogen levels of 150 mg/dl or greater.¹⁹²

Amniotic Fluid Embolism

In women who survive amniotic fluid embolism (mortality rate of up to 80% in early studies), DIC with severe hemorrhage may develop within 1 to 2 hours.^{162, 193} More recent surveys indicate a mortality rate of 20% to 30%¹⁹⁴; 50% of patients with amniotic fluid embolism had DIC.¹⁸⁸ Often, the syndrome is complicated by significant fibrinolysis and even fibrinogenolysis.¹⁴⁸ Hypoxia and other sequelae of pulmonary vascular obstruction dominate the clinical picture and usually determine the outcome. The release of serotonin and other vasoactive substances from platelets may contribute to the profound pulmonary vasoconstriction.

Miscellaneous Obstetric Disorders

Intravascular coagulation has been documented after abortions induced by intra-amniotic injection of hypertonic saline solutions¹⁹⁴ and hypertonic urea,¹⁹⁵ but it apparently does not complicate abortions performed by suction curettage or those induced by prostaglandin F₂ α .

Disseminated Intravascular Coagulation in Neonates and Infants

Several disorders unique to the neonate and infant may be associated with DIC (Table 54.2).¹⁹⁶ The transplacental passage of thromboplastins or other procoagulant substances has been the apparent cause of DIC in neonates born of mothers

affected with DIC owing to abruptio placentae, eclampsia, or septicemia. Asphyxia may be a common precipitating factor for DIC in these disorders.¹⁹⁷ Bacterial infection and generalized viral infections (e.g., herpes simplex, cytomegalic inclusion disease, and rubella), acidosis, and hypoxia are more common causes of DIC in infants than in adults.¹⁹⁸ DIC secondary to giant hemangiomas and purpura fulminans has been reported in neonates.

Management of septic DIC in the neonate should emphasize treatment of underlying infection. A controlled study that compared treatment with heparin, extensive replacement therapy with blood products, and supportive care only revealed no significant differences in outcome for the three groups.¹⁹⁹ A more recent study confirms that clinical trials in neonatal sepsis have not identified a beneficial therapy.²⁰⁰

The diagnosis seldom is difficult, but DIC must be distinguished from septic shock, endotoxin shock, or simple thrombocytopenia, all of which may develop independently of DIC in severe infections.²⁰¹

In many patients, no additional measures other than treating infection and shock (if present) are required. No evidence has been cited that heparin has diminished mortality.¹⁶⁸ In one series, the alleviation of septic shock appeared to be more important in the ultimate prognosis than did correction of the coagulation abnormalities.¹⁶⁸ Recombinant APC (r-APC) was demonstrated in one study to reduce mortality in adult patients with sepsis²⁰²; however, a Cochrane database review of the effects of r-APC in neonates with sepsis concluded that there were insufficient data to support the use of the drug in the pediatric setting.²⁰³ Subsequent studies in adult patients demonstrating no clinical benefit of r-APC in sepsis led to withdrawal of this drug.

Purpura Fulminans

The hemorrhagic manifestations of purpura fulminans develop several days after an acute infection; these are most commonly scarlet fever or various viral respiratory diseases. Purpura fulminans is most common in children but is also well documented in adults. The most common manifestations are symmetric ecchymoses of the lower extremities and buttocks, sharply circumscribed infarcts of the skin and genitalia, and gangrene of the extremities that often involves the digits symmetrically.²⁰⁴ These ecchymotic lesions often become necrotic, ultimately forming blood-filled bullae (Fig. 54.4). Petechiae are rare. Fever and prostration are seen, but visceral lesions, including renal involvement, are relatively uncommon.

The mortality rate associated with purpura fulminans ranges from 18%²⁰⁵ to 40% to 70%.²⁰⁶ Heparin in therapeutic doses has often proved therapeutically effective, and it has been suggested that poor results obtained previously with this anticoagulant reflect late treatment of moribund patients. In patients with purpura fulminans, relapses are particularly common after cessation of heparin therapy,²⁰⁵ and the administration of this anticoagulant, possibly in reduced doses, should always be continued for 2 to 3 weeks. The subject of purpura fulminans diagnosis and treatment has been recently reviewed.²⁰⁷ Evidence that purpura fulminans may be a manifestation of homozygous protein C deficiency is discussed in Chapter 55. The efficacy of protein C in patients with sepsis and purpura fulminans is discussed below.

Neoplastic Disorders

Carcinoma

In patients with DIC associated with carcinoma, the clinical picture is quite variable and often consists of a combination of bleeding and thromboembolic phenomena, including arterial embolism.^{98, 102, 103} The association of chronic DIC,

P.1200

thromboembolism, and cancer is often called Trousseau syndrome.⁹⁸ Laboratory findings are variable. Evidence of chronic DIC, hypercoagulability, or acute DIC may be found. In a study of more than 1,000 patients with solid tumors, 7% were diagnosed with DIC using standard coagulation tests (platelet count, fibrinogen, D-dimer, FDPs).²⁰⁸ Risk factors associated with the occurrence of DIC included older age, male gender, advanced disease, breast cancer, and necrosis of the tumor specimen.²⁰⁸

One reason for the variability in cancer patients having venous thromboembolism relates to the histology of the malignancy. Analysis of a very large database of Medicare patients with cancer identified tissue-specific differences in thrombotic risks among cancers.²⁰⁹ Those cancers with a high risk of thrombosis included uterine, brain, leukemia, ovary, and pancreas (twofold or greater risk), whereas prostate, liver, head or neck, bladder, and breast cancer had less than a onefold risk (compared to noncancer patients).²⁰⁹

DIC in association with carcinoma resolves with effective treatment of the underlying tumor. Heparin or low-molecular-weight heparin (LMWH) in therapeutic doses has proved effective in controlling the hemorrhagic and thromboembolic

symptoms.^{98, 102, 210} There is a suggestion in the literature that the use of LMWH therapy is associated with improved mortality in cancer patients. A large European study of patients with noncurable solid tumors evaluated the survival effects of a LMWH (nadroparin) given in therapeutic dose for 2 weeks followed by half-dose for 4 weeks.²¹¹ There was significant improvement in survival in the LMWH group with minimal toxicity.²¹¹ The basis for this antitumor activity of LMWH may not relate to anticoagulant activity.²¹² A recent Cochrane literature review of the effects of anticoagulation on cancer patient survival found improved survival after 24 months, but not 12 months.²¹³

A significant minority of patients with cancer and thrombosis will experience recurrent thrombosis with oral anticoagulation⁹⁸ and will benefit from long-term heparin or LMWH.²¹⁴ Based on these data, optimal anticoagulant therapy for cancer patients with thrombosis is LMWH. In the case of DIC associated with prostate cancer, adjunctive therapy with ketoconazole²¹⁵ or antiandrogens²¹⁶ may be useful.

An animal model of cancer has provided evidence that tumors may activate coagulation through overexpression of the MET oncogene.²¹⁷ When MET-induced carcinogenesis was established in mice, a hypercoagulable state resulted. Inhibition of the activated MET oncogene may be a potential therapeutic target in patients with cancer and DIC. The spectrum of mechanisms of thrombosis in Trousseau syndrome has been reviewed.²¹⁸

Acute Promyelocytic Leukemia

DIC has been reported in association with all forms of acute leukemia, but it is most common in the “hypergranular” promyelocytic variety,²¹⁹ in which it may occur in 60% to 100% of cases. The cause of the coagulopathy is multifactorial: Tissue factor is present in the granules of the abnormal promyelocytes¹⁰⁵ as well as leukocyte proteases, including elastase.²²⁰ Enhanced fibrinolysis also results from increased promyelocyte expression of annexin II, a receptor for plasminogen and tissue plasminogen activator.¹⁰⁷ Additionally, the malignant promyelocytes contain plasminogen activators.²²¹ The clinical picture usually is one of chronic progressive DIC with a significant fibrinolytic component that may antedate the other manifestations of the disease. Acute fulminant DIC may develop spontaneously or may be triggered by the administration of chemotherapeutic agents, which cause the release of thromboplastic contents of the promyelocytes.

In some patients with acute leukemia, accelerated fibrinolysis is a conspicuous finding. In one study, depletion of α_2 -antiplasmin developed during induction of chemotherapy, a finding that was more predictive of bleeding complications than traditional indices of DIC, such as levels of fibrinogen, antithrombin, and plasminogen.²²² This study suggests that “unregulated” fibrinolysis, by destroying functional hemostatic plugs and depleting fibrinogen, may be more important than DIC in some cases.

In the past, heparin has produced clear-cut remissions in patients with chronic forms of DIC associated with acute leukemia. An earlier approach²²⁰ recommended fibrinogen replacement therapy for fibrinogen levels <100 mg/dl and platelet transfusion for platelet counts <20,000/ μ l. Fresh frozen plasma is given to patients with prolonged PT and PTT values who are bleeding. If the fibrinogen level is difficult to maintain over 100 mg/dl, or if FDP levels are rising, heparin is infused at 500 U/hour.²²⁰ When α_2 -antiplasmin levels are below 30% of normal, EACA or another antifibrinolytic agent should be added to this regimen,²²² and α_2 -antiplasmin levels should be monitored during induction of chemotherapy.

A newer approach that has virtually replaced the need for heparin and antifibrinolytic agents in the treatment of acute promyelocytic leukemia is the early administration of all-trans retinoic acid.²²³ However, these patients still may require replacement therapy for hypofibrinogenemia and thrombocytopenia.²²³ Current protocols for acute promyelocytic leukemia combine all-trans retinoic acid and combination chemotherapy (or arsenic trioxide) to ameliorate the coagulopathy; all-trans retinoic acid is more effective than chemotherapy alone in improving the coagulopathy.²²⁴

Kasabach-Merritt Syndrome (Giant Hemangiomas)

The severity and incidence of DIC tends to parallel the size of the vascular tumors in the Kasabach-Merritt syndrome.²²⁵ Platelet consumption, activation of coagulation, and microangiopathic red cell destruction take place mainly within the hemangioma (“sequestered” or localized intravascular coagulation), but laboratory evidence of DIC in the general circulation usually is clearcut.^{130, 225} Recurrent bleeding from the surface of the tumor is the major hemorrhagic manifestation; in the presence of DIC, this bleeding may be intractable. Periodic swelling of the lesions often is observed. This phenomenon may be a consequence of intermittent obstruction of blood outflow from the hemangioma and may provoke serious hemorrhage. Irradiation and corticosteroids have produced favorable results in a few cases, but surgical removal of the tumors has ultimately been required in most patients.²²⁵ Interferon- α has been successful in large numbers of patients; this cytokine probably acts as an antiproliferative/antiangiogenic agent.²²⁵ Antifibrinolytic therapy has been reported to be useful in controlling the coagulopathy.^{226, 227} Other useful therapies include cryoprecipitate and platelets for replacement therapy to correct a severe coagulopathy. The use of heparin therapy is uncertain.²²⁵

For patients with aneurysms associated with DIC, LMWH has been reported to be useful in resolving the coagulopathy.²²⁸

Shock and Massive Trauma

Heparin therapy may be hazardous for patients with massive injuries. Even in the face of DIC, intensive supportive care and replacement therapy with plasma and platelets are the mainstays of treatment.²²⁹

Hemolytic Transfusion Reactions

DIC is present in many patients with hemolytic transfusion reactions. Severe, acute hemolytic transfusion events are triggered by antigen-antibody reactions that initiate complement activation and activation of coagulation. These reactions are usually a result of ABO incompatibility. These patients may experience not only DIC, but also shock and renal failure. Primary therapy is directed to control of hypotension and restoration of renal blood flow. Fluid, diuretics, and dopamine may be useful therapies. Heparin therapy for DIC in hemolytic transfusion reactions is controversial.²³⁰

P.1201

Snakebite

DIC associated with snakebite differs from the usual form of the syndrome in several respects. Hemorrhage may be relatively inconspicuous,²³¹ even in the presence of incoagulable blood. When present, it is mainly the result of a vascular toxin. Platelets often are spared, although the venom of the timber rattlesnake (*Crotalus horridus horridus*) contains a unique serine protease that acts as a potent platelet activator.²³² In some cases, a disorder manifested mainly by brisk fibrinolysis in the absence of evidence of DIC has been described.²³³ The specific coagulopathy seen in individual patients in large part depends on venom constituents present in the particular snake species. Detailed lists of venom constituents affecting hemostasis have been published.^{132, 134, 135}

The treatment of snakebite involves the administration of specific antivenom and intensive supportive care. Heparin therapy has proved marginally effective at best.^{231, 234} In general, it is not indicated when specific antivenom is available. Cryoprecipitate should be given to maintain the fibrinogen level over 100 mg/dl.

Pathology

The fatality rate associated with DIC is up to 60%.²³⁵ In many cases, death is attributed to bleeding or thrombosis. Mortality increases with age, underlying co-morbidities, the number of clinical manifestations, and the severity of laboratory abnormalities.

The deposition of fibrin in small vessels represents the ultimate result of DIC. In many patients, fibrin can be formed and lysed without significant vascular occlusion. Indeed, at autopsy, fibrin thrombi in some subjects were absent or were demonstrated only with special stains or by electron microscopy. This may result from postmortem lysis or from deposition of thin films of fibrin on the vast endothelial surface and on the erythrocytes. The localization of fibrin thrombi varies somewhat with the cause of DIC. The kidney is the single most common site of fibrin thrombi. Renal lesions range from patchy tubular necrosis to massive bilateral cortical necrosis and have been attributed to a sieving effect of the renal microvasculature. Nonthrombotic endocarditis and pulmonary hyaline membranes have been found in many patients,^{98, 236} especially those with cancer.

Emerging Therapies for Disseminated Intravascular Coagulation

The recognition of pathogenic mechanisms critical in initiation or progression of DIC has led to investigation of new therapeutic agents in animal models of DIC and clinical trials in humans. For example, protease inhibitors such as aprotinin²³⁷ or gabexate²³⁸ have been studied. However, survival advantages have not been shown with these agents. Similarly, high-dose antithrombin replacement therapy had no effect on mortality in patients with severe sepsis.¹⁸⁶

The key role of tissue factor in triggering DIC²³⁹ has led to studies in which neutralizing antibodies to this procoagulant were found to prevent lethal septic shock in animal models.^{240, 241} Two published clinical trials in sepsis patients used tissue factor pathway inhibitor as therapy; there was no significant benefit observed.²⁴²

The role of protein C in ameliorating the mortality of sepsis has also been demonstrated; neutralization of protein C activity in an animal model exacerbated the lethal response,²⁴³ and infusion of protein C²⁴⁴ or APC²⁴³ prevented the lethal response in humans with meningococemia or in a primate model, respectively. APC had previously been demonstrated to improve survival in sepsis²⁰²; subsequent studies demonstrated no clinical benefit of the drug, and it is no longer available.

PRIMARY FIBRINOLYSIS (FIBRINOGENOLYSIS)

Fibrinolysis is an appropriate response to thrombosis and necessary in the re-establishment of blood flow. This localized response, termed physiologic fibrinolysis, is discussed in Chapter 18. The term pathologic fibrinolysis has been used indiscriminately to refer to any situation in which *in vitro* evidence of fibrinolysis was associated with bleeding. In retrospect, it seems probable that fibrinolysis in many cases was secondary to DIC and that in others it represented an essentially physiologic response to anoxia, shock, or stress. In fibrinogenolysis, on the other hand, the proteolytic destruction of fibrinogen and other proteins occurs in the general circulation, and severe bleeding may develop. The pathophysiology of fibrinogenolysis may represent a disproportionate or "inappropriate" response to underlying DIC or may result from a defective fibrinolytic mechanism that may be inherited or acquired.

Etiology

Fibrinogenolysis may complicate various disorders, among which severe liver disease⁴⁹ is the most common. Fibrinogenolysis is a predominant laboratory feature in several patients with disseminated neoplasms,^{245, 246, 247} especially urogenital neoplasms.²⁴⁸ The mechanism for enhanced fibrinolysis in these patients is probably increased tumor cell secretion of plasminogen activators such as urokinase.²⁴⁶ Fibrinogenolysis and marked fibrinolysis rarely complicate the immediate puerperium,^{192, 193} and they have been reported in association with acute promyelocytic leukemia.^{220, 221} Enhanced fibrinolysis has also been associated with cardiac bypass surgery²⁴⁹ and aortic clamping during vascular surgery.²⁵⁰ Inherited deficiency of plasminogen activator inhibitor type-1²⁵¹ or α_2 -plasmin inhibitor²⁵² also results in hyperfibrinolysis and a bleeding tendency.

Pathophysiology

Fibrinogenolysis is a consequence of the generation of plasmin within the general circulation (plasminemia). Potent plasmin inhibitors (antiplasmins) normally neutralize free plasmin rapidly (see Chapter 18); the result is that the proteolytic effects of this enzyme normally are restricted to fibrin. Fibrinogenolysis occurs only when the neutralizing capacity of the antiplasmins is exceeded.

The proteolytic action of plasmin is nonspecific. In addition to fibrin and fibrinogen, this enzyme may degrade factor VIIIc, factor XIII, other coagulation factors, and a wide variety of other plasma proteins, such as complement and various hormones. Free plasmin also may activate bradykinin, a phenomenon that may underlie the marked hypotension present in some patients with fibrinogenolysis. Thus, pathologic proteolysis is an appropriate synonym for fibrinogenolysis.

Fibrinogenolysis is activated by mechanisms that are remarkably similar to those that initiate DIC. Therefore, tumor tissue contains plasminogen activators in addition to tissue factor.²⁴⁶ The secretion of these activators into the circulation may rapidly activate most of the circulating plasminogen.

Hypoxia and hypoperfusion may lead to plasminogen activation and, occasionally, to fibrinogenolysis. However, in many of these patients, bleeding is minimal; when present, it cannot be clearly related to the presence of fibrinogenolysis. In these patients, fibrinogenolysis probably is a nonspecific, essentially physiologic response. Fibrinogenolysis may also result from therapy with thrombolytic agents, as discussed in Chapter 55.

Clinical Features and Laboratory Diagnosis

The clinical picture in most reported cases of fibrinogenolysis is similar to that of DIC. The usual laboratory findings are

summarized in Table 54.2 and are discussed in an earlier section of this chapter. Hypofibrinogenemia may be seen. The PTT, PT, and thrombin time may be prolonged because of the anticoagulant effects of FDPs. Moderate concentrations of EACA (4×10^{-4} mol/L) inhibit plasminogen activators but not free plasmin. Thus, the euglobulin lysis time, which invariably is shortened in patients with fibrinogenolysis, is unaffected by the addition of EACA if free plasmin is present. Among the coagulation factors, factors V and VIIIc are the most sensitive to the proteolytic action of plasmin; factor XIII also is deficient in some patients. The plasma levels of other factors (e.g., factors VII and IX), including some that are degraded by plasmin *in vitro*, usually are normal in patients with fibrinogenolysis. Depletion of plasminogen and α_2 -antiplasmin and the presence of α_2 -antiplasmin-plasmin complexes in the plasma also may be demonstrated in many patients with fibrinogenolysis and in those with DIC and active fibrinolysis.²⁵³

The standard FDP test does not discriminate between fibrinogen degradation products and fibrin degradation products. Measurements of fibrinopeptide A and the D-dimer, which is a specific indication of degraded cross-linked fibrin, yield normal results in fibrinogenolysis. Thus, patients with hypofibrinogenemia, prolonged PT and PTT values, elevated FDP

levels, and a normal D-dimer may have primary fibrinogenolysis. In the absence of intravascular coagulation, paracoagulable complexes containing fibrin monomers do not form in plasma; thus, plasma protamine gelation tests are negative in fibrinogenolysis. Assays for plasminogen and for the various inhibitors of the fibrinolytic enzyme system may reveal a pattern of depletion. In addition to normal results for D-dimer, patients with fibrinogenolysis have normal platelet counts or mild thrombocytopenia with bleeding out of proportion to the reduction in platelet count.²⁴⁶

Treatment

Antifibrinolytic agents would seem therapeutically desirable in the treatment of fibrinogenolysis; however, these drugs are hazardous in the presence of DIC. EACA and tranexamic acid are specific and potent inhibitors of fibrinolysis and fibrinogenolysis.²⁵⁴ In low concentrations (10^{-4} mol/L), EACA inhibits plasminogen activation competitively; in high concentrations (0.06 M), it inhibits plasmin directly in a noncompetitive manner. The clinical effectiveness of this drug is dramatic in carefully selected patients.²⁵⁵ For severe bleeding, EACA should be administered intravenously (0.1 g/kg every 6 hours, up to 24 g/day), or intravenous doses of 1 g/hour, after a 5-g loading dose. The drug can also be given orally. The total dosage should not exceed 24 g in a 24-hour period. Tranexamic acid is a newer antifibrinolytic agent that, like EACA, possesses the ability to bind to the lysine-binding sites of plasminogen, thereby preventing plasmin that is generated from binding to fibrin. The oral dosage of tranexamic acid is 25 mg/kg, three or four times daily. The intravenous dosage is 10 mg/kg given three or four times daily.

Because antifibrinolytic agents are potentially dangerous drugs in the presence of DIC,²⁵⁶ the diagnosis of DIC should be excluded in these patients using a specific test, such as D-dimer, before administering these agents. Patients with DIC and a substantial secondary fibrinolytic component should be considered for heparin therapy before administration of antifibrinolytics.²⁴⁸

Patients with hormone-refractory prostate cancer and fibrinogenolysis have been reported to benefit from docetaxel, with resolution of bleeding symptoms and laboratory evidence of hyperfibrinolysis.²⁵⁷

Pathologic Inhibitors of Coagulation

Circulating anticoagulants are pathologic endogenous inhibitors that can act at any stage in the process of coagulation. Most are antibodies that act as specific inhibitors, inactivating a single coagulation protein. The clinical and laboratory manifestations resemble the corresponding inherited coagulation disorders in many respects. Antibody disorders with wider effects on the coagulation system are sometimes seen, especially in the antiphospholipid-protein antibody (APA) disorders. Other inhibitors of coagulation often have heparinlike activities and are much less common.

Antibodies to Factor VIII

Factor VIII is the most common target of monospecific acquired anticoagulant antibodies. Conditions that are associated with monospecific factor VIII antibodies are outlined in Table 54.5. Factor VIII inhibitors are termed alloantibodies when they appear in treated hemophilia patients and autoantibodies when they appear in nonhemophilia patients.

Alloantibodies in Hemophilia A

Frequency of Inhibitors

Prospective studies suggest a higher incidence of inhibitors than that historically appreciated^{258, 259, 260} (up to 45%), even in patients treated with traditional factor VIII concentrates. However, many patients have only transient inhibitors, and perhaps only 5% to 10% of hemophiliacs have persistent inhibitors.²⁶¹ As a consequence, initial concerns based on historical prevalence controls suggesting that newer factor VIII concentrates, such as those purified by monoclonal antibody affinity chromatography or produced by recombinant technology, might be inducing an increased percentage of inhibitors appear to be allayed. In fact, continued longitudinal surveillance of patients receiving such products indicates a similar or perhaps lower incidence of clinically significant persistent inhibitor induction.^{262, 263} Those at high risk of development of inhibitors include patients with severe hemophilia A whose factor VIII mutation prevents factor VIII synthesis (nonsense mutation or intron 22 inversion), or patients with mild or moderate hemophilia A whose factor VIII mutation in the A2 domain or near the junction of the C1-C2 domains results in an abnormal factor VIII molecule.²⁶¹ This latter mutation results in a factor VIII molecule identified by the patient's immune system as abnormal. Other factors affecting the risk of inhibitor development include the patient's human leukocyte antigen (HLA) class II haplotype, the type of factor VIII therapy used,²⁶¹ African-American

P.1203

ancestry,^{264, 265} periods of intensive therapy,²⁶⁶ and early use of factor VIII at the time of a major bleed or surgery.²⁶⁷

Additional reports have confirmed these conclusions in patients with mild to moderate hemophilia.^{268, 269} A more recent literature metaanalysis observed that use of recombinant factor VIII products was associated with an almost twofold increase in inhibitor development compared to plasma-derived factor VIII products,²⁷⁰ and an initial study identifies an increased risk of inhibitor development with second-generation full-length recombinant products.^{270a} A provocative study reported that patient age at initiation of therapy was an independent risk factor for inhibitor development.²⁷¹ Patients beginning therapy before 6 months of age had three times the rate of inhibitors than patients beginning therapy after 1 year of age.²⁷¹ If these data are confirmed, exposure of hemophilia A patients to factor VIII should be delayed, and patients should be treated with other products during the first year of life (such as rVIIa). A United Kingdom epidemiology study reported that there is a bimodal distribution of factor VIII antibodies in hemophilia A patients, with peaks in early childhood and >60 years of age.²⁷² The genetic and immunologic aspects of induction of antifactor VIII alloantibodies have been reviewed.^{267, 273}

Plasma cell dyscrasias

Medications: penicillin, sulfa antibiotics, chloramphenicol, phenytoin

Idiopathic

Induced Antibody Titer

It is recognized, particularly in patients with mild hemophilia, that 50% to 75% of inhibitors are subclinical, occur relatively early (median of 10 days) after product exposure, are of low titer, are transient, and often resolve even with continuing product exposure.^{260, 262} Hemophiliacs with inhibitors can be categorized as either strong or weak responders to administered factor VIII. Once an antibody has developed in a hemophiliac, further administered factor VIII may act as an inducing antigen. Additionally, it has been appreciated that certain factor VIII products, depending on the manufacturing process, may be immunogenic in hemophilia A patients.^{261, 270, 270a}

Autoantibodies to Factor VIII in the Nonhemophilic Patient

It is estimated that acquired factor VIII autoantibodies are seen in 1 to 2 persons per million population annually.²⁷⁴ Monospecific antibodies to factor VIII can arise spontaneously in association with various autoimmune and chronic inflammatory diseases, such as systemic lupus erythematosus (SLE), rheumatoid arthritis, and ulcerative colitis.^{275, 276} Antibodies to factor VIII can develop in the puerperium,²⁷⁷ usually appearing at term or within several months after parturition in association with a first pregnancy. The antibody may disappear spontaneously in postpartum patients after 12 to 18 months. Reappearance during subsequent pregnancy seems to be very unusual, and in those patients who have persistent antibodies, remission can occur during a subsequent pregnancy.²⁷⁸ Acquired hemophilia may also be seen in association with hematologic malignancies and solid tumors,^{279, 280, 281} certain medications such as penicillin,²⁸² sulfa antibiotics, chlorpromazine, and phenytoin²⁸³; and dermatologic conditions such as psoriasis and pemphigus vulgaris.²⁸⁴

Most often, acquired factor VIII antibodies are idiopathic, particularly in older persons without apparent underlying disease.^{276, 284}

Pathophysiology of Development of Antibodies to Factor VIII

The immunologic mechanism that underlies inhibitor induction in a select minority of patients with hemophilia A and the corresponding presumed lack of immunologic tolerance is unclear. Although inhibitor induction is more common in more severely affected patients, inhibitors are also seen in mild hemophilic patients.^{268, 285} In patients with severe hemophilia, major deletions, the intron 22 inversion, nonsense mutations, and early initiation of replacement therapy are risk factors for antibody development.^{261, 264, 276} Underlying genetic susceptibility factors have been suggested by studies of brother pairs with a significant predisposition to the development of inhibitors.²⁸⁶ Specific associations between factor VIII genotype and HLA class II phenotype have been made,²⁸⁷ but the associations are weak. Genetic influences on inhibitor development are postulated to be additive and polygenic.²⁸⁷ Mutations resulting in a major loss of factor VIII gene coding information and a lack of circulating factor VIII antigen are associated with a high incidence of inhibitor formation.²⁸⁸ For example, a high frequency (70%) of inhibitor development is seen in patients with either large, multidomain deletions or nonsense mutations in the factor VIII A3 domain.²⁸⁹ Fewer patients with other gene defects (missense point mutation) form inhibitors. However, the presence of inhibitors is not consistent, even in a given family with similar factor VIII mutations, suggesting that other factors contribute to induction of factor VIII antibodies.²⁶¹ A clinical prediction score to identify the risk of untreated hemophilia A patients to develop an inhibitor has been reported.²⁹⁰

Another hypothesis as to how inhibitors to factor VIII might occur is that these antibodies arise from the expansion of preexisting natural factor VIII clones that possess neutralizing properties²⁹¹; such antibodies have been identified from the IgG fraction of plasma from normal people.²⁹¹ Clonal expansion of antifactor VIII antibodies may be modulated by the presence of anti-idiotypic antibodies.²⁹²

Characteristics of Factor VIII Inhibitory Antibodies

The majority of antibodies to factor VIII are IgG immunoglobulins that appear to be specific for the coagulant subunit of the factor VIII complex (VIIIc).^{293, 294} Common epitopes for allo- and autoantibodies include those in the A2 domain, the C2 domain, or both.²⁹⁵ Typically, hemophilic alloantibodies recognize both domains,²⁹⁶ whereas autoantibodies recognize the C2 domain more frequently than the A2 domain.²⁹⁵ Circulating factor VIII immune complexes have been identified in plasma from patients with acquired hemophilia A with autoantibodies.²⁹⁷ IgA or IgM inhibitors are rare, as are antibodies that inhibit both VIIIc and vWF. The factor VIII inhibitory antibody subunits in hemophilia A show limited heterogeneity²⁹⁸ but are not truly monoclonal. In nonhemophiliacs, antibodies to factor VIII more often reveal normal heterogeneity of their subunits. Antibodies to factor VIII are disproportionately often of the IgG₄ subclass and do not fix complement.

Antibodies inactivate factor VIII in a time- and temperature-dependent process,²⁹⁹ the kinetics and stoichiometry of which are variable. Two types of antibody inhibition are described³⁰⁰: Type I inhibitors completely inhibit factor VIII activity following second-order kinetics (linear time course of inactivation); these antibodies are seen in hemophilia patients.³⁰¹ Type II inhibitors have complex kinetics and do not completely inhibit factor VIII activity; these are autoantibodies seen in nonhemophilic patients.³⁰² The type II inhibition phenomenon may produce aberrations in the assay system and may explain certain puzzling laboratory features in atypical cases, such as detectable factor VIII clotting activity in a patient with a high-titer inhibitor.³⁰³ A report on alloantibody inhibition of factor VIII activity indicated that certain alloantibodies possess catalytic activity that can proteolyze factor VIII.³⁰⁴

Laboratory Evaluation

Simple mixing techniques based on the PTT usually suggest the presence of an inhibitor. Factor VIII levels usually are undetectable in severely affected patients but may be detectable in patients with autoantibodies. Specific tests for antibodies involve the demonstration of progressive and time-dependent inactivation of factor VIII in vitro by the plasma or serum of the patient. Methods

P.1204

for detecting low-titer inhibitors and for quantifying the levels of antibody have been devised,³⁰⁵ and standardized inhibitor units (the Bethesda unit in the United States³⁰⁶ and the Oxford unit in Britain³⁰⁷) have been defined. In the Bethesda assay, in vitro tests are performed at 37°C using 2-hour incubation mixtures of various dilutions of patient plasma with normal plasma. The inhibitor titer is the reciprocal of the dilution of inhibitor plasma that neutralizes 50% of normal factor VIII activity. Because the Bethesda assay may underestimate the inhibitor titer in acquired hemophilia, it is recommended that the titer should be calculated from the lowest dilution that results in 50% residual factor VIII activity

after the incubation period.³⁰⁸ The New Oxford method measures residual activity at 37°C after a 4-hour incubation. A Bethesda unit is generally equivalent to 1.21 Oxford units. The standard Bethesda assay does not control pH, permitting variable low-level inactivation of factor VIII by nonimmunologic mechanisms. The Nijmegen modification controls pH, thus improving classification of positive and negative samples.³⁰⁶ The Nijmegen modification of the Bethesda assay has been endorsed by the ISTH.³⁰⁹ Additional improvements in this assay have been described.³¹⁰ Although an inhibitor unit does not imply that any specific number of factor VIII units infused into the patient will neutralize any specific number of inhibitor units, the titer provides a general estimate of the initial likelihood of response to infusion of factor VIII products.

Clinical Manifestations

The bleeding manifestations resulting from antibodies to factor VIII are often similar to those seen in hemophilia A.^{275, 284} Prolonged or unexpectedly severe hemorrhage may occur after comparatively trivial trauma, postoperatively, or postpartum. Soft tissue or muscle hematomas, hematuria, and spontaneous and intractable epistaxis seem relatively common. For unknown reasons, hemarthrosis is relatively less common in acquired hemophilia than in congenital hemophilia A. Figure 54.5 illustrates soft tissue hematomas occurring in a nonhemophilic patient with an acquired inhibitor to factor VIII. When antibodies arise in patients with mild hemophilia A, bleeding typical of severe deficiency may develop; more significantly, the bleeding may be refractory to replacement therapy. This condition may have serious consequences, and fatal events are seen in 10% to 20% of clinically symptomatic patients.^{275, 311} Antibodies to factor VIII arising during pregnancy may cross the placenta.

Treatment

The treatment of bleeding in patients with antibodies to factor VIII presents several challenges.^{312, 313} No adequate randomized trials have been conducted to evaluate different forms of therapy or to investigate the timing and sequence of their application; therefore, practical treatment decisions are somewhat arbitrarily based on estimates of benefits and risks deduced from retrospective literature review and consideration of each patient's circumstances and co-morbidities. A consensus group from the United Kingdom and an international panel have published guidelines on treatment of inhibitors in patients with hemophilia,^{314, 314a, 315} and a literature review of acquired hemophilia therapy options has summarized treatment recommendations.³¹⁶ An algorithm that has some general applicability is shown in Figure 54.6. As a first step, basic clinical information should be obtained, including whether the inhibitor arose in the setting of hemophilia or is acquired; the severity of bleeding; anticipated surgical procedures; inhibitor titer and persistence; prior inhibitor response and relation in time to previous factor infusions; possible triggering events such as recent medication exposure or pregnancy; and the presence of other diseases. For example, the mere presence of an inhibitor may in itself not warrant immediate therapy because many inhibitors are present in low titer and are often transient. Spontaneous remissions may occur in a significant number of patients, particularly if the inhibitor develops during the puerperium.²⁷⁶ At the other end of the spectrum, an unfortunate clinical scenario might involve significant spontaneous clinical hemorrhage, a persistent high-titer inhibitor, and incidental co-morbidities such as cardiac, hepatic, or renal insufficiency. Principles of management include stopping bleeding using bypass therapy, eradication of the inhibitor with immunosuppression, and recognizing and treating any underlying disorder that may have triggered autoantibodies to factor VIII.

FIGURE 54.5. Soft tissue hemorrhage in a 76-year-old man with a high-titer factor VIII inhibitor. This patient has a history of ischemic cardiomyopathy and diabetes and developed spontaneous extremity bruising as shown. The antihuman factor VIII antibody titer was 10 Bethesda units. (Courtesy of Alan Grosset.)

In patients with low-titer inhibitors who do not have any clinical bleeding and for whom no surgical procedures are foreseen, the most reasonable approach may be to monitor the abnormal laboratory finding. Steroids and cytotoxic therapy (usually cyclophosphamide) are usually ineffective when inhibitors arise in patients with congenital hemophilia A, but they are effective in the setting of nonhemophilic patients.^{275, 316} Cyclosporin has also been used to treat acquired antibodies to factor VIII.³¹⁷ Procedures or medications (antiplatelet drugs) that would increase hemostatic risks should be avoided, and ancillary local therapeutic measures to control minor bleeding are recommended and may in themselves be sufficient. For patients with minor bleeding who have residual factor VIII activity >5% of normal, DDAVP therapy may be helpful (0.3 µg/kg, up to 24 µg maximal dose).^{273, 318} Antifibrinolytic therapy, such as the administration of EACA or tranexamic acid, may be helpful, especially for oral or nasal bleeding; however, this therapy should be used cautiously in muscle bleeds because it appears to be less effective, and it should not be used in conjunction with PCCs, activated PCCs (APCCs), or rVIIa.

The inhibitor titer and its prior response to factor VIII infusion may be of particular use in guiding therapeutic decisions (Fig. 54.6). As a rule, replacement therapy with factor VIII in the usual doses is ineffective. If clinical bleeding mandates active therapy, patients with a low Bethesda titer (<5 U/ml), particularly if they are known to be low responders, usually respond to high-purity or recombinant human factor VIII³¹⁴ given as a large initial 150 U/kg bolus followed by a continuous infusion of 1,000 U/hour. The therapeutic response to human factor VIII should be clinically assessed; factor VIII levels and repeat assays of inhibitor titer response may be helpful. Therapy with human factor VIII is seldom successful in patients with high-titer antibodies (>5 Bethesda U/ml), high-affinity antibodies, and infinite coagulation times. As an alternative, particularly in patients with high-titer inhibitors or a history of an anamnestic response, or routinely in medical centers that prefer to reduce the uncertain risk of inducing an increased inhibitor titer, the use of inhibitor-bypassing products may be useful. These include the PCCs, APCCs, and rVIIa. The best-studied treatment options are FEIBA (factor VIII inhibitor bypassing activity) and rVIIa.³¹⁶ There is no consensus as to the best therapeutic approach between these options.³¹⁹

A literature review of efficacy and safety of FEIBA and rVIIa in treating bleeding events in acquired hemophilia indicates “indistinguishable” efficacy between the two products³¹⁶; if one agent is not successful in stopping bleeding, the other agent should be used. A typical dose for FEIBA in this indication is 75 U/kg every 8 to 12 hours. Both therapies (FEIBA, rVIIa) are associated with thrombosis.³¹⁶

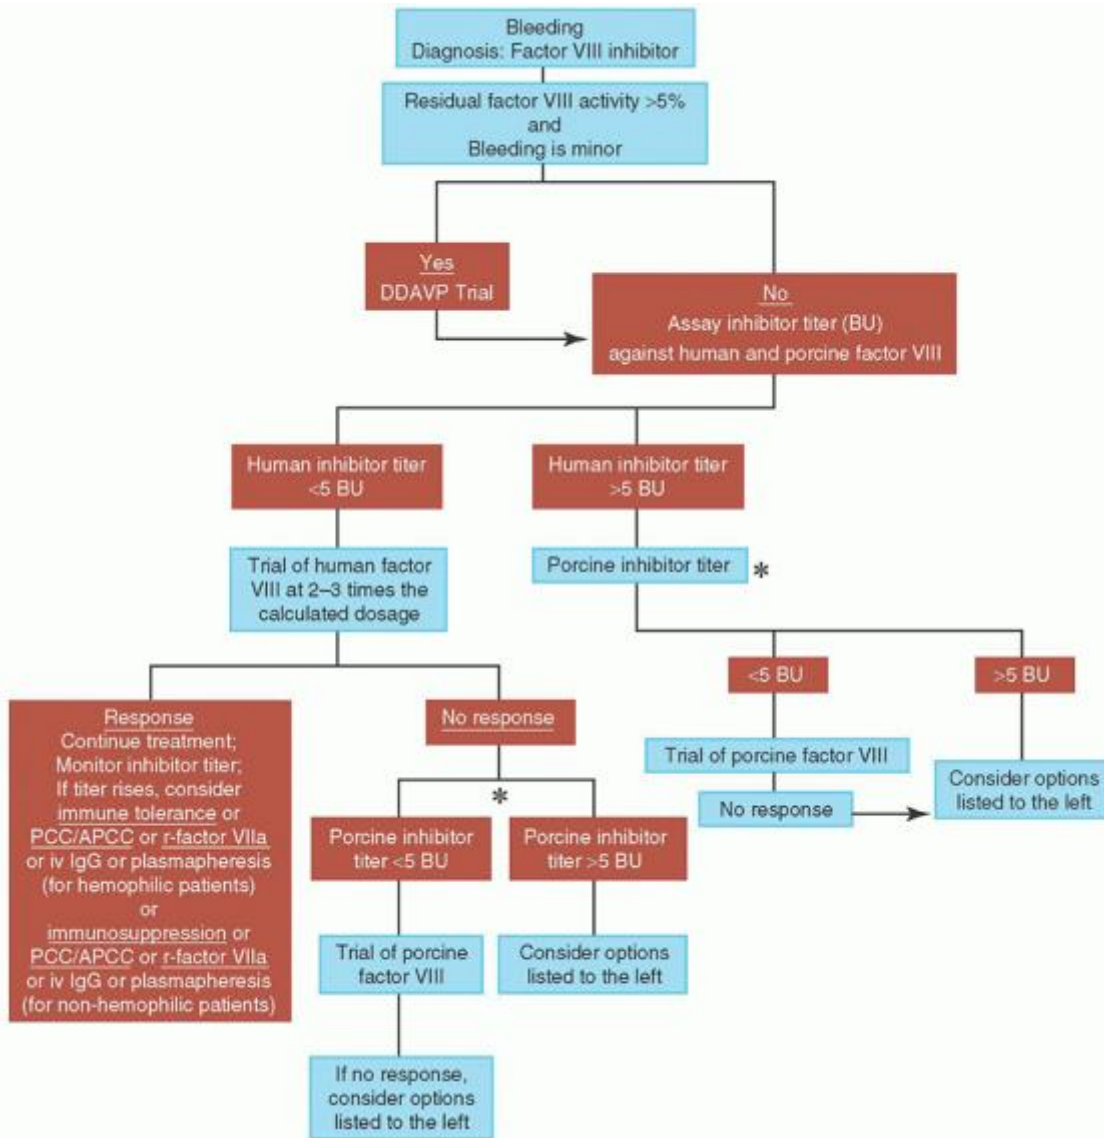

FIGURE 54.6. A strategy for management of factor VIII inhibitors in hemophilic and nonhemophilic patients. Key decisions are based on antihuman and antiporcine factor VIII inhibitor titers. Multiple options for patients not responding to human or porcine factor VIII are available. BU, Bethesda units; DDAVP, 1-desamino-8-D-arginine vasopressin; PCC/APCC, prothrombin complex concentrate/activated prothrombin complex concentrate. The underlined options are preferred. Immunosuppression options include rituximab, steroids, and cytotoxic drugs. *As of early 2013, porcine factor VIII was not routinely available, so testing porcine inhibitor titers should not be done. If a recombinant porcine product becomes available, then these tests will be relevant. (Information in this figure is from the literature, including Morrison AE, Ludlam CA. Acquired haemophilia and its management. *Br J Haematol* 1995;89:231-236.)

rVIIa is a treatment option for inhibitor patients.^{320, 321} This drug was originally thought to exert activity by binding to tissue factor at sites of vascular injury to initiate coagulation. More recent data indicate that at the pharmacologic concentrations of factor VIIa achieved during rVIIa therapy, there may be platelet-dependent, tissue factor-independent mechanisms to mediate hemostasis.³²² The standard dose of rVIIa is 90 µg/kg every 2 hours for serious bleeding³²³ or 90 µg/kg every 3 hours for mild to moderate bleeding in home treatment.³²⁴ Recent trial data indicate that a single rVIIa dose of 270 µg/kg is effective home treatment for hemarthroses.³²⁵ Continuous infusion of rVIIa is also effective, targeting

factor VII levels to 30 to 40 U/ml.³²⁶ rVIIa, like FEIBA therapy, is associated with potential thrombotic complications; a comparative evaluation of the thrombotic event rate of rVIIa versus FEIBA revealed that rVIIa was associated with approximately threefold more thrombotic events than APCC.³²⁷ FEIBA has been successfully used as a prophylaxis therapy for hemophilia patients with inhibitors.³²⁸

There are few studies directly comparing the efficacy of rVIIa versus FEIBA or other activated PCCs in inhibitor patients with serious bleeding. These products have similar efficacies,^{316, 329, 330} and consensus recommendations generally include multiple treatment options.^{314, 331, 332} For patients refractory to both drugs used as single agents, sequential therapy with FEIBA and rVIIa has been reported.³³³

P.1206

Another potentially useful product in inhibitor patients is porcine factor VIII. Obtaining an antiporcine antibody titer is useful, but as a rule of thumb, the initial antiporcine titer is often 5% to 10% of the antihuman titer. However, the antiporcine titer may rapidly rise after administration of porcine factor VIII. For these reasons, porcine factor VIII is usually reserved for one-time use.³³² Some investigators consider porcine factor VIII to be the therapy of choice for patients with factor VIII antibodies in which the antibody has minimal cross-reactivity to porcine factor VIII,³³⁴ and consensus groups consider porcine factor VIII an appropriate treatment option.^{314, 331} Porcine factor VIII is currently unavailable in the United States; however, a recombinant B-domain-deleted porcine factor VIII product is in clinical trials.

Long-term eradication of antibodies to factor VIII requires immunosuppressive therapy. Numerous treatment options exist.³¹⁶ A literature review³³⁵ of the efficacy of intravenous Ig in the treatment of acquired factor VIII antibodies found a cumulative response rate of only 12%, suggesting that other modalities should be attempted first for these patients.

Standard immunosuppression should be reserved for patients with autoantibodies because this therapy is rarely beneficial in the alloimmune setting. Corticosteroids (e.g., prednisone in doses of 1.0 to 1.5 mg/kg/day) produced improvement in approximately 50% of patients when administered on a long-term basis,²⁷⁵ with the best results obtained with nonhemophilic patients. Similar therapeutic responses have been reported when immunosuppressive drugs, such as cyclophosphamide (2 to 3 mg/kg/day), were administered alone or with prednisone.^{316, 336} Remission of bleeding and reduction of antibody titer have been well documented, but total suppression of the antibody is rare.

Rituximab, a monoclonal antibody to the CD20 antigen on B cells, has been reported to be effective in case series of patients with acquired factor VIII antibodies,^{316, 337, 338} and a United Kingdom practice guideline recommends rituximab as second-line therapy if patients have not responded to steroids and cyclophosphamide.³¹⁴

One aggressive treatment regimen for acquired hemophilia combined protein A immunosorption, factor VIII, intravenous IgG, and immunosuppression; this regimen resulted in abolition of antibody levels within 3 days and a complete response rate of 88%.³³⁹ This aggressive regimen should be considered for patients with severe, life-threatening bleeding.³¹⁶ Cyclosporin A has been reported to be useful in patients failing first-line eradication therapy.³¹⁶

In many patients with hemophilia A who have developed alloantibodies to factor VIII, infused factor VIII provokes a rapid increase in the antibody titer. However, in many of these patients, the administration of large doses of factor VIII for periods of months to years may produce immune tolerance (IT) to factor VIII. An international registry of patients treated with this approach reported that approximately 70% of patients achieved long-lasting tolerance.³⁴⁰ A 1997 update of this registry indicated that 52% of patients were successfully treated with IT.³⁴¹ Several IT regimens have been summarized.³⁴² The registry data suggest that success of inducing tolerance is greatest in patients given more than 100 U/kg/day factor VIII who had an initial inhibitor titer of <10 Bethesda U before starting IT.^{340, 341} Data from the North American Immune Tolerance Registry have been reported; the overall success rate was 70%.³⁴³ The cost effectiveness of IT therapy has been demonstrated.³⁴⁴

The International Immune Tolerance Study compared high-dose (200 U/kg daily) versus low-dose (50 U/kg daily) factor VIII. Both dosage regimens were equivalent in terms of inducing tolerance; however, the low-dose regimen was associated with more bleeding.³⁴⁵ The use of factor VIII products that contain vWF may be more effective in IT induction.³⁴⁶ The topic of IT induction in hemophilia A and B patients has been recently reviewed.³⁴⁷

Monospecific Antibodies to Other Coagulation Factors

Table 54.6 summarizes certain conditions associated with antibodies to other coagulation factors.

Factor IX

Inhibitors of factor IX have been demonstrated in approximately 5% of patients with hemophilia B^{348, 349} and rarely in previously normal persons (acquired hemophilia).³⁵⁰ Hemophilia B patients who acquire antibodies to factor IX often have gross

P.1207

gene deletions.³⁵¹ In contrast to antibodies to factor VIII, factor IX antibodies act instantaneously. One series of eight hemophilia B inhibitor patients found that antibodies typically were IgG₁ and IgG₄, and that the antibodies targeted the Gla domain and protease domain epitopes of factor IX.³⁵² rVIIa³⁵³ or IT therapy³⁴³ has been used to treat these patients, although IT for hemophilia B inhibitor patients may be less effective than for hemophilia A inhibitor patients.³⁵⁴ PCCs are also a treatment option.³⁵⁵ Patients with antibodies to factor IX may experience anaphylaxis when treated with factor IX-containing products³⁵⁴; rVIIa may be the appropriate therapy for this patient group. A British consensus group has published guidelines on treating factor IX inhibitor patients,^{314, 314a} and an ISTH registry of factor IX inhibitor patients has been established.³⁵⁶

TABLE 54.6 ACQUIRED DISORDERS ASSOCIATED WITH DEFICIENCY OF A SINGLE COAGULATION FACTOR

Deficient Factor	Specific Inhibitors^a	Other Disorders
Fibrinogen	Hereditary afibrinogenemia ³⁸⁶ ; lupus erythematosus; liver disease	—
Prothrombin	Previously normal persons ³⁸⁷	Lupus inhibitors ³⁸⁹
Factor V	Previously normal persons; ³⁵⁷ often associated with streptomycin; ³⁵⁷ rarely in inherited factor V deficiency; postoperative patients who received bovine thrombin ^{361, 362, 363, 364, 365, 366}	Chronic myelocytic leukemia ⁶²⁰
Factor VII	Bronchogenic carcinoma, ³⁹⁸ acquired immunodeficiency syndrome ³⁹⁹	Aplastic anemia, ⁵⁹³ liposarcoma ⁵⁹⁴
Factor VIII (VIIIc)	Hemophilia A; ^{258, 259} puerperium; ²⁷⁷ inflammatory disorders; drug reactions; in absence of underlying disease ²⁷⁵	—
von Willebrand factor	Previously normal persons; lymphoproliferative disorders; ^{372, 373, 374, 375, 376, 377, 378} rarely in von Willebrand disease; thrombocytosis	Wilms tumor ⁶¹⁹
Factor IX	Hemophilia B; ^{348, 349} rarely in previously normal persons ³⁵⁰	Nephrotic syndrome; ⁵⁸⁷ Sheehan syndrome ⁵⁹¹ ; Gaucher disease ⁵⁹² Factor X — Amyloidosis; ^{577, 578, 579, 580, 581, 582, 583} upper respiratory infection; ³⁹⁴ other associations ⁵⁸⁴
Factor XI	Lupus erythematosus; rarely in inherited factor XI deficiency and chronic lymphocytic leukemia; previously normal persons ³⁹²	—
Factor XII	Lupus erythematosus, rarely	Nephrotic syndrome; chronic myelocytic leukemia
Factor XIII	Previously normal persons, often associated with isoniazid; ³⁸¹ rarely in inherited factor XIII deficiency; ³⁸⁰ other associations ⁵⁹⁷	Acute and chronic leukemia; ⁵⁹⁵ Crohn disease ⁵⁹⁶

^a Evidence suggests these inhibitors are antibodies. In patients with inherited deficiencies of the various factors, their development usually is related to transfusion of blood or blood products.

Factor V

Inhibitors of factor V³⁵⁷ have developed spontaneously in previously normal older persons after administration of streptomycin,³⁵⁸ gentamicin, or penicillin and after surgical procedures. More rarely, factor V inhibitors have been associated with tuberculosis, femoral fracture, and bullous pemphigoid. These antibodies are usually of IgG isotype. An Australian survey estimated the annual incidence of factor V inhibitors at 0.29 cases per million population,³⁵⁹ and a Singapore incidence rate was 0.09 cases per million person years.³⁶⁰ Alloantibodies to factor V may occur in factor V-deficient patients who receive blood products.³⁶¹

Over the past 30 years, an iatrogenic coagulopathy has been identified: The occurrence of antibodies to thrombin and factor V in patients treated with bovine thrombin during surgery.^{361, 362, 363} The antithrombin antibody neutralizes bovine thrombin and therefore can prolong the thrombin time when bovine thrombin is used for this test.^{364, 365} However, no clinically significant hemostatic defect appears to result from this single laboratory abnormality. Some patients acquire additional antibodies to human factor V, which may result in significant factor V deficiency and bleeding.^{364, 365} In a large surgical series of patients exposed to bovine thrombin, more than 95% of patients developed antibodies to bovine thrombin or factor V, and 50% of these patients had antibodies cross-reacting to human coagulation proteins.³⁶⁶ These latter patients have a bleeding risk.³⁶⁶

In contrast to most other specific inhibitors, antibodies to factor V seldom produce serious hemorrhage.^{361, 367} Patients with alloantibodies to factor V typically have significant bleeding.³⁶⁶ Patients with antibody recognition of the C2 domain of factor V have also been reported to have a significant bleeding risk. A literature review identified a bleeding mortality rate of 12% in patients with factor V antibodies not due to exposure to bovine factor V or noninherited acquired factor V antibodies.³⁶⁰ In several patients with severe hemorrhage, platelet transfusions were therapeutically more effective than plasma.^{360, 363, 368} This clinical benefit of platelet transfusions likely relates to platelet α -granule content of factor V which is released at sites of bleeding to improve local hemostasis. Plasmapheresis,³⁶⁹ immunosuppression, and intravenous IgG³⁷⁰ have been reported to be effective in resolving antibodies to factor V. In some cases, these antibodies resolve spontaneously.³⁶⁶

A small number of patients have been described with thrombosis symptoms associated with factor V antibodies. These patients may³⁵⁷ or may not^{361, 371} have coexisting antiphospholipid antibodies.

von Willebrand Factor

Acquired von Willebrand disease (vWD) has been reported in association with a variety of disorders, primarily including patients with lymphoproliferative disorders, myeloproliferative disorders, solid tumors, autoimmune disease, aortic stenosis, and artificial heart devices. An international registry identified lymphoproliferative and myeloproliferative disease as accounting for more than 60% of acquired vWD.³⁷² A literature review concluded that most cases of acquired vWD result from an antibody that recognizes high-molecular-weight multimers of vWF and mediates subsequent antigen-antibody clearance.³⁷³ Another mechanism for the development of this disorder includes adsorption of vWF by tumor cells³⁷⁴ or platelets. Acquired vWD has also been reported in patients with aortic stenosis³⁷⁵ and in patients with ventricular-assist devices and artificial hearts.³⁷⁶ In these cardiac conditions, vWF is subjected to shear stress and proteolysis.^{375, 376} Ristocetin co-factor activity is usually decreased, whereas factor VIII activity may be normal.³⁷³ In most patients, the hemostatic abnormalities disappear when the underlying disorder is treated.³⁷⁷ For patients with acquired vWD resulting from a lymphoproliferative disorder or monoclonal gammopathy, intravenous Ig may be effective.³⁷⁸ The consensus group recommends a trial of DDAVP as initial therapy³⁷⁹; DDAVP failures are then treated with vWF concentrates (e.g., Humate-P or Wilate).³⁷² Intravenous Ig is reserved for those patients having no success with DDAVP and vWF concentrates.³⁷² For patients with acquired vWD associated with monoclonal gammopathy of uncertain significance, a trial comparing DDAVP and vWF concentrates versus intravenous Ig found that the latter treatment provided a sustained response compared to DDAVP/vWF concentrates.³⁷⁹

Factor XIII

Inhibitors of factor XIII have been described after transfusions in patients with inherited deficiency of this proenzyme and in previously normal persons.³⁸⁰ Many of the latter group had received isoniazid,³⁸¹ and it was suggested that this drug may alter factor XIII in such a manner that it becomes antigenic.³⁸² These inhibitors may recognize the zymogen, impair the activation of factor XIII by thrombin, or be directed against the cross-linking sites of fibrin, or to the B-subunit.^{383, 384} Therapeutic options include factor XIII replacement therapy (plasma, cryoprecipitate), rVIIa, as well as inhibitor

eradication options (steroids, cyclophosphamide, rituximab, etc.).³⁸⁴ A factor XIII concentrate, Fibrogammin, if available, may also be useful.³⁸⁴ A survey of hemophilia treatment centers reported that ~38% of inherited factor XIII-deficient patients developed antibodies as a treatment complication³⁸⁵; these patients may require bypassing agents to treat bleeding.

Fibrinogen and Prothrombin

A precipitating antibody to fibrinogen has been demonstrated after transfusions in patients with hereditary afibrinogenemia.³⁸⁶ Acquired hypofibrinogenemia is usually seen in acute DIC. Dysfibrinogenemia may occur in patients with liver disease or hepatoma, or in plasma cell disorders (discussed in the section "Deficient or Aberrant Synthesis of Coagulation Factors"). Antibodies to prothrombin have also been reported.³⁸⁷ An unusual case of an autoantibody to prothrombin was described; the antibody induced protease activity from the zymogen, leading to neutralization by antithrombin.³⁸⁸ Acquired hypoprothrombinemia usually occurs in the setting of the lupus anticoagulant (LA) when patients have antibodies to prothrombin that clear prothrombin activity from blood.³⁸⁹

Factor XI

A survey of prevalence of acquired inhibitors to factor XI in patients with inherited factor XI deficiency found that ~5% of patients with severe deficiency developed antibodies after plasma therapy.³⁹⁰ Of those factor XI-deficient patients homozygous for a null allele, one third developed antibodies.³⁹⁰ A combination of

P.1208

low-dose rVIIa and tranexamic acid was reported to be safe and effective for such patients requiring surgery.³⁹¹ Specific inhibitors of factor XI have been described primarily in association with autoimmune disease.^{392, 393}

Factor X

Antibodies to factor X are very uncommon and may be associated with upper respiratory tract infections,³⁹⁴ either viral or mycoplasma; however, in these cases, inhibitors to factor X have been directly proved infrequently. Bleeding has been controlled using PCCs,³⁹⁵ or ivIgG and steroids.³⁹⁶ Acquired factor X deficiency has been frequently reported in amyloidosis (discussed below).

Factor VII

Antibodies to factor VII are rare, with fewer than 20 cases reported in the English literature.³⁹⁷ They have been reported in lung cancer³⁹⁸ and human immunodeficiency virus infection,³⁹⁹ and with no apparent disorder.⁴⁰⁰ Immunosuppression has been used successfully in anecdotal case reports of autoantibodies to factor VII.⁴⁰¹

Tissue Factor

Antibodies to tissue factor are very uncommon, with one group reporting two patients who developed antitissue factor antibodies after liver surgery.⁴⁰² Similar to patients who acquire antithrombin and antifactor V antibodies after use of topical bovine thrombin,^{361, 362, 363, 364} the patients who developed antitissue factor antibodies were both treated with a topical hemostatic agent prepared from bovine tissue that contained tissue factor. The antibodies to bovine tissue factor did not cause clinical bleeding but did prolong PT values.⁴⁰²

Antiphospholipid-Protein Antibodies: Lupus Anticoagulants and Anticardiolipin Antibodies

Historical Considerations and Nomenclature

The two best-known clinical types of APAs are traditionally called LA and anticardiolipin (aCL) antibodies. These antibodies are associated in some patients, but not in others, with clinical illness^{403, 404} of varying severity. Individual patients may manifest arterial or venous thromboembolic disease, recurrent pregnancy loss, thrombocytopenia or other cytopenias, and neurologic and skin abnormalities. The clinical importance, particularly of the LA or higher-titer aCL antibodies, has been increasingly recognized; these antibodies or their functional consequences are found in approximately 10% of patients with venous thromboembolic events.^{405, 406} Bleeding is quite uncommon, and when present, it is usually the result of severe thrombocytopenia, platelet dysfunction, hypoprothrombinemia, or the effects of an underlying disease. On the other hand, thrombosis and its many manifestations are common.

Synonyms for LA and aCL antibodies include antiphospholipid (aPL) antibodies, APAs, and autoantibodies to phospholipid-binding plasma proteins.⁴⁰⁷ The associated clinical manifestations including thrombosis are variously called the LA syndrome, antiphospholipid syndrome (APS), or antiphospholipid-protein syndrome. APS without a known well-

defined autoimmune disease is termed primary APS (PAPS). A few patients with APA develop an acute, severe, multiple-organ APS illness. These patients are designated as having catastrophic APS (CAPS).

The existence of these antibodies was first detected more than 50 years ago when it became apparent that approximately 15% of patients with active SLE have a false-positive Venereal Disease Research Laboratory (VDRL) test.⁴⁰⁸ The VDRL test assesses antibody reactivity to “reagin” (antigen), an acidic-phospholipid complex that is chemically extracted from bovine heart tissue. Reagin consists of a mixture of lecithin, cholesterol, and cardiolipin. A nonspecific antibody reaction to reagin is also seen less often in other autoimmune disorders and in some apparently healthy patients. Other laboratory assays discussed in this section identified a family of antibodies that were initially thought to have direct specificity to various phospholipids, although it is now known that the antibodies recognize phospholipid-protein complexes. The proteins often serve a critical cofactor role,⁴⁰⁹ and the antibodies collectively are thus most accurately called APAs.⁴¹⁰

Coagulation assays are sensitive to some of these antibodies. Plasma samples from some patients with SLE, often those with the abnormal VDRL tests, show an *in vitro* inhibitor effect in several coagulation assays. This association gave rise to the term LA.⁴¹¹ Most often, a prolonged PTT result that is not corrected on mixing with normal plasma is observed; other phospholipid-dependent assays, including the modified Stypven time (dilute Russell viper venom time [DRVVT]), are also affected.³⁶⁷ Despite persistent clinical use, it is now known that most patients with an LA phenomenon do not have SLE. Moreover, clinical thrombosis is much more often seen than is bleeding with APS antibodies. Patients with SLE occasionally have inhibitors to other hemostatic factors,⁴¹² but these inhibitors are not considered LAs.

In addition to the biologically false-positive VDRL results and the paradoxical *in vitro* lupus-anticoagulant effect, laboratory studies found a third phenomenon, initially detected by radioimmunoassay: Antibodies to cardiolipin.⁴¹³ In aCL-antibody assay systems, serum Igs bind to various anionic phospholipid-protein complexes, most commonly to cardiolipin in a coated microwell enzyme-linked immunosorbent assay (ELISA). The sensitivity and specificity of this assay are substantially higher than those of the VDRL. A phospholipid-binding protein, β_2 -glycoprotein I (β_2 gpl), has been identified,⁴¹⁴ and antibodies to this antigen can also be demonstrated in patients with APS.⁴¹⁵ Thus, the most useful assays to evaluate patients for antiphospholipid antibodies include the LA, aCL antibodies, and antibodies to β_2 gpl.

Epitope Specificity

In these disorders, the antibodies were initially thought to react with anionic phospholipids directly, but the presence of specific plasma proteins associated with phospholipids is now known to be of great importance.⁴¹⁶ In the case of LAs, the seemingly paradoxical discordance between laboratory screening test results and clinical symptoms is frequently the consequence of antibodies that bind to a complex of phospholipid-bound prothrombin.^{389, 417} This antibody binding impairs the function of the standard prothrombin-binding synthetic anionic phospholipids⁴¹⁸ that are used routinely in the laboratory to replace platelets in phospholipid-dependent coagulation assays, such as the PTT. Other more natural phospholipids, or platelets themselves, are less affected by this phenomenon and are used in some assays as correction factors in mixing studies.

In the case of aCL antibodies, especially in autoimmune and drug-induced aCL, β_2 gpl⁴¹⁹ serves as a mandatory protein cofactor.⁴¹⁴ Patient-derived antibodies directed against β_2 gpl that have LA activity have also been reported.⁴²⁰ β_2 gpl is a 57-kD plasma protein with an uncertain physiologic role, but it is often considered a noncomplement member of the complement-control family of proteins, with structural similarity to complement factor H. A recent study reported that β_2 gpl inhibited complement activation at the level of C3.⁴²¹ β_2 gpl has a number of anticoagulant activities,^{422, 423} but inherited deficiency of β_2 gpl has no thrombophilic association.⁴²⁴ The antibodies in these settings are often of the IgG isotype, are relatively persistent and high in titer, are associated with an LA phenomenon in approximately 60% of patients, and are clearly associated with the clinical syndromes

P.1209

discussed subsequently. IgM and IgA antibodies occur less often. aCL antibodies are not directed primarily against cardiolipin itself, but against epitopes formed after β_2 gpl binds to anionic phospholipid membranes or anionic synthetic surfaces. One study observed that pathogenic antibodies targeted an epitope in domain 1 of β_2 gpl, and that these antibodies had LA activity.⁴²⁵ β_2 gpl may also mediate aCL binding to endothelial cell membranes.⁴²⁶ Other proteins have been occasionally implicated as possible obligatory cofactors, including annexin A5,⁴²⁷ annexin A2,⁴²⁸ factor Xa, protein C, protein S, and vimentin.⁴²⁹ Anti- β_2 gpl antibodies have been reported to induce acquired resistance to APC.⁴³⁰

It was previously thought that APA recognized neoepitopes of the above phospholipid-binding proteins expressed on cell surface binding. Another hypothesis is that the true antibody target is an appropriate density (“clustering”) of proteins bound to phospholipid surfaces, which is necessary for antibody recognition.⁴³¹ For example, based on *in vitro* data, it has

been proposed that β_2 gpl acts as an antigen in vivo only when the antigen (β_2 gpl) clusters on membrane surfaces such as endothelium. When clustering occurs, this increased antigenic density allows antibody recognition to occur, leading to antibody binding and endothelial cell activation and potentially triggering cellular events resulting in thrombosis.⁴³² Figure 54.7 illustrates how this phenomenon might occur. Additional studies found that β_2 gpl undergoes a conformational change (circular to “fishhook”) upon cell binding to anionic phospholipids, leading to clustering⁴³³ and antibody binding.⁴³⁴ Involvement of the MyD88 signal transduction pathway in antibody-mediated endothelial cell activation has been described,⁴³⁵ and others have reported involvement of the p38 mitogen-activated protein kinase pathway.⁴³⁶ Receptors that have been described that could possibly mediate the APA response include a toll-like receptor on endothelium,⁴³⁵ annexin A2, and apoER2'. The latter receptor has been demonstrated to promote leukocyte-endothelial cell adhesion and thrombosis by inhibition of endothelial cell nitric oxide synthase activity.⁴³⁷ Other investigators have identified cell signaling through the toll-like receptor 4 mediated by a multiprotein complex as a pathway for endothelial cell activation by APS antibodies.⁴³⁸

FIGURE 54.7. A proposed mechanism by which antiphospholipid antibodies induce endothelial cell activation and thrombosis. A: Endothelial cells express a phospholipid-binding protein (e.g., β_2 gpl). In the absence of high antigenic density (“clustering”), antibody binding is inefficient. B: Endothelial cells display dimerized (“clustered”) antigen, which

allows for efficient antibody binding, resulting in endothelial cell activation and promotion of thrombosis (C).

In other settings, particularly those related to infection, the aCL antibodies are often of IgM isotype, are often of low titer and relatively transitory, and have no identified co-factor protein.⁴⁰⁹ Although β_2 gpl is an absolute protein co-factor requirement for aCL activity in autoimmune settings, it may, in contrast, be inhibitory in the infection-related circumstance.⁴⁰⁹ The clinical association of IgM antibodies with thrombophilia is less strong,⁴³⁹ particularly thrombosis occurring after drug administration,⁴⁴⁰ although exceptions to this generalization have been noted.⁴⁴¹ The detection of subgroups of aPLs has been reviewed.⁴⁰³

Another key question related to the pathogenesis of APS is, how are antiphospholipid antibodies generated? One report found that only β_2 gpl bound to phospholipids could be successfully presented to T lymphocytes to elicit a pathogenic immune response.⁴⁴² Oxidation of β_2 gpl increases its immunogenicity, and patients with APS have increased amounts of oxidized β_2 gpl.⁴⁴³

Mechanism of Thrombosis

Potential mechanisms to explain how aPL induces thrombosis⁴⁰⁵ include (a) endothelial cell activation, (b) oxidant-mediated vascular injury, (c) interference with the function of phospholipid-binding proteins in regulating coagulation, and (d) complement activation.⁴⁰⁴ In the first hypothesis, aPL antibodies directly bind to endothelium to up-regulate expression of adhesion molecules and cytokine secretion.⁴⁰³ In the second hypothesis, autoantibodies to oxidized low-density lipoprotein occur with aCL antibodies, and aCL antibodies recognize oxidized phospholipids and phospholipid-binding proteins.⁴⁴⁴ In the third hypothesis, aPL antibodies may interfere with the anticoagulant functions of protein C or annexin V or enhance procoagulant activity.^{403, 427, 428} In the fourth hypothesis, complement activation by aPL antibodies leads to neutrophil expression of tissue factor.⁴⁴⁵

Immunologic studies lend strong support for a direct pathophysiologic role of these antibodies in the clinically observed thrombotic syndromes.⁴⁴⁶ In animal models using standardized vessel injury to induce thrombosis, either passively conferred APA⁴⁴⁷ or active induction of antibody with either APA or β_2 gpl⁴⁴⁸ resulted in thrombosis; this suggested that APAs are not merely epiphenomena of thrombi arising for other reasons but, in some cases, play a direct role in initiation, propagation, or maintenance of thrombosis. Immunization of mice or rabbits with β_2 gpl produces two populations of antibodies: One with specificity for β_2 gpl alone without binding to phospholipids and the other with specificities for both cardiolipin and β_2 gpl.⁴⁴⁹ This dual specificity of antibodies is also seen with those aPLs that are present in patients with autoimmune diseases.

The concept of hexagonal phase configuration has been popularized. This configuration is thought to arise in vivo in response to membrane damage.^{450, 451} Normally, polar heads of phospholipids exist on the external surface, whereas in the hexagonal phase, lipid cylinders exist with internal aqueous channels formed by polar head groups.⁴⁵² LA and aCL may represent antibodies generated in response to these neoantigens. APAs have been generated in mice immunized with hexagonal phase phospholipid⁴⁵³; these antibodies reacted with cardiolipin and possessed functional LA activity.

The precise cause of thrombosis in APS is uncertain, and is likely multifactorial. Presumably, APAs act by interfering with coagulation,⁴⁰⁴ possibly involving dysfunction or apoptosis⁴⁵⁴ of endothelial cells, platelets, and coagulation proteins, and affect pregnancy outcome by interfering with embryo implantation and fetal development.⁴⁰³

P.1210

Specific mechanisms of thrombosis that have been implicated include inhibition of APC,⁴⁰⁴ acquired free protein S deficiency, platelet activation, and abnormalities in the antigenic levels or activity of endothelium-derived hemostatic factors, including inhibition of prostacyclin secretion, fibrinolysis, nitric oxide synthesis, or disruption of annexins A5 or A2.^{404, 427, 428, 437} The thrombogenicity of APAs may also result from their interference with endothelial cell phospholipids required for antithrombin and proteins C and S anticoagulant activity, and increased endothelial cell expression of the following procoagulants: Tissue factor, vWF, platelet-activating factor, and plasminogen activator inhibitor type-1.^{403, 404, 455, 456} Tissue factor was identified as a mediator of complement-induced APS fetal loss in a mouse model.^{445, 457}

Epidemiology and Clinical Associations

Young, apparently healthy control subjects are reported to have a prevalence of 1% to 5% of aPL antibodies.⁴⁵⁸ In patients with systemic lupus, aPL occurs in 12% to 34%. After prolonged followup, APS may develop in more than 50% of patients with systemic lupus.⁴⁰³

LA and aCL antibodies have been reported in a variety of clinical disorders, including SLE and other autoimmune and connective tissue diseases, and in disorders that are unrelated to SLE (Table 54.7). The presence of phospholipid-binding antibodies could in some cases be an epiphenomenon. In other cases, APAs may be of profound direct etiologic relevance. In general terms, although there are individual patient exceptions, clinical symptoms are seen less often with aCL than with LA, particularly when APAs are associated with infection or medication, are of low titer, and are of IgM isotype.

Interpretation of estimates of APA frequency must consider the sensitivity of the diverse assay systems that have been used by investigators. Different LA assay systems have been tested with plasma samples from a rigorously defined group of patients with the antiphospholipid-protein syndrome, confirming the importance of variables such as the concentration and composition of phospholipids used in the assay,⁴⁵⁹ phospholipid reagent conformation,⁴⁵² and so forth.

TABLE 54.7 CLINICAL DIAGNOSES ASSOCIATED WITH ANTIPHOSPHOLIPID-PROTEIN ANTIBODIES

Primary antiphospholipid-protein antibody syndrome

Autoimmune disorder with no apparent cause

Secondary autoimmune disorders

Systemic lupus erythematosus; other autoimmune and connective tissue diseases; drug induced: procainamide, hydralazine, quinidine, phenothiazines, penicillin

Malignancies

Leukemia, lymphoproliferative and plasmacytic disorders, solid tumors, essential thrombocytosis

Infections

Viral, bacterial, protozoal, fungal

Neurologic disorders

Liver disease

Valvular heart disease

Peripheral arterial disease

Chronic renal failure

Sickle cell disease

Ethylenediaminetetraacetic acid-dependent pseudothrombocytopenia

In a large series of internal medicine patients, 7% were APA positive, and 2% fulfilled the criteria of antiphospholipid antibody syndrome.⁴⁶⁰ The most commonly associated diseases were cancer and chronic or acute alcoholic intoxication. In another study, elevations of APA were found in approximately 20% of an unselected autopsy population, 10% of age- and sex-matched controls, and 2% of healthy normal subjects.⁴⁶¹

Inhibitors of the lupus type originally were recognized in association with SLE.³⁶⁷ The prevalence of LA in patients with SLE strongly depends on the type of LA assay system used; three standard PTT reagents detected LA in only 10% of SLE patients.⁴⁶² A modified PTT with a reduced concentration of phospholipid detected LA activity in approximately 50% of SLE patients.^{462, 463} The kaolin clotting time, a test similar to the PTT, detected LA in 70% of patients with SLE.⁴⁶⁴ LA activity was associated with higher mortality in SLE patients.⁴⁶⁵ APAs have been seen in other connective tissue disorders, including rheumatoid arthritis and Behçet syndrome.

APAs are present in many patients with malignancy.⁴⁶⁶ APAs have been associated with monoclonal gammopathy of undetermined significance and Waldenström macroglobulinemia. APAs have been identified in liver disease, the prevalence increasing significantly as the liver disease progresses; APA positivity was as high as 80% in patients with alcoholic hepatitis or cirrhosis.⁴⁶⁷ The antibodies have been found in many infections, including hepatitis C,⁴⁶⁸ infection with human immunodeficiency virus,^{469, 470} human T-cell lymphotropic virus-1-associated tropical spastic paraparesis, Q fever, and malaria.⁴⁷¹ Children with viral infections often acquire a transient LA effect.⁴⁶² Perhaps as a result of the structural changes in the red cell membrane with increased hexagonal-phase content, APAs are common in sickle cell disease.⁴⁷² Patients with transient ischemic attacks and cardiac valve lesions had a high incidence of APAs.⁴⁶¹ APAs have

been seen in a variety of unrelated neurologic disorders.⁴⁷³ Patients with essential thrombocythosis have an increased prevalence of APA and increased risk of thrombosis.⁴⁷⁴

Several medications are associated with APA, most often, phenothiazines such as chlorpromazine,⁴⁴⁰ procainamide,⁴⁷⁵ quinine and quinidine,⁴⁷⁶ hydralazine, and penicillin.⁴⁷⁷ APAs were common in patients with ethylenediaminetetraacetic acid-dependent pseudothrombocytopenia.⁴⁷⁸ aCL antibodies can occur in both active and quiescent Crohn disease, usually without concomitant LA expression,⁴⁷⁹ but their role in the thrombotic complications that can occur in the active phase of this disease is uncertain.

APA positivity is a common finding in patients with idiopathic thrombocytopenic purpura,⁴⁸⁰ with either LA or elevated aCL antibodies in almost one half of patients. Moreover, APA levels were not influenced by immunosuppressive therapy with steroids and are not related to the activity of idiopathic thrombocytopenic purpura.

aCL antibodies and, less often, LA are seen in apparently healthy people,^{458, 481} especially in the elderly.⁴⁸² In studies of normal blood donors, 5% to 10% have aCL antibodies, often present transiently and in relatively low titer without a concomitant LA effect; these donors do not have an increased risk of developing thrombosis.⁴⁸³ An inherited predisposition to the development of lupus inhibitors was suggested by their presence in two pairs of siblings⁴⁸⁴ and in familial studies.⁴⁸⁵ Further investigations have suggested associations with certain HLA types.^{486, 487}

Clinical Manifestations

Although LAs are immunologically distinct from aCL antibodies, clinical manifestations associated with each antibody appear to be similar. Clinical experience suggests that venous thrombosis is more likely associated with the LA, and arterial thrombosis is more likely associated with high-titer aCL antibodies. However,

P.1211

a literature meta-analysis found that the LA was a stronger risk factor for all thrombosis.⁴⁸⁸

The antiphospholipid-antibody syndrome is characterized by the clinical events of pregnancy morbidity or thromboembolic disease (arterial, venous, or small vessel), or both (Table 54.8).⁴⁸⁹ These clinical features are most highly associated with aPL antibodies in prospective studies.⁴⁸⁹ Older definitions included immune thrombocytopenia as a clinical event, but the newer classification omits thrombocytopenia.⁴⁸⁹ A wide variety of clinical features may be seen with APA.^{404, 489, 490, 491, 492} However, many patients with APA are asymptomatic. A proportion of asymptomatic patients develop SLE⁴⁹³ or other disorders.⁴⁹⁴ The diverse clinical manifestations of APA are listed in Table 54.9.

Arterial and Venous Thromboembolic Disease

The most common clinical presentation of patients with LA or aCL antibodies, or both, is arterial or venous thromboembolism,^{404, 495, 496} affecting up to 70% of patients in some series but averaging approximately 30% to 40% of patients in most studies.^{463, 496, 497} The most common site is extremity deep vein thrombosis, but occasionally, unusual sites are involved, such as the axillary, retinal, and hepatic veins and cerebral venous sinus thrombosis.⁴⁹⁸ Cerebral thrombosis, often heralded by repeated transient ischemic attacks, is a common arterial lesion.^{404, 499} Mesenteric artery occlusion, adrenal infarction, gastrointestinal ischemia or ulceration, and subclavian thrombosis with “pulseless” disease also have been described. Multiple cerebral infarcts with dementia in addition to coronary occlusions have occurred in unusually young age groups.⁵⁰⁰ A paradoxical syndrome of cerebral infarction with concurrent severe thrombocytopenia and bleeding has been reported in several cases.⁴⁹⁹ Antibodies to β_2 gpl are highly associated with venous thrombosis,⁵⁰¹ and in other studies, assays for the LA correlated best with thrombosis, compared with assays for other APAs.^{488, 502} Another unusual ischemic syndrome associated with APA is avascular osteonecrosis.⁵⁰³

TABLE 54.8 CRITERIA FOR DIAGNOSIS OF THE ANTIPHOSPHOLIPID-ANTIBODY SYNDROME (APS)

Clinical Event	Laboratory Abnormality
Venous thrombosis	Positive lupus anticoagulant test (according to guideline in Table 54.11)
<i>or</i>	<i>or</i>
Arterial thrombosis	Positive anticardiolipin antibody test (moderate titer or high-titer IgG or IgM antibodies)

or

Small-vessel thrombosis

or

Complications of pregnancy

One or more unexplained deaths of normal fetuses at or after 10 wk of gestation with normal fetal morphology

One or more premature births of normal neonates before 34 wk of gestation

Three or more unexplained consecutive spontaneous abortions before 10 wk of gestation, excluding anatomic, hormonal, and chromosomal abnormalities

Note: A diagnosis of definite APS requires the presence of at least one clinical event and at least one laboratory abnormality.

Ig, immunoglobulin.

Criteria from Miyakis S, Lockshin MD, Atsumi T, et al. International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). *J Thromb Haemost* 2006;4:295-306.

or

Positive β_2 gpI antibody test (titer >99th percentile, IgG or IgM antibodies)

and

Laboratory abnormality should persist for two or more occasions at least 12 wk apart

TABLE 54.9 CLINICAL MANIFESTATIONS OF ANTIPHOSPHOLIPID ANTIBODIES

Asymptomatic

Arterial and venous thromboembolism

Avascular osteonecrosis

Hematologic

Cytopenias: thrombocytopenia, autoimmune hemolytic anemia, leukopenia

Coagulopathy: platelet dysfunction, prothrombin deficiency, lupus anticoagulant

Neurologic

Acute ischemia (cerebrovascular accident, transient ischemic attack, encephalopathy); severe migraine; multiple infarct dementia; cognitive dysfunction; seizures

Dermatologic

Livedo reticularis; acrocyanosis (distal cutaneous ischemia, ulceration, gangrene); widespread cutaneous necrosis; pyoderma gangrenosum-like skin lesions; anetoderma

Cardiopulmonary

Marantic endocarditis; myocardial ischemia and infarction; intracardiac thrombotic mass; peripheral arterial disease; thromboembolic and nonthrombotic pulmonary hypertension

Obstetric

Recurrent spontaneous abortion; intrauterine growth restriction; preeclampsia; chorea gravidarum; low

Apgar scores; prematurity

Catastrophic antiphospholipid syndrome

Thrombocytopenia

Moderate immune thrombocytopenia is noted in approximately 50% of patients with lupus inhibitors, but in many cases, it apparently is the result of the underlying disorder.⁵⁰⁴ Immune thrombocytopenia is no longer considered a clinical criterion for diagnosis of APS.⁴⁸⁹ When bleeding occurs in patients with aPLs,⁵⁰⁵ this is generally attributed to co-existent thrombocytopenia, platelet dysfunction,⁵⁰⁶ prothrombin deficiency,⁵⁰⁷ or other underlying coagulopathies. Other cytopenias may be associated with APA, including autoimmune hemolytic anemia and leukopenia.

Neurologic Syndromes

Various neurologic disorders have been linked with APA, including dementia, migraines, chorea, seizures, transverse myelopathy, Guillain-Barré syndrome, mononeuritis multiplex, transient global amnesia, and myasthenia gravis. Many of these disorders are not associated with ischemia or thrombosis, and the pathologic relationship of these disorders with APA is uncertain. A consensus statement on stroke and APS proposed criteria to determine the likelihood that APA is associated with ischemic stroke.⁵⁰⁸ A literature survey determined that the presence of APA in patients with ischemic stroke did not predict recurrence of stroke or differential response to treatment, and that routine screening for APA in these patients was not warranted.⁵⁰⁹

Dermatologic Disorders

A variety of ischemic-dermatologic syndromes have been associated with aCL antibodies, including livedo reticularis, P.1212

acrocyanosis (distal cutaneous ischemia, ulceration, gangrene), widespread cutaneous necrosis, and pyoderma gangrenosum-like skin lesions.^{489, 510} Livedo reticularis is more prevalent among APS patients with systemic lupus, and in females.⁴⁸⁹

Cardiac Disorders

A high incidence of APA is seen in patients with peripheral arterial disease who experience an associated increased risk of early graft thrombosis.⁵¹¹ This may justify routine testing for APA before reconstructive vascular surgery, with consideration of perioperative antiplatelet agents or anticoagulation. Some reports have noted the presence of APA in survivors of myocardial infarction.⁵¹² A variety of valvular heart lesions is associated with APS.⁴⁸⁹ The consensus group recommends that patients with biopsy-proven myocardial small-vessel thrombosis or those with intracardiac thrombi be considered for meeting criteria for APS. Coronary artery disease also fulfills the APS thrombosis criterion.⁴⁸⁹

Pulmonary Disorders

Ischemic and thrombotic pulmonary disease is linked to APA, including pulmonary embolism, pulmonary hypertension, intraalveolar pulmonary hemorrhage, and adult respiratory distress syndrome.^{513, 514} The latter syndrome has been reported in patients with CAPS.⁵¹⁴

Obstetric Aspects

APAs are associated with obstetric complications,^{403, 489, 515, 516, 517} including intrauterine growth restriction, preeclampsia, chorea gravidarum, and, primarily, recurrent spontaneous fetal loss (RSFL). Pregnancy losses in women with aPLs are often caused by fetal death despite normal fetal karyotypes. Spontaneous fetal loss is perhaps most common in the first trimester, but paradoxically, early first-trimester pregnancy losses are relatively less common than in other patients with recurrent fetal loss.⁵¹⁸ The international consensus statement listed obstetric criteria for diagnosis of APA: (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation (with normal fetal morphology); (b) one or more premature births of a morphologically normal neonate before the 34th week of gestation because of preeclampsia, eclampsia, or placental insufficiency; or (c) three or more unexplained consecutive spontaneous abortions before the 10th week of pregnancy (with maternal anatomic or hormonal abnormalities, and paternal and maternal chromosomal causes excluded).⁴⁸⁹

There is a significantly increased incidence of elevated APA in women with a history of two or more miscarriages in the first trimester of pregnancy.⁵¹⁹ Women with a history of RSFL should be tested for both LA and aCL antibodies.⁵²⁰ Repeat testing is important because only 66% of LA-positive, 37% of IgG aCL-positive, and 36% of IgM aCL-positive women had a

positive test result on repeat evaluation. Laboratory screening for LA is confounded in pregnancy because altered coagulation factor concentrations in normal pregnancy may change the observed normal range of coagulation tests, including the PTT. In two studies, the DRVVT was the most frequently positive test for the LA in this population. Rigorous adherence to diagnostic criteria is particularly appropriate in pregnancy because treatment may require potentially hazardous antithrombotic therapy. Elevated maternal serum levels of α -fetoprotein⁵²¹ or human chorionic gonadotrophin⁵²² are common in women with aPLs and are significantly associated with fetal loss. Maternal APA testing may be appropriate if prenatal screening reveals an elevated human chorionic gonadotrophin level and ultrasonography demonstrates an otherwise normal singleton gestation.

It is generally considered not appropriate to screen for APA in asymptomatic pregnancies without a history of RSFL.⁵²³ APAs were identified at the first pre-natal visit in almost 25% of healthy pregnant women.⁵²⁴ LA appears to be much rarer than aCL antibodies in pregnancy.⁵²⁵ It appears that women with isolated IgM aCL or with low levels of IgG aCL are a distinct group that is not at risk for APA-related complications beyond the risk conferred by their medical histories.⁵²⁶

Although the mechanism by which APA causes recurrent pregnancy loss has not been fully explained, these antibodies may induce intervillous thrombosis and intravillous infarctions, resulting in poor placental perfusion, and have been shown to affect cytotrophoblast tissue *in vitro*. The thrombotic phenomenon may be mediated by aPL antibodies interfering with trophoblastic annexin V.^{404, 527}

The role of inflammation and the complement pathway in APS-associated pregnancy complications was reported.⁵²⁸ Anticoagulants that prevented complement activation (unfractionated or LMWH) were successful in preventing pregnancy loss in an animal model of APS; anticoagulants that did not inhibit complement activation (fondaparinux, hirudin) did not prevent pregnancy loss. These data suggest that the beneficial effects of anticoagulants in APS-associated pregnancy loss result from inhibition of complement activation.⁵²⁸

Catastrophic Antiphospholipid-antibody Syndrome

Some patients with APA develop an acute, severe, multiorgan illness^{403, 514, 529} characterized by diffuse small vessel ischemia and occlusion with extensive tissue damage, including myocardial infarction, limb ischemia, DIC, and a high mortality rate of 50%.⁵³⁰ The patients present with a dramatic illness, often without an obvious precipitating event, that prompts consideration of a wide differential diagnosis including severe lupus vasculitis, thrombotic thrombocytopenic purpura, or severe DIC. The syndrome is defined by clinical involvement of at least three different organ systems with histologic evidence of thrombosis.^{529, 530} Typically, small vessel thrombotic lesions occur, with common sites of involvement including the kidney, lung, central nervous system, heart, and skin.^{529, 530} In a larger series of CAPS patients, nearly one half of the cases had systemic lupus, and 40% had PAPS.⁵³¹ Precipitating factors for development of CAPS included infections, trauma/procedures, cancer, and subtherapeutic anticoagulation.⁵³¹ LA activity and, particularly, high aCL antibody titers are usually present. Central nervous system symptoms and hypertension are common, and leukocytosis and a significantly elevated sedimentation rate are often also present. The clinical manifestations of this syndrome can include all the symptoms and signs indicated in Table 54.9. Preliminary criteria for the classification and diagnosis of CAPS have been published.⁵²⁹ Effective therapies include therapeutic anticoagulation, steroids, ivIgG, plasma exchange, and cyclophosphamide.⁵²⁹ A literature review of rituximab use in CAPS found encouraging results.⁵³² A summary of CAPS registry cases reported that anticoagulation with steroids \pm plasma exchange/ivIgG was associated with at least a 70% success rate.⁵³³

Laboratory Diagnosis of Antiphospholipid-Protein Antibodies

LA and high-titer aCL antibodies have similar clinical implications, although studies suggest a higher thrombotic risk in patients with the LA.^{488, 502} In patients with SLE, the LA is the best predictor for both venous and arterial thrombosis. The laboratory should perform both fibrin-based coagulation assays to detect LA and solid-phase ELISA assays for aCL and β_2 gpl antibodies in patients suspected of having APA.

A considerable array of phospholipid-responsive laboratory tests, such as the PTT, dilute PTT, kaolin clotting time, and DRVVT, may serve to screen for the LA.⁴⁰⁹ LA may be defined as an immunoglobulin (IgG, IgM, IgA, or a mixture) that interferes with one or more of these *in vitro*, phospholipid-dependent coagulation tests. A more recent definition of the LA would be antibodies to β_2 gpl or to prothrombin that prolong phospholipid-dependent coagulation

P.1213

assays. Coagulation tests that are phospholipid independent are not affected by LA. Unless concurrent additional factor deficiencies are present, the standard PT is usually normal because of the large amount of phospholipids in this reagent.

No individual test seems to have a universal detection rate; this observation may reflect LA subtypes with distinct activities or the requirement of various co-factors. Consequently, it is recommended to perform at least two independent assays for the LA.^{489, 534} A simplified algorithm approach for diagnosis of the LA has been described that uses two assays, the DRVVT and a hexagonal phase assay.⁵³⁵ Comparative studies suggest that activated PTT reagents with reduced levels or different types of phospholipids are more sensitive than routine PTT reagents.^{409, 536} Platelet-poor plasma should be used in these screening assays, particularly if frozen plasma samples are to be tested.⁵³⁷ A recent update of LA guidelines has reviewed these issues.⁵³⁸ Table 54.10 indicates some of the clinical and laboratory differences between specific anticoagulant antibodies to particular factors, such as factor VIII and LA. Other nonspecific anticoagulants are uncommon but include the heparinlike anticoagulants discussed in the section "Other Acquired Coagulation Disorders." Confirmatory tests for LA based on activated PTT or DRVVT include abnormal mixing studies with normal plasma and correction with mixing using phospholipids, such as lysed washed platelets (platelet neutralization procedure), or with added hexagonal-phase phospholipids.⁵³⁹ A high concentration of liposomes prepared from rabbit brain extracts may achieve the most efficient correction of the defect,⁵⁴⁰ but this method is not widely used. The College of American Pathologists has published detailed recommendations for LA testing,⁵⁴¹ and testing issues affecting the LA have been reviewed.⁵⁴²

Several clinical points are worth stating. The search for LA or aCL antibodies should not be abandoned even if normal plasma in a mixing study corrects the test patient plasma, particularly in a human immunodeficiency virus-positive population.⁵⁴³ It is sometimes important for the clinician to discern the possible effect that heparin in the test patient plasma can have on the confirmatory laboratory assay; satisfactory correction procedures should be resistant to heparin, and many commercial LA reagents have heparin neutralizers. The ideal test to identify the LA is controversial; some investigators have reported the kaolin clotting time to be the most sensitive test.^{536, 544} On the other hand, some DRVVT assays are more able to identify LA associated with thrombosis.⁵⁴⁵ A subgroup of patients with unexplained thrombosis with antibodies to phosphatidylethanolamine as the only abnormal APA test has been identified.⁵⁴⁶ Optimal detection of the LA requires more than one of the phospholipid-dependent assays described earlier.^{489, 538, 547} This latter suggestion is supported by reports that different phospholipid-dependent coagulation tests detect different populations of LA antibodies.⁵⁴⁸ Table 54.11 summarizes the recommendations of an ISTH consensus group on laboratory diagnosis of LA.⁴⁸⁹

TABLE 54.10 COMPARISON OF FACTOR VIII ANTIBODIES AND ANTIPHOSPHOLIPID-PROTEIN ANTIBODIES

Clinical Event or Laboratory Test	Factor VIII Antibodies	Antiphospholipid-Protein Antibodies
Bleeding	Often severe	Uncommon
Thrombosis	Rare	Common
Obstetric complications (abortion and intrauterine fetal death)	Rare	Common
Prothrombin time	Normal	May be prolonged
Thrombin time	Normal	Occasionally prolonged
Thrombocytopenia	Rare	Common
Inhibitory effect in plasma mixtures	Usually time dependent	Often is instantaneous; occasionally, mixing studies show time-dependent inhibition
Prothrombin level	Normal	Occasionally deficient
Factor VIII level	Deficient; one-stage assay curve is aberrant with low-affinity antibodies	Normal when assayed in a dilute system; all one-stage assay curves are aberrant
Anticardiolipin and β_2 gpI antibodies	Rare	Common
Phospholipid or platelet correction of abnormal assay	No	Usually

result

Ig, immunoglobulin.

aPLs may also be detected by ELISA⁴⁸⁹ or by radioimmunoassay. Commercial ELISA systems are reasonably well standardized. The aCL-antibody assay used to improve sensitivity and specificity has undergone several modifications. Using anti- β_2 gpl-dependent assay systems is useful to discriminate between transiently positive aCL antibodies that are associated with infection, which characteristically do not have a β_2 gpl cofactor requirement, and those aCL antibodies associated with an increased risk of thrombosis.⁵⁴⁹ IgA aCL antibodies should not be considered a laboratory criterion for diagnosis of APS.⁴⁸⁹

Definitional standardization of the criteria for clinical and laboratory APA has been published.^{403, 489} For the diagnosis of APS, in addition to a clinical event (e.g., at least one venous, arterial, or small-vessel thrombosis, pregnancy morbidity/mortality), positive laboratory tests for LA, aCL, or β_2 gpl antibodies (in medium or high titer) should be found on two occasions at least 12 weeks apart (Table 54.8). It is recommended that aCL antibodies be measured by a standardized ELISA for β_2 gpl-dependent antibodies.^{403, 489} Although consensus criteria require persistence of the laboratory abnormality for at least 12 weeks, in clinical practice, a functional definition taking into account the number of clinical manifestations and the titer of aCL antibodies or positivity for the LA on even a single occasion may help categorize patients as having definite, probable, or doubtful APS and may direct immediate treatment options. A "triple positive"

P.1214

profile (positive results for all three assays: LA, aCL antibodies, and β_2 gpl antibodies) has been identified as a strong independent risk factor for thrombosis.⁵⁵⁰

TABLE 54.11 LABORATORY DIAGNOSIS OF LUPUS ANTICOAGULANT: INTERNATIONAL SOCIETY ON THROMBOSIS AND HAEMOSTASIS CRITERIA

- Prolongation of at least two phospholipid-dependent coagulation tests with the use of platelet-poor plasma (e.g., the activated partial thromboplastin time, dilute prothrombin time, dilute Russell viper venom time, kaolin clotting time). The DRVVT should be the first test considered.
- Failure to correct the prolonged coagulation time by mixing patient and normal plasma.
- Confirmation of lupus anticoagulant by demonstrating correction of the prolonged coagulation time by addition of excess phospholipids or freeze-thawed platelets.
- Exclusion of alternative coagulopathies using specific assays (e.g., factor VIII antibodies).

Diagnostic criteria from Levine JS, Branch DW, Rauch J. The antiphospholipid syndrome. *N Engl J Med* 2002;346:752-763; and Brandt JT, Triplett DA, Alving B, et al. Criteria for the diagnosis of lupus anticoagulants: an update. On behalf of the Subcommittee on Lupus Anticoagulant/Antiphospholipid Antibody of the Scientific and Standardisation Committee of the ISTH. *Thromb Haemost* 1995;74:1185-1190. Additional laboratory details and patient selection criteria are discussed in Pengo V, Tripodi A, Reber G, et al. Update of the guidelines for lupus anticoagulant detection. *J Thromb Haemost* 2009;7:1737-1740.

Even if the patient is asymptomatic, lupus inhibitors should always be identified correctly when discovered, even though costly and time-consuming laboratory study is required. If the cause for a prolonged PTT is not identified, the necessity for definitive laboratory evaluation almost invariably arises again, often in the context of an emergency. This may result in the unnecessary use of blood products and a delay of required surgical procedures.

Treatment of Antiphospholipid-Protein Antibody Syndrome

The optimal treatment of patients with APA syndrome is undefined, although randomized treatment trials are providing useful therapy recommendations. Depending on the clinical symptoms, patients with APA may need no treatment or may need anticoagulant or immunosuppressive therapy. Although spontaneous remissions are uncommon and aCL antibodies and LA can be associated with life-threatening thromboembolic events, only 10% to 15% of asymptomatic patients with APA develop these complications. Based on the uncertainty of predicting when thrombotic events might occur, as well as

the risks of anticoagulation, most investigators do not treat asymptomatic patients prophylactically, with the possible exception of short-term intervention when additional thrombophilic hazards such as immobilization or surgery are anticipated.

Patients with significant thrombotic events (e.g., deep vein thrombosis, arterial ischemia, or fetal loss) are appropriate candidates for antithrombotic therapy. Two randomized trials investigated the optimal intensity of warfarin therapy in APS patients.^{551, 552} Both studies found that high-intensity warfarin (INR 3.1 to 4.0 or 4.5) was not superior to standard intensity warfarin (INR 2.0 to 3.0).^{551, 552} Long-term treatment with oral anticoagulation therapy is advised because of the high rate of recurrence even if the venous or arterial occlusion occurred many years previously.^{553, 554} Patients receiving oral anticoagulants had no recurrence over 8 years, whereas patients in whom anticoagulant drugs had been discontinued had a 50% probability of a recurrent venous thromboembolic episode after 2 years and an almost 80% probability of recurrence after 8 years.⁵⁵⁵ This strategy is supported by a study that found that APS patients with thrombosis benefited from prolonged oral anticoagulation because persistent elevation of aCL levels predicted an increased risk of thrombosis recurrence and death.⁵⁵⁶ Many investigators follow this approach,⁴⁰⁴ unless all laboratory evidence of LA and aCL in patients in whom high titers were initially detected or in whom a thrombotic risk was attributed to APA has been continually absent for at least 6 months; no other thrombophilic risk is present; and close surveillance is feasible. An emerging treatment strategy in APS patients is to consider single-positivity test results for β_2 gpl or aCL antibodies as a lesser risk for recurrent thrombosis, and perhaps less-intense or shorter duration treatment periods.⁴⁰⁴

A literature review of treatment for APS patients with ischemic stroke concluded that treatment with either aspirin or low-intensity warfarin (INR 2.0 to 3.0) is effective.⁵⁵⁷ For noncerebral arterial thrombosis, combined therapy with low-intensity warfarin (INR 2.0 to 3.0) plus aspirin (81 mg) was recommended.⁵⁵⁷

A relatively new therapy for APS is hydroxychloroquine, an immunosuppressive agent used to treat patients with SLE. Hydroxychloroquine therapy decreases thrombosis risk in SLE patients,⁵⁵⁸ perhaps by interfering with aPL antibody binding to phospholipid.⁵⁵⁹

Patients with the uncommon LA hypoprothrombinemia syndrome who either have bleeding or need surgery may benefit from steroid therapy or intravenous IgG.⁵⁶⁰

Patients with the LA and acute thrombosis pose difficulty in terms of monitoring heparin anticoagulation. The usually prolonged PTT value seen with the LA renders this test unreliable. These patients can be monitored using heparin assays, which are available by automated methodology (see Chapter 55). Alternatively, patients can be treated using a LMWH, without the necessity for laboratory monitoring (see Chapter 55).

In those patients with an LA and hypoprothrombinemia, or an LA that affects the PT, the use of the INR to monitor anticoagulation has been questioned. These patients may require monitoring with a test that is insensitive to the LA, such as a prothrombin-proconvertin assay or a chromogenic factor X assay.⁵⁶¹

Corticosteroid use often diminishes or abolishes the coagulation abnormalities and immune thrombocytopenia of APA syndrome within a short time. However, for most patients, the role of steroids, other immunosuppressive agents, or aspirin is uncertain. Although immunosuppression with cyclophosphamide in pulse form is effective in reducing elevated antibody levels, there is often a rapid rebound to pre-treatment levels shortly after discontinuation of the therapy. Consequently, additional therapies with aspirin or steroids or more aggressive immunosuppression are not used unless recurrent thrombotic or ischemic events are seen despite optimal warfarin therapy. High-dose corticosteroid therapy has equivocal efficacy and considerable toxicity and is reserved for treatment of underlying co-morbid conditions such as active lupus and not for the laboratory phenomena of the antiphospholipid antibody syndrome itself.

In patients with CAPS who experience multisystem involvement, intensive treatment with corticosteroids, immunosuppression, intravenous IgG, or plasmapheresis may be useful.^{530, 532, 533} In one literature analysis of CAPS therapy, the highest response to therapy occurred in patients treated with anticoagulation and steroids (64%).⁵³¹ Immune thrombocytopenia and autoimmune hemolytic anemia in patients with APA are treated similarly as in patients without APA.

Obstetric Treatment

Because the risk of pregnancy loss in women with APS and prior pregnancy loss may exceed 60%, a history of recurrent fetal loss is an indication for treatment during pregnancy. Antiplatelet agents such as aspirin 80 mg/day,⁵⁶² low-dose immunosuppressive agents such as prednisolone 10 mg/day,⁵⁶³ or anticoagulants (heparin or LMWH) have all been used in an attempt to improve pregnancy outcome.^{403, 404} Several randomized studies have provided information about useful treatment strategies in pregnancy-associated APS (reviewed in References 403 and 564). Intravenous IgG is of no benefit

in these patients, and heparin may be more effective than aspirin. A meta-analysis recommends that a combination of unfractionated heparin (5,000 U s.c. twice daily) and low-dose aspirin be used,⁵⁶⁴ and a recent consensus guideline recommends “prophylactic or intermediate-dose unfractionated heparin or prophylactic LMWH combined with low-dose aspirin (75 to 100 mg/day)”.⁵⁶⁵

Transfusion-associated Coagulation Abnormalities

The administration of blood products in a volume >1.5 times the patient's estimated blood volume or replacement of total blood volume in <24 hours constitutes massive blood transfusion.⁵⁶⁶ Traditional resuscitation efforts were initiated with large volumes of crystalloid and packed red cell transfusions; a new paradigm is termed “damage control resuscitation” which includes administration of tranexamic acid for cases of uncontrolled hemorrhage, use of a massive transfusion protocol with fixed blood product

P.1215

ratios, avoidance of large-volume crystalloid use, and usage of permissive hypotension.^{567, 568}

The importance of core body temperature on hemostasis parameters has been demonstrated; at a temperature of 33°C, platelet function is impaired. Below 33°C, both coagulation factor activity and platelet function are reduced.⁵⁶⁹

Bleeding Associated with Extracorporeal Circulation

Defective hemostasis with cardiopulmonary bypass is associated with multiple contributory causes, including hemodilution of coagulation factors, inadequate neutralization of heparin, acquired platelet dysfunction, and thrombocytopenia. These latter two defects are further discussed in Chapter 52. In general, extracorporeal-circulation-induced hemostatic defects may be ascribed to activation of platelets and coagulation proteins by artificial surfaces.

Platelet dysfunction (acquired storage pool defect) is considered the major hemostatic insult induced by bypass.⁵⁷⁰ Although DDAVP was shown to reduce bleeding and transfusion requirements in these patients in earlier studies, subsequent trials indicated no benefit from DDAVP,⁵⁷¹ and routine DDAVP therapy may be hazardous in older patients with significant vascular disease.⁵⁷² Aprotinin should not be used in this setting.⁵⁷³

Drug-induced Coagulation Abnormalities

Broad-spectrum antibiotics, such as the β -lactam antibiotics, may induce a coagulopathy by inhibition of vitamin K synthesis by gut bacteria and direct inhibition of essential carboxylation reactions.²² A number of antibiotics may also inhibit platelet function (see Chapter 52).

L-Asparaginase produces hypofibrinogenemia and deficiency of other coagulation factors.⁵⁷⁴ Hematin produces a complex coagulopathy.⁵⁷⁵ Valproic acid therapy has been associated with acquired vWD.⁵⁷⁶

Acquired Deficiencies of Single Coagulation Factors

An uncommon phenomenon is the development of deficiency of a single coagulation factor during the course of an acquired disorder (Table 54.6). Isolated deficiency of factor X is well documented in patients with primary amyloidosis and amyloidosis associated with multiple myeloma.⁵⁷⁷ Factor X levels in these patients do not rise even after massive replacement therapy, and studies using ¹³¹I-labeled factor X suggest that this proenzyme is bound to subendothelial amyloid fibrils in blood vessels.⁵⁷⁸ A combined deficiency of factors IX and X in amyloidosis also has been reported.⁵⁷⁹ In many patients, the hemostatic defect is complicated by other abnormalities, such as vascular infiltration, liver disease, high levels of antithrombins, and azotemia with platelet dysfunction.⁵⁸⁰ Splenectomy abolished the factor X deficiency and produced complete remission of bleeding in several cases,⁵⁸¹ presumably because of extensive amyloid infiltration in the splenic vasculature. Chemotherapy with melphalan and prednisone may also resolve factor X deficiency in amyloidosis.⁵⁸² High-dose chemotherapy with stem cell transplantation is also effective therapy.⁵⁸³ Factor X deficiency has also been associated with upper respiratory tract infections.³⁹⁴ A detailed literature review of acquired factor X deficiency has been published.⁵⁸⁴

Hypoprothrombinemia has been reported as an isolated finding,⁵⁸⁵ most commonly in association with LAs, as discussed previously. Deficiencies of prothrombin, factors IX and XII, plasminogen, and antithrombin have been reported in some patients with the nephrotic syndrome,^{586, 587, 588, 589, 590} presumably as the result of massive protein loss in the urine. In one patient with Sheehan syndrome, a selective deficiency of factor IX responded to treatment with corticosteroids and thyroid replacement.⁵⁹¹ Isolated deficiency of factor IX in several patients with Gaucher disease also has been documented.⁵⁹² Acquired factor VII deficiency has been reported with aplastic anemia⁵⁹³ and liposarcoma.⁵⁹⁴

Factor XIII deficiency has been associated with chronic myelocytic leukemia and with various forms of acute leukemia.⁵⁹⁵ Factor XIII deficiency has also been associated with inflammatory bowel disease,⁵⁹⁶ and isoniazid-induced antibodies to factor XIII have been reported.^{381, 382, 597} Factor XII deficiency has been described in association with chronic myelocytic leukemia⁵⁹⁸ and antiphospholipid antibodies.⁵⁹⁹ Factor XI deficiency has been linked to Gaucher disease⁶⁰⁰ and Ehlers-Danlos syndrome.⁶⁰¹ Factor V deficiency has been reported in chronic myeloid leukemia and in celiac disease. Acquired vWD was discussed earlier in the section on vWF.

Other Acquired Coagulation Disorders

Heparinlike anticoagulants have been reported in patients with hematologic malignancies (e.g., plasma cell dyscrasias⁶⁰² or leukemias^{603, 604} or solid tumors⁶⁰⁵). A prolonged thrombin time and normal reptilase clotting time are typically seen in these patients. Significant clinical bleeding may occur with heparinlike anticoagulants; a titrated protamine sulfate infusion may be helpful in these patients.

Malignancy may also be associated with other inhibitors of coagulation, including FDPs and paraproteins, dysfibrinogenemias, and specific antibodies to coagulation factors (discussed earlier). A monoclonal antithrombin antibody associated with bleeding has been reported in a patient with myeloma.⁶⁰⁶

Chapter 55

Thrombosis and Antithrombotic Therapy

Robert C. Pendleton

George M. Rodgers

The term thrombosis refers to the formation, from constituents of the blood, of a mass within the venous or arterial vasculature of a living animal. Hemostatic thromboses, namely, self-limited and localized thromboses that prevent excessive blood loss, represent the body's natural and desired response to acute vascular injury. Pathologic thromboses such as deep venous thrombosis (DVT), pulmonary embolism (PE), coronary arterial thrombosis leading to myocardial infarction (MI), and cerebrovascular thrombotic occlusion represent the body's undesired response to acute and chronic perturbations of the vasculature, blood, or both. The terms coagulated blood and clot are not synonymous with thrombosis and refer to the formation of a solid mass of blood components outside of the vascular tree. Examples of clots include soft tissue, body cavity (e.g., peritoneal), and visceral hematomas. Coagulated blood best describes clots formed *ex vivo*.

Thrombosis of the veins and arteries, together with complicating embolic phenomena, is perhaps the most important cause of sickness and death in the developed countries of the world at the present time. Deaths from MI and thrombotic stroke consistently represent the major causes of death in the United States, numbering >700,000 people annually

(almost 30% of all deaths) in a recent report.¹ Venous thromboembolic disease is the third most common cardiovascular disease, after atherosclerotic heart disease and stroke. It has been estimated that between 500,000 and 2 million venous thromboembolic events (VTE) including calf vein thrombosis, proximal DVT (e.g., lower extremity and pelvic veins), and PE occur annually in the United States alone.² The incidence of pathologic thrombosis, prevalence of disorders that predispose to thrombosis, and morbidity and mortality associated with thrombotic events all reflect the magnitude of the importance of the study of thrombotic mechanisms and development of effective antithrombotic and thrombolytic therapies.

In this chapter, the pathophysiology of arterial and venous thrombosis and mechanisms of action of antithrombotic pharmacologic agents including antiplatelet drugs, anticoagulants, and fibrinolytic agents are summarized and discussed. Inherited conditions that predispose an individual to thrombosis, also termed hypercoagulable states, and the management of venous thromboembolic disease are covered. The management of arterial thrombotic events is beyond the scope of this chapter, and the reader is referred to several excellent recent review articles.^{3, 4, 5}

PHYSIOLOGY AND PATHOPHYSIOLOGY OF THROMBOSIS

The human hemostatic system consists of multiple independent, yet integrally related, cellular and protein components that function to maintain blood fluidity under normal conditions and promote localized, temporary thrombus (hemostatic thrombus) formation at sites of vascular injury. A normal hemostatic system is the human physiologic defense against exsanguination. An abnormal hemostatic system can result in pathologic bleeding, vascular thrombosis, or both.

The hemostatic system is comprised of six major components: Platelets, vascular endothelium, procoagulant plasma protein “factors,” natural anticoagulant proteins, fibrinolytic proteins, and antifibrinolytic proteins. Each of these six hemostatic components must be present in fully functional form, in adequate quantity, and at the proper location to prevent excessive blood loss after vascular trauma and, at the same time, to prevent pathologic thrombosis. The hemostatic system is highly regulated and maintains a delicate balance between a prohemorrhagic state and a prothrombotic state. Any significant acquired or congenital imbalance in the hemostatic “scales” can lead to a pathologic outcome.

Normal hemostasis in response to vascular injury can be divided into two major processes of equal importance, known as primary and secondary hemostasis. Primary hemostasis comprises the reactions needed to form a platelet plug at a site of vascular damage, whereas secondary hemostasis comprises a series of reactions (coagulation cascade) needed to generate cross-linked fibrin required to stabilize the platelet plug and form a durable thrombus. Natural anticoagulants (antithrombin [AT] and activated protein C [APC]) function to confine thrombus formation to the sites of vascular injury and limit thrombus size to prevent vessel occlusion and flow interruption in the affected vessel. The activity of AT is greatly enhanced by endothelial cell heparan sulfate and pharmacologic heparins. The function of APC is enhanced by its cofactor, protein S. Physiologic fibrinolysis is initiated by endothelial-cell-derived tissue-type plasminogen activator (t-PA), which converts plasminogen to plasmin. Plasmin can degrade cross-linked fibrin, limit thrombus size, and help dissolve a thrombus once the vascular injury has been repaired. The fibrinolytic system is regulated and localized by antiplasmin and PA inhibitor (PAI)-1. Details of the hemostatic mechanisms and endothelial cell regulation of hemostasis are given in Chapters 18 and 19.

Specific alterations in the quantitative and qualitative status of any hemostatic cellular or protein element can lead to pathologic thrombosis. A marked increase in the platelet count (thrombocytosis) and accentuated platelet aggregation (“sticky platelet syndrome”) are associated with thromboembolic events. Elevated levels of procoagulant factors such as fibrinogen, factors VIII, IX, XI, and VII, as well as resistance to inactivation of factor Va by APC, are recognized risk factors for vascular disease and thrombosis. Deficiency of a natural anticoagulant protein such as protein C, protein S, or AT is associated with venous thromboembolic disease. Deficiency of a fibrinolytic cascade component, such as t-PA or plasminogen, and excess plasma levels of the fibrinolytic inhibitor PAI-1 have been linked to hypercoagulability and thrombosis. It is the net balance between the participating and, at times, opposing groups of proteins and not the level of any individual factor that is most critical to hemostatic regulation.

VIRCHOW TRIAD

In the mid-19th century (1854), German pathologist Rudolph Virchow postulated that vascular obstruction was precipitated by, and thrombosis resulted from, three interrelated factors:

P.1219

(a) “Decreased blood flow” (stasis of blood flow), (b) “inflammation of or near the blood vessels” (vascular endothelial

injury), and (c) "intrinsic alterations in the nature of the blood itself" (hypercoagulability).⁶ Many students of coagulation medicine, though, do not realize that Virchow actually recognized his "triad" as being the result of vascular occlusion, not necessarily as the original precipitant of vascular thrombosis. Nonetheless, the vascular, rheologic, and hematologic aspects of thrombosis known as the Virchow triad remain relevant and instructive today (Fig. 55.1).

Abnormalities of Blood Flow

Arterial thrombosis initially occurs under conditions of rapid blood flow (high shear stress), a condition in which von Willebrand factor (vWF) is critical for platelet adhesion.⁷ Arterial thrombi usually are composed of tightly coherent masses of platelets, which contain small amounts of fibrin and a few erythrocytes and leukocytes. These thrombi are the classic "white thrombi," which resemble, in many respects, normal hemostatic plugs. As arterial thrombi enlarge, progressive or intermittent deposition of new layers of platelets and fibrin produces the characteristic lines of Zahn; partial or complete obstruction of blood flow may produce a "tail" of "red thrombus." The most serious consequences of arterial thrombosis are vascular occlusion with resultant ischemia and infarction of tissue and distal thrombus embolization.

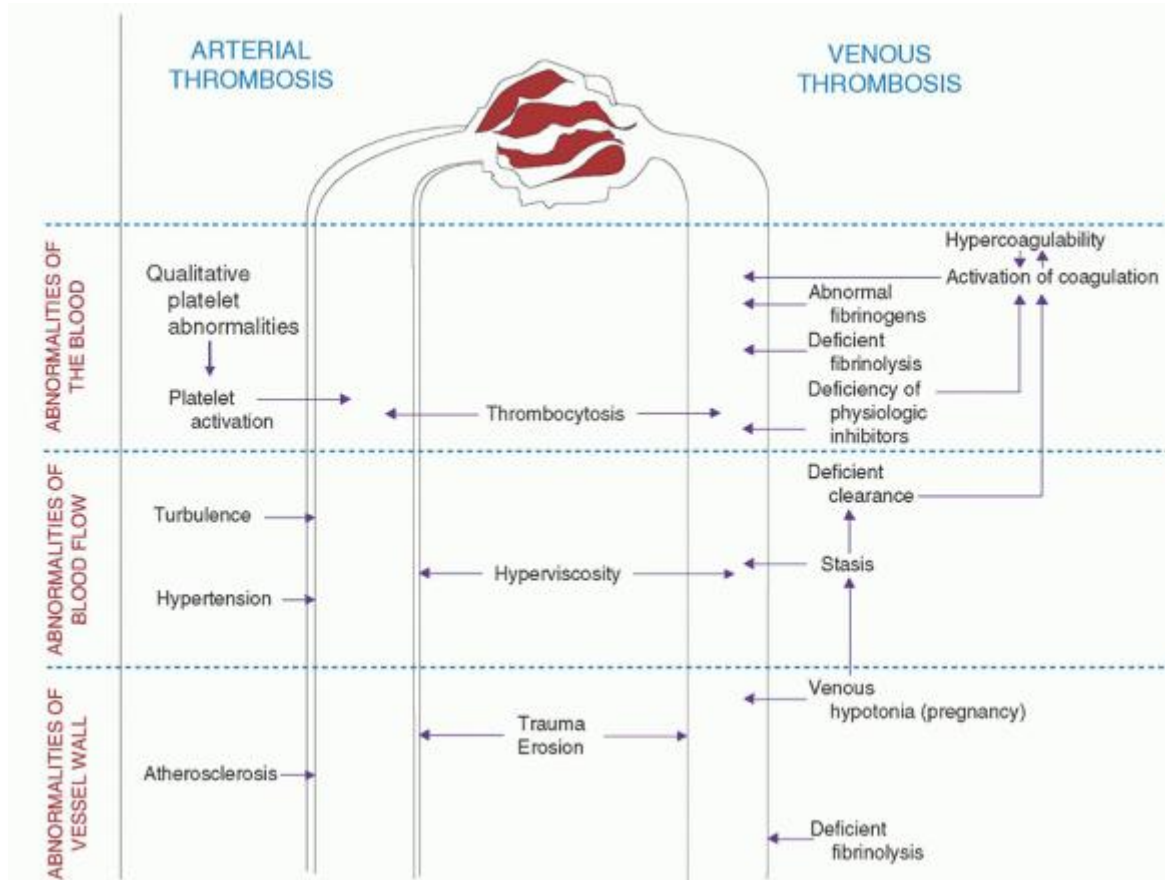

FIGURE 55.1. Pathophysiology of thrombosis. Factors implicated in the pathogenesis of arterial thrombosis (left) and venous thrombosis (right) are depicted. Examples of disorders leading to platelet activation and arterial thrombosis include atherosclerosis, the myeloproliferative disorders, heparin-associated thrombocytopenia/thrombosis syndrome, thrombotic thrombocytopenic purpura, and certain platelet polymorphisms. Examples of disorders leading to venous thrombosis in the category of deficiency of physiologic inhibitors include the inherited disorders, factor V Leiden, proteins C and S deficiencies, and AT deficiency. Many patients with thrombosis may have more than one of the risk factors listed. Estrogen therapy is a risk factor for venous thrombosis; its use is associated with activation of coagulation.

Hypertension, turbulent blood flow at arterial branch points and at sites of focal atherosclerosis, and hyperviscosity may be contributory factors in certain forms of arterial thrombosis. Causes of plasma hyperviscosity that can precipitate thrombosis and exacerbate ischemia include acute myeloid leukemia, myeloproliferative syndromes such as polycythemia rubra vera, cryoglobulinemia, and the plasma cell dyscrasias, including multiple myeloma and Waldenström macroglobulinemia. Immunoglobulin (Ig) paraproteins produced by plasma cell dyscrasias can increase viscosity, and promote red blood cell agglutination.

Venous thrombosis typically develops under conditions of slow blood flow (low shear stress) and is augmented by further retardation and stagnation of flow caused by the developing thrombus itself. Right-sided heart failure, pre-existent venous thrombosis, extrinsic vascular compression by tumor, and chronic venous insufficiency all promote venous stasis, blood pooling, and a concentration of procoagulant factors.⁸ The anatomic structure of venous valves results in retrograde eddy currents, which produce pockets of stasis even in normal veins.⁹ The venous arcades in the soleus muscles of the calves may represent another site of physiologic venous stasis. These structures may enlarge and lose vascular tone with aging.^{10, 11} These facts may partially explain why DVT most commonly occurs in the valve cusps and veins of the pelvis and lower extremities, and why older age is an important risk factor for venous thrombosis.¹²

P.1220

Venous thrombi are composed of large amounts of fibrin containing numerous erythrocytes. In these loose, friable masses (the red thrombus), the platelets and leukocytes are enmeshed in random fashion. Venous thrombi resemble blood clots formed *in vitro*, and they usually produce significant obstruction to blood flow from the outset, but their most serious consequence is embolization. Blood flow obstruction secondary to venous thrombosis itself promotes the further formation of thrombus. Results of studies of clots formed in a thromboviscometer at varying rates of shear suggest that the differences in the structure of venous and arterial thrombi may be mainly the result of the velocity of blood flow. The many and complicated rheologic factors that may be involved in thrombosis have been reviewed.¹³ Although traditional teaching holds that risk factors for arterial and venous thrombotic disease are distinct, new epidemiologic data suggest that common risk factors exist for both disorders, and that appropriate management of thrombosis patients should address secondary prevention of both arterial and venous thrombosis.¹⁴ The pathogenesis of venous and arterial thrombosis has been recently reviewed.¹⁵

Vascular Injury

Permanent and transient vascular injuries play major roles in the development of arterial thrombosis. Intraluminal vascular endothelial cell injury, atherosclerotic plaque rupture, hyperhomocysteinemia, arterial outflow obstruction, aneurysm formation, and vessel dissection are among the recognized risk factors for arterial thrombosis.¹⁶ Arterial thrombosis usually begins with platelet adhesion to an abnormal vascular endothelial surface or exposed subendothelial constituent such as collagen. The adherent platelets become activated, leading to the release of α - and dense granule contents.¹⁵ Platelet-dense granules (dense bodies) release adenosine diphosphate (ADP), adenosine triphosphate (ATP), calcium, and serotonin into the surrounding milieu, resulting in the recruitment and activation of additional platelets.¹⁶ This release reaction and platelet synthesis of thromboxane A₂ (TxA₂) and other agonists induce the aggregation of more platelets and enlargement of the temporary platelet plug. In addition to the recruitment of additional platelets, the original nidus of adherent platelets provides a phospholipid surface rich in phosphatidylserine to support and concentrate the generation of thrombin and fibrin necessary to reinforce and stabilize the platelet plug.

New insights into arterial thrombus formation have been gleaned from experiments using confocal and wide-field microscopy to image real-time thrombus formation in live-mouse cremaster muscle arterioles.¹⁷ Thrombosis is precipitated by laser-induced endothelial injury. These experiments demonstrated that the initiation of blood coagulation *in vivo* involves the initial accumulation of tissue factor (TF) on the upstream and thrombus-vessel wall interface of the developing thrombus. The TF is biologically active and is associated with intrathrombus fibrin generation. TF density is highest at the thrombus-vessel wall interface and is eventually observed throughout the thrombus. Leukocyte rolling is noted approximately 2 minutes after endothelial cell injury and correlates with P-selectin expression on the outer aspect of the thrombus. Minimal TF and fibrin are detected in platelet thrombi formed in mice lacking P-selectin or the P-selectin glycoprotein ligand, PSGL-1.

In venous thrombosis, the luminal surface of the vessel wall is usually histologically normal, and factors extrinsic to the vessel appear to have a major pathophysiologic role. Exceptions to this generalization are direct venous trauma, extrinsic venous compression, and vascular endothelial cell injury resulting from the toxic effect of cancer chemotherapy and excess levels of homocysteine. A limited quantity of activated platelets likely serves as a phospholipid surface to support local thrombin and fibrin formation. A generalized reduction in venous tone may be an important pathophysiologic factor in venous thrombosis in pregnant women and in women taking oral contraceptives.¹⁸ vWF-mediated platelet adhesion was shown to be essential for venous thrombosis in an animal model.¹⁹ Additional mechanisms may contribute to a prothrombotic state, including up-regulation of stress-response genes, endothelial cell activation, formation of neutrophil extracellular traps, and activation of the intrinsic coagulation pathway.²⁰

Studies indicate that human platelets express TF pre-mRNA, and when activated, splice this message into mature mRNA which is expressed.²¹ These results suggest that both platelets and the vessel wall may contribute to initiation of thrombosis.

Abnormalities of the Blood: Hypercoagulability

The term hypercoagulable state and its synonym thrombophilia refer to any inherited or acquired abnormality of the hemostatic system that places an individual at increased risk for venous or arterial thrombosis (or both). Blood from patients with active thrombosis or with a hypercoagulable state may clot at an abnormally rapid rate *in vitro*.²² The concept of hypercoagulability has gained widespread acceptance, and it is generally appreciated that these hemostatic changes are important in the pathogenesis of thrombosis; however, whether testing for these disorders may be helpful in patient management is uncertain.^{23, 24, 25}

Platelet Abnormalities

Although platelets may be incorporated into virtually any thrombus, they appear to be pathogenetically most important in arterial thrombosis. Increased platelet turnover (shortened platelet survival, compensated platelet destruction) occurs in vascular disease and thrombosis, including arterial and venous thrombosis, coronary artery disease, vasculitis, hyperhomocysteinemia, and valvular heart disease.^{26, 27, 28, 29} Increased platelet turnover can also be seen in patients with risk factors for vascular disease, including those who use tobacco and those with hyperlipidemia.^{30, 31} Increased platelet turnover and activation can reflect thromboembolic disease and also probably contribute to an exacerbation of thrombotic events.

As a consequence of platelet-vessel wall interactions in patients with vascular disease, platelet adhesion, activation, and aggregation occur, resulting in acquired storage pool disease and the presence in the blood of platelet-granule-derived proteins such as platelet factor-4 (PF4) and β -thromboglobulin.^{32, 33} Although elevated blood levels of these proteins indicate increased platelet turnover, improper blood collection technique may artifactually result in abnormal levels, and the clinical value of such testing is uncertain.

Vascular endothelium possesses multiple antiplatelet properties that may be important in preventing platelet adhesion, promoting vasodilation, and inhibiting platelet aggregation.^{34, 35, 36, 37} However, interruption of endothelial cell prostacyclin synthesis by aspirin does not result in a net thrombotic tendency. The potential role of hyperactive platelets in patients with thrombosis, as well as the use of platelet function testing in this setting, is somewhat controversial.

Because of the importance of vWF in mediating platelet adhesion to subendothelium, the role of vWF in human vascular disease has been a topic of investigation. An association between elevated plasma vWF levels and recurrent MI has been demonstrated, and vWF antigen is an independent predictor of coronary artery disease.³⁸

Platelet polymorphisms have been evaluated as risk factors for arterial thrombosis. These include polymorphisms for glycoprotein (gp) IIIa (PI^{A2}), gpl α (807 T allele), and gpl β .³⁹ The PI^{A2} polymorphism is linked with coronary artery disease; PI^{A2}-positive platelets exhibit a lower threshold for activation and also have variable aspirin sensitivity.³⁹

P.1221

Coagulation Abnormalities

Coagulation disorders that can contribute to hypercoagulability can be divided into three risk-factor categories: Transient, inherited, and acquired.⁴⁰ Transient risk factors represent well-defined, temporary clinical circumstances that are associated with increased thrombosis risk both while they are present and for a short period after they have resolved. Examples include surgery, prolonged immobilization, oral contraceptive pill (OCP) use, hormone replacement therapy (HRT), pregnancy, cancer chemotherapy, and heparin-induced thrombocytopenia (HIT). Inherited risk factors represent genetic mutations and polymorphisms that result in deficiency of a natural anticoagulant (e.g., protein C, protein S, or AT), procoagulant factor accumulation (e.g., prothrombin G20210A), or coagulation factor resistance to inactivation by a natural anticoagulant (i.e., factor V G1691A, also known as factor V Leiden). These conditions are characterized by a disruption in the normally highly regulated coagulation mechanism, resulting in greater thrombin generation and an increased risk of clinical thrombosis. Acquired risk factors result either from medical conditions or from nonfamilial hematologic abnormalities that interfere with normal hemostasis or blood rheology. Examples include cancer, inflammatory bowel disease, nephrotic syndrome, vasculitis, antiphospholipid antibodies, myeloproliferative syndromes, paroxysmal nocturnal hemoglobinuria, and hyperviscosity syndromes. These acquired risk factors are distinct from

transient risk factors by the fact that they represent alterations in hemostatic homeostasis as a result of disease or, for the most part, nonreversible processes. In contrast, transient risk factors result from either a therapeutic intervention or an adverse reaction to such an intervention. Hyperhomocysteinemia and increased factor VIII functional activity are examples of thrombosis risk factors that can be acquired in nature or have a genetic predisposition.^{41, 42} Age defies categorization but remains the single most predictable risk factor for thrombosis. The estimated baseline annual age-associated risk of VTE is 1 in 10,000 people <40 years of age, increasing to 1 in 100 people >75 years of age.^{43, 44, 45}

Recent reports have focused on elevated levels of various coagulation factors, particularly fibrinogen and factors V, VII, VIII, X, and XI, that have been documented in patients with thrombosis and prethrombotic disorders, including pregnancy and use of estrogen-containing contraceptives.⁴⁶ Fibrinogen and factors V and VIII are acute-phase reactants, and their plasma levels may rise in patients with virtually any disorder associated with tissue damage or inflammation, including most thrombotic processes. Whether increased because of a genetic factor or an acute-phase reaction, excess procoagulant factor concentrations may tilt the hemostatic scales in favor of hypercoagulability and may be associated with an increased risk of thrombosis. Epidemiologic studies have identified dose-dependent elevations in plasma levels of vWF, fibrinogen, factor VII, factor IX, and factor XI as independent risk factors for cardiovascular disease.^{47, 48, 49, 50}

Fibrinolytic Abnormalities

Abnormal fibrinolysis has also been linked to vascular disease. Low fibrinolytic activity (measured by dilute clot lysis) was a significant determinant of coronary artery disease in the Northwick Park Heart Study, and elevated PAI-1 activity was associated with major ischemic events in other studies.^{51, 52} In the European Concerted Action on Thrombosis and Disabilities study, an increased incidence of vascular events was associated with higher baseline PAI-1 antigen concentrations ($p = .02$) and PAI-1 activity ($p = .001$).⁵³ Defects in endogenous fibrinolytic capacity have also been found in young patients with severe limb ischemia or unexplained arterial thromboembolism. Deficient t-PA release was found in 45% of such patients, and elevated levels of PAI-1 were found in 59%.⁵⁴ Excess PAI-1 resulting in impaired endogenous fibrinolysis has also been associated with venous thrombosis in select cases.⁵⁵

ACTIVATION OF COAGULATION

Mechanisms leading to activation of coagulation in patients with thrombosis have been proposed. TF is thought to be the primary initiator of *in vivo* coagulation.^{56, 57} In the absence of TF expression, endothelial cells actively maintain thromboresistance. TF may be expressed in trace amounts during various physiologic processes, such as during normal parturition and after even minimal trauma, including minor head injuries. Immunologic injury of endothelium may lead to the exposure of TF.⁵⁸ Antibodies formed to exogenous heparin may bind to heparan sulfate on the endothelium, resulting in cell injury, the expression of TF, and the initiation of coagulation.⁵⁹ In a similar manner, endothelial cells may be induced to express TF by interleukin-1, homocysteine, tumor necrosis factor, and endotoxin.^{60, 61, 62, 63} TF antigen expression by endothelium has been demonstrated in pathologic primate and human tissues.^{64, 65, 66} Activation of coagulation may also occur on monocytes, and platelets can be activated to mediate factor-Xa-catalyzed prothrombin conversion to thrombin.^{67, 68} Deficient hepatic clearance of activated coagulation factors may represent an important thrombogenic factor in premature infants and in patients with liver disease, especially after administration of prothrombin complex concentrates that contain trace amounts of activated vitamin-K-dependent coagulation factors.

Various other mechanisms may be responsible for low-grade *in vivo* coagulation under certain conditions. Certain tumor cells can promote thrombin generation directly, by producing TF, expressing the coagulation factor X activator known as cancer procoagulant, or displaying surface sialic acid residues that can support nonenzymatic factor X activation.^{69, 70} Tumor cells can also promote thrombin generation indirectly, by eliciting TF expression by monocytes and endothelial cells. Tumor-associated coagulation cascade activation can result in the generation of thrombin that can promote angiogenesis by signaling through protease-activated receptors PAR-1, PAR-3, and PAR-4. In addition to its normal role in coagulation, evidence is mounting that TF plays a direct role in growth, invasion, dissemination, and angiogenesis of tumors.^{71, 72} Clotting-independent signaling through the TF cytoplasmic tail can lead to vascular endothelial growth factor (VEGF) up-regulation. Because VEGF can promote TF up-regulation, the potential for a self-perpetuating proangiogenic amplification loop exists. The TF:factor VIIa complex can also activate PAR-2 directly in a manner that results in gene expression related to angiogenesis and cell migration.⁷² Selected tumors may mediate an accentuation of platelet activation and accumulation, whereas other tumor cells may express surface phospholipid species such as phosphatidylserine, which can support prothrombin and factor X activation.⁷³

A laboratory picture similar to that described in the hypercoagulable state may also be seen in patients with nonovert (compensated or chronic) disseminated intravascular coagulation (DIC).⁷⁴ In such patients, the prothrombin time (PT) and the activated partial thromboplastin time (aPTT) may be shortened because of the presence of traces of thrombin or other

activated coagulation factors. These activated factors affect one-stage, but not two-stage, clot endpoint coagulation assays. High levels of factor V and factor VIII activity may reflect the presence of thrombin-activated forms of these factors in the circulation. Pregnancy, which can be regarded as a hypercoagulable state, has also been described as a physiologic form of nonovert DIC by some clinicians.⁷⁵ Pregnancy increases the risk of venous thromboembolism (VTE) approximately fivefold among the general population, and female patients who have experienced prior venous thrombosis have a threefold risk of venous thrombosis during pregnancy.⁷⁶ The use of estrogen-containing oral contraceptives and estrogen HRT is clearly associated with an increased risk of VTE.^{77, 78, 79} A prospective study of these patients indicates that estrogens induce activation of coagulation as well as reduction in levels of natural anticoagulants

P.1222

such as AT and protein S.⁸⁰ However, many patients who experience VTE while taking oral contraceptives have a common inherited thrombotic disorder, APC resistance (APC-R), or prothrombin G20210A.⁸¹ Another report indicated that oral contraceptives induced "acquired APC-R" in women.⁸² The relative risk of VTE in postmenopausal women using estrogen replacement is 2.14, and the risk is highest during the first year of use.⁸³ The thrombotic risk imparted by pharmacologic estrogens appears to dissipate following medication discontinuation.⁸⁴ One study found that transdermal estrogen products were safer than oral estrogens in women receiving HRT.⁸⁵ One literature review of hormonal therapy and venous thrombosis concluded that all oral estrogen-containing products used for contraception or HRT, as well as therapeutic doses of progesterone-only products increased thrombosis risk.⁷⁹ The risk of venous thrombosis is not clearly increased for the levonorgestrel-containing intrauterine device, transdermal estrogen, and tibolone.⁷⁹ Regarding the risk of thrombotic stroke and MI, a very large Danish study found that use of ethinyl estradiol increased risk by 0.9 to 2.3, depending on drug concentration in the contraceptive pill.⁸⁶ Table 55.1 summarizes acquired etiologies that predispose to thrombosis.

INHERITED THROMBOTIC DISORDERS

Several monographs and reviews have covered the topic of inherited thrombotic disorders in detail.^{40, 46, 86, 87, 88} Table 55.2 summarizes the prevalence of selected inherited and acquired hypercoagulable states in different populations, whereas Table 55.3 summarizes the clinical presentations of venous thrombosis that may be suggestive of particular hypercoagulable states. Many patients who experience thrombosis are found to have a combination of defects, for example, APC-R plus use of oral contraceptive agents,⁸¹ or a combination of inherited defects.⁴⁰ Although people with inherited hypercoagulable states are at a greater risk for developing a thrombotic event than those without such disorders, not all people with a well-defined hypercoagulable state develop an overt thrombosis, and not all people with thrombosis have an identifiable hypercoagulable state. Testing for an inherited hypercoagulable state is likely to uncover an abnormality in >60% of patients presenting with idiopathic (i.e., spontaneous or unprovoked) venous thrombosis.⁸⁹ Although the remaining

P.1223

30% to 40% have unremarkable test results, this does not imply a true absence of a hypercoagulable state. Some of these individuals may have an acquired condition such as cancer or antiphospholipid antibodies, whereas others may have a disorder or genetic defect that has not yet been discovered or characterized.

TABLE 55.1 ACQUIRED DISORDERS PREDISPOSING TO THROMBOSIS

Vascular disorders

Atherosclerosis

Diabetes

Vasculitis

Prosthetic materials (grafts, valves, indwelling vascular catheters)

Abnormal rheology

Stasis (immobilization, surgery, congestive heart failure)

Hyperviscosity (polycythemia vera, Waldenström macroglobulinemia, acute leukemia, sickle cell disease)

Other disorders associated with hypercoagulability

- Cancer (Trousseau syndrome)
- Cancer chemotherapeutic agents, thalidomide, bevacizumab
- Oral contraceptives, estrogen therapy, selective estrogen-receptor modulators
- Pregnancy
- Infusion of prothrombin complex concentrates and recombinant factor VIIa
- Nephrotic syndrome
- Myeloproliferative disorders
- Paroxysmal nocturnal hemoglobinuria
- Inflammatory bowel disease
- Thrombotic thrombocytopenic purpura
- Disseminated intravascular coagulation
- Antiphospholipid antibody syndrome
- Heparin-induced thrombocytopenia/thrombosis
- Human immunodeficiency virus infection

TABLE 55.2 PREVALENCE OF SELECTED INHERITED AND ACQUIRED HYPERCOAGULABLE STATES IN DIFFERENT PATIENT POPULATIONS

Hypercoagulable State	General Population (%)	Patients with First Venous Thromboembolism (%)	Thrombophilic Families (%)
Factor V Leiden	3-7 ^a	20	50
Prothrombin G20210A	1-3	6	18
Protein C deficiency	0.2-0.4	3	6-8
Protein S deficiency	N/A	1-2	3-13
Antithrombin deficiency	0.02	1	4-8
Mild hyperhomocysteinemia	5-10	10-25	N/A
Elevated factor VIII	11	25	N/A
Lupus anticoagulant	0-3	5-15	N/A
Elevated anticardiolipin antibodies	2-7	14	N/A

N/A, not available or unknown.

^a Prevalence as high as 15% in northern Europe.

TABLE 55.3 CLINICAL PRESENTATIONS OF VENOUS THROMBOEMBOLISM THAT MAY SUGGEST CERTAIN HYPERCOAGULABLE STATES

Venous Thromboembolism Presentation	Hypercoagulable State
Cerebral vein thrombosis in women using oral contraceptives	Prothrombin G20210A mutation
Cerebral vein thrombosis in general	Paroxysmal nocturnal hemoglobinuria, essential

	thrombocytopenia, antiphospholipid antibodies, antithrombin deficiency, PT G20210A mutation
Intra-abdominal vein thrombosis (inferior vena cava, renal vein, portal vein, mesenteric and hepatic veins)	Antiphospholipid antibodies, paroxysmal nocturnal hemoglobinuria, myeloproliferative syndromes, cancer, antithrombin deficiency
Warfarin skin necrosis	Protein C, protein S deficiencies
Unexplained recurrent fetal loss	Antiphospholipid antibodies; factor V Leiden
Recurrent superficial thrombophlebitis	Factor V Leiden, polycythemia vera, protein C, protein S, or antithrombin deficiency
Migratory superficial thrombophlebitis (Trousseau syndrome)	Adenocarcinoma (particularly of the gastrointestinal tract)
Neonatal purpura fulminans	Homozygous protein C or protein S deficiency
PT, prothrombin.	

Antithrombin Deficiency

AT, formally known as AT-III, deficiency was first described by Egeberg in 1965.⁹⁰ AT, a serine protease inhibitor, regulates coagulation by inactivating thrombin and other procoagulant enzymes, including factors Xa, IXa, XIa, and XIIa. As are most inherited thrombotic disorders, AT deficiency is inherited as an autosomal dominant disorder.^{91, 92} A blood bank survey reported that 1 in 600 people has AT deficiency.⁹³ The interactions of unfractionated and low-molecular-weight heparin (LMWH) with AT are discussed in the section "Heparin."

Pathophysiology and Genetics

Patients with AT deficiency may have either type I (quantitative deficiency) or type II (qualitative abnormality) disease. Type I AT-deficient patients usually have concordant reductions in AT measured by both immunologic and functional assays. Type II patients have reduced functional AT activity associated with normal amounts of AT protein. Plasma concentrations of the thrombin activation peptide, prothrombin fragment 1+2, are elevated in patients with AT deficiency, indicating persistent activation of coagulation as a result of deficient neutralization of factor Xa in these patients.⁹⁴

The genetic basis for type I AT deficiency is either deletion of a gene segment or the occurrence of point mutations or deletions, resulting in a nonsense mutation and an incomplete protein. The genetic basis for type II AT deficiency is the occurrence of point mutations that do not impair synthesis of the protein, but that result in a dysfunctional protease inhibitor. A summary of AT mutations (>100) has been reported.⁹⁵ A database of AT mutations is located at: <http://www1.imperial.ac.uk/departmentofmedicine/divisions/experimentalmedicine/haematology/coag/AT/>. In general, mutant AT molecules exhibit deficient heparin binding, deficient protease inhibition, or both.

Clinical Aspects

AT deficiency is manifested primarily by recurrent VTE.^{91, 92} Almost every vein site has been reported to be involved with thrombosis in AT-deficient patients, including unusual sites such as mesenteric vessels.⁹⁶ Thrombosis may occur in the absence of precipitating factors or may result from events such as pregnancy, estrogen use, trauma, or surgery. AT deficiency can result in heparin resistance manifesting as a normal to minimally increased aPTT in patients receiving large doses of heparin.⁹⁷ However, most patients with AT deficiency do not exhibit heparin resistance, and most cases of heparin resistance are not due to AT deficiency. In family studies, venous thrombosis occurred in 85% of AT-deficient relatives before 55 years of age.⁹⁷ The estimated increased lifetime relative risk of venous thrombosis has been reported to be up to 40-fold.^{98, 99} An annual absolute risk of venous thrombosis of 27.5% has been reported in female carriers of AT deficiency who also use OCPs.¹⁰⁰ Early studies reported pregnancy-related venous thrombosis rates as high as 70% for AT-deficient women.^{101, 102} Most AT-deficient patients are heterozygotes and possess ~50% of normal activity levels. Although homozygotes have been reported in consanguineous kindreds, in general, homozygous type I AT deficiency is believed to be fatal in utero.¹⁰³

Laboratory Diagnosis

Results of the PT and aPTT are normal in AT-deficient patients. A variety of commercial assays is available to measure AT levels, including functional and immunologic assays. Functional assays are preferable because they detect both type I and

type II patients. One report found that 2% of patients with AT deficiency had type II disease.¹⁰⁴ Functional assays for AT measure heparin cofactor activity using a chromogenic substrate method to quantitate thrombin or factor Xa neutralization.¹⁰⁵ A potential disadvantage of functional AT assays is that plasma AT levels may be overestimated because of the presence of heparin cofactor II (HCII) in the sample. The use of bovine thrombin and a low heparin concentration (3 U/ml) in the assay system can minimize this problem.¹⁰⁶

Immunologic assays for AT use Laurell rocket immunoelectrophoresis, microlatex-particle immunoassay, radial immunodiffusion, or enzyme-linked immunosorbent assay (ELISA) methods.¹⁰⁷ Ideally, patients should be evaluated for AT deficiency at a time when they are not receiving therapeutic heparin or oral anticoagulants, because heparin depresses AT levels, whereas long-term warfarin therapy increases plasma AT levels in some patients.^{92, 108} Laboratory tests for AT deficiency have been summarized.¹⁰⁹

Treatment

Some AT-deficient patients may experience heparin resistance, requiring the administration of AT by using virally inactivated, plasma-derived, or transgenic AT concentrates, or fresh-frozen plasma. Supplemental AT may make it easier to achieve therapeutic anticoagulation with heparin in these patients.¹¹⁰ Patients with recurrent thrombosis should receive long-term warfarin therapy at a dosage to maintain an international normalized ratio (INR) value of 2.0 to 3.0 (discussed in the section "Warfarin"). Patients with a single thrombotic event should receive at least 3 to 6 months of warfarin therapy and, because of an increased recurrence rate, should be considered for long-term therapy beyond 6 months. Patients with massive venous thrombosis or PE may be candidates for thrombolytic therapy. AT-deficient patients who become pregnant or who will undergo general surgery should be considered for anticoagulant prophylaxis, including AT concentrate administration.^{110, 111} Most asymptomatic patients should not be treated. The avoidance of estrogens should be considered in AT-deficient patients, who are not therapeutically anticoagulated.

Acquired Antithrombin Deficiency

AT deficiency is also associated with numerous disorders, including DIC, liver disease, nephrotic syndrome, and preeclampsia, and is seen in patients taking oral contraceptive agents and during pregnancy.^{112, 113, 114, 115} Although logic suggests that correction of AT deficiency might be clinically useful in disorders such as DIC or liver disease, there are no conclusive data supporting AT replacement therapy outside the setting of prophylaxis of high-risk patients, such as pregnant, AT-deficient patients.¹¹⁶

Heparin Cofactor II Deficiency

HCII is another heparin-dependent thrombin inhibitor, differing from AT in that a glycosaminoglycan other than heparin, dermatan sulfate, catalyzes this inhibitor of coagulation.¹¹⁷ HCII deficiency is inherited as an autosomal dominant trait. Although there have been anecdotal studies of thrombosis associated with HCII-deficient kindreds, a larger study has concluded that HCII deficiency by itself may not be an inherited risk factor for thrombosis.^{118, 119, 120} Commercial assays to measure HCII levels are available, but the clinical utility of such assays in routine evaluation of patients for inherited thrombosis is uncertain.

Protein C Deficiency

Protein C is a vitamin-K-dependent plasma protein that, when activated by the thrombin-thrombomodulin complex to APC,

P.1224

inactivates factors Va and VIIIa to inhibit coagulation.¹²¹ APC also possesses profibrinolytic activity that results from neutralization of PAI-3 activity.¹²² Inherited deficiency of protein C and its association with thrombosis were first described by Griffin and coworkers in 1981.¹²³ Protein C deficiency was believed to be inherited in an autosomal dominant pattern with incomplete penetrance. More recent studies have suggested that protein C deficiency may be an autosomal recessive disorder and that coinheritance of another defect (particularly factor V Leiden) results in a high degree of penetrance that appears as the dominant inheritance in double-heterozygous carriers.^{124, 125}

Pathophysiology and Genetics

As with AT deficiency, patients with protein C deficiency may have type I (quantitative deficiency) or type II (qualitative abnormality) disease. Most patients are heterozygotes with ~50% of normal protein C levels. A hypercoagulable state can be demonstrated in nonanticoagulated protein-C-deficient patients using activation peptide (fragment 1+2) assays.¹²⁶

In type I protein C deficiency, more than half of the gene mutations identified are missense mutations. Point mutations affecting protein function appear to be common in patients with type II protein C deficiency. At least 195 different gene abnormalities have been associated with both types of protein C deficiency.¹²⁷ Despite the clear association of protein C deficiency with thrombosis in large epidemiologic studies, there are also definitive data indicating that many protein-C-deficient patients are asymptomatic.¹²⁸ For example, one report found that heterozygous protein C deficiency occurred in approximately 1:250 subjects, whereas a large Scottish study estimated the prevalence to be approximately 1:500.^{124, 129} No patient in either study had a history of symptomatic venous thrombosis. These findings indicate that additional risk factors—acquired, genetic, or both—are necessary to provoke thrombosis in heterozygous protein-C-deficient patients. Indeed, in one study, up to 20% of symptomatic protein-C-deficient patients also had APC-R, supporting the concept that many patients with recurrent thrombosis have more than one risk factor.¹²⁵

Clinical Aspects

Three clinical syndromes are associated with protein C deficiency: VTE in heterozygous adults, neonatal purpura fulminans in homozygous newborns, and warfarin-induced skin necrosis in certain heterozygous adults. The predominant clinical symptom of protein-C-deficient patients is recurrent VTE, although arterial thrombotic events, including stroke, have been reported.^{130, 131} As mentioned above, many patients are found to have risk factors other than inherited protein C deficiency on investigation, such as APC-R, use of oral contraceptive agents, and pregnancy. Protein C deficiency has also been linked to fetal loss.¹³²

Neonatal purpura fulminans is seen in homozygous newborns of heterozygous parents. These children develop DIC at birth, associated with extensive venous or arterial thrombosis (or both) and very low levels of protein C (<5% of normal).¹³³ Warfarin-induced skin necrosis is an unusual syndrome seen in certain patients with heterozygote protein C deficiency.¹³⁴ Most patients who develop this syndrome have received large doses of warfarin in the absence of concomitant overlapping therapeutic parenteral anticoagulation. The basis for this syndrome is that warfarin therapy, especially in large loading doses, reduces protein C levels more rapidly than the vitamin-K-dependent procoagulant factors, leading to exacerbation of the basal hypercoagulable state and thrombosis.

In family studies, venous thrombosis occurred in 50% of protein-C-deficient relatives of affected probands before 40 years of age.¹³⁵ The estimated increased lifetime relative risk of venous thrombosis has been reported to be up to 31-fold.⁹⁸ As stated above, other studies did not detect an increased thrombosis risk in carriers of protein C deficiency. Differences in risk between family- and population-based studies can be in part explained by greater difficulty in obtaining reliable population-based estimates because of the overall low prevalence of this and other natural anticoagulant deficiencies. In studies of unselected patients with venous thrombosis, the odds ratio (OR) of having protein C deficiency is increased six- to ninefold compared to controls.^{40, 135, 136, 137} An annual absolute risk of venous thrombosis of 4.3% has been reported in women carriers of a natural anticoagulant deficiency such as protein C deficiency who also use OCPs.^{100, 138}

Laboratory Diagnosis

Patients with heterozygous protein C deficiency have normal PT and aPTT values, whereas patients with homozygous protein C deficiency have abnormal coagulation tests consistent with DIC. Because both type I and type II disorders may occur, functional assays are suggested to optimize identification of affected patients. Some investigators prefer the clot endpoint-based assay, because it measures complete function of the protein C molecule, including those patients with abnormal protein C molecules that possess normal activity by a chromogenic substrate assay. However, therapeutic heparin levels affect the clot-based assay. A College of American Pathologists' consensus conference on thrombophilia recommends use of the chromogenic substrate assay.¹³⁹ One report indicated that measurement of the ratio of protein C to protein S antigen was useful in identifying carriers of protein C deficiency.¹⁴⁰

Protein C levels can also be measured by immunologic methods, including Laurell rocket immunoelectrophoresis and ELISA. However, immunologic assays may not detect type II patients and may overestimate protein C levels in warfarin-treated patients. Immunologic assays may be more useful in evaluating patients with homozygous deficiency and DIC.

Age-related changes occur with protein C levels.¹⁴¹ Consequently, it is important to consider this when testing younger patients (<30 years); otherwise, normal subjects may be misclassified as protein C deficient.

A common problem faced by laboratories is measuring protein C levels in patients taking oral anticoagulants. Many clinicians forget that protein C is a vitamin-K-dependent molecule, and that otherwise hemostatically normal people taking warfarin may have low protein C levels. Griffin and coworkers suggested that protein C data be normalized against the level of another vitamin-K-dependent protein to distinguish inherited protein-C-deficient patients from normal subjects taking warfarin.¹²³ One author reported that using a ratio between protein C and prothrombin optimally categorized patients.¹⁴² However, for this method to be useful, patients must be stably anticoagulated for at least 2

weeks, and the laboratory must obtain plasma samples and reference ranges from patients taking warfarin for reasons other than recurrent thrombosis. The consensus conference did not recommend assaying protein C levels in patients on oral anticoagulants.¹³⁹ Laboratory tests for protein C deficiency have been reviewed.¹⁴³

Treatment

Many patients with protein C deficiency are asymptomatic, especially those identified in screening studies. Asymptomatic patients should not be treated but should be considered for prophylaxis when they experience high-risk procedures, such as surgery. Symptomatic protein-C-deficient patients should be anticoagulated with heparin and then considered for long-term secondary prophylaxis with warfarin at an INR of 2.0 to 3.0. Those patients with a single thrombotic event should receive at least 3 to 6 months of warfarin. Patients with more than one thrombotic event, patients with a single life-threatening thromboembolic event, and those with a significant family history of thrombosis should be

P.1225

considered for long-term anticoagulation. Patients with massive thrombosis or PE may be candidates for thrombolytic therapy.

Infants with neonatal purpura fulminans should be treated with protein C replacement therapy. Protocols using a purified protein C concentrate or prothrombin complex concentrates have been described.^{144, 145} Use of the purified concentrate normalizes activation of coagulation in these homozygous patients.¹⁴⁶

Acquired Protein C Deficiency

Because protein C is a vitamin-K-dependent protein, any disorder associated with vitamin K deficiency may result in protein C deficiency, including warfarin use, liver disease, and malnutrition.¹⁴⁷ Protein C levels are also reduced in DIC, presumably reflecting thrombin activation of the zymogen and consumption of APC.¹⁴⁸ Protein C levels may also be reduced in renal disease, especially the nephrotic syndrome.¹⁴⁹

Protein S Deficiency

Protein S is a vitamin-K-dependent plasma protein that facilitates the anticoagulant activity of APC. Protein S deficiency in association with inherited thrombotic disease was first described by two groups in 1984.^{150, 151} As with AT and protein C deficiencies, protein S deficiency is inherited as an autosomal dominant trait. Many patients with a previous diagnosis of protein S deficiency actually have APC-R.^{152, 153} This diagnostic error results from interference in the functional protein S assay of patients with the inherited disorder, APC-R, and misclassification of patients. These patients have a "pseudo" protein S deficiency, often display a type II deficiency pattern, and have protein S activity levels that correlate with the APC ratio. Based on these reports and the high incidence of APC-R in the general population, the true importance of protein S deficiency in inherited thrombosis is uncertain.^{152, 153, 154}

Pathophysiology and Genetics

As described for AT and protein C deficiencies, patients with protein S deficiency may have quantitative or qualitative disorders. Under normal circumstances, protein S exists in plasma in two forms: Bound to C4b-binding protein (60% of total protein S) and free (40% of total). Because only free protein S has APC co-factor activity, a revised classification system has been proposed for protein S deficiency.¹⁵⁵ Type I protein S deficiency is a quantitative disorder in which protein S functional activity, total antigen, and free antigen levels are equally reduced to ~50% of normal. Type IIa protein S deficiency is a deficiency of free protein S with preserved normal levels of total protein S. In type IIb protein S deficiency, the levels of both total and free protein S antigen are normal. Apparent type IIb protein S deficiency has been described in patients with APC-R.¹⁵⁴ An acquired type IIa protein S deficiency may result from excess levels of C4b-binding protein or the presence of free protein S inhibitory and clearing autoantibodies.¹⁵⁶ Almost 200 different mutations have been identified in the gene that codes for protein S.^{95, 157} A full listing of protein S gene mutations and polymorphisms can be found at www.ISTH.org.

As with protein C deficiency, many patients with protein S deficiency and thrombosis have additional risk factors. In one study, among patients with protein S deficiency, ~40% also had APC-R; of family members with thrombosis, 72% had both defects, whereas <20% of patients with single defects experienced thrombosis.¹⁵⁸

Clinical Aspects

Like AT and protein-C-deficient patients, most patients with protein S deficiency and thrombosis have experienced VTE.^{150, 151} However, unlike most other inherited thrombotic disorders, up to 25% of patients with protein S deficiency may experience arterial thrombosis, including stroke.^{131, 159} As mentioned previously, many patients with protein S deficiency

and thrombosis have other risk factors, including APC-R, estrogen use, or pregnancy.¹⁵⁸ Neonatal purpura fulminans, fetal loss, and warfarin-induced skin necrosis have also been associated with protein S deficiency.^{132, 160} In family studies, venous thrombosis occurred in 100% of protein-S-deficient relatives of affected probands by 70 years of age.¹⁶¹ The estimated lifetime increased relative risk of thrombosis has been reported to be as high as 36-fold for protein S deficiency.⁹⁸

Laboratory Diagnosis

Patients with heterozygous protein S deficiency have normal PT and aPTT values. The laboratory diagnosis of protein S deficiency is complicated by four factors: The levels of C4b-binding protein, the coexistence of APC-R in certain patients, elevated factor VIII activity levels, and warfarin therapy. C4b-binding protein is an acute-phase-reactant protein-S-binding protein, often elevated in thromboembolism, resulting in reduced free protein S levels from the patient's true baseline. Consequently, measurement of protein S levels in patients with acute thrombosis may yield misleading results. Similarly, false-positive results may be seen when functional protein S assays are performed on patients who have APC-R or factor VIII activity levels $\geq 250\%$.¹⁵⁵ Patients should not be assumed to have protein S deficiency (diagnosed by functional assay) until APC-R has been excluded. Lastly, because protein S is a vitamin-K-dependent protein, warfarin therapy and vitamin K deficiency pose the same difficulty as described for patients evaluated for protein C deficiency. Protein S levels may also be decreased in the setting of pregnancy but are not necessarily associated with thrombotic events.

Both functional and immunologic assays are commercially available to quantitate plasma protein S levels. Functional assays may be PT- or aPTT-based, measuring inhibition of factor Va by APC.¹⁶² These assays have the advantage of measuring free protein S activity. Immunologic assays to measure either total (free plus C4b-binding-protein bound) or free protein S levels are available.^{163, 164} Immunologic assays may be useful in evaluating patients who have co-existing APC-R. Total protein S levels are measured by Laurell rocket immunoelectrophoresis or ELISA. In the interpretation of immunologic assays, one should consider the report that the mean plasma level of protein S antigen in males is higher than it is in females.¹⁶⁴

Treatment

Asymptomatic patients should not be treated but should be considered for prophylaxis when they experience high-risk procedures such as surgery. Symptomatic protein-S-deficient patients should be anticoagulated as described for protein-C-deficient patients.

Protein Z Deficiency

Protein Z is a vitamin-K-dependent plasma protein that serves as a co-factor for activated factor X inhibition by the protein-Z-dependent protease inhibitor.¹⁶⁵ Reduced circulating levels of protein Z have been implicated in thrombosis.^{166, 167} Protein Z deficiency has also been linked to early and late fetal demise and intrauterine growth restriction.¹⁶⁷ Protein Z deficiency has also been found in the setting of acute coronary syndromes, whereas a deficiency state and the presence of a series of protein Z variants that modulate protein Z plasma levels have been associated with stroke.^{167, 168, 169, 170} Further data are required before routine protein Z testing can be recommended.

Activated Protein C Resistance (Factor V Leiden)

Before 1993, most patients with idiopathic venous thrombosis evaluated for inherited thrombosis were not given a diagnosis,

P.1226

because AT, protein C, and protein S deficiencies together were found in <20% of patients. In 1993, Dahlback and colleagues in Sweden postulated that certain patients with recurrent thrombosis might have additional abnormalities of the protein C pathway, resulting in a hypercoagulable state.¹⁷¹ They found that addition of APC to plasma obtained from patients with recurrent thrombosis did not prolong the aPTT to the same degree as that seen when APC was added to normal plasma.¹⁷¹ These patients did not have any previously recognized inherited thrombotic disorder. The term APC resistance was used for these patients. Other investigators then used the aPTT-based APC screening test to examine other populations for this phenotype. APC-R was found in 20% to 60% of patients with recurrent thrombosis.^{172, 173, 174} Like other inherited thrombotic disorders, APC-R was inherited in an autosomal dominant manner.

Pathophysiology and Genetics

APC inactivates factor Va in an orderly and sequential series of cleavages, first at Arg506, and then at Arg306 and Arg679.^{175, 176, 177} Although the affected factor V cleavage site in APC-R is not directly responsible for complete

inactivation of factor Va, APC cleavage at this site is necessary for subsequent proteolytic events. This “partial resistance” is explained by the fact that cleavage of factor Va by APC at Arg306 continues to occur, albeit at a slower rate.¹⁷⁸ In fact, factor V Arg506Gln (factor V Leiden) is inactivated 10 times more slowly than normal factor Va. This provides a pathophysiologic explanation for why factor V Leiden, although common, is a relatively weak risk factor for VTE. Because factor Va functions as a cofactor in the conversion of prothrombin to thrombin, the mutation results in greater amounts of factor Va being available for coagulation reactions, “shifting” the hemostatic balance toward greater thrombin generation.⁹⁵

APC-R due to factor V Leiden is the most common inherited predisposition to hypercoagulability in Caucasian populations of northern European background.⁹⁵ Factor V Leiden follows a geographic and an ethnic distribution: The mutation occurs most frequently in northern and western Europe (the highest prevalences, 10% to 15%, have been reported in Cyprus, Sweden, and Turkey) but is rare in the Asian and African continents as well as in ethnic groups of Asian descent, such as Inuit Eskimos, Amerindians, Australian Aborigines, and Polynesians.¹⁷⁹ In the United States, factor V Leiden is most commonly seen in Caucasians (6.0%), with lower prevalences in Hispanics (2.2%), African and Native Americans (1.2%), and Asian Americans (0.45%).¹⁸⁰

Factor V Leiden accounts for 92% of cases of APC-R, with the remaining 8% of cases resulting from pregnancy, oral contraceptive use, cancer, selected antiphospholipid antibodies, plasma glucosylceramide deficiency,^{181, 182, 183} and other factor V point mutations. Therefore, the terms factor V Leiden and APC-R should not be considered synonymous; in fact, APC-R is an independent risk factor for VTE even in the absence of factor V Leiden.¹⁸⁴ It is estimated that the mutation arose in a single Caucasian ancestor some 21,000 to 34,000 years ago, well after the evolutionary separation of non-Africans from Africans (~100,000 years ago) and of Caucasoid (white Caucasians) from Mongoloid (Asians) subpopulations (~60,000 years ago).¹⁸⁵

Clinical Aspects

Heterozygous carriers of factor V Leiden have a 2- to 10-fold increased lifetime relative risk of developing VTE.^{98, 138, 172, 186, 187, 188, 189, 190} This risk is further increased in combination with pregnancy (9-fold), OCP use (36-fold), and HRT (13- to 16-fold).^{191, 192, 193, 194} VTE is the most common clinical symptom of APC-R in patients who experience thrombosis. In general, there is a notable lack of association of APC-R with arterial thrombosis (exceptions discussed below).¹⁸⁸ Another clinical association with APC-R is recurrent miscarriage, with one study reporting that 20% of patients with second-trimester pregnancy loss have APC-R.^{132, 195} Factor V Leiden does not appear to be a cause of recurrent pregnancy loss occurring late in the first trimester.^{195, 196} Neonatal purpura fulminans has been reported in a patient with factor V Leiden who did not have protein C or S deficiency.¹⁹⁷ APC-R is also a common inherited risk factor for cerebral venous thrombosis.¹⁹⁸ The factor V Leiden mutation has also been identified in children who experience thrombosis.¹⁹⁹ However, this mutation does not appear to play a major role in the hypercoagulability of cancer.²⁰⁰ An intriguing report has demonstrated that the factor V Leiden mutation is a risk factor for MI in young women; the combination of factor V Leiden with smoking increased the risk of MI more than 30-fold.²⁰¹ Factor V Leiden has also been associated with MI in individuals with coronary artery thrombosis in the absence of evidence of underlying fixed atherosclerotic lesions.²⁰²

There are conflicting data on the role of factor V Leiden heterozygosity as an independent risk factor for VTE recurrence.^{203, 204} Two studies (“positive studies”) have found an increased risk of VTE recurrence compared to control subjects, with relative risk of 4.1 and 2.4, respectively. Six other studies (“negative studies”) have found no such association.^{205, 206, 207, 208, 209, 210} The positive studies by Ridker et al. and Simioni et al. were prospective but included a small number of patients with factor V Leiden heterozygosity (14 and 41, respectively).^{203, 204} The Physicians' Health Study (by Ridker et al.) included only men.²⁰³ Among the negative studies, four were prospective and two were retrospective.^{205, 206, 207, 208, 209, 210} Three of the prospective studies and the large retrospective cohort study by De Stefano et al. each included 80 to 112 patients with factor V Leiden heterozygosity.^{205, 206, 208, 210} A recent re-evaluation of the study by Simioni et al. did confirm the original study findings of increased relative risk of recurrent VTE in heterozygous carriers of factor V Leiden.²¹¹ The PREVENT trial later demonstrated equivalent rates of recurrent VTE in patients with and without factor V Leiden.²¹²

Homozygous carriers of the factor V Leiden mutation are estimated to have an 80-fold increased lifetime relative risk of VTE.¹⁸⁸ A more recent estimate, derived from a pooled analysis of a larger population, has confirmed an increased risk of VTE but of lower magnitude (10-fold).¹⁹¹ The discrepancy is likely due to the very low prevalence of factor V Leiden homozygosity found in the healthy controls from the general population. Most homozygous carriers present with VTE before 40 years of age, but some can live thrombosis-free until the sixth or seventh decade of life or even remain asymptomatic for life.^{213, 214} The majority of VTE is situational, and women appear more likely to develop VTE than men, suggesting an important role of OCP use and pregnancy in triggering thrombosis.^{213, 214, 215} Based on data from the first

prospective Duration of Anticoagulation trial, the risk of VTE recurrence is significantly increased in homozygous factor V Leiden carriers (36.4% at 48 months) when compared to heterozygous carriers (16.1%) and controls (12.4%).²⁰⁶

Laboratory Diagnosis

The intense interest in this common inherited thrombotic disorder has focused substantial attention on laboratory methods for its diagnosis. Laboratory aspects of its discovery have been reviewed by Dahlback.²¹⁶ The disorder can be evaluated by coagulation assays that have as their basis inhibition of factor Va by APC and prolongation of the clotting time. Typically, APC is added to patient plasma, and a clotting assay is performed (usually the PTT), with results expressed as a ratio:

$$\frac{\text{Patient PTT} + \text{APC}}{\text{Patient PTT}}$$

Reference ranges are established for normal patients with and without addition of APC. Affected patients with mutant factor V have clotting times prolonged to a lesser extent (lower ratio) than

P.1227

normals. Alternatively, a DNA test can be done to look specifically for the Arg506Gln mutation; this highly conserved point mutation is present in most patients with APC-R.

With properly collected plasma samples, the APC-R clotting test can correctly classify nearly 100% of patients, when normalized to a control plasma pool.²¹⁷ Predilution of the patient sample with factor-V-deficient plasma has improved the performance characteristics of most currently available commercial assays.²¹⁸ Samples from patients with baseline abnormal coagulation studies (e.g., anticoagulant therapy, lupus anticoagulants, liver disease) yield uninterpretable results. A TF-dependent factor V assay has been described that is useful in patients taking oral anticoagulants or with the lupus anticoagulant.²¹⁹ The polymerase chain reaction test for factor V Leiden uses the restriction enzyme MnlI to digest a 267-base pair amplified fragment of patient DNA.¹⁷⁶ Consensus recommendations on methodologies to assay for factor V Leiden and APC-R have been presented.^{220, 221}

Treatment

Therapy of VTE in patients with APC-R is similar to that described for patients without an identified hypercoagulable state. Long-term secondary prophylaxis is not necessary for heterozygotes unless they experience more than one thrombotic event or experience life-threatening thromboembolism. Asymptomatic patients with APC-R should not be treated, but female patients with this disorder should be informed about the additional thrombotic risk associated with oral contraceptive use, pregnancy, and HRT.^{82, 222} Prophylaxis for high-risk situations, such as surgery, should be given. Homozygotes who experience VTE should be considered for long-term anticoagulation.

Prothrombin Mutations

The prothrombin G20210A mutation is the second most common inherited predisposition to hypercoagulability. Heterozygous prothrombin G20210A has been found in 18% of probands of thrombophilic families, 6% of unselected patients with deep vein thrombosis (DVT), and 2% of normal Caucasian individuals.^{40, 223}

More recently, a novel single-point mutation of the prothrombin gene at position 20209 has been reported in four unrelated patients, two of whom had a history of VTE and one of whom had a history of stroke.²²⁴ Although the clinical significance of the prothrombin C20209T mutation is unknown, it may be underrecognized because it is not detected by the polymerase chain reaction/digestion assay commonly used for prothrombin gene mutation testing. Interestingly, all four reported individuals with prothrombin C20209T were African-Americans.

Pathophysiology and Genetics

Prothrombin G20210A is a single-point mutation (G-to-A substitution at nucleotide 20210) in the 3' untranslated region of the prothrombin gene.²²³ This autosomal dominant mutation results in elevated concentrations of plasma prothrombin.²²³ In fact, the VTE risk increases as the plasma prothrombin level increases, with levels >115 IU/dl leading to a 2.1-fold increased relative risk of VTE.²²³ The G20210A mutation leads to a "gain of function" of the prothrombin gene, perhaps by

resulting in an altered polyadenylation pattern in mutant prothrombin mRNA.²²⁵ An in vitro study of thrombin generation found that increasing prothrombin levels to 150% of normal resulted in enhanced thrombin activity.²²⁶

The mutation appears to follow a geographic and ethnic distribution, with the highest prevalence occurring, unlike factor V Leiden, in Caucasians from southern Europe (3%).²²⁷ This prevalence is nearly twice that observed in northern Europe (1.7%).²²⁷ Similar to factor V Leiden, the prothrombin G20210A mutation is also found in the Middle East and Indian regions, but it is virtually absent in individuals of Asian and African backgrounds.²²⁷ These distributions provide support to the estimate that both mutations (factor V Leiden and prothrombin G20210A) originated relatively recently in the European founding population, after the evolutionary divergences of subpopulations. An evaluation of patients in northeast Ohio who underwent hypercoagulability evaluations revealed an equivalent prevalence of prothrombin gene mutations in whites and blacks.²²⁴

Clinical Aspects

Heterozygous prothrombin G20210A is associated with a two- to sixfold increased lifetime relative risk of VTE.^{40, 214, 223, 228} The risk appears to be further increased in combination with pregnancy (15-fold) and OCP use (16-fold).^{191, 229} The relative risk of cerebral vein thrombosis is increased 10-fold in women with this mutation who are not on OCPs, as opposed to 150-fold in OCP users.²³⁰ Homozygosity for prothrombin G20210A has an estimated population prevalence of 0.014%, and homozygous carriers appear to have greater predisposition to develop early (before 40 years of age) idiopathic recurrent VTE than heterozygotes.^{223, 231, 232}

The role of prothrombin G20210A as a risk factor for VTE recurrence is less controversial than it is for factor V Leiden, but data are also somewhat conflicting. Simioni et al., re-evaluating a prospective study from 1997, retrospectively determined patients' prothrombin G20210A mutation status and found that the hazard ratio of VTE recurrence was 2.4.²¹¹ However, three prospective studies, which each included 28 to 52 patients, found no increased risk of recurrent VTE in heterozygous prothrombin G20210A carriers.^{206, 233, 234}

A fourfold increased risk of MI has been demonstrated, particularly in young women carriers of this mutation. A large case-control study of >14,000 men, though, revealed no increased risk of stroke or MI associated with this abnormal prothrombin gene. The reasons for this apparent male/female disparity are unknown.^{201, 235}

Laboratory Diagnosis

The prothrombin G20210A and C20209T mutations can only be reliably and routinely identified using molecular biologic techniques. Measurements of functional prothrombin activity do not sufficiently differentiate between carriers and noncarriers of this gene mutation. Testing can be performed accurately despite concomitant treatment with any form of anticoagulation.

Treatment

Treatment paradigms for patients with prothrombin G20210A heterozygosity parallel those for patients with heterozygous factor V Leiden. Patients with concomitant prothrombin G20210A heterozygosity and factor V Leiden heterozygosity should be considered for long-term anticoagulation following a first thrombotic event.

Hyperhomocysteinemia

Homocysteine is a sulfhydryl amino acid formed during the conversion of methionine to cysteine. Hyperhomocysteinemia results when homocysteine metabolism is abnormal. Hyperhomocysteinemia has been identified as an independent risk factor for stroke, MI, peripheral arterial disease, and venous thrombotic disease.^{236, 237, 238} Even mild to moderate hyperhomocysteinemia is a significant risk factor for vascular disease. However, lowering homocysteine levels with vitamin therapy has not resulted in improved outcomes in vascular disease and thrombosis.^{239, 240}

Pathophysiology and Genetics

The amino acid homocysteine is normally metabolized via the transsulfuration pathway by the enzyme cystathionine- β -synthase (CBS), which requires vitamin B₆ as co-factor, and via the

P.1228

remethylation pathway by the enzymes methylenetetrahydrofolate reductase (MTHFR), which is folate dependent, and methionine synthase, which requires vitamin B₁₂ as co-factor.^{241, 242} Inherited severe hyperhomocysteinemia (plasma level >100 μ mol/L), as seen in classic homocystinuria, may result from homozygous MTHFR and CBS deficiencies and, more rarely, from inherited errors of cobalamin metabolism.^{241, 242} Inherited mild to moderate hyperhomocysteinemia (plasma

level >15 to 100 $\mu\text{mol/L}$) may result from heterozygous MTHFR and CBS deficiencies, but most commonly results from the thermolabile variant of MTHFR (tMTHFR) that is encoded by the C677T gene polymorphism.^{241, 242}

Acquired hyperhomocysteinemia may be caused by folate deficiency, vitamin B₆ or B₁₂ deficiency, renal insufficiency, hypothyroidism, type II diabetes mellitus, pernicious anemia, inflammatory bowel disease, advanced age, climacteric state, carcinoma (particularly involving breast, ovaries, or pancreas), and acute lymphoblastic leukemia, as well as methotrexate, theophylline, and phenytoin therapy.^{241, 242}

The precise mechanisms underlying the thrombogenicity of homocysteine remain unclear. Several diverse mechanisms have been proposed, including endothelial cell desquamation, low-density lipoprotein (LDL) oxidation, promotion of monocyte adhesion to endothelium, and factor V activation and promotion of thrombin generation.^{241, 242, 243} Homocysteine also enhances platelet aggregation and adhesiveness as well as turnover, presumably as a result of endothelial cell injury.²⁴⁴ One study found that moderate hyperhomocysteinemia does not impair the activation of protein C by thrombin and does not impair the inactivation of factor Va by APC.²⁴⁵

Severe homocysteinemia usually results from homozygous CBS deficiency. The incidence of this disorder is ~1 in 335,000 live births. Classic symptoms for homozygous patients include premature vascular disease and thrombosis, mental retardation, ectopic lens, and skeletal abnormalities.²⁴⁶ Heterozygous homocysteinemia has been recognized as a disease entity; this disorder may affect 0.3% to 1.0% of the general population.²⁴⁶

Clinical Aspects

Heterozygous carriers of the tMTHFR mutation have normal plasma homocysteine levels unless folate levels are reduced.²⁴⁷ More important, the majority of case-control studies have not demonstrated an increased VTE risk in homozygous carriers of the tMTHFR, and the majority of individuals with hyperhomocysteinemia do not have the tMTHFR polymorphism. Thus, characterization of the tMTHFR polymorphism is not useful to determine an individual's VTE risk. VTE risk is most closely related to elevated fasting plasma homocysteine levels, regardless of etiology. Hyperhomocysteinemia (plasma level >18.5 $\mu\text{mol/L}$) has been associated with a two- to fourfold increased VTE risk.^{248, 249} It is interesting that, in the Physicians' Health Study, hyperhomocysteinemia (plasma level above the 95th percentile; 17.2 $\mu\text{mol/L}$) did increase the risk of idiopathic VTE (relative risk, 3.4) but not the risk of all (transient and idiopathic) VTE.¹⁸⁹

The majority of reports linking hyperhomocysteinemia to thrombosis have focused on venous thromboembolic disease. Kottke-Marchant et al. compared 23 patients with documented arterial peripheral thrombosis to age- and sex-matched controls.²⁵⁰ Elevated homocysteine levels (>13 $\mu\text{mol/L}$) conferred an OR of 7.8 for thrombosis. Elevated homocysteine levels were found in 73% of cases versus 28% of controls. Only smoking and homocysteine level were independent risk factors for arterial thrombosis. Currie et al. evaluated homocysteine and cardiovascular risk factors in 66 adult patients with vascular disease. Hyperhomocysteinemia was identified in 29% of patients and was an independent risk factor for the failure of vascular procedures ($p = 0.006$).²⁵¹

Laboratory Diagnosis

The initial step in the evaluation of the patient with suspected hyperhomocysteinemia involves measurement of fasting total plasma homocysteine (the sum of nonprotein-bound and proteinbound).²⁴¹ Many laboratories report homocysteine values in reference to published "normal" ranges such as 5 to 15 $\mu\text{mol/L}$, but, ideally, a local, laboratory-specific normal range should always be established. A normal value in the nonfasting setting does not normally require repeating. Testing 2 to 8 hours after an oral methionine load (100 mg/kg) increases the sensitivity of detecting occult vitamin B₆ deficiency and obligate heterozygotes for CBS deficiency,²⁵² but methionine loading is not routinely recommended.²⁵³ Vitamin B₁₂ and folate deficiency do not affect post-methionine loading homocysteine values. In patients found to have elevated levels of homocysteine, testing for vitamin B₁₂ deficiency is advocated to avoid missing subclinical deficiency before beginning oral folic acid therapy. Methodologies to measure homocysteine levels have been reviewed.²⁵⁴

Treatment

Folic acid supplementation is the mainstay of effective hyperhomocysteinemia therapy.²⁴¹ A recent meta-analysis of 1,114 patients enrolled in 12 randomized studies of vitamin supplementation to lower homocysteine levels demonstrated a 25% reduction in homocysteine levels, with similar effects across a dosage range from 0.5 to 5.0 mg daily.²⁵⁵ The usual recommended dose is 0.4 to 1.0 mg daily. Whether patients who are not responsive to one dose benefit from an escalation in dose is unclear. Because patients with subclinical vitamin B₁₂ deficiency may be prone to developing peripheral neuropathy if they receive folic acid supplementation alone, additional treatment with 0.5 mg/day of oral vitamin B₁₂ has been advocated. In the same meta-analysis, an additional 7% reduction of homocysteine levels was noted with vitamin B₁₂ supplementation.²⁵⁵ Vitamin B₁₂ administration results in normalization of homocysteine levels in B₁₂-

deficient individuals. In these patients, a monthly intramuscular injection of 200 to 1,000 µg of vitamin B₁₂ is considered adequate replacement. Vitamin B₆ supplementation did not appear to have any effect on homocysteine levels. Betaine, a nutritional supplement derived from beets, functions as an alternative methyl donor in the remethylation of homocysteine to methionine. Betaine has been used in individuals with homocystinuria and may facilitate homocysteine reduction in individuals who are not responsive to folate and vitamin B₆.²⁵⁶

Thrombotic events in hyperhomocysteinemic patients should be treated as described for other inherited disorders. An additional treatment strategy is to lower plasma homocysteine levels, with the hope of alleviating a risk factor for recurrent thrombosis. However, results of the Heart Outcomes Prevention Evaluation (HOPE)-2 trial and Norwegian Vitamin (NORVIT) trial do not support the utility of homocysteine lowering in patients with arterial disease.^{257, 258} In patients with a history of coronary artery, cerebrovascular, or peripheral artery disease, or diabetes with at least one risk factor for atherosclerosis, lowering plasma homocysteine levels with folic acid and B vitamins did not reduce risk for the composite endpoint of MI, stroke, or death from cardiovascular causes more than placebo despite a 22% reduction in plasma homocysteine.²⁵⁷ In NORVIT, folic acid and vitamin B₁₂, with or without vitamin B₆, did not reduce risk for the composite endpoint of MI, stroke, or death from coronary artery disease in patients with an index MI.²⁵⁸ Other clinical trials have also failed to show a cardiovascular benefit of lowering homocysteine levels.^{239, 240} Secondary analysis of the HOPE-2 trial regarding effects of vitamin therapy on VTE risk found that there was no significant risk reduction in VTE with vitamin therapy.²⁵⁹ These trials yielding negative results with vitamin therapy raise questions about the utility of testing and treating homocysteinemia.

P.1229

Increased Factor VIII Activity

It is now appreciated that elevated levels of procoagulant coagulation factors, in addition to deficiencies of natural anticoagulant proteins, are risk factors for VTE. Factor VIII levels >1.5 IU/ml (150%) are associated with a threefold and a sixfold greater relative risk of VTE when compared to levels <1.5 IU/ml (150%) and <1.0 IU/ml (100%), respectively.²⁶⁰ VTE risk is increased 11-fold with levels >200%, but it does not appear to be accentuated by concomitant OCP use.^{261, 262} Elevated activity levels of factor VIII associated with VTE risk seem to be persistent and not solely attributable to acute-phase response.²⁶³ Transiently elevated factor VIII levels associated with acute-phase protein release, though, may in part explain the hypercoagulability associated with inflammatory disorders such as inflammatory bowel disease and cancer. Individuals with plasma factor VIII activity >234% (above the 90th percentile cutoff point for the study population) have a 6.7-fold increased relative risk of recurrent VTE compared to those with activity levels of <120%.⁴²

Because factor VIII is indeed an acute-phase reactant and its levels can be affected by many factors, including blood type and vWF concentration, determination of the true meaning of an elevated factor VIII level in an individual patient with VTE is challenging. In the study by Koster et al., in which blood samples for factor VIII activity were obtained a minimum of 6 months after the VTE, it was impossible to distinguish completely between inherited elevation and postthrombotic, transient elevation of factor VIII.²⁶⁰ Nonetheless, the fact that an increased factor VIII level is prevalent in persons with VTE may, in fact, imply that elevated factor VIII is not only frequent, but also an important risk factor for VTE.²¹⁴ More recent studies support the concept that elevated factor VIII levels are a significant risk factor in asymptomatic individuals for both arterial and venous thrombosis.^{264, 264a} The College of American Pathologists' consensus conference recommendations are not to routinely measure factor VIII levels in patients with venous or arterial thrombosis.²⁶⁵

Increased Levels of Factors IX, X, XI, and XIII

The Longitudinal Investigation of Thromboembolism Etiology study investigated the possible role of elevated factors IX, X, XI, and XIII in VTE risk²⁶⁶ and found that of these coagulation proteins, only elevated factor XI levels were associated with VTE risk. Elevated factor XI levels have also been linked to stroke²⁶⁷ and coronary disease.²⁶⁸ This effect of elevated factor XI levels may be mediated by increased fibrin formation and decreased fibrinolysis.²⁶⁹

Impaired Endogenous Fibrinolysis

The endogenous fibrinolytic system is comprised of plasminogen, PAs, and antifibrinolytic regulatory proteins. Intravascular plasminogen is converted to the active fibrinolytic enzyme plasmin primarily by t-PA derived from vascular endothelial cells and by urokinase-type PA (u-PA) from leukocytes. The principal physiologic inhibitor of t-PA is PAI-1, whereas plasmin itself is inactivated by circulating and thrombus-bound α₂-antiplasmin, and to a lesser extent, α₂-macroglobulin. Decreased endogenous fibrinolytic activity as a result of qualitative and quantitative abnormalities of

plasminogen, an inadequate release of t-PA in response to vascular injury, and excessive production of PAI-1, such as is found in inflammatory and malignant diseases, can result in impaired endogenous fibrinolysis and accumulation of pathologic thrombus.²⁷⁰

Abnormal fibrinolysis was previously thought to account for a large proportion of patients with inherited thrombosis. However, the discovery of APC-R as a common inherited disorder and a literature review that concluded that a causal relationship between abnormal fibrinolysis and inherited thrombosis had not been clearly demonstrated diminished enthusiasm for routinely evaluating patients with recurrent thrombosis for abnormal fibrinolysis.²⁷¹ However, newer data from the Leiden Thrombophilia Study indicate that reduced plasma fibrinolytic potential is a risk factor for venous thrombosis,²⁷² and another group identified an elevated level of thrombin-activatable fibrinolysis inhibitor (TAFI) as a risk factor for recurrent venous thrombosis.²⁷³ Additionally, elevated levels of α_2 -antiplasmin are linked to increased risk of MI,²⁷⁴ and elevated levels of PAI-1 are associated with venous thrombosis.²⁷⁵

Plasminogen Deficiency

Quantitative and qualitative abnormalities of plasminogen have been reported in patients with recurrent venous thrombosis.^{276, 277} Quantitative deficiency is inherited as an autosomal dominant disorder, whereas qualitative plasminogen defects (dysplasminogenemia) are usually inherited as autosomal recessive disorders. Dysplasminogenemia is more common in Japanese subjects, and a single mutation accounts for >90% of cases in this population.²⁷⁸ Two reports have suggested that quantitative plasminogen deficiency²⁷⁹ and dysplasminogenemia²⁸⁰ may not be risk factors for thrombosis, and a recent large series of 50 patients with quantitative plasminogen deficiency found the major clinical manifestation to be ligneous conjunctivitis; venous thrombosis was not observed.²⁸¹ The College of American Pathologists Consensus Conference on Thrombophilia does not recommend routine assay for plasminogen deficiency in thrombophilia patients.²⁸²

Tissue Plasminogen Activator Deficiency

Defective synthesis or release of t-PA from the vessel wall represents a potential mechanism for thrombosis. Plasma t-PA activity is unstable, and for accurate assays, citrated plasma samples must be immediately acidified and red blood cells removed.^{283, 284} Addition of a platelet activation inhibitor to the blood collection tube may help reduce the release of platelet-derived PAI-1, which can interfere with t-PA activity quantification. A plasminogenchromogenic substrate assay is used to measure t-PA activity; t-PA antigen can be measured by ELISA using citrated plasma. The CAP Consensus Conference on Thrombophilia does not recommend routine assay for t-PA deficiency in thrombophilia patients.²⁸²

Increased Plasminogen Activator Inhibitor-1 Levels

Increased levels of PAI-1 have been associated with venous or arterial thrombosis. Plasma PAI-1 activity is measured in citrated plasma using a back-titration method with single-chain t-PA.²⁸⁵ Because blood fibrinolytic activity exhibits a diurnal rhythm (decreased fibrinolysis in the morning as a result of peak PAI-1 levels; increased fibrinolysis in the evening as a result of low PAI-1 levels), plasma samples should be obtained at standardized times, such as between 8:00 and 9:00 a.m..²⁸⁶ In addition, because fibrinolytic component levels can be affected by acute-phase changes, patients should not be evaluated for abnormal fibrinolysis until 2 to 3 months after an acute thrombotic event.

In the European Concerted Action on Thrombosis and Disabilities study, an increased incidence of vascular events was associated with higher baseline PAI-1 antigen concentrations ($p = .02$) and PAI-1 activity ($p = .001$).⁵³ Elevated levels of PAI-1 may effectively reduce t-PA activity levels, thereby blocking the activation of plasminogen to plasmin and inducing impaired fibrinolysis that may ultimately lead to thrombosis. Theoretically, markedly elevated levels of PAI-1 might also impair attempts at pharmacologic thrombolysis in the setting of acute arterial and venous thrombosis.²⁸⁷ Defects in endogenous fibrinolytic capacity have also been found in young patients with unexplained arterial thromboembolism. Deficient t-PA release was found in 45% of such patients, and elevated levels of PAI-1 were found in 59%.⁵⁴

P.1230

Similar defects have been detected in individuals with recurrent venous thrombosis.²⁷⁵ It has been noted that patients who have undergone major surgical procedures might experience a transient "fibrinolytic shutdown" as a result of elevated PAI-1 levels as part of an acute-phase response.²⁸⁸

Avoidance of obesity and associated insulin resistance, correction of hypertriglyceridemia, cessation of smoking, and exercise may improve the innate fibrinolytic status.^{53, 289, 290} Treatment of hypertension with angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists has been associated with significantly reduced PAI-1 production.^{291, 292} The lipid-lowering agent gemfibrozil has also been shown to decrease the PAI-1 synthesis rate.²⁹³

Modest alcohol consumption and hormone replacement treatment in postmenopausal women also seem to be beneficial.^{294, 295}

Dysfibrinogenemia

The clinical and biochemical aspects of dysfibrinogens are reviewed in Chapter 53. In general, dysfibrinogens associated with thrombosis have as their molecular defect generation of an abnormal fibrin that is resistant to fibrinolysis. An updated summary of dysfibrinogen molecular abnormalities is presented at www.ISTH.org. Dysfibrinogenemia as a cause of inherited thrombosis is uncommon.

Certain patients with dysfibrinogenemia may have a prolonged PT; more typically, these patients are detected by prolonged thrombin and reptilase times, suggesting a defect in the conversion of fibrinogen to fibrin.²⁹⁶ Confirmation of a dysfibrinogen can be done by simultaneous measurement of functional and immunologic fibrinogen levels. Typically, immunologic levels are found to be higher than levels measured by functional assay. Published data for the healthy population indicate that for fresh plasma samples, the ratio of immunologic to functional fibrinogen ranges from 1.12 to 1.65; ratios >1.65 are suggestive of dysfibrinogenemia.²⁹⁷

Another potentially useful test to evaluate patients for dysfibrinogenemia is the fibrinogen lysis time. This test requires partial purification of the patient's fibrinogen, followed by clotting and lysis in a standardized assay.²⁹⁸ Dysfibrinogens may also result in a false positive test for fibrin(ogen)-degradation products (FDPs) as assayed by latex agglutination, because residual fibrinogen remains in serum after clotting and is detected by the antibody-coated latex beads. An algorithm for the laboratory diagnosis of dysfibrinogenemia has been reported.²⁹⁹

Thrombomodulin Deficiency

Thrombomodulin complexed with thrombin is required to activate protein C. In theory, thrombomodulin deficiency should result in hypercoagulability. A number of mutations in the thrombomodulin gene have been identified in patients with venous thrombosis and their families.³⁰⁰ Routine laboratory testing for this disorder is not yet available, but an Italian study of thrombosis patients indicated that thrombomodulin deficiency is not a common cause of thrombosis.³⁰¹ Thrombomodulin gene mutations have been linked to MI.³⁰² In the prospective Atherosclerosis Risk in Communities study, soluble thrombomodulin levels had a graded inverse association with, and were a good predictor of, coronary artery disease.³⁰³ The levels correlated in their extreme quartiles with the coagulation activation marker prothrombin fragment 1+2.³⁰³

Lipoprotein(a)

Lipoprotein(a) (Lp[a]) is a lipoprotein moiety similar to LDL cholesterol in core lipid composition, and it has apolipoprotein (apo) B-100 as a surface apolipoprotein. In addition, Lp(a) has a unique glycoprotein, apo(a), which is bound to apoB-100. Apo(a) is structurally similar to plasminogen but lacks fibrinolytic activity.³⁰⁴ Lp(a) has both atherogenic and thrombogenic properties. Its thrombogenic effect is derived from stimulation of PAI-1 synthesis, promotion of intercellular adhesion molecule-1 expression by vascular endothelium, inhibition of both plasminogen and t-PA binding to fibrin, inhibition of plasminogen activation by t-PA, and competition with plasminogen for binding sites on endothelial cells and fibrin.³⁰⁵ The cumulative effect is impaired activation of plasminogen to plasmin at the vessel wall, inhibition of fibrinolysis, and increased risk for thrombosis.

The exact mechanisms that control Lp(a) levels are unknown, but genetic factors that regulate hepatic synthesis of apo(a) are likely important. One's plasma Lp(a) level is stabilized during infancy and maintained throughout life.³⁰⁶ Plasma concentrations >20 mg/dl seem to increase the risk of coronary artery disease, peripheral arterial occlusive disease (PAOD), and stroke.³⁰⁵ Lippi et al. evaluated Lp(a) in 68 patients subjected to vascular and endovascular surgery.³⁰⁷ Significant restenosis or reocclusion occurred in 23 (34%) patients. Lp(a) concentrations were significantly higher in those with restenosis and reocclusion compared with those in the no-restenosis group. Occlusive complications were unlikely to occur in patients with Lp(a) concentrations <5 mg/dl.³⁰⁷ Different isoforms of the apo(a) component of Lp(a) have different atherogenic potential and possibly different thrombogenic potential.

Measurement of Lp(a) should be considered mainly in individuals with atherosclerosis in the absence of classic risk factors, rapidly progressive atherosclerotic lesions despite aggressive risk factor modification, and individuals with acute arterial thrombosis.^{306, 308} Because it is an acute-phase reactant, an elevated Lp(a) level must be carefully interpreted if drawn shortly after surgery, acute thrombosis, or acute coronary syndromes.³⁰⁹

Patients with elevated Lp(a) benefit most from aggressive LDL cholesterol lowering. Although hepatic 3-methylglutaryl coenzyme A reductase inhibitors ("statins") may be the ideal agents for LDL lowering and atherosclerotic plaque stabilization, this class of drug does not appreciably lower Lp(a) levels themselves.³¹⁰ Nicotinic acid (niacin), usually in high

doses, is the first-line pharmacologic therapy to lower Lp(a) levels. Reductions up to 38% have been reported.³¹¹ Because nicotinic acid therapy may be poorly tolerated, a gradual escalation in dose and pretreatment with aspirin are recommended. In women, estrogen replacement therapy can lower Lp(a) levels by as much as 50%.³⁰⁸

Tissue Factor Pathway Inhibitor

Tissue factor pathway inhibitor (TFPI) is a major anticoagulant, present in plasma, and associated with vascular endothelium. TFPI binds to and neutralizes the TF/factor VIIa complex to inhibit activation of factor X. Low levels of TFPI are a weak risk factor for a first venous thrombosis, as well as recurrent VTE events.^{312, 313} Recent studies have also linked TFPI deficiency to arterial thrombosis.³¹⁴

Combined Defects

Compound heterozygosity for two different natural anticoagulant deficiencies is extremely rare, because of the low prevalence of each individual defect. The phenotypic presentation of such compound heterozygotes does not appear to be as severe as it is for the homozygous forms of each deficiency, with the rarely reported patient presenting with VTE of early onset (in the teenage years).^{98, 214} Because factor V Leiden is the most common inherited thrombophilia, double heterozygosity for factor V Leiden and a natural anticoagulant deficiency has been described in some families.^{125, 315} In families with both factor V Leiden and protein C deficiency, 73% of compound heterozygotes reported a history of VTE, compared with 31% and 13% of relatives with

P.1231

protein C deficiency only and factor V Leiden only, respectively.¹²⁵ In families with factor V Leiden and AT deficiency, 92% of double-heterozygous carriers had a history of VTE, as opposed to 57% and 20% of individuals with AT deficiency only and factor V Leiden only, respectively.³¹⁵

Combined heterozygosity for both the factor V Leiden and prothrombin G20210A mutations, which is estimated to occur in 1 in 1,000 persons, does appear to be associated with an increased relative risk of both first and recurrent VTE.^{190, 210, 316} In a pooled analysis of eight case-control studies including more than 2,000 patients with VTE, a 2.2% prevalence for the combined mutations was found in patients.¹⁹⁰ Double heterozygosity was associated with a 20-fold increased relative risk of VTE.¹⁹⁰ The risk of recurrent VTE for heterozygous carriers of both factor V Leiden and PT G20210A also appears to be increased (2.6-fold).²¹⁰

The prevalence of factor V Leiden carriership in combination with acquired hypercoagulable states has also been studied. Factor V Leiden appears to increase the risk of VTE in patients with antiphospholipid antibodies but is not a prerequisite for the development of VTE in those patients.³¹⁷ The interaction between factor V Leiden and hyperhomocysteinemia has been a matter of interest since the observation, not corroborated by further studies, that factor V Leiden appeared to be a prerequisite for VTE in individuals from families with classic homocystinuria.³¹⁸ Nonetheless, two studies on the interaction between mild to moderate hyperhomocysteinemia and factor V Leiden have yielded somewhat different findings. Den Heijer et al. found that the risk of VTE associated with the combination of conditions (2-fold) did not exceed the risk associated with each condition alone (9.5-fold for factor V Leiden, 2.2-fold for hyperhomocysteinemia).²⁴⁸ However, in the large Physicians' Health Study, the concomitant presence of both conditions did appear to be synergistic.¹⁸⁹

Inherited Risk Factors in Childhood Venous Thrombosis

Many of the common inherited thrombotic disorders described in adult patients have been linked to pediatric thrombosis. A prospective European study identified a single genetic risk factor in 54% of pediatric thrombosis patients.³¹⁹ Common defects identified were factor V Leiden (32%), protein C deficiency (9%), protein S deficiency (6%), prothrombin gene mutation (4%), and AT deficiency (3%).³¹⁹ In most patients, thrombosis is precipitated by superimposed nongenetic risk factors that included central venous catheters, cancer, sepsis, immobility, surgery, trauma, or use of oral contraceptives.³²⁰ For neonatal patients with thrombosis, the most significant factor associated with thrombosis is the presence of a central venous catheter.³²¹ In children with recurrent thrombosis, the factor V Leiden mutation is present in most patients.³²² Homozygous deficiencies of protein C or protein S are causal in neonatal purpura fulminans.^{133, 160} When pediatric patients are evaluated for protein C, protein S, or AT deficiency, pediatric reference ranges are mandatory, because age-related changes occur in the levels of these proteins.^{322a}

A consensus panel of the International Society on Thrombosis and Haemostasis has recommended that pediatric patients with thrombosis be routinely tested for inherited and acquired disorders in a comprehensive fashion.³²³ However, many of the suggested tests are not recommended by the College of American Pathologists' consensus panel, and there are no

data to indicate that patients with a genetic predisposition to thrombosis—children or adults—should be treated differently^{324, 325} from those without risk factors (discussed in the following section).

Perspective on Laboratory Testing for Inherited Thrombotic Disorders

Increased availability of hypercoagulable-state test “panels” and enhanced ability to identify an abnormality in tested patients have prompted widespread testing of thrombosis patients. Testing for acquired and inherited hypercoagulable states uncovers an abnormality in >50% of patients presenting with an initial VTE but may have minimal actual impact on management in most of these patients.^{24, 98, 326, 327} Such laboratory screening should be reserved for patients for whom the results of individual tests significantly affect the choice of anticoagulant agent, intensity of anticoagulant therapy, therapeutic monitoring, family screening, family planning, prognosis determination, and, most of all, duration of antithrombotic therapy. Testing “just to know” is neither cost-effective nor clinically appropriate. Table 55.4 lists situations in which hypercoagulable-state testing should be considered, but not necessarily performed, unless an a priori use of the test results has been determined. Table 55.5 lists potential elements of an initial battery of tests to detect a defined hypercoagulable state.

Patients should be considered for evaluation of these disorders if they are young (<45 years of age) with recurrent thrombosis, or if they have had a single idiopathic thrombotic event and have a positive family history.⁸⁹ This recommendation is based on the fact that, with the exception of hyperhomocysteinemia and qualitative abnormalities of plasminogen, inherited thrombotic disorders, especially the five most common (APC-R, prothrombin G20210A, protein C deficiency, protein S deficiency, and AT deficiency), are autosomal dominant disorders, and most patients with these disorders (but not all³²⁸) have supportive family histories. Patients without a family history of thrombosis should be evaluated for common acquired etiologies for thrombosis, including malignancy, myeloproliferative disorders, PNH, and antiphospholipid antibodies.⁸⁹ Because thrombosis may induce an acute-phase response that may affect functional coagulation assays, testing is ideally done when the patient has fully recovered from the acute event and is not receiving anticoagulants. Functional assays are preferred over immunologic assays, so that both type I and type II disorders can be detected. An important exception to this recommendation is APC-R, which can be screened for using a DNA test that is not affected by acute-phase responses or anticoagulant therapy. Diagnosis of protein C or S deficiency in patients already anticoagulated with warfarin can be facilitated by parental testing, testing symptomatic family members who are not receiving anticoagulation, referral to a reference laboratory that has standardized assays for these natural anticoagulants in anticoagulated patients, or temporary cessation of warfarin therapy (minimum of 3 to 4 weeks).⁸⁹ Patients with arterial thrombosis should be considered for testing for hyperhomocysteinemia, Lp(a), and, possibly, protein S deficiency and antiphospholipid antibodies.³

Anticardiolipin and β_2 -glycoprotein 1 antibody testing by enzyme-linked immunosorbent assays

Factor VIII activity^a

^a Assays should not be done at the time of acute thrombosis or while the patient is anticoagulated.

^b aPTT and dRVVT mixing studies that do not correct should be further evaluated for the lupus anticoagulant with phospholipid correction tests.

In addition to a positive family history of thrombosis, other clinical features may suggest inherited thrombosis, including recurrent spontaneous thromboses, thrombosis in unusual sites (mesenteric vein), thrombosis at an early age, heparin resistance (suggestive of AT deficiency), warfarin-induced skin necrosis and neonatal purpura fulminans (suggestive of protein C or protein S deficiency), and thrombosis occurring with estrogen therapy or pregnancy (suggestive of APC-R or prothrombin G20210A). The presence of these clinical events may justify laboratory evaluation of these patients. Even in situations in which the relative risk of thrombosis and recurrent thrombosis is increased, the absolute risk for a particular patient may not warrant the risks of chronic anticoagulation. Thus, one should always assess the pretest use of hypercoagulable-state testing before embarking on an expensive investigation.

A more fundamental question is whether routine laboratory testing for inherited thrombotic disorders will change treatment (intensity or duration of anticoagulation). This is a controversial subject because the available data do not support the contention that patients with an inherited thrombotic disorder should be managed differently from patients without such a disorder.^{24, 327} Several prospective trials performed to address this question found that positive inherited thrombophilia testing results did not affect the rate of recurrent VTE (reviewed in Reference 24). Another study found that thrombophilia testing at a major urban medical center was overutilized, and that a majority of tests were ordered at suboptimal times.³²⁹

There are three thrombotic risk factors that may influence treatment strategy: The presence of antiphospholipid antibodies (discussed in Chapter 54), AT deficiency, and (perhaps) hyperhomocysteinemia. Patients with antiphospholipid antibodies may require a longer duration of oral anticoagulation, and some patients with hyperhomocysteinemia may respond to vitamin therapy to resolve this thrombosis risk factor (although clinical trial data have not demonstrated a benefit of lowering homocysteine levels^{257, 258, 259}). Patients identified as having AT deficiency may benefit from this diagnosis because availability of AT concentrates may optimize their management. Table 55.6 summarizes the clinical laboratory testing recommendations of the College of American Pathologists' Consensus Conference on Thrombophilia.

Laboratory Testing for the Prethrombotic State

Levels of fibrin degradation products, including cross-linked fibrin degradation products (D-dimer), are usually increased in the presence of acute VTE. Absence of an elevated level of D-dimer in patients undergoing an evaluation for acute DVT or PE has an excellent negative predictive value for thrombosis.³³⁰ D-dimer measured 3 months after oral anticoagulation for DVT treatment was discontinued has been shown to have a negative predictive value of 95.6% for VTE recurrence.³³¹ It has also been shown that baseline elevations of D-dimer are strongly and positively related to the occurrence of future venous thrombosis.³³² Plasma levels of fibrinopeptide A can be increased in venous thrombosis patients, but this assay has the disadvantage of requiring rigorous attention to specimen collection to avoid an activated plasma sample. The activation peptide generated when prothrombin is cleaved to form thrombin, prothrombin fragment 1+2, is a sensitive measure of thrombin formation.³³³ Other markers of activation of coagulation include thrombin-AT complex and plasmin-antiplasmin complex.

One active area of investigation is optimizing the combination of a sensitive D-dimer assay with clinical criteria to exclude VTE^{334, 335} or risk of recurrent VTE.^{336, 337} Figure 55.2 depicts one strategy algorithm to incorporate D-dimer testing in thrombosis evaluation.

ANTITHROMBOTIC THERAPY

Arterial and venous thrombotic events combined, including acute coronary syndromes, stroke, peripheral arterial thrombosis, DVT, and PE, are likely responsible for more morbidity and mortality than any other condition in the developed world.

Cardiovascular disease was reported to be the underlying cause of death in ~30% of all deaths in the United States in 2010.¹ Every year 750,000 new strokes occur in the United States, of which 85% are ischemic in nature.³³⁸ Because approximately one third of these patients die as a direct or indirect result of their cerebrovascular-thrombosis-related occlusion, stroke is the third leading cause of death in this country. In addition, stroke is the leading cause of serious long-term disability in the United States, with roughly 4.7 million total stroke survivors.³³⁸ Acute limb ischemia secondary to peripheral arterial thrombosis and thromboembolism involving native and prosthetic vessels is a relatively uncommon but ominous form of vascular accident. National databases suggest a rate of 16 events annually per 100,000 population.³³⁹ In a fashion similar to coronary artery thrombosis, acute peripheral arterial thrombosis typically develops at sites of pre-existing peripheral atherosclerotic occlusive disease (PAOD). PAOD has been diagnosed in as many as 17% of men and 20% of women >55 years of age and is highly predictive for the coexistence of coronary and cerebral vascular disease. It has been estimated that PAOD progresses to critical limb ischemia in 15% to 20% of patients.^{340, 341}

Acute VTE, including DVT and PE, is a common, potentially life-threatening, often preventable vascular condition associated with trauma, major surgery, advanced congestive heart failure, pregnancy, HRT, malignancy, and inherited hypercoagulability. Proximal lower-extremity DVT can result in venous limb gangrene (phlegmasia cerulea dolens), chronic stasis changes related to the postthrombotic syndrome (PTS), and symptomatic PE. PE in its most severe presentation can result in pulmonary hypertension, right-sided heart failure, cardiopulmonary collapse, and death.

A common feature of the management of all thromboembolic vascular diseases is the use of antithrombotic agents. Antithrombotic agents, including antiplatelet drugs, anticoagulants, and thrombolytic agents, are used to prevent thrombotic events, prevent or mitigate the complications of thrombotic events, and restore vascular patency to prevent loss of tissue, organ, and limb function, as well as life. Based on the pathologic basis of thrombosis involving different vascular beds, drugs that inhibit platelet activation and aggregation play a primary role in arterial disease management, whereas drugs that inhibit thrombin and fibrin generation play a primary role in venous disease

P.1233

management. The following sections describe the pharmacodynamics, pharmacokinetics, and clinical uses of select antithrombotic agents.

TABLE 55.6 SUMMARY OF THE COLLEGE OF AMERICAN PATHOLOGISTS™ RECOMMENDATIONS ON LABORATORY TESTING FOR INHERITED THROMBOSIS

Thrombotic Disorder	Who Should Be Tested?	Test Method(s)	Comments
FVL	First VTE at age <50 y Recurrent VTE First unprovoked VTE First VTE, unusual site First VTE, positive family history First VTE related to pregnancy or hormonal therapy Unexplained second- or third-trimester pregnancy loss	APC-R assay using factor V-deficient plasma <i>or</i> DNA-based assay	Patients with relatives who are known to have FVL should be tested directly with DNA-based assays. Patients with positive APC-R assays should have confirmatory DNA tests.
Prothrombin gene	As above	DNA-based assay	Prothrombin activity assays should not be

mutation			used.
Homocysteinemia	Arterial vascular disease; controversial for VTE	High-performance liquid chromatography or immunoassays	Genotyping for methylenetetrahydrofolate reductase mutations is not recommended. Fasting may not be necessary. Proper sample processing is necessary. Testing in VTE patients may be appropriate to identify and treat affected patients with vitamins.
PC deficiency	Infants with neonatal purpura fulminans; VTE patient from a family with known PC deficiency Asymptomatic female from a known PC-deficient family before hormonal therapy	Chromogenic substrate assays preferred Functional assays are useful Immunologic assays are discouraged	Avoid testing during acute thrombosis or anticoagulant therapy. Exclude causes of acquired PC deficiency. Consider age-dependent reference ranges.
PS deficiency	Patient with VTE from a family with known PS deficiency	Functional assay <i>or</i> immunoassay for free PS Total PS antigen assays not recommended	Abnormal functional assay results should be confirmed with an immunoassay for free PS. Exclude acquired causes of PS deficiency. Avoid testing during acute thrombosis, anticoagulant therapy, and pregnancy. Consider age- and gender-dependent reference ranges.
AT deficiency	Patient with VTE from a family with known AT deficiency Asymptomatic female from a known AT-deficient family before hormonal therapy	Chromogenic substrate assays preferred AT antigen assays not recommended	Exclude acquired causes of AT deficiency. Avoid testing during acute thrombosis or anticoagulant therapy.
Elevated factor VIII levels	Controversial	Factor VIII activity assay	Test 6 mo after thrombosis. Avoid anticoagulant therapy.
Dysfibrinogenemia	Not recommended		
Heparin cofactor II	Not recommended		
Factor XIII polymorphisms	Not recommended		
Plasminogen	Not recommended		

activator inhibitor-1

Plasminogen deficiency Test in non-DVT patients with ligneous conjunctivitis

APC, activated protein C; AT, antithrombin; FVL, factor V Leiden; PC, protein C; PS, protein S; VTE, venous thromboembolism.

Antiplatelet Drugs

Given the important role of platelets in mediating arterial thrombosis and the significant morbidity and mortality of arterial thrombotic disorders, the safety and efficacy of antiplatelet drugs have been evaluated in numerous primary and secondary prevention trials. A 1988 meta-analysis indicated that antiplatelet treatment reduced overall mortality from vascular disease by 15% and that nonfatal vascular events were reduced by 30%.³⁴² A 2002 update on this subject supports the original observation of the efficacy of antiplatelet therapy.³⁴³ The American College of Chest Physicians' consensus conference has summarized the status of clinical trials with aspirin and other antiplatelet drugs.³⁴⁴

Numerous potential targets exist for antiplatelet therapy (Fig. 55.3). Platelet cyclo-oxygenase (COX) is the target of acetylation and irreversible inactivation by aspirin.^{345, 346} ADP-induced platelet aggregation can be selectively inhibited by the thienopyridines, ticlopidine, clopidogrel, prasugrel, and by ticagrelor, a member of the cyclopentyltriazolopyrimidine class of drugs.^{345, 346} Dipyridamole alters platelet function, in part, by inhibition of cyclic nucleotide phosphodiesterase to increase platelet cyclic AMP levels.³⁴⁶ Other potential targets for antiplatelet therapy include the platelet membrane receptor, gpIb, mediator of platelet adhesion, and inhibitors to thrombin, the most potent stimulus to platelet activation.^{345, 346} Interference with fibrinogen-mediated platelet aggregation by anti-gpIIb-IIIa antibodies and peptides is well established.³⁴⁴

P.1234

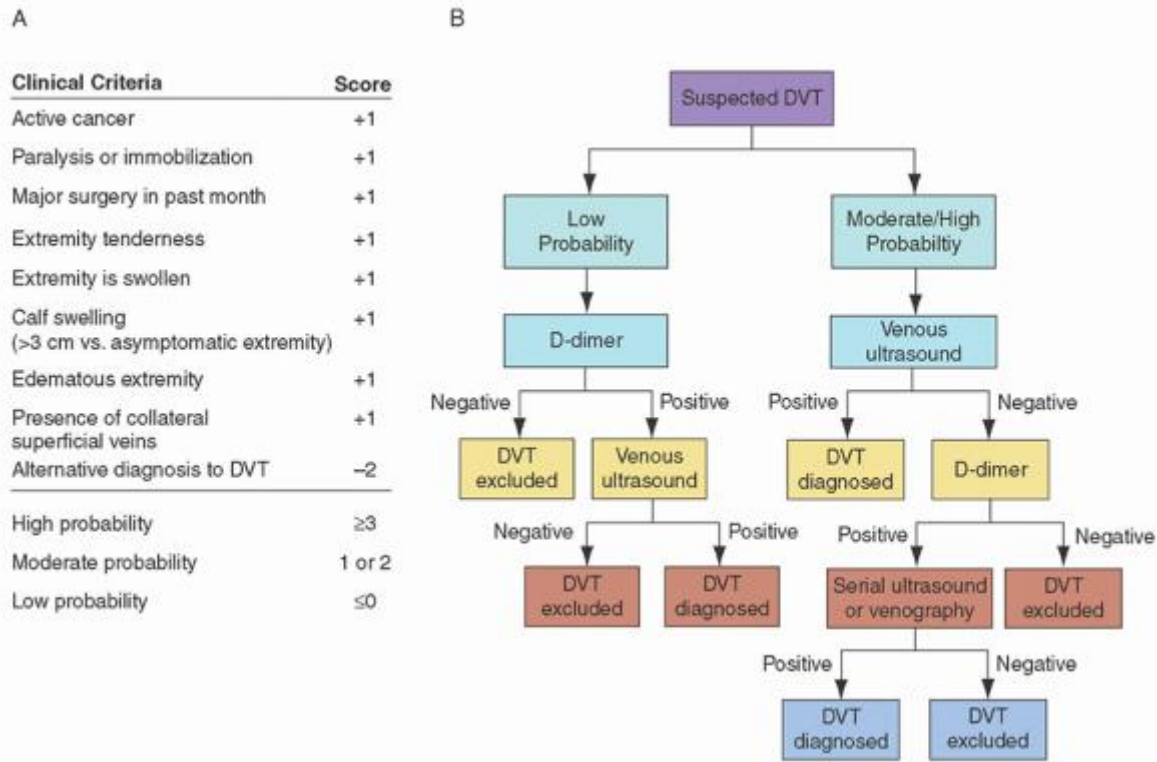

FIGURE 55.2. Algorithm for excluding deep vein thrombosis (DVT) using clinical criteria, D-dimer testing, and venous ultrasound. Clinical criteria are based on those of Wells PS, Anderson DR, Bormanis J, et al. Value of assessment of pretest probability of deep-vein thrombosis in clinical management. *Lancet* 1997;350:1795-1798. D-dimer methods are similar to those described by Hirsh J, Lee AY. How we diagnose and treat deep vein thrombosis. *Blood* 2002;99: 3102-3110. A: Based on clinical criteria fulfilled by the patient, the cumulative score is tallied. High probability is a score ≥3, moderate probability is 1 or 2, low probability is ≤0. B: The probability score is used with D-dimer assay and ultrasound to determine which patients may be excluded from DVT testing.

FIGURE 55.3. Targets for antiplatelet agents. This diagram summarizes certain aspects of platelet function relevant to antiplatelet therapy. Platelet metabolic pathways, membrane receptors, and enzymes are depicted with specific therapeutic targets enumerated. Four target categories for antiplatelet drugs are the arachidonic acid pathway, which

regulates production of prostaglandins (PGs) and thromboxanes; the cyclic adenosine monophosphate (cAMP) mechanism, which modulates important metabolic events; platelet membrane glycoproteins (GPs), which act as receptors for platelet agonists; and thrombin, a key stimulus to platelet activation. Specific targets for antiplatelet therapies include the following: (1) COX is the target of acetylation and irreversible inactivation by aspirin, as well as reversible inactivation by the nonsteroidal anti-inflammatory agents; (2) inhibitors to thromboxane synthetase prevent generation of thromboxane A₂ (TxA₂); (3) an example of a TxA₂ receptor antagonist is BM 531; (4) infusion of PGE₁ or stable analogs of prostacyclin (Iloprost) increases platelet concentrations of cAMP via stimulation of adenylate cyclase; (5) dipyridamole increases platelet cAMP concentrations by inhibition of cyclic nucleotide phosphodiesterase (PDE), and cilostazol inhibits PDE3 to increase platelet cGMP concentrations; (6) because thrombin is the most potent stimulus to platelet activation, inhibitors of thrombin (heparin, argatroban, and bivalirudin) are important agents in preventing platelet-dependent thrombosis; (7) ticlopidine, clopidogrel, prasugrel, and ticagrelor inhibit platelet activation by inhibition of adenosine-diphosphate (ADP)-induced aggregation; (8) monoclonal antibodies or peptides directed against the GPIIb-IIIa complex inhibit fibrinogen binding to platelets and subsequent platelet aggregation; (9) inhibitors to the von Willebrand factor receptor (GPIb) are being developed to prevent platelet adhesion; and (10) inhibitors to protease-activated receptors 1 and 4 (PAR 1 and 4) such as vorapaxar antagonize thrombin activation of platelets. ATP, adenosine triphosphate. Reproduced and modified from Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524-599.

P.1235

Aspirin

Aspirin (acetylsalicylic acid) is the prototypical antiplatelet drug, exerting its antithrombotic action by irreversibly inactivating (by acetylation) the COX activity of platelet prostaglandin H synthase-1 (COX-1) and prostaglandin H synthase-2 (COX-2).³⁴⁷ This COX inhibition leads to the prevention of TxA₂ synthesis and impairment of platelet secretion and aggregation.³⁴⁸ A variety of nonsteroidal anti-inflammatory drugs can inhibit TxA₂-dependent platelet function via competitive reversible inhibition of COX-1. A lesser degree of COX-1 inhibition may explain why long-term use of nonaspirin nonsteroidal anti-inflammatory drugs is not protective against first MIs in postmenopausal women.³⁴⁹ Aspirin is the least expensive, most widely studied, and most widely used antiplatelet drug.

Aspirin (when not enteric-coated) is rapidly absorbed from the upper gastrointestinal tract; plasma salicylate concentrations peak within 1 hour of ingestion. The effects of aspirin on platelet function occur within 1 hour and last for the duration of the affected platelets' lifespan (~1 week). The toxicity of aspirin is dose-related, explaining why clinical studies have focused on finding the lowest effective antithrombotic dose of the drug. Toxicities include gastrointestinal discomfort and blood loss, and the risk of systemic bleeding. Clinical trials suggest that aspirin doses as low as 75 mg/day or 30 mg/day are antithrombotic.^{343, 344}

In addition to reducing aspirin toxicity, lower aspirin doses also inhibit vascular endothelial cell prostacyclin production to a lesser extent, because inhibition of endothelial cell COX is of shorter duration and requires higher aspirin doses than does platelet COX inhibition.³⁵⁰ The inhibitory effects of chronic low-dose aspirin administration are cumulative.³⁵¹ However, even when taken chronically in large doses, aspirin is not believed to be thrombogenic.³⁵²

The 2012 consensus conference statement on antiplatelet therapy indicates that aspirin has been convincingly demonstrated to be effective in treatment of the following thrombotic disorders: Stable and unstable angina, acute MI, transient ischemic attack and incomplete stroke, stroke after carotid artery surgery, atrial fibrillation (low risk), and prosthetic heart valves (in combination with warfarin).³⁴⁴ The minimum effective aspirin dose for these indications is 75 to 325 mg/day. Aspirin has also been shown to reduce mortality post-coronary-artery bypass surgery and to be effective for primary prevention of cardiovascular events,^{353, 354} although more recent meta-analysis data of aspirin use for primary prophylaxis show less-certain benefits.³⁵⁵

Data from the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial highlight aspirin's pre-eminent antiplatelet role in cardioprevention.³⁵⁶ CHARISMA assessed whether adding clopidogrel (75 mg/day) to aspirin therapy (75 to 162 mg/day) provided any benefit over aspirin monotherapy in preventing MI, stroke, or death from cardiovascular disease. The study involved 15,603 patients aged 45 years or older who were at high risk for these events. The study showed that the addition of clopidogrel to aspirin did not result in a significant lowering of risk of the primary composite endpoint. In addition, the rate of severe bleeding was 1.7% and 1.3% for the clopidogrel-plus-aspirin and aspirin-only groups, respectively. Clopidogrel in addition to aspirin did reduce the

relative risk of a recurrent MI, stroke, or cardiovascular death by 12.5% in the subgroup of patients with established atherothrombotic disease. The subgroup of patients with multiple risk factors but no clearly established vascular disease did not benefit from the addition of clopidogrel and actually had nonstatistically significant increases in cardiovascular events and bleeding. Clopidogrel plus aspirin remains an approved and standard therapy in conjunction with coronary artery stenting.

Aspirin may modify the natural history of intermittent claudication from lower-extremity arteriosclerosis. Because these patients are at high risk for future cardiovascular and cerebrovascular atherothrombotic events, life-long aspirin therapy is recommended.³⁵⁷ Similar therapy is advisable after peripheral arterial bypass surgery and carotid endarterectomy.

The Pulmonary Embolism Prevention trial was a large-scale, double-blind, multicenter study of 13,356 patients undergoing surgery for hip fracture and an additional 4,088 patients undergoing elective knee or hip arthroplasty.³⁵⁸ Patients were assigned to a regimen of 160 mg of aspirin or placebo once daily for 5 weeks, with the first dose given before surgery. Other forms of prophylaxis were allowed, and 40% of patients received unfractionated heparin (UFH) or LMWH in addition to the aspirin. The study demonstrated that aspirin reduced the incidence of fatal PE (58% risk reduction) and symptomatic nonfatal DVT or PE (36% risk reduction) in patients with hip fracture.³⁵⁸ Although beneficial when compared to placebo, aspirin cannot be recommended as first-line VTE prophylaxis in hip fracture patients, because the benefit of aspirin is less than with anticoagulants.³⁵⁹ The potential role of aspirin in treating VTE has been resurrected by the results of a VTE treatment trial that demonstrated that aspirin therapy, begun after 6 to 18 months of oral anticoagulant treatment, reduced VTE recurrence by ~40% compared to placebo.³⁶⁰ Aspirin, used as prophylaxis for VTE recurrence, would have the advantage of being an active drug to also prevent arterial thrombosis.^{360a}

The concept of "aspirin resistance" has been popularized. This term refers to persistent platelet activation that occurs in patients treated with aspirin who experience treatment failure. There are numerous reasons for aspirin resistance;³⁶¹ current recommendations are to not test routinely for aspirin resistance and to not change therapy based on such test results.³⁶² One literature review concluded that the most common cause for aspirin resistance was noncompliance.³⁶³ Routine laboratory monitoring for aspirin resistance is not recommended.³⁶⁴

Thienopyridines

Ticlopidine and clopidogrel are structurally related compounds that selectively inhibit ADP-induced platelet aggregation and likely ADP-mediated amplification of the platelet response to other agonists.³⁶⁵ A lack of in vitro platelet aggregation inhibition suggests that in vivo hepatic transformation to an active metabolite is necessary for an antiplatelet effect. Both agents were initially used as aspirin substitutes in aspirin-intolerant patients. Enthusiasm for ticlopidine has been dampened by associated hematologic complications. Ticlopidine has been associated with neutropenia, thrombocytopenia, aplastic anemia, and thrombotic thrombocytopenic purpura.^{366, 367, 368, 369}

Clopidogrel, an irreversible inhibitor of the P2Y₁₂ ADP receptor, is rapidly absorbed and extensively metabolized. The plasma half-life of the main systemic metabolite, SR 26334, is roughly 8 hours.³⁷⁰ Platelet function returns to normal approximately 7 days after the last dose of clopidogrel. The Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events trial compared clopidogrel to aspirin in patients who had experienced a recent stroke or a recent MI and in those presenting with symptomatic peripheral arterial disease.³⁷¹ A modest difference in efficacy was observed. The annual ischemic event rate for aspirin was 5.83% compared to 5.32% for clopidogrel. The majority of the difference in efficacy occurred in the patients who entered the trial because of symptomatic peripheral arterial disease, with a 23.8% relative risk reduction.³⁷¹ The Clopidogrel in Unstable Angina to Prevent Recurrent Events trial has demonstrated an advantage of clopidogrel plus aspirin over aspirin alone in patients with acute coronary syndromes.³⁷² Clopidogrel, like ticlopidine, can rarely precipitate thrombotic thrombocytopenic purpura.³⁷³

Despite the current standard antiplatelet regimen of aspirin and clopidogrel (with or without glycoprotein IIb/IIIa inhibitors) in percutaneous coronary intervention (PCI) patients, peri-procedural and postprocedural ischemic events continue to occur. Prasugrel, a newer potent thienopyridine P2Y₁₂ receptor antagonist, can

P.1236

achieve more rapid and higher levels of inhibition of ADP-induced platelet aggregation than clopidogrel.³⁷⁴ However, although a major clinical trial with prasugrel found that it did not reduce overall mortality, it did increase major bleeding (reviewed in Reference 344).

Ticagrelor, a new antiplatelet agent of the cyclopentyltriazolopyrimidine class, reversibly inhibits the P2Y₁₂ ADP receptor in platelets.³⁴⁶ An international trial that compared clopidogrel versus ticagrelor in patients with an acute coronary

syndrome found that although the overall trial results demonstrated that ticagrelor was the superior drug, the results for United States' patients showed the opposite, with clopidogrel associated with better outcomes. Major bleeding rates between the two drugs were similar.³⁴⁶ Perioperative management of patients on antiplatelet therapy has been reviewed.^{374a}

Integrin $\alpha_{IIb}\beta_3$ (Glycoprotein IIb/IIIa) Receptor Antagonists

Because of the multitude of pathways that lead to platelet aggregation, it is not surprising that the clinical efficacy of the antiplatelet agents described above is only partial. Even combination therapy with clopidogrel and aspirin, resulting in partial inhibition of TxA_2 - and ADP-mediated platelet aggregation, leaves platelets susceptible to agonists such as thrombin and collagen.³⁴¹ Because expression of functionally active gPIIb/IIIa on platelet surfaces is the final common pathway of platelet aggregation regardless of initial stimulus, it is logical to target this glycoprotein receptor with antiplatelet agents for maximal platelet inhibition.

gPIIb/IIIa is a member of the integrin family of receptors. These receptors recognize the amino acid sequence arginine-glycine-aspartate (Arg-Gly-Asp [RGD]), which represents the cell attachment regulation sequence present in certain adhesive proteins such as fibrinogen.³⁷⁵ Inhibitors of fibrinogen binding to gPIIb/IIIa , called the disintegrins, include a chimeric monoclonal antibody against the receptor, naturally occurring RGD sequence-containing peptides from snake (pit viper) venoms, synthetic RGD peptides, synthetic Lys-Gly-Asp (KGD) peptides, peptidomimetics, and nonpeptide RGD mimetics.^{344, 376, 377, 378}

Three parenteral gPIIb/IIIa inhibitors have been extensively studied, primarily in the settings of PCI, unstable angina, and non-Q-wave MI. These are abciximab, eptifibatide, and tirofiban.^{344, 346} Abciximab (c7E3 Fab) is a chimeric Fab fragment of human and murine protein that binds to gPIIb/IIIa . Abciximab is unique among the gPIIb/IIIa antagonists because it also blocks the $\alpha_v\beta_3$ receptor.³⁷⁹ Eptifibatide is a synthetic cyclic heptapeptide with a KGD sequence that is more specific for gPIIb/IIIa than the RGD sequence.^{344, 376} Tirofiban is a synthetic peptidomimetic based on the RGD sequence.³⁸⁰ Oral gPIIb/IIIa inhibitors have been generally unsuccessful. Current and emerging antiplatelet therapies have been reviewed.³⁴⁶

Anticoagulant Drugs

Anticoagulant drugs are ubiquitous in medical and surgical practice. Anticoagulants are used to prevent and treat thrombosis. Traditionally, short-term anticoagulation is provided in the form of an intravenous infusion or subcutaneous injection whereas more chronic anticoagulation is facilitated by the use of oral agents. However, narrow-spectrum (single-protein-target) oral anticoagulants (e.g., dabigatran, rivaroxaban, and apixaban) are beginning to supplant more broad-spectrum anticoagulants (e.g., heparin and warfarin) and this trend will likely continue. The 2012 version of the American College of Chest Physicians Clinical Practice Guidelines has been published.³⁸¹

FIGURE 55.4. Structure of the common active saccharide moieties found in commercial unfractionated heparin. These polymeric structures are termed glycosaminoglycans. From left to right, the saccharide structures are 2-deoxy-2-sulfamino- α -D-glucose-6-sulfate; α -L-iduronic acid-2-sulfate; 2-acetamido-2-deoxy- α -D-glucose; β -D-glucuronic acid; and α -L-iduronic acid. Reproduced from Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524-599, with permission.

Heparin

Heparin is a naturally occurring, highly sulfated glycosaminoglycan that is normally present in human tissues (Fig. 55.4). McLean first isolated heparin from ox liver and identified its anticoagulant properties.³⁸² Commercial UFH is obtained from either bovine lung or porcine intestinal mucosa and consists of a heterogeneous mixture of polysaccharides (glycosaminoglycans) with molecular weights ranging from 4,000 to 30,000 D, with a mean molecular weight of approximately 15,000 D (approximately 45 saccharide units). UFH molecules possessing anticoagulant activity constitute approximately one third by weight of commercial heparin products.³⁸³ Sodium and calcium salts of heparin are available, and most commercial heparin preparations have specific activities of ~ 150 U/mg. Heparin structure consists of alternating residues of uronic acid and glucosamine that are variably sulfated.³⁸⁴ Sulfation of residues in heparin is a major

determinant of the anticoagulant activity of a given heparin preparation; the heparin molecules with anticoagulant activity exhibit high-affinity binding to AT.

UFH molecules contain a randomly distributed unique pentasaccharide sequence that binds to AT. Once bound to UFH, the natural anticoagulant effect of AT is potentiated, resulting in the accelerated binding and inactivation of serine proteases in general, and factor Xa and thrombin in particular.^{385, 386} The inhibition of these factors affects the common pathway of coagulation, resulting in decreased formation of thrombin and fibrin.

Heparin's interaction with AT is thought to occur as follows and is depicted in Figure 55.5. A ternary complex with heparin, thrombin, and AT first occurs; this association permits inactivation of thrombin by the active site inhibitor domain of AT. Lastly, heparin dissociates from the AT-thrombin complex to subsequently catalyze additional AT-mediated reactions.³⁸⁷ A pentasaccharide series interacts only with the AT-binding sequence and promotes factor Xa inhibition substantially but has minimal effect on thrombin inhibition.³⁸⁸ In this case, only the conformational change induced by the pentasaccharide is necessary for factor Xa inhibition to occur. Oligosaccharides of greater length (at least 18 residues) are necessary for enhancement of thrombin inhibition by AT. It is likely that in this latter case, a ternary complex of ATIII, thrombin, and heparin forms to mediate protease inhibition.³⁸⁹ In vitro experiments suggest that UFH exerts its major anticoagulant effect by promoting AT suppression of thrombin-dependent amplification reactions.³⁹⁰

In addition to its anticoagulant activity, heparin possesses other, unrelated biologic effects.³⁹¹ Heparin hydrolyzes triglycerides

P.1237

from chylomicrons and very-low-density lipoproteins by release of endothelial cell lipoprotein lipase into the blood.³⁹² Heparin can also activate platelets, suppress cell-mediated immunity, and affect metabolism of aldosterone and thyroxine. Heparin is active when given parenterally, either intravenously or subcutaneously. Because of its highly charged nature and inability to cross biologic membranes alone, oral use of heparin has historically been viewed as impossible. Recently, delivery systems have been developed that make oral heparin a possibility and when sufficient amounts of heparin are administered orally, a prophylactic intensity of anticoagulation can be achieved.³⁹³

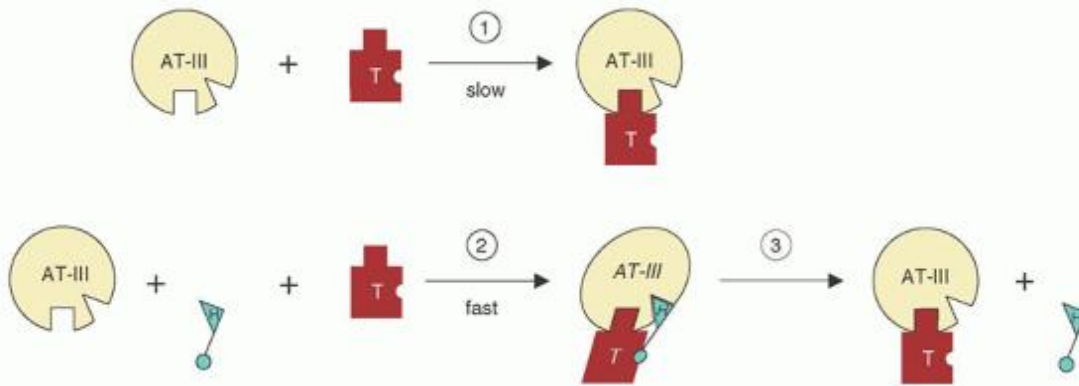

FIGURE 55.5. Inhibition of thrombin activity by the heparin (H)-antithrombin (AT) mechanism. Reaction 1 indicates that in the absence of heparin catalysis, AT can irreversibly inactivate thrombin (T), albeit in an inefficient manner. In the presence of H, a conformation change occurs in the AT molecule, and heparin also acts as a template to bind both AT and T, promoting rapid inactivation of coagulation (reaction 2). In reaction 3, heparin is released from the AT-T complex and is available to catalyze subsequent reactions. Inhibition of factor Xa by AT-H does not require binding of heparin to the factor Xa molecule.

The half-life of heparin varies with the dosage given, with the half-life increasing with increasing dosage.³⁹⁴ A 100-U/kg intravenous dose is cleared with a half-life of ~1 hour. The clearance of heparin is also affected by the extent of thromboembolism, with extensive thrombosis decreasing heparin half-life.³⁹⁵ Heparin is cleared by the reticuloendothelial system and metabolized by the liver, and metabolic products are excreted in the urine. The anticoagulant effect of heparin is also altered by its nonspecific binding to plasma proteins and cells.³⁹⁶ Given these numerous variables affecting the plasma half-life of heparin, therapeutic use of this drug generally requires close laboratory monitoring to ensure attainment of a therapeutic effect and regulation of heparin levels within a targeted range to optimize safety and efficacy. When using intravenous heparin, the use of established nomogram-guided therapy is preferred.³⁹⁷ Table 55.7 illustrates an example of a weight-based nomogram for using UFH. This assumes that the hospital laboratory has calibrated the aPTT

values such that an aPTT range from 1.5 to 2.5 times the mean laboratory control aPTT is equivalent to plasma heparin levels of 0.3 to 0.7 U/ml, as measured by anti-factor Xa activity.³⁹⁷

Pharmacologic reversal of UFH anticoagulant activity can be achieved with protamine sulfate. Protamine is a positively charged moiety derived from salmon sperm that can interact with the negatively charged UFH to form a stable complex that lacks anticoagulant activity. One milligram of protamine can inactivate ~100 U of UFH. Protamine, in excess, can promote an anticoagulant state. Because of a clinically meaningful risk of anaphylaxis, protamine should be administered with caution and is normally reserved for use in case of life-threatening bleeding or UFH overdose and reversal of anticoagulation following cardiopulmonary bypass.

An additional challenge to the use of heparin to prevent and treat thrombosis is heparin resistance. "True" heparin resistance manifests as inadequate anticoagulant and antithrombotic responses from what would otherwise be perceived as an adequate, and probably weight-based, dose of heparin. Some have deemed a requirement of >35,000 U of heparin per 24-hour period, regardless of patient weight, to reflect this form of heparin resistance.³⁹⁸ With true heparin resistance, both a measurement of anticoagulant activity such as the aPTT and a measurement of antithrombotic activity such as the anti-factor Xa activity assay demonstrate inadequate degrees of heparin activity. True heparin resistance most likely results from the nonspecific binding of heparin to mononuclear white cells, vascular endothelial cells, and acute-phase proteins such as histidine-rich glycoprotein, vitronectin, and PF4, resulting in an inadequate quantity of free or AT-bound heparin.³⁹⁶ Another potential cause of heparin resistance is acquired AT deficiency such as can be seen in cancer patients.

Patients can also manifest an "apparent" heparin resistance characterized by dissociation between the aPTT and heparin assays.³⁹⁸ In these patients, the aPTT may be normal or near normal, whereas the anti-factor Xa activity assay reveals an appropriate target heparin activity level between 0.3 and 0.7 U/ml. Simply escalating the dose of heparin to achieve the desired aPTT without checking a heparin assay may result in a pronounced bleeding risk. Dissociation between the aPTT and

P.1238

heparin concentration likely reflects elevated levels of factor VIII that can shorten the in vitro aPTT without affecting the antithrombotic actions of the drug.

TABLE 55.7 WEIGHT-BASED NOMOGRAM OF UNFRACTIONATED HEPARIN (UFH) IN TREATMENT OF VENOUS THROMBOEMBOLISM

Initial UFH Bolus	80 U/kg
Initial UFH infusion rate	18 U/kg/h
Check aPTT after 6 h of IV infusion; modify infusion rate as follows:	
If aPTT < 1.2 × control, repeat bolus (80 U/kg) and increase infusion rate by	4 U/kg/h
If aPTT is 1.2-1.5 × control, repeat bolus (40 U/kg) and increase infusion rate by	2 U/kg/h
If aPTT is 1.5-2.3 × control, no change	—
If aPTT is 2.3-3.0 × control, decrease infusion rate by	2 U/kg/h
If aPTT > 3 × control, hold infusion for 1 h, then decrease infusion by	3 U/kg/h

aPTT, activated partial thromboplastin time.

Data from Raschke RA, Reilly BM, Guidry JR, et al. The weight-based heparin dosing nomogram compared with a "standard care" nomogram. *Ann Intern Med* 1993; 119:874-881.

Low-molecular-weight Heparins

LMWH is derived from the enzymatic or chemical cleavage of UFH to produce a mixture of low-molecular-weight glycosaminoglycan molecules with a mean molecular weight of ~5,000 D (~15 saccharide units).³⁹⁶ For example, enoxaparin sodium is produced by benzoylation followed by alkaline hydrolysis, dalteparin sodium is produced by controlled nitrous acid depolymerization, and tinzaparin sodium is produced by enzymatic digestion with heparinase. LMWH binds AT via the same pentasaccharide sequence as UFH.³⁹⁶ However, because of the predominance of molecules <18 saccharide units in length, LMWH has limited anti-thrombin (IIa) activity compared to its anti-factor Xa activity.

Whereas UFH has an anti-factor Xa to anti-IIa activity ratio of 1:1, LMWHs have reported ratios of 1.9:1 to 4.1:1.³⁹⁶ Because of limited thrombin inhibition, LMWH therapy cannot be monitored using the aPTT. Other differences between LMWH preparations include the degree of TF pathway inhibitor release, degree of sulfation, and degree of stimulated vWF release.^{399, 400, 401} These differences form the basis for many medical organizations' stating that LMWHs are unique drugs and not therapeutically interchangeable.^{402, 403, 404}

At low doses, subcutaneous LMWH has 90% bioavailability, compared to 30% for UFH. LMWHs have limited nonspecific binding to plasma proteins and platelets, endothelial cells, and macrophages compared to UFH, as well as a predictable clearance and a longer half-life that facilitates once- or twice-daily administration.^{396, 405} Unlike UFH, the half-life of LMWH is not dose-dependent.³⁹⁶ These characteristics make LMWH preferred in settings that may normally result in heparin resistance. These advantages of LMWH allow these drugs to be given subcutaneously, once or twice daily and without the need for laboratory monitoring.³⁹⁶ Similar to UFH, absolute contraindications for LMWH include active bleeding, HIT, or a history of HIT, and known sensitivity to LMWH, UFH, or pork products.

LMWHs have substantial renal clearance; therefore, multi-day therapeutic use of LMWH in patients with significant renal insufficiency (creatinine clearance <30 ml/minute) should be avoided.⁴⁰⁶ In the setting of less severe renal insufficiency, LMWH should be used with caution and with a reduced dosing frequency. Only ~60% of LMWH anticoagulant activity can be reversed after the administration of protamine sulfate.⁴⁰⁷ Table 55.8 summarizes the LMWH products available in the United States and their properties and U.S. Food and Drug Administration (FDA)-approved indications.

Heparinoids

Heparinoids are low-molecular-weight glycosaminoglycans that are not derived from heparin. Heparinoids include dermatan sulfate and danaparoid sodium. Dermatan sulfate and low-molecular-weight dermatan sulfate act as anticoagulants by activating HCII.^{408, 409} Danaparoid sodium is a glycosaminoglycan mixture derived from porcine intestinal mucosa and composed of heparan sulfate (84%), dermatan sulfate (12%), and chondroitin sulfate (4%).⁴¹⁰ Danaparoid has an anti-factor Xa activity to anti-IIa activity ratio of greater than 22:1 (compared to a 1:1 ratio for heparin), which explains why it is minimally neutralized by protamine sulfate.⁴¹⁰

The largest collection of clinical experience with danaparoid is in the setting of HIT. Danaparoid may cross-react with 10% to 50% of HIT sera, but in vivo cross-reactivity, although reported, has not been commonly observed.^{411, 412} Danaparoid has a relatively long half-life of ~24 hours, which may make its use less desirable in patients at high risk for developing bleeding or those likely to need surgery. Significant experience exists with the administration of danaparoid by both intravenous and subcutaneous routes. Danaparoid anticoagulation is monitored using an anti-factor Xa activity chromogenic assay calibrated with danaparoid standards. The drug is approved for deep vein thromboprophylaxis after orthopedic surgery at a dose of 750 U anti-Xa twice daily by subcutaneous injection. A common dose for the treatment of active thrombosis in patients with normal renal function is 1,500 U as an intravenous bolus followed by 1,500 U subcutaneously twice daily. The target therapeutic anti-factor Xa activity is 0.5 to 0.8 U/ml. Danaparoid's potential for cross-reactivity and the longer half-life make it less desirable than a direct thrombin inhibitor (DTI) for the treatment of patients with HIT.³⁹⁶ The manufacturer of the drug has discontinued availability of danaparoid in the United States.

Pentasaccharides

Because factor Xa is situated at the start of the common pathway of coagulation and upstream of thrombin in the cascade, it is an attractive target for new anticoagulants. By not directly inhibiting thrombin activity, factor Xa inhibitors might allow small amounts of thrombin to be generated, facilitating hemostasis and theoretically leading to a more favorable bleeding-risk profile. Fondaparinux is an FDA-approved synthetic pentasaccharide (molecular weight, 1,728 D) that causes selective indirect (i.e., AT-mediated) inhibition of factor Xa.⁴¹³ Fondaparinux is administered subcutaneously, has a half-life of ~17 hours, and does not require therapeutic monitoring. Fondaparinux elimination is prolonged in patients with renal impairment. The reduction in clearance increases as the creatinine clearance decreases. Elimination is also prolonged in patients >75 years of age and in those weighing <50 kg. Fondaparinux has been used with success to treat HIT.⁴¹⁴ Fondaparinux is approved for the prevention and treatment of VTE.

A long-acting, hypermethylated pentasaccharide, idraparinix, and a similar compound with a biotin moiety at the reducing end unit allowing for neutralization with avidin, idrabiotaparinix, have a half-life of up to 130 hours, which may facilitate anticoagulation with once-weekly subcutaneous dosing.⁴¹⁵ However, Phase III trials to date have been disappointing. In the VTE treatment studies, idraparinix was less effective than comparators, and in a large atrial fibrillation trial, idraparinix was equally effective as vitamin K antagonists, but caused more bleeding.^{416, 417}

Parenteral Direct Thrombin Inhibitors

The parenteral DTIs have been studied for use in patients with acute coronary events, but are most widely utilized in patients with HIT. In these patients, elimination of all heparin exposure is the most essential element in the treatment. This includes discontinuing heparin intravenous catheter flushes, prophylactic subcutaneous heparin or LMWH, and heparin-coated indwelling catheters. Yet, despite heparin discontinuation and platelet count recovery, patients with isolated, serologically confirmed HIT have up to a 50% risk of developing a confirmed thrombotic event during the 30-day period after heparin cessation.⁴¹⁸ The persistent prothrombotic tendency associated with HIT and the patient's original indication for heparin therapy warrant use of an alternative anticoagulant agent such as the DTIs after heparin cessation (Table 55.9).

Hirudins

Hirudin, a polypeptide originally isolated from the salivary glands of the medicinal leech, directly inhibits thrombin. Two recombinant forms of hirudin, lepirudin, and desirudin, are available for clinical use. Lepirudin is a recombinant hirudin analog that received FDA approval in 1998 for anticoagulant treatment in patients with HIT in the setting of thromboembolic disease to

P.1239

P.1240

prevent further thrombosis.⁴¹⁹ Lepirudin differs from native hirudin in that it lacks sulfation on the tyrosine at position 63 and has a leucine at position 1 rather than isoleucine.⁴²⁰ Lepirudin is a potent DTI that lacks any structural homology with heparin, does not cross-react with heparin, has a short half-life, is able to inactivate clot-bound thrombin, and can be monitored using the ubiquitous aPTT assay or the less readily available ecarin clotting time.⁴²¹

TABLE 55.8 LOW-MOLECULAR-WEIGHT HEPARIN AND POLYSACCHARIDE PRODUCTS AVAILABLE IN THE UNITED STATES

Low-Molecular-Weight Heparin

Low-Molecular-Weight Heparin	Approved Indications	FDA-Approved Dosage Regimen
Dalteparin (Fragmin®)	DVT/PE prophylaxis for abdominal surgery	2,500 U SC daily, starting 1-2 h before surgery and continued 5-10 d postoperatively.
		High-risk patients (e.g., malignancy): 5,000 U SC daily, starting the evening before surgery and continued for 5-10 d postoperatively. Or, give 2,500 U SC 1-2 h before surgery, then give 2,500 U SC 12 h later, and 5,000 U SC daily for 5-10 d postoperatively.
	DVT/PE prophylaxis for hip replacement surgery	<p>Preoperative start, evening before surgery: 5,000 U SC daily, starting 10-14 h before surgery. The usual duration is 5-10 d postoperatively, although 14 d has been studied. Allow 24 h between doses.</p> <p>Preoperative start, day of surgery: 2,500 U SC within 2 h before surgery, then 2,500 U SC 4-8 h after surgery, then 5,000 U SC daily postoperatively. The usual duration is 5-10 d postoperatively, although 14 d has been studied. Allow at least 6 h between the first postoperative dose and the next postoperative dose.</p> <p>Postoperative start: 2,500 U SC 4-8 h after surgery, then 5,000 U SC daily. The usual duration is 5-10 d postoperatively, although 14 d has been studied. Allow at</p>

		least 6 h between the first postoperative dose and the next postoperative dose.
	DVT/PE prophylaxis in medical patients with severely restricted mobility due to acute illness	5,000 U SC daily for 12-14 d.
	Prophylaxis of ischemic complications of non-Q-wave myocardial infarction in patients on concurrent aspirin therapy	120 U/kg SC every 12 h for 5-8 d, given concurrently with aspirin 75-165 mg/d PO. Do not exceed 10,000 U/dose. Continue until patient is clinically stabilized.
	Prophylaxis of ischemic complications of unstable angina in patients on concurrent aspirin therapy	120 U/kg SC every 12 h for 5-8 d, given concurrently with aspirin 75-165 mg/d PO. Do not exceed 10,000 U/dose. Continue until patient is clinically stabilized.
	Extended treatment of DVT/PE in cancer patients	200 U/kg SC daily (max. 18,000 U) for 1 mo, then 150 U/kg SC daily (max. 18,000 U) for 5 mo
Enoxaparin (Lovenox [®])	DVT/PE prophylaxis for abdominal surgery	40 mg SC daily, starting 2 h before surgery. The usual duration is 7-10 d postoperatively, although 12 d has been studied.
	DVT/PE prophylaxis for hip replacement surgery	30 mg SC every 12 h, starting 12-24 h after surgery. The usual duration is 7-10 d postoperatively, although 14 d has been studied. An alternative regimen is 40 mg SC daily, starting 9-15 h before surgery and continued for 3 wk.
	DVT/PE prophylaxis for knee replacement surgery	30 mg SC every 12 h, starting 12-24 h after surgery. The usual duration is 7-10 d postoperatively, although 14 d has been studied.
	DVT/PE prophylaxis in medical patients with severely restricted mobility due to acute illness	40 mg SC daily. The usual duration is 6-11 d, although 14 d has been studied.
	Treatment of DVT with or without PE (inpatient therapy) in patients starting on warfarin sodium	1 mg/kg SC every 12 h, or 1.5 mg/kg SC daily (at the same time each day). Start warfarin when appropriate (usually within 72 h of starting enoxaparin). Continue enoxaparin for at least 5 d, until INR is therapeutic; usually an additional 7 d is needed, although up to 17 d may be required.
	Treatment of DVT without PE (outpatient therapy) in patients starting on warfarin sodium	1 mg/kg SC every 12 h. Start warfarin when appropriate (usually within 72 hr of starting enoxaparin). Continue enoxaparin for at least 5 d, until INR is therapeutic; usually an additional 7 d is needed, although up to 17 d may be required.
	Prophylaxis of ischemic	1 mg/kg SC every 12 h given concurrently with aspirin

	complications of non-Q-wave myocardial infarction in patients on concurrent aspirin therapy	100-325 mg/d PO. The usual duration is 2-8 d, although up to 12.5 d has been studied.
	Prophylaxis of ischemic complications of unstable angina in patients on concurrent aspirin therapy	1 mg/kg SC every 12 h given concurrently with aspirin 100-325 mg/d PO. The usual duration is 2-8 d, although up to 12.5 d has been studied.
Fondaparinux (Arixtra®)	DVT/PE prophylaxis following abdominal surgery	2.5 mg SC daily, starting 6-8 h after surgery. The usual duration is 5-9 d, although up to 10 d has been studied.
	DVT/PE prophylaxis following hip replacement surgery	2.5 mg SC daily, starting 6-8 h after surgery. The usual duration is 5-9 d, although up to 11 d has been studied.
	DVT/PE prophylaxis following hip fracture surgery	2.5 mg SC daily, starting 6-8 h after surgery. The usual duration is 5-9 d, although up to 11 d has been studied.
	DVT/PE prophylaxis following knee replacement surgery	2.5 mg SC daily, starting 6-8 h after surgery. The usual duration is 5-9 d, although up to 11 d has been studied.
	Treatment of DVT and PE in patients starting on warfarin sodium	5 mg SC daily for patients <50 kg, 7.5 mg SC daily for patients 50-100 kg, or 10 mg SC daily for patients >100 kg. Start warfarin when appropriate (usually within 72 h of starting fondaparinux). Continue fondaparinux for at least 5 d, until INR is therapeutic; The usual duration is 5-9 d, although up to 26 d has been studied.

DVT, deep vein thrombosis; INR, international normalized ratio; IV, intravenous; PE, pulmonary embolism; PO, orally; SC, subcutaneously.

TABLE 55.9 COMPARISON OF DIRECT THROMBIN INHIBITORS

Drug Profile	Lepirudin (Refludan)*	Argatroban (Argatroban)	Bivalirudin (Angiomax)
Derivative	Recombinant hirudin	L-Arginine derivative	Synthetic hirudin-based peptide
Action	Direct thrombin inhibitor	Direct thrombin inhibitor	Direct thrombin inhibitor
Clearance	Renal	Hepatic	Renal
Administration	IV (or SC)	IV	IV or SC
Half-life	1.5 hr	40 min	25 min
Monitoring	aPTT	aPTT	aPTT or ACT

Heparin cross-reactivity	None	None	None
Effect on international normalized ratio	Yes	Yes	Yes
Approved for heparin-induced thrombocytopenia	Yes	Yes	Yes
Immunogenic	Yes	No	Unknown

ACT, activated clotting time; aPTT, activated partial thromboplastin time; IV, intravenous; SC, subcutaneous.

* No longer available in the U.S.

In composite, when compared to historical controls in patients with HIT with associated thrombosis, lepirudin (n = 389 patients, 3 cohorts) demonstrates a relative risk of 0.70 (95% confidence intervals [CIs], 0.27 to 1.8), 0.28 (0.15 to 0.52), and 2.31 (0.94 to 5.71) for limb amputation, new thrombosis, and major bleeding, respectively.⁴²²

Current lepirudin dosing recommendations are an infusion of 0.15 mg/kg/hour (up to 110 kg) with or without an initial bolus of 0.4mg/kg.³⁹⁷ The target aPTT is 1.5 to 2.5 times the median value for the normal range. Monitoring during bypass requires performance of the less readily available ecarin clotting time with a target plasma lepirudin concentration of 2.0 µg/ml.⁴²³ The activated clotting time (ACT) and point-of-care aPTT assays do not appear to be suitable for lepirudin therapeutic monitoring.⁴²⁴ Outpatient subcutaneous lepirudin has been used to treat patients with HIT and thrombosis and patients who are refractory to other anticoagulant therapy.⁴²⁵

The major challenges of lepirudin treatment are the lack of an antidote, the extreme care needed when treating patients with even mild renal insufficiency, and immunogenicity. In the event of lepirudin overdose or lepirudin-induced bleeding, infusions of prothrombin complex concentrates or recombinant factor VIIa may help promote hemostasis.⁴¹⁹ High-flux capillary hemodialysis membranes may facilitate the hemofiltration of lepirudin in some cases.⁴²⁶ Partial-exchange transfusions, plasmapheresis, and immobilized thrombin affinity columns have also been tried to neutralize the effects of lepirudin.⁴¹⁹ Marked bolus and infusion rate reductions are necessary in patients with a creatinine clearance of <60 ml/minute (serum creatinine >1.6 mg/dl). Lepirudin is to be avoided completely or administered with extreme care in the settings of hemodialysis and acute renal failure and in patients undergoing continuous venovenous hemodialysis, even in the setting of a normal serum creatinine. Careful monitoring of both the aPTT and serum creatinine is indicated during lepirudin therapy. Approximately 40% of HIT patients treated with lepirudin develop antihirudin antibodies of the IgG class.⁴²⁷ The antibodies seem to be capable of decreasing renal elimination of the drug rather than exerting any in vivo neutralizing effect. This paradoxical enhancement of the anticoagulant effect of lepirudin often warrants a significant reduction of infusion rate. Lepirudin is no longer available in the United States.

Desirudin is another recombinant form of hirudin that is approved in the United States for VTE prevention after elective hip replacement surgery. When used for thromboprophylaxis, desirudin is given subcutaneously at a dose of 15 mg twice daily.³⁹⁷ More recently, a small open-label study comparing desirudin, dosed at 30 mg twice daily, to argatroban in patients with HIT has been reported.⁴²⁸

Argatroban

Argatroban is a synthetic, small-molecule, L-arginine derivative that received FDA approval in June 2000 for prophylaxis and treatment of thrombosis in patients with HIT. Argatroban is a rapid and reversible DTI, in contrast to lepirudin, which is an irreversible thrombin inhibitor. Argatroban is capable of inhibiting both free and fibrin-associated thrombin. Argatroban exerts its antithrombotic effects by inhibiting thrombin-mediated reactions including fibrin formation; activation of coagulation factors V, VIII, and XIII; activation of the natural anticoagulant protein C; and platelet activation.⁴²⁹ Like lepirudin, argatroban does not cross-react with heparin. Argatroban is metabolized by the liver with biliary excretion and has a half-life of only 40 minutes. Renal excretion has also been documented; however, renal impairment has been shown to have little adverse effect on drug clearance and half-life. Unlike lepirudin, argatroban does not require dose adjustment in the setting of renal insufficiency. Dose reduction is required in patients with significant hepatic disease.⁴²⁹

In two cohorts (n = 419) of patients with HIT treated with argatroban and compared to historical controls who were followed for 37 days, the relative risk for death due to thrombosis, limb amputation, new thrombosis, and major bleeding

was 0.12 (95% CI, 0.05 to 0.34), 1.26 (95% [CI]; 0.53 to 2.99), 0.45 (95% [CI]; 0.28 to 0.71), and 3.70 (95% [CI]; 0.52 to 26.5), respectively.⁴²²

Argatroban is dosed based on patient weight. The recommended starting intravenous infusion rate is 2 µg/kg/minute with a target aPTT of 1.5 to 3.0 times the baseline value. Therapy may also be monitored by whole-blood ACT and the ecarin clotting time. Like lepirudin, argatroban prolongs the PT as well as the aPTT. This PT prolongation makes determination of an accurate INR during conversion to oral warfarin therapy a challenge. Holding the infusion of either DTI for several hours before INR determination is prudent. Argatroban has been shown to provide adequate anticoagulation with minimal bleeding risk while enabling procedural success in HIT patients undergoing PCI.⁴³⁰ Patients were given a 350-µg/kg bolus of argatroban followed by 25 µg/kg/minute infusion titrated to achieve an ACT of 300 to 450 seconds. This dosing regimen may provide satisfactory anticoagulation during cardiopulmonary bypass and allow intraoperative dose adjustments based on the readily available ACT.

Bivalirudin

Bivalirudin is a semisynthetic, bivalent DTI consisting of a dodecapeptide analog of the carboxy-terminus of hirudin.⁴³¹ Bivalirudin has four glycine residues that connect the thrombin exosite 1 and thrombin active-site moieties. After binding to bivalirudin, thrombin cleaves a Pro-Arg bond at the amino-terminus of the molecule, making it a reversible thrombin inhibitor. The short half-life of bivalirudin (~25 minutes) may enhance its safety profile. Bivalirudin is used primarily during PCIs, in which it has been

P.1241

shown to be at least as effective as heparin with gpIIb/IIIa inhibition, but with an improved safety profile.^{432, 433} Bivalirudin has also been evaluated in patients presenting with acute coronary syndromes as an alternate to heparin.⁴³⁴ In patients with moderate- or high-risk acute coronary syndromes who were undergoing invasive treatment including gpIIb/IIIa inhibition, bivalirudin was associated with rates of ischemia and bleeding similar to those in heparin-treated subjects. However, bivalirudin alone was associated with similar rates of ischemia and significantly lower rates of bleeding compared to heparin plus gpIIb/IIIa blockade.⁴³⁴ Bivalirudin has also been evaluated for the management of patients with HIT, especially those requiring cardiac surgery. The currently recommended dose of bivalirudin is a bolus of 0.75 mg/kg followed by an infusion of 1.75 mg/kg/h for the duration of the procedure.³⁹⁷ Bivalirudin is also recommended for anticoagulation in managing hemodialysis patients with HIT.⁴²²

Warfarin

In the 1920s, cattle developed a bleeding disorder when they were fed spoiled sweet clover. Campbell and Link later identified the active agent as bishydroxycoumarin (dicoumarol).⁴³⁵ Drugs that inhibit the biosynthesis of the vitamin-K-dependent coagulation proteins are derived either from 4-hydroxycoumarin or 1,3-indanedione. Although the indanediones are used in Europe, a coumarin derivative, warfarin, is the major formulation used in the United States. Warfarin inhibits γ-carboxylation of select glutamic acid residues in the N-terminus of prothrombin and factors VII, IX, and X, as well as the vitamin-K-dependent natural anticoagulants, protein C and protein S.⁴³⁶ Warfarin inhibits the two enzymes critical for the generation of reduced vitamin K, namely, vitamin K epoxide reductase and vitamin K reductase.^{437, 438} Reduced vitamin K is necessary for catalyzing γ-carboxylation of glutamic acid residues. Inhibition of γ-carboxylation by warfarin leads to synthesis of incomplete, hypofunctional coagulation proteins that are unable to bind to cellular surfaces to mediate coagulation reactions. The effect of warfarin on vitamin-K-dependent procoagulant protein production is depicted in Figure 55.6. Details of vitamin K metabolism are presented in Chapter 18.

Commercially available warfarin is a racemic mixture of levorotatory and dextrorotatory forms of the drug. The half-life of warfarin in blood is ~36 hours.⁴³⁹ Laboratory monitoring of warfarin therapy is best done using functional coagulation tests, such as the PT. Plasma warfarin levels are most useful in evaluating the unusual patient who does not respond to standard warfarin dosages or in whom malabsorption, noncompliance, or inherited drug resistance is an issue.^{438, 440}

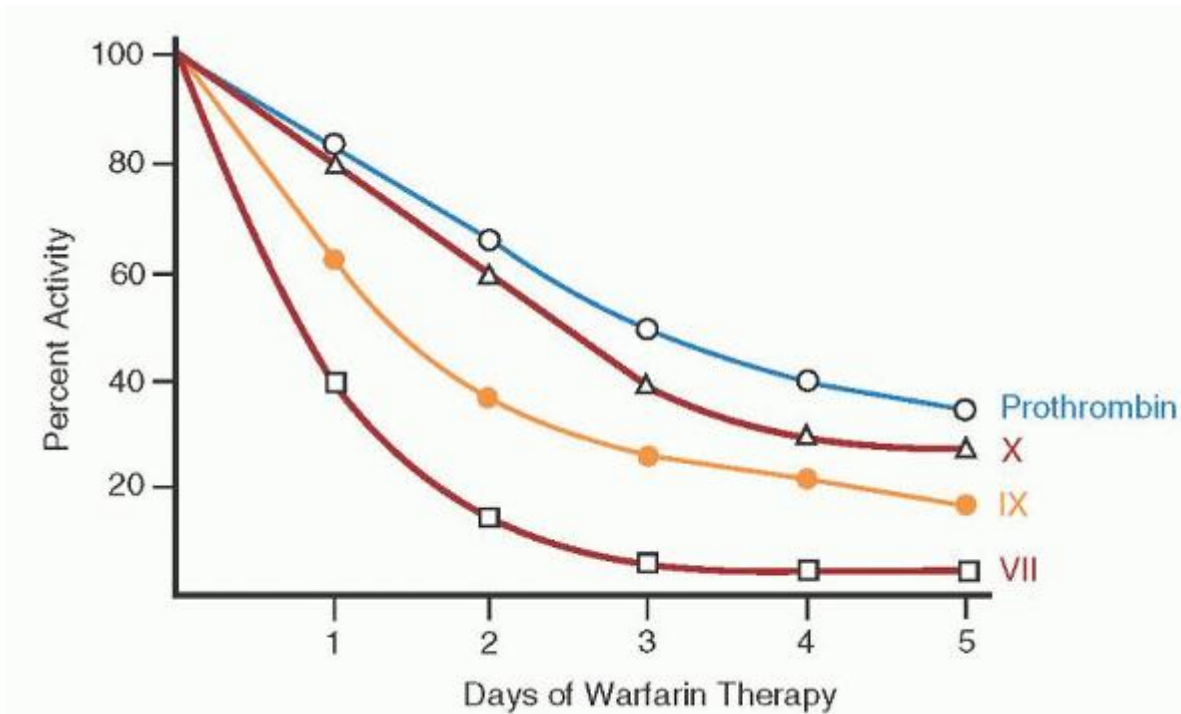

FIGURE 55.6. Effects of standard warfarin therapy on the plasma vitamin-K-dependent procoagulant coagulation proteins. Administration of 5 to 10 mg daily of warfarin results in inhibition of synthesis of functional vitamin-K-dependent proteins. The coagulant activity of these proteins in plasma declines as a function of their half-life. Half-lives of factors VII, IX, and X and prothrombin are 6, 24, and 40 and 60 hours, respectively. Although 1 to 2 days of warfarin prolongs the PT assay (because of the rapid decrease in factor VII concentration), therapeutic anticoagulation requires at least 4 to 5 days. Data from O'Reilly RA. The pharmacodynamics of the oral anticoagulant drugs. *Prog Hemost Thromb* 1974;2:175-213; reproduced from Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. *Clinical pharmacology: basic principles in therapeutics*, 3rd ed. McGraw-Hill, 1992:524-599, with permission.

Because factor X and prothrombin have half-lives >2 days, reduction of all vitamin-K-dependent coagulation proteins into the therapeutic range (~20% of normal) requires 4 to 5 days of therapy.⁴⁴¹ This is the basis for the “parenteral anticoagulant overlap” period of 4 to 5 days during which patients receive therapeutic parenteral anticoagulant while waiting to achieve the therapeutic effects of warfarin.⁴⁴² An animal study indicated that depression of both factor X and prothrombin levels by warfarin was important in the prevention of hypercoagulability.⁴⁴¹

Warfarin dosage is influenced by numerous variables, including the patient's age, body mass, dietary stores of vitamin K, liver function, co-existing medical disorders, concurrent medications,⁴⁴³ and presence or absence of cytochrome P-450 complex (CYP2C9) and vitamin K epoxide reductase complex subunit 1 (VKORC1) single-nucleotide polymorphisms that affect coumarin metabolism or sensitivity.^{444, 445, 446} Patients with liver disease, malnutrition, or other factors associated with sensitivity to warfarin should receive lower warfarin dosages. The most common adverse interaction of warfarin use occurs in a patient with marginal dietary vitamin K intake (postoperative state) who is given a broad-spectrum antibiotic, reducing enteric bacterial synthesis of vitamin K, resulting in increased sensitivity to warfarin.⁴³⁸ Starting warfarin therapy early after heparin therapy (day 1 or 2) has many advantages, including earlier hospital discharge on adequate oral anticoagulation and potential reduction in the incidence of HIT.⁴⁴⁷ The metabolism of warfarin may be affected by other drugs metabolized by the cytochrome P-450 enzyme complex, drugs that displace albumin-bound warfarin into the circulation, drugs that impair gastrointestinal absorption, and many antibiotics that alter the natural flora of the colon (an endogenous source of vitamin K)^{438, 443} (Table 55.10).

Certain genotypes for CYP2C9 and VKORC1 have a significant effect on the pharmacokinetic and pharmacodynamic response to warfarin dosing, respectively. Although there is a clear gene-dose relationship, it is uncertain if the routine use of genotype-guided warfarin dosing improves clinical outcomes.⁴⁴⁶ Yet, as clinical dosing algorithms are increasingly refined, the prospects for warfarin pharmacogenetics increase.⁴⁴⁸ Clinical outcome trials are underway to determine definitively the role of genetic testing in routine warfarin therapy.

Certain patients may require very large doses of warfarin (>50 mg/day) to achieve therapeutic anticoagulation; the term warfarin resistance has been applied.⁴⁴⁰ Patients who are difficult to anticoagulate with warfarin, either because they exhibit warfarin resistance or because they are very sensitive to the drug and cannot be safely regulated, may be candidates for long-term parenteral anticoagulants, or a novel oral anticoagulant.

Laboratory Monitoring of Warfarin Therapy

The PT assay is useful to monitor warfarin therapy, because this assay measures three vitamin-K-dependent coagulation proteins: Factors VII, X, and prothrombin. The PT is particularly sensitive to factor VII deficiency; with a half-life of 4 to 6 hours, the factor VII level may drop rapidly after only 1 day of warfarin therapy and prolong the PT value. However, because the other vitamin-K-dependent proteins have longer half-lives, therapeutic anticoagulation takes 4 to 5 days. There is no advantage to giving larger loading doses of warfarin (e.g., >10 mg); this regimen only results in a more rapid drop in factor VII levels, delay in attainment of a stable PT, a precipitous fall in protein C levels, and predisposition to warfarin-induced skin necrosis.^{439, 449, 450}

To understand current recommendations for monitoring warfarin therapy, it is important to appreciate the concept of the INR,

P.1242

a method that standardizes PT assays.^{438, 451} An international reference thromboplastin preparation has been adopted by the World Health Organization (WHO). Each new commercial thromboplastin is calibrated against the primary WHO reference preparation. These results are used to calculate the relative sensitivity of the unknown preparation compared with the WHO standard (international sensitivity index [ISI]). The method to determine the ISI for a particular thromboplastin is depicted in Figure 55.7. By adjusting for the ISI of a particular thromboplastin, an INR, defined as the PT ratio that would have been obtained if the WHO standard thromboplastin had been used, can be determined. The INR is calculated using the following formula: $INR = (PT\ ratio)^{ISI}$ (Fig. 55.8).

TABLE 55.10 DRUGS AND MEDICAL CONDITIONS AFFECTING WARFARIN POTENCY

Potentiators	Antagonists
Drugs	Drugs
Acetaminophen	Adrenal corticosteroids
Anabolic steroids	Barbiturates
Broad-spectrum antibiotics	Carbamazepine
Chloral hydrate	Chlordiazepoxide
Cimetidine	Cholestyramine
Clofibrate	Efavirenz
Disulfiram	Griseofulvin
Fluconazole	Nafcillin
Indomethacin	Rifampin
Influenza vaccine	Sucralfate
Lovastatin	Trazodone
Metronidazole	Medical Conditions
Omeprazole	Excess dietary vitamin K
Phenylbutazone	Inherited resistance to warfarin
Phenytoin	Hypothyroidism
Propranolol	Nephrotic syndrome

Protease inhibitors (except ritonavir)

Quinine/quinidine

Salicylates

Tamoxifen

Thyroid drugs

Trimethoprim/sulfamethoxazole

Medical Conditions

Older age

Liver disease

Biliary disease

Malabsorption

Congestive heart failure

Fever

Hyperthyroidism

Malnutrition

Vitamin K deficiency

Cancer

Data from the 2003 Physicians' Desk Reference. Montvale, NJ: Thomson Healthcare; Hirsh J, Dalen JE, Anderson DR, et al. Oral anticoagulants: mechanism of action, clinical effectiveness, and optimal therapeutic range. *Chest* 2001;119(Suppl):108S-121S.

The American College of Chest Physicians' consensus panel recommends low-intensity warfarin therapy (INR, 2.0 to 3.0) for all indications except prosthetic mechanical heart valves and prophylaxis of recurrent MI, for which higher-intensity warfarin therapy (INR, 2.5 to 3.5) is suggested.⁴³⁸

FIGURE 55.7. Method for determination of an international sensitivity index (ISI) value for a laboratory's thromboplastin preparation. Log prothrombin time (PT) values are determined using a reference thromboplastin reagent and the commercial laboratory thromboplastin reagent on patients receiving stable (2 weeks) oral anticoagulant therapy and a group of normal, untreated volunteers. The best-fit line is determined, and the slope of this line multiplied by the ISI of the reference thromboplastin reagent is the ISI value for the commercial thromboplastin reagent. From Rodgers GM. Laboratory monitoring of anticoagulant and fibrinolytic therapy. In: Kjeldsberg C, McKenna R, Perkins S, et al., eds. Practical diagnosis of hematologic disorders, 2nd ed. Chicago, IL: ASCP Press, 1995:745-755, with permission.

Adverse Effects of Warfarin Therapy

Bleeding. A direct relationship exists between the risk of bleeding and the intensity of anticoagulation, with patients receiving higher-intensity (INR > 3.0) therapy having a fivefold greater risk of bleeding.⁴⁵² Other major factors contributing to bleeding include co-existing conditions such as structural gastrointestinal lesions, hypertension, renal disease, and cerebrovascular disease.^{453, 454} Investigation of patients who experience visceral bleeding while on warfarin therapy often results in identification of structural disease.⁴⁵⁵ Highest bleeding rates occur early in the course of warfarin therapy and in patients with cerebrovascular disease.^{456, 453} For patients given low-intensity warfarin therapy for prophylaxis of VTE, the risk of major bleeding is <1%. Antiplatelet medications or other drugs

P.1243

that potentiate warfarin activity are important contributors to bleeding (Table 55.10).

FIGURE 55.8. Relationship between a patient's prothrombin time (PT) ratio on warfarin therapy and the corresponding international normalized ratio (INR) value. The slope of the line represents the international sensitivity index (ISI) value of the particular thromboplastin preparation used in the laboratory's PT assay. In this example, for low-intensity warfarin therapy (INR 2.0 to 3.0), a PT ratio between 1.50 and 1.75 would be required. Thromboplastins with higher ISI values would have slopes greater than that shown and would be less sensitive reagents for the PT assay, whereas thromboplastins with lower ISI values would have slopes less than that shown (more sensitive reagents). From Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524-599, with permission.

Treatment strategy of bleeding in patients receiving warfarin depends on several factors: The duration of expected warfarin therapy, the severity of bleeding, and the extent of INR elevation. Patients with minor bleeding (bruising, microscopic hematuria) and an INR of <6.0 can have warfarin withheld until the INR approaches the desired INR target. Warfarin can then be resumed at a lower maintenance dosage. If patients have visceral bleeding that is not immediately life threatening, their coagulopathy can be reversed with vitamin K, 2.5 to 10 mg, IV or PO. Patients with significant emergent bleeding should be reversed with freshfrozen plasma (4 to 5 U) or prothrombin complex concentrates in addition to parenterally administered vitamin K. If the INR <10 and no clinical bleeding exists, several warfarin doses should be held and the INR reassessed; the routine administration of vitamin K in these patients does not lead to improved outcomes and is not recommended.^{438, 457} For an INR >10 in patients without bleeding, oral vitamin K can be given (2 to 10 mg) and repeated at 12- to 24-hour intervals, depending on posttreatment INR values and the patient's clinical condition. Failure of vitamin K to correct the coagulopathy suggests that another process is present, such as liver disease or DIC. The management of warfarin overdosage and reversal has been reviewed.⁴³⁸

Patients who ingest rodenticides that contain long-acting vitamin K antagonists ("superwarfarins") may require massive daily doses (≥ 100 mg) of vitamin K to correct the coagulopathy, for periods of weeks to months (see Chapter 54).

For patients on long-term warfarin therapy who require temporary interruption for procedures or elective surgery, an individualized risk-benefit assessment should be performed to determine the need for bridging therapy with a parenteral anticoagulant during the period of interruption (i.e., when warfarin is discontinued 4 to 5 days before surgery; Table 55.11). Postoperatively, heparin or LMWH can be used to achieve anticoagulation overlap until re-initiation of therapeutic warfarin has been achieved; however, in most cases after a major surgical procedure, the use of therapeutic-dosed

parenteral anticoagulants should be avoided in the first 48 to 72 hours postoperatively due to a high risk of bleeding.^{458, 459, 460, 461}

Nonhemorrhagic adverse effects of warfarin therapy include alopecia, gastrointestinal discomfort, rash, and liver dysfunction.⁴⁵³ A warfarin embryopathy can occur when pregnant mothers receive warfarin during the first trimester. A bone matrix protein, osteocalcin, is vitamin-K-dependent, and in the presence of vitamin K deficiency induced by warfarin, osteocalcin is synthesized in a nonfunctional manner, resulting in fetal bone malformations.⁴⁶² Additional fetal abnormalities have been noted when warfarin is used during pregnancy. Because of these fetal risks, most practitioners avoid warfarin during pregnancy.⁴⁶³

TABLE 55.11 GENERAL APPROACH TO PERI-PROCEDURAL ANTICOAGULATION FOR PATIENTS ON LONG-TERM WARFARIN THERAPY

Thromboembolic Risk Group	Indication for Warfarin		
	Mechanical Valve	Atrial Fibrillation	Venous Thromboembolism (VTE)
High	Mitral	CHADS ₂ ^a Score = 5-6	VTE past 3 mo
Management strategy:	Older generation	Stroke past 3 mo	Severe thrombophilia
Bridge(caution in postoperative dosing)	Recent stroke	Rheumatic valve disease	
Intermediate	Bileaflet aortic valve + stroke risk factors	CHADS ₂ Score = 3-4	VTE past 3-12 mo
Management strategy:			Thrombophilia
Bridge (caution in postoperative dosing)			Recurrent VTE
			Active cancer
Low	Bileaflet Aortic valve	CHADS ₂ Score = 0-2	VTE past > 12 mo and no
Management strategy:	No stroke risk factors	(and no prior stroke)	other risk factors
No Bridge			

^aCHADS₂ stroke score is calculated by adding one point for each of: congestive heart failure, hypertension, Age > 75 years old, diabetes and 2 points for prior stroke. Adapted from Douketis JD, Spyropoulos AC, Spencer FA, et al. Perioperative management of antithrombotic therapy: antithrombotic therapy and prevention of thrombosis, 9th ed: American college of chest physicians evidence-based clinical practice guidelines. Chest 2012;141(2):e326S-e350S.

Warfarin-induced Skin Necrosis. Skin necrosis is an unusual but devastating complication of warfarin therapy, occurring within the first week of initiating therapy. Affected patients have usually received large loading doses of warfarin, perhaps in the absence of therapeutic heparin anticoagulation. The basis for this complication is thought to be a warfarin-induced rapid reduction in protein C levels in patients with a pre-existing inherited protein C deficiency that results in a hypercoagulable state and thrombosis. Not all heterozygous protein-C-deficient patients receiving warfarin experience this complication, and not all patients with this complication have protein C deficiency.

Clinically, the skin lesions begin on certain subcutaneous areas of the body (breasts, abdomen, thighs) as erythematous patches.⁴⁶⁴ Lesions progress to blebs followed by demarcated skin necrosis. Skin biopsy reveals generalized thrombosis of skin vessels. This complication may require amputation, plastic reconstructive surgery, or both. The use of standard maintenance doses of warfarin (5 to 10 mg/day) beginning after patients are therapeutically anticoagulated with heparin may avoid this complication. Patients who experience warfarin-induced skin necrosis should be heparinized, warfarin should be discontinued, and vitamin K should be administered promptly. Patients experiencing this complication should be screened for protein C deficiency. A few cases of warfarin-induced skin necrosis have been reported in protein-S-deficient patients.⁴⁶⁵ A literature review of warfarin-induced skin necrosis found that warfarin therapy could be reinstated in affected patients; smaller initial doses of warfarin were recommended.⁴⁶⁶

The “purple toe syndrome” is an uncommon disorder that has been described in patients with underlying atherosclerotic vascular disease who are receiving anticoagulants including warfarin therapy.^{467, 468, 469} These patients present with atheroembolic symptoms including ischemic toes (purple toes), livedo reticularis, gangrene, abdominal pain, or symptoms of renal infarction. Involved visceral organs include the kidneys, pancreas, spleen,

P.1244

and liver. This complication may be difficult to distinguish from warfarin-induced skin necrosis, except that on biopsy, cholesterol emboli are present in the purple toe syndrome, and widespread vascular thromboses are seen in skin necrosis. Treatment involves prompt recognition of the syndrome and discontinuation of warfarin therapy.⁴⁷⁰

Novel Oral Anticoagulants. Warfarin has substantial limitations including inter- and inpatient dosing variability, drug-drug and drug-diet interactions, and a narrow therapeutic index. These limitations necessitate routine laboratory monitoring and dose adjustment that can be cumbersome for some patients. An oral anticoagulant that is safe and effective, has predictable pharmacology, has few drug-drug and drug-dietary interactions, and does not require laboratory monitoring has the potential to revolutionize the chronic management of patients with atrial fibrillation, prosthetic heart valves, and recurrent venous thrombosis as well as facilitate better compliance with out-of-hospital thromboprophylaxis regimens. Over the past 5 years, there has been a rapid emergence of such novel oral anticoagulants (NOACs) into the clinical landscape. At the forefront are the oral DTI dabigatran etexilate and the oral factor Xa inhibitors (e.g., rivaroxaban, apixaban, and edoxaban). Tables 55.12 and 55.13 summarize the properties of the NOACs that are currently available for clinical use and the comparative results of large-scale studies in patients with atrial fibrillation, respectively.⁴⁷¹ It is important to note that numerous additional agents are also currently under investigation.⁴⁷¹

Dabigatran Etexilate

Dabigatran etexilate is an oral prodrug that is rapidly converted by serum esterases to dabigatran, a potent univalent DTI. Oral bioavailability is ~6% to 7%, and uptake is reduced by proton pump inhibitors and delayed with food; however, these kinetic alterations are not thought to be clinically significant and do not require dose adjustments. Peak dabigatran serum levels occur ~2 hours after an oral dose; dabigatran is primarily eliminated by renal clearance, and has a half-life of ~14 to 17 hours.⁴⁷¹ Although a reduced dose has been approved for use in the United States by the FDA for patients with a creatinine clearance of less than 30 ml/minute, this recommendation is solely based upon drug kinetic modeling, and the drug is contraindicated in patients with a clearance <15 ml/minute.⁴⁷² A reduced dose should also be considered for frail elderly patients with a reduced creatinine clearance; however, no dose reduction is needed at any age for patients with normal renal function. Strong p-glycoprotein inhibitors (e.g., quinidine, ketoconazole) and inducers (e.g., rifampin, St John's Wort) affect serum levels. Because of the predictability in dose-response, laboratory monitoring is unnecessary. If, however, laboratory assessment is required (e.g., need for urgent surgery or management of bleeding) a normal aPTT, thrombin time, or ecarin clotting time suggest little drug activity is present. Conversely, the INR is insensitive to the presence of dabigatran and is not a useful test for drug presence.⁴⁷³ Table 55.14 suggests a management approach to patients requiring temporary interruption of anticoagulation for an invasive procedure. As with all anticoagulants, the primary adverse effect of dabigatran is an increase in bleeding risk. In addition, dabigatran is associated with an increased risk of dyspepsia, and in some clinical trials has been associated with higher gastrointestinal bleeding rates and myocardial ischemia events as compared to warfarin.⁴⁷³ In cases of overdose, the rapid administration of charcoal may decrease absorption, and hemodialysis can remove 60% of plasma drug levels.⁴⁷⁴ Management of bleeding is problematic as there is no known reversal agent. Patients who have bleeding on dabigatran should be managed with aggressive conservative measures including active control of bleeding site. In cases of life-threatening bleeding, the administration of recombinant factor VIIa or activated prothrombin complex concentrates can be tried, although their utility is unproven.⁴⁷³

TABLE 55.12 PHARMACOLOGY OF NOVEL ORAL ANTICOAGULANTS

	Dabigatran (Pradaxa®)	Rivaroxaban (Xarelto®)	Apixaban (Eliquis®)
Target	Thrombin (Binds Reversibly)	Factor Xa (Binds Reversibly)	Factor Xa (Binds Reversibly)
Dosage Form	Capsule	Tablet	Tablet
Bioavailability	6%	60-80%	50-85%

Time to Peak	1-2 h	2-4 h	1-3 h
Metabolism	Conjugation; No CYP involvement	Oxidation (via CYP3A4 + CYP2J2) + hydrolysis	Oxidation (via CYP3A4) + conjugation
Drug-Interactions	Strong p-gp inducers and inhibitors	Strong p-gp and CYP3A4 inducers and inhibitors	Strong p-gp and CYP3A4 inducers and inhibitors
Renal Excretion	80%	66%	25%
Half-life	14-17 h	9-13 h	9-14 h
Dosing Frequency, Major Trials	BID	QD	BID

BID, twice daily; CYP, cytochrome p 450; p-gp, p-glycoprotein; QD, daily.

To date, dabigatran etexilate has undergone extensive clinical investigation in the RE-VOLUTION program, a large clinical trials program assessing the efficacy and safety of dabigatran across a variety of indications. For a recent and thorough survey of clinical trial results, we refer the reader to a recent review.⁴⁷³ Based upon the results of the RE-LY trial, dabigatran etexilate is currently approved in the United States for the prevention of stroke and systemic embolism in patients with atrial fibrillation.⁴⁷⁵ In RE-LY, 18,113 patients with nonvalvular atrial fibrillation and at least one additional stroke risk factor were randomized to receive warfarin or dabigatran dosed either 110 mg or 150 mg twice daily. Dabigatran dosed at 110 mg twice daily was demonstrated to be noninferior to warfarin (RR, 0.91; 95% [CI], 0.74 to 1.11; $p < 0.001$), and dabigatran dosed at 150 mg twice daily was demonstrated to be superior to warfarin (RR, 0.66; 95% [CI], 0.53 to 0.82; $p < 0.001$) in preventing the primary outcome of stroke or systemic embolism. As compared to warfarin, major bleeding, the primary safety outcome, was less common in the 110-mg twice-daily dabigatran group (RR, 0.80; 95% [CI], 0.69 to 0.93; $p = 0.003$), but was similar when compared to the 150-mg twice-daily dose (RR, 0.93; 95% [CI], 0.81 to 1.07; $p = 0.31$), but hemorrhagic stroke was lower for both dabigatran doses.⁴⁷⁵ Using a composite of adverse clinical events (stroke, systemic embolism, MI, death, PE, and major bleeding), dabigatran was clearly superior for those patients on warfarin who have a time in TTR of less than 57.1% whereas benefit was less certain in those with a TTR of >72.6% with hazard ratios of 0.67 (95% CI, 0.56 to 0.80) and 1.11 (95% CI, 0.91 to 1.35), respectively.⁴⁷⁶

Oral Factor Xa Inhibitors

Because of the demonstrated efficacy and safety of factor Xa inhibition with fondaparinux, oral factor Xa inhibitors have entered the clinical landscape. Oral factor Xa inhibitors that are available for clinical use or are in development include rivaroxaban (Bayer Healthcare), apixaban (Bristol Myers Squibb/Pfizer),

P.1245

edoxaban (Daiichi), betrixaban (Portola), and TAK-442 (Takeda).⁴⁷¹ Currently, rivaroxaban and apixaban are the most advanced in their clinical trials programs and are approved for use in the European Union, Canada, or the United States.

TABLE 55.13 NOVEL ORAL ANTICOAGULANT ATRIAL FIBRILLATION CLINICAL TRIAL OVERVIEW

Trial	RE-LY	ROCKET-AF	ARISTOTLE	AVERROES
Drug and dose	Dabigatran etexilate 150 mg and 110 mg BID ^a	Rivaroxaban 20 mg QD ^a	Apixaban 5 mg BID ^a	Apixaban 5 mg BID ^a
Adjusted dose?	No	Yes: 15 mg QD if CrCl 30-49 ml	Yes: 2.5 mg BID if 2 of: age >80, weight <60 kg, Cr >1.5	Yes: 2.5 mg BID if 2 of: age >80, weight <60 kg, Cr >1.5
Design	Randomized open label ($n = 18,113$)	Randomized double blind ($n = 14,000$)	Randomized double blind ($n = 18,201$)	Randomized double blind ($n = 5,599$)
Mean age (y)	71.5	73	70	70

Prior stroke/TIA	20%	55%	19%	13.5%
Mean CHADS2	2.1	3.5	2.1	2.1
Warfarin naïve (%)	50.4	37.5	43	60.5
Comparator	Warfarin: INR 2-3 67% TTR	Warfarin: INR 2-3 57.8% TTR	Warfarin: INR 2-3 TTR	66% Aspirin 81-324 mg

^a BID, twice daily; Cr, creatinine; CrCl, creatinine clearance; INR, international normalized ratio; QD, daily; TIA, transient ischemic attack; TTR, time in therapeutic range; wt, weight.

Data from references 475, 479, 480, 481.

Rivaroxaban is a reversible small molecule direct factor Xa inhibitor that binds to and inactivates both fluid-phase factor Xa as well as factor Xa associated with the prothrombinase complex. Rivaroxaban has an oral bioavailability of ~60% to 80%, with peak levels achieved 2 to 3 hours after an oral dose. The drug is metabolized in part by both CYP3A4-dependent and CYP3A4-independent pathways, and has an elimination half-life of ~7 to 11 hours.⁴⁷¹ The kidneys eliminate approximately 35% of active drug as well as inactive metabolites. Potent combined P-gp and CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, lopinavir/ritonavir, ritonavir, indinavir/ritonavir, and conivaptan) and inducers (e.g., carbamazepine, phenytoin, rifampin, St John's Wort) should be avoided in patients on rivaroxaban because they can significantly increase or decrease plasma drug concentrations, respectively.⁴⁷⁷

Rivaroxaban is currently approved for the prevention of VTE in patients undergoing elective joint replacement surgery, the prevention of stroke and systemic embolism in patients with nonvalvular atrial fibrillation, and the treatment of VTE.⁴⁷⁷ In the RECORD trials, rivaroxaban (10 mg daily) was compared to enoxaparin for thromboprophylaxis in patients undergoing elective joint replacement surgery. In a pooled analysis, the combined endpoint of symptomatic VTE and mortality occurred less often in patients receiving rivaroxaban (1.3% vs. 0.6%, $p < 0.001$), whereas clinically relevant bleeding was more frequent (2.6% vs. 3.3%, $p = 0.026$).⁴⁷⁸ The ROCKET-AF trial was a large ($n = 14,000$) double-blind, noninferiority, randomized trial comparing rivaroxaban (20 mg daily in patients with normal renal function and 15 mg daily in patients with a creatinine clearance of 30 to 49 ml/min) to adjusted-dose warfarin (target INR 2 to 3) in patients with atrial fibrillation who were at an increased risk of stroke or systemic embolism.⁴⁷⁹ Rivaroxaban met the prespecified endpoint of stroke/systemic embolism occurrence with a HR of 0.88 (95% CI 0.74 to 1.03, $p < 0.001$ for noninferiority), had similar rates of major bleeding (HR 1.04, 95% CI 0.9 to 1.2, $p = 0.58$), and less intracranial hemorrhage (HR 0.67, 95% CI 0.47 to 0.93, $p = 0.02$).⁴⁷⁹

TABLE 55.14 NOVEL ANTICOAGULANT AGENTS: PERI-PROCEDURAL MANAGEMENT

Preprocedure	Half-life (Range) Hours	Low Bleeding Risk Procedures (Average of 2-3 Drug Half-lives Separate Last Dose and Surgery)	Moderate to High Bleeding Risk (Average of 5 Drug Half-lives Separate Last Dose and Surgery)
DABIGATRAN			
CrCl >50	14 (11-24)	Skip 2 doses (1 d)	Skip 4 doses (2 d)
CrCl 30-50	18 (13-23)	Skip 4 doses (2 d)	Skip 6-8 doses (3-4 d)
CrCl <30	27 (22-35)	Skip 4-10 doses (2-5 d)	Skip >10 doses (>5 d)
RIVAROXABAN			
CrCl >50	8 h	Skip 1 dose (1 d)	Skip 2 doses (2 d)
CrCl <50	9-10 h	Skip 2 doses (2 d)	Skip 3-4 doses (3-4 d)
APIXABAN			
	9 h	Skip 1 dose (1 d)	Skip 2 doses (2 d)

Postprocedure Delay re-initiation until hemostasis is certain (24-72 h) and no epidural catheter is present

CrCl, creatinine clearance (ml/min).

Apixaban is a reversible, small molecule, direct factor Xa inhibitor that, as does rivaroxaban, binds to and inactivates both fluid-phase as well as clot-bound factor Xa. Apixaban has an oral bioavailability of >45%, achieves peak levels ~3 hours after an oral dose, has an elimination half-life of ~8 to 14 hours, and

P.1246

is eliminated via multiple mechanisms. Similar to rivaroxaban, potent inhibitors of CYP3A4 (e.g., ketoconazole, itraconazole, lopinavir/ritonavir, ritonavir, indinavir/ritonavir, and conivaptan) and inducers (e.g., carbamazepine, phenytoin, rifampin, St John's Wort) should be avoided.⁴⁷¹

Apixaban has also been studied for thromboprophylaxis, stroke prevention in atrial fibrillation, and VTE treatment. Apixaban is currently approved for use in the European Union, Canada, and approved in the United States for the treatment of non-valvular atrial fibrillation. The AVERROES trial was a large (n = 5,599) double-blind, randomized trial comparing apixaban (5 mg twice daily) to aspirin (81 to 324 mg) in patients with atrial fibrillation who were unsuitable candidates for warfarin therapy. Compared to aspirin, apixaban was more effective and equally safe with a HR of 0.45 (95% CI 0.32 to 0.62, p < 0.001) for stroke/systemic embolism occurrence, HR 1.13 (95% CI 0.74 to 1.75, p = 0.57) for major bleeding, and a HR 0.85 (95% CI 0.38 to 1.9, p = 0.69) for intracranial bleeding.⁴⁸⁰ The ARISTOTLE trial was a large (n = 18,201) double-blind, double dummy, randomized trial comparing apixaban (5 mg twice daily) to adjusted dose warfarin (INR 2 to 3) in patients with atrial fibrillation. Compared to warfarin, apixaban was more effective and safer with a HR of 0.79 (95% CI 0.66 to 0.95, p = 0.01) for stroke/systemic embolism occurrence, HR 0.69 (95% CI 0.6 to 0.8, p < 0.001) for major bleeding, and a HR 0.42 (95% CI 0.3 to 0.58, p < 0.001) for intracranial bleeding.⁴⁸¹

Because of the predictability in dose-response, laboratory monitoring of the oral factor-Xa inhibitors is unnecessary. If, however, lab assessment is required (e.g., need for urgent surgery or management of bleeding), a normal aPTT and a normal INR suggest little anticoagulant presence, although clinical judgment is required.^{274a, 482} Table 55.14 suggests a management approach to patients requiring temporary interruption of anticoagulation for an invasive procedure. Like all anticoagulants, the primary adverse effect of the factor Xa inhibitors is an increase in bleeding risk. Both rivaroxaban and apixaban have significant protein binding and so are not anticipated to be dialyzable. Management of bleeding in patients on these agents is problematic as there is no known reversal agent. Patients who have bleeding on rivaroxaban or apixaban should be managed with aggressive conservative measures including active control of bleeding site.⁴⁷⁴ In cases of life-threatening bleeding, the administration of activated prothrombin complex concentrates may be effective in reversing the effect.⁴⁸³

Thrombolytic Drugs

The major reaction of the fibrinolytic (plasminogen) system involves the conversion by PAs of the inactive proenzyme, plasminogen, into the active enzyme, plasmin. Plasmin can degrade fibrinogen, fibrin monomers, and cross-linked fibrin (as found in thrombi) into FDPs. These plasmin-mediated reactions generate many species of FDPs including unique species of FDP such as fragment X from fibrinogenolysis and cross-linked FDPs such as (DD)E- and D-dimer from cross-linked fibrin.^{484, 485} Knowledge of these reactions is necessary to appreciate the mechanisms of action and limitations of commercial PAs.

A common feature of the management of all thromboembolic diseases is the desire to restore vascular patency in a timely fashion to prevent loss of tissue, organ, and limb function, as well as life. Acute arterial thrombosis warrants an attempt at immediate thrombolysis, whereas venous thrombosis only warrants such intervention in extreme cases. Recognition of the importance of the endogenous fibrinolytic system in limiting the size of hemostatic thrombi, clearing hemostatic thrombi after vascular repair, and preventing pathologic thrombosis has resulted in the development of pharmacologic fibrinolytic (thrombolytic) agents to facilitate rapid restoration of vascular patency. Most thrombolytic agents are recombinant forms of physiologic PAs. The commercially available PAs differ with regard to plasma half-life, fibrin selectivity, primary clinical usage, primary infusion strategy, and immunogenicity. Currently available and investigational PAs and their key characteristics are summarized in Table 55.15.

Most thrombolytic agents are fashioned after endogenous t-PA or urokinase. Traditional thrombolytic drugs include bacteriaderived streptokinase (SK), anisoylated plasminogen SK activator complex, urokinase (two-chain u-PA), and recombinant t-PA (rt-PA). Newer molecules have been and are being developed in an attempt to improve on the

traditional agents. Major goals of new thrombolytic agent development include increasing fibrin specificity, theoretically to reduce bleeding complications, prolonging initial plasma half-life to facilitate single- or double-bolus administration, reducing sensitivity to inactivation by PAI-1, and improving production efficiency. New thrombolytic agents include mutants of PAs, chimeric PAs, conjugates of PAs with monoclonal antibodies, and novel PAs from animal or bacterial origin. Non-PA thrombolytic agents that can degrade fibrin and/or fibrinogen directly (e.g., microplasmin, alfineprase, and ancred) are also under investigation.

TABLE 55.15 PROPERTIES OF CURRENTLY AVAILABLE AND INVESTIGATIONAL THROMBOLYTIC AGENTS

Thrombolytic Agent	Molecular Weight (Daltons)	Plasma Half-life (Minutes)	Key Properties
Streptokinase	47,000	20 (drug); 90 (lytic effect)	Complexes with plasminogen to achieve activity
Anisoylated plasminogen streptokinase activator complex	131,000	40-90	Streptokinase and plasminogen complex
Urokinase	34,000/54,000	15	Direct plasminogen activator derived from fetal kidney cells
Recombinant urokinase	54,000	7	Recombinant high-molecular-weight urokinase
Recombinant prourokinase	49,000	7	Active after conversion to urokinase
Alteplase	65,000	4-8	A recombinant t-PA
Reteplase (recombinant plasminogen activator)	39,000	15	Truncated t-PA with an extended half-life
Tenecteplase	65,000	20 (initial); 90-130 (terminal)	A modified t-PA with an extended half-life, enhanced plasminogen activator inhibitor-1 resistance, and greater fibrin specificity
Desmoteplase (rDSPA α 1)	52,000	2.8 h	Highly fibrin specific and lacking in neurotoxic effects of alteplase
Plasmin	85,000	—	Catheter-directed therapy

t-PA, tissue-type plasminogen activator.

P.1247

Streptokinase

SK is obtained from cultures of β -hemolytic streptococci. By itself, SK has no PA activity, but after combining with plasminogen, a complex is formed that is capable of activating other plasminogen molecules to plasmin.⁴⁸⁶ Purified SK has a molecular weight of 47,000 D. SK was the first clinically used thrombolytic agent. It is not fibrin-selective in that its therapeutic use results in systemic fibrin(ogen)olysis and what is termed the lytic state from proteolysis of fibrinogen, factors V and VIII, and other plasma proteins.⁴⁸⁶ Platelet function may also be perturbed, because plasmin can proteolyze key platelet membrane receptors.⁴⁸⁷ Generation of FDPs also contributes to the significant hemostatic defect of thrombolytic therapy. Although the lytic state predisposes patients to bleeding, the benefit of decreased blood viscosity that results from the lytic state may be clinically important. The half-life of SK is ~20 minutes. Because SK is a bacterial protein, it is antigenic, and allergic reactions occur in ~6% of patients. Anaphylaxis during SK use occurs in ~0.1% of patients.⁴⁸⁸ Patients previously exposed to SK or those with previous streptococcal infections may acquire

antistreptococcal antibody levels sufficient to neutralize the activity of SK. Therefore, all patients receiving SK should be monitored to ensure attainment of the lytic state. This can be done with the thrombin time assay. SK has been used primarily to treat VTE and MI, as well as to treat central venous access-device-associated thrombosis.

Urokinase-type Plasminogen Activator

In the past, u-PA was obtained from human fetal kidney cell cultures. It is currently produced using nonhuman mammalian tissue cultures. Its molecular weight is 34,000 D. u-PA is not fibrin-selective, and this drug also produces a lytic state. The half-life of u-PA is ~15 minutes. u-PA is used to treat VTE, MI, and thrombolysis of clotted catheters.

Tissue-type Plasminogen Activator

Currently, t-PA is produced by recombinant technology as a two-chain species, with a molecular weight of ~65,000 D.⁴⁸⁹,⁴⁹⁰ In vitro, t-PA is fibrin-specific, because of its high affinity for fibrin with which it forms a ternary complex with plasminogen. However, with t-PA dosage regimens currently being used, the lytic state is produced in vivo.⁴⁹¹ Consequently, bleeding complications with t-PA are similar to those with SK or u-PA.⁴⁹² The half-life of t-PA is much shorter than that of SK or u-PA, ~5 minutes. t-PA is used to treat VTE and acute MI⁴⁹²,⁴⁹³,⁴⁹⁴,⁴⁹⁵,⁴⁹⁶ and has also been approved for use in acute ischemic stroke (within 3 hours of stroke onset) and venous catheter withdrawal occlusion.⁴⁹⁷ Laboratory monitoring of t-PA therapy is usually not recommended.

Tissue-type Plasminogen Activator Variants

Recombinant PA (r-PA; reteplase) is a nonglycosylated deletion mutant of wild-type human t-PA comprised of only the kringle 2 and the protease domains of the parent molecule. Lack of the finger domain imparts lower fibrin-binding affinity.⁴⁹⁸ Lack of glycosylation, a finger domain, and an epidermal growth factor domain impart an extended half-life (15 minutes vs. 5 minutes). The longer half-life allows for double-bolus administration. The longer half-lives of r-PA and TNK-rt-PA compared with t-PA facilitate bolus administration primarily for acute coronary thrombosis.

Other Plasminogen Activators

Recombinant glycosylated prourokinase (single-chain u-PA) has a greater stability than recombinant nonglycosylated prourokinase and has been evaluated for catheter-directed, intra-arterial treatment of stroke.⁴⁹⁹ Staphylokinase is produced by *Staphylococcus aureus*. It appears to have substantial thrombolytic activity, but it may also be immunogenic.⁵⁰⁰ Vampire bat (*Desmodus rotundus*) salivary PA (rDSPA α 1, desmoteplase) possesses >72% primary structure homology to human t-PA but lacks a kringle 2 domain⁵⁰¹ which may impart greater fibrin specificity. Finally, although not a PA, plasmin therapy has been investigated in arterial vascular disease.⁴⁷¹

Thrombolytic Therapy-Associated Bleeding

Bleeding is the most common complication associated with thrombolytic therapy, regardless of the agent. The bleeding stems from plasmin's inability to distinguish between hemostatic and pathologic thrombi. This complication can range from minor bleeding at an intravenous infusion site to life-threatening hemorrhage.⁵⁰² Intracranial hemorrhage is a relatively uncommon but serious complication of thrombolysis in patients being treated for acute MI.

The factors that increase the risk for bleeding during thrombolytic therapy are not fully understood. However, Gurwitz and associates used the National Registry for MI to determine risk factors for this adverse event in individuals treated with t-PA.⁵⁰³ Their analysis of 673 patients with intracranial hemorrhage indicated that older age, female sex, black ethnicity, systolic blood pressure \geq 140 mm Hg, diastolic blood pressure \geq 100 mm Hg, history of stroke, t-PA dose \geq 1.5 mg/kg, and lower body weight were all significantly associated with an increased risk for intracranial hemorrhage. It is also possible that the properties of the agent used for thrombolysis may contribute to the risk for bleeding complications.

Thrombolytic Fibrin Specificity and Hemorrhagic Risk

Thrombolytic agents can be characterized along a variety of dimensions, but one that is often mentioned is fibrin specificity.⁵⁰⁴ The ability of a thrombolytic agent (PA) to distinguish between plasminogen in the general circulation and plasminogen bound to fibrin surfaces dictates its fibrin specificity. Activation of fibrin-bound plasminogen results in the generation of fibrin-bound plasmin that is protected from inactivation by α_2 -antiplasmin. Bound plasmin generates soluble fibrin degradation products; circulating plasmin degrades fibrinogen into FDPs. Fibrin specificity differs from fibrin affinity, which is a measure of how avidly a given agent binds to fibrin, but not its specificity for this molecule.⁵⁰⁴ At present, there is little evidence to support the view that differences in fibrin affinity among PAs are significantly correlated with either the efficacy or safety of these preparations.⁵⁰⁵ High fibrin specificity is thought to be associated with lower risk for hemorrhagic complications in patients undergoing thrombolytic therapy because of the belief that plasmin generated on

the fibrin surface of a thrombus restricts its activity only to that surface. This view is not universally supported by available data from large-scale clinical trials.

A relationship between high fibrin specificity and reduced bleeding risk has been demonstrated.⁵⁰⁶ The results of the Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT)-2 trial, which included 16,949 patients with acute MI, showed that the use of the highly fibrin-specific thrombolytic agent TNK-tPA, compared with rt-PA, was associated with a significantly lower risk for major noncerebral bleeding.⁵⁰⁶ This lower rate of bleeding complications was correlated with a significant reduction in the need for blood transfusions. The ASSENT-2 investigators also reported that TNK-tPA was associated with a significantly lower risk for noncerebral bleeding than the less-specific agent alteplase.⁵⁰⁷ Intracranial bleeding rates were comparable with the two agents.

Results from other large-scale studies support the opposing view that high fibrin specificity may actually be associated with increased risk for intracranial bleeding in patients undergoing

P.1248

thrombolytic therapy for acute MI. For example, the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) trial showed that the risk of intracranial bleeding was slightly higher in 41,021 patients with MIs who received treatment with rt-PA as compared with SK.⁵⁰⁸ These findings are consistent with those from another very large-scale comparison of SK with rt-PA in 20,768 patients with MI (Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico 2 [GISSI-2]), which showed a significantly higher risk of stroke in patients who received the latter, more fibrin-specific agent.⁵⁰⁹ Similarly, the Third International Study of Infarct Survival (ISIS-3) showed that treatment of patients with anisoylated plasminogen SK activator complex was associated with increased risk for intracranial bleeding compared with SK in a large cohort of 41,299 patients who received thrombolytic therapy for suspected MI.⁵¹⁰

There are a number of potential explanations for the association between high fibrin specificity and increased intracranial bleeding observed in the patients treated in the GUSTO, GISSI-2, and ISIS-3 trials. These include the inability of fibrin-specific agents to distinguish between pathologic thrombi and hemostatic thrombi, and the possibility that treatment with fibrin-specific agents resulted in greater degradation of hemostatic fibrinogen and other circulating coagulation factors than SK. Finally, it may be that fibrin-specific therapy resulted in increased production and accumulation of fragment X, and that this enhanced the bleeding risk.⁵¹¹

VENOUS THROMBOEMBOLIC DISEASE

VTE, encompassing both DVT and PE is a common disease that carries a substantial risk of morbidity and mortality, is associated with high healthcare costs, and for many patients can be prevented. It has been estimated that between 500,000 and 2 million VTE cases, including calf vein thrombosis, proximal DVT, and PE, occur annually in the United States alone. It is estimated that up to 50% of DVT and PE are asymptomatic or undetected.⁵¹²

The major clinical consequences of extremity DVT include the PTS (chronic swelling, stasis dermatitis, stasis ulceration, and venous claudication: All secondary to venous insufficiency) and PE. The major clinical consequences of PE include acute lung infarction, chronic dyspnea, chronic pulmonary hypertension, and death. DVT restricted to the calf veins uncommonly results in clinically important PE and is rarely associated with a fatal outcome. In contrast, inadequately treated DVT involving the popliteal or more proximal leg veins is associated with a 20% to 50% risk of clinically relevant recurrence and is strongly associated with both symptomatic and fatal PE.^{513, 514} In untreated patients, death from PE occurs most frequently within 24 to 48 hours of initial presentation. All-cause mortality rates in treated patients with PE is as high as 11% at 2 weeks and 17% at 3 months.⁵¹² Even small PE in patients with emphysema, cardiac disease, or lung involvement with malignancy may result in death. Any VTE in a patient with a contraindication to anticoagulation presents a therapeutic challenge and greater likelihood of adverse outcome.

Management of Venous Thromboembolism

For a majority of patients with VTE, treatment is traditionally straightforward and includes an initial treatment phase (first 5 to 7 days) wherein there is an immediate initiation of a therapeutically dosed parenteral anticoagulant (e.g., heparin or low-molecular-weight heparin) and simultaneous initiation of long-term therapy (e.g., vitamin K antagonist), followed by a long-term treatment phase (from 5 to 7 days to 3 months) where the parenteral anticoagulant is discontinued, and VKA therapy is continued, and then an extended treatment phase (3 months to indefinite) where there is a decision to continue treatment or not.^{515, 516, 517} The emergence of the NOACs will greatly simplify this approach for a majority of patients.

Initial Treatment of Venous Thromboembolism

The mainstay of pharmacologic therapy for VTE is anticoagulation. A delay in achieving therapeutic anticoagulant intensity may have a negative effect on a patient's long-term VTE recurrence rate.^{518, 519} VKA have a delayed onset of action and the necessity of instituting a rapid-onset parenteral anticoagulant (e.g., heparin) in patients with acute VTE during VKA initiation has been highlighted.⁵²⁰ As long as warfarin is dosed to a therapeutic level, overlap therapy with heparins can be minimized to 5 days.^{517, 521, 522}

UFH remains the preferred initial parenteral anticoagulant for certain patients with acute VTE such as those with end-stage renal disease. When heparin is used, weight-based dosing (80-U/kg bolus followed by 18 U/kg/hour) with subsequent dose adjustments based on a standardized nomogram (Table 55.7) facilitates achieving a target aPTT.⁵²³ Use of any published nomogram helps facilitate the rapid achievement of target intensity anticoagulation. Adjusted-dose subcutaneous UFH, intermittent intravenous UFH boluses, and fixed dose subcutaneous heparin have also been used effectively in the treatment of VTE.^{513, 524, 525} The therapeutic intensity of UFH is monitored using the aPTT. An aPTT therapeutic range that correlates with an anti-FXa activity level of 0.3 to 0.7 U/ml is preferred.³⁹⁷ The aPTT should be checked every 4 to 6 hours until the aPTT surpasses the minimum of the therapeutic range.

As compared to heparin, weight-based subcutaneous LMWH is a preferred treatment option for most patients with acute VTE.⁵¹⁷ In 1992 two separate groups of investigators demonstrated that fixed-dose LMWH therapy was at least as safe and effective as adjusted-dose intravenous heparin in patients with proximal vein thrombosis.^{526, 527} Subsequently, numerous other comparative trials have been performed, and in a meta-analysis of 13 comparative trials Dolovich et al.⁵²⁸ demonstrated the LMWHs to be comparable to heparin for the initial treatment of VTE with regard to recurrence, major bleeding, and total mortality.⁵²⁸ Similarly, in a meta-analysis of 2,110 patients who presented with acute symptomatic PE, LMWH were found to be at least as effective (OR for recurrence, 0.68, 95% CI, 0.42 to 1.09) and safe (OR for major bleeding, 0.67, 95% CI, 0.36 to 1.27) as heparin.⁵²⁹ Enoxaparin sodium is dosed at 1.0 mg/kg body weight every 12 hours or 1.5 mg/kg once daily.⁵³⁰ Tinzaparin is dosed at 175 U/kg once daily.⁵¹⁷ Dalteparin is dosed at 200 U/kg (up to 18,000 U) once daily. The Matisse trials also support the use of fondaparinux in patients with VTE with efficacy and safety at least as good as LMWH.^{517, 531}

Efficient initial dosing of VKA therapy in patients with VTE minimizes excessive duration (i.e., beyond 5 to 7 days) of potentially costly parenteral anticoagulants and may allow for shorter hospitalization. The use of standardized warfarin initiation dosing nomograms has been shown to be efficient and safe.^{450, 532, 533} In two separate studies of predominantly inpatients, dosing nomograms using a 5-mg initial dose was compared to 10 mg and shown to be effective in achieving a therapeutic INR within 5 days with less risk of excessive anticoagulation.^{450, 532} More recently a 10-mg initial VKA dose nomogram in outpatients being treated for VTE had a greater percentage of patients achieving a therapeutic INR by day 5 of therapy with no difference in excessive anticoagulation or adverse events as compared to a lower initial dose.⁵³³ Lower initial doses (e.g., 5 mg or less) may be most appropriate for those patients who are elderly, have low body weight, are on interacting medications, or have poor nutrition, whereas a higher dose (e.g., 10 mg) may be acceptable for others.

The initial treatment of VTE used to be confined to the inpatient setting; however, two clinical trials demonstrated that

P.1249

outpatient LMWH treatment for carefully selected patients with acute DVT is safe and effective and can lead to substantial cost savings.^{534, 535, 536} Assuming an appropriate care-delivery system is in place, outpatient DVT treatment has become appropriate for a majority of DVT patients except perhaps, those with massive iliofemoral DVT, a high bleeding risk, or substantial co-morbid illness that otherwise necessitates hospitalization.⁵³⁷ Appropriate initial site-of-care for patients who present with acute PE is more controversial. Unlike patients with acute DVT, patients with acute PE represent a very heterogeneous risk-group with 3-month mortality rates ranging from 1.4% to 17.4%.^{512, 538} Standardized clinical assessments, biomarkers, and right ventricular size on imaging can all help to identify patients with a favorable prognosis. For carefully selected, low-risk patients with acute PE, a predominantly outpatient management approach has been shown to be safe and effective.⁵³⁹

Anticoagulation Considerations in Special Populations with Venous Thromboembolism

In occasional patients with thrombosis, the aPTT assay may not be reliable in monitoring UFH therapy, for example, patients with the lupus anticoagulant and a prolonged baseline aPTT. For these patients, one option would be to use UFH levels that can be obtained by an automated assay using an anti-factor Xa method. In this instance, the targeted therapeutic range would be 0.35 to 0.7 U/ml. Alternatively, these patients could be given LMWH or fondaparinux, with

the dosage determined solely by body weight and no necessity for laboratory monitoring. Patients with marked elevation in factor VIII levels may also be more reliably anticoagulated using LMWH.⁴⁰⁰

Obese patients are underrepresented in VTE treatment trials, and that has led to uncertainty about optimal LMWH dosing in these patients.^{540, 541} Studies evaluating drug (e.g., dalteparin, enoxaparin, tinzaparin) activity with the use of anti-Xa activity levels, suggest the pharmacodynamics of LMWHs in obese patients (weighing up to 190 kg) are similar to nonobese patients.^{542, 543, 544} Consequently, weight-based dosing (using total body weight) in obese patients without dose-capping and without anti-Xa monitoring appears appropriate.^{397, 540} However, due to limited published experience, anti-Xa monitoring with subsequent dose adjustment should be considered in patients at extreme weights, i.e., those patients weighing over 190 kg in whom LMWH are used.⁵⁴⁰

The concomitant presence of renal insufficiency (creatinine clearance [CrCl] <30 ml/minute) is associated with worse outcomes, including fatal bleeding, in patients with VTE.⁵⁴⁵ Although inconsistent, the LMWHs have a significant degree of renal clearance with anti-Xa activity levels strongly correlating with CrCl and drug accumulation occurring in those patients with a CrCl less than 30 ml/minute.³⁹⁷ Clinically, unadjusted LMWH therapy is associated with greater bleeding complications (OR 2.25, 95% CI 1.19 to 4.27) in patients with CrCl <30 ml/min compared to those without renal impairment.⁵⁴⁶ Because of potentially worse outcomes with LMWHs in patients with significant renal impairment, weight-based adjusted-dose UFH is recommended over LMWH for VTE treatment.^{397, 540, 541}

Extended Treatment of Venous Thromboembolism

The optimal duration of anticoagulation should be determined for each individual patient. Patients with DVT secondary to a time-limited (transient) risk factor such as recent surgery, immobilization, trauma, or pregnancy may be anticoagulated for a short duration of 3 months, as long as the risk factor has resolved. Patients with recurrent unprovoked VTE (two or more events) or ongoing major risk factors, such as malignancy or antiphospholipid antibody syndrome, require indefinite therapy. Patients with a first unprovoked VTE should be anticoagulated for a minimum of 3 months and consideration should be given to longer duration of therapy.⁵¹⁷ In general, patients with an unprovoked VTE have a risk of recurrence of ~5% to 7%/year after 3 months of therapy if anticoagulation is discontinued.⁵¹⁷ Continuation of anticoagulation beyond 3 months (e.g., 6 or 12 months) reduces this risk as long as the patient remains on anticoagulation, but the heightened long-term recurrence risk remains unchanged once anticoagulation is discontinued. Unfortunately, residual thrombus on repeat imaging and the presence of the most common thrombophilias (e.g., heterozygote factor V Leiden mutation, prothrombin gene mutation, etc.) are only weak predictors of recurrence risk and so their utility in helping to decide whether to continue or stop anticoagulation after the initial 3 months in patients with unprovoked VTE is controversial.^{547, 548, 550} For these reasons, current guidelines suggest extended duration of therapy for patients with unprovoked VTE as long as the predicted long-term bleeding risk is estimated to be low.⁵¹⁷ The use of posttreatment D-dimer to guide the decision to continue or stop anticoagulation after 3 months has potential utility.⁵⁵¹ It is probable that with additional data, D-dimer testing will continue to have an emerging role in helping with duration of therapy decisions in some patients with unprovoked VTE. Guidelines for the duration of anticoagulant therapy are suggested in Table 55.16.

For those patients assigned to extended (e.g., beyond initial 3 months) duration therapy, the intensity of oral anticoagulation has been a subject of controversy. A consensus group concluded that low-intensity oral anticoagulation (INR 1.5 to 2.0) was less effective and no safer than standard-intensity therapy (INR 2.0 to 3.0).⁵⁵²

All patients anticoagulated with warfarin should be educated regarding maintaining a stable diet. Patients should be encouraged to consume a constant intake of dietary vitamin K and avoid large variations or fluctuations in their diet. Because of the number of pharmacologic interactions that exist between warfarin and other drugs (Table 55.10), patients should be instructed to inform their physician of the addition or withdrawal of any medication during warfarin therapy. In addition, patients should be encouraged to avoid over-the-counter multivitamin supplements or herbal preparations that contain vitamin K or vitamin K analogs and those known to have an effect on warfarin anticoagulation (e.g., ginkgo biloba). The risk of bleeding during therapy should be explained to all patients. It is strongly recommended that patients avoid high-risk activities, including contact sports. Patients should be instructed to seek medical attention for severe bleeding or bleeding that is not controlled after 10 to 15 minutes of continuous compression. The appropriate use of protective gear, such as bicycle helmets, should be emphasized. Patients should be instructed to carry a wallet card that identifies their use of an anticoagulant. In addition, they should be encouraged to wear a medical identification bracelet or necklace.

P.1250

Patient instruction is best provided by anticoagulation clinics that focus specifically on anticoagulation monitoring and education. Studies suggest that anticoagulation services offer better control of anticoagulation (time in therapeutic range,

TTR).⁵⁵³ Point-of-care instruments that can reliably monitor a patient's INR values in the hospital or home setting are being increasingly used.⁵⁵⁴ Patient self-testing and self-management of oral anticoagulation therapy have been demonstrated to be effective, but overall impact on clinical outcomes, cost-effectiveness, and patient selection remain incompletely defined.^{555, 556, 557}

TABLE 55.16 DURATION OF ANTICOAGULATION IN VENOUS THROMBOEMBOLIC DISEASE

Disease	Duration
Situational DVT or PE (transient risk factors)	3 mo
Unprovoked DVT or PE	3 mo (minimum)/indefinite
Recurrent unprovoked DVT or PE	Indefinite
DVT with ongoing risk factors ^a	Long-term/indefinite
Massive PE	Long-term/indefinite
Calf vein DVT	3 mo
DVT, deep venous thrombosis; PE, pulmonary embolism.	

^aFor example, malignancy, antiphospholipid antibody syndrome, or natural anticoagulant deficiency.

In select cases, LMWH may be used in lieu of oral warfarin for chronic-phase anticoagulation. Because of its teratogenic effects, warfarin therapy is contraindicated in pregnancy, so long-term heparin or LMWH is prudent for pregnant patients; LMWH may be preferred in pregnancy, because osteopenia occurs less often with LMWH than with UFH.⁵⁵⁸

In addition, patients with variable oral intake, episodic vomiting, malabsorption, and difficult to regulate INR values on warfarin may be better served by chronic subcutaneous LMWH administration.

The management, efficacy, and safety of VKA are particularly problematic in cancer patients with VTE.⁵⁵⁹ Both recurrent VTE and major bleeding events are significantly more common in patients with cancer compared to those without in the first month of therapy and are not explained by anticoagulant intensity outside the target range.⁵⁶⁰ Due to the limitations of VKA in this population, long-term LMWH therapy has been evaluated as an alternative to LMWH followed by VKA in cancer patients with VTE. In the pivotal 2003 CLOT trial, Lee et al. randomized 672 patients with acute proximal DVT, PE, or both to either 6 months of dalteparin (200 IU per kilogram of body weight once daily for 1 month followed by 150 IU per kilogram once daily for 5 months) to 5 to 7 days of dalteparin followed by 6 months of VKA with a target INR of 2.5. During the 6-month study period, recurrent VTE was significantly less common in the long-term LMWH group (hazard ratio 0.48, 95% CI 0.30 to 0.77) without a difference in bleeding events or mortality.⁵⁶¹ In a separate randomized open-label clinical trial comparing usual care to long-term tinzaparin in patients with a proximal DVT in the setting of cancer (n = 200), Hull et al.⁵⁶² demonstrated long-term tinzaparin to be associated with fewer recurrent VTE events, 16% versus 7% (absolute risk difference -9%, 95% CI -21.7% to -0.7%).⁵⁶² Most recently, a Cochrane meta-analysis of six randomized trials showed that long-term LMWH, compared to usual therapy provided a reduction in VTE (HR 0.47, 95% CI 0.32 to 0.71) with no statistically significant survival benefit (HR 0.96, 95% CI 0.81 to 1.14) or difference in bleeding outcomes (RR 0.91, 95% CI 0.64 to 1.31).⁵⁶³ From a patient perspective, long-term LMWH therapy is deemed acceptable and is preferable to VKA.⁵⁶⁴ Based upon favorable outcomes, long-term LMWH therapy in cancer patients is currently endorsed by numerous practice guidelines as the preferred therapeutic approach in these patients.^{517, 565, 566, 567}

Novel Oral Anticoagulants for the Treatment of Venous Thromboembolism

Rivaroxaban has recently been approved for VTE treatment, and the continued emergence of the NOACs will likely change the treatment approach for many patients with VTE. Noninferiority trials have compared a single drug treatment approach (e.g., rivaroxaban) or treatment after an initial course of LMWH (e.g., dabigatran etexilate) to standard therapy in patients with acute VTE. Other similar trials evaluating apixaban and edoxaban are near completion. In the EINSTEIN-DVT trial (n = 3449), oral rivaroxaban, 15 mg twice daily for 3 weeks and then 20 mg once daily, was compared to standard therapy in patients with acute DVT.⁵⁶⁸ Rivaroxaban was demonstrated to have both similar efficacy (hazard ratio for the primary endpoint of symptomatic recurrence was 0.68, 95% CI 0.44 to 1.04) and safety.⁵⁶⁸ In a companion study of patients with acute PE, the EINSTEIN-PE trial (n = 4,832), as compared to usual therapy, rivaroxaban was similarly effective and safe, HR 1.12 (95% CI 0.75 to 1.68) and 0.49 (95% CI .031 to 0.79), respectively.⁵⁶⁹ In the RE-COVER trial (n = 2,539), patients with acute VTE received either VKA or dabigatran, 150 mg twice daily, after an initial period of parenteral

anticoagulation with LMWH. After 6 months of therapy recurrence, HR 1.10, 95% CI 0.65 to 1.84, and major bleeding, HR 0.82, 95% CI 0.45 to 1.48, were similar.⁵⁷⁰

Calf Deep Venous Thrombosis

Many perceive that calf DVT is of limited clinical significance. This misunderstanding and underappreciation of the potential morbidity and mortality associated with calf DVT have resulted in a lack of clear consensus on the optimal management strategy for this condition. Isolated calf DVT may account for as few as 6.2% of all symptomatic acute DVT and as many as 43.0% of all acute VTE.⁵⁷¹ Studies have also demonstrated that although calf DVT and proximal DVT may be considered separate diseases at their outset, 15% to 25% of calf DVT propagate into the proximal veins within 2 to 3 weeks wherein a risk of embolism ensues.^{572, 573, 574, 575} Such “proximal conversion” renders what was initially a calf DVT just as dangerous as any proximal DVT.

Whereas the primary goals of proximal DVT treatment include the prevention of DVT recurrence and PE, the most essential goals of calf DVT treatment should be to treat severe symptoms and to prevent early proximal conversion. Current treatment approaches for isolated calf DVT are either to implement the same intensity and duration of anticoagulant therapy as is used for proximal DVT or to implement serial duplex ultrasound surveillance, with therapy begun only in the event of proximal conversion or significant extension. Surveillance consists of serial imaging (e.g., twice weekly) for 2 weeks, the usual period for proximal conversion. The limitations of serial surveillance include cost, compliance, and convenience whereas anticoagulant therapy has limitations of cost, inconvenience, and risk of bleeding. Anticoagulation is preferable for those patients with a low bleeding risk who have severe symptoms or risk factors for extension (thrombus >5 cm, involves multiple calf veins, proximal extent near the calf trifurcation, ongoing underlying risk factors such as immobility or cancer, prior history of VTE, or occurrence without provocation).⁵¹⁷

Whereas 6 months of anticoagulation has been shown to be superior to 6 weeks' duration of therapy in patients with proximal DVT, the shorter course of therapy has not been shown to be inferior in patients with initial distal thrombosis.⁵⁷¹ In general, calf vein DVT should be treated for 3 months.⁵¹⁷ However, patients with situational calf DVT (DVT with a clear precipitant such as major surgery or hospitalization) can be considered for only 6 weeks of treatment, assuming the precipitating illness or event has resolved. Inferior vena cava (IVC) filter placement is not recommended for calf DVT in most circumstances.

Advanced Therapies for Venous Thromboembolism

Vena Caval Filter

Patients with acute VTE and active bleeding require placement of an IVC filter, as do patients with acute VTE who have failed therapeutic anticoagulation. Relative contraindications to anticoagulation are listed in Table 55.17. It is important to note that active bleeding may be a treatable and transient contraindication to anticoagulation. An IVC filter should not be viewed as an equivalent substitute to anticoagulation in the setting of acute VTE and is certainly not an “insurance policy” against subsequent PE. The use of IVC filters has been associated with an increased

P.1251

risk of recurrent DVT, reduced PE, and no difference in overall mortality.^{576, 577} In patients with filters placed because of bleeding, appropriate anticoagulation should begin as soon as the bleeding source has been properly and completely treated. Because of the significant risk of rebleeding, such a patient should have his or her anticoagulation begun in the hospital. Placement and subsequent removal of a temporary (or retrievable) IVC filter once the contraindication to anticoagulation has passed seems ideal. Placement of an IVC filter because of a “free-floating” DVT may not be necessary in all patients.⁵⁷⁸ Guidelines on using IVC filters have been published.^{517, 579}

TABLE 55.17 RELATIVE CONTRAINDICATIONS TO ANTICOAGULATION THERAPY

Bacterial endocarditis

Recent organ biopsy or noncompressible arterial intervention site

Recent gastrointestinal or genitourinary bleeding (<10 d)

Thrombocytopenia or marked anemia

History of a bleeding disorder

History of intracranial, spinal, or ocular bleeding

Recent (<2 wk) history of major surgery, stroke, or trauma

Hepatic insufficiency

Catheter-directed Thrombolysis of Deep Venous Thrombosis

Catheter-directed thrombolytic therapy is usually reserved for patients with extensive DVT involving the IVC or iliac veins and for patients who have signs and symptoms of actual or impending phlegmasia cerulea dolens.^{580, 581, 582, 583, 584, 585} An initial venogram is performed via a distal vessel, usually a popliteal or foot vein, to delineate fully the extent of the DVT. Access for the vascular access sheath is best accomplished via the popliteal vein, typically using ultrasound guidance to assure nontraumatic, single-puncture catheter placement. A multiple-side-hole catheter is advanced and embedded within the thrombus. Thrombolytic agent is infused through this catheter. At a minimum, low-dose heparin (500 U/hour) should be infused through the sheath to prevent sheath thrombosis. Periodic surveillance with venography should be performed to assess resolution of the DVT. As lysis is achieved, the infusion catheter may require repositioning to maintain infusion within the thrombus.⁵⁸¹

Lytic therapy for DVT carries the same contraindications as for lysis of PE. Active bleeding is an absolute contraindication to the procedure; relative contraindications include those for any anticoagulant. In addition, a history of contrast allergy or renal insufficiency is a relative contraindication to the procedure. Complications are similar to the complications for PE lysis. The major complication associated with the use of lytic agents is bleeding. Access-site bleeding is the most common complication. Bleeding in the popliteal space may be particularly significant because the popliteal vein is poorly compressible. Additional complications such as intracranial bleeding are also seen with lytic infusion for DVT lysis. PE, potentially fatal, has been reported in patients undergoing DVT lytic therapy.

Only SK has an approved indication for use in lytic treatment of DVT. Urokinase, rt-PA, r-PA, and TNK-t-PA are not approved for DVT lysis. After the completion of thrombolytic therapy, patients should be anticoagulated with an appropriate parenteral agent (UFH, LMWH, or DTI) and converted to warfarin in the usual fashion. Patients who have a contraindication to lysis may be able to derive some benefit from mechanical thrombectomy performed at the time of venography/intervention. However, mechanical thrombectomy should not be attempted in patients with a contraindication to anticoagulation, because any benefit from suction thrombectomy would likely be lost without maintenance of therapeutic anticoagulation.

Benefits of DVT thrombolysis include the ability subsequently to diagnose and treat any underlying venous stenosis, venous compression (as in May-Thurner syndrome), or venous webs that may be discovered after thrombolysis.^{582, 583} The use of angioplasty, stent placement, or both may improve outcomes in these patients.⁵⁸⁴ Most recently, the combined use of localized pharmacomechanical intervention has been demonstrated to reduce subsequent PTS occurrence but increase overall bleeding.^{586, 587} These more recent findings are important as the primary goal of catheter-based interventions for the management of DVT is to reduce the subsequent occurrence of PTS. PTS develops in up to 50% of patients with symptomatic DVT.⁵⁸⁸ Pain, swelling, edema, pigmentation changes, and skin ulcers may occur. PTS results from damage to venous valves by clot, leading to valvular incompetence and venous reflux.⁵⁸⁸ Management of PTS involves use of graduated elastic compression stockings⁵⁸⁹ and, as discussed, consideration of use of invasive catheter-directed approaches to treat DVT (and prevent PTS); however, consensus opinion currently recommends against the routine use of thrombolytic therapy, and large randomized trials are in progress.⁵¹⁷

Thrombolysis for Pulmonary Embolism

Most patients with symptomatic PE should be treated solely with anticoagulation. Some patients with PE may derive benefit from thrombolytic therapy to actively degrade the thrombus obstructing the pulmonary vasculature. Clear indications for PE thrombolysis are debatable.^{590, 591} Thrombolysis has been demonstrated to improve survival in patients with massive PE plus shock and is probably indicated in these patients. When compared to anticoagulation alone, thrombolytic therapy results in more rapid thrombus lysis, an early improvement in pulmonary blood flow, and improvement of right ventricular function.⁵⁹² However, these improvements in cardiopulmonary function alone have not resulted in decreased mortality in stable patients without significant hemodynamic compromise. Even in patients with submassive PE, initial thrombolysis with intravenous alteplase did not reduce mortality.⁵⁹³ It remains unclear whether patients with PE and evidence of right ventricular dysfunction or elevated cardiac troponin levels (or both) benefit from thrombolysis.

Currently approved drug regimens for PE lysis include the following: SK, 250,000-U intravenous bolus over 30 minutes followed by 100,000-U/hour intravenous infusion for 24 hours; rt-PA, 100-mg intravenous infusion over 2 hours; and urokinase, 4,400-U/kg bolus over 10 minutes followed by intravenous infusion of 4,400 U/kg/hour for 12 hours. Reteplase

is not FDA-approved for PE management, but when administered as two 10-U boluses separated by 30 minutes, it has been shown to improve pulmonary vascular resistance and blood flow more rapidly than standard-dose rt-PA.⁵⁹⁴ Lytic therapy is contraindicated in patients with an increased risk of bleeding. Active bleeding is an absolute contraindication to therapy. In addition, recent organ biopsy or arterial puncture in a noncompressible site and recent cardiopulmonary resuscitation, uncontrolled hypertension, and pregnancy or recent delivery are relative contraindications. For all patients, the potential benefits of lysis must be weighed heavily against the potential risks of bleeding.⁵⁹⁵

Major hemorrhage rates have varied between 4% and 22% in studies at the currently recommended doses. Extrapolation from acute MI thrombolysis trials supports intracranial hemorrhage rates between 1% and 3%, approximately one half of which are

P.1252

fatal. There is no benefit to lytic infusion via a centrally placed catheter when compared to peripheral infusion in patients with PE. Many believe that heparin should not be administered concomitantly with the lytic agent. An aPTT should be determined at the completion of the lysis; if the aPTT is ≤ 2.5 times the control, then heparin infusion should be started/resumed. If the aPTT is >2.5 times the control, the aPTT should be repeated every 4 hours; once it decreases into an acceptable range, the heparin infusion may be initiated. If a complication of therapy occurs, the lytic agent and any other anticoagulants should be held. Freshfrozen plasma and cryoprecipitate may be used to replete fibrinogen and clotting factors. Consideration should be given to the use of antifibrinolytic agents to reverse excessive fibrinolysis.^{590, 591}

PREVENTION OF VENOUS THROMBOEMBOLIC DISEASE

If physicians focused more on VTE prophylaxis, much less time would be needed to emphasize methods for VTE diagnosis and treatment. Fatal PE is considered to be the most common preventable cause of hospital death.⁵⁹⁶ Because the clinical diagnosis of VTE is unreliable and serial surveillance of all high-risk patients is expensive, widespread use of anticoagulants (or other prophylactic measures) has been recommended and is the subject of recent comprehensive practice guidelines by the American College of Chest Physicians.^{359, 597, 598, 599}

Optimal delivery of thromboprophylaxis requires an assessment of risk versus benefit, and this is particularly relevant to medically-ill patients wherein the absolute risk of clinically relevant VTE may be less than in patients undergoing major surgical procedures. There is an abundance of literature supporting the benefits of thromboprophylaxis in surgical patients, but the absolute clinical impact in nonsurgical patients is less certain. In a recent meta-analysis by Lederle and colleagues, medically-ill patients who received pharmacologic prophylaxis had reduced incidence of symptomatic PE (number needed to treat 306), but increased bleeding events (number needed to harm 296 for major bleeding), and no reduction in total mortality.⁶⁰⁰ Risk assessment, however, is imperfect and can be viewed as group risk (e.g., all orthopedic patients) or individualized risk (e.g., based upon individual patient characteristics). Figure 55.9 illustrates several VTE risk assessment models that have been validated.^{601, 602, 603} It is important to note that not all patients at risk develop a thrombosis, and not all thromboses result in symptoms, morbidity, or death. The benefit of pharmacologic thromboprophylaxis must always be weighed against the bleeding risk. Patients at high risk for bleeding should still receive prophylaxis in the form of an intermittent pneumatic compression device, thromboembolism-deterrence stockings, or both. Furthermore, prophylaxis strategies must take into account whether a patient has a history of HIT. Figure 55.10 illustrates a general approach to thromboprophylaxis, and Table 55.17 lists relative contraindications to anticoagulant therapy.

All Hospitalized*		Medical†		Non-orthopedic Surgical Patients‡	
Risk Factor	Points	Risk Factor	Points		
Cancer	3	Prior VTE	3	5 points each: Joint replacement surgery, hip/pelvic/leg fracture, stroke, multiple trauma, SCI	
Prior VTE	3	Thrombophilia	2	3 points each: Age >75, history of VTE, family history of thrombosis, HIT, thrombophilia	
Thrombophilia	3	LE paralysis	2	2 points each: Age 60–74, cancer, major surgery, laparoscopic or arthroscopic surgery, CVC, bed rest >72h, immobilizing cast	
Major Surgery	2	Cancer	2	1 point each: Age 41–60, minor surgery, IBD, edema, BMI > 25, sepsis, serious lung disease, medical patient on bed rest, CHF, AMI, varicose veins, OCP/ERT, pregnant/postpartum	
Age >75 years	1	Immobility 7+ days	1	High Risk = 8+ points

- High Risk = >4% Symptomatic VTE Rate
- Greater # RF = Greater RAM Sensitivity

FIGURE 55.9. Individualized venous thromboembolism risk assessment models (RAMs). Individualized risk assessment for venous thromboembolism using validated risk assessment models may optimize patient selection and subsequent net benefit of thromboprophylaxis for acutely ill hospitalized patients or those undergoing major surgical intervention. In general, RAMs have a good positive predictive value in identifying high-risk patients, but may be relatively less useful in identifying lower-risk patients. AMI, acute myocardial infarction; BMI, body mass index; CHF, congestive heart failure; CVC, central venous catheter; HIT, heparin-induced thrombocytopenia; IBD, inflammatory bowel disease; ICU/CCU, intensive care unit or critical care unit; LE, lower extremity; OCP/ERT, oral contraceptives/estrogen replacement therapy; SCI, spinal cord injury; VTE, venous thromboembolism. Adapted from Kucher N, Koo S, Quiroz R, et al. Electronic alerts to prevent venous thromboembolism among hospitalized patients. *N Engl J Med* 2005;352:969-977. †Spyropoulos AC, Anderson FA, Fitzgerald G, et al. Predictive and associative models to identify hospitalized medical patients at risk for VTE. *Chest* 2011;140:706-714. ‡Bahl V, Hu HM, Henke PK, et al. A validation study of a retrospective venous thromboembolism scoring method. *Ann Surg* 2010;251:344-350.

Duration of thromboprophylaxis has also received attention. In general, extended prophylaxis (i.e., up to 4 weeks) has been suggested for patients undergoing elective hip arthroplasty, hip fracture repair, and high-risk abdominal-pelvic cancer surgery. Extending prophylaxis in medical patients, however, has not been shown to be effective and is associated with increased bleeding.^{604, 605}

HEPARIN-INDUCED THROMBOCYTOPENIA

Although bleeding is the most common adverse event associated with heparin and LMWH therapy, HIT, also known as the white clot syndrome, is increasingly recognized as a potentially severe, albeit paradoxical, immune-mediated complication of heparin therapy.^{606, 607} HIT is a “clinical-pathologic” syndrome, meaning that the diagnosis is optimally based on compatible clinical features as well as laboratory assay results positive for heparin-dependent antibodies. Platelet activation occurs in vivo in normal people. This results in release of PF4, a tetrameric platelet α-granule constituent into blood where it may also bind to the external platelet surface. Heparin is a polyanion, i.e., a chain of negatively

P.1253

charged oligosaccharides, that can bind to positively charged PF4 tetramers, resulting in heparin-PF4 complex formation that is immunogenic under certain circumstances.⁶⁰⁸ Binding of IgG to the heparin-PF4 complex forms an immune complex that triggers cross-linking of the platelet FcγIIa receptor, an event that leads to platelet activation and formation of thrombogenic microparticles.⁶⁰⁹ The end result is development of thrombocytopenia in the setting of a profound hypercoagulable state.

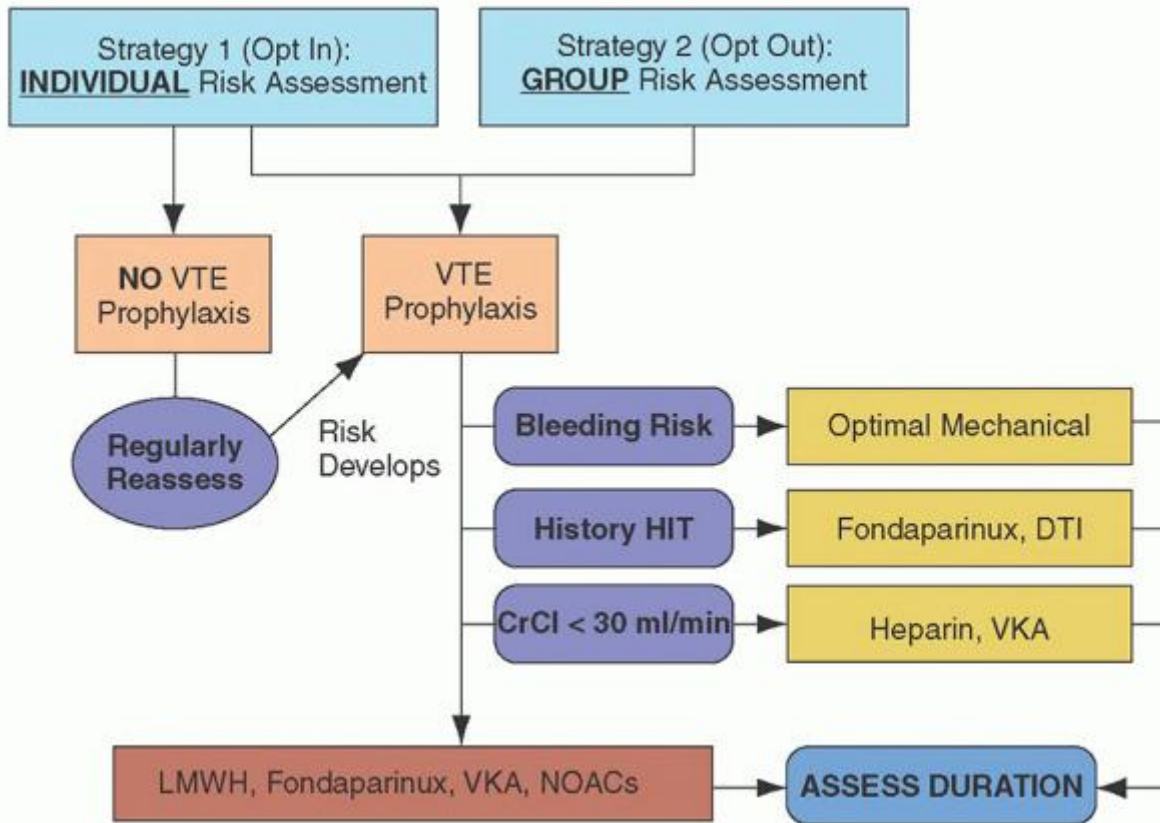

FIGURE 55.10. General approach to venous thromboembolism (VTE) prophylaxis in hospitalized patients. Some form of venous thromboembolism risk assessment should be performed in patients admitted to the hospital to identify those patients who are most likely to benefit from thromboprophylaxis. Risk assessment can be either individualized or considering at-risk patient groups (e.g., orthopedic surgery patients). Once risk has been identified, the choice of prophylactic strategy should be based upon the patient's bleeding risk, history of heparin-induced thrombocytopenia, renal function, duration of therapy, and cost. CrCl, creatinine clearance; DTI, direct thrombin inhibitor; HIT, heparin-induced thrombocytopenia; LMWH, low-molecular-weight heparin; ml/min, milliliters per minute; NOACs, novel oral anticoagulants; VKA, vitamin-K-antagonists.

HIT typically develops between 5 and 14 days after the commencement of heparin therapy and produces a variable but often moderate degree of thrombocytopenia wherein nadir platelet counts are typically in the range of 60,000/ μ l and the development of severe thrombocytopenia (<20,000/ μ l) is unusual.^{610, 611, 612} A platelet count fall that begins before day 5 of heparin is unlikely to represent HIT except in patients with a recent (within 3 months) heparin exposure.⁶⁰⁶ These patients may experience an abrupt onset of thrombocytopenia on re-exposure to heparin as a result of acute platelet activation due to preformed, circulating HIT-associated antibodies. In contrast, delayed-onset HIT represents a clinical challenge as patients may develop thrombocytopenia with or without thrombosis days to weeks after heparin cessation.⁶¹³

Although the exact incidence of HIT has not been well established, HIT has been noted to develop in up to 3% to 5% of patients exposed to unfractionated porcine-intestine-derived heparin.⁶¹⁰ Patients exposed to bovine-lung-derived UFH have been reported to have a greater likelihood of developing HIT than those exposed to porcine-intestine-derived UFH, and UFH induces pathogenic HIT antibodies to a greater extent than LMWH (~5% vs. ~1%, respectively, in orthopedic patients).^{614, 615} Warkentin et al. evaluated the incidence of HIT in 665 patients randomized to receive subcutaneous UFH or LMWH for venous thromboprophylaxis after elective hip surgery. HIT was diagnosed in 2.7% (9/332) of patients given UFH versus 0% (0/333) of those given LMWH. HIT with thrombosis developed in 88.9% (8/9) of the patients who developed HIT, compared with a thrombosis rate of 17.8% (117/656) in patients without HIT.⁶⁰⁶ The clinical setting also influences the frequency of HIT; patients undergoing cardiac surgery who receive UFH have a higher incidence of pathogenic HIT antibodies (2.5%) compared to medical (<1%) or obstetric (<0.1%) patients, and HIT may develop more commonly in women.^{614, 616}

The most feared complication of HIT is thrombosis. Thirty-six to fifty percent of patients with HIT have been noted to develop life- or limb-threatening thromboses.⁶¹⁰ The thrombotic tendency associated with HIT can last for at least 30 days, and HIT with thrombosis can develop well after the discontinuation of heparin and platelet-count recovery. Venous thrombosis is more common than arterial thrombosis in HIT patients, especially in those who receive UFH for postoperative DVT prevention.^{612, 617} Extremity DVT is the most frequently encountered venous thrombotic complication in HIT patients, followed in frequency by PE and cerebral sinus thrombosis.⁶¹⁰ Most HIT-associated arterial thromboses involve the extremities, but stroke, MI, and renal artery thrombosis related to heparin infusions have been described. HIT with thrombosis after coronary artery bypass grafting may present as bypass-graft occlusion, left atrial thrombus formation, valvular thrombosis, or PE.⁶¹⁸ Acute graft occlusion secondary to HIT has been described in vascular surgery patients even after platelet-count normalization. It is reasonable to assume that patients with pre-existing vascular lesions, intravascular catheters, sepsis, or postoperative venous stasis are particularly susceptible to the thrombotic complications of HIT.

Other clinical presentations of HIT include heparin-induced skin lesions, heparin “resistance,” and adrenal vein thrombosis leading to hemorrhagic infarction.^{619, 620} Heparin-induced skin lesions have been observed in ~10% to 20% of patients who generate HIT-IgG in response to subcutaneous UFH injections. The skin lesions develop at heparin injection sites and can range from painful red plaques to overt skin necrosis reminiscent of warfarin-induced skin necrosis. Thrombocytopenia may not develop in the majority of patients with heparin-induced skin lesions, but those who develop skin lesions and thrombocytopenia appear to be at extremely high risk for arterial thrombosis. The thrombocytopenia that develops in HIT is not normally associated with hemorrhagic events, and platelet transfusion may exacerbate the HIT-induced prothrombotic tendency.⁶¹⁰

HIT is primarily a clinical diagnosis. HIT should be strongly suspected in any patient who develops thrombocytopenia while receiving heparin in any dose or by any route of administration. Whereas HIT is usually associated with a platelet count below the lower limits of normal (150,000/μl in most laboratories), the extent of thrombocytopenia is quite variable, and the diagnosis should be strongly considered in any patient in whom the platelet count falls below 50% of the baseline value (even if still within the normal range) after the fifth day of heparin treatment.⁶¹⁰ Similarly, a 30% fall in baseline platelet count combined with any form of thrombosis in a patient receiving heparin should be

P.1254

considered due to HIT until proven otherwise. Thrombotic events occurring or progressing during therapeutic-intensity heparin therapy, even if the platelet count is normal, may also constitute a HIT variant.^{621, 622, 623}

Limitations of laboratory assays for HIT (discussed below) have led to development of a clinical scoring system to determine the pretest probability of HIT, in an attempt to identify patients with the likely diagnosis more rapidly. The “4T’s” scoring system (Table 55.18) uses easily available clinical information (nadir platelet count, timing of thrombocytopenia, presence or absence of thrombosis, and alternative explanations for thrombocytopenia) to classify patients into high (score of 6 to 8), intermediate (score of 4 to 5), or low (score of ≤3) probability of HIT.⁶²⁴ Study results indicate that this scoring system has a high negative predictive value. Consequently, a low pretest score may be useful in ruling out an HIT diagnosis.⁶²⁴ A meta-analysis of clinical trials using the 4T’s scoring system found that the negative predictive value of a low probability score was 99.8%.^{624a}

The currently available in vitro diagnostic assays for HIT are either immunoassays or functional assays.⁶²⁵ Immunoassays detect the presence of heparin-PF4 antibodies using ELISA methodology.⁶²⁶ HIT ELISAs have high sensitivity, but poor specificity for the diagnosis.⁶²⁷ Most will detect IgG, IgM, and IgA antibodies, but only IgG antibodies are thought to be pathogenic in the disorder. In addition, not all antibodies to the heparin-PF4 complex will induce platelet activation.⁶²⁷ Recent data indicate that the optimal immunoassay uses ELISA methodology to detect only IgG antibodies.⁶²⁸ The reliability of an IgG ELISA in diagnosing HIT can be further improved by considering the “positivity” of the result. ELISA optical density results near the upper limit of the normal range (usually ~0.4 O.D. units) are less likely to be associated with clinical HIT than a much higher positive result (≥1.0 O.D. units).⁶²⁹

TABLE 55.18 THE 4T'S CLINICAL PREDICTION SCORE FOR THE DIAGNOSIS OF HEPARIN-INDUCED THROMBOCYTOPENIA

4T's	Score = 2 points	Score = 1 point	Score = 0 points
<i>Thrombocytopenia</i>	Platelet count fall >50% and platelet count nadir ≥20,000 and no surgery	Platelet count fall 30-50% or platelet count nadir 10-19,000	Platelet count fall <30% <i>or</i>

	within preceding 3 d	<i>or</i>	Platelet count nadir <10,000
			Platelet count fall >50% but surgery within preceding 3 d
<i>Timing of platelet count fall</i>	Onset of fall 5-10 d after heparin start	Uncertain as to time course but likely platelet count fall 5-10 d after heparin start	Platelet count fall <4 d after heparin start and no recent heparin exposure
	<i>or</i>		
	Platelet count fall ≤ 1 d after heparin start with prior heparin exposure within 30 d	<i>or</i>	
		Platelet count fall after day 10 of heparin start	
		<i>or</i>	
		Platelet count fall within 1 d after heparin start with prior heparin exposure in past 31-100 d	
<i>Thrombosis (or other clinical events)</i>	Confirmed new thrombosis	Recurrent VTE in a patient receiving therapeutic anticoagulation	—
	<i>or</i>		
	Skin necrosis at injection site	<i>or</i>	
		Suspected thrombosis	
	<i>or</i>	<i>or</i>	
	Acute systemic reaction to IV UFH	Erythematous skin lesions at heparin injection sites	
	<i>or</i>		
	Adrenal hemorrhage		
<i>Other cause for thrombocytopenia</i>	None obvious	Possible	Probable/definite (DIC, sepsis, drug-induced, etc.)

Each 4T's parameter is evaluated and scored; patients with scores ≤ 3 points are at low risk for HIT. Those with scores of 4-5 points are at intermediate risk, and patients with scores of 6-8 points are at high risk of HIT.

DIC, disseminated intravascular coagulation; UFH, unfractionated heparin; VTE, venous thromboembolism.

Data from references 422, 624.

Functional assays detect platelet aggregation or platelet activation after exposure to suspected HIT serum and heparin. Functional assays include the platelet aggregation test, the heparin-induced platelet aggregation test, heparin-induced platelet release of ATP detected by lumi-aggregometry, the ^{14}C -serotonin release assay (^{14}C -SRA), heparin-induced platelet microparticle formation detected by flow cytometry, and enzyme immunoassay detection of platelet serotonin release. Traditionally, the ^{14}C -SRA has been considered the "gold standard" for HIT diagnostic confirmation. However, most studies evaluating the diagnostic use of the available functional assays and immunoassays, including studies of ^{14}C -SRA, used a clinical diagnosis of HIT as the true "gold standard." Also, the SRA is tedious to perform, has a lengthy turnaround time, and is offered by few laboratories. Patients should be assessed clinically (Table 55.18) using the 4T's pretest likelihood scoring system to determine their likelihood of having HIT while awaiting immunoassay results. Those patients with a low pretest likelihood for HIT probably need no further testing or alternative anticoagulation, and an alternate explanation for thrombocytopenia should be pursued. Conversely, patients with a high pretest probability for HIT should receive

alternative anticoagulation, and for any positive immunoassay result, no further testing is indicated. Patients with a high pretest probability, but who have negative immunoassay results should be tested with the SRA to confirm or refute a diagnosis of HIT. Patients with an intermediate likelihood of HIT should receive an alternative anticoagulant while awaiting immunoassay results. If the result is strongly positive (e.g., >1 O.D. units), no further testing may be necessary. If the result is negative or only weakly positive, the SRA should be performed to diagnose or exclude HIT definitively. Alternative anticoagulation should be continued while awaiting the SRA results. Figure 55.11 suggests an initial diagnostic and management approach to HIT.

P.1255

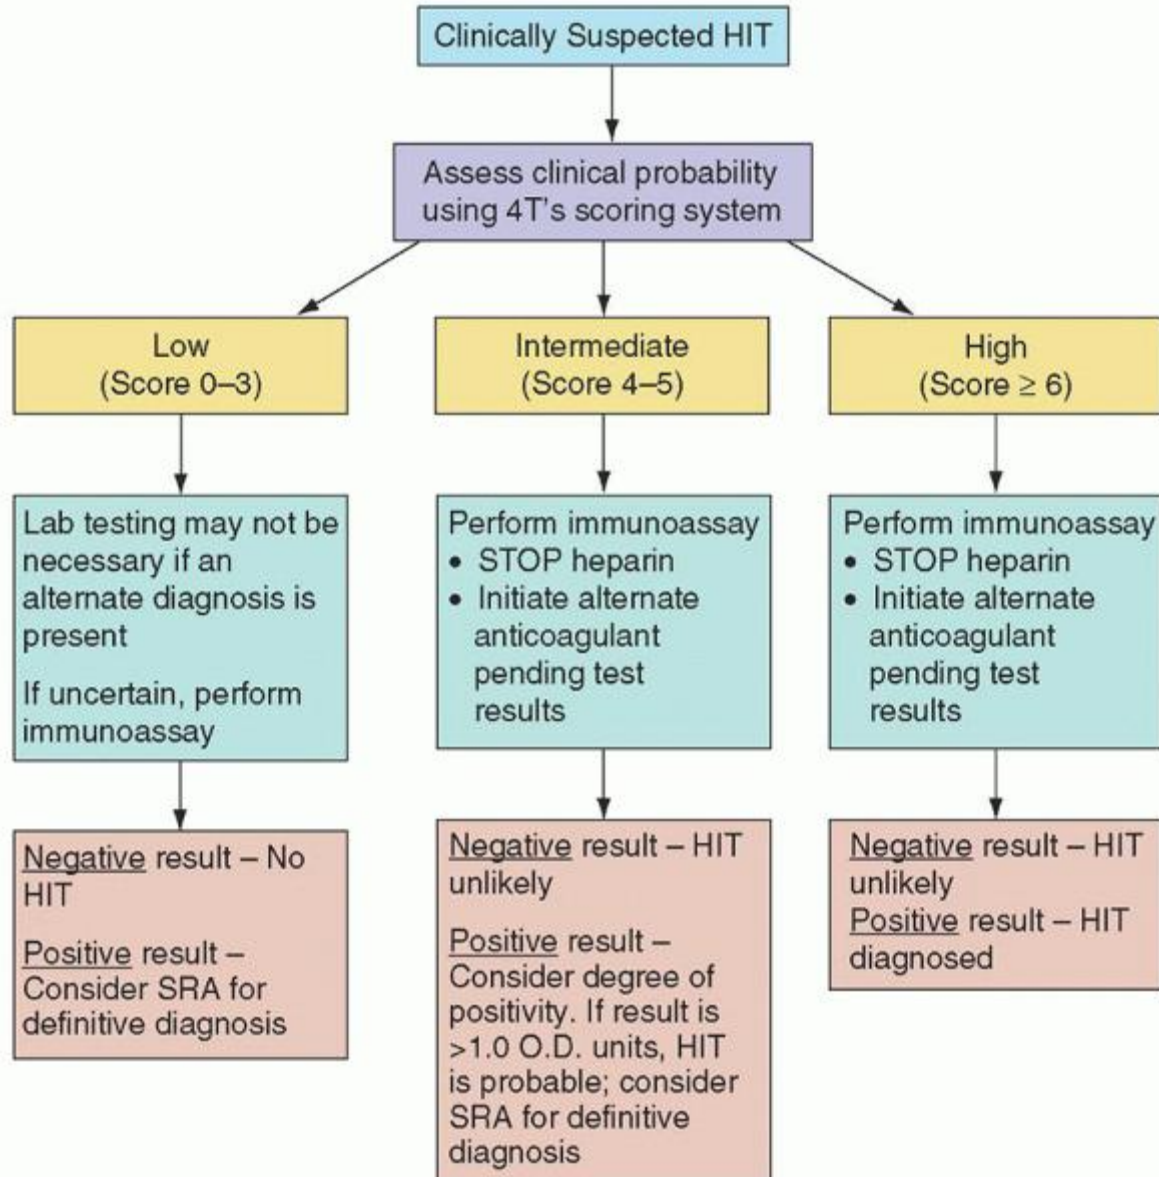

FIGURE 55.11. Initial management of patients with suspected heparin-induced thrombocytopenia (HIT). Patients with suspected HIT should be approached in a rapid and evidence-based fashion, wherein a pretest probability assessment is completed (e.g., using the 4T's scoring system, Table 55.18) and application of an immunoassay test, in particular to those patients at intermediate to high pretest probability. While awaiting immunoassay test results, implementation of an

alternative anticoagulant (e.g., direct thrombin inhibitor) is recommended. Patients with discordant clinical probability assessment and immunoassay results or those with intermediate findings should undergo additional testing with a functional platelet activation assay, such as the serotonin release assay (SRA). HIT, heparin-induced thrombocytopenia; O.D., optical density.

The initial treatment of HIT with or without thrombosis is to discontinue all exposure to heparin or LMWHs (including heparin-coated catheters) and immediately begin an alternative anticoagulant, usually a DTI, such as argatroban, lepirudin, or bivalirudin.⁴²² DTI therapy is continued as monotherapy until normalization of the platelet count, at which time bridging therapy with warfarin is started. Warfarin anticoagulation may be desired for long-term therapy, but should never be used as the sole alternative anticoagulant in patients with HIT. Warfarin treatment is the major factor contributing to limb amputation caused by progression of otherwise unremarkable deep vein thromboses to phlegmasia cerulea dolens in patients with HIT.^{630, 631} The combination of HIT-associated hypercoagulability and warfarin-induced protein C deficiency most likely produces a profound procoagulant state that causes venous limb gangrene. After both platelet count normalization and subsequent initiation of warfarin, both warfarin and DTI are continued for at least 5 days, or until a therapeutic INR (2.0 to 3.0) is achieved on warfarin alone. For isolated HIT without and with thrombosis, respectively, warfarin therapy duration of 4 weeks and 12 weeks is recommended.⁴²² Fondaparinux has also been used to treat HIT in small case series, but is not approved to treat HIT.⁶³² Patients should be informed that they should never be exposed to heparin again, although protocols are available in which short-term exposure to heparin can be safely done in patients who require heparin therapy.⁶³³

Considering the complexity of HIT diagnosis and treatment, HIT prevention must be emphasized. Patients receiving UFH should have platelet-count monitoring at baseline and at least every third day between day 5 and day 14 of heparin exposure. Platelet count monitoring recommendations in patients receiving heparin have been published in the recent ACCP guidelines.⁴²² Appropriate medical record documentation and patient education should help avert heparin re-exposure in patients with a history of HIT. Re-exposure to heparin in patients with past HIT should be delayed at least 3 months, kept to a minimum duration to provide succinct anamnesis, and avoided whenever possible. LMWH and fondaparinux may be preferable to UFH for both the treatment and prevention of thromboembolic disease because of the greatly reduced likelihood of initiating HIT.⁶³⁴ For those patients with acute or subacute HIT who require urgent cardiac surgery or PCI, the use of bivalirudin is recommended.⁴²²

Part VI - Benign Disorders of Leukocytes, The Spleen, and/or Immunoglobins

Chapter 56 Diagnostic Approach to Malignant and Nonmalignant Disorders of the Phagocytic and Immune Systems

> Table of Contents > Part VI - Benign Disorders of Leukocytes, The Spleen, and/or Immunoglobins > Chapter 56 - Diagnostic Approach to Malignant and Nonmalignant Disorders of the Phagocytic and Immune Systems

Chapter 56

Diagnostic Approach to Malignant and Nonmalignant Disorders of the Phagocytic and Immune Systems

Daniel A. Arber

Thomas L. McCurley

John P. Greer

Cost-effective, efficient evaluation of patients with hematologic diseases is often based on the quality of collaboration between clinicians and pathologists. This has become even more important as the number and complexity of diagnostic tests has exploded. Flow cytometry, cytogenetic, fluorescence in situ hybridization (FISH), and molecular genetic testing present opportunities for improving diagnostic precision but are expensive, and each has its limitations and shortcomings. The goal of this chapter is to guide selection of testing to minimize the cost and time involved in making diagnoses in common clinical problems in hematology.

This chapter introduces an approach to disorders that produce abnormalities of circulating blood cells, constitutional symptoms, or enlargement of lymph nodes or the spleen. The emphasis is on distinguishing benign from malignant disease. The disorders may take the form of (a) immune reactions, particularly infection resulting in changes in blood leukocytes, lymphadenopathy, and/or organomegaly; (b) neoplastic diseases (leukemias, lymphomas, and plasmacytic neoplasms and related diseases); and (c) inherited or acquired diseases that result in immunodeficiency.

APPROACH TO DIAGNOSIS

Patients with disorders of the immune system (innate and adaptive) usually come to medical attention with symptoms and signs suggestive of infection. Many patients with hematopoietic lymphoid neoplasms may also present with fever or other nonlocalizing constitutional signs and symptoms such as fatigue, generalized lymphadenopathy, abnormal bleeding, weight loss, bone pain, arthralgias, and pruritus. Suspicion of an underlying immune disorder, benign or malignant, may be raised during the course of a routine examination or during the evaluation of unrelated disorders by the detection of

skin lesions, lymphadenopathy, splenomegaly, or hilar or mediastinal masses. In other instances, routine blood examination may disclose abnormalities in the numbers or morphology of circulating red cells, white cells, or platelets.

A detailed history should be obtained, and a thorough physical examination should be performed. Age of the patient, immunocompetence (focusing on types and number of infections), family history, travel history, animal exposure, history of prior therapy, and drug ingestion are particularly important areas to address. Complete blood cell count (CBC) and blood examination (including morphologic assessment of red cells, white cells, and platelets) may be diagnostic or help determine the next step in diagnosis. Chest x-ray and computed tomography (CT) may assist in identifying possible biopsy sites. Electrophoresis to characterize serum or urine immunoglobulins, marrow examination, lymph node aspiration or biopsy, liver biopsy, and splenectomy with flow cytometry immunophenotyping of blood, marrow, or tissue, may be necessary. In addition, evaluation of delayed type hypersensitivity and tests of neutrophil and/or lymphocyte function may be required. Finally, cytogenetic and molecular genetic testing may be necessary for a complete assessment. Clearly, not all or even most of these tests and surgical procedures are indicated for each patient who has the symptoms or signs described. Rather, a logical sequence is undertaken for each patient, tailored to the particular findings. A diagrammatic summary of a sequential approach is shown in Figure 56.1.

The examination of stained tissues by light microscopy remains the principal means of establishing a diagnosis in most of the benign and malignant conditions considered in Parts VI (Nonmalignant Disorders of Leukocytes, the Spleen, and/or Immunoglobulins) and VII (Hematologic Malignancies). Other studies, however, including immunophenotypic studies, cytogenetics, and molecular genetics, are increasingly valuable in making, confirming, and “fine-tuning” diagnoses as well as in defining clinically important subcategories of disease.^{1, 2}

Flow cytometry has become a primary immunophenotyping method in the diagnosis, classification, and detection of residual disease in patients with hematologic malignancies, and is covered in more detail in Chapter 2. For example, flow cytometry is helpful in the differential diagnosis of reactive and neoplastic lymphoid proliferations, but requires specimens that are submitted fresh or in saline. Figure 56.2 demonstrates the difference between immunoglobulin light chain distribution in a patient with follicular hyperplasia (with polytypic light chain expression) versus a patient with a diffuse large B-cell lymphoma (with monotypic light chain expression). In T-cell neoplasms, the detection of a population of lymphocytes with aberrant phenotypes (e.g., lost or diminished expression of pan T-cell markers) as illustrated in Figure 56.3, is very helpful in detecting abnormal T-cell populations. Flow cytometry is essential for classification of acute leukemia, in part because most diagnostic studies can be completed in less than 2 hours. Additionally, flow cytometry immunophenotyping detects myeloid antigen expression in cases that are myeloperoxidase or Sudan black B negative by cytochemical studies. Finally, flow cytometry can detect aberrant blast cell immunophenotypes, which are useful for the detection of minimal residual disease in post-therapy specimens. The level of detection of minimal residual disease by flow cytometry is well

P.1260

below what can be identified by morphologic assessment of aspirate smears. However, flow cytometry does have limitations. It requires fresh or viable tissue and is of less value in the diagnosis of Hodgkin lymphoma (HL), T-cell-rich B-cell lymphomas, and subclassification of reactive processes (see Table 56.1), and may miss some T-cell neoplasms that do not demonstrate aberrant immunophenotypes. Most laboratories do not use methods that are effective in detecting the rare tumor cells of HL, but some studies have used this method effectively and this application of flow cytometry may emerge in the future.³ Additional applications in morphologically difficult areas such as myelodysplastic syndromes are evolving.

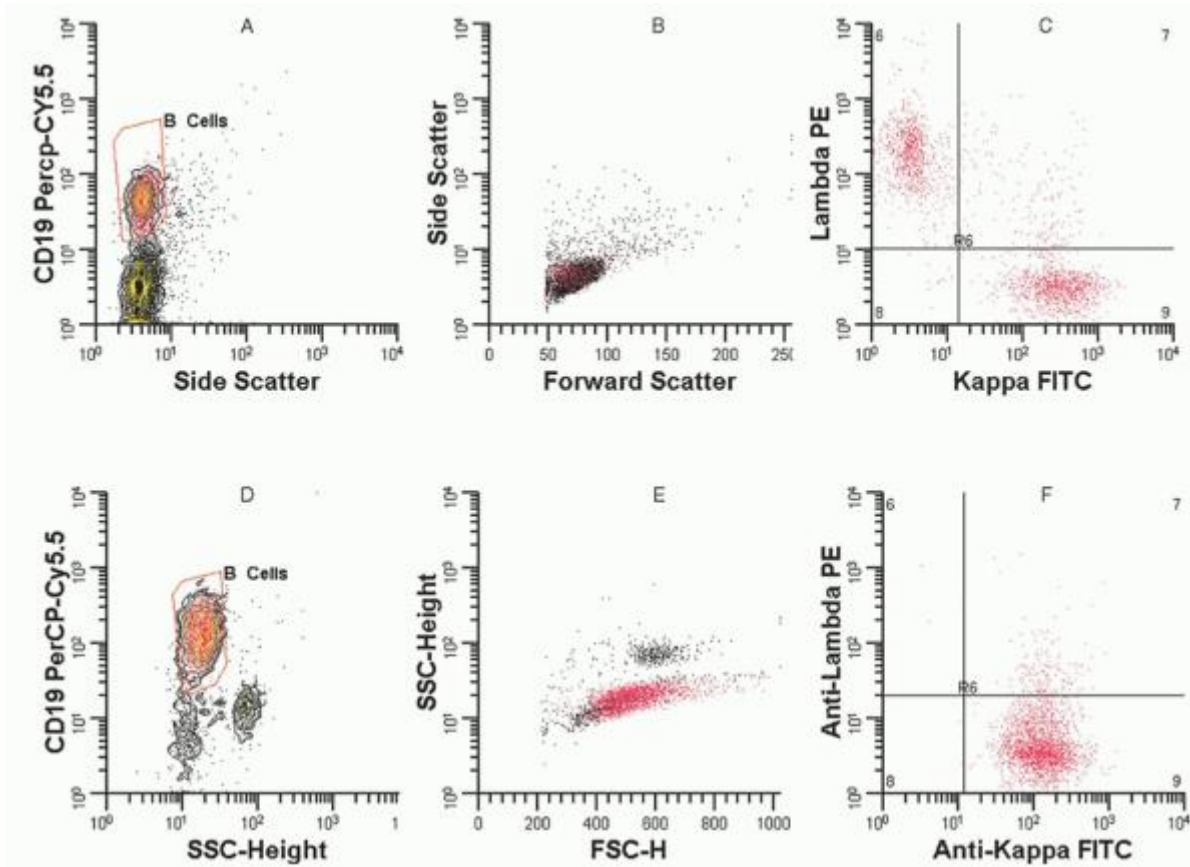

FIGURE 56.2. Flow cytometry of reactive B cells and monoclonal B cells. A: Histogram (picture) of pan B-cell anti-CD19 antibody expression versus this log side scatter signal (related to cellular complexity), which is used to define and identify the B-cell lymphocytes. B: Histogram shows lymphocytes based on forward scatter signal (size) versus log side scatter signal. The red population shows that the CD19⁺ B cells and predominantly T-cell CD19⁻ population (black dots) are of similar small size. (1) C: A two-parameter histogram gating on CD19⁺ B cells with anti-Kappa fluorescein isothiocyanate (FITC) versus anti-lambda phycoerythrin. This pattern, which shows a mix of kappa and lambda, is consistent with a reactive polyclonal B-cell population. D: Histogram (picture) of anti-CD19 antibody expression versus log side scatter in a second patient. E: Histogram shows lymphocytes based on forward scatter signal versus log side scatter signal. The red population which represents the CD19⁺ B cells is larger in size than the smaller CD19⁻ population (black dots). F: A two-parameter histogram of anti-kappa fluorescein isothiocyanate (FITC) versus anti-lambda phycoerythrin. Red dots are the CD19⁺ B cells from histogram and show a dominant kappa expressing B-cell population consistent with a large B-cell lymphoma. (Diagrams courtesy of Bruce Grieg, MT, Vanderbilt University.)

Cytogenetic studies have made enormous contributions to our understanding of the genetic pathogenesis of hematologic malignancies, and the field has established itself as a primary player in the diagnosis of prognostically important subsets of leukemia and lymphoma (e.g., Burkitt lymphoma, mantle cell lymphoma, and acute promyelocytic leukemia) (see Chapter 3). FISH has an expanding role in diagnosis (Table 56.2), and has several key advantages over routine cytogenetics: (1) it can be performed on interphase nuclei in fixed tissues (including paraffin-embedded), (2) results are available in 24 to 48 hours, and (3) it shows enhanced sensitivity over routine cytogenetics for critical translocations. Figure 56.4 illustrates FISH studies showing a MYC break apart probe in a patient with an 8;14 translocation in Burkitt lymphoma.

Molecular genetic studies, primarily polymerase chain reaction (PCR) techniques, are the most sensitive for detecting small critical genetic mutations or translocations in samples which may contain very few (less than one in a million) tumor cells (see Chapter 4). PCR has also replaced Southern blot analysis as the standard for the demonstration of T-cell and B-cell clonality and is ideal for detecting minimal residual disease in patients with lymphoma as well as in patients with chronic myelogenous leukemia (CML) (Table 56.3). Many of these applications work in fixed tissues. These studies are of limited or no value in patients with HL, myelodysplasia (MDS), or translocations that have widely spaced, variable breakpoints, as in mantle cell lymphoma.

Hematologic neoplasms are clonal tumors, and methods that can prove clonality of a cell population are extremely useful when the differential diagnosis is between a benign and neoplastic proliferation. The demonstration that an expanded B-cell population is clonal by immunoglobulin light chain restriction, karyotype analysis, or gene rearrangement studies facilitates the distinction between benign and malignant proliferations. However, clonality does not always indicate malignancy, and small clonal populations and pseudoclonal populations may exist in non-neoplastic conditions.^{1, 2, 4, 5} Clinicians have recognized for years that the vast majority of patients with monoclonal gammopathies do not have an underlying B-cell neoplasm. Similarly, sensitive molecular genetic techniques frequently identify oligoclonal and monoclonal T- and B-cell populations in “benign” disorders,

P.1262

including lymphomatoid papulosis, autoimmune disorders (e.g., Sjögren syndrome and Hashimoto thyroiditis) in association with viral infections, celiac disease, and other lymphoid hyperplasias (particularly those in extranodal sites)^{5, 6, 7} (Table 56.4). Although these disorders may evolve into frank malignancy, they can remain clinically benign, remit spontaneously, or regress in the setting of antibiotics and removal of an antigen (*Helicobacter pylori* in gastric marginal zone lymphoma). Thus, although new techniques to identify clonality have astonishing sensitivity, the clinical, laboratory, and histopathologic data must be correlated to distinguish benign from malignant disorders. A major pitfall in diagnosis is failure to recognize that very sensitive studies for clonality by flow cytometry, protein electrophoresis, or molecular techniques are accompanied by a corresponding loss of specificity for the diagnosis of frank neoplasia.

FIGURE 56.3. Histograms demonstrating a phenotypically aberrant T-cell population in a patient with peripheral blood involvement by a T-cell lymphoproliferative disorder. In A, a side scatter versus forward histogram, the lymphocytes (low forward scatter, low side scatter) are painted red. The granulocytes with high side scatter and high forward scatter are painted yellow and the monocytes with forward scatter similar to granulocytes but with intermediate side scatter are painted blue. B displays the granulocytes and monocytes stained with anti-CD3 and anti-CD4, both of which do not stain with the pan T-cell marker anti-CD3 but the monocytes express intermediate levels of CD4. In C which displays CD3 and CD4 expression on the lymphocytes (painted red), normal T helper cells express CD4 and CD3 while the neoplastic T-cell population (upper left) expresses bright CD4 but have lost CD3. (Histograms courtesy Bruce Grieg, MT, Vanderbilt University.)

In the next sections, the examination of the blood, marrow, nodes, and spleen are reviewed in the context of making a diagnosis, introducing the subsequent chapters, and outlining overviews on the evaluation of fever of unknown origin (FUO) and patients with recurrent infection.

TABLE 56.1 MAJOR CLINICAL APPLICATIONS OF FLOW CYTOMETRY

Established	Evolving	Limited Value or Superseded by Other Techniques
<ul style="list-style-type: none"> Acute leukemia (diagnosis and detection of residual disease) Chronic lymphoid leukemias 	Myelodysplastic syndromes	
Suspected non-Hodgkin lymphoma ^a	Multiple myeloma ^b	Hodgkin lymphoma
Paroxysmal nocturnal hemoglobinuria		Myeloproliferative disease (except

blast crisis)

Major disadvantage of this technique: Requires viable cells. False negatives occur with necrotic or sclerotic tissues, partial tissue involvement and in tumors where neoplastic cells are in a minority (e.g., T-cell-rich B-cell lymphoma).

Major advantages of this technique: Can be applied to any tissue or body fluid. Rapid turnaround times.

^a Flow cytometry should be performed on all fine-needle aspirations and tissue biopsies in which a hematopoietic lymphoid process is suggested by clinical history or touch preps/frozen sections.

^b Flow cytometry using cytoplasmic immunoglobulin light chain markers is effective in establishing clonality of plasma cells in multiple myeloma, but not useful in accurately enumerating plasma cells.

TABLE 56.2 COMMON CLINICAL APPLICATIONS OF CYTOGENETICS INCLUDING FLUORESCENCE IN SITU HYBRIDIZATION

Acute Leukemia with prognostically important translocations

APL with t(15;17)(q24.1;21.1) (*PML/RARA*) and *RARA* variants

AML with t(8;21)(q22;q22) (*RUNX1-RUNX1T1*)

AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22) (*CBFB/MYH11*)

AML with t(9;11)(p22;q23); *MLLT3-MLL* and other *MLL* translocations

ALL with t(12;21)(p13;q22) (*ETV6-RUNX1*)

ALL with t(4;11)(q21.3;q23) (*AFF4-MLL*) and other *MLL* translocations

ALL with t(9;22)(q34;q11.2) (*BCR-ABL1*)

Non-Hodgkin lymphoma with diagnostically critical translocations

Burkitt lymphoma: t(8;14)(q24;q32.33) (*MYC-IGH@*) and other *MYC* variants

Mantle cell lymphoma: t(11;14)(q13;q32.33) (*CCND1-IGH@*)

Follicular lymphoma: t(14;18)(q32.33;q21.3) (*IGH@-BCL2*)

Diffuse large B-cell lymphoma: 8q24 (*MYC*), 18q21.2 (*BCL2*) and 3q27 (*BCL6*) translocations

Anaplastic large cell lymphoma: t(2;5)(p23;5q35.1) (*ALK-NPM1*) and other *ALK* variants

Myelodysplasia

5q31 deletion

Gains and loss of chromosomes 5 and 7

Myeloproliferative neoplasms

Chronic myelogenous leukemia: t(9;22)(q34;q11.2) (*BCR-ABL1*)

Myeloid (and lymphoid) neoplasm with *PDGFRA*, *PDGFRB* and *FGFR1* abnormalities

Chronic lymphocytic leukemia

13q deletion

11q deletion

17q deletion

Trisomy 12

Plasma cell myeloma

13q deletion

17q deletion

t(11;14)(q13;q32.33) (*CCND1-IGH@*)

t(14;16)(q32.33;q22-q23)(*IGH@-MAF*)

t(4;14)(p16.3;q32.33)(*FGFR3-IGH@* or *WHSC1-IGH@*)

t(6;14)(p21;q32.33)(*CCND3-IGH@*)

t(14;20)(q32.33;q11.1-q13.1)(*IGH@-MAFB*)

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; APL, acute promyelocytic leukemia.

P.1263

FIGURE 56.4. FISH studies demonstrating a MYC translocation in Burkitt lymphoma using a dual color MYC break apart probe with the red labeled probe binding the 5 prime end of MYC and the green labeled probe binding the 3 prime end of MYC. In the chromosomes with unarranged MYC, the green and red signals are together but the colors separate when MYC is part of a translocation with the *IGH@* gene on chromosome 14.

EXAMINATION OF THE BLOOD

Physicians are too busy to examine peripheral blood smears in all of their patients. They usually do so in one of these circumstances: (a) patients with constitutional symptoms, particularly fever (see section on “Fever of Unknown Origin”) or weight loss, without an obvious underlying cause; (b) an abnormality in blood counts, either cytosis or cytopenia; or (c) as a part of the evaluation of a patient with clinical features of immunodeficiency.

The blood counts and peripheral smear are frequently abnormal in patients with constitutional symptoms, immunodeficiency, hematologic neoplasms, or a variety of other syndromes associated with lymphadenopathy or splenomegaly. Anemia, when present, usually is normochromic and normocytic. Many patients with chronic disease, MDS,

plasma cell myeloma, and, rarely, acute leukemias have anemia but no other abnormalities. In patients with anemia of unknown origin, the evaluation begins with examination of the blood smear, red cell indices, and reticulocyte count. The evaluation proceeds based on the results of these simple tests as outlined in Chapter 22.

TABLE 56.3 COMMON APPLICATIONS OF NON-FLUORESCENCE IN SITU HYBRIDIZATION MOLECULAR GENETIC TECHNIQUES

Established	Of Little or Limited Value
	Myelodysplastic syndromes ^a
B-cell lymphoma	Hodgkin lymphoma
B-cell clonality

<i>IGK@</i> PCR	
<i>IGH@/BCL2</i> PCR	
T-cell lymphoma	Non-Hodgkin lymphoma with translocations with widely spaced breakpoints (e.g., mantle cell lymphoma)
T-cell clonality	
<i>TRG@</i> PCR	
<i>TRB@</i> PCR	
Acute leukemia	
<ul style="list-style-type: none"> • Balanced translocation PCR (similar to those listed in Table 56.2 for FISH) • <i>NPM1</i>, <i>FLT3</i>, <i>KIT</i>, <i>CEBPA</i>, <i>DNMT3A</i> mutations 	
Myeloproliferative neoplasms	
<i>BCR/ABL1</i> PCR	
<i>JAK2</i> mutations	
Post-transplant engraftment	

^aEmerging mutations may become prognostically significant in myelodysplastic syndromes.

TABLE 56.4 EXAMPLES OF CLONAL PROCESSES WHICH MAY BE CLINICALLY IRRELEVANT

B-Cell Clonality

Monoclonal gammopathies on protein electrophoresis with immunofixation

Small circulating monotypic B-cell populations in healthy adults by flow cytometry

Transient clonal *IGH@* rearrangements by PCR in(1) salivary glands in Sjögren syndrome, (2) in thyroid tissues in Hashimoto thyroiditis, (3) in bone marrow following solid organ or bone marrow transplantation, (4) small biopsies (i.e., skin, gastric)

Clonal *IGH@-BCL2* rearrangements detected in low quantity in normal children and adults in blood and tonsil by ultrasensitive PCR methods

T-Cell Clonality

Transient clonal T-cell receptor rearrangements by PCR in blood of healthy elderly patient

Clonal T-cell receptor rearrangement by PCR in skin of patients with reactive dermatitis

Clonal T-cell receptor rearrangement by PCR in celiac disease

PCR, polymerase chain reaction.

Abnormal Platelet Counts

Thrombocytopenia

The major differential diagnosis of patients with thrombocytopenia includes (a) thrombocytopenia secondary to autoantibody-mediated platelet destruction (idiopathic thrombocytopenic purpura [ITP], systemic lupus erythematosus [SLE], drug-related thrombocytopenia, and perhaps human immunodeficiency virus [HIV]); (b) primary marrow disease, particularly MDS or acute leukemia; and (c) peripheral consumption secondary to intravascular activation of clotting (e.g., disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, or hemolytic uremic syndrome). Although thrombocytopenia can be secondary to a nutritional deficiency (e.g., folate, vitamin B₁₂), usually the macrocytic anemia is the dominant clinical feature.

In ITP and drug-related thrombocytopenias, the peripheral smear red cell and white cell morphology should be normal and rare giant platelets (megathrombocytes) are present. Thrombocytopenic patients with SLE may also be neutropenic and lymphopenic. Thrombocytopenia is present in up to 50% of patients with antiphospholipid antibody syndrome.⁸ Thrombocytopenia is the first sign of HIV infection in 10% of patients who may also be lymphopenic.⁹ Thrombocytopenia occurs in up to 45% of patients with hepatitis C viral infection. MDS and leukemia rarely present with isolated thrombocytopenia. Most MDS patients are anemic and have white blood cell (WBC) abnormalities (e.g., blasts or hyposegmented or hypogranulated polymorphonuclear neutrophils [PMNs]) that indicate primary marrow disease. Schistocytes and polychromatophilic red cells in patients with disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, and hemolytic uremic syndrome are helpful in pointing away from marrow disease or an autoimmune thrombocytopenia. In rare patients, platelets will satellite around PMNs or clump in blood collected in ethylenediaminetetraacetic acid. This artifact, readily apparent on examination of stained blood smears, disappears

P.1264

when blood is anticoagulated in heparin.¹⁰ Similarly, when blood is collected for platelet counts on heel sticks, clumping (also seen on smears) may produce spurious thrombocytopenia.

Congenital thrombocytopenias are rare, but can be misdiagnosed as ITP, and size of platelets may guide further evaluation.¹¹ Small platelets in a male suggest X-linked Wiskott Aldrich syndrome (WAS). Large platelets are found in von Willebrand 2B, May-Hegglin anomaly, Bernard-Soulier syndrome, and the gray platelet syndrome. Normal-sized platelets are found in amegakaryocytic thrombocytopenia, thrombocytopenia with absent radii, and familial platelet disorders with a predisposition to acute myeloid leukemia (AML).

Drug-induced thrombocytopenia (DITP) may be misdiagnosed as ITP and overlooked if patients are not asked about over-the-counter medicines, food, beverages, and/or herbal supplements.¹¹ DITP can be due to immune-mediated or non-immune processes. In a large series of patients initially diagnosed as ITP, 8% were found to have DITP with quinine (including tonic water) as the most common cause.¹² Hematologists are frequently consulted about heparin-induced thrombocytopenia (HIT) which is due to antibodies against platelet factor 4 heparin complexes and leads to an increased risk of thrombosis.¹³

Bone marrow examination with cytogenetic studies is essential only in the cases of thrombocytopenia in patients with suspected MDS or acute leukemia or in those for whom the diagnosis of autoimmune or consumptive thrombocytopenia is in doubt. In most children or young adults with otherwise normal counts and a normal blood smear, a bone marrow is probably not needed.¹⁴ Amegakaryocytic thrombocytopenias secondary to genetic or autoimmune disease are exceedingly rare.

Thrombocytosis

Thrombocytosis with platelet counts of greater than $600 \times 10^9/L$ are commonly seen transiently during a variety of infections, after splenectomy, after acute blood loss, or during recovery from marrow injury or nutritional deficiency. The concern in persistent thrombocytosis is the presence of an underlying myeloproliferative neoplasm or occult malignancy. The presence of a myeloproliferative neoplasm is almost always suggested by the peripheral blood counts and smear (e.g., polycythemia in polycythemia vera [PV], leukoerythroblastic changes in primary myelofibrosis [PMF or agnogenic myeloid metaplasia], and leukocytosis with immature myeloid precursors in CML). The one myeloproliferative neoplasm in which thrombocytosis is often an isolated finding is essential thrombocythemia (ET), a diagnosis that is supported by the

demonstration of megakaryocytic dysplasia on bone marrow examination or the demonstration of JAK2 mutations on molecular genetic studies of peripheral blood.^{15, 16} The JAK2 V617F mutation is estimated to occur in 60% of ET and myelofibrosis and 95% of PV.¹⁷ Congenital thrombocytosis is rare and results from mutations in either thrombopoietin (THPO) or its receptor (MPL).¹⁸

Morphologic Changes in Leukocytes

Morphologic changes in WBC are often diagnostic of certain rare diseases such as Alder-Reilly or Pelger-Huët anomaly, some of which are associated with infection (Chediak-Higashi syndrome) (Chapter 58).

Changes in the blood of patients with acute leukemia strongly suggest the diagnosis in virtually all patients.⁷ In approximately 60% of these individuals, the smear confirms the diagnosis by the presence of a large proportion of immature cells, whether or not the leukocyte count is increased. Blasts are easily demonstrable in blood smears of more than 90% of patients, and, even in patients whose blood smears have few blasts, anemia, thrombocytopenia, neutropenia, or combinations of these changes are suggestive of acute leukemia. For almost all such patients, bone marrow aspiration proves diagnostic and should be supplemented by flow cytometry immunophenotyping and karyotype analysis.

Lymphocytosis of Small Mature Lymphocytes

More than 5.0×10^9 small lymphocytes/L of blood in adults over 50 years of age is usually indicative of chronic lymphocytic leukemia (CLL). Many patients are asymptomatic and one-fourth are diagnosed while undergoing blood work for another problem. Flow cytometry demonstrating small B lymphocytes with weak CD20 and weak, monotypic light chain expression and coexpression of CD5 and CD23 is characteristic. Proceeding with other examinations in such patients, such as lymph node biopsy or bone marrow examination, is usually unnecessary, but immunophenotyping is required to exclude other B-cell lymphomas in the blood, such as mantle cell lymphoma, that may mimic CLL. In children, pertussis is associated with lymphocytosis of small CD4 T cells¹⁹ that may be worrisome for a lymphoid leukemia on review of the blood smear. Chronic polyclonal B-cell lymphocytosis is well described in young to middle-aged asymptomatic women who usually smoke.²⁰ These women typically present with a lymphocyte count that is less than 5×10^9 /L, the number required for a diagnosis of CLL, and the B cells are polytypic by immunoglobulin light chain studies and by PCR studies of the immunoglobulin heavy chain. Monotypic B-cell proliferations that present with less than 5×10^9 /L B cells are now classified as monoclonal B lymphocytosis rather than as overt CLL.²¹

Lymphocytosis of "Atypical Lymphocytes"

Atypical or abnormal lymphocytes are a classic feature of Epstein-Barr virus (EBV) infectious mononucleosis but also occur in other acute viral infections including cytomegalovirus (CMV), hantavirus, hepatitis, HIV, and less commonly in lymphomas with a leukemic phase (e.g., human T-lymphotropic virus -1, hepatosplenic T-cell lymphoma, etc.). Thrombocytopenia, an elevated hematocrit, neutrophilia, and circulating lymphoblasts in a patient from the desert Southwest strongly suggest hantavirus infection.²² Usually the clinical features and other routine laboratory tests such as serologic studies for viral infection make the diagnosis straightforward. When distinguishing reactive lymphocytes from leukemic blasts or the leukemic phase of a lymphoma is difficult, flow cytometry can provide invaluable help in defining the phenotype and clonality of circulating cells.

Neutrophilic Leukocytosis

The presence of CML is strongly considered in a patient with neutrophilic leukocytosis, particularly when the WBC count is greater than 50.0×10^9 /L and is accompanied by an increase in circulating immature myeloid cells and basophilia. Additional findings suggesting the diagnosis of CML include (a) symptoms of fatigue, bone pain, left upper quadrant pain, or fullness; (b) sternal tenderness and splenomegaly on physical examination; and (c) thrombocytosis. A leukemoid reaction must also be considered and can be caused by either benign, particularly infectious, or malignant conditions. Interphase FISH studies on peripheral blood for the BCR/ABL1 translocation can establish the diagnosis of CML, obviating the need for bone marrow examination; but many recommend an initial bone marrow to screen for other cytogenetic abnormalities that could affect prognosis.

Chronic idiopathic neutrophilia is defined by leukocytosis of 11.0 to 40.0×10^9 /L and is associated with smoking and obesity.²³ Familial neutrophilia (WBC $> 20.0 \times 10^9$ /L) is a rare autosomal dominant disorder which is caused by a mutation in the granulocyte colony-stimulating factor (G-CSF) receptor.²⁴ A transient myeloproliferative disorder is seen in up to 10% of children

with Down syndrome.²⁵ Neonates with persistent leukocytosis, delayed separation of the umbilical stump, and recurrent infections should be screened for leukocyte adhesion deficiency (LAD) (see section "Recurrent Infections").

Monocytosis

Monocytosis ($> 1.0 \times 10^9/L$) is commonly caused by infections, including granulomatous disease (tuberculosis [TB], fungal disease), brucellosis, infectious mononucleosis, syphilis, protozoal infections (kala-azar, malaria) and rickettsial infections. Monocytosis may be prominent in chronic myelomonocytic leukemia (CMML), juvenile myelomonocytic leukemia, or AMLs with a monocytic component.²⁶ These neoplastic monocytic proliferations cannot be distinguished on peripheral blood evaluation alone and a bone marrow examination is necessary to separate CMML from AML. Autoimmune disease, inflammatory bowel disease, and sarcoidosis may be associated with monocytosis. Monocytosis has been associated with carcinomas (lung, colorectal, renal) and has been caused by secretion of interleukin (IL)-6 by the neoplastic cells.²⁷

Eosinophilia

Unexpected eosinophilia is most commonly seen in patients with atopy or reactions to drugs or environmental allergens.²⁸ Autochthonous parasitic disease as a cause of eosinophilia is rare in the United States, but visceral larva migrans caused by *Toxocara canis* or *cati* can be seen. In international travelers and immigrants, evaluations for tissue invasive parasites is warranted. In patients who are immunosuppressed (particularly organ transplant recipients and patients on high-dose steroids for autoimmune diseases) strongyloides should be excluded.

Persistently high eosinophilia ($> 1.5 \times 10^9/L$ for > 6 months) carries significant risk for end organ damage and requires thorough investigation. A minority of these patients have elevated IL-5 levels with circulating clonal T-cell populations with aberrant phenotypes by flow cytometry.²⁹ Several neoplastic eosinophil proliferations are now recognized (see Chapter 84), including a group with a cryptic translocation involving FIP1LI-PDGFR α .^{30, 31} The latter patients can respond to imatinib therapy, while other genetic subtypes do not.

Increased Circulating Plasma Cells

Patients with plasma cell (multiple) myeloma usually have a few plasma cells in the blood, although occasionally large numbers are noted (plasma cell leukemia). Such patients almost invariably have other symptoms and signs of myeloma. A few plasma cells may also be observed in blood smears of patients with infectious mononucleosis or other viral infections. Plasma cells also are seen in the blood of persons recovering from bacterial infections or having allergic reactions, especially serum sickness. The first step when the diagnosis of myeloma is considered is to perform studies of serum and urine immunoglobulins. The technique of immunoelectrophoresis has been replaced by electrophoresis with immunofixation. This sensitive and specific technique identifies a monoclonal serum Ig and/or light chain in urine in more than 5% of patients with myeloma. The diagnosis is confirmed on bone marrow examination.

Neutropenia

Neutropenia may be mild ($ANC < 1.5$ but $> 1.0 \times 10^9/L$), moderate ($ANC < 1.0$ but $> 0.5 \times 10^9/L$), or severe ($ANC < 0.5 \times 10^9/L$).³² There can be ethnic variation, as exemplified by a prevalence of neutropenia of 4.5% among African-Americans in the United States compared to 0.79% and 0.38% in whites and Mexican-Americans, respectively.³³ While infections and drugs are the leading causes of neutropenia, nutritional deficiencies (B_{12} , folate, copper) should be ruled out early because of their responsiveness to replacement therapy. Alcohol abuse may present with isolated neutropenia, but is usually accompanied by other features of alcohol or nutritional marrow injury (macrocytosis, ringed sideroblasts). Immune-mediated neutropenia can be primary without an etiology or secondary to drugs, particularly β -lactam antibiotics and antithyroid medications; and autoimmune disease, including SLE, rheumatoid arthritis, and Graves' disease.^{34, 35, 36} Late-onset neutropenia following rituximab therapy has been reported in 5% to 27% of lymphoma patients.³⁷

Chronic idiopathic neutropenia (CIN) is a diagnosis of exclusion, rarely has increased infections, and is due to increased inflammatory changes within the bone marrow microenvironment. CIN is associated with activated T cells and increased levels of interferon γ (IFN- γ), tumor necrosis factor α , Fas-ligand, and transforming growth factor $\beta 1$, which suppresses IL-10, an antiinflammatory cytokine, and promotes apoptosis of neutrophil progenitor cells.³⁸

Hematologists should be familiar with congenital neutropenias, particularly cyclic neutropenia and severe congenital neutropenia (Kostmann syndrome), because the former can be mild and not be recognized until adulthood and the latter, which is supported by G-CSF, can evolve into leukemia in one-fifth of patients.³⁹ Mutations in the neutrophil elastase gene (ELA2) account for 60% of cases of severe congenital neutropenia, either in autosomal dominant or sporadic forms, while mutations in the HS-1-associated protein X (HAX1) gene are found in 30% of cases and are autosomal recessive.⁴⁰

Bone marrow aspiration and biopsy are usually reserved for neutropenia patients where there is an index of suspicion of malignancy usually due to immature cells in the differential; physical clues, such as adenopathy or splenomegaly; and/or other hematologic and laboratory abnormalities. MDS rarely presents as an isolated neutropenia and usually will have accompanying dysplastic abnormalities in more than one cell line. Patients with two indolent leukemias, hairy cell leukemia and large granular lymphocyte (LGL) leukemia, often present with bacterial infections secondary to neutropenia. Circulating hairy cell cases may be few in number, but a bone marrow examination with flow cytometry is usually diagnostic. LGL leukemia can be either T-cell (85% to 90%) or NK-cell (10% to 15%) in origin, is suspected when there are LGLs in the peripheral blood smear, and can be diagnosed by flow cytometry.⁴¹ Molecular genetic studies of the T-cell receptor gene can be confirmatory of clonality in T-LGL.⁴²

Lymphopenia

Lymphopenia is defined as an absolute lymphocyte count $< 1.5 \times 10^9/L$ in adults and $< 2.0 \times 10^9/L$ in children. Since 70% to 80% of circulating lymphocytes are T cells (most of which are CD4 T cells), severe lymphopenia implies T-cell deficiency and warrants serologic investigation for HIV infection. In infants with infection, the possibility of severe combined immunodeficiency (SCID) or DiGeorge syndrome is suggested. Lymphopenia is common in systemic autoimmune diseases like lupus and sarcoidosis and in serious illness/infections associated with hypercortisolism.

A variety of viral infections including influenza and measles may produce transient lymphopenia in association with loss of skin test reactivity and transient susceptibility to reactivation of TB.⁴³ One rare but noteworthy population with persistent lymphopenia is HIV-negative patients with CD4 T-cell counts less than $0.3 \times 10^9/L$. These patients fall into two categories, those susceptible to infection (who usually have low CD4/CD8 ratios) and those who have no increased susceptibility for infection with normal CD4/CD8 ratios.⁴⁴

P.1266

Peripheral Blood Findings in Infection

Blood leukocyte changes that are secondary to a variety of diseases usually consist of neutrophilia, eosinophilia, monocytosis, or abnormal-appearing lymphocytes. Changes in the distribution or appearance of circulating WBCs may provide important clues to the presence and type of an underlying infection. Eosinophilia is common in atopic individuals but can be seen in many parasitic infections. Atypical lymphocytosis is a helpful diagnostic clue in viral infections, particularly EBV infection. In many parasitic diseases, such as malaria, acute Chagas disease, and filariasis, the infectious agent may be demonstrated on peripheral blood smears. However, these three parasitic diseases are rarely autochthonous in North America, and the diagnosis is suggested by the nationality as well as the recent travel history of the patient.^{45, 46, 47}

FIGURE 56.5. Wright-stained peripheral blood smears demonstrating (A) *Mycobacteria avium-intracellulare* as negative staining rods in a monocyte from patient with human immunodeficiency virus infection, (B) *Histoplasma capsulatum* with three intracellular yeast forms in a monocyte at the feather edge of smear in patient with acquired immunodeficiency syndrome, (C) *Ehrlichia chaffeensis* as a single basophilic cytoplasmic inclusion (photomicrograph courtesy of Dr. Charles Coleman, University of Missouri), (D) *Babesia* as single intracellular ring forms in two erythrocytes, (E) *Malassezia furfur* as extracellular budding yeasts (one of which is overlying an erythrocyte) in an infant on total parenteral alimentation, and (F) intracellular bacteria in a neutrophil with an adjacent vacuolated neutrophil in a patient with septicemia.

Although in most infections the causative agents are not demonstrable in peripheral blood, there are certain notable exceptions. In acquired immunodeficiency syndrome (AIDS) patients or in other severely immunocompromised patients, mycobacteria (Fig. 56.5A), fungi, such as histoplasmosis (Fig. 56.5B), or *Candida* may occasionally be identified on the peripheral blood smear. Residents of the central United States (particularly Arkansas and Missouri) and the Southeast may acquire ehrlichiosis through tick vectors. Anaplasmosis, formerly called human granulocytic

P.1267

ehrlichiosis, is a closely related tickborne disease found more often in the Northeast and upper Midwest. The typical inclusions in mononuclear cells (*Ehrlichia chaffeensis*) (Fig. 56.5C) or in neutrophils (*Anaplasma phagocytophilum*) are present in up to one-third of these patients, who often present with unexplained fever with accompanying leukopenia and elevated transaminases. The diagnosis of ehrlichiosis/anaplasmosis may be confirmed either serologically or by PCR methods.⁴⁸ Babesiosis, first recognized in the 1890s as the cause of Texas cattle fever, has now been identified in febrile

patients in the Northeast (Nantucket, Martha's Vineyard, Connecticut), Wisconsin, and on the West Coast. Infections can be life threatening in splenectomized patients. The diagnosis is suggested by finding single ring forms (1.0 to 3.5 μm in diameter) in red blood cells (Fig. 56.5D) (characteristic tetrads are usually seen only in infected animals).⁴⁹ In nonimmunocompromised patients with indwelling venous catheters, *Malassezia furfur* (Fig. 56.5E), *Candida*, and *Torulopsis* (*C. glabrata*) may be identified in the peripheral blood.^{50, 51} In bacterial sepsis, visible circulating bacteria are rare, but the presence of cytoplasmic neutrophilic vacuoles in a fresh finger stick blood smear is a specific clue to the diagnosis of septicemia⁵² (Fig. 56.5F). Toxic granulation (also seen in patients with sepsis) is often quite prominent in uninfected patients receiving granulocyte or granulocyte/macrophage colony-stimulating factor.

EXAMINATION OF THE BONE MARROW

If a diagnosis is not established by examining the blood, bone marrow examination may be helpful (Table 56.5). Needle biopsy is usually performed in addition to aspiration, particularly if lymphoma, carcinoma, granulomatous conditions, or myelofibrosis are under consideration. To adequately triage marrow, the stained aspirate smear is reviewed along with the clinical information and any previous studies shortly after the procedure. This allows rapid decisions about cytogenetics (including FISH), molecular genetics, and flow cytometry to be made when viable cells are still available and also limits inappropriate studies (Table 56.6). In the case of inaspirable marrows, touch preparations should be made for morphologic assessment, and sufficient cells for flow cytometry may be obtained by maintaining negative pressure on withdrawal of the biopsy or aspirate needle and then rinsing the needle in nutrient media or buffered saline. In some cases, a second, fresh core biopsy can be minced and processed for flow cytometry and cytogenetic studies.

In cases of acute leukemia, the first question is whether it is lymphoid or nonlymphoid. Identification of Auer rods on Wright-stained aspirate smears is specific for a myeloid leukemia; however, Auer rods are found only in a minority of cases. Morphology is very important in the early identification of myeloid leukemias with promyelocytic differentiation, which can be sent for confirmatory FISH studies for the 15;17 translocation and can be completed in less than 24 hours. Flow cytometry is now a standard part of the diagnosis of many hematologic diseases, including all acute leukemias (Table 56.1), and for detecting minimal residual disease post therapy.^{53, 54, 55, 56, 57} Most cases (> 95%) can be classified as to lineage in less than 2 hours during the normal working hours of the laboratory. Flow cytometry is helpful in suggesting possible promyelocytic differentiation (DR^- , $\text{CD}2^+$, bright myeloperoxidase), megakaryoblastic differentiation ($\text{CD}61^+$, $\text{CD}41^+$, myeloperoxidase $^-$), or the t(8;21)(q22;q22) ($\text{CD}19^+$, $\text{CD}34^+$, myeloid antigen $^+$), but is not as useful in identifying other subsets in the French-American-British Cooperative Group (FAB) or World Health Organization classification. Cytochemical stains which were essential for FAB classification are now being performed infrequently and are now used most commonly when flow cytometry findings are ambiguous, especially in the case of possible mixed phenotype acute leukemia. Immunohistochemistry on the bone marrow core biopsy is helpful for lesions that may not be present in aspirated material, such as fibrosed areas of lymphoma or metastatic tumors. In some cases, both flow cytometry immunophenotyping and immunohistochemistry are required due to sampling differences between the aspirate and biopsy. Some cytoplasmic markers, such as BCL2 and cyclin D1, are only available by immunohistochemistry in most laboratories.

TABLE 56.5 INDICATIONS FOR BONE MARROW EXAMINATION

Unexplained cytopenia
 Evaluation of leukemia
 Confirmation of myeloproliferative neoplasm
 Unexplained lymphadenopathy
 Splenomegaly without a diagnosis
 Diagnosis or staging of lymphoid neoplasms
 Constitutional symptoms (fever, weight loss) without a diagnosis
 Bone pain with abnormal laboratory work (e.g., complete blood cell count, \uparrow protein, \uparrow lactate dehydrogenase, and \uparrow uric acid)

TABLE 56.6 SUSPECTED DIAGNOSIS ON MARROW SMEAR

Suspected Diagnosis	Flow Cytometry Cytogenetics/FISH
---------------------	----------------------------------

Acute leukemia		+	+
Suspected myelodysplasia		<i>a</i>	+
Myeloproliferative neoplasm (particularly chronic myelogenous leukemia)		<i>b</i>	+
Lymphocytosis (predominantly small cells)	Child	No	No
	Adult	+	<i>c</i>
Suspected non-Hodgkin lymphoma with large cells		+	+
Plasma cell myeloma	<i>d</i>	+	

FISH, fluorescence in situ hybridization.

^a Evolving application but not well established in many centers

^b Helpful only in blast crisis

^c If flow cytometry shows an aberrant T-cell or monotypic B-cell population

^d Flow cytometry underestimates the percentage of plasma cells in bone marrow which is better assessed by immunohistochemistry on tissue sections

FISH and cytogenetics are playing an expanded role in the classification of hematologic neoplasia and the identification of prognostically favorable and unfavorable subsets of disease.^{54, 58, 59, 60, 61} Favorable cytogenetics in AML include t(15;17)(q24.1;q21.1) (PML/RARA) of APL, t(8;21)(q22;q22) (RUNX1-RUNX1T1), and inv(16) (p13.1q22) or t(16;16)(p13.1;q22) (CBFB/MYH11); these identify patients who are predominantly treated with either all-transretinoic acid plus chemotherapy (APL) or chemotherapy alone without early transplantation. Hyperdiploidy (more than 50 chromosomes per leukemia cell) and t(12;21)(p13;q22) (ETV6-RUNX1) are found in approximately 50% of childhood acute lymphoblastic leukemia (ALL) and confer a favorable prognosis.⁶² Hypodiploidy (less than 45 chromosomes per leukemia cell), t(4;11)(q21.3;q23) (AFF4-MLL), and t(9;22)(q34;q11.2) (BCR-ABL1) are associated with a poor prognosis in ALL.

In suspected MDS, FISH and cytogenetic studies are helpful when morphologic abnormalities in hematopoietic cells are

relatively subtle.^{63, 64} Identifying 5q31 deletion in MDS is important because the patients may respond to lenalidomide.⁶⁵ Patients with abnormalities of chromosome 7 and/or complex cytogenetics are more likely to evolve to AML and should be considered for early allogeneic transplantation. Flow cytometric evaluation of MDS is an evolving application which holds great promise, although it is not well standardized in this application and thus not available at many institutions.⁶⁶ Flow cytometry is of no help in the evaluation of myeloproliferative neoplasms except when the presence of increased blasts on marrow smear point to an evolving acute leukemia/blast transformation.⁵³

Molecular genetics can identify clonality in lymphoid neoplasms, confirm diagnoses in CML and subtypes of acute leukemia, and monitor minimal residual disease when a molecular marker is present (Table 56.3). NPM1 and CEBPA mutations, when present alone, are favorable mutations in AML while FLT3 and DNMT3 mutations are usually unfavorable. In the core binding factor leukemias (AML with t[8;21][q22;q22][RUNX1-RUNX1T1] and AML with inv[16][p13.1q22] or t[16;16][p13.1;q22][CBFB/MYH11]), mutations of KIT are usually unfavorable. JAK2 mutations are present in most patients with PV and over one-half of patients with PMF and ET.^{15, 17} Genomic profiles are being evaluated in hematopoietic neoplasms and can discriminate prognostic subgroups. Restriction fragment length polymorphisms and chimerism studies identifying percentage of donor myeloid and lymphoid cells are employed to monitor engraftments in allogeneic transplantation.

Lymphocytosis on a marrow smear is common in very young children. Phenotypically, the lymphocytes are usually B cells in all stages of differentiation (so-called hematogones). In such cases, the numbers and morphology of the myeloid, megakaryocytic, and erythroid cell lines are usually normal, which is helpful in differentiating these non-neoplastic

precursor B cells from the blasts of the pre-B ALL.⁶⁷ Lymphocytosis on marrow smear in an older adult should always have phenotypic studies by flow cytometry. Further cytogenetic/FISH studies are helpful in small B-cell lymphomas with ambiguous phenotypes or in confirmation of the diagnosis of mantle cell lymphoma (by FISH).⁶⁸ In unusual proliferations, cells from the bone marrow aspiration should be frozen for possible future studies.

Bone marrow examination should also be considered in patients who complain of bone pain whether or not bone lesions have been demonstrated radiographically and particularly if there is an abnormal CBC or abnormal chemistries, such as an elevated lactate dehydrogenase (LDH), total protein, or uric acid. Some processes, including myeloma, lymphoma, carcinoma, neuroblastoma, and granulomatous infections, may be quite focal and missed on marrow examination. Occasionally, radionuclide scans with gallium-67 or indium,¹¹¹ CT, magnetic resonance imaging (MRI), and/or positron emission tomography (PET) scans may be helpful in localizing various types of tumors and identifying specific marrow sites for biopsy.^{69, 70, 71, 72, 73} Again, serum and urine electrophoresis, with immunofixation (which allows detection of monoclonal immunoglobulins hiding in the beta region) should be performed on adults with bone pain. Screening tests for neuroblastoma, including urine catecholamines, should be performed in children with bone pain and a nondiagnostic marrow examination.

EXAMINATION OF LYMPH NODES AND TISSUES

This section is concerned with the evaluation of the patient with palpable or visible enlargement of cervical, supraclavicular, axillary, inguinal, mediastinal, or hilar lymph nodes or tonsils. If the blood and marrow (when indicated, as discussed in the previous sections) fail to provide a diagnosis, the clinician should consider a fine-needle aspiration (FNA) or biopsy of enlarged lymphoid tissue. The presence of a variety of signs and symptoms may modify and shorten the diagnostic evaluation. For example, if the patient is ill with B symptoms or the clinical picture is fairly typical of a lymphoma, lymph node biopsy or aspiration should be performed immediately.

The causes of enlargement of lymph nodes are extremely varied. Table 56.7 outlines the major categories of disease leading to lymphadenopathy. This table is in no sense exhaustive. The approach to lymphadenopathy is similar to that of FUO, with the most common broad diagnoses being infection, cancer, and immune disorders. The first step is determining whether adenopathy is localized or generalized, and this differentiation points to a local disease versus systemic illness.

The most common cause of lymphoid enlargement is lymphocyte proliferation in response to antigenic stimulation.

P.1269

The frequency of trichophyton infection of toes and trauma to feet and legs is reflected in the frequency of palpable inguinal nodes (usually smaller than 1 cm in diameter). If the patient's occupation or hobby leads to frequent trauma of hands and arms, small palpable epitrochlear and axillary nodes are expected. Thus, the assessment of the lymphoid system in a laborer differs somewhat from that of an educator (unless the latter's hobby is gardening or hunting).

TABLE 56.7 CONDITIONS LEADING TO LYMPH NODE ENLARGEMENT

Lymphadenopathy Primarily Related to Immune Response from Infections

Viral infections

Local or generalized lymphadenopathy with systemic infections (e.g., infectious mononucleosis (cervical), rubella (occipital), infectious hepatitis, and acquired immunodeficiency syndrome)

Pyogenic infections

Local enlargement of nodes draining areas of local infection (e.g., furuncles caused by staphylococci and oral infection)

Local enlargement of nodes draining the portal of entry of infections such as cat scratch fever, cryptococcosis, lymphogranuloma venereum, primary chancre of syphilis, and tularemia

Generalized lymphadenopathy from (e.g., *Salmonella* septicemia bacterial endocarditis, secondary syphilis, and toxoplasmosis)

Lymphadenopathy primarily from infection of the node by organisms

Pyogenic infection: the classic example is the bubo of *Pasteurella pestis*; more commonly, abscess

formation by staphylococcal invasion

Granuloma formation: the entrance of tubercle bacilli or fungi, such as *Histoplasma capsulatum*, into nodes often results in granuloma formation as well as hypertrophy; identifiable organisms can be present within the granuloma.

Neoplasia

Primary neoplastic diseases of nodes: non-Hodgkin and Hodgkin lymphomas

Metastatic neoplastic processes occurring in nodes

Lymphoid leukemias: acute lymphoblastic leukemia and chronic lymphocytic leukemia

Myeloid leukemias: acute myeloid leukemia (granulocytic sarcoma) and chronic myelogenous leukemia

Primary myelofibrosis with extramedullary hematopoiesis, producing lymph node enlargement

Metastases from carcinoma, producing lymph node enlargement

Autoimmune Diseases (e.g., systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, and Hashimoto thyroiditis)

Reaction to Drugs, such as the Hydantoins

Dermatopathic Related to Skin Diseases

Miscellaneous Diseases

Granuloma formation as seen with sarcoid or in patients exposed to beryllium

Reactive hyperplasia, as seen in hyperthyroidism

Progressive transformation of germinal centers

Kikuchi-Fujimoto disease (histiocytic necrotizing lymphadenitis)

Kawasaki disease

Castleman disease

Histiocytic disorders

Langerhans cell histiocytosis

Erdheim Chester disease

Rosai Dorfman disease

Children and adolescents commonly have more palpable nodes than do adults.⁷⁴ This difference is presumed to reflect their more frequent exposure to new antigens and a larger total lymphoid mass in relation to body weight as compared to adults. Thus, significant generalized adenopathy has a more liberal definition in the young than in adults. Prominently visible tonsils, protruding into the oropharynx, are expected in preschool children but are uncommon in adults.

Retroperitoneal lymphadenopathy must be extreme before an abdominal mass becomes palpable. CT scan and lymphangiography (LG) provide complementary information concerning the status of retroperitoneal lymph nodes, although LG is no longer used.⁷⁵ Abdominal CT scan provides images of nodal areas that usually are not visualized with LG, such as pararectal, omental, and superior retroperitoneal areas, and the hilus of the spleen and liver. Other imaging techniques, such as PET scan, gallium scan, and radiolabeled monoclonal antibody scans, may further delineate worrisome lymph nodes.

Improvements in imaging and clinical dependence upon imaging has led to its increased use and contributed to the rising cost of health care.⁷⁶ Additionally, imaging techniques are so sensitive that incidental findings of uncertain clinical significance such as chest, adrenal, or renal masses may require additional evaluation, which further contributes to the expense.⁷⁷ In conjunction with CT scans, PET scans are used to assess extent of disease and response to therapy in HL and many types of non-Hodgkin lymphoma (NHL).⁷⁸

Experience with many patients is the best guide in the selection and timing of lymph node biopsies or FNA. If doubt exists as to whether enlargement is significant, the choice between immediate biopsy or periodic observation to discover whether the nodes will enlarge or shrink should be made on the basis of ancillary findings. If other signs and/or symptoms are suggestive of lymphoma, biopsy of small, questionably enlarged nodes may yield a diagnosis. Biopsy should be performed after no more than 1 or 2 months of observation if the physician is still suspicious that the nodes are abnormal. Again, however, the physician's suspicion must be tempered by experience. Persistently enlarged lymph nodes considered abnormal in an adult may be well within the limits of normal in a child or adolescent patient.

There is no absolute size which can be used to determine the presence of pathology. Age of the patient, history, location, and physical evaluation assist in making a decision about biopsy. A size of 1.5 cm was used as a discrimination measurement in a study of 220 lymph node biopsies.⁷⁹ Others have suggested that a persistent lymph node of 10 mm or more except in the inguinal region is a reasonable guideline. A multifactorial, retrospective analysis involving 22 clinical findings was made of 123 patients, ages 9 to 25 years, in whom results of lymph node biopsies were known.⁸⁰ Only three variables proved to have significant discriminatory function; nodes larger than 2 cm in diameter on physical examination and abnormal findings on chest radiographs favored the diagnosis of a disorder necessitating treatment, whereas a history of recent symptoms related to otolaryngologic disease in the presence of enlarged cervical nodes was strong evidence against the presence of a disease requiring therapy.

Certain physical characteristics of nodes aid in the diagnosis of the cause of lymphadenopathy. Infected nodes usually are tender, and the overlying skin often is inflamed. Such nodes may be matted together. In certain types of infection, such as TB, aspergillosis, or actinomycosis, sinus tract formation is common. Infected nodes may be fluctuant. Nodes undergoing an immune response to infection also may be tender, but other signs of inflammation usually are absent. Tenderness may be related to other conditions, but this is uncommon. Carcinomatous nodes usually are hard and may be bound to one another and to surrounding tissue. Lymphomatous nodes are more often firm, rubbery, discrete, and freely movable; occasionally, anaplastic large cell lymphoma has a significant inflammatory component.

The location of the nodes may be helpful in diagnosis, and, again, the age and immunocompetence of the patient are critical factors in determining the approach. Axillary and inguinal adenopathy are often enlarged because of trauma or infection distally. Cervical lymphadenopathy is often due to localized infection but also can represent metastatic disease from the head and neck. Posterior occipital lymphadenopathy is classically seen in rubella (also toxoplasmosis) usually in conjunction with a maculopapular rash. Supraclavicular lymphadenopathy more often represents distant metastases or contiguous spread from the mediastinum. Isolated mediastinal adenopathy in a young person is usually HL. Large, bilateral hilar nodes without other detectable adenopathy are unusual in lymphomas and are more suggestive of sarcoidosis.

Infections may be either localized or generalized as the cause of lymphadenopathy. The most common forms of localized infections with cervical lymphadenopathy are pharyngitis and tonsillitis due to viral, mycoplasmal, and pyogenic infections (*Streptococcus*, *Staphylococcus aureus*, and *S. epidermidis*).⁸¹ Although the above usually cause bilateral adenopathy, unilateral adenopathy occurs with tonsillar abscesses, salivary adenitis, and dental abscesses.⁸² Systemic infections that may present with localized adenopathy include cat scratch disease, Lyme disease, tularemia, toxoplasmosis, and bubonic plague, but these patients usually have constitutional symptoms and may give a history of animal or tick exposure, or have a characteristic rash (e.g., Lyme disease). TB involving the cervical lymph nodes (scrofula) is one of the more common presentations of extrapulmonary TB.⁸³ Adenopathy in HIV patients tends to be generalized and painless and can be due to HIV alone or other infections (e.g., atypical mycobacteria, toxoplasmosis, syphilis) or lymphoma.

Immunologic disorders may present with adenopathy as a prominent clinical feature. Kikuchi-Fujimoto disease (histiocytic necrotizing lymphadenitis) is a self-limiting illness characterized by cervical adenopathy and systemic symptoms; excisional biopsy is often performed to rule out neoplasia.^{84, 85} Kawasaki disease is a multisystem vasculitis of infants and children usually with mucocutaneous lesions and cervical adenopathy; therapy with intravenous gammaglobulin and aspirin can prevent or ameliorate coronary artery abnormalities.^{86, 87} Patients with SLE and rheumatoid arthritis may develop adenopathy but usually have characteristic clinical features and serology. Early lymph node biopsy should be considered in patients at increased risk for developing lymphoma such as those with an underlying autoimmune disorder (e.g., Sjögren syndrome and rheumatoid arthritis treated with methotrexate) or immunodeficiency (e.g., HIV infection and posttransplant). Drugs, such as phenytoin, allopurinol, and cephalosporins, can be associated with diffuse adenopathy that may regress with discontinuation of the drug.

In the event of a strong presumption of malignancy (particularly metastatic carcinoma or in patients with a previous diagnosis of lymphoma), or in lymphadenopathy in areas difficult to biopsy (retroperitoneum), needle biopsy or aspiration is becoming the primary procedure for diagnosis^{88, 89} (Table 56.8). The procedure for lymph node aspiration is simple and can produce diagnostic information in the time it takes to stain and examine the smears. In addition the use of cultures,

flow cytometry, and cytogenetic studies on aspirated material greatly amplify the quality of diagnostic information and its availability.⁹⁰ This approach requires a two-step triage: 1) rapid examination of the smear to determine

P.1270

if flow cytometry is warranted; 2) if flow shows evidence for a neoplasm, deciding whether or which cytogenetic/FISH/molecular genetic studies are indicated. However, the frequency of indeterminate or incorrect diagnosis is higher with needle biopsy aspiration than with excisional biopsy, as the histologic diagnosis often depends on changes in the overall architecture of the lymph node in addition to the cytology of individual cells.⁹¹ Excisional biopsy yields more tissue for diagnostic studies, facilitating preparation of multiple histologic sections for routine and special stains as well as providing more adequate material for cultures and immunophenotypic and genetic studies. Therefore, when appropriate, excisional lymph node biopsy is preferred over FNA or core biopsy for complete diagnostic evaluation.

TABLE 56.8 APPLICATION OF FINE-NEEDLE ASPIRATION OF LYMPH NODES AND EXTRANODAL MASSES

Established^a	Limitations
Diagnosis of relapse in lymphoma	Primary diagnosis of lymphoma ^a
Diagnosis of nonhematologic malignancies	Specific diagnoses of reactive processes
Presumptive diagnosis of reactive processes	
Primary diagnosis of many nonhematologic malignancies and metastases	

^aMost of these require flow cytometry as an adjunct. In processes which are focally neoplastic or tumor cells are in minority (Hodgkin and T-cell-rich B-cell lymphoma), a missed diagnosis is possible.

For excisional biopsy or FNA, the largest palpable node available is given preference. More than one node should be removed, if possible, avoiding irradiated areas. When other considerations are equal, biopsy of cervical or supraclavicular nodes is preferable to biopsy of axillary nodes, and biopsy of nodes from any of these regions is preferable to that of inguinal nodes. As previously mentioned, inguinal nodes frequently are enlarged from chronic foot infection, in which case the architecture often is distorted. Axillary nodes, unless enlarged, may be difficult to find during surgical procedures because of the complex and changed anatomy during exposure of this area.

TABLE 56.9 GUIDELINES FOR EVALUATION OF LYMPH NODE BIOPSIES/FINE-NEEDLE ASPIRATION

Tests to Consider	Touch Prep Cytology					
	Small Lymphocytes	Adult	Mixed Small Lymphocytes and Large Lymphocytes (No Atypical Large Cells)	Child or young adult	Adult	Mixed Small and Large Lymphocytes (A Few Large Atypical Cells)
Age of patient	Child or young adult	Adult	Child or young adult	Adult	Child or adult	Child or adult
Flow cytometry	No	Yes ^a		Yes ^b		Yes
Cytogenetics/molecular genetics/FISH	No	^c	^d	^d	^d	Yes

FISH, fluorescence in situ hybridization.

^aIf clinical features are highly suggestive of non-Hodgkin lymphoma or tissue is from a site difficult to sample (e.g., mediastinum or retroperitoneum) a limited panel for B-cell clonality and T-cell

distribution may be helpful.

^b If clinical features and gross appearance are typical for Hodgkin lymphoma, flow cytometry and genetic studies are unlikely to be helpful.

^c If flow cytometry suggests a neoplastic process.

^d Usually not helpful except if screening flow cytometric studies demonstrate an abnormal B- or T-cell population.

In the “good old days” when most diagnoses of disease involving marrow or lymph nodes were made (or not made) based solely on the morphology of smears and tissue sections, coordination of the efforts of the clinician, surgeon, and pathologist was less important and much less complex. Today, with a bewildering array of morphologic, cytochemical, immunologic, molecular genetic, and cytogenetic techniques available (and essential for many diagnoses), the clinician, surgeon, and pathologist must work closely together to optimize the diagnostic information of any biopsy while, at the same time, limiting expense. The major pitfall in these efforts is improper specimen handling, precluding the use of important techniques available only in fresh tissue (i.e., cultures for pathogens, cytogenetics, and flow cytometry for surface markers).

The process of evaluation begins before the procedure. The studies that are done are guided by clinical information and a review of previous biopsy material. At the time of biopsy or needle aspiration, the studies available within minutes of the procedure (i.e., the Wright-stained marrow aspirate smear of bone marrow or the hematoxylin- and eosin-stained smear of a lymph node biopsy touch prep) are used to decide which diagnostic techniques will be applied to any given case. If the suspicion of infection is high, material for cultures is best obtained in the sterile environment of the operating room before sending it to pathology.

Table 56.9 includes guidelines for the diagnostic evaluation of tissue biopsies and aspirations based on clinical information and the aspirate smear/touch prep appearance. The most important clinical information is the likelihood that a process is (a) NHL, (b) HL, (c) a carcinoma, or (d) a reactive process. The clinical information, including the age of the patient along with the touch prep or smear appearance, often helps in determining whether flow cytometry or cytogenetics is needed (as in many cases of NHL or leukemia).

NHL would be uncommon in a child or young adult with a predominance of small lymphocytes on touch preps (Fig. 56.6A), but would more likely occur in an elderly patient. In a child or teenager, the major differential diagnosis would be between a reactive node or lymphocyte-predominant HL. In neither diagnosis would flow cytometry or cytogenetics be of much benefit. On the other hand, in an older patient in whom a small B-cell NHL is more likely, immunophenotyping is of great help in proving clonality and in identifying immunophenotypic patterns characteristic of subsets of NHL of therapeutic and prognostic significance (e.g., hairy cell leukemia and mantle cell lymphoma). The role of FISH

P.1271

and cytogenetic studies is assuming increasing importance in the diagnosis of small B-cell lymphomas, particularly follicular (t[14;18]) and mantle cell (t[11;14]) lymphoma, and is prognostically important in subsets of extranodal marginal zone lymphoma (e.g., t[11;18]).^{92, 93, 94, 95}

FIGURE 56.6. High power of hematoxylin eosin-stained touch preps of lymph node biopsies demonstrating (A) predominance of small lymphocytes in an adult with small lymphocytic lymphoma/chronic lymphocytic leukemia; (B) mixed pattern of small and large lymphocytes, macrophages, plasma cells, and neutrophils in a child with reactive adenitis; (C) mixed population of small and large lymphocytes with occasional large atypical cells in a patient with classical Hodgkin lymphoma; and (D) predominance of large lymphocytes (many with polylobate nuclei) in a patient with large B-cell lymphoma of the mediastinum.

In children and young adults with a touch prep showing a polymorphous mix of small and large lymphocytes and inflammatory cells (Fig. 56.6B), flow cytometry is not routinely performed. Most patients with this mixed pattern on touch preps will have a reactive process or HL (Fig. 56.6C); however, a few B-cell NHL and peripheral T-cell lymphomas may show such patterns. If the clinical likelihood of NHL is high, or in those patients with occasional large atypical cells who do not have clinical features of HL, a limited and inexpensive panel for B-cell clonality and T-cell antigen loss can be performed. If these studies demonstrate an abnormality either in the small or large cell population, then more expanded panels can be run. If the case is not typed and on permanent tissue sections appears to be NHL, immunophenotyping can be performed on paraffin sections and information about clonality (T and B) can be retrieved from frozen tissue or the paraffin-embedded tissue as needed.^{96, 97}

In patients with numerous large cells or blasts on a touch prep (Fig. 56.6D) typing studies (and in many, cytogenetics) are essential in identifying prognostically significant patient subgroups. For example, in patients with blast cells on touch prep, the differential diagnosis would be lymphoblastic lymphoma (both B and T), blastic transformation of mantle cell lymphoma, and extramedullary acute leukemia. Flow cytometry is quite useful in the differential diagnosis and can provide an answer in hours (well in advance of other cytogenetic or immunohistologic techniques) (Figs. 56.2 and 56.3). Tissue should also be placed in glutaraldehyde for electron microscopy in these cases, because poorly differentiated tumors, such as neuroblastoma or rhabdomyosarcoma, may mimic hematopoietic neoplasms on touch prep.

A histologic appearance of reactive hyperplasia or of nonspecific granulomatous changes does not rule out the possibility of HL or NHL at another site. For example, not all enlarged nodes from patients known to have HL show evidence of the disease⁹⁸; it is not surprising that the first biopsy may give negative findings in a patient in whom a second biopsy is diagnostic.^{99, 100} Similarly, analysis of surface antigens on cells from an initial biopsy that may not contain the tumor may indicate that the B-cell population is polyclonal when later specimens containing the tumor show a monoclonal

proliferation.¹⁰¹ Molecular studies may identify monoclonal lymphoid populations earlier than flow cytometry or routine immunoperoxidase stains in selected cases. In equivocal or difficult cases, particularly those in which there are discrepancies between the histologic diagnosis, the clinical picture, and the results of ancillary studies, consideration should be given to obtaining consultation in hematopathology.¹⁰² If more than one node is removed initially, the likelihood of positive findings is enhanced. In nondiagnostic biopsies, the decision to obtain more

P.1272

tissue for further study must be individualized. If no other nodes are enlarged and the patient has few or no symptoms, observation may be advisable. Prompt diagnosis and proper therapy are important in bacterial and fungal infections, HL, aggressive NHL, and acute leukemias, but are less important for the eventual outcome of the other conditions listed in Table 56.7.

EXAMINATION OF THE SPLEEN

Many of the conditions that lead to lymphadenopathy also produce a palpably enlarged spleen. Consequently, the preceding discussion regarding evaluation of the patient with lymphadenopathy is equally applicable to the patient with splenomegaly. When splenomegaly is associated with systemic infection (acute splenic tumor), the spleen usually is barely palpable, soft to firm, but not hard, and splenomegaly disappears shortly after recovery from the infection. A palpable spleen usually indicates disease, but a soft spleen tip can be palpated by an experienced physician in approximately 1% to 2% of apparently healthy persons.¹⁰³

Splenic puncture may be helpful in the evaluation of patients with certain conditions (e.g., leishmaniasis and kala-azar), but is rarely used in North America.^{104, 105} Diagnostic splenectomy is required in some patients, especially those in whom the only palpably enlarged tissue is the spleen. Before this procedure is considered, however, numerous other studies should be considered and may include CT scan, liver/spleen scan, and other imaging studies to outline splenic vein patency, as well as hepatic blood flow and any associated adenopathy. In many cases, results of these studies indicate the diagnosis. For instance, splenic hypertrophy owing to increased red cell destruction, such as occurs in hereditary spherocytosis and thalassemia, should be detected by means of appropriate blood and other examinations. Biopsy of enlarged nodes should always be carried out before splenectomy is undertaken. Examination of the marrow should also be considered. Liver function tests (LFTs) and needle biopsy of the liver also are warranted to exclude, among other considerations, the possibility that the splenomegaly results from hepatic disease, producing increased portal pressure.

Indications for splenectomy are discussed in Chapter 65 and elsewhere in relation to the various diseases associated with splenomegaly. If no explanation is found for splenomegaly, splenectomy should be considered to make or to exclude a diagnosis of lymphoma.

FEVER OF UNKNOWN ORIGIN

The classic definition of FUO proposed by Petersdorf and Beeson in 1961 is a temperature elevation of 38.3°C (101°F) or higher persisting over 3 weeks in duration and without a diagnosis after 1 week of intensive in-hospital investigation.¹⁰⁶ The definition of FUO has been modified due to the changing medical environment which required a shift to an initial outpatient evaluation. Durack and Street proposed the duration of evaluation for FUO be changed to only 3 days of hospitalization or at least 3 outpatient visits or 1 week of ambulatory investigation.¹⁰⁷ Because of changing medical practices and different types of patients with prolonged fever, FUO is currently subdivided according to four categories: (a) classic FUO, (b) nosocomial FUO, (c) immune-deficient FUO, and (d) HIV-related FUO. Host factors (e.g., age of the patient and immunocompetence) and environment (e.g., socioeconomic status and geographic location) are factors in the evaluation of FUO. Arnow and Flaherty have proposed a minimum number of tests to be performed prior to labeling a patient with FUO.¹⁰⁸

The “big three” categories of FUO remain infections, autoimmune or non-infectious inflammatory disease (NIID), and malignancies (Table 56.10), although the incidence of cancer has

P.1273

declined due to improved diagnostic techniques.¹⁰⁹ Miscellaneous diseases and undiagnosed conditions round out the main five categories of FUO. There are over 200 different causes of FUO, but most patients have common illnesses presenting with unusual manifestations.¹⁰⁶ In a systematic review of the literature for 1995 to 2004 which identified 1,488 cases of FUO, 74% of the patients were accurately diagnosed, with 37% due to infections, 16% due to NIID, 11% due to neoplasms and 10% due to miscellaneous diseases.¹¹⁰ In developing countries, infections, particularly TB, often represent

more than one-half the cases of FOU, whereas developed countries have a higher incidence of NIID and neoplasms.¹¹¹ Undiagnosed conditions and infections are more common in younger patients, whereas NIID, including temporal arteritis and polymyalgia rheumatica, and malignancies are more common in the elderly. Despite improved imaging and better culture techniques, the percentage of undiagnosed conditions has increased to the 25% to 50% range in recent series and is higher in children.^{112, 113}

TABLE 56.10 DISEASES CAUSING FEVER OF UNKNOWN ORIGIN

Malignancy

Common

Hodgkin lymphoma

Non-Hodgkin lymphoma

Hypernephroma

Metastatic carcinoma: liver, central nervous system

Uncommon/rare

Hepatomas

Pancreatic carcinoma

Acute leukemia/myelodysplastic syndrome

Atrial myxoma

Neuroblastoma

Central nervous system tumor

Infection

Common

Tuberculosis: extrapulmonary— renal, meningitis, miliary

Abscesses

Intraabdominal

Subdiaphragmatic (periappendiceal, pericolic, hepatic)

Pelvic

Uncommon

Abscesses: splenic, perinephric, dental, brain

Subacute bacterial endocarditis (if culture-negative, suspect rightsided endocarditis, intravenous drug abuse)

Cytomegalovirus

Toxoplasmosis

Salmonella enteric fevers

Rare

Localized, culture-negative infections: sinusitis, osteomyelitis, chronic meningitis, cholecystitis, urinary tract infection, mastoiditis

Viruses: Epstein-Barr, hepatitis (all types), human immunodeficiency virus, parvovirus, other

Cat scratch disease

Brucellosis

Listeriosis

Spirochetal infections

Relapsing fever

Lyme disease

Leptospirosis

Rat bite fever

Rickettsial infections: Rocky Mountain spotted fever, endemic typhus,

Q fever, ehrlichiosis, trench fever, bacillary angiomatosis

Parasitic disease: malaria, babesiosis, toxoplasmosis, trypanosomiasis, leishmaniasis, trichinosis, amebic liver abscess

Fungal infections: blastomycosis, histoplasmosis, coccidioidomycosis, cryptococcosis, candidiasis

Yersinia infections

Chlamydial infections: psittacosis, lymphogranuloma venereum

Foreign object-related infections: vascular grafts, indwelling catheters, prosthetic devices

Vascular infections: aortic aneurysm, jugular phlebitis

Autoimmune Disease

Common

Still disease

Giant cell (temporal) arteritis

Uncommon

Periarteritis nodosa

Rheumatoid arthritis

Wegener granulomatosis

Rare

Systemic lupus erythematosus

Vasculitis (Takayasu arteritis, hypersensitivity vasculitis)

Felty syndrome

Acute rheumatic fever

Pseudogout

Sjögren syndrome

Behçet disease

Familial Mediterranean fever

Polymyositis

Tumor necrosis factor receptor-associated periodic syndrome

Miscellaneous

Common

Drug fever

Cirrhosis

Alcoholic hepatitis

Uncommon: granulomatous hepatitis

Rare

Gastrointestinal: regional enteritis,

Whipple disease

Endocrine: hyperthyroidism, hyperparathyroidism, pheochromocytoma, Addison disease, subacute thyroiditis, hypothalamic dysfunction

Granulomatous disease: sarcoidosis

Vascular related: pulmonary emboli, subacute dissecting aneurysm, giant hepatic hemangioma, occult hematomas

Immune-related: hyper-immunoglobulin D syndrome, pseudolymphoma

Factitious fever

Habitual hyperthermia

Cyclic neutropenia

Other: Fabry disease, Kikuchi-Fujimoto disease, Weber-Christian disease, mesenteric fibromatosis, malakoplakia, Castleman disease, hemophagocytic syndromes

Undiagnosed Conditions

Adapted from Cunha BA. Fever of unknown origin. In Gorbach SL, Bartlett JB, Blacklow NR, eds. *Infectious diseases*, 3rd ed. Philadelphia, PA: Lippincott, Williams and Wilkins, 2004: 1569-1578.

Nosocomial FUO is a particular problem for the patient in an intensive care unit and is related to the type of instrumentation (indwelling vascular lines, Foley catheters, and endotracheal tubes),¹¹⁴ the specific spectrum of microorganisms and their antimicrobial sensitivity, and the degree of immunodeficiency. Common conditions causing nosocomial FUO include septic thrombophlebitis, pulmonary embolism, *Clostridium difficile* enterocolitis, and drug fever.¹¹⁵ More than 60% of FUO in the immunodeficient host is due to infections; the type and severity of infection correlate with the severity and length of neutropenia.¹¹⁶ Occult fungal infections, including hepatosplenic candidiasis, aspergillosis, and mucormycosis should be considered in the immunodeficient host with prolonged neutropenia.¹¹⁵

The initial exposure to HIV may cause FUO, and the HIV may go undetected due to lack of seroconversion.^{117, 118} FUO in HIV patients is due to an opportunistic infection in over 70% of patients.¹¹⁹ Atypical and typical mycobacteria are the most common infections in HIV patients; other infections causing FUO in AIDS include CMV, *Pneumocystis jiroveci*, toxoplasmosis, histoplasmosis, leishmaniasis, and cryptococcosis. In Asia, *Penicillium marneffei* is a common cause of FUO in HIV patients; papular skin lesions with central necrosis are seen in 70% of HIV patients.¹²⁰ Lymphoma, both aggressive B-cell NHL and HL, multicentric Castleman, and drug reactions may also be a cause of FUO in HIV patients. Long-lasting fever in HIV without a diagnosis is seen in patients with advanced HIV and low CD4⁺ T lymphocytes.¹¹⁸ The use of highly active antiretroviral therapy (HAART) in AIDS has led to a decline in FUO.^{118, 121} After the start of HAART, an immune reconstitution inflammatory syndrome is seen in 25% to 35% of HIV-positive patients and usually occurs within 2 months. The patient can deteriorate due to worsening of an opportunistic infection, particularly *Mycobacterium tuberculosis*, *M. avium* complex, or *Cryptococcus neoformans*.¹²²

The pattern of fever has been extensively evaluated, but rarely is so specific as to be diagnostic of a disease. Possible exceptions include a Pel-Ebstein pattern of recurrent high fever with intermittent afebrile, asymptomatic periods in HL; the tertian and quartan patterns of malaria; the pulse-temperature dissociation of typhoid fever; the reversal of the normal diurnal pattern observed in disseminated TB; and a cyclical pattern (every 3 to 4 weeks) with cyclic neutropenia.¹²³

A continuous fever is more likely to be diagnosed than a periodic fever.^{124, 125} The prognosis of a patient with undiagnosed FUO is favorable, with mortality less than 5%.¹²⁶

In the evaluation of a patient with FUO, history and physical examinations often need to be repeated.^{119, 127, 128} Host factors (e.g., HIV, sickle cell disease, prior malignancy, organ transplant, cardiac valve disease, diabetes, and prior surgery) and external factors (e.g., occupation; travel; and exposures to infections, animals, and drugs) may point to the types of studies warranted to diagnose the etiology of FUO. The goal of the history and physical examination is to identify potentially diagnostic clues. The physical examination should pay particular attention to the skin (e.g., rashes, subcutaneous nodules, aphthous ulcers, and nail beds), eyes (e.g., uveitis and Roth spots and infections on fundoscopic examination), sinuses, lymph nodes, heart (e.g., rubs and murmurs), lungs, organomegaly, and perirectal area. Bone, joint, and musculoskeletal examinations are important when symptoms of pain, limping, or weakness are associated with FUO.

The laboratory evaluation of FUO involves a minimal set of tests which may further direct the investigation: CBC, sedimentation rate, C-reactive protein; comprehensive metabolic profile, including lactose dehydrogenase; urinalysis, antinuclear antibodies, rheumatoid factor; viral screens, particularly CMV, EBV, and HIV; tuberculin skin test, and chest x-ray and/or CT scans of specific areas as determined by history and/or physical exam. Three sets of routine blood cultures have been added to the initial battery of tests.¹⁰⁸ If a patient has two of the three laboratory abnormalities: elevated C-reactive protein, elevated ferritin but < 500 µg/L, or eosinopenia, infection is more likely than non-infection.¹²⁹

Table 56.11 outlines possible etiologies as suggested by the findings on CBC and sedimentation rate or C-reactive protein. Anemia, an abnormal white cell count, elevated LFTs, and elevated LDH were independent predictors of having a serious illness, commonly neoplasia, and a poor prognosis for patients with FUO.¹³⁰ Examination of the blood smear for abnormal cells or pathogens may be warranted according to history, such as travel or tick exposure; or physical exam, particularly petechia, adenopathy, or organomegaly. Flow cytometry can be confirmatory in specifying the type of malignant cell. Ehrlichiosis, malaria, leishmaniasis, histoplasmosis, TB, and babesiosis are among the diseases in which organisms may be seen in the peripheral blood.

NIID that have remained a cause of FUO are those that are not readily diagnosed by serologic testing, such as temporal arteritis and Still disease.¹³¹ Giant cell, or temporal, arteritis (GCA) represented 17% of cases of FUO in the elderly and is suggested by jaw or tongue claudication, localized headaches, visual disturbances, and temporal artery abnormalities (e.g., decreased pulse, tenderness, or nodularity). The diagnosis is suggested by an elevated sedimentation rate (> 50 mm/hour) and formerly was confirmed by an abnormal temporal artery biopsy. Color Doppler ultrasonography and high resolution MRI can diagnose GCA in most patients so that biopsy may be reserved for patients with

P.1274

negative imaging.¹³² Adult onset Still disease can present as an FUO in a younger patient with or without a characteristic rash. Four variables associated with Still disease are arthritis, pharyngitis, splenomegaly, and neutrophilia.¹³³ The highest elevations in serum ferritin are seen in Still disease and hemophagocytic lymphohistiocytosis (HLH).

TABLE 56.11 COMPLETE BLOOD CELL COUNT CLUES TO FEVER OF UNKNOWN ORIGIN

Monocytosis	Eosinophilia	Elevated Erythrocyte Sedimentation Rate (> 100 mm/h)
Tuberculosis	Trichinosis	Adult Still disease
Brucellosis	Lymphomas	Temporal arteritis
Subacute bacterial endocarditis	Drug fever	Hypernephroma
Polyarteritis nodosa	Addison disease	Subacute bacterial endocarditis
Temporal arteritis	Polyarteritis nodosa	Drug fever
Cytomegalovirus	Hypersensitivity vasculitis	Carcinomas
Sarcoidosis	Hypernephroma	Lymphomas
Systemic lupus erythematosus	Myeloproliferative neoplasms	Myeloproliferative neoplasms

Lymphomas	Thrombocytopenia	Abscesses
Carcinomas	Acute leukemias	Subacute osteomyelitis
Regional enteritis	Lymphomas	Polymyositis
Myeloproliferative neoplasms	Myeloproliferative neoplasms	Hyperimmunoglobulin D syndrome
Myelodysplastic syndrome		
Atypical Lymphocytosis	Relapsing fever	Basophilia
Epstein-Barr virus	Epstein-Barr virus	Carcinomas
Cytomegalovirus	Drug fever	Lymphomas
Brucellosis	Systemic lupus erythematosus	Myeloproliferative neoplasms
Toxoplasmosis	Human immunodeficiency virus	Lymphocytosis
Drug fever	Leukopenia	Tuberculosis
Thrombocytosis	Miliary tuberculosis	Epstein-Barr virus
Myeloproliferative neoplasms	Brucellosis	Cytomegalovirus
Tuberculosis	Systemic lupus erythematosus	Toxoplasmosis
Carcinomas	Lymphomas	Non-Hodgkin lymphoma
Lymphomas	Acute leukemia	Lymphocytopenia
	Myelodysplastic syndrome	
Sarcoidosis	Typhoid fever	Human immunodeficiency virus
Vasculitis	Kikuchi disease	Hodgkin lymphoma
Temporal arteritis		Whipple disease
Subacute osteomyelitis		Tuberculosis
Hypernephroma		Systemic lupus erythematosus
		Sarcoidosis

Adapted from Cunha BA. Fever of unknown origin. In Gorbach SL, Bartlett JB, Blacklow NR, eds. Infectious diseases, 3rd ed. Philadelphia, PA: Lippincott, Williams and Wilkins, 2004:1569-1578.

HLH may be familial, with 70% to 80% occurring in children under the age of 1 year, or sporadic secondary to infections, malignancies, particularly peripheral T/NK lymphomas, or autoimmune diseases. The most common features of HLH are FUO, hepatosplenomegaly, and cytopenias; and a diagnosis can be made by confirmation of an underlying genetic defect (in 80% of familial cases), or by having five of eight clinical criteria, including ferritin ≥ 500 $\mu\text{g/L}$, soluble CD25 (IL-2 receptor) $\geq 2,400$ U/ml, and decreased natural killer cell activity.^{134, 135, 136} Early diagnosis of HLH is critical because of a high early mortality, varying from 20% to 70%, and the availability of effective therapy.^{134, 137} After the syndrome is controlled by immunotherapy with a combination of dexamethasone, etoposide, and cyclosporine, familial forms of HLH which have mutations in genes regulating the granule-dependent exocytosis pathway, and genetic immune deficiencies, such as X-linked lymphoproliferative (XLP), Chediak-Higashi, and Hermansky-Pudlak, should undergo allogeneic stem cell transplant.^{134, 136, 138}

Rare, hereditary disorders characterized by recurrent episodes of fever and autoimmune features include familial Mediterranean fever, tumor necrosis factor receptor-associated periodic syndrome, and the hyperimmunoglobulinemia D syndrome.¹³⁹ Familial Mediterranean fever is an autosomal recessive disorder and is caused by mutations in the pyrin-marenostrin gene MEFV, which provides inhibitory signals to inflammatory cells.¹⁴⁰ Tumor necrosis factor receptor-associated periodic syndrome is an autosomal dominant condition caused by missense mutations in the gene encoding type I tumor necrosis factor receptor (TNFRSF1A), which results in an exaggerated response to tumor necrosis factor.¹⁴¹ Hyperimmunoglobulin D syndrome is due to mutations in the gene mevalonate kinase (MVK), but the mechanism producing fever and autoimmune features is unknown.¹⁴²

Two diseases that can be overlooked are factitious fever and Whipple disease.¹⁴³ Patients presenting with factitious fever tend to be young adults who are often in the medical field and have a relative bradycardia. Intravenous injections of organisms or a

P.1275

febrile child with a Munchausen by proxy parent are other indications of factitious fever. Whipple disease should be suspected in patients with FUO, arthritis, mental status changes, and malabsorption. Diagnosis is made by demonstration of PAS-positive macrophages on small bowel biopsy and can be confirmed by detecting *Tropheryma whipplei* by PCR.

Imaging tests (e.g., CT, MRI, PET/CT, transesophageal echocardiography, and radioisotope scans) have altered the distribution but not the type of illnesses causing FUO.^{144, 145} Endocarditis and abscesses, as well as neoplasia, have decreased with improved imaging and cultures.¹⁴⁶ The ability to diagnose an etiology of FUO has paradoxically decreased and led to a higher incidence of unclassifiable causes in some recent series.¹⁴⁶ [18F]-fluorodeoxyglucose (FDG-PET) in conjunction with fusion CT is emerging as an effective modality in the diagnostic work-up of FUO.^{147, 148} Advantages of PET/CT over gallium scintigraphy include completion of the exam within a short period of time and improved resolution, while disadvantages include a relatively high cost and limited availability in most of the world.¹⁴⁸ A meta-analysis of FUO studies indicated that 32% of FDG-PET scans and 62% of FDG-PET/CT scans contributed to a final diagnosis.¹⁴⁹ Indium 111 granulocyte scintigraphy may be more helpful than PET scans in diagnosing infections.¹⁵⁰

Invasive tests have a variable yield and depend upon the type of host, the initial evaluation of FUO, physical exam findings, and laboratory abnormalities. Bone marrow aspiration with biopsy was diagnostic in nearly a fifth of patients with FUO and was particularly helpful in the presence of anemia or thrombocytopenia.¹⁵¹ Bone marrow exam with cultures is more rewarding in immunocompromised than in immunocompetent hosts. Percutaneous liver biopsy is similarly helpful in HIV-infected patients with FUO, organomegaly, and increased LFTs.¹⁵² Lymph node biopsy is useful in diagnosing lymphomas for which an excisional or core needle biopsy is preferable over a FNA for the initial diagnosis. Necrotizing lymphadenopathy may be present in lymphomas or in reactive processes, including infections (toxoplasmosis, lymphogranuloma venereum, *Yersinia pseudotuberculosis*, cat scratch, tularemia), rheumatologic disorders, Kawasaki, and Kikuchi-Fujimoto disease. The latter is usually seen in middle-aged women of Asian descent who present with fever, cervical adenopathy, and leukopenia and have a self-limited course over 1 to 4 months.¹⁵³ Granulomas in lymph node biopsies are nonspecific and may be seen in sarcoidosis, infections, both HL and NHL, and carcinoma. Laparotomy is rarely performed unless there is adenopathy that is not easily approached by less invasive procedures, including FNA, mediastinoscopy, thoracoscopy, and laparoscopy. The goal is to identify treatable disease as expediently as possible.

Empirical antibiotic trials are rarely warranted except in the immunocompromised patient with neutropenia and fever.^{154, 155} Empirical antifungal therapy was established as an effective strategy in the 1980s for acute leukemia patients with prolonged neutropenia following chemotherapy and for patients undergoing stem cell transplantation (SCT).^{155, 156} Prophylaxis against infections and pre-emptive antiviral strategies are routinely used in SCT.¹⁵⁷ Occasionally, antibiotics are given in culture-negative endocarditis; and antituberculosis therapy is used in the elderly with suspected miliary TB.^{158, 159} High-dose steroids with or without alkylating agents can be considered in cases of vasculitis which have diagnostic images or proven biopsies.¹⁵⁸ Naprosyn has been advocated as a means to distinguish fever of malignancy from infection but should not prevent the search for infection.¹⁶⁰ Treatment for malignancy should almost never be instituted without a tissue diagnosis.

RECURRENT INFECTIONS

The most common clinical presentation of immunodeficiency (either congenital or acquired) is infection (Table 56.12). More than one infection requiring hospitalization, infection with unusual pathogens, or an inappropriately delayed response to optimal therapy should all be tip-offs to possible underlying immunodeficiency.¹⁶¹ Chronic sinusitis, recurrent otitis, persistent thrush, chronic diarrhea, or skin rashes may be an early manifestation of immunodeficiency. Delayed

umbilical cord stump separation is indicative of neutrophil defects, including LAD and interleukin-1 receptor (ILR-1)-associated complex deficiency.^{162, 163} Eczema or pustular rash, skin abscesses, and sinopulmonary infections within the first few weeks of life suggest hyper-IgE (HIES or Job) syndrome.¹⁶⁴ Patients may present with sequelae of immunodeficiency (e.g., delayed growth or failure to thrive in children or unexplained chronic obstructive pulmonary disease). Cytopenias, including lymphopenia or thrombocytopenia, or splenomegaly, may be an early finding.¹⁶⁵ In some patients, particularly those with HIV infection, lymphoma or a nonhematologic malignancy may be the presenting manifestation. In congenital immunodeficiency diseases, such as IgA deficiency, or deficiency of classic pathway complement components, features of autoimmunity may dominate the clinical picture.¹⁶⁶

TABLE 56.12 CLINICAL APPROACH TO IMMUNODEFICIENCY

Red Flags for Immunodeficiency

More than one hospitalization for infection
 Infection with organisms not usually pathogenic
 Recurrent otitis, sinusitis or pneumonia
 Persistent thrush
 Deep skin or organ abscesses
 Growth failure in children
 Delayed or absent response of infection on appropriate therapy

Initial Evaluation

History
 Family history of primary immunodeficiency
 Age of onset of infection
 Type of infection
 Physical examination

Initial Investigation for:

Bacterial infection (implies B-cell, phagocyte, or complement deficiency)
 Infection with intracellular organisms (implies deficient T-cell/cellular immunity)
 CBC and differential for neutrophil count and morphology, quantitative immunoglobulins, CH50
 Human immunodeficiency virus serology, CBC and differential for lymphocyte count, T-subset analysis, skin testing in adults
 CBC, complete blood count.

Age of onset of infection, family history, including parental consanguinity, and clinical findings provide clues to diagnosis, but laboratory tests identifying abnormal component(s) of the immune system are essential. Testing is directed at different parts of the immune system: T cells and cell-mediated immunity, B cells and humoral immunity, phagocytes, and complement. Congenital defects in T-cell-mediated immunity may appear in the neonatal period and usually effect antibody production which is dependent on intact T-cell function, whereas antibody deficiencies appear at the 6 to 9 months stage after the waning of maternal antibodies. Immunoglobulin levels, flow cytometry, and complement levels detect deficiencies of the immune system, but immune function studies, such as lymphocyte response to mitogens, specific antibody response to vaccine antigens, skin testing, and assays of neutrophil function may be more important in diagnosis. Skin testing is of little value in children younger than 1 year because they are unlikely to have previously been exposed to antigen used in testing. In older children and adults, the presence of reactive skin tests to recall antigens virtually excludes a significant defect in cell-mediated immune response. In utero or neonatal screening

for immune deficiencies can be critical in identifying congenital disorders, many of which are optimally treated with early SCT.¹⁶⁷ T-cell receptor excision circles and kappa-deleting recombination circles can detect T- and B-cell lymphopenia and suggest a diagnosis of SCID and X-linked agammaglobulinemia, respectively.¹⁶⁸ Detecting a molecular mutation in a gene and/or protein controlling part of the immune system is the ideal diagnosis.

Primary immunodeficiency disorders (PIDs) refer to a heterogeneous group of diseases characterized by defects in one of more parts of the immune system (Chapter 63). PIDs are usually inherited and are rare, with an estimated prevalence of 1 in 1,200 live births.¹⁶⁹ IgA deficiency is the most common; it occurs in 1 in 300 to 500 births, but only one-third have significant infections.¹⁷⁰ Although PID may present as life-threatening infections in childhood, more than 40% may not be diagnosed until adulthood. Time until diagnosis of any PID has decreased with better awareness and improved diagnostic tests.¹⁶⁸ Antibody deficiency syndromes comprise approximately 50% to 65% of PID, followed by 30% to 40% combined immune deficiencies, 10% to 18% phagocyte dysfunctions, and 1% to 2% complement deficiencies.^{167, 171}

An early test in any patient of any age with suspected immunodeficiency is HIV serology. In the HIV-negative patient, the age of the patient, geographic location, and type of infection or problem should dictate the tests ordered.¹⁷² Congenital immunodeficiencies predisposing to sepsis can be subdivided into those affecting innate immunity and those affecting the adaptive immune system. The subdivision is somewhat arbitrary and there can be clinical overlap, as some molecular lesions will affect both types of immunity. The former involves the immediate response of the immune system to a pathogen and includes defects in complement proteins and mannose-binding lectin (MBL), nuclear factor kappa B (NF- κ B) activation, phagocyte quantity and quality, and the type-1 cytokine axis.¹⁷² *Neisseria* bacteremia and meningitis are seen in complement deficiencies. Neutrophil defects result in periodontal disease, oral ulceration, or cutaneous and visceral abscesses; and they have a narrow spectrum of infections: *Staphylococcus aureus*, *Burkholderia cepacia*, *Serratia marcescens* spp., or *Aspergillus* spp.¹⁷³ In the absence of immune suppression, invasive aspergillosis is seen only in chronic granulomatous disease (CGD), and disseminated nontuberculous mycobacterial infection is seen in patients with defects of the IFN- γ /IL-12 axis. An overwhelming EBV infection may be the initial presentation of XLP syndrome. XLP1 results from defects in signaling lymphocytic activation molecule-associated protein, which is required for the activation of NK and cytotoxic lymphocytes. The adaptive immune system requires time after the initial exposure and representative defects include the different types of SCID, ataxia telangiectasia, and WAS.

In a patient with recurrent bacterial infection, the three major screening tests are a CBC with differential and peripheral blood smear, quantitative immunoglobulins, and a CH50.¹⁷⁴ Giant granules in neutrophils in a patient with oculocutaneous albinism indicates Chédiak-Higashi syndrome. Neutropenia in a neonate suggests Kostmann syndrome (congenital agranulocytosis). Thrombocytopenia with small platelets in a patient with eczema and abnormal gamma globulin levels is consistent with WAS. Interpretation of quantitative immunoglobulins depends on an awareness of the variation in the normal ranges with age. IgG, IgA, and IgM are markedly decreased in children with physiologic hypogammaglobulinemia of infancy, common variable immunodeficiency (CVID), and X-linked agammaglobulinemia. In the first two conditions, patients have circulating B cells by flow cytometry, whereas in X-linked agammaglobulinemia B cells are absent.^{175, 176, 177} Thymoma is another circumstance with decreased immunoglobulins and decreased or absent B cells.¹⁷⁸ In hyper-IgM syndrome, the presence of markedly elevated IgM with depressed IgG and IgA is virtually diagnostic.¹⁷⁹ Patients with WAS who respond poorly to encapsulated bacteria often have an isolated decrease in IgM or may also have increases in IgE and IgA. Marked elevations of IgE (HIES or Job syndrome) are seen in patients with chemotactic defects, recurrent staphylococcal skin disease, cyst-forming pneumonia, and musculoskeletal abnormalities.^{164, 180} An autosomal dominant form involving a mutation in signal transducer and activator of transcription 3 (STAT3) and an autosomal recessive form resulting from mutation of the dedicator of cytokinesis 8 protein (DOCK8) have been described.¹⁸¹ In occasional patients with recurrent bacterial infection, measurement of IgG subclasses or responses to individual antigens (e.g., tetanus and diphtheria) may be helpful in making a diagnosis.¹⁸²

In adults with low IgG, the three major considerations are CVID, CLL, and multiple myeloma. Patients with CVID not only have recurrent infections but also may develop ITP, autoimmune hemolytic anemia, sarcoid-like granulomatous disease, inflammatory bowel disease, hepatitis, and NHL.^{183, 184} Patients with CLL have hypogammaglobulinemia, lymphocytosis, and immunophenotypic studies demonstrating a monotypic CD5⁺, CD23⁺ B-cell population.¹¹¹ In myeloma patients with a decreased IgA, IgM, or IgG, electrophoresis of serum identifies a paraprotein in more than 80% of patients, although immunofixation may be required to uncover IgA monoclonal protein hiding in the beta region. Some myeloma patients have a negative serum electrophoresis with immunofixation. Most of these patients have a monoclonal light chain on urine electrophoresis. Serum light chain assays can identify and quantify the kappa and lambda light chains.

The complement system is a part of innate immunity and can be activated by three pathways.¹⁸⁵ The classical pathway (C1, C4, C2) is activated by binding C1q to immunoglobulins on microbes or by direct binding to cells undergoing apoptosis. Patients with deficiency in the early classic complement pathway often have autoimmune disease (e.g., SLE and rheumatoid arthritis), which in part may be related to the physiologic role of the classic pathway in clearing immune complexes from the circulation.¹⁸⁶ The alternative pathway can be directly activated by microbes; and the lectin pathway is activated by carbohydrate moieties present on microbes. Hemolytic assays to assess the classical and alternative pathways have been available for years, but a complement kit can now assess all three pathways.¹⁸⁷

Congenital complement deficiencies are rare autosomal recessive diseases except for properdin deficiency which is X-linked. All patients with deficiency of C1, C2, C3, C4, C5, C6, C7, or C8 have a zero CH50 (also seen with improperly handled specimens and occasionally in patients with severe immune complex disease).¹⁸⁶ Deficiency of C3, the central component of all three pathways is associated with SLE, glomerulonephritis, and bacterial infections. Deficiencies of properdin and factor D, components of the alternative pathway, and deficiencies of the late components C5, 6, 7, 8, and 9 often present with fulminant infection due to *Neisseria* species. Deficiency of MBL, an initiator of the lectin pathway, is due to point mutations of the MBL2 gene and is associated with an increased risk to a variety of infections.^{186, 187}

If quantitative immunoglobulins, CH50, the absolute neutrophil count, and neutrophil morphology are normal in a patient with recurrent bacterial infections, WBC functional studies for CGD or other enzyme deficiencies are indicated (Chapter 58). The nitroblue tetrazolium test is abnormal in many, but not all, of these defects.¹⁷³ CGD is due to deficient function of the reduced nicotinamide adenine dinucleotide phosphate oxidase, which is responsible for the respiratory burst in phagocytes.¹⁷¹ The diagnosis of CGD is now made by assays that rely on superoxide production. There are four genetic subtypes of CGD, with two-thirds X-linked due to mutations of the cytochrome b-245, beta polypeptide (CYBB) gene, and one-third autosomal recessive with the most common due to mutation of the neutrophil cytosolic factor 1 (NCF1) gene on chromosome 7q11.23.¹⁷¹

Flow cytometry for the CD11b/CD18 complex is diagnostic of patients with LAD type I.^{188, 189} LAD1 is an autosomal recessive

P.1277

disorder due to mutations in the gene ITGB2, which encodes the common beta 2 subunit of the integrin (CD18) on chromosome 21q22.3.^{162, 188} There is diminished CD18 on leukocytes, which affects the third phase of the adhesion cascade, the firm adhesion of leukocytes to the endothelium. The severe type of LAD1 is caused by less than 1% expression of CD18 and presents early in life often with delayed umbilical stump separation; while moderate types have 1% to 30% expression, have fewer severe infections, and are diagnosed later in life.¹⁹⁰ LAD2 is due to mutations in the guanosine diphosphate fucose transporter which lead to a lack of sialyl Lewis X (CD153) and a defect in the first phase, the rolling phase. LAD3 is caused by mutations in FERMT3 (KINDLIN-3), encoding a molecule responsible for integrin activation, the second phase.^{162, 173}

Defects affecting phagocyte signaling via the Toll-like receptor canonical pathway include mutations of the myeloid differentiation primary response gene 88 (MYD88) and ILR-1-associated kinase 4 (IRAK4) which lead to invasive bacterial infections, primarily caused by *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*.¹⁶³ Mutations in IKBKG, encoding the NF- κ B essential modulator (NEMO), result in a susceptibility to a wider variety of infections and frequently have ectodermal dysplasia.^{163, 191} Mutations in the alternative pathway lead primarily to herpes simplex encephalitis.

WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis) syndrome is due to heterozygous mutations of the intracellular c-terminus of the chemokine receptor 4 (CXCR4).¹⁹² Hyperfunction of CXCR4 delays egress of neutrophils leading to neutropenia, and reduces circulating CD27⁺ memory B cells resulting in B-cell lymphopenia and hypogammaglobulinemia.

In HIV-negative children with infections suggesting defective cell-mediated immunity (viral, fungal, or mycobacterial), the evaluation begins with the absolute lymphocyte count (Chapter 63). Because 75% of circulating lymphocytes are T cells, moderate lymphopenia implies T-cell lymphopenia. Distinct forms of SCID are characterized by different combinations of T/B/NK counts: T⁺B⁻NK⁻, T⁺B⁺NK⁻, T⁻B⁻NK⁺, T⁻B⁺NK⁺. There are over 20 different gene mutations associated with SCID.¹⁹³ Most newborns with SCID appear normal at birth, and the median age at diagnosis is 4 to 7 months.¹⁹³ X-linked SCID, the most common type, has absent T and NK cells with normal or elevated B cells, which can mask T-cell lymphopenia and is due to mutation of the IL2RG gene, localized at Xq13.1 and encoding the γ chain of the ILR-2. In adenosine deaminase

deficiency, the second most common type of SCID, purine nucleoside phosphorylase deficiency, and reticular dysgenesis, all lymphocytes are absent ($T^-B^-NK^-$).

$T^-B^-NK^+$ SCID can be due to mutations in recombination activating genes RAG1 and RAG2, which lead to defects of the first step of antigen receptor V(D)J recombination for both T and B lymphocytes.¹⁹⁴ Defects of the second step of recombination affect nonhomologous end-joining proteins and result not only in immunodeficiency, but also in defects in DNA repair, which predispose to neoplasia and toxicity to conditioning regimens.¹⁹⁵ In DiGeorge syndrome (suggested by hypocalcemia and congenital heart disease), T-cell numbers are decreased, whereas B cells are normal or elevated (sometimes masking T-cell lymphopenia).^{166, 196} In the bare lymphocyte syndrome in which either class I or class II HLA antigens are observed, the CD8 T-cell subset is decreased in defects involving class I HLA, and CD4 T cells are decreased in defects involving class II.¹⁹⁷ T^+ SCID can be due to engraftment of transplacentally derived maternal T lymphocytes or to Omenn syndrome, characterized by erythroderma, hepatosplenomegaly, and eosinophilia, and caused by hypomorphic mutations ("leaky SCID") of RAG 1/2 and other genes whose null mutations cause typical SCID.^{193, 198}

In HIV-negative adults, acquired defects in cell-mediated immunity with unusual susceptibility to viral, fungal, or mycobacterial infection are most commonly secondary to immunosuppressive therapy, chemotherapy (particularly nucleoside analogs), or malnutrition. Patients with sarcoidosis and neoplasms, such as HL, may be anergic on skin testing but usually do not develop infection before immunosuppressive therapy.^{199, 200} In 1992, idiopathic CD4 lymphocytopenia (ICL) was defined in HIV-negative patients who had low CD4 T lymphocytes ($0.3 \times 10^9/L$ or $< 20\%$ of total T cells) on a minimum of two separate points at least 6 weeks apart. Patients with a profound decrease in CD4 T-cell numbers and low CD4/CD8 ratios present with opportunistic infections similar to those seen in AIDS.^{201, 202} Hypomorphic gene mutations, which control T-cell receptor recombination or signaling, have been identified in a few patients with ICL.^{203, 204} Rarely, ICL patients have normal CD4/CD8 ratios and do not have increased susceptibility to infection.^{44, 202}

SUMMARY

This chapter is a brief overview and introduction to the subsequent chapters in Part VI on nonmalignant disorders of the phagocytic and immune system. A primary objective is to separate benign from malignant disorders. Identifying a specific defect in the immune system begins with a history and physical examination followed by tests to identify the defect. A single gene mutation may account for a congenital immune deficiency, and prenatal diagnosis may be possible by sex determination in utero if X-linked or by fetal blood sampling if the defective gene is known or if characteristic abnormalities in the peripheral blood can be identified. Some of the congenital immune deficiencies, such as SCID and its variants, represent medical emergencies. Acquired immune abnormalities, particularly functional asplenia, severe hypogammaglobulinemia, and iatrogenic neutropenia or T-cell deficiency, can also be life threatening. Knowledge of the site of the defect in a host's immune system—whether in the neutrophils, humoral, cell-mediated, or complement arms or a combination thereof—is critical in predicting types of infections that can occur and instituting appropriate therapy.

Chapter 57

Neutropenia

Caron A. Jacobson

Nancy Berliner

INTRODUCTION

The normal range for the peripheral white blood count (WBC) is between $4.5 \times 10^9/L$ and $10.0 \times 10^9/L$, with a mean of $7.5 \times 10^9/L$. The total WBC includes neutrophils and lymphocytes, as well as smaller numbers of monocytes, basophils, and eosinophils. Leukopenia, a depressed WBC, may reflect either neutropenia or lymphopenia. Neutrophils constitute about 60% of the peripheral WBC, and therefore, reduction of WBC number most commonly reflects a decreased absolute neutrophil count (ANC). Neutropenia can occur as a secondary manifestation of an underlying disease or exposure or may reflect primary hematologic disease. This chapter focuses on the primary and secondary causes of neutropenia.

NORMAL NEUTROPHIL KINETICS

The circulating neutrophil pool represents only approximately 5% of the body's total neutrophil number. It is therefore a fairly distant reflection of the dynamics of neutrophil maturation within the bone marrow.¹ Neutrophils arise in the bone marrow from a multipotent progenitor cell that also gives rise to all other formed elements of the blood. Maturation of neutrophil precursors occurs over 6 to 10 days. The majority of mature neutrophils constitute a storage pool that remains in the bone marrow poised for release as needed. The proliferating pool and storage pool together make up about 95% of the total granulocyte mass. Of the remaining 5% of neutrophils that enter the peripheral circulation, about 60% are a "marginating pool" that adheres to the vascular endothelium. These marginated neutrophils are easily mobilized into the circulation in response to stress. Circulating neutrophils survive for only 6 to 12 hours; when mobilized to sites of infection or inflammation, they can migrate into tissues where they survive for 1 to 4 days. Neutropenia can occur upon disruption of any of these processes: it may reflect decreased marrow production, increased margination (especially in the setting of splenomegaly and sequestration by the spleen), or peripheral immune destruction of mature cells.

DEFINITION AND CLASSIFICATION OF NEUTROPENIA

Neutropenia is defined by a decreased ANC, calculated by multiplying the total WBC by the percentage of neutrophils and bands noted on the differential cell count. What constitutes a low ANC differs by age, sex, race, and other factors; the normal range for the ANC for a given population, then, is defined as the mean ANC for that population +/- two standard deviations.^{2, 3} In general, however, an ANC less than $1.5 \times 10^9/L$ is considered neutropenic in most patient populations. Neutropenia can be further classified as mild, moderate, or severe based on the degree of ANC depression: an ANC of 1.0 to $1.5 \times 10^9/L$ is considered mild, 0.5 to $1.0 \times 10^9/L$ is considered moderate, and less than $0.5 \times 10^9/L$ is considered severe. Although this classification is useful in predicting the risk of severe bacterial infection, other features may modify the risk. The risk of infection may be modified by the neutrophil storage pool.⁴ Risk may also be modified by the cause of neutropenia. For instance, chemotherapy-induced neutropenia is associated with a much greater risk of serious infection than chronic immune or nonimmune neutropenia. The risk of infection is also a function of both the degree and duration of neutropenia.⁵

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of neutropenia includes pseudoneutropenia, primary or congenital neutropenias (Table 57.1), and acquired neutropenias (Table 57.2). Global marrow defects such as aplastic anemia, leukemia, myelodysplasia, or myeloproliferative disorders can also cause neutropenia and are discussed in other chapters. Here we outline and discuss the causes of isolated neutropenia.

Pseudoneutropenia

Neutropenia may be the result of laboratory or clerical error, an artifact due to prolonged processing time of a peripheral blood specimen, the consequence of neutrophil clumping due to the presence of a paraprotein or certain anticoagulants, or as a result of marginalization of the circulating neutrophil pool.^{6, 7} In each of these situations, the ANC is not actually low and these patients are not at increased risk of infection. Manual examination of the peripheral blood smear and repeated measurements can help to differentiate these causes of pseudoneutropenia from true neutropenia.

Primary Causes of Neutropenia

Ethnic and Benign Familial Neutropenia

A number of racial and ethnic groups have neutrophil counts that fall below the published normal range, which is largely based on Caucasian populations. These include African Americans, Yemenite Jews, Falasha Jews, and African Bedouins.^{8, 9, 10, 11} The occurrence of ethnic neutropenia has been linked to single nucleotide polymorphisms in the gene encoding the Duffy antigen receptor for chemokine (DARC), which is also the receptor for the malarial parasite. Loss of expression of the Duffy blood group is prevalent in the areas where malaria is endemic, which are also areas where ethnic neutropenia has been described.¹² There is also an autosomal dominantly inherited condition called benign familial neutropenia characterized by neutrophil counts in the 800 to 1,400/ μ l range, for which the responsible gene is not known.

Ethnic and benign familial neutropenias are not associated with an increased risk of infection.^{13, 14} Bone marrow biopsies have normal cellularity but a reduction in mature granulocytes and neutrophil kinetic studies reveal a reduced myeloid precursor pool in the marrow, reduced mitotic pool size, and reduced concentration of colony-forming unit culture (CFU-C) consistent with the faulty release of mature neutrophils from the bone marrow.^{15, 16}

Nonfamilial Chronic Benign and Idiopathic Chronic Severe Neutropenia

Nonfamilial chronic benign neutropenia is a condition defined by neutropenia in the absence of a familial pattern and without an increased risk of infection. There is often a compensatory monocytosis and eosinophilia and bone marrow biopsies show hypercellularity and myeloid hyperplasia with maturation arrest at the band stage of myeloid ontogeny. Neutrophil counts do

P.1280

rise, however, under conditions of stress such as infection or exogenous epinephrine or corticosteroid administration, perhaps explaining the absence of risk for infection.¹⁷ Some cases are associated with the presence of autoantibodies pointing toward an immune mechanism in the pathophysiology of this condition.^{18, 19} Other cases seem to be the result of abnormal phagocytosis of normal marrow neutrophils by macrophages or the result of T-cell and cytokine-mediated suppression of granulopoiesis in the bone marrow.^{20, 21} Included in this diagnosis is chronic benign granulocytopenia of infancy and childhood which typically resolves spontaneously around age 4 years.¹⁷ Although neutrophil counts do rise in response to G-CSF administration, G-CSF therapy is not recommended given the relatively benign clinical course associated with this condition.^{22, 23}

TABLE 57.1 DIFFERENTIAL DIAGNOSIS AND FEATURES OF CONGENITAL NEUTROPENIA

Syndrome	Inheritance Pattern	Gene (Frequency)	Clinical Features
Ethnic neutropenia	?	<i>DARC</i> SNPs (?%)	African American, Yemenite and Falasha Jews, African Bedouins; Mild and clinically insignificant neutropenia
Benign familial neutropenia	AD	?	Mild and clinically insignificant neutropenia
Severe congenital neutropenia	AR	Unknown (~40%)	Severe (ANC <500), chronic neutropenia; increased risk of severe infection and MDS/AML; responsive to G-CSF
	AD	<i>HAX1</i> (~0-2%) <i>G6PC3</i>	
	X-linked	(~4%)	

			<i>ELANE</i> (~55%) <i>WASP</i> (~2%)	
Cyclic neutropenia	AD		<i>ELANE</i> (100%)	Severe (ANC <200) neutropenia for 3-5 d every 21 d; increased risk of infection during nadir; responsive to G-CSF; no increased risk of MDS/AML; sporadic forms a/w diseases such as LGL
Shwachman-Diamond syndrome	AR		<i>SBDS</i> (100%)	ANC 200-800 at infancy; progresses to marrow failure; pancreatic dysfunction, skeletal abnormalities, and developmental retardation; increased risk of MDS/AML; responsive to G-CSF and SCT
Fanconi anemia	AR X-linked		<i>FANCA</i> ^a - <i>SLX4</i>	Marrow failure; short stature with upper limb abnormalities; <i>café-au-lait</i> spots; increased risk of malignancies; neutropenia is responsive to G-CSF and RIC SCT
Dyskeratosis congenita	X-linked AD		<i>DKC1</i> (~80%) <i>TERC</i> (0-20%) <i>TERT</i> (0-20%)	Marrow failure; nail dystrophy; leukoplakia; skin pigmentation abnormalities; pulmonary and liver fibrosis; osteoporosis; premature graying of the hair; increased risk of MDS/AML and other malignancies
Glycogen storage disease Ib	AR		Misc (0-20%) <i>SLC37A4</i> (100%)	Hepatomegaly; metabolic crises; neutropenia
Myelokathexis	AD		<i>CXCR4</i> (100%)	Neutropenia due to marrow retention; can be part of the WHIM syndrome; responsive to G-CSF and the CXCR4 antagonist plerixafor
Chediak-Higashi syndrome	AR		<i>LYST</i> (100%)	Oculocutaneous albinism; platelet dysfunction; neurologic disease; neutropenia; risk of HLH
Griscelli syndrome II	AR		<i>RAB27A</i> (100%)	Oculocutaneous albinism; neutropenia
Hermansky-Pudlak syndrome II	AR		<i>AP3B1</i> (100%)	Oculocutaneous albinism; platelet dysfunction; pulmonary fibrosis; neutropenia
Cartilage-hair hypoplasia	AR		<i>RMRP</i> (100%)	Moderate-severe neutropenia; short-limb dwarfism; fine hair; defects in cellular immunity

AD, autosomal dominant; ANC, absolute neutrophil count; AR, autosomal recessive; G-CSF, granulocyte colony stimulating factor; HLH, hemophagocytic lymphohistiocytosis; LGL, large granular lymphocytosis; MDS/AML, myelodysplastic syndrome/acute myelogenous leukemia; Misc, miscellaneous; RIC, reduced intensity conditioning; SCT, stem cell transplantation; SNPs, single nucleotide polymorphisms; WHIM syndrome, warts, hypogammaglobulinemia, immunodeficiency, myelokathexis syndrome.

^a Indicates the most commonly mutated complementation group in Fanconi anemia.

Idiopathic chronic severe neutropenia is distinguished from this benign condition in that it typically affects patients in their late childhood or as adults and has a more severe clinical course with increased risk and number of infections.²⁴ There is evidence of myeloid hypoplasia, maturation arrest, or abnormal myeloid morphology on bone marrow biopsy; the form

associated with severe myeloid hypoplasia is called chronic hypoplastic neutropenia.^{25, 26} To diagnose patients with idiopathic chronic severe neutropenia, other causes of neutropenia must be ruled out, including autoimmune etiologies. The pathogenesis of this form of severe neutropenia is completely unknown. Despite ANC's that may be in the 100 to 250 cells/ μ l range, these patients have a remarkably benign course, although some have recurrent infections requiring chronic cytokine support with G-CSF.

A large body of literature has focused on chronic neutropenia in Greece. The incidence of neutropenia on the island of Crete is quite high. This should be distinguished from chronic severe neutropenia, in that nearly all these patients have an ANC in the 0.8 to $1.4 \times 10^9/L$ range, and an ANC of $<0.5 \times 10^9/L$ rarely if ever occurs. There is evidence that these patients may have a cytokine-mediated, inflammatory component to their illness.²¹ It is unknown whether these patients have an increased prevalence of the DARC polymorphism associated with neutropenia.

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN) is a disorder of severe neutropenia first described in 1956 by Rolf Kostmann. He postulated that this was the first described congenital disorder of neutrophil number, presenting as an autosomal recessive disorder in neonates and infants with neutrophil counts <500 cells/ μ l associated with recurrent bacterial infections, most commonly due to *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa*.^{27, 28} His original report described this syndrome in nine families from a remote region in northern Sweden where consanguinity was common, explaining the increased incidence

P.1281

of this rare autosomal recessive syndrome.²⁷ The syndrome was named infantile genetic agranulocytosis, which later was renamed SCN or Kostmann syndrome. Afflicted children suffer from infections that can occur as early as the first months of life and often include omphalitis and perirectal abscesses; otitis media, pneumonia, gingivitis, and urinary tract infections are also common. The diagnosis is usually apparent within the first 3 months of life. Death may occur as a result of septicemia, peritonitis, and enteritis, with fatal infections common in infancy and early childhood. All patients have severe neutropenia with an ANC $<0.5 \times 10^9/L$, but often $<0.2 \times 10^9/L$, and there is often an increase in other myeloid cell lines including monocytes and eosinophils. SCN was previously hypothesized to be a result of a deficiency in G-CSF or its receptor but further studies have demonstrated that G-CSF production is not impaired in patients with SCN, G-CSF receptor number and function are normal in patients with SCN, and the administration of G-CSF results in correction of neutropenia and improved clinical outcomes.^{29, 30, 31, 32, 33} Kostmann's early studies suggested that intramedullary apoptosis of myeloid precursors was a prominent feature of SCN, and more recent studies have confirmed that accelerated apoptosis is a central defect of this disorder, suggesting that G-CSF functions to correct the phenotype in part through its activity as an antiapoptotic agent.^{34, 35, 36, 37}

TABLE 57.2 DIFFERENTIAL DIAGNOSIS AND FEATURES OF ACQUIRED NEUTROPENIAS

Cause	Mechanism	Management
<i>Infection</i>		
Viral	Redistribution; decreased production; immune destruction	Supportive care; treatment of the underlying infection; G-CSF or WBC transfusions reserved for protracted or severe cases; IVIg may be useful for immune or complement mediated neutrophil destruction
Atypical organisms	Redistribution; decreased production; immune and complement mediated destruction; direct marrow suppression	
Sepsis	Consumption of the marrow neutrophil reserve; increased margination	
<i>Drug-induced</i>		
Penicillin, PTU, gold	Immune-mediated destruction via hapten-induced antibody formation and complement	Supportive care; removal of the offending agent; G-CSF reserved for protracted or severe cases

	fixation or the formation of circulating immune complexes	
Valproic acid, Carbamazepine, β -lactams	Dose-dependent inhibition of CFU-GM resulting in marrow suppression	
<i>Immune-mediated</i>		
Systemic/autoimmune disease	Pan-reactive antibodies against neutrophils and neutrophil precursors	Supportive care; treatment of the underlying condition; G-CSF as needed
LGL/Felty's syndrome	Antineutrophil antibodies and immune complex mediated neutrophil destruction; increased neutrophil adhesion to the endothelium; FAS mediated apoptosis of neutrophils; impaired myelopoiesis; splenic destruction	Supportive care; immunosuppression with methotrexate, cyclosporine, cyclophosphamide, and/or rituximab; G-CSF as needed
Neonatal alloimmune neutropenia	Maternal IgG antibodies to paternally inherited neutrophil antigens	Self-limited; supportive care with antibiotics as needed; plasma exchange, IVIg, maternal neutrophils for life-threatening infections
Autoimmune neutropenia of infancy and childhood;	Antibody mediated neutrophil destruction, usually against a specific neutrophil antigen	Supportive care; G-CSF therapy to prevent recurrent or severe infection
Primary autoimmune neutropenia of adults		
Pure white cell aplasia	Cellular and humoral immune mediated; associated with thymoma	Thymectomy; adjuvant cyclophosphamide, steroids, cyclosporine, IVIg, and/or SCT
<i>Neutrophil margination/hypersplenism</i>	C5a and complement activation leading to increased adhesion and aggregation within pulmonary vessels; splenic sequestration	
<i>Nutritional deficiency (B12, folate, copper)</i>	Ineffective myelopoiesis and maturation arrest	Vitamin and mineral replacement

Abbreviations: G-CSF - granulocyte colony stimulating factor; WBC - white blood cell; IVIg - intravenous immunoglobulin; PTU - propylthiouracil; CFU-GM - colony forming unit granulocyte macrophages; LGL - large granular lymphocytosis; IgG - immunoglobulin class G; SCT - stem cell transplantation.

Since the initial description in 1956, SCN has come to be recognized as a syndrome resulting from a heterogeneous mix of genetic mutations with different patterns of inheritance. SCN can follow autosomal dominant, autosomal recessive, and X-linked patterns of inheritance and has been shown to be associated with mutations in a variety of genes including those for neutrophil elastase, HAX-1, WAS (WASP), GF11, SBDS, and G6PC3.^{38, 39, 40, 41, 42} Neutrophil elastase (ELANE) is a serine protease that is synthesized predominantly at the promyelocyte stage of neutrophil maturation and stored in primary granules. It has been hypothesized that ELANE mutations lead to cytoplasmic accumulation of defective protein, subsequently triggering apoptosis. Evidence supports activation of the unfolded protein response as the driver of

apoptosis in ELANE-associated SCN.^{43, 44} SCN due to ELANE mutations is inherited in an autosomal dominant fashion. It was the first SCN gene to be identified and is responsible for the majority of cases of SCN. It is not the mutation found in the original Swedish cohort described by Kostmann, however, which is an autosomal recessive disorder that results from mutations in HAX-1.⁴⁵ "Kostmann's syndrome" now refers only to SCN with mutant HAX-1.⁴¹ HAX-1 is a mitochondrial protein with weak homology to BCL-2 and its absence results in mitochondrial-dependent apoptosis. WASP regulates actin polymerization in hematopoietic cells. Absolute deficiency in this protein resulting from gene-inactivating mutations results in the Wiskott-Aldrich syndrome, characterized by thrombocytopenia, small platelets, sinopulmonary infections, and eczema. WASP mutations resulting in hypomorphic alleles, however, may lead to X-linked thrombocytopenia and neutropenia.^{40, 42} GFI1 encodes a transcription factor, growth factor independent-1, that regulates the expression of genes involved in granulopoiesis, Shwachman-Bodian-Diamond syndrome gene (SBDS) encodes a gene involved in ribosomal RNA regulation and is responsible for Shwachman-Diamond syndrome (SDS) (which is discussed in a later section), and G6PC3 encodes the catalytic subunit 3 of glucose-6-phosphatase. Mutations in each of these three genes have been associated with SCN.^{46, 47, 48}

P.1282

The gene(s) responsible for approximately 40% of SCN, however, remains unknown.⁴⁰

Although G-CSF receptor signaling is intact in the vast majority of patients with SCN, rare patients have been described in which SCN arises from a congenital abnormality in the G-CSF receptor. Not surprisingly, these patients are marked by resistance to therapy with G-CSF.^{49, 50, 51, 52} The most important observation to emerge from the studies of the G-CSF receptor in SCN, however, is the finding of frequent somatic mutations in the G-CSF receptor arising in patients with SCN on cytokine therapy. When searching for potential constitutional mutations in the G-CSF receptor that might cause SCN, investigators identified a somatic missense mutation that appeared to be associated with transformation to myelodysplastic syndrome (MDS) and acute myelogenous leukemia (AML).⁴⁹ This mutation introduces a stop codon leading to truncation of the distal intracellular domain of the receptor. The distal portion of the receptor is known to be the site of JAK-STAT activation and maturation signaling.⁴⁹ Some investigators have postulated that the mutation causes proliferation at the expense of maturation, explaining why patients with this mutation have a higher risk of MDS/AML.⁵³ It has clearly been demonstrated that the mutation shifts the dose-response curve for G-CSF, rendering the cells hyperproliferative, and permitting clonal dominance of the mutant clone in the setting of G-CSF therapy. Whether the mutation actually blocks differentiation or merely predisposes to further genetic events by virtue of increasing cell proliferation remains controversial. Regardless, these G-CSF receptor mutations have been found to confer resistance to apoptosis and enhance cell survival in patients with SCN.⁵⁴

In general, patients with SCN have an increased risk of developing MDS and AML at a rate of approximately 2% to 8% per year.^{55, 56, 57} In patients who do develop MDS and/or AML, there appears to be a sequential gain of mutations that were not present in the subpopulation of progenitor cells in the early SCN phase such that over two thirds of patients with SCN that develop MDS or leukemia have a G-CSF receptor mutation (CSF3R).⁵⁸ Increasing mutations in the G-CSF receptor gene point toward a role for aberrant G-CSF receptor signaling in leukemogenesis.^{58, 59} The role of G-CSF in causing or promoting these mutations remains unknown and a subject of considerable controversy.

G-CSF has revolutionized the treatment and management of SCN. Prior to the development of G-CSF as a clinical agent, SCN was almost uniformly fatal, with death from infection occurring in infancy or early childhood. Patients were treated with corticosteroids, testosterone, splenectomy, vitamin B6, and lithium, all of which were largely ineffective.^{60, 61, 62, 63} The use of G-CSF for this disease began in the 1980s, and has prevented infection in the vast majority of patients (80% to 90%), although some patients require higher doses.^{57, 64} The resultant increased life expectancy of these patients has coincided with an increased incidence of MDS and AML. This has led some to posit that G-CSF therapy facilitates the transformation to these malignant diseases, whereas others contend that prolonged survival allows for the emergence of a predisposition to MDS/AML as part of the natural history of this disease. The potential role of G-CSF in the development of MDS/AML in SCN is discussed later in this chapter. Chronic G-CSF therapy in this disease has led to other complications, including osteoporosis, vasculitis, splenomegaly, hepatomegaly, and glomerulonephritis.^{57, 64}

Cyclic Neutropenia

Cyclic neutropenia (CN) is a periodic disorder characterized by neutropenia ($ANC \leq 0.2 \times 10^9/L$) occurring at approximately 21-day intervals, although one quarter of patients may have cycles as short as 12 days or as long as 36 days.^{65, 66, 67} Nadirs of the ANC last 3 to 5 days and may be associated with recurrent fevers, aphthous ulcers, and infections of the skin, upper respiratory tract, and ears. The severity of infection reflects the severity and duration of neutropenia.⁶⁸ Fatal infections

are uncommon, however, owing to the relatively brief period of neutropenia that is the hallmark of this disease, and as a result patients enjoy favorable overall survivals. With time, the cyclic nature of the disorder becomes less prominent, however, and patients can look more like patients with chronic neutropenia.⁶⁹ It was first described in 1910 in an infant with recurrent episodes of fever, stomatitis, skin infections, and neutropenia.⁷⁰ Diagnosis of CN can be demonstrated by documenting intermittent neutropenia via blood counts every 2 to 3 weeks over a course of 6 weeks, but can now be confirmed by the detection of a pathogenic mutation in the setting of a suggestive pattern of WBC fluctuation. CN is inherited as an autosomal dominant disorder, although it may arise sporadically. CN can also be acquired in association with systemic diseases such as large granular lymphocytosis.^{71, 72} Virtually 100% of patients with congenital CN also have point mutations in the gene for neutrophil elastase (ELANE).⁷³ These mutations are largely distinct from those that are associated with SCN, although both syndromes have been seen arising from the same mutation within the same pedigree.^{74, 75}

Serial measurements of other hematopoietic cells in patients with CN reveal a periodicity to the numbers of platelets, reticulocytes, monocytes, and eosinophils as well, and the condition is sometimes referred to as cyclic hematopoiesis.⁷⁶ As opposed to the depression seen in the neutrophil count, these other cells are often increased in number on or around periods of neutropenia.⁷⁷ Bone marrow biopsies done during times of neutropenia and times of normal neutrophil counts reveal an absence of neutrophils and neutrophil precursors immediately preceding the period of neutropenia, whereas neutrophil precursors increase in number before recovery of peripheral neutrophil counts.⁷⁸ The periodicity of the cell counts is thought to be the result of variations in the rate of release of mature cells from the marrow. Although knock-in mice fail to reproduce the phenotype of either SCN or CN, a dog model of CN has provided insight into its pathogenesis.⁷⁹ In grey collie dogs, the disease can be transmitted to unaffected animals following bone marrow transplantation from an affected animal and can be cured following transplantation from an unaffected animal.⁸⁰ In humans, a patient with acute lymphoblastic leukemia treated with a donor stem cell transplantation from a sibling with this disorder developed the disease.⁸¹ These observations and experiments support the notion that this disease is the result of an intrinsic stem cell regulatory defect, possibly related to accelerated apoptosis.⁸² A comparison of bone marrow biopsies from patients with CN and SCN, and normal subjects revealed that there were no differences in the frequency of CD34, KIT, and G-CSFR expression on marrow precursor cells between CN patients and normal subjects.⁸³ Differences emerged, however, in response to hematopoietic growth factors with impaired granulopoiesis in both CD34⁺/KIT⁺/G-CSFR⁺ and CD34⁺/KIT⁺/G-CSFR⁻ cells in patients with CN; in SCN impaired granulopoiesis was only observed in the former.

Despite the impairment of granulopoiesis observed in response to hematopoietic growth factors, this disease is successfully treated with G-CSF and is not associated with an increased risk of leukemic transformation.^{57, 69, 84} G-CSF therapy does not prevent the cyclical depressions in neutrophil counts but does decrease the duration of neutropenia. GM-CSF therapy, on the other hand, has been noted to prevent the cycles but not to increase the neutrophil numbers to the same extent as seen with G-CSF.⁸⁵ G-CSF remains the treatment of choice for this disease when therapy is required. Lower doses of G-CSF are needed for the treatment of CN than SCN, with a median dose of 2.5 µg/kg/day in one cohort.⁶⁵ G-CSF is safe and well tolerated, although patients may develop a gradual asymptomatic splenic enlargement.⁶⁹ The acquired, adult-onset forms of CN that are associated with systemic diseases are treated differently and are often successfully managed with immunosuppression including daily or alternatedaily corticosteroids or cyclosporine.^{86, 87} These therapies are not successful in the congenital forms of this disease.^{65, 68}

P.1283

Congenital Immune Defects with Associated Neutropenia

Patients with inherited immunodeficiencies of humoral and/or cellular immunity are at risk of developing neutropenia. The infectious consequences in such patients are magnified due to the co-existing immune defects. Diseases involving immunoglobulin production, including X-linked agammaglobulinemia, hyper-IgM syndrome, dysgammaglobulinemia type I, isolated IgA deficiency, and familial forms of hypogammaglobulinemia have all been associated with periodic neutropenia and in some are thought to be related to the production of autoantibodies.^{88, 89, 90, 91, 92} These patients should be treated with intravenous immunoglobulin, which may correct both immune defects, with growth factors reserved for patients who do not respond to immunoglobulin replacement.⁹³ Likewise, neutropenia has been associated with defects in cellular immunity; one familial syndrome was described in 1976 in which patients manifested severe neutropenia coincident with decreased antibody production in response to tetanus and poliomyelitis vaccines with resultant infectious complications.⁹⁴ Finally, reticular dysgenesis is a rare immunodeficiency marked by severe neutropenia, lymphopenia, agammaglobulinemia and absent cellular immunity believed to be due to an inherent defect in

hematopoietic stem cells committed to myeloid and lymphoid development.^{95, 96} It is not responsive to G-CSF but can be cured with stem cell transplantation.^{97, 98, 99}

Other Congenital Syndromes with Associated Neutropenia

Neutropenia is an important feature of several other congenital disorders. (see also Chapter 37.) These include SDS, Fanconi anemia (FA), dyskeratosis congenita (DKC), glycogen storage disease Ib, myelokathexis, Chediak-Higashi syndrome (CHS), Griscelli syndrome type II (GS2), Hermansky-Pudlak syndrome II (HPSII), and cartilage-hair hypoplasia.

SDS usually presents with neutropenia in infancy and subsequently progresses to marrow failure. It is also associated with pancreatic dysfunction and skeletal abnormalities.¹⁰⁰ It was initially described in 1964 and is also associated with anemia, thrombocytopenia, developmental and mental retardation, diarrhea, weight loss, failure to thrive, eczema, recurrent otitis media and pneumonia, and neutrophil motility defects.^{101, 102, 103} SDS is an autosomal recessive disease caused by mutations in the SBDS on chromosome 7q, which is involved in the regulation of ribosomal RNA processing.⁴⁷

Neutropenia, in the range of 0.2 to $0.8 \times 10^9/L$, appears to be the result of myeloid hypoplasia.¹⁰⁴ The mechanism of neutropenia is unknown, but neutrophils from affected patients appear to have increased ubiquitin-proteasome-rich cytoplasmic structures.¹⁰⁵ SDS patients are predisposed to the development of MDS/AML, with myelodysplasia or clonal cytogenetic abnormalities (usually monosomy 7) present in up to one third of patients. The risk of severe hematologic complications is greatest in patients with cytopenias and symptoms before 3 months of age.^{106, 107} Before the use of G-CSF for this disease mortality reached 25% and was the result of infection, marrow failure, and/or malignancy.¹⁰⁸ The use of G-CSF, at an average dose of $4.3 \mu\text{g/kg/day}$, corrects the neutropenia and decreases the risk and mortality from infection.¹⁰⁹ As seen in SCN, however, the use of G-CSF and improvements in survival have also been associated with increased risk of MDS and AML and it is unclear if this is due to G-CSF or the natural history of the disease; the risk of MDS/AML is similar to that seen in SCN in the International Registry but was slightly lower than this in the French Registry.¹¹⁰ Stem cell transplantation can be curative but is associated with increased transplant-related morbidity and mortality and thus requires careful consideration and consultation with experienced transplant centers.^{111, 112, 113, 114} The successful use of reduced intensity conditioning transplantation for this disease may make transplant a more widely available option for these patients.¹¹⁵

FA is the most common cause of congenital aplastic anemia. It can be inherited in an autosomal recessive or X-linked manner and is due to mutations in genes involved in DNA repair. Marrow failure develops somewhat later than in other congenital marrow syndromes (median age 7 years), presumably because marrow failure occurs secondary to acquired mutations in the setting of defective DNA repair.^{116, 117, 118} Multiple genes have been found to be mutated in FA and 15 complementation groups have been identified (FANCA-SLX4 I [FA-P]), with FANCA being the most common.¹¹⁹ In addition to marrow dysfunction, up to two thirds of patients with FA have a constellation of other abnormalities, including short stature with upper limb anomalies, and hyperpigmented, café-au-lait spots. FA patients are at increased risk for malignancies, especially MDS/AML and squamous cell carcinomas.¹²⁰ The diagnosis of FA is established by demonstrating chromosomal fragility following exposure to diepoxybutane or mitomycin C; subsequent gene analysis can then identify mutations in one of the genes involved in the DNA repair complex.¹²¹ Stem cell transplantation can treat the hematologic manifestations of the disease but carries a high risk of morbidity and mortality due to the effects of conditioning on these patients with impaired DNA repair; consequently, reduced intensity conditioning regimens are necessary.^{122, 123, 124, 125, 126} Other therapies for the hematologic manifestations of this disease include androgens, which may be effective in half of FA patients, and growth factors such as G-CSF at doses starting at $5 \mu\text{g/kg/d}$.^{127, 128}

DKC is a rare multiorgan syndrome associated with neutropenia and/or aplastic anemia; patients may also have other abnormalities, including nail dystrophy, leukoplakia, and abnormal skin pigmentation.^{129, 130, 131} Additional clinical manifestations include premature graying of the hair, idiopathic pulmonary fibrosis, cancer predisposition (including AML and solid tumors including squamous cell carcinomas), osteoporosis, and cirrhosis.¹³² The majority of cases involve mutations in the DKC1 gene on chromosome Xq28 but DKC can also be due to genetic mutations that are inherited in an autosomal dominant or recessive manner such as mutations in TERT and TERC.^{133, 134} The DKC1 gene encodes dyskerin, a protein that is involved in RNA function and telomere maintenance. TERT and TERC are the genes for the reverse transcriptase portion of telomerase and the telomerase RNA component, respectively, and as is DKC1, are crucial for maintenance of telomere length. Clinical manifestations reflect progressive telomere shortening, and are therefore not present at birth; clinical symptoms typically do not present until the second decade of life. The severity and penetrance of some variants of DKC is unpredictable. However, inasmuch as offspring of affected individuals will inherit shortened telomeres, this is a syndrome that can manifest anticipation, with earlier and more severe symptoms occurring in consecutive generations. Telomere length in three different lymphocyte subsets can be measured to screen for this disease; patients with DKC have telomere lengths less than the first percentile for age in all three cell lines.¹³⁵ Genetic

testing for known mutations can be helpful but does not rule out the disease as a subset of patients lack identifiable mutations. G-CSF or GM-CSF is effective in improving neutrophil counts in patients with DKC, and allogeneic stem cell transplantation, with reduced intensity conditioning given the sensitivity to genotoxic agents, is effective in treating the hematologic manifestations of this disease.^{131, 136, 137, 138} DKC affects other organ systems, however, which will not improve following stem cell transplantation, and pulmonary disease and solid tumors remain a major source of morbidity and mortality following stem cell transplantation.

Glycogen storage disease Ib is an autosomal recessive disorder caused by mutations in the gene for glucose-6-phosphatase translocase. This leads to hepatomegaly and a metabolic disorder related to intracellular accumulation of polysaccharide. It is also

P.1284

associated with defects in the neutrophil respiratory burst that increase apoptosis of circulating neutrophils and lead to neutropenia.^{139, 140} Patients typically present at 6 months of age with hepatomegaly, hypoglycemia, and lactic acidosis.¹⁴¹ Neutropenia presents within the first year of life in the majority of patients and although it is usually intermittent, it has no faithful periodicity or cycle.¹⁴² Diagnosis is made by looking for the most common genetic mutations but if none are identified, liver biopsy to confirm excess glycogen stores and steatosis without prominent fibrosis is recommended. A strict carbohydrate-restricted diet is necessary to control the disease and G-CSF can be used to treat the neutropenia.^{143, 144} Liver transplantation has been used to correct many complications of this disease but neutropenia persists.¹⁴⁵ Neutropenia has also been reported in other metabolic disorders, including propionic academia, methylmalonic academia, and isovaleric academia.^{146, 147, 148}

Myelokathexis is a rare syndrome in which mature neutrophils are retained in the bone marrow, leading to a decreased peripheral ANC.¹⁴⁹ Retained neutrophils display an abnormal morphology with cytoplasmic vacuolization, pyknotic nuclei, nuclear hypersegmentation, and thin nuclear strands connecting nuclear lobes.¹⁵⁰ There is also evidence that neutrophils undergo accelerated apoptosis in affected patients, resulting in a shortened peripheral lifespan. Evidence suggests that this is a cell-intrinsic defect, as neutrophil survival is also reduced following injection into unaffected volunteers.^{150, 151} Accelerated apoptosis may be due to decreased expression of Bcl-x, an inhibitor of apoptosis. The storage pool of mature neutrophils is not reduced, and neutrophil counts rise in response to infection in patients with myelokathexis, making the risk of overwhelming infectious complications low. There is a female predominance in this disease and most patients are diagnosed in infancy.¹⁵² The combination of myelokathexis with hypogammaglobulinemia and warts is termed WHIM syndrome (warts, hypogammaglobulinemia, immunodeficiency, myelokathexis),¹⁵³ which is caused by heterozygous mutations in the gene for the chemokine receptor CXCR4.¹⁵⁴ These mutations cause hyperreactivity of CXCR4, leading to retention of neutrophils in the marrow. These patients respond to growth factor therapy with G-CSF or GM-CSF, which down-regulate the expression of CXCR4.^{155, 156} The CXCR4 antagonist, plerixafor, has been given to nine patients with the WHIM syndrome with resultant transient normalization of WBC counts.^{157, 158}

Congenital disorders of vesicular trafficking are also associated with neutropenia. These include CHS, GS2, and HPSII.¹⁵⁹ These diseases are also associated with disorders of other granulated cells, leading to oculocutaneous albinism (from disrupted melanin granules), bleeding (from abnormal platelet secretory granules), and neurologic disease (from abnormal trafficking and release of neuronal granules). All of these diseases can enter a terminal phase of hemophagocytic syndrome, often in the setting of Epstein-Barr virus (EBV) infection. In all cases, this is postulated to occur because of abnormal secretion of perforin-containing granules into the immunologic synapse, impairing natural killer-cell-mediated killing. CHS is an autosomal recessive disorder caused by mutations in the LYST gene (lysosomal trafficking regulatory gene) and is associated with characteristic neutrophils containing giant granules.^{159, 160, 161} Three quarters of patients with CHS develop moderate to severe neutropenia, thought to be the result of increased destruction of peripheral neutrophils and decreased marrow release of neutrophils.^{160, 162} Infectious risk is increased above that expected for the ANC due to concomitant humoral and cellular immune defects in this disease.^{163, 164} GS2 is also an autosomal recessive disorder, due to mutations in a small GTPase RAB27A, which is part of the protein complex necessary for granule release.^{165, 166} HPSII is due to defects in AP3B1 which encodes a part of a protein transport complex that mediates sorting of lysosomal proteins.¹⁶⁷ Defects in AP3B1 lead to widespread functional impairment of cells carrying secretory granules. As for many of the syndromes and diseases noted above, stem cell transplantation can cure the hematologic manifestations of these diseases and may be necessary to control the hemophagocytosis associated with CHS and GS2, but does not treat the other systemic findings.^{168, 169} Otherwise, growth factor support and antibiotics provide supportive care and steroids, splenectomy, intravenous immunoglobulin, and chemotherapy have been used to manage the accelerated phase of CHS.^{170, 171}

Lastly, cartilage-hair hypoplasia is a rare syndrome associated with moderate to severe neutropenia, as well as short-limb dwarfism, fine hair, and defects in cellular immunity.¹⁷² It is inherited in an autosomal recessive manner and has increased prevalence in the Amish and Finnish populations.^{173, 174} It is caused by mutations in the RMRP gene on chromosome 9 which has an unknown function but is a noncoding RNA essential for early murine development.^{175, 176} As in other syndromes with combined neutropenia and cellular immune defects, infectious risk is additive. G-CSF is effective and stem cell transplantation can cure the hematologic and immunologic manifestations of this disease.^{177, 178}

Secondary Causes of Neutropenia

Post-infectious Neutropenia

Several viral infections have been shown to cause a transient neutropenia, including varicella, measles, rubella, hepatitis A and B, Epstein-Barr, influenza, parvovirus, and cytomegalovirus. Neutropenia typically corresponds to the period of peak viremia during the first 1 to 2 days of clinical symptoms. Neutropenia usually resolves within 3 to 7 days. Neutropenia results from a combination of decreased production and immune destruction of neutrophils; in addition, some viral infections increase neutrophil adherence to the vasculature, causing increased margination.^{179, 180} Because neutropenia is short lived, it rarely results in bacterial superinfection regardless of its severity. However, the neutropenia associated with hepatitis B and EBV infections can be more prolonged and thus more dangerous. Human immunodeficiency virus (HIV) infection is commonly associated with neutropenia that arises from a combination of decreased marrow production of neutrophils and peripheral immune destruction.¹⁸¹ As with EBV and hepatitis B infection, this neutropenia may be protracted as a result of direct viral infection of hematopoietic precursor cells or as a result of antineutrophil antibodies. Moderate neutropenia can also be seen in association with atypical bacterial infections, including those caused by *Mycobacterium tuberculosis*, ehrlichiosis, rickettsia, tularemia, and brucellosis. This may be related to by direct bone marrow suppression of myelopoiesis by toxins released by the pathogenic organisms, decreased neutrophil production as a result of infection-mediated decrease in growth factor production, and complement mediated peripheral neutrophil destruction. Neutropenia is fairly common in the setting of overwhelming sepsis, and reflects consumption of marrow reserves of neutrophils. This is usually seen at the extremes of life, in infants and elderly patients, in which patients typically have decreased marrow reserves.¹⁸² Management of patients with infection-related neutropenia requires good supportive care with treatment of the underlying infection. G-CSF or white blood cell transfusions are reserved for protracted and severe cases.^{183, 184} Intravenous immunoglobulin may be effective for neutropenia that results from autoimmune or complement-mediated destruction as a result of the underlying infection.¹⁸⁵

Drug-induced Neutropenia and Neutropenia due to Marrow Injury

Although accurate estimates of the incidence of drug-induced neutropenia are not readily available, a 10-year Swedish experience, a 5-year Dutch experience, a 22-year Spanish experience, and the

P.1285

International Aplastic Anemia and Agranulocytosis Study demonstrate an annual incidence of severe drug-induced neutropenia of 1.0 to 3.4 cases per million population per year.^{186, 187, 188} Multiple drugs have been implicated in neutropenia and agranulocytosis, both in predictable and idiosyncratic patterns. Antineoplastic, antiviral, and immunosuppressive agents all cause an expected dose-dependent decrease in neutrophils, often accompanied by general marrow suppression. Common drugs known to cause neutropenia that is more idiosyncratic include clozapine, the thionamides, and sulfasalazine. Most drugs cause direct dosedependent marrow suppression and others incite immune-mediated destruction; these mechanisms may not be mutually exclusive.^{189, 190, 191, 192} Immune-mediated destruction may occur by one of two mechanisms: the drug may act as a hapten and induce antibody formation and complement fixation, or the drug can cause the formation of circulating immune complexes that bind to neutrophils. The former is the mechanism associated with penicillin, propylthiouracil, and gold and the latter is associated with quinine administration. Marrow suppression, on the other hand, is the result of dose-dependent inhibition of colony-forming unit granulocyte macrophages and can be seen with valproic acid, carbamazepine, and β -lactam antibiotics. Finally, drugs can cause damage to the marrow microenvironment and myeloid precursors; certain patients with specific genetic polymorphisms or other medical problems may be at increased risk for drug-induced neutropenia by this mechanism.^{193, 194, 195}

Drug-induced neutropenia typically occurs after 1 to 2 weeks of exposure to the drug, although it may occur after a longer period of exposure. Recovery usually begins within days of stopping the drug, but this pattern is highly variable depending on the mechanism of neutropenia. For example, immune-mediated neutropenia may be immediate, occurring within hours of administration of the drug especially if there has been a previous exposure and prior antibody production, whereas drugs that cause direct marrow suppression or toxicity follow the paradigm above.¹⁹⁶ Some patients may present

with agranulocytosis, fever, and possible sepsis; in these patients mortality may be significant. Neutrophil recovery is often preceded by the appearance of monocytes and immature neutrophil forms. Although marrow examination is rarely necessary, one can roughly predict the duration of neutropenia from the cellularity of the marrow, as patients with hypercellular marrows or marrows with abundant metamyelocytes and later forms tend to have more rapid reconstitution following discontinuation of the offending medication. Management is similar to that for post-infectious neutropenia with supportive care and removal of the offending agent, although growth factor support is recommended for patients presenting with agranulocytosis.¹⁹⁷

Radiation can also result in acute or chronic marrow failure. Exposure to radiation is also a risk factor for AML/MDS. These diseases are discussed in greater detail in Chapters 75 and 79, respectively. Likewise, metastatic carcinoma to the bone can also cause marrow failure as the marrow becomes increasingly occupied by the metastatic cells.

Immune Neutropenia

As previously discussed, infection and drugs can cause immune-mediated neutrophil destruction. However, primary immune neutropenia can occur in the absence of other inciting events, or can also arise in association with an underlying systemic autoimmune disease. Antineutrophil antibodies are implicated in mediating neutrophil destruction either by destruction in the spleen or by intravascular complement mediated neutrophil lysis. A number of neutrophil-specific antigens have been identified in patients with a history of autoimmune neutropenia, including human neutrophil antigen (HNA)-1, an isoform of the Fcγ IIIb receptor, and HNA-4 and HNA-5, which are CD11b and CD11a, respectively.^{198, 199} The clinical presentation is variable, and depends on whether the antineutrophil antibodies react primarily with mature neutrophils or with myeloid progenitor cells, whether the antibodies are primary or secondary to an underlying condition, and whether the antibody is of restricted or nonrestricted clonality.^{200, 201} Some patients may have an absence of only mature neutrophils, whereas others may be missing all or some myeloid forms. In primary immune neutropenia, antibodies are more likely to be directed against a specific neutrophil-specific antigen whereas secondary conditions are commonly associated with pan-reactive antibodies. Similarly, antibodies that are produced as a result of an exposure to a foreign antigen are more likely to be polyclonal and short lived, whereas those due to the loss of suppression of a clone of cells producing an autoantibody are associated with a more protracted and severe course of neutropenia. Bone marrow biopsy findings will depend on the stage in neutrophil maturation against which the antibodies are directed, but in most cases, the marrow is hyper- or normocellular with a “maturation arrest” that reflects destruction of later stage cells.

Hyperthyroidism, Wegener granulomatosis, rheumatoid arthritis, systemic lupus erythematosus (SLE), chronic hepatitis and other systemic infections, and malignancy are autoimmune and systemic disorders associated with antineutrophil antibodies. In many of these diseases, especially SLE, neutropenia is often mild and reflects the activity of the underlying disease. It rarely requires treatment outside of treatment of the underlying disease.²⁰²

Felty syndrome and large granular lymphocytic (LGL) leukemia can also cause immune-mediated neutrophil destruction, and may be associated with profound neutropenia and increased infections. LGL is a syndrome of autoimmune neutropenia in association with marrow infiltration by clonal large granular lymphocytes.²⁰³ These lymphocytes are cytotoxic T-cells with the following immunophenotype: CD3⁺, CD8⁺, CD16⁺, and CD57⁺. LGL can occur sporadically or in association with systemic autoimmune diseases, especially rheumatoid arthritis.²⁰⁴ LGL is closely related to Felty syndrome, a syndrome associated with splenomegaly and neutropenia in the setting of rheumatoid arthritis.²⁰⁵ Ninety percent of patients with Felty syndrome and LGL associated with RA are HLA-DR4+, leading many investigators to postulate that the two syndromes are in a spectrum of the same disease.²⁰⁶ The pathophysiology of neutropenia is complex, including both antibody-mediated and cell-mediated destruction, immune complexes, and increased FAS mediated apoptosis.^{207, 208, 209, 210, 211} The neutropenia is responsive to G-CSF, which is usually utilized until the primary disease can be treated.²¹² Treatment options for LGL and Felty syndrome include immunosuppressive therapies including methotrexate, cyclosporine, cyclophosphamide, and, most recently, rituximab for Felty syndrome.^{213, 214, 215, 216, 217}

Neonatal neutropenia, or neonatal alloimmune neutropenia, is caused by transplacental passage of maternal IgG antibodies against paternal neutrophil antigens, resulting in neutropenia in a similar manner to anemia in Rh hemolytic disease. During gestation, the mother is sensitized to unique fetal neutrophil antigens and produces IgG antibodies against these antigens that can cross the placenta. These antigens will be shared with the father and so will be reactive against the father's neutrophils, thus facilitating the diagnosis. Neutropenia typically resolves within 2 months, and appropriate antibiotics will usually be sufficient to support the patient. In the event of severe or life-threatening infection, plasma exchange, intravenous immunoglobulin, and transfusion of maternal neutrophils have all been used.²¹⁸

Autoimmune neutropenia of infancy and childhood, termed “primary immune neutropenia,” occurs in children ages 6 months to 10 years and is the most frequent primary immune neutropenia.²¹⁹ Infections tend to be mild and include otitis

media, gastroenteritis, and/or cellulitis. Resolution of neutropenia occurs in over 95% of patients by age 2.²²⁰ Primary autoimmune neutropenia in adults is rare, and tends to be more chronic. However, even adults tend to have a mild clinical course.

P.1286

Lastly, pure white cell aplasia is a rare disease associated with severe pyogenic infections, and associated with a thymoma in over two thirds of cases.²²¹ It has also occurred following ibuprofen therapy.²²² There is a complete absence of myeloid precursors on bone marrow examination. It is immune-mediated but removal of the thymoma in thymoma-associated cases may not be sufficient for remission. Adjuvant therapy with cytoxan, steroids, cyclosporine, IVIg, and even stem cell transplantation may be needed.^{223, 224, 225}

Neutropenia Due to Increased Margination and Hypersplenism

Complement activation increases margination of neutrophils and can suppress the peripheral ANC.²²⁶ This has been seen in patients suffering from burns and transfusion reactions as well as a result of exposure to artificial membranes used in dialysis, cardiopulmonary bypass, apheresis, and extracorporeal membrane oxygenation.^{227, 228, 229} Neutropenia in the setting of transfusion is due to an anamnestic response to foreign antigens on neutrophils in a prior transfused blood product. Complement activation may also lead to direct neutrophil destruction, as in the case of paroxysmal nocturnal hemoglobinuria. Splenomegaly with hypersplenism can also reduce the neutrophil count.²³⁰

Neutropenia Due to Nutritional Deficiency

Neutropenia is part of the clinical spectrum of megaloblastic anemia arising from deficiency of vitamin B12, folate, and copper.^{231, 232} These diseases typically cause pancytopenia because of disordered maturation of all cell lines.

CLINICAL PRESENTATION AND DIAGNOSTIC APPROACH TO NEUTROPENIA

One of the first definitions of the syndrome of neutropenia and infection was in 1922 by Werner Schultz who described the findings of sore throat, prostration, and neutropenia in a cohort of middle-aged women and called this entity agranulocytosis.²³³ This fulminant form of neutropenia has sometimes been referred to as Schultz disease.²³⁴ The description highlights that the first evidence of neutropenia is often the development of infection, and that severe neutropenia is associated with a risk for spontaneous infection. Although the lower level of the normal ANC is 1,500 cells/ μ l, patients rarely develop infectious complications of neutropenia until their ANC falls below 500 cells/ μ l, and in fact, patients with chronic neutropenia rarely develop fever unless their ANC is below 200 cells/ μ l. Common sites of infection include the oral cavity and mucous membranes including mouth ulcers, pharyngeal inflammation, and periodontitis, the skin with rashes, cellulitis, abscesses, and poor wound healing, the perirectal and anal areas, and the respiratory tract. Endogenous flora are the primary pathogens. It should be remembered that most of the signs and symptoms of infection are generated by neutrophils. Consequently, patients with neutropenia may have minimal signs and symptoms of infection, with minimal inflammatory infiltrates. Fever is the most informative sign in neutropenia patients, and should be evaluated emergently, because in the setting of profound neutropenia, patients may rapidly develop fatal sepsis. A presentation of neutropenia should prompt a careful evaluation for signs and symptoms of infection with cultures and antibiotic administration when indicated.

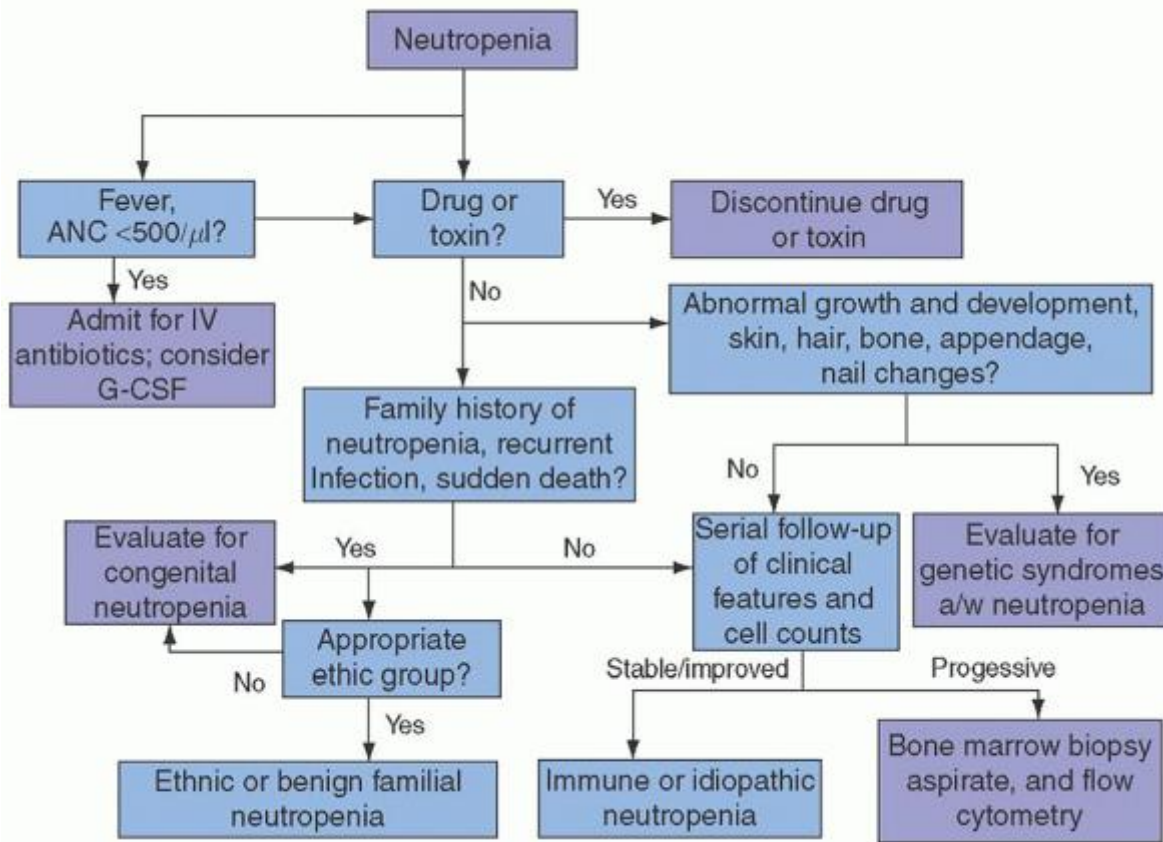

FIGURE 57.1. Diagnostic approach to neutropenia in the infant. ANC, absolute neutrophil count; a/w, associated with; G-CSF, granulocyte colony stimulating factor; IV, intravenous.

In children presenting for the first time with neutropenia, growth and development should be documented (Fig. 57.1). Attention should be paid to the skin, bones/appendages, and nails as abnormalities in these may point toward one of the congenital neutropenia syndromes. Family history of recurrent infections and sudden death may be helpful in this regard. If congenital neutropenia is suspected, appropriate genetic testing should be obtained. In adults previously known to have a normal ANC who present with profound neutropenia (agranulocytosis) and an otherwise normal CBC, the diagnosis is almost invariably drug-induced neutropenia. These patients usually present with an acute febrile episode. A thorough history of drug and toxin exposure should be obtained and all potential offending agents discontinued. For patients of all ages, the perineum and perirectal area should be examined, in addition to a complete physical exam. The peripheral blood smear should be examined and tests for vitamin B12 and folate levels obtained. Older tests included hydrocortisone stimulation tests (for marrow myeloid reserve), the epinephrine challenge test (for estimation of the size of the marginated neutrophil pool), and the Rebutck skin window (which evaluates neutrophil margination into tissues) but these are rarely

P.1287

used today.^{235, 236, 237} Bone marrow examination is not required unless there are other features to suggest an alternative diagnosis.

In patients presenting with unexplained neutropenia in the absence of a well-documented normal ANC in the past, evaluation depends on the severity of the neutropenia (Fig. 57.2). There is little information to be gained from an extensive evaluation of healthy patients with no history of infections and ANC of 1,200 to 1,500 cells/ μ l that has been present for many years. In appropriate ethnic groups the diagnosis of constitutional neutropenia obviates the need for further evaluation. Even in patients who do not have clear ethnic or familial neutropenia, studies to rule out marrow pathology in the absence of clinical sequelae or evidence of continued decrease in the blood counts are unlikely to be informative.

In patients with severe neutropenia of indeterminate duration, the pace and extent of diagnosis should be determined by the clinical presentation. In patients in whom cycling is suspected, genetic testing for ELANE mutations and peripheral blood flow cytometry and T-cell receptor rearrangement studies to assess for LGL should be obtained. In the cases of a selective severe chronic neutropenia, even in the absence of a history of infection or drug/toxin exposure or an evident B12 or folate deficiency, a single bone marrow examination is recommended to assess for myelodysplasia. If marrow morphology is unremarkable and cytogenetics are normal, repeated bone marrow examination is not recommended unless there is a significant change in the peripheral blood counts that suggests a new intervening diagnosis. Bone marrow biopsy should be performed in all patients with bi- or tricytopenias to evaluate the adequacy of hematopoietic marrow pools, the relative maturation of these pools, and the morphology of these pools for clues as to the etiology of the cytopenias.

MANAGEMENT OF NEUTROPENIA

Decisions regarding the treatment of neutropenia depend primarily on the presence or absence of fever. Neutropenia with fever should be treated as a medical emergency, with the goal of evaluating patients and initiating antibiotics within 30 to 60 minutes. The administration of empiric broad-spectrum antibiotics to patients with febrile neutropenia has been demonstrated to improve survival.^{238, 239} Third- or fourth-generation cephalosporins as single agents have become the standard initial empiric therapy, replacing previous combinations that emphasized double coverage for pseudomonal species.²⁴⁰ In patients with indwelling lines, the addition of vancomycin may be considered, and patients at increased risk for fungal infection or who remain febrile despite 3 to 5 days of antibiotics should receive antifungal agents.²⁴¹

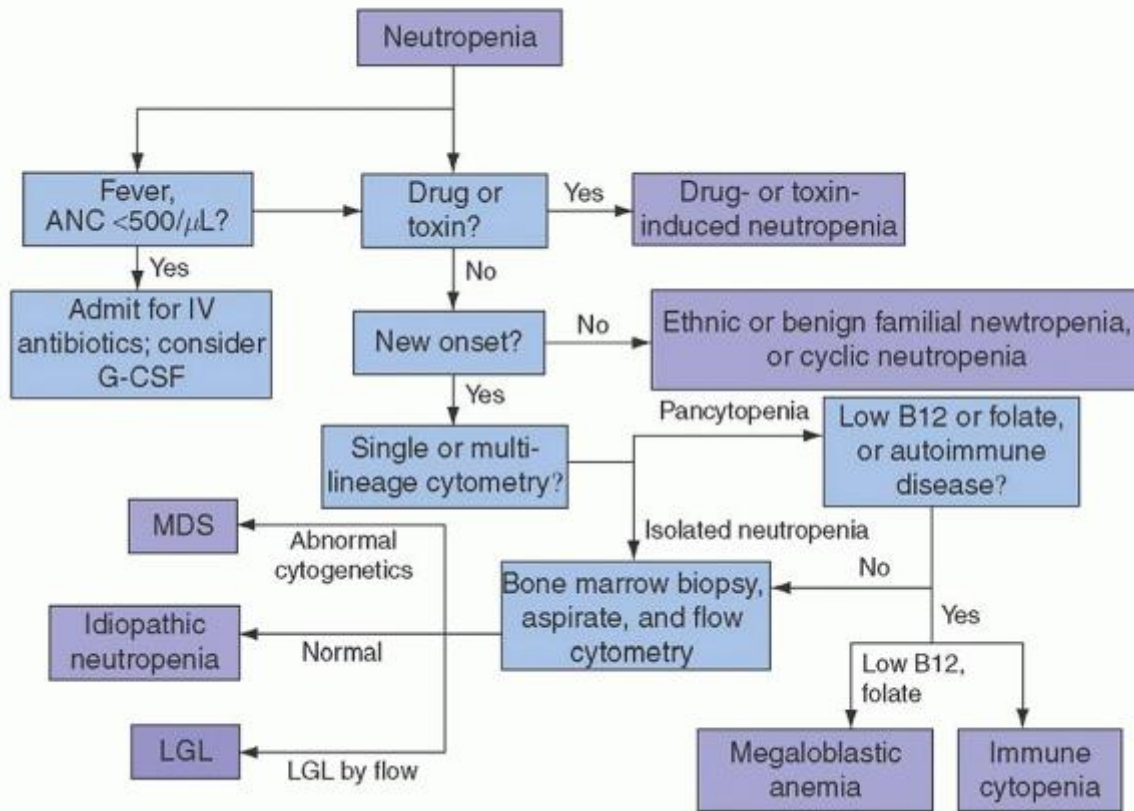

FIGURE 57.2. Diagnostic approach to neutropenia in the adult. ANC, absolute neutrophil count; G-CSF, granulocyte colony stimulating factor; IV, intravenous; LGL, large granular lymphocytosis; MDS, myelodysplastic syndrome.

For patients with mild neutropenia and infections, outpatient antibiotic therapy may be warranted and is based on the clinical judgment of the treating physician. The cause of neutropenia is important in determining further therapies: transient neutropenia due to a drug, infection, or chemotherapy administration may require no further therapy, although G-CSF can be used for high-risk patients with pneumonia, hypotension, and/or fungemia whereas neutropenia due to autoantibodies, an underlying systemic disease, or a congenital syndrome may require preventative approaches including immunologic therapies such as corticosteroids, intravenous immunoglobulin, and/or plasmapheresis, treatment of the

underlying disease, G-CSF therapy, or possibly a hematopoietic stem cell transplant. For cases of severe life-threatening infection that is unresponsive to antibiotics, granulocyte transfusion may be warranted.²⁴²

In patients with neutropenia who have not had a history of infection, treatment is rarely necessary. Patients should be educated to simple approaches to preventing infection, including skin and mouth care, good oral and dental hygiene, avoidance of rectal trauma by rectal thermometers and prevention of constipation with stool softeners, proper cleaning and topical antibiotic application to all skin abrasions. For patients with profound neutropenia not on G-CSF, they should be instructed to notify a physician as soon as they develop a fever. It is advisable that they also be supplied with prophylactic antibiotics such as trimethoprim-sulfamethoxazole or ciprofloxacin to take in the event there is a delay in seeking medical attention; it should be emphasized, however, that use of these agents is for emergencies only and should not be used in place of seeking appropriate medical evaluation and care.

Patients with SCN require lifelong G-CSF therapy. The use of G-CSF has extended the life expectancy for these patients from 2 to 3 years to adulthood.⁵⁷ Some patients with CN also require G-CSF, but can often restrict treatment to low daily doses of G-CSF or cyclical administration during the period around the nadir of the ANC. Dose requirements vary depending on G-CSF response.^{57, 69, 84} As previously mentioned, with improved survival of patients with SCN, a significant risk of MDS/AML has emerged.^{55, 56, 57} The risk of MDS/AML appears to be associated

P.1288

with higher doses of G-CSF, but whether this is a reflection of the underlying disease phenotype or whether transformation is enhanced or accelerated by G-CSF itself is unknown.^{53, 54, 58, 59}

Other congenital syndromes associated with neutropenia, such as SDS, FA, and DKC, respond to doses of G-CSF similar to those used in SCN and these patients are also at increased risk of MDS and/or AML, but again it is not clear if this is due to the G-CSF or the underlying disease.^{109, 128, 131} Patients with idiopathic and CN, as well as neutropenia associated with glycogen storage Ib, and myelokathexis, however, do not develop MDS or AML, despite therapy with G-CSF.^{69, 84, 144, 155} One could argue, though, that this may be a dose-dependent phenomenon as patients with SCN, SDS, FA, and DKC require higher doses of G-CSF than do those with idiopathic and CN. Long-term use of G-CSF or GM-CSF has been associated with osteoporosis and organomegaly.

Severe drug-induced neutropenia/agranulocytosis requires the permanent discontinuation of the causative agent. However, agents that cause dose-related marrow suppression and mild neutropenia can be continued if necessary, provided the neutropenia is not progressive or severe. Patients with agranulocytosis frequently present with life-threatening infections. They should be admitted to the hospital for broad-spectrum antibiotics. G-CSF speeds the recovery of the ANC and, given the morbidity and mortality associated with this syndrome, is recommended.

Immune neutropenia related to SLE or other systemic autoimmune disease rarely needs direct treatment, and ANC usually responds to decreased disease activity with therapy directed at the underlying rheumatologic disorder. Patients with LGL respond well to low-dose immunosuppression with cyclophosphamide or methotrexate.

Finally, stem cell transplantation can be useful to reverse the hematologic effects and neutropenia associated with a number of the congenital neutropenia and bone marrow failure syndromes such as SDS, FA, DKC, and cartilage-hair hypoplasia. The risk of transplant in many of these patients is greater than that seen in transplantation for hematologic malignancies due to the nature of the underlying genetic disorder. Furthermore, many of these disorders are associated with disease of other organs, including pulmonary fibrosis, or a risk of solid tumors. Transplantation does nothing to prevent these manifestations of the underlying disease and should be considered before undertaking the procedure.

Chapter 58

Qualitative Disorders of Leukocytes

Ashish Kumar

Keith M. Skubitz

DISORDERS OF PHAGOCYtic LEUKOCYTES CHARACTERIZED BY MORPHOLOGIC CHANGES

For the most part, the disorders considered here are rare, are usually familial, and often reflect a general metabolic defect, the major manifestation of which may be more serious in tissues than in leukocytes. Nevertheless, the leukocytic morphologic abnormalities may come to the attention of the hematologist, and familiarity with them and the associated diseases may facilitate diagnosis.

Pelger-Huët Anomaly

Pelger-Huët anomaly is a benign anomaly of leukocytes and is inherited as a non-sex-linked, dominant trait. It is characterized by distinctive shapes of the nuclei of leukocytes, a reduced number of nuclear segments (best seen in the neutrophils), and coarseness of the chromatin of the nuclei of neutrophils, lymphocytes, and monocytes. The nuclei appear rod-like, dumbbell-shaped, peanut-shaped, and spectacle-like (“pince-nez”) with smooth, round, or oval individual lobes, contrasted with the irregular lobes seen in normal neutrophils.¹ The incidence of this disorder in different studies has ranged from as high as 1 in 1,000 persons^{2, 3} to 1 in 4,000,^{4, 5} 6,000,⁶ or even 10,000.⁷ Originally observed mainly in Holland, Germany, and Switzerland, the anomaly has now been described in other parts of the world, including individuals of Asian⁸ and African descent and whites. The practical importance of identifying the Pelger-Huët anomaly lies in distinguishing this defect from the shift to the left that occurs in association with infection.

The discovery of this anomaly in rabbits led to breeding experiments and the production of homozygotes.^{2, 5} These studies demonstrated that in the heterozygote, bilobed, rod-shaped, and spectacle forms predominate, whereas in the homozygote, round nuclei with no evidence of segmentation are predominant. In rabbits, the homozygous form was often lethal, with most animals dying in utero; some survivors suffered skeletal malformations.

TABLE 58.1 DISTRIBUTION OF NUCLEAR LOBES IN NEUTROPHILS OF NORMAL PERSONS AND IN THOSE WITH PELGER-HUËT ANOMALY

	Cases Examined	Number of Lobes ^a				
		1	2	3	4	5
Normals ^b	50	2.8	22.0	54.3	18.1	2.8

		±2.8	±6.3		±5.3	±6.9	±2.1
Pelger-Huët heterozygotes ^b	34	31.3	63.8		4.9	0.3	0
		±9.2	±9.5		±3.7	—	—
Pelger-Huët homozygotes ^{2, 9}	2	100.0	—		—	—	

^a Mean and variance.

^b Modified from Davidson WM, Lawler SD, Ackerly AG. The Pelger-Huët anomaly: Investigation of family "A." *Ann Hum Genet* 1954;19:1.

Two human homozygotes have been reported.^{2, 9} In them, the cytoplasm of the neutrophils appeared mature, but the nuclei were round or oval in all the neutrophils, in contrast to the fewer than 40% single-lobed neutrophils present in heterozygotes (Table 58.1).^{2, 6, 9} In the homozygotes, the eosinophils, basophils, and megakaryocytes also were characterized by dense nuclear chromatin and rounded nuclear lobes; these individuals had fewer nuclear lobes than normal subjects.² Examination of the bone marrow revealed normal morphologic features in myeloid precursors through the myelocyte stage, and electron microscopy revealed persistence of nucleoli in the otherwise mature neutrophils that contained single oval nuclei.⁹ This finding was interpreted as indicating some retardation of nuclear maturation, because no cytochemical defects were noted in the cytoplasm. This syndrome is now known to be due to mutations in the lamin B receptor (LBR) gene, a gene important in maintaining nuclear structure.^{10, 11, 12}

Pelger-Huët cells appear to be normal functionally,^{9, 13, 14} are able to phagocytize and kill microorganisms,⁵ and survive normally in the circulation in both humans¹⁵ and dogs.^{16, 17}

The Pelger-Huët heterozygote is recognized by finding (a) 69% to 93% of the neutrophils to be of the bilobed, pince-nez type; (b) few cells with three lobes (usually <10%); and (c) rare or no cells with four lobes (Table 58.1).^{4, 5, 6} In normal blood smears, no more than 27% of the cells are bilobed, and significant numbers of cells have three or more lobes.⁵ The presence of similar abnormalities in the blood smear in other family members also is helpful in establishing the diagnosis. In heterozygotes, mature neutrophils with round or oval nuclei of the type that is characteristic of the homozygous state may increase after stress, such as the injection of colchicine^{18, 3} A shift toward increased numbers of neutrophil lobes was described in a patient with the anomaly who developed pernicious anemia.¹⁹

Pseudo- or Acquired Pelger-Huët Anomaly

Cells with morphologic changes, such as those just described, have been observed occasionally in association with myxedema, acute enteritis, agranulocytosis, multiple myeloma, malaria,

P.1291

leukemoid reactions secondary to metastases to the bone marrow,²⁰ drug sensitivity,²¹ or chronic lymphocytic leukemia.³ More commonly, pseudo-Pelger-Huët cells (Fig. 58.1)²² are seen in patients with myeloid leukemia of either the acute or chronic type or in those with myeloid metaplasia.^{23, 24} In these subjects, the pseudo-Pelger-Huët cells tend to appear late in the disease, often after considerable chemotherapy has been administered. In addition, most of the nuclei are of the single oval type characteristic of the homozygous state.²³

FIGURE 58.1. A: Pseudo-Pelger-Huët cells. B: From a patient with acute myeloblastic leukemia.

Alder-Reilly Anomaly

Alder-Reilly anomaly, inherited as a recessive trait,²⁵ apparently does not interfere with leukocyte function.²⁶ It is characterized by the presence of larger-than-normal azurophil and basophil granules (Alder-Reilly bodies), which may be easily confused with granulations due to toxic states (Fig. 58.2). These granules stain dark lilac with Wright-Giemsa stains and are seen in patients with various types of bone and cartilage abnormalities.^{27, 28} They are most common, however, in association with Hurler syndrome, Hunter syndrome, and Maroteaux-Lamy polydystrophic dwarfism.²⁹

Similar inclusions may be seen in blood lymphocytes (Gasser cells) and monocytes.^{30, 31} The lymphocyte inclusions stain dark red or purple with May-Grünwald-Giemsa stain and metachromatically with toluidine blue; normal azurophilic granules do not stain at all.^{31, 32} Such lymphocyte granules are found in all types of mucopolysaccharidoses except Morquio syndrome, but they are most common in the Hurler, Hunter, Sanfilippo, and Maroteaux-Lamy syndromes.^{29, 31, 32} They tend to occur in clusters rather than diffusely throughout the cytoplasm, are surrounded by vacuoles, and are shaped like a dot or comma. In one series of 19 patients, 8% to 50% of the lymphocytes contained the inclusions, and their presence was thought to be of diagnostic significance.³²

These inclusions are seen inconsistently in the blood but are more common in the bone marrow. For example, in a series of 18 patients with Hurler form of mucopolysaccharidosis, Alder-Reilly bodies were present in the blood of <10% of them. Careful examination of the bone marrow, however, revealed mucopolysaccharide granules in large mononuclear cells (Buhot cells) in 17 of 18 patients.^{33, 34, 35}

FIGURE 58.2. Neutrophils with Alder-Reilly bodies (A) compared with neutrophils exhibiting toxic granulation (B,C).

The type of inclusion seen is not diagnostic of a particular type of mucopolysaccharidosis, and the frequency of the inclusions is not correlated with clinical severity.³⁶ The basic defect in this group of diseases lies in the incomplete degradation of the protein-carbohydrate complexes known as mucopolysaccharides, and the different forms of mucopolysaccharidosis involve different enzymatic deficiencies.²⁹ The accumulation of partially degraded mucopolysaccharides within lysosomes has been demonstrated by electron microscopy²⁹; the degradation of the protein core of the mucopolysaccharide appears to proceed normally, but catabolism of the carbohydrate side chains is impaired.

May-Hegglin Anomaly

The May-Hegglin anomaly is a rare, dominantly inherited disorder characterized by large (2 to 5 μm), well-defined, basophilic, and pyroninophilic inclusions in granulocytes (neutrophils, eosinophils, basophils, monocytes), and accompanied by variable thrombocytopenia and giant platelets containing few granules.³⁷ For the most part, affected family members have not been ill, but occasionally abnormal bleeding has occurred.^{38, 39, 40, 41} Clot retraction time is prolonged, and the reaction to the tourniquet test may be positive. Platelet survival was short (half-life = 3 days, as compared with the normal, which is 6.9 ± 1.5 [1 standard deviation] days).⁴² Platelet aggregation and retraction were normal, but spreading and serotonin uptake were increased.⁴³ Enzyme and substrate content per platelet were increased, but this value was decreased as related to platelet volume.⁴³ The granulocyte inclusions are similar to Döhle bodies in appearance, but they often are larger, are more round and discrete, and may be present in a large percentage of the cells.^{40, 41, 44} It is claimed that these inclusions differ from the Döhle bodies of infection in morphologic appearance in that they are present in granulocytes other than neutrophils.⁴⁴ Like Döhle bodies,^{40, 44} the inclusions were felt to consist mainly of RNA and may exhibit differing ultrastructure.^{41, 45, 46, 47} More recently, mutations in MYH9, the gene encoding NMMHC-A,

P.1292

have been found in this syndrome.^{48, 49, 50} NMMHC-A is a nonmuscle myosin heavy chain that is part of a family of genes coding for proteins that form part of the actin-myosin force-generating complexes.⁵¹ In the bone marrow, clumping of the megakaryocyte cytoplasm has also been reported.³⁹

Mutations in MYH9 are inherited in an autosomal dominant fashion, but depending on the mutation generate a spectrum of clinical findings manifest as several syndromes due to variable expressivity of the clinical features.^{52, 53, 54, 55, 56, 57, 58} These clinical syndromes include May-Hegglin anomaly, Sebastian syndrome, Fechtner syndrome, and Epstein syndrome and are characterized by giant platelets, leukocyte inclusions, and variable thrombocytopenia, in addition to problems with hearing, vision, or renal function.^{52, 53, 54, 55, 56, 57}

Chédiak-Steinbrinck-Higashi Anomaly (Congenital Gigantism of Peroxidase Granules)

Chédiak-Steinbrinck-Higashi anomaly, an autosomal recessive disorder, has been reported in humans,^{59, 60, 61, 62} mice,⁶³ mink,⁶⁴ cattle,⁶⁴ cats,⁶⁵ rats,⁶⁶ and a killer whale.⁶⁷ It is characterized by partial ocular and cutaneous albinism, increased susceptibility to pyogenic infections, the presence of large lysosome-like organelles in most granule-containing cells, and a bleeding tendency.⁶⁸ The abnormal granules are most readily seen in blood and marrow leukocytes, especially granulocytes (Fig. 58.3), and in melanocytes.

In the first families that were reported with this anomaly, the mothers noted that some of their children exhibited pale hair (Fig. 58.4) and photophobia.^{59, 60} Because these children often had infections and adenopathy and died at an early age, the children born subsequently who were similarly affected were brought to medical attention in the hope of avoiding a fatal outcome.⁶⁰ It was then that the large, peroxidase-positive granules were noted in their blood and marrow granulocytes.^{59, 60, 61} Nevertheless, without definitive treatment (bone marrow transplantation, described later) most patients die in infancy or early childhood; only a few survive into early adult life.^{69, 70, 71}

FIGURE 58.4. The characteristic silver-gray hair of a child (left) with Chédiak-Steinbrinck-Higashi anomaly contrasted with that of her mother. (Courtesy of Dr. Dorothy Windhorst, National Institutes of Health.)

During the 30 years after the first description of Chédiak-Higashi syndrome (CHS)⁷² 59 cases were reported.⁶⁹ The similar disorder in animals is of use in investigations of the pathogenic defect and is of significant economic impact in mink, in that affected animals, inbred for their unusual color, seldom survive more than a year and exhibit increased susceptibility to a slow viral infection that produces hepatitis and a myeloma-like illness (Aleutian mink disease).⁶⁴

Etiology and Pathogenesis

The manifestations of this disorder appear to result from abnormal intracellular protein transport, resulting in abnormal granule fusion with larger, fewer-than-normal, and perhaps defective granules being formed in most granule-containing cells throughout the body.^{73, 74, 75, 76, 77} The resulting abnormalities can be found in the hematopoietic tissues, hair, ocular pigment, skin, adrenal glands, pituitary gland, gastrointestinal organs, peripheral nerves, and elsewhere.⁷⁴

In neutrophils, the anomalously large, peroxidase-positive granules seen by light microscopy^{59, 60} have been shown by electron microscopy to be abnormal primary (azurophilic) granules, the contents of which remain pleomorphic, the normal granule crystalloid structure not being formed.^{73, 78} Characterization of the abnormal granules by means of immunofluorescence microscopy demonstrated that they were formed by the progressive aggregation and fusion of azurophilic granules.^{79, 80}

In a subsequent electron microscopic study, investigators demonstrated the presence of two types of giant, peroxidase-positive granules in CHS neutrophils: large, round, or oval granules with homogeneous internal structure similar to normal azurophilic granules; and irregular granules much larger than those of the first type. Because basophils and eosinophils from CHS patients do not contain type 2 granules, and because type 2 granules are less common in promyelocytes, myelocytes, and young neutrophils in the bone marrow than in blood neutrophils, the authors suggested that normal primary (azurophil) granules are formed, but progressive granule fusion occurs during maturation, especially in the blood. In this process, granules and bits of cytoplasm are trapped within the fused granules.⁸¹ An abnormal calcium uptake pump in CHS lysosomes may be part of the underlying defect.^{82, 83} Also noted is an increased tendency to autophagic vacuole formation in Chédiak-Higashi neutrophils, perhaps because of increased permeability and leakage of injurious materials from the massive granules.⁸⁴ A secretory defect appears to prevent granule release in CHS T cells.⁸⁵ Abnormal granules have been observed less often in erythroid cells, whereas in megakaryocytes and platelets, the granules appear normal by light microscopy.⁷³ By electron microscopy, however, a decrease in dense bodies was seen,⁷³ and decreased serotonin, adenosine triphosphate, and adenosine diphosphate levels were noted.⁶⁸

P.1293

Similar large granules containing a glycolipid have been observed in the Schwann cells of peripheral nerves, in neurons in the central nervous system,^{84, 86} in renal tubular cells,⁸⁶ and in the vascular endothelium and fibroblasts.^{69, 87} In addition, giant pigment granules have been demonstrated in melanosomes⁸⁶ and in hair strands.^{69, 86} In the several different tissues affected, the consistent feature is that the histochemical reactions of the large abnormal granules are those usually seen in normal granules of that cell line⁸⁶; no qualitative alteration in granule enzyme content is noted, but some decrease in granule enzymes and an increase in cytoplasmic enzyme content have been described.⁸⁸ The effects of the abnormality in different tissues depend on granule function in that tissue. Thus, the large but fewer melanin granules produce pigment dilution, which explains the peculiar hair color, partial albinism, photophobia, and nystagmus.⁸⁶

The abnormal large granules in neutrophils lead to increased susceptibility to infection. Infection occurs despite an above-normal rate of phagocytosis and a normal postphagocytic metabolic burst (H_2O_2 production).⁸⁹ Apparently, the intracellular destruction of some bacteria by Chédiak-Higashi leukocytes is delayed because the postphagocytic delivery of lysosomal enzymes into phagosomes is inefficient and incomplete.⁹⁰ A similar defect in granule extrusion has been noted in the renal tubule.⁹¹

Chédiak-Higashi neutrophils from humans lack cathepsin G and elastase⁹² and have reduced C3bi receptor expression.⁹³ Because measurements of elastase and cathepsin G were normal in the bone marrow of beige mice, the primary lesion is thought not to be a gene defect but rather is likely a disorder of protein processing, protein synthesis, or granule assembly.⁹² In addition, a defect in cellular response to chemotactic stimuli both in *in vitro* and in *in vivo* skin windows has been demonstrated in humans, mice, and mink,^{94, 95} and a neutrophil membrane abnormality consisting of spontaneous cap formation has been described.⁹⁶ Recent studies show that lysosomes function as calcium-regulated secretory compartments and may play an important role in membrane resealing. Lysosomal exocytosis triggered by membrane wounding is defective in human CHS and beige mouse fibroblasts, and this defect may be central to the CHS phenotype.⁸²

Inheritance

In 1972, in families with 127 children, 59 were reported to be affected.⁶⁹ This statistic and animal studies⁶⁴ indicate that this disorder is inherited as an autosomal recessive trait. Male and female subjects are affected at a ratio of 0.87:1.00. A high proportion of marriages producing affected children have been consanguineous. Some heterozygotes may be identifiable by the presence of granulation in some of their lymphocytes.^{97, 98}

Clinical Features and Course

The partial albinism (more properly, pigment dilutional defect),⁸⁶ silvery hair (Fig. 58.4), and photophobia are usually noted early in infancy. The poor resistance to respiratory and cutaneous infection, especially by *Staphylococcus* and other Gram-positive organisms, soon becomes evident. Four patients studied for more than 1 year experienced 29 episodes of fever and pyogenic infection.⁷¹ Increased bleeding with abnormal platelet function has also been recognized.⁹⁹ Many of the afflicted children develop potentially fatal infections during infancy or early childhood. In others, the disease remains quiescent. Eventually, in more than 85% of patients, it changes to an accelerated phase that is characterized by lymphadenopathy, hepatosplenomegaly, neuropathy, anemia, neutropenia, and, less often, thrombocytopenia.¹⁰⁰ During this phase, infiltration of the tissues by mononuclear cells is widespread and the accelerated phase is now considered akin to the disorder hemophagocytic lymphohistiocytosis.¹⁰¹ During the accelerated phase, neurologic manifestations (peripheral neuropathy) may become prominent, and hemorrhage may occur.

Laboratory Findings

The characteristic microscopic findings are the large, often multiple, peroxidase-positive lysosomal granules in the granulocytes of the blood and bone marrow, and the large melanosomes in the hair. Less common are granules in the lymphocytes. Abnormal platelet aggregation can be demonstrated regularly.⁶⁸ During the early phases of the disease, blood counts yield normal values, but as the disease progresses, anemia, neutropenia, and thrombocytopenia often develop. Immunoglobulin (Ig) and complement levels are normal, as are cellular immune reactions. In the accelerated phase, erythrocyte and granulocyte survival may be shortened.⁶⁹

Gene Defect

The origin of CHS in mice has been found to be a mutation in the CHS/LYST gene on chromosome 1 in humans, which codes for a lysosomal trafficking regulatory protein.^{102, 103} The human homologue CHS1 has since been cloned, and mutations of this gene have been found in patients with CHS.^{76, 77, 102, 104, 105, 106, 107, 108, 109, 110}

Management

Some believe that the prophylactic administration of antibiotics may be beneficial.⁷¹ The administration of ascorbic acid corrected the defective leukocyte function *in vitro* and *in vivo* in several patients,^{111, 112} and the administration of cholinergic agonists was effective in mice.^{96, 113} The increased susceptibility to infection has been corrected in mice by the transplantation of normal bone marrow, and the hematopoietic defects can be transmitted to normal mice by transplanting marrow from an animal with CHS.¹¹⁴ In the accelerated phase, splenectomy has been only temporarily helpful⁶⁹; a few patients have been treated with a combination of vincristine and prednisone. Bone marrow transplantation appears to be a logical treatment, if possible,^{115, 116, 117} but does not alter the neurologic deterioration.^{109, 117}

Familial Vacuolization of Leukocytes (Jordan Anomaly)

Jordan anomaly is characterized by the presence of vacuoles in the cytoplasm of granulocytes, monocytes, and occasionally lymphocytes and plasma cells. In members of one family, all of the blood neutrophils and more than 70% of the monocytes contained three to ten vacuoles ranging in size from 2 to 5 μm ; fewer and smaller vacuoles were seen in eosinophils, basophils, and lymphocytes.¹¹⁸ By means of histochemical and fluorescence microscopic analysis, the vacuoles were shown to contain lipids. These lipids were seen in promyelocytes, myelocytes, metamyelocytes, and occasionally plasma cells in the bone marrow, but they were not present in myeloblasts, erythroblasts, or megakaryocytes.¹¹⁸ This type of vacuolization must be distinguished from that characterized by fat-staining vacuoles occurring in people with serious infections, toxic hepatitis, or diabetic ketoacidosis.¹¹⁹

The disorder appears to be familial. Two members were affected in each of two unrelated families.^{118, 119} None of the four patients had acute disease, but in members of one family, progressive muscular dystrophy was present,¹¹⁸ whereas in members of the other, ichthyosis was associated.¹¹⁹

Other Inclusions in Leukocytes

In an infant with congenital bile duct atresia, amorphous, round-to-oval bodies stained green or gray-green with Romanovsky stains in 3% to 13% of the blood neutrophils and in 1% to 5% of the monocytes.¹²⁰ Similar inclusions were present in all stages of myeloid cells in the bone marrow but not in lymphocytes or plasma cells. Electron microscopic analysis showed that the inclusions were not enclosed in a phagocytic vesicle.

P.1294

In the blood monocytes of patients with the Hermansky-Pudlak syndrome,¹²¹ a rare familial disorder characterized by albinism, mild bleeding related to platelet dysfunction, accumulation of ceroidlike pigment in marrow macrophages, and deficiency of the tetraspan protein CD63 in platelets,¹²² lipopigment bodies as well as another type of inclusion were demonstrated.

Abnormal Specific (Secondary) Granule Formation

A syndrome of recurrent staphylococcal skin and sinus infections associated with abnormal chemotaxis, impaired staphylococcal killing, and morphologic abnormalities in the neutrophils was described in a 14-year-old boy.¹²³ No other family members were affected. The patient's polymorphonuclear neutrophils exhibited bilobed nuclei with unevenly distributed chromatin, drumsticklike nuclear projections, and nearly absent cytoplasmic granules that stained with peroxidase but not with alkaline phosphatase. Electron microscopy revealed primary granules, but specific granules were small and reduced in number. These neutrophils were capable of phagocytosis, generated H_2O_2 , reduced nitroblue tetrazolium (NBT) dye, and killed *Candida*, but staphylococcal killing was impaired.

Since the original report, at least five cases of specific granule deficiency (SGD) have been identified with both sexes affected, leading to the assumption that the disorder is an autosomal recessive disease.^{124, 125} SGD neutrophils exhibit decreased chemotaxis and bacterial killing *in vitro* and decreased migration into skin windows *in vivo*, and they fail to upregulate CD11/CD18, laminin, or f-met-leu-phe (FMLP) receptors after activation,¹²⁴ although oxygen radical generation is apparently normal. Myeloperoxidase (MPO)-positive primary granules are present, but the specific secondary granules appeared to be absent in Wright-stained blood smears and were decreased in number and small when viewed with

electron microscopy.¹²³ These structures do not stain with alkaline phosphatase. The specific granule constituents lactoferrin and B₁₂ binding protein are reduced or absent.

Lactoferrin deficiency in patients with SGD is tissue specific (i.e., confined to myeloid cells, whereas lactoferrin is secreted normally in nasal secretions) and is secondary to a deficiency of RNA transcripts.¹²⁶ Because morphologic changes have been described in the primary granule¹²⁷ and because other granule proteins, such as primary granule defensin⁹² and "tertiary" granule gelatinase, are also deficient in SGD neutrophils, it was suggested that the basic defect in SGD is one of regulation of production of these proteins.¹²⁶ Thus, this disorder may be one of incomplete granule synthesis rather than a true SGD.¹²⁷

C/EBPE is an important regulator of neutrophil secondary granule genes,¹²⁸ and mutations in the C/EBPE gene have been found in two patients with SGD.^{129, 130, 131} Neutrophils from Cebp-deficient mice have functional defects very similar to those of patients with SGD,^{129, 132} and these mice have defects in eosinophil and macrophage function as well.^{133, 134} Monocyte/macrophage abnormalities have also been noted in an SGD patient.¹³⁵ One case of SGD has been reported with no mutation in the C/EBPE gene.¹³⁶

Hereditary Giant Neutrophilia

Neutrophils with a diameter of approximately 17 μm (as compared with a normal diameter of about 13 μm) are rare in blood smears from normal people (1 in 20,000 neutrophils or less). They may be seen with greater frequency in patients who are ill, but even then the number rarely exceeds 0.2% unless a disease involving leukocyte production is present or a reaction to a cytotoxic drug occurs.¹³⁷ A family with giant neutrophils in healthy members of three generations has been reported.¹³⁷ Over several years, the propositus had an average of 1.6% giant neutrophils in the blood. The large neutrophils appeared to be nearly double the normal cell volume and contained from six to ten nuclear lobes. Therefore, it was suggested that the cells may have been tetraploid. This anomaly appeared to be transmitted as an autosomal dominant trait.

Hereditary Hypersegmentation of Neutrophil Nuclei

Several families have been described whose members had a hereditary (autosomal dominant) increase in the number of neutrophil nuclear segments (Fig. 58.5).¹³⁸ The proportion of neutrophils containing five lobes or more exceeded 10% in most heterozygotes and was >14% in several suspected homozygotes, as compared with no more than 10% in normal controls.¹³⁸ The bone marrow findings suggested a tendency toward nuclear indentation in early myeloid forms (eosinophils and basophils as well as neutrophils).¹³⁸ The normal size of these neutrophils was thought to provide evidence against tetraploidy, but in one study of five female family members, the mean number of nuclear drumsticks appeared to be increased above normal.¹³⁹ The chief significance of this anomaly is in its differentiation from other causes of hypersegmentation such as folate or vitamin B₁₂ deficiency.

Hypersegmentation of Eosinophils and Negative Staining for Peroxidase and Phospholipids

Hypersegmentation of eosinophils can be inherited as an autosomal recessive trait, and the abnormality is characterized by a lack of sudanophilia and peroxidase activity in all of the eosinophils, whereas these histochemical reactions remain positive in the neutrophils and monocytes.^{140, 141} In addition, the number of eosinophilic granules per cell appears to be reduced, and some hypersegmentation of the eosinophil nucleus may occur. No disease accompanies the disorder. This has been most commonly reported in people of Jewish (predominantly Yemenite) extraction, although members of other races have not been studied adequately.

FUNCTIONAL DISORDERS OF LEUKOCYTES NOT CHARACTERIZED BY MORPHOLOGIC CHANGES

The topic of neutrophil dysfunction is under active study. Several reviews summarize this topic^{142, 143, 144, 145}; the reader is also referred to the current literature.

Chronic Granulomatous Disease of Childhood

Chronic granulomatous disease (CGD) is a rare clinical syndrome that results from genetically heterogeneous inherited defects of

P.1295

leukocyte function, that result from mutations in one of four genes coding for subunits of the neutrophil NADPH oxidase.^{146, 147, 148, 149, 150, 151, 152, 153}

FIGURE 58.5. Hypersegmented neutrophil.

Activation of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase requires protein kinases, lipid-mobilizing enzymes, and factors that activate the Rac GTPase, and thus the CGD phenotype could be due to a variety of other mutations as well. Recent reviews have been published.^{145, 150, 151, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163}

CGD neutrophils are characterized by a defective respiratory burst during phagocytosis and an inability to generate superoxide. The impaired superoxide production usually occurs transiently in each phagosome with phagocytosis and leads to recurrent bacterial and fungal infections, most commonly at epithelial surfaces. CGD is characterized by recurrent infections with catalase-positive bacteria. CGD neutrophils can use H_2O_2 produced by ingested bacteria to generate hypochlorous acid (HOCl) via MPO and aid in killing the bacteria. Catalase-positive bacteria generate H_2O_2 levels in the phagocytic vacuole that are too low for generation of sufficient HOCl to contribute to significant bacterial killing via this mechanism.¹⁵⁵ This syndrome can be the result of different genetic defects in the superoxide generating system. Variable inheritance patterns have been observed with approximately two-thirds of the pedigrees being X-linked and one-third autosomal recessive. Multiple molecular defects have been identified that result in the CGD phenotype.^{144, 145, 155, 157, 158, 161, 164, 165} Potential treatments include prophylactic antibiotics, interferon- γ , and bone marrow transplantation. Knowledge in this field is changing rapidly.¹⁵¹

CGD neutrophils, eosinophils, monocytes, and macrophages fail to generate superoxide, hydrogen peroxide, and other oxygen radicals after particle phagocytosis (or other stimulation), and thus have decreased microbicidal activity. CGD is associated with no leukocyte morphologic abnormalities and was first noted in male children with a history, beginning in early childhood, of recurrent suppurative infections caused by organisms of low-grade pathogenicity, including fungi, or by staphylococci. The eczematoid, granulomatous, and sometimes purulent skin infections recur repeatedly and clear slowly. Associated adenopathy develops and may persist. Pulmonary and other infections (e.g., osteomyelitis) also are common, and progressive granulomatous disease of the lungs, liver, and other sites develops. Hepatosplenomegaly is common, and biopsy reveals necrotizing granulomas, often with associated purulent inflammation. The disorder often progresses to death in early childhood,^{166, 167} but some patients survive longer.^{152, 168} Although rare, CGD has assumed great importance as a prototype of defects in leukocyte bactericidal capacity.

History and Mode of Inheritance

CGD was first described from 1954 to 1957^{166, 167} as affecting only males. By 1970, more than 90 cases were reported.^{148, 168} X-linked inheritance was established, and female heterozygotes were identifiable by the presence of defective leukocyte bactericidal capacity intermediate in degree between that of affected patients and that of normal individuals.¹⁶⁹

Measurements of postphagocytic release of $^{14}\text{CO}_2$ from glucose-1- ^{14}C or reduction of NBT dye were used to detect the defect. By means of the NBT dye test, female carriers were found to have a mixed population of neutrophils, approximately one-half being NBT negative and one-half being NBT positive. The defect is transmitted on an X chromosome, and the degree of deficit in female subjects varies according to random X chromosome inactivation. Consequently, one may expect to find an occasional female carrier with clinical disease as severe as that in male patients.^{169, 170}

Because of the clinical and pathologic picture of chronic recurrent infection caused by low-grade pathogens and the resultant granuloma formation, it was suggested that a defect in inflammatory response results in lesions comparable to those that normal people develop after infection with tubercle bacilli or brucella.¹⁴⁷ No abnormality in antibody response to diphtheria, tetanus, or poliovirus was demonstrated in these patients, and their delayed hypersensitivity response also was normal.¹⁴⁷ In addition, leukocyte migration and surface phagocytosis were normal.¹⁴⁷ Nevertheless, when leukocytes of CGD patients were incubated with bacteria, such as staphylococci, serratia, or other organisms causing infection in these patients, decreased bacterial killing and prolonged bacterial survival in the phagocytic vacuoles were observed.^{171, 172} Decreased killing of fungi and incomplete inactivation of vaccinia and herpes virus also was reported,^{147, 173} but streptococci were killed normally by CGD leukocytes.^{172, 174}

Although the mechanisms of bacterial killing by normal leukocytes are still incompletely understood, it is clear that phagocytosis is followed by fusion of lysosomes with the phagocytic vacuole, discharge of lysosomal enzymes into the phagosome, and a burst of postphagocytic metabolic activity. These events are usually accompanied by bacterial death and digestion (see Chapters 7 and 10). Early studies of CGD reported that a deficiency of NADPH oxidase or an abnormality in its activation is the underlying cause of this syndrome.¹⁷⁵ The finding that iodination of bacteria in the phagosome appears to be one mode of bacterial killing, and that this process is defective in CGD leukocytes and can be partially repaired by the insertion of an oxidase into the phagosome, either carried on oxidase-coated polystyrene particles^{176, 177} or as part of the ingested bacteria,¹⁴⁹ provided strong evidence incriminating defective generation of H_2O_2 , superoxide,¹⁷⁸ or related ions¹⁷⁹ as the pathogenic defect in this disorder.^{176, 180} Although most studies have focused on neutrophils, it was recognized in the earliest reports that lipid-laden macrophages were present in the granulomatous lesions,¹⁸¹ and a defect in the mononuclear phagocytes¹⁸² and in eosinophils¹⁸³ also has since been demonstrated. The platelets appear normal.¹⁸⁴

In the late 1960s and 1970s, an autosomal recessive form of CGD was described.^{148, 149} It is clinically identical to the X-linked forms, with the exception that the parents of affected children usually have normal neutrophil function, and the clinical course may be milder.¹⁴⁶

Molecular Pathology

In 1978, a unique cytochrome β , termed β_{558} (named for its absorption spectrum) or β_{245} (named for its midpoint potential), present only in phagocytic cells, was described and suggested to be a primary component of the oxidase that normally generates superoxide but, when defective, results in CGD.¹⁸⁵ This cytochrome was absent from X-linked CGD phagocytes (thus termed X⁻) but was present in phagocytes from patients with autosomal recessive inheritance patterns (A⁺).¹⁸⁵

In 1985, a family with CGD and an autosomal recessive inheritance pattern but with absence of cytochrome β was reported, thus identifying a third type of CGD (A⁻).¹⁸⁶ In these studies, a somatic cell hybridization technique was used to demonstrate that fusing monocytes from any two of these three types of CGD (X⁻, A⁺, or A⁻) restored their ability to oxidize NBT, thus defining three distinct molecular defects.¹⁸⁶ Also in 1985, several groups demonstrated that both membrane and cytosolic components are necessary for superoxide generation, and deficiencies in either can result in CGD.¹⁴⁶

In 1987, cytochrome β was purified and shown to be a heterodimer composed of two polypeptides, a heavily glycosylated, 91,000-dalton heavy chain (approximately 50,000 of the molecular weight is peptide) and a 22,000-dalton light chain.¹⁸⁷ Antibodies to these two polypeptides showed them both to be absent from the phagocytes of two types of CGD (X⁻ and A⁻). The defective gene in X-linked, cytochrome-negative CGD has since been cloned and shown to encode for the polypeptide portion of the 91,000-dalton subunit of cytochrome β now known as gp91phox.^{187, 188} Because postphagocytic activation of the

P.1296

respiratory burst with generation of superoxide and peroxide, as well as bacterial killing, involves complex reactions and multiple enzymes (e.g., phospholipases, protein kinases, NADPH oxidase, glucose-6-phosphate dehydrogenase [G6PD],

glutathione peroxidase),¹⁴⁶ one might expect that defects other than those described in NADPH oxidase would result in a disorder phenotypically like that described in the section Variants.

Clinical and Laboratory Features

The clinical picture of CGD includes the development of recurrent infections, especially of the skin and lungs, with septic lymphadenitis, development of hepatosplenomegaly and granulomas, and ultimately death from infection.^{147, 152, 166}

The blood neutrophil count is not reduced, and it increases appropriately with infection or after endotoxin injection; monocytosis is sometimes observed.¹⁴⁷ Because chronic infection is common, the Ig levels often are elevated, and plasma cells may be present in increased numbers in the bone marrow. Ig deficiencies have not been encountered, and antibody titers (both IgM and IgG) increase normally after antigenic stimulation. Reticuloendothelial clearance of colloidal gold also is normal. Peroxidase staining of blood cells demonstrates more intense dye uptake in CGD neutrophils than in normal cells.¹⁸³ The classical method for detecting the defect is the postphagocytic, intraphagosomal reduction of almost colorless NBT dye to blue-black formazan.^{183, 189} When tests are properly standardized with respect to time of incubation of leukocytes with the dye-tagged zymosan particles, affected patients and most carriers are readily recognized. When the reaction to this test is negative in suspected carriers, the reaction to the quantitative dye reduction test usually is positive.¹⁸³ Nowadays, the preferred diagnostic test is flow cytometry-based detection of the conversion of the nonfluorescent dye dihydrorhodamine to its oxidized form that emits green fluorescence.¹⁹⁰ The sensitivity and quantitative nature of this method make it more reliable and also allow for detection of residual oxidase activity that can be important in prognosis.¹⁹¹

An alteration in the B-cell compartment in patients with CGD has been reported.¹⁹² It appears that CGD is associated with a reduction in the peripheral blood memory B-cell compartment, suggesting a role for NADPH in memory B-cell formation.¹⁹²

Course and Prognosis

There is considerable heterogeneity in the severity of the clinical course of patients with CGD. Without treatment, this disease usually runs a progressive downhill course because of repeated infections and granuloma formation. The average life expectancy was reported to be 5 to 7 years in 1968.¹⁴⁷ One-half of patients are projected to survive into the fourth decade in 2008.¹⁵⁰ Recent studies suggest that the clinical course may be predictable by the specific mutation and those individuals with higher residual ability to produce reactive oxygen intermediates might fare better.¹⁹¹

Treatment

Treatment of infections with appropriate antibiotics and surgical procedures remains the cornerstone of management.^{149, 156, 193, 194} Prophylactic use of antibiotics, including trimethoprim-sulfamethoxazole and itraconazole with interferon- γ , is generally recommended.^{150, 151, 155, 156, 158, 194, 195} Trimethoprim-sulfamethoxazole alone or in combination with dicloxacillin can prolong the infection-free interval in many CGD patients.¹⁹³

In some patients with CGD, the administration of interferon- γ has induced partial correction of cytochrome β content and restored phagocyte bactericidal capacity toward normal, and reports have suggested that interferon- γ increases the ability of CGD neutrophils to kill *Aspergillus* and decreases the number of serious infections in patients with CGD.^{194, 195, 196, 197} The exact mechanism by which interferon- γ exerts its beneficial effect in CGD is unclear and may include other effects in addition to augmentation of the respiratory burst. Bone marrow transplantation and gene therapy are potential experimental approaches.^{115, 193, 198, 199, 200}

Variants

Because the clinical picture of CGD results from delayed killing of catalase-positive bacteria, enzymatic defects in the bactericidal system other than decreased NADPH oxidase may produce an almost identical picture. Results of several studies demonstrate clearly that such biochemical variants exist. For example, in a brother and sister with the clinical picture of CGD, after phagocytosis of latex particles by their neutrophils, all oxidative metabolic reactions were absent. If the latex particles were opsonized with Ig, however, postphagocytic oxidative changes were stimulated dramatically.¹⁸⁶ Another patient was reported in whom no oxidative changes (measured by chemiluminescence) occurred after phagocytosis of a variety of opsonized particles (latex, bacteria, or zymosan), but normal chemiluminescent responses occurred when the neutrophils were stimulated with soluble agents (concanavalin A and phorbol myristate acetate).²⁰¹ These patients appear to have a defect in signal transduction and activation of the oxidase system rather than in the oxidase enzyme(s). Another patient with clinically mild, X-linked CGD exhibited normal membrane depolarization (and therefore presumably normal activation), but NADPH oxidase apparently had a low affinity for NADPH and thus produced low but measurable amounts of superoxide.²⁰²

Neutrophil dysfunction also occurs in a variety of immunodeficiency states. Deficiency in any of the steps of oxidase assembly and activation could result in decreased superoxide production. In the primary immunodeficiency state interleukin-1 receptor-associated kinase 4 deficiency, there was decreased phosphorylation of p47phox, and decreased translocation to the membrane of p47phox, p67phos, and other oxidase components with associated decreased oxidase activity.²⁰³ In NF-kappaB essential modulator (NEMO) deficiency, NEMO-deficient cells had similar but less prominent changes, although p47phox translocation was normal.²⁰³ With Bruton tyrosine kinase (Btk) deficiency (also known as X-linked agammaglobulinemia), the picture is less clear. In patients with X-linked agammaglobulinemia there is both a deficiency of the kinase Btk and neutropenia.²⁰⁴ Studies suggest that in humans Btk-deficient neutrophils produce excessive NADPH oxidase activity after various stimuli, and that this was associated with increased apoptosis.²⁰⁴ It appears that the NADPH oxidase complex is partially assembled in resting Btk-deficient human neutrophils, making them ready for activation; that is, human Btk-deficient neutrophils are in a primed state. This is in contrast to studies of BTK-deficient mouse neutrophils where impaired NADPH oxidase activity was found. The model is that in humans BTK functions as a cytosolic component that inhibits translocation of NADPH oxidase components to the membrane and subsequent interactions with other NADPH components.

Lipochrome Histiocytosis

A clinical variant lipochrome histiocytosis was described in three sisters with rheumatoid arthritis, hyperglobulinemia, splenomegaly, pulmonary infiltrates, and increased susceptibility to infection.^{205, 206} No granulomas were found in tissue biopsies, but lipochrome pigmentation in large macrophages was present throughout the tissues. Studies of blood leukocyte function in two of the sisters revealed impaired postphagocytic respiration, NBT reduction, and hexose monophosphate shunt activity identical to that seen in patients with CGD.

P.1297

Glucose-6-Phosphate Dehydrogenase Deficiency

NADPH is the major substrate for the respiratory burst oxidase. A bactericidal defect similar to CGD has been described in a patient with a complete deficiency of G6PD, an enzyme important in the generation of NADPH.^{207, 208} Apparently, almost complete absence of G6PD activity is necessary to interfere with bacterial killing, because no difference from normal could be detected in cells with 25% activity or greater.²⁰⁹

Glutathione Peroxidase Deficiency

Two unrelated 9- and 13-year-old girls presented a clinical picture similar to that of CGD and with decreased bactericidal capacity.²¹⁰ The findings in these girls differed from those in males with CGD only in that no heterozygotes were detected in their families and their clinical course was somewhat milder. These patients were reported before the nature of the NADPH oxidase was known, and it was suggested that the CGD phenotype was due to glutathione peroxidase deficiency, resulting in inhibition of the oxidase by accumulated peroxides. A subsequent study, however, suggested that glutathione peroxidase activity was normal in these patients and that both had mutations in the NADPH oxidase.²¹¹ Thus, there is no firm evidence that glutathione peroxidase deficiency is a cause of the CGD phenotype.

Glutathione Synthetase or Reductase Deficiency

Reduced glutathione plays an important role in protecting neutrophils (including the NADPH oxidase system) from reactive metabolites, including H₂O₂. Because glutathione levels are generated by both direct synthesis via glutathione synthetase and the reduction of oxidized glutathione by glutathione reductase, deficiencies of these enzymes might be expected to result in defective neutrophil function. The neutrophils of a normally growing infant with a relatively benign history of recurrent otitis and repeated episodes of neutropenia were found to have 5% of normal glutathione synthetase activity and 10% to 20% of normal glutathione content. The cells ingested particles and metabolized 1-¹⁴C glucose normally, but after phagocytosis, excess peroxide accumulated and impaired iodination and killing of bacteria were demonstrable. Electron microscopic examination showed damage to the microtubules and membranes of the neutrophils.^{212, 213} Neutrophil dysfunction resulting from a deficiency of glutathione reductase has also been reported.²¹⁴ Patients with glutathione reductase deficiency or glutathione synthetase deficiency generally pursue a fairly benign clinical course. Vitamin E may be useful in patients with severe glutathione synthetase deficiency.²¹²

Catalase Deficiency

The neutrophil is protected from products of the NADPH oxidase not only by glutathione but also by superoxide dismutase, which generates H_2O_2 from superoxide, and by catalase, which converts H_2O_2 to H_2O and O_2 . A deficiency in neutrophil catalase has been reported in which the surface of the neutrophil was more susceptible to damage by H_2O_2 than normal.²¹⁵ These patients do not appear to have severe complications with infections.²¹⁵

Job Syndrome

Job syndrome (also known as hyperimmunoglobulinemia E syndrome) was reported as occurring in two unrelated girls with red hair and fair skin who suffered from repeated staphylococcal cold abscesses, sinusitis, eczema, and pulmonary disease, a syndrome not unlike the affliction of Job.²¹⁶ The leukocytes of these patients were capable of normal phagocytosis, bacterial killing, NBT reduction, and iodine fixation,^{216, 217} unlike those of patients with CGD. Subsequently, hyperimmunoglobulinemia E and defective chemotaxis were demonstrated.^{218, 219} It is now clear that this disorder is not limited to red-haired women, in that it is seen in both sexes and in patients of varied racial backgrounds and hair colors.²²⁰ The common features are increased susceptibility to infection (usually evident in the first 6 weeks of life), chronic dermatitis, and hyperimmunoglobulinemia E.

Job syndrome is now recognized as a multisystem disease, characterized by not only recurrent infections, elevated IgE, and dermatitis, but also retained primary dentition, unusual facial phenotype, bone fragility, and hyperextensible joints.^{221, 222} While typically sporadic, autosomal dominant transmission in kindreds has been reported.²²⁰ Most cases of Job syndrome have been associated with mutations of STAT3, though others with the syndrome do not have this finding and mutations in other genes have been reported.^{223, 224, 225} Less frequent autosomal recessive transmission is now also recognized, with the gene defect being localized to DOCK8.²²⁶

Job syndrome is rare but with the advent of genetic diagnosis, more patients are being identified and the complete clinical repertoire of the disease is now being realized.²²⁷ Fungal, viral, and bacterial infections are common. Survivors with DOCK8 mutations have developed T-cell lymphomas and squamous cell carcinoma of the skin in early adulthood.²²⁸ Blood eosinophilia and elevated IgE levels are the most common laboratory findings. Prophylactic treatment with dicloxacillin or trimethoprim-sulfamethoxazole may be helpful in managing afflicted patients. The role of interferon- γ is unclear.²²⁹

Myeloperoxidase Deficiency

An inherited deficiency of MPO was described in 1969.²³⁰ The 49-year-old male propositus, one of his two sisters, and all four sons exhibited decreased MPO activity; no increased frequency of infections accompanied this defect. In two other families, apparently similarly affected, infection was also not a problem.²³⁰

Until the late 1970s, this disorder was described in only rare cases (some familial, others apparently sporadic and acquired).^{231, 232, 233} This frequency seemed consistent with the apparently pivotal role of MPO in the oxygen-dependent killing of microorganisms.^{230, 232} With the development of flow cytometry and automated differential cell-counting techniques, however, MPO deficiency was often detected (approximately 1 in 2,000 subjects) during routine hematologic evaluation of patients admitted to the hospital.^{231, 233, 234} From these studies, MPO deficiency clearly is the most common disorder of neutrophil function.²³³ This disorder is now known to be autosomal recessive with mutations localized in the MPO gene on chromosome 17q23.²³⁵

Most studies of MPO-deficient neutrophils reveal that bacteria and fungi are phagocytized normally, and ingestion is followed by a vigorous respiratory burst. Bactericidal killing, however, is somewhat delayed, reaching normal levels only after 1 to 3 hours.²³² The findings of these studies and the rarity of clinical infections in MPO-deficient individuals support the concept of MPO-independent microbicidal mechanisms.^{230, 232} In contrast, although ingested normally, several *Candida* species and *Aspergillus* are killed poorly, if at all; and several MPO-deficient patients, including one of the first reported cases, suffered from disseminated fungal infection.^{230, 232} MPO-deficient mice also have impaired defense against *Candida*,^{237, 238} and have also been noted to have increased atherogenesis.^{236, 237}

The respiratory burst in MPO-deficient cells is actually prolonged and supernormal, and evidence exists that MPO normally acts to modulate and terminate the inflammatory response; for example, MPO oxidizes the methionine group in FMLP, thus modulating chemotaxis, and it also modulates NADPH oxidase activity.²³²

Results of studies of the structure of MPO have shown it to be a tetramer (150,000 D) composed of two heavy and two light

P.1298

chains ($\alpha_2\beta_2$) of 55,000 to 60,000 and 10,000 to 15,000 daltons, respectively.^{238, 239} MPO is encoded by a single gene

generating an 80-kD product that is modified and glycosylated generating a 90-kD enzymatically inactive apopro-MPO that is further modified to the active 90-kD pro-MPO, which is further modified and dimerizes before entering the primary granule.^{240, 241} In one study, completely MPO-deficient neutrophils lacked all of these subunits but contained the precursor protein, whereas partially MPO-deficient neutrophils contained decreased amounts of the precursor protein and the subunits derived from it. In some cases, specific mutations in the MPO gene in MPO deficiency have been described. In spite of these abnormalities, a majority of the patients are asymptomatic and a small percentage suffer from *Candida* infections.^{239, 240, 241}

MPO deficiency also occurs as an acquired defect in a variety of situations (e.g., pregnancy, lead intoxication, Hodgkin lymphoma, and activated coagulation),²³² but it is encountered most commonly in association with acute myeloblastic leukemia (up to 48% of patients), myeloproliferative states (20% to 60% in chronic myelogenous leukemia, 32% in myelofibrosis), and myelodysplastic syndromes (25%).²³² In many of these conditions, only some of the circulating myeloid cells are deficient, presumably those produced by the abnormal clone.²³²

Other Enzymatic Defects

Two siblings with negative peroxidase, oxidase, and lipid reactions in the neutrophils and monocytes also have been reported.²⁴²

Cystic Fibrosis

As described above, an important mechanism of bacterial killing by neutrophils involves the production of HOCl from H₂O₂ and chloride. Cystic fibrosis (CF) is caused by mutations in the gene encoding the CF transmembrane conductance regulator (CFTR), a cyclic adenosine monophosphate-regulated chloride channel. CFTR is present in neutrophil secretory vesicles and phagolysosomes.²⁴³ Although CF neutrophils produce extracellular HOCl normally, they have impaired chlorination and killing of phagocytosed bacteria due to defective HOCl production in phagolysosomes.²⁴³

Leukocyte Adhesion Defects

As described in Chapter 7, cell-cell adhesion plays an important role in neutrophil function. Three types of leukocyte adhesion deficiency (LAD) have been described.^{151, 244}

Leukocyte Adhesion Deficiency-1 (CD11/CD18 Deficiency)

CD11/CD18 deficiency is a rare, inherited disorder of leukocyte function first reported in 1974. It usually is detected in infancy or early childhood as a result of frequent bacterial (and sometimes viral) infections or delayed umbilical cord separation, and high neutrophil counts.²⁴⁵ The infections are recurrent, often life threatening or fatal, and usually involve the skin and subcutaneous tissues, middle ear, and oropharynx. Neutrophils are present in the blood in increased numbers (even between infections) and appear normal, but fail to migrate into Rebeck skin windows or sites of infection in normal numbers. When studied *in vitro*, they exhibit defects in motility, phagocytosis, granule secretion, and particle-stimulated respiratory burst activity. Humoral (immunoglobulins and complement) and cellular immunity (skin tests and lymphocyte stimulation tests) otherwise appeared normal, and no specific enzyme deficiencies were detectable.²⁴⁶

The pathogenesis of this disorder was first suggested in 1980 when a patient's neutrophils were found to lack a high-molecular-weight glycoprotein.²⁴⁷ Subsequent work revealed the absence of CD11/CD18. As described in Chapter 7, the CD11/CD18 family consists of three heterodimeric proteins each composed of a noncovalently associated α (α_L , α_M , or α_X) and β (β_2) chain (Table 58.2). Translocation of α - and β -chains to the cell surface requires assembly of the $\alpha\beta$ heterodimer. Mutations in the β_2 -chain (ITGB2) prevent normal assembly of the $\alpha\beta$ heterodimer and subsequent translocation to the surface. CD11/CD18-deficient neutrophils roll normally on endothelial cells but do not adhere or migrate with chemotactic stimulation²⁴⁸ (Table 58.2). Studies involving eight patients revealed two distinct phenotypes: patients with severe deficiency (<0.3%) and patients with moderate deficiency (2.5% to 31.0%) of CD11a/CD18 glycoproteins on the neutrophil surface. The severity of clinical manifestations correlated directly with the degree of glycoprotein deficiency.²⁴⁹ Results of other studies further expand the heterogeneity of defects causing this disorder in which mutations in CD18 have been identified.^{245, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263} The disease has also been reported in cattle.^{264, 265, 266} Hematopoietic cell transplantation is curative for this disease and recommended.²⁶⁷

Leukocyte Adhesion Deficiency-2

A second form of LAD has also been described in which the patients have severe mental retardation, short stature, a distinctive facial appearance, the Bombay (hh) blood phenotype, and recurrent bacterial infections, including pneumonia, otitis media, periodontitis, and localized cellulitis without the accumulation of pus, in association with an elevated white count.^{248, 268, 269, 270, 271, 272, 273} Phagocytosis was normal, but motility and homotypic aggregation were defective. Surface

CD18 expression was normal. As described in Chapter 7, cell surface selectins, including CD62E (E-selectin), CD62P (P-selectin), and CD62L (L-selectin), and their ligands (carbohydrates whose structures appear to be related to sialyl-Le^x [CD15s]), play an important role in neutrophil adhesion. The critical structure of CD15s is (NeuAc α2 → 3 Gal β1 → 4, [Fuc α1 → 3] GlcNAc) and the Bombay phenotype is a deficiency of Fuc α1 → 2 Gal linkages, which serve as the core of the A, B, and O blood groups.²⁷⁴ LAD-2 neutrophils were found to lack CD15s expression and did not bind interleukin-1β-stimulated endothelial cells (which express E-selectin). Because these patients had deficiencies of several fucosylated carbohydrates, the syntheses of which depend on different fucosyltransferase genes, a general defect in fucose metabolism was postulated.²⁶⁸ This syndrome has since been termed congenital disorder of glycosylation, type IIc, and is a member of a group of disorders characterized by defects in processing protein-bound glycans. In some of these patients mutations in SLC35C1, a GDP-fucose transporter, have been described.^{272, 273} LAD-2 neutrophils do not roll well on endothelial cells and do not adhere under shear stress.²⁴⁸ However, under

P.1299

static conditions, LAD-2 neutrophils can adhere and migrate.²⁴⁸ Few patients have been described, and these cases may represent different biochemical defects.^{275, 276, 277, 278, 279, 280} Oral fucose supplementation may be useful in some patients.^{276, 279} Bone marrow transplantation might be considered in some cases.

TABLE 58.2 LEUKOCYTE β₂ INTEGRINS

Neutrophil Integrin	Expression	Ligand
α ₁ β ₂ LFA-1, CD11a/CD18	All leukocytes	ICAM-1 (CD54) ICAM-2 (CD102) ICAM-3 (CD50)
α _M β ₂ HMac-1, CD11b/CD18	Monocytes, neutrophils, some natural killer cells	ICAM-1, iC3b, fibrinogen, factor X
α _X β ₂ p150,95, CD11c/CD18	Monocytes, neutrophils	iC3b, fibrinogen

Leukocyte Adhesion Deficiency-3

A third form of LAD was described in four patients, which appeared to be due to a defect in integrin activation following stimulation of G-protein-coupled chemokine receptors.²⁸¹ LAD-3 follows an autosomal recessive pattern, and is associated with recurrent infections and leukocytosis, with a bleeding tendency like Glanzmann thrombasthenia. LAD-3 has been associated with mutations of FERMT3, formerly known as KIND3, which codes for a protein that associates with β-integrins.^{282, 283} These mutations interfere with β-integrin activation.

Rac2 GTPase Mutation

A defect of neutrophil adhesion, oxidase activation, degranulation, and chemotaxis in response to chemoattractants has been reported in one patient who had a double negative mutation in Rac2 GTPase.^{284, 285} This patient had leukocytosis with a deficiency of pus at sites of infection, exhibiting a similar phenotype as that of Rac2 knockout mice.^{286, 287}

FcγRIII Deficiency

Several patients who lack the IgG receptor FcγRIII (CD16) have been reported.^{288, 289, 290, 291, 292} Two homologues of FcγRIII (FcγRIIIA and FcγRIIIB) have been identified. FcγRIIIB is glycosyl-phosphatidyl inositol-linked and expressed on neutrophils. Because FcγRIII bears the NA1 and NA2 polymorphic neutrophil-specific antigens, these cells are NA1 and NA2 negative. The clinical expression of this deficiency ranges from a normal state to one characterized by multiple infections.^{288, 289, 290, 291, 292}

Actin Dysfunction

A genetic disorder of neutrophil actin function, characterized by recurrent bacterial infections and defects in chemotaxis, adhesion, and phagocytosis, due to neutrophil actin dysfunction (NAD) also has been described.^{293, 294, 295, 296} These cells appeared to have actin that does not polymerize well and had lower levels of F-actin in both the resting state and after stimulation. Subsequent studies after the death of the index case found that one, but not both, parent was heterozygous for LAD-1. Most patients with LAD-1 do not have abnormal actin polymerization. Patients with this syndrome and

overexpression of 47- and 89-kD proteins (NAD 47/89) were also described.²⁹⁴ A more recent patient was described with overexpression of leufactin—an F-actin-binding protein that regulates microfilaments—and NAD with serious infections.^{297, 298} Leufactin was shown to be the 47-kD protein overexpressed in NAD 47/89. Overexpression of leufactin, also known as lymphocyte-specific protein 1, can create the morphologic and motility abnormalities seen in leufactin-overexpressing neutrophils.²⁹⁹

Localized Juvenile Periodontitis

Localized juvenile periodontitis is an adolescent disease characterized by alveolar bone loss, most prominently of the incisors and first molars.^{300, 301} Interestingly, these patients do not have demonstrable problems with extra-oral infections. Abnormal neutrophil chemotaxis to FMLP and C5a in these patients has been reported,^{300, 301} and a similar chemotactic defect was also observed in siblings of patients before developing clinical disease. Neutrophils from patients with localized juvenile periodontitis have been reported to express CR2 (the C3d receptor) on the cell surface, in contrast to control cells, which do not.³⁰² CR2 is present on normal immature neutrophils but is lost during maturation before release from the marrow. The mechanism of this abnormality has not been defined.

Desensitization

After previous exposure to a stimulus, neutrophils react less to subsequent stimulation by the same stimulus.^{303, 304, 305} This phenomenon has been termed desensitization. In some cases, the desensitization appears specific to the original stimulus, but in other cases desensitization to different stimuli is also observed (cross-desensitization).^{303, 304, 305}

Such desensitization has been observed in patients undergoing hemodialysis, in which exposure of blood to a cuprophane dialyzer membrane results in the generation of C5a, which causes a transient neutropenia due to pulmonary leukostasis, as described in Chapter 7.^{306, 307} Although C5a generation persists throughout dialysis, the neutropenia is transient.³⁰⁸ In contrast to neutrophils obtained at the start of dialysis, neutrophils obtained after 2 hours of dialysis (after the leukostasis has resolved) do not aggregate in response to plasma leaving the dialyzer membrane, demonstrating desensitization in vivo.³⁰⁸ A patient with cytomegalovirus infection and serum-induced granulocyte aggregation (presumably due to C5a) did not experience neutropenia during dialysis; and his neutrophils did not aggregate in response to serum leaving the dialyzer, in contrast to control cells, also demonstrating in vivo desensitization.³⁰⁸ Similar desensitization was demonstrated in rabbits using the chemotactic peptide FMLP, wherein continuous intravenous infusion of FMLP reproduced a transient neutropenia due to pulmonary sequestration.³⁰⁹ It is likely that neutrophil desensitization may also occur in other pathologic states, including infection, trauma, and multiorgan failure syndrome, and may contribute to neutrophil dysfunction, although the clinical significance of this phenomenon is unclear.

The phenomenon of desensitization has also been implicated as part of the mechanism by which glucocorticoids inhibit neutrophil function. It appears that the glucocorticoid-regulated protein annexin 1 (lipocortin 1) can bind a formyl-peptide receptor, induce calcium transients, and desensitize neutrophils to subsequent stimulation by other agents.³¹⁰ Two formyl-peptide receptors are expressed in neutrophils, the classic FPR and the related receptor FPRL-1/AXL. Annexin 1 appears to bind to FRPL-1/AXL, while some peptides derived from annexin 1 may bind both receptors.³¹¹

Viral Infection

Neutrophil dysfunction has been reported to occur in response to influenza A exposure. Both influenza A virus and its purified hemagglutinin activate neutrophils, and neutrophil responses to other stimuli are depressed after preexposure to influenza A and parainfluenza.^{312, 313, 314, 315, 316, 317, 318, 319} Neutrophils from patients with human immunodeficiency virus (HIV) infection also may exhibit abnormal function. In one study, neutrophils from patients with early HIV infection had enhanced superoxide production in response to bacterial products.³²⁰ Another study found evidence for neutrophil activation in patients with HIV infection as manifested by increased CD11b expression, decreased CD62L expression, increased H₂O₂ production, and increased actin polymerization.³²¹ Interestingly, H₂O₂ production, in response to FMLP after tumor necrosis factor and interleukin-8 priming, was decreased, and CD62L downregulation in response to FMLP was less complete; these abnormalities correlated with the clinical stage of disease. Whether these abnormalities are a direct effect of the HIV virus, a manifestation of desensitization as described in the previous section, or the result of another mechanism is unclear. These observations suggest that neutrophil dysfunction

P.1300

may occur in response to other viral infections as well, although the clinical significance of such a phenomenon is unclear.

Hyperalimentation Hypophosphatemia

In the past, the use of hyperalimentation without adequate phosphate occasionally resulted in hypophosphatemia that was associated with neutrophil dysfunction, including impaired chemotaxis.³²² The exact mechanism of this defect is unclear, and this syndrome is now rarely encountered, although evidence suggests that the impairment of phagocytosis seen in phosphate depletion may result from an increase in intracellular calcium.³²³

Hyperglycemia

Abnormalities have been observed in several neutrophil functions in patients with poorly controlled diabetes, including phagocytosis, chemotaxis, adhesion, and the oxidative burst.^{324, 325, 326, 327, 328, 329, 330} Improvement in glucose control is associated with an improvement in neutrophil function.³³⁰ Improvement in neutrophil function can occur after incubation with insulin for as little as 15 minutes.³³⁰ In patients with non-insulin-dependent diabetes, neutrophil dysfunction is associated with an increased intracellular calcium that returns to normal in association with normalization of phagocytic function when glucose control is improved.³²⁴

Miscellaneous

Other apparently unique neutrophil disorders have been reported. One patient with leukocytosis, severe bacterial infections, and impaired wound healing had neutrophils that appeared to have a defect in signal transduction.³³¹ These cells had a severe defect in chemotaxis, activation of the respiratory burst, and azurophil granule release in response to a variety of chemotaxis. In contrast, FMLP induced a normal increase in intracellular free calcium and specific granule release. Actin polymerization was defective in response to FMLP but normal in response to some other stimuli. Phagocytosis of opsonized bacteria was normal. Presumably, these cells have a defect in the intracellular signal transduction pathway.

Neutrophil Dysregulation in the Systemic Inflammatory Response Syndrome

Although this chapter has primarily addressed disorders resulting in decreased neutrophil function, neutrophil activity may also be increased. For example, one study reported increased neutrophil functional activity in patients with severe acute pancreatitis.³³² The clinical significance of this phenomenon is unclear.

FREQUENCY OF IDENTIFIABLE QUALITATIVE NEUTROPHIL DISORDERS

Most patients suspected of having a defect in neutrophil function do not have a well-defined abnormality. In one study of 100 patients referred for evaluation of a suspected neutrophil abnormality, only four were identified as a described syndrome.³³³ Some degree of impaired chemotaxis or superoxide production was found in 53 of 100 patients, but no abnormality was found in 41 of 100.

Chapter 59

Lysosomal Abnormalities of the Monocyte-Macrophage System: Gaucher and Niemann-Pick Diseases

Margaret M. McGovern

Robert J. Desnick

Abnormalities of the monocyte-macrophage system include certain of the inherited lysosomal storage diseases that result from specific defects in lysosomal function. Most of these disorders are caused by the deficiency of a particular hydrolytic enzyme, but others are due to impaired receptors, transporters, or deficiencies of crucial cofactors or protective proteins. Prevalent among these disorders are the sphingolipidoses, which are a unique family of diverse diseases related by their molecular pathology. Here, the clinical, biochemical, and genetic features of two of these disorders are presented: Niemann-Pick types A and B disease, caused by defects in the acid sphingomyelinase (SMPD1) gene, and Gaucher disease, caused by defects in the acid α -glucosidase (GBA) gene. In each of these autosomal recessive disorders, mutations in the gene that encodes the lysosomal enzyme result in a defective gene product (i.e., a noncatalytic enzyme) that is unable to perform its normal function as a hydrolase. The deficiency of these lysosomal hydrolases results in abnormal metabolism of the enzyme's specific sphingolipid substrate, and the substrate accumulates in the cells of the monocyte-macrophage system, causing the clinical manifestations. For example, in Gaucher disease and Niemann-Pick types A and B diseases, anemia, thrombocytopenia, leukopenia, and/or hepatosplenomegaly can be the presenting symptoms. Thus, these disorders are frequently diagnosed by the hematologist and must be included in the differential diagnosis for patients with monocyte-macrophage involvement.

PATHOPHYSIOLOGY OF THE LYSOSOMAL STORAGE DISEASES

The underlying defect in the inherited lipidoses is the accumulation of metabolites, including glycolipids and sphingomyelin. The glycosphingolipids, which are present in the membranes of many cell types, are formed by the addition of various carbohydrates to a ceramide backbone (Fig. 59.1). The fatty acid portion of ceramide consists primarily of stearic acid (C₁₈) in the brain, whereas in non-neural tissues it is somewhat longer (C₂₀ to C₂₄). Each sphingolipid is characterized by the nature of the compound that is esterified to the first carbon of the ceramide molecule. For example, the addition of hexoses and N-acetylneuraminic acid to ceramide forms the gangliosides, which are found in brain, whereas the neutral glycolipids are found more ubiquitously in cell membranes. The blood group antigens are also glycosphingolipids. In the lysosomal storage diseases, these lipid compounds vary in amount in different cell types, so their rate and amount of accumulation because of a specific lysosomal enzyme defect will vary, leading to their cell-related manifestations (Fig. 59.2). Tables 59.1 and 59.2 outline the biochemical and phenotypic characteristics and the molecular basis of the lysosomal storage diseases, respectively.

FIGURE 59.1. Formulas of some of the sphingolipids.

GAUCHER DISEASE

Definition and History

Gaucher disease is a lipid storage disease characterized by the deposition of glucocerebroside in cells of the macrophage-monocyte system. It was first described by Gaucher in 1882, and the storage of glucocerebroside was first recognized by Epstein in 1924. The metabolic defect, which is the deficiency of the lysosomal hydrolase acid β -glucosidase, or β -glucocerebrosidase, was identified by Brady et al.¹ There are three clinical subtypes, which are delineated by the absence or presence and progression of neurologic involvement: type 1 or the non-neuronopathic form; type 2, the infantile-onset, acute neuronopathic form; and type 3, the juvenile-onset neuronopathic form.² All three subtypes are inherited as autosomal recessive traits. Type 1 disease is the most common lysosomal

P.1303

storage disease and one of the most prevalent genetic disorders among Ashkenazi Jewish individuals, with an incidence of about 1 in 1,000 and a carrier frequency of about 1 in 15.³

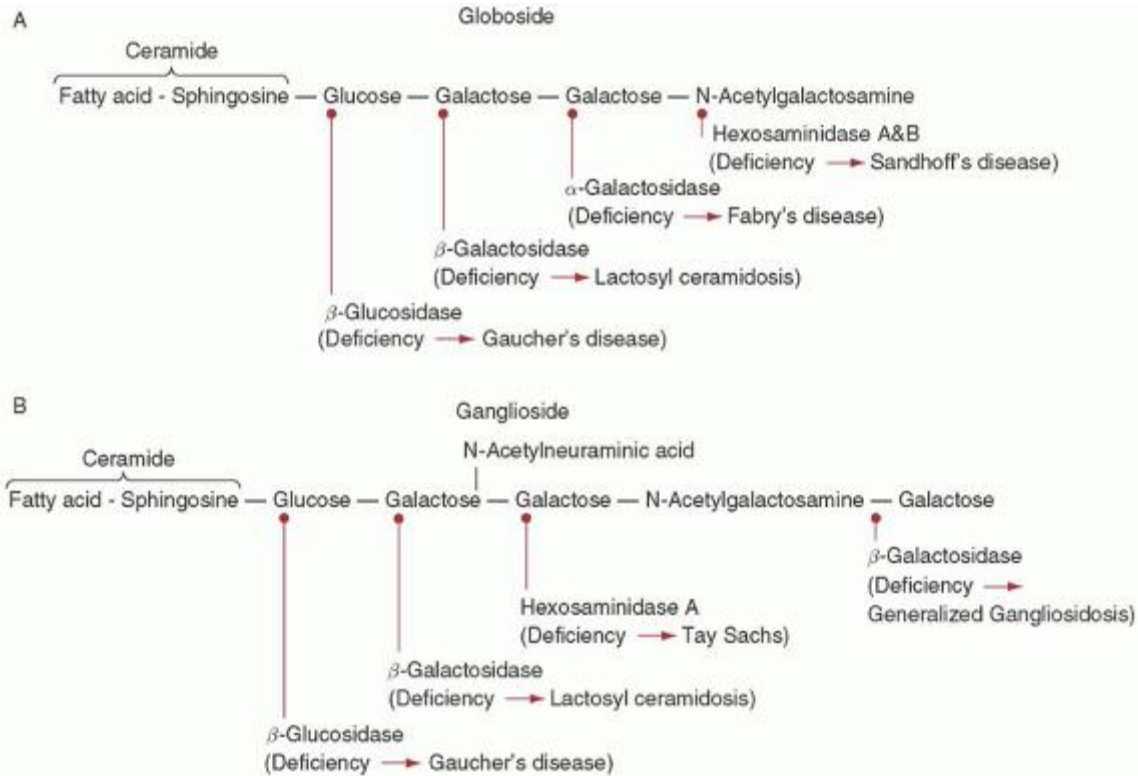

FIGURE 59.2. Schematic structure of globoside (A) and ganglioside (B) to show site of action of the several catabolic enzymes, which result in one of the storage diseases when defective.

Etiology and Pathogenesis

All three subtypes of Gaucher disease result from the deficient activity of the lysosomal hydrolase, acid β -glucosidase (Table 59.1). The major acid β -glucosidase gene mutations that cause Gaucher disease among Ashkenazi Jewish patients have been identified (Table 59.2). Genotype/phenotype correlations have been made for the different subtypes and provide insight into the molecular basis for the remarkable clinical variation in Gaucher disease. Presumably, the amount of residual enzymatic activity determines disease subtype and severity. For example, the mutations that cause the severe type 2 (infantile) disease express little, if any, enzymatic activity in vitro, whereas type 1 patients who are homozygous for the milder N370S mutation tend to have a later

P.1304

onset and a milder course than patients with one N370S allele and another mutant allele. However, the wide variability in clinical presentation among Gaucher disease patients cannot be fully explained by the underlying acid β -glucosidase mutations, and presumably other “modifier” genes can influence disease severity.

TABLE 59.1 BIOCHEMICAL AND PHENOTYPIC CHARACTERISTICS OF GAUCHER AND NIEMANN-PICK DISEASES

Disease	Enzyme Deficiency	Substance Accumulated	Site	Complications
Gaucher Disease				
Type 1	Acid β -glucosidase	Primarily glucosylceramide	Macrophage-monocyte system	Infiltration of bone marrow, progressive hepatosplenomegaly, skeletal complications
Type 2	Acid β -glucosidase	Primarily glucosylceramide	Macrophage-monocyte system, CNS	Infiltration of bone marrow, progressive hepatosplenomegaly, skeletal complications,

Type 3	Acid β -glucosidase	Primarily glucosylceramide	Macrophage-monocyte system, CNS	neurodegeneration Progressive neurodegeneration
Niemann-Pick Disease				
Type A	Acid sphingomyelinase	Sphingomyelin	Monocyte-macrophage system, CNS	Hepatosplenomegaly, progressive neurodegeneration
Type B	Acid sphingomyelinase	Sphingomyelin	Monocyte-macrophage system	Progressive hepatosplenomegaly, infiltrative lung disease
Type C	Abnormal cholesterol transport	Primarily cholesterol	Most cells, especially liver, CNS	Hepatosplenomegaly, progressive neurodegeneration

CNS, central nervous system.

TABLE 59.2 MOLECULAR BASIS OF GAUCHER AND NIEMANN-PICK DISEASES

Disease	Chromosome Assignment	Molecular Characteristics	Comments
Gaucher disease	1q21	cDNA, functional and pseudogenomic sequences, >200 mutant alleles known	Four mutations (N370S, L444P, 84insG, IVS2 ⁺ 1) account for 90 to >95% of mutant alleles in Ashkenazi Jewish patients
Niemann-Pick disease			
Types A and B	11p15.1 to p15.4	cDNA, entire genomic sequence, >70 mutant alleles known	Four mutations account for >95% of mutant alleles in Ashkenazi Jewish patients with type A disease
Type C	18q11-q12 region	cDNA, entire genomic sequence, >100 mutant alleles known	More than 100 mutations in NPC1 gene

Pathology

The pathologic hallmark in Gaucher disease is the presence of Gaucher cells in the macrophage-monocyte system, particularly in the bone marrow. These cells, which are 20 to 100 μ m in diameter, have a characteristic wrinkled-paper appearance resulting from intracytoplasmic substrate deposition. These cells stain strongly positive with periodic acid-Schiff reagent, and their presence in bone marrow and/or other tissues suggests the diagnosis (Fig. 59.3). The accumulated glycosphingolipid, glucosylceramide, is derived primarily from the phagocytosis and degradation of senescent leukocytes and, to a lesser extent, erythrocyte membranes. Glucosylceramide storage results in organomegaly and pulmonary infiltration. Neuronal cell loss in patients with types 2 and 3 disease presumably results from the neural accumulation of the cytotoxic glycosphingolipid, glucosphingosine, due to the severe deficiency of acid β -glucosidase activity. Glucosylceramide accumulation in the bone marrow, liver, spleen, lungs, and kidney leads to pancytopenia, massive hepatosplenomegaly, diffuse infiltrative pulmonary disease, and nephropathy or glomerulonephritis. The progressive infiltration of Gaucher cells in the bone marrow causes thinning of the cortex, pathologic fractures, bone pain,

bony infarcts, and osteopenia, particularly in type 1 disease. Central nervous system (CNS) involvement occurs only in patients with types 2 and 3 disease.

FIGURE 59.3. Splenic histopathology in Gaucher disease. There are sheets of histiocytes with bland nuclei and abundant pink cytoplasm with a fine “tissue paper” appearance.

Clinical Manifestations

Type 1 Disease

There is a broad spectrum of clinical expression among type 1 disease patients, in part because of the combination of different mutant alleles. Onset of clinical manifestations occurs from early childhood to late adulthood, with more symptomatic patients presenting in childhood or adolescence. At presentation, patients may have easy bruisability resulting from thrombocytopenia, chronic fatigue secondary to anemia, hepatomegaly with or without elevated liver function tests, splenomegaly, and bone pain or pathologic fractures. Occasional patients present with pulmonary involvement. Patients who are diagnosed in the first 5 years of life are frequently non-Jewish and typically have a more malignant disease course. Milder patients are discovered later in life during evaluations for hematologic or skeletal problems, or are found to have splenomegaly on routine examinations. In symptomatic patients, splenomegaly is progressive and can become massive. Clinically apparent bony involvement can present as bone pain or pathologic fractures. Most patients have radiologic evidence of skeletal involvement, including an “Erlenmeyer flask” deformity of the distal femur, which is an early skeletal change. In patients with symptomatic bone disease, lytic lesions can develop in the long bones, ribs, and pelvis, and osteosclerosis may be evident at an early age. Bone crises with severe pain and swelling can occur. Bleeding secondary to thrombocytopenia may manifest as epistaxis and bruising and is frequently overlooked until other symptoms become apparent. Children with massive splenomegaly are short of stature because of the energy expenditure required by the enlarged organ.

Type 2 Disease

Infants with the rare and panethnic type 2 subtype have a rapid neurodegenerative course with extensive visceral involvement and death within the first 2 years of life. The disease presents in infants with increased tone, strabismus, and

organomegaly. Failure to thrive and stridor resulting from laryngospasm are typical. The progressive psychomotor degeneration leads to death, usually due to respiratory compromise.

Type 3 Disease

Patients with type 3 Gaucher disease typically present in infancy or childhood. In addition to the organomegaly and bony involvement, neurologic involvement is present. There is a high frequency of type 3 disease in Sweden (1 in 50,000), which has been

P.1305

traced to a common founder in the 17th century. Type 3 has been further classified as type 3a or 3b based on the extent of neurologic involvement and whether there is progressive myotonia and dementia (type 3a) or isolated supranuclear gaze palsy (type 3b).

Diagnosis

Gaucher disease should be considered in the differential diagnosis of patients who present with unexplained organomegaly, easy bruisability, and/or bone pain.⁴ In the past, bone marrow examination revealing the presence of Gaucher cells was used for diagnosis. Today, all suspect diagnoses should be confirmed by demonstrating deficient acid β -glucosidase activity in isolated leukocytes or cultured fibroblasts. For genotype/phenotype correlations, the specific acid β -glucosidase gene mutation should be determined, particularly in Ashkenazi Jewish patients. Carrier identification can be achieved by enzymatic assay, although in the Ashkenazi this can be achieved by detection of the common mutations. Testing should be offered to all family members, keeping in mind that heterogeneity even among members of the same kindred can be significant and that asymptomatic affected individuals may be diagnosed during such testing. Prenatal diagnosis is available by determining the enzymatic activity and/or the parent's specific mutations in chorionic villi or cultured amniotic fluid cells.

Treatment

Enzyme replacement with recombinant acid β -glucosidase (imiglucerase [Cerezyme, Genzyme Corporation, Cambridge, MA] or velaglucerase alfa [VPRIV, Shire HGT, Lexington, MA]) is the standard of care for the treatment of patients with type 1 disease. Clinical trials have demonstrated that most extra-skeletal symptoms are reversed within 12 to 36 months by an initial debulking dose of enzyme (60 units/kg) administered by intravenous infusion every other week. Initial higher doses may be indicated in patients with severe disease (type 3) at the time of diagnosis and in those with rapid progression or significant comorbidities.⁵ Early treatment may be efficacious in normalizing linear growth and bone morphology in affected children. Experience during the last 20 years has proven enzyme replacement therapy to be safe and effective in preventing the complications of type 1 disease. However, enzyme replacement does not alter the neurologic progression of patients with Gaucher disease types 2 and 3. It has been used in these patients as a palliative measure, particularly in type 3 patients with severe visceral involvement. Alternative treatments being evaluated include therapies targeted to reducing the synthesis of glucosylceramide by chemical inhibition of glucosylceramide synthase, as well as pharmacologic chaperone monotherapy to increase the residual activity of missense mutations, and pharmacologic chaperone coadministration with the recombinant enzyme to stabilize it in the circulation and to increase its delivery to other tissues.

NIEMANN-PICK DISEASE

Definition

Niemann-Pick disease (NPD) types A and B are lipid storage disorders that result from the deficiency of the lysosomal enzyme, acid sphingomyelinase, and the subsequent accumulation of its substrate, sphingomyelin.⁶ The original description of NPD referred to what is now known as type A NPD, which is a fatal neurodegenerative disorder of infancy characterized by failure to thrive, hepatosplenomegaly, and a rapidly progressive neurodegenerative course that leads to death by the age of 2 or 3 years. Type B NPD has a wide phenotypic spectrum that can include neurologic manifestations, but typically does not.^{6, 7, 8} Type C NPD is a neurodegenerative disorder that results from defective intracellular cholesterol transport and accumulation of unesterified cholesterol in lysosomes.^{7, 8} Previously, a type D disease was identified in patients from Nova Scotia; however, these patients actually have type C disease. All the subtypes are inherited as autosomal recessive traits and display variable clinical features.

Etiology and Pathogenesis

Types A and B NPD result from the deficient activity of the lysosomal hydrolase, acid sphingomyelinase (Table 59.1). In type C NPD, the genetic defect involves the defective transport of cholesterol from the lysosome to the cytosol. Two different genes causing the altered cholesterol transport in type C disease have been identified (NPC1 and NPC2), permitting more precise diagnosis, carrier detection, and prenatal diagnosis in affected families. Only types A and B are discussed here; for type C, see Refs. 7 and 8.

Pathology

Types A and B Niemann-Pick Disease

The pathologic hallmark in types A and B NPD is the histochemically characteristic lipid-laden foam cell, often referred to as the "Niemann-Pick cell." These cells, which can be readily distinguished from Gaucher cells by their histologic and histochemical characteristics, are not pathognomonic for NPD, because histologically similar cells are found in patients with Wolman disease, cholesterol ester storage disease, lipoprotein lipase deficiency, and in some patients with GM1 gangliosidosis, type 2 (Fig. 59.4). Sphingomyelin is the major lipid that accumulates in the cells and tissues of patients with types A and B NPD. In most normal tissues, sphingomyelin constitutes from 5% to 20% of the total cellular phospholipid content; however, in patients with types A and B NPD, the sphingomyelin levels may be elevated up to 50-fold, constituting ~70% of the total phospholipid fraction. Lysosomal sphingomyelin accumulation in liver, kidney, and lungs has been documented with organs from types A and B NPD patients containing about the same amount of sphingomyelin, with the notable finding of significant sphingomyelin and psychosphingosine in the CNS of type A NPD patients. In general, patients with type A disease have <5% of normal acid sphingomyelinase activity when assayed in cultured fibroblasts and/or lymphocytes, whereas cells from type B patients typically have >5% of normal activity,

P.1306

which presumably prevents the development of the neurologic symptoms.

FIGURE 59.4. Splenic histology in Niemann-Pick disease type B. Aggregates of histiocytes are present with distinct

vacuoles. Although some large vacuoles are seen, most are small. (Image provided by Professor Attilio Orazi, Department of Pathology, Indiana University.)

Clinical Manifestations

Types A and B Niemann-Pick Disease

The clinical presentation and course of type A NPD is relatively uniform and is characterized by a normal appearance at birth. Hepatosplenomegaly and psychomotor retardation are evident by 6 months of life, followed by rapid neurodegeneration and death by 3 years. The loss of motor function and the deterioration of intellectual capabilities are progressive. In later stages, spasticity and rigidity are evident, with affected infants experiencing complete loss of contact with their environment.

In contrast to the stereotyped type A phenotype, the clinical presentation and course of patients with type B disease are more variable. Most patients are diagnosed in infancy or childhood, when enlargement of the liver and/or spleen is detected during a routine physical examination. At diagnosis, type B patients also have evidence of mild pulmonary involvement, usually detected as a diffuse reticular or finely nodular infiltration on chest roentgenogram. In most patients, hepatosplenomegaly is particularly prominent in childhood, but with increasing linear growth the abdominal protuberance decreases and becomes less conspicuous. In mildly affected patients, the splenomegaly may not be noted until adulthood, and there may be minimal disease manifestations. In most type B patients, decreased pulmonary diffusion resulting from alveolar infiltration becomes evident in childhood and progresses with age. Severely affected individuals may experience significant pulmonary compromise by age 15 to 20 years. Such patients have low pO_2 values and dyspnea on exertion. Lifethreatening bronchopneumonias may occur, and cor pulmonale has been described. Severely affected patients also may have liver involvement leading to life-threatening cirrhosis, portal hypertension, and ascites. Clinically significant pancytopenia resulting from secondary hypersplenism may necessitate partial or total splenectomy, although removal of the spleen can exacerbate the pulmonary disease.

Cholesterol abnormalities characterized by low high-density lipoprotein cholesterol and increased total cholesterol are found in most patients and can be associated with early atherosclerotic changes. Some type B patients have neurologic involvement, which can include cerebellar signs and nystagmus, extrapyramidal involvement, mental retardation, and psychiatric disorders. As in other lysosomal storage diseases, it is evident that neurologic manifestations in acid sphingomyelinase deficiency may occur along a continuum among patients. Nevertheless, there is a distinctive, fatal neurodegenerative form (NPD-A), characterized by a brief period of normal development followed by a severe neurodegenerative course and death in early childhood.

Patients with NPD type C disease often have prolonged neonatal jaundice, appear normal for 1 to 2 years, and then experience a slowly progressive and variable neurodegenerative course. Their hepatosplenomegaly is less severe than that in patients with type A or B disease, and they may survive into adulthood.

Diagnosis

Type A NPD patients are diagnosed in the first year of life with failure to thrive, organomegaly, and severe psychomotor retardation. In type B NPD patients, splenomegaly is usually noted early in childhood; however, in very mildly affected patients, the enlargement may be subtle and detection may be delayed until adolescence or adulthood. The presence of the characteristic Niemann-Pick cells in the bone marrow supports the diagnosis. However, patients with type C disease also have extensive infiltration of these cells in the bone marrow. Thus, all suspect cases should be evaluated enzymatically to confirm the clinical diagnosis by measuring the acid sphingomyelinase activity in peripheral leukocytes, or cultured fibroblasts and/or lymphoblasts. Patients with type A or B disease will have markedly decreased levels of enzymatic activity (1% to 10% of normal), whereas patients with type C disease may have slightly decreased sphingomyelinase activities (50% to 75% of normal), and patients with Gaucher disease and other storage disorders presenting with hepatosplenomegaly and/or neurologic involvement will have normal or near-normal acid sphingomyelinase levels. Type C NPD can be documented biochemically by demonstrating the cholesterol transport defect in cultured fibroblasts or by determining the specific mutations in the NPC1 or NPC2 genes.

The enzymatic identification of type A and B carriers is problematic. However, in families in which the specific molecular lesion has been identified, family members can be accurately tested for heterozygote status by DNA analysis. Prenatal diagnosis of types A and B disease may be made reliably by measuring the acid sphingomyelinase activity in cultured amniocytes or chorionic villi. In families in which the specific gene mutations are known, the prenatal diagnosis can be made by DNA analysis of fetal cells. In type C disease, the cholesterol defect can be demonstrated by filipin staining, but DNA diagnosis using fetal cells is most accurate.

Treatment

Orthotopic liver transplantation in an infant with type A disease and amniotic cell transplantation in several type B patients have been attempted, with little or no success. Bone marrow transplantation of type B patients has reduced the spleen and liver volumes, the sphingomyelin content of the liver, the number of Niemann-Pick cells in the marrow, and the radiologic infiltration of the lungs. However, no long-term information is available, as these patients often lose their engraftment or have significant morbidity and mortality in the post-transplant period. To date, lung transplantation has not been reported in any severely compromised type B patient. Clinical trials of enzyme replacement therapy have begun for NPD type B. Treatment of types A and C disease is limited by the severe neurologic involvement.

Chapter 60

Langerhans Cell Histiocytosis

Suman Malempati

H. Stacy Nicholson

Langerhans cell histiocytosis (LCH) is a disorder characterized by clonal proliferation of cells in the mononuclear phagocyte system. Since the first case was described more than a century ago,¹ LCH has often been a source of confusion, perhaps best demonstrated by the several labels given to the disorder during the past 100 years. Since 1985, Langerhans cell histiocytosis has been the preferred term,^{2, 3} replacing histiocytosis X, coined in 1953.⁴ The X demonstrated the lack of knowledge about the etiology and pathophysiology of LCH, and about how the different clinical syndromes were related. The term histiocytosis X did serve to bind the syndromes, which included Hand-Schuller-Christian syndrome, Letterer-Siwe disease, eosinophilic granuloma, Hashimoto-Pritzker syndrome,⁵ self-healing histiocytosis,⁶ and pure cutaneous

histiocytosis,⁷ into one clinical entity. The term Langerhans cell histiocytosis reflects the central role of the Langerhans cell in these diseases. LCH also distinguishes these disorders from other histiocytic syndromes, which include primary and secondary hemophagocytic lymphohistiocytosis, Rosai-Dorfman disease, and neoplastic disorders such as acute monocytic leukemia, malignant histiocytosis, and true histiocytic lymphoma.³ This chapter focuses on LCH.

HISTORY

The clinical triad of defects in membranous bone, exophthalmos, and polyuria in children, which became known as Hand-Schuller-Christian disease,⁸ was described in 1921 in a review by Hand.⁹ Hand described the first six reported cases, including those of Christian, Schuller, and his own first case reported in 1893.¹ All six patients had hepatosplenomegaly, lymphadenopathy, and bone lesions. However, not all had exophthalmos and polyuria. Attempts to link the disorder to xanthoma tuberosum, lipid storage disease, and the xanthomatoses proved unsuccessful, and to this day, no evidence exists that a specific biochemical defect is responsible for the condition. However, the foamy or xanthoma cell came to be regarded as a pathognomonic feature of the syndrome.¹⁰

A different syndrome, consisting of fever, bilateral otitis media, hepatosplenomegaly, and adenopathy in a young infant who died, was described by Letterer in 1924.¹¹ In 1933, Siwe described a 16-month-old girl who died after a 3-month illness characterized by fever, hepatosplenomegaly, lymphadenopathy, neutrophilia, and a destructive lesion in her fibula.¹² At autopsy, massive infiltrates of large cells resembling histiocytes were found. Siwe reviewed five other cases from the literature (including that of Letterer) and concluded that they constituted a single clinical entity.¹²

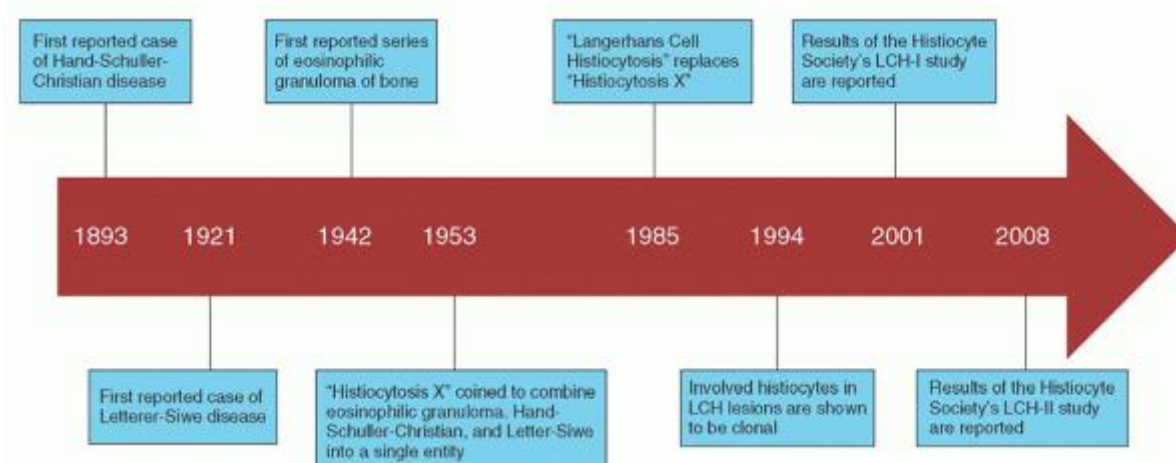

FIGURE 60.1. Historical timeline demonstrating the major discoveries regarding the pathogenesis and treatment of Langerhans cell histiocytosis (LCH).

In 1940, two groups of investigators described a syndrome in which a characteristic feature was infiltration of bone by eosinophilic granulomas.^{13, 14} In 1942, Green and Farber described a series of patients with eosinophilic granulomas of bone, which usually healed promptly after irradiation or curettage.¹⁵ They noted that these cases shared pathologic features similar to those of the Letterer-Siwe and Hand-Schuller-Christian syndromes. In 1953, because of the similarity of the histiocytes observed in these three disorders, Lichtenstein combined them into a single entity called histiocytosis X to indicate their unknown cause.⁴ The recognition that these three disorders were related was an important contribution. The term Langerhans cell histiocytosis, proposed in 1985, reflects an improved understanding of these disorders.³

Despite our understanding of the central role played by the Langerhans cells in LCH, little is known about the etiology of LCH. Although clinical features of LCH were first recognized over a century ago, the pathogenesis remains uncertain. In 1994, two separate groups detected clonality of the involved histiocytes from LCH lesions.^{16, 17} Clonality was demonstrated in LCH cells from unifocal lesions as well as disseminated disease. However, debate continues as to whether LCH represents a neoplastic disorder or a reactive proliferation of histiocytes (Fig. 60.1).

EPIDEMIOLOGY

Although estimates vary by region and time period, the annual childhood incidence of LCH has been estimated to be approximately 4 to 9 cases per million.^{18, 19, 25} The discrepancy between epidemiologic studies is likely due to variation in reporting and data collection. Across studies, there is consistently a slight

predominance of cases in males.^{18, 19, 20} LCH occurs less frequently in adults with an incidence of 1 to 2 cases per million per year.²¹ The disease is more common and tends to be more severe in younger children. For children under 1 year of age, the annual incidence is 9.9 cases per million.²² Almost all cases of multisystem LCH occur before 5 years of age.^{23, 24, 25} In an exploratory case-control study comparing 177 children with LCH to children with cancer and community controls,²⁰ LCH was associated with a family history of benign tumors and less strongly with feeding problems during infancy. Other factors associated with LCH in this study were maternal urinary tract infections during pregnancy and blood transfusions during infancy. Factors not associated with LCH were the typical childhood viral infections and medication use. In a case-control study of 459 children with LCH, which compared risk factors in children with LCH to those in both community and cancer controls,²⁶ LCH was associated with neonatal infections, solvent exposure, and thyroid disease in the proband or the family. Childhood immunizations appeared to be protective. Reports of seasonal variation in incidence are conflicting.^{18, 25} Familial clustering of LCH has been observed, suggesting that a genetic predisposition may exist.²⁷ The concordance rates between dizygotic and monozygotic twins are 33% and 80%, respectively. In addition, patients with LCH may have a predisposition to cancer and vice versa. Links with both solid tumors and leukemia have been documented.²⁸ Several cases of LCH developing in patients with acute lymphoblastic and acute myelogenous leukemia have been reported.^{29, 30, 31, 32} Patients with LCH have genetic instability and increased chromosomal breakage, which also suggests a genetic predisposition to malignancy.^{33, 34, 35}

PATHOLOGY AND PATHOPHYSIOLOGY

The basic histologic lesion in LCH is granulomatous, with lesions containing histiocytes, mature eosinophils, and lymphocytes.³⁶ Other cells present may include giant cells, neutrophils, and plasma cells. Initially, lesions are proliferative and dominated by histiocytes, some of which are Langerhans cells. Although mitotic figures may occasionally be identified, the histiocytes are not neoplastic by histologic criteria. As lesions progress, necrosis may develop, and the number of eosinophils and phagocytic cells containing cellular debris increases. Ultimately, xanthomatous changes and fibrosis may occur, and late in the course of disease, Langerhans cells may no longer be demonstrable. Multinucleated giant cells occasionally are prominent, especially in bone and lymph nodes. The histologic findings do not correlate with the extent or aggressiveness of disease.³⁷

The Langerhans cell is the sine qua non of the diagnostic lesion. Langerhans cells are dendritic antigen-presenting cells that are normally found in skin and other organs. Langerhans cells are classified as dendritic cells because of their capacity to form long cytoplasmic extensions through which they establish intimate contact with other cells. The presence of fascin, a highly selective marker of dendritic cells, on the surface of Langerhans cells confirms their derivation from dendritic cells.³⁸ Langerhans cells are found primarily in normal epidermis, but also are evident in lymph nodes and spleen. A hematopoietic progenitor of Langerhans cells has been identified in normal bone marrow.³⁹ In the skin, Langerhans cells form a trap for external contact antigens and are involved in delayed hypersensitivity. Despite low phagocytic activity, they fix antigens for presentation to other cells, especially T lymphocytes.⁴⁰

Although its demonstration is essential for diagnosis, the Langerhans cell may constitute no more than a small proportion of histiocytes within lesions. Viewed by light microscopy, these cells appear as large mononuclear cells with few cytoplasmic vacuoles and little or no phagocytic material.⁴¹ The nuclei are irregularly shaped and contain a fine chromatin pattern. Electron microscopic or immunohistochemical studies may be required to identify Langerhans cells with confidence. The former demonstrate structures known as Birbeck granules (Langerhans bodies, X granules),⁴² rod-shaped organelles with a central striation and occasional terminal vesicular dilation, giving them a tennis racket appearance (Fig. 60.2). Birbeck granules are thought to be produced by invagination of the cell membrane, and their function is not known. The other feature that conclusively establishes the diagnosis of LCH is the demonstration of either CD1a antigen or CD207 (Langerin) on the surface of LCH cells by immunohistochemical staining.^{36, 43} Langerin is a cell-surface receptor that induces the formation of Birbeck granules.⁴⁴ Langerin expression has recently been recognized as a sensitive and relatively specific marker in establishing the diagnosis of LCH. Other distinctive features of Langerhans cells that can be demonstrated with immunohistochemical techniques include the expression of S-100 protein,⁴¹ Ia-like antigen,⁴⁵ and CD101.⁴⁶

FIGURE 60.2. Electron micrograph of Langerhans cells from a bone lesion demonstrating characteristic Birbeck granules with a trilaminar structure. (Magnification $\times 45,000$; courtesy of Roma Chandra.)

The intralesional histiocytes of LCH were previously thought to be similar to normal Langerhans cells found in skin. However, it is now recognized that pathologic Langerhans cells or LCH cells are a less differentiated and more activated type of dendritic cell.⁴⁷ CD1a-positive LCH cells from bone lesions express CD14 and CD68, monocyte antigens that are not expressed or are expressed at low levels in normal skin Langerhans cells.⁴⁸ A recent study demonstrated a gene expression profile of intralesional LCH cells that was distinct from that of normal skin Langerhans cells.⁴⁹ LCH cells also express the immature dendritic cell marker CCR6 in the absence of CCR7, which is expressed on mature dendritic cells.⁵⁰ LCH cells exhibit a degree of migration capability, which is absent in mature dendritic cells. LCH cells can be induced to differentiate in the presence of CD40 ligand *in vitro*.⁴⁸ However, as CD40 ligand is abundant in LCH lesions, the reason for maturational arrest is unclear.⁵¹ Abnormal cellular adhesion molecules in LCH cells, suggested by the presence of CD2, CD11a, CD11b, and CD11d, may contribute to the migration of Langerhans cells into LCH lesions, as well as their abnormal persistence and proliferation.⁵² Compared to normal Langerhans cells, LCH cells are defective in their alloantigen-presenting activity.⁵³

The focal accumulation of Langerhans cells, macrophages, lymphocytes, and eosinophils suggests that LCH is immunologically mediated. This reasoning is supported by both histologic abnormalities of the thymus and disturbances of immunoregulation in patients with active disease.⁵⁴ Thymic abnormalities were noted by Letterer in his initial description of the disorder, later known as Letterer-Siwe disease.¹¹ Abnormalities noted on pre-therapy biopsy samples and postmortem materials include dysmorphic

P.1309

changes, dysplasia, and nonspecific involution.^{55, 56, 57} In patients with LCH, the number of normal thymocytes (expressing CD6) and late differentiating suppressor lymphocytes (expressing CD8) is decreased.⁵⁸ These abnormalities are noted even when the disease is limited in its distribution.

Recognition of the possible pathogenic significance of thymic abnormalities prompted several studies of T lymphocytes in blood. The demonstration of decreased numbers of H2 receptors on blood lymphocytes suggested loss of T-suppressor cells.⁵⁹ This loss was confirmed by quantitation of T-cell subsets in patients with active disease. Both the relative and absolute numbers of suppressor T lymphocytes (CD8⁺ cells) are decreased, resulting in an increase in the T4-to-T8 ratio.

Suppressor cell activity as measured by the concanavalin A and indomethacin stimulation assays also is poor.⁵⁹ That T-suppressor cell deficiency may be causally related to a functionally abnormal thymus is suggested by the normalization of T4-to-T8 ratios with thymic extract.⁵⁷ Moreover, the apparent ability of crude thymic extract to reverse disease activity in some patients suggests that the T-cell abnormalities may be of primary pathogenic significance.⁵⁷

Although less consistent, other abnormalities in immune regulation also have been described, including hypergammaglobulinemia,⁶⁰ deficiency in antibody-dependent monocyte-mediated cytotoxicity,⁶¹ and abnormal in vitro response to mitogens and antigens.⁵⁵ However, most investigators note normal mitogeninduced responses and normal delayed hypersensitivity.⁶² Also, several cytokines are increased in LCH.^{63, 64} Cytokines serve as mediators of inflammation, regulators of lymphocyte growth and differentiation, and activators of specialized effector cells. In tissue culture, Langerhans cells purified from bony LCH lesions secrete interleukin-1 (IL-1) and prostaglandin E2, both of which induce bone resorption in vitro.⁶⁵ These lesions also secrete angiotensin converting enzyme, transforming growth factor-β1 and IL-2.⁶⁶ These mediators are probably responsible for the osteolytic lesions that are a prominent clinical feature of LCH. Other cytokines that have been demonstrated to be increased in the serum of LCH patients include granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, IL-8, IL-10, and tumor necrosis factor-α.⁶⁷ These cytokines are related to local activation of T lymphocytes and other inflammatory leukocytes. In addition, GM-CSF receptors are expressed by Langerhans cells.⁶⁸ GM-CSF induces Langerhans cell proliferation and activation in vitro, and serum levels of GM-CSF have been correlated with the extent of disease.⁶⁸

The link between proliferation of Langerhans cells and immune dysfunction has not been worked out entirely. One suggestion is that the disorder results from a physiologically appropriate response of the Langerhans cell to an external antigen or neoantigen, possibly infectious in origin. However, the lack of seasonal variation or geographic clustering argues against an infectious basis. In addition, no direct evidence for a viral etiology (viral particles or nuclear material) in LCH lesions has been demonstrated.^{69, 70} Alternatively, LCH may result from an appropriate response of the Langerhans cell to abnormal signals from other cells in the immune system, perhaps from T lymphocytes. In either event, deficiency of T-suppressor cells may disrupt the mechanism for termination of immune responses. Failure of this homeostatic mechanism could result in unrestrained macrophage proliferation. Patients with interferon-γ deficiency present with findings that mimic LCH.⁷¹

TABLE 60.1 SYSTEMS AFFECTED ON DIAGNOSIS OF LANGERHANS CELL HISTIOCYTOSIS BY AGE

Age Group	Number	Multisystem Disease (%)	Percentage of Cases with Each System Affected on Diagnosis							
			Bone	Skin	Soft Tissue	Lymph Nodes	Liver/Spleen	Lung	Ear	Other

From Alston RD, Tatevossian RG, McNally RJ, et al. Incidence and survival of childhood Langerhans cell histiocytosis in Northwest England from 1954 to 1998. *Pediatr Blood Cancer* 2007;48:555-560, with permission.

Whether LCH is primarily a reactive or neoplastic process has long been debated. The predominant theory has been that LCH is a reactive process to an unknown stimulus.⁷² However, in 1994 two groups showed that the lesional cells are clonal^{16, 17}; clonality occurred in patients with all forms of LCH, including acute disseminated LCH and unifocal LCH, and in those with intermediate forms of the disease. T-cells within LCH lesions were polyclonal.¹⁶ Interestingly, LCH occurs in some individuals with malignant disorders.²⁸ Most cases of malignancy occur after treatment for LCH, although acute lymphoblastic leukemia, in particular, may precede the diagnosis of LCH.^{31, 32} The presence of chromosomal instability and mutational events reported in a few studies support a neoplastic process.^{34, 35} However, at least some cases of pulmonary LCH are not clonal.⁷³ Moreover, the immature phenotype of LCH cells appears dependent on the microenvironment,

suggesting a reactive process. Therefore, although the clonality of LCH cells has fueled the argument that LCH may be a neoplastic disorder, the debate continues.

CLINICAL FEATURES

LCH can present along a continuum of illness, ranging from indolent to explosive disease. In some patients, pathologic lesions are solitary, whereas in others they are widely disseminated. Moreover, the distribution of lesions in a given patient may vary considerably over time. Although LCH can occur at any age, it occurs with greatest frequency in infants and children. The median age at diagnosis for all disease variants is 3 to 6 years.^{18, 19} The acute disseminated form of the disease characteristically occurs in younger children and almost all cases occur before the age of 5 years.²⁵ Children younger than 1 year old, in particular, often present with multiple organ involvement.^{22, 74} The more indolent forms of LCH occur primarily in older children and young adults.⁷⁵ Approximately 70% of cases of LCH in children involve a single organ system, with bone being the most common site.^{18, 19, 22, 25} Table 60.1 shows the distribution of involved sites

P.1310

by age at diagnosis of LCH. The most commonly involved organ in adults is bone, often accompanied by an adjacent soft tissue mass.^{76, 77} Other organs that are involved less often in adults include the lungs and pituitary gland.⁷⁶ In adults, multisystem disease, including liver, lymph node, and bone marrow involvement, is extremely rare.

The traditional classification of clinical variants was based on patterns of organ involvement.⁸ Eosinophilic granuloma was used to describe a syndrome characterized by single or multiple bone lesions in the absence of visceral involvement.¹³ When granulomas involved the liver, spleen, lymph nodes, skin, central nervous system (CNS), or bone marrow as well as bones, the disorder was called Letterer-Siwe disease.^{11, 12} The triad of multiple bone lesions, exophthalmos (resulting from retro-orbital granulomas), and diabetes insipidus (DI; the result of hypothalamic or pituitary involvement) constituted Hand-Schuller-Christian disease (Figs. 60.3 and 60.4).⁹ The separation of eosinophilic granuloma of bone from syndromes characterized by visceral dissemination proved to be useful prognostically. However, the distinction between Letterer-Siwe disease and Hand-Schuller-Christian disease was often subtle and clinically irrelevant. The current classification is based on the number of organ systems involved and the number of sites involved within an organ system.^{23, 78} The main classifications of disease are unifocal eosinophilic granuloma (i.e., single-system, single-site disease, usually in bone), multifocal eosinophilic granuloma (i.e., single-system, multiplesite disease, usually in bone), and acute disseminated histiocytosis (i.e., multisystem disease). The presence and degree of organ dysfunction are important distinctions in those with multisystem disease.⁷⁸

FIGURE 60.3. A: Axial magnetic resonance image of the orbits in a 4-year-old boy with recurrent disseminated Langerhans cell histiocytosis and marked proptosis. There are large orbital soft tissue masses bilaterally. B: Computed tomography scan of the same patient showing marked bony erosion of skull and orbit.

FIGURE 60.4. Sagittal magnetic resonance imaging scan showing thickened pituitary stalk in the same patient shown in Figure 60.3. He had a long-standing history of diabetes insipidus.

Bone is the most commonly involved organ, with the skull being the most commonly involved site in both children and adults.^{79, 80} Unifocal eosinophilic granuloma of bone is the most common form of the disease.^{10, 81} Multifocal bone involvement may or may not be associated with visceral disease. Characteristically, patients note mild discomfort at the site of bone involvement. However, skull lesions are often painless and are found only because of a soft tissue mass over the bony defect. In young children, multifocal lesions of the skull are often associated with other head and neck manifestations. Gingival swelling and inflammation, usually associated with cervical adenopathy, may be the first manifestations of disease. Premature eruption or loss of teeth and breakdown of the lower alveolar ridge result from involvement of the mandible.⁸² Mandibular lesions may be palpable and painful, giving rise to facial swelling.⁸³ The maxilla and upper gingival ridge are involved less often. Involvement of the Petrous ridge of the temporal bone and mastoid is common, predisposing to chronic otitis media. Vertebral lesions pose special problems because of the risk of injury to the spinal cord. Vertebral collapse gives rise to vertebral plana (Fig. 60.5). Extension of granulomas into the spinal space may compress the cord, causing permanent neurologic damage. Recurrent bony lesions in children, particularly those involving the craniofacial region, are often associated with DI.^{84, 85}

Radiographically, skeletal lesions are characterized by sharply demarcated rarefactions of the medullary portions of bone, producing a “punched out” appearance (Fig. 60.6).^{79, 81} Reactive sclerosis in surrounding uninvolved bone is unusual at diagnosis, but when present, signifies that healing has begun. As healing occurs, the sharp endosteal margins become less distinct, and sclerosis is often seen. Both tables of the skull characteristically are involved, the outer more so than the inner. Erosion of mandibular bone around unerupted teeth gives them the appearance of floating in space. Skeletal lesions are well delineated with conventional radiography, computed tomography, and magnetic resonance imaging.⁸⁶ The relative benefit of radionuclide bone scintigraphy, on the other hand, is controversial.^{87, 88, 89} Radionuclide bone scans

often are falsely negative for skull lesions, but may be more sensitive in identifying lesions in the ribs, spine, and pelvis.^{90, 91}

P.1311

Positron emission tomography (PET) may have greater specificity in identifying active osseous lesions, but its clinical utility in LCH requires further study.^{92, 93}

FIGURE 60.5. Sagittal magnetic resonance image of the thoracic spine showing collapse of the T8 vertebral body, more prominent in the anterior aspect, in a patient with reactivation of Langerhans cell histiocytosis.

Skin involvement occurs in about one third of patients overall.^{22, 25} Although skin manifestations are seen in only 10% of patients with single-system disease, it is a much more common feature of acute disseminated histiocytosis.^{81, 94} Even in

those with skin-only disease, the rate of progression to multisystem disease is 30% to 40%.⁹⁵ The skin lesions are typically vesiculopustular and may have a hemorrhagic crust. They are similar in appearance to those of seborrheic dermatitis. LCH is often suspected after a seborrheic rash fails to respond to treatment. The rash has a predilection for the scalp, postauricular areas, and diaper area (Fig. 60.7). The back, axillae, and intertriginous areas also may be involved.⁹⁴ With advanced stages of the disease, the entire integument may be affected. Breakdown of severely affected areas is common, and concurrent thrombocytopenia imparts a hemorrhagic component to the rash.

FIGURE 60.6. Skull radiograph showing active osteolytic lesions in a patient with disseminated Langerhans cell histiocytosis. Note absence of reactive sclerosis.

A rash indistinguishable from that seen in acute disseminated histiocytosis may occur as a congenital, self-limited phenomenon not associated with skeletal or visceral disease. This form of histiocytosis has been called congenital self-healing histiocytosis or Hashimoto-Pritzker syndrome.^{5, 96} The lesions are present at birth or appear within the first 2 or 3 weeks of life. They are most numerous over the scalp and face, but also may extend over the trunk and proximal extremities. Mucous membranes are spared. Langerhans cells present in biopsy material have the same immunophenotypic characteristics as those in the other variants of histiocytosis, although they contain fewer Birbeck granules.⁹⁶ The lesions typically undergo spontaneous regression, with complete healing by the time the patient is 3 to 4 months of age. The prognosis is generally excellent without therapy, although occasionally isolated cutaneous LCH in infants can progress to multisystem disease.⁹⁷

Increasingly appreciated as a problem in LCH, CNS involvement^{98, 99} occurs by contiguous spread of skull lesions into brain substance or by granulomatous infiltration of deep structures. The disease demonstrates a predilection for the hypothalamic nuclei¹⁰⁰ and cerebellum,^{101, 102} although focal lesions may occur in the temporal lobe, occipital lobe, and spinal cord. Rarely, CNS

P.1312

lesions are found in patients who have no other evidence of histiocytosis. Neurologic signs and symptoms include ataxia, nystagmus, dysmetria, seizures, dysphagia, cranial nerve deficits, and spastic paraparesis.¹⁰³ DI resulting from infiltration of the hypothalamus or pituitary stalk is common.¹⁰⁴ Whereas mass lesions are satisfactorily visualized by computed tomography or magnetic resonance imaging, infiltrative lesions within the hypothalamus and elsewhere often are of similar density to adjacent brain tissue and produce little or no mass effect. Some of these lesions may be seen with magnetic resonance imaging.⁹⁸ CNS involvement may leave survivors with permanent sequelae.^{98, 84}

Of the endocrinopathies associated with LCH, DI is the most common.¹⁰⁵ LCH is a common cause of DI in both adults and children.¹⁰⁶ DI is caused by infiltration of the hypothalamus, pituitary stalk, or posterior pituitary by Langerhans cells. The

prevalence of DI in large series of patients ranges from 10% to 50%.^{84, 85, 105, 106, 107, 108, 109} In a study of 1,741 children with LCH, the cumulative risk of DI was 20% at 15 years from diagnosis.⁸⁵ DI is more common in patients with multisystem disease and in those with proptosis.¹⁰⁹ Patients with multiple craniofacial bone lesions are also at increased risk.⁸⁵ DI is not typically a complication of unifocal bone disease not involving the skull. Characteristically, the onset of DI is after the diagnosis of LCH is made. Symptoms of DI occur at or preceding the diagnosis of LCH in only about one third of patients.⁸⁴ However, LCH should be considered in the differential diagnosis in patients who present with central DI.¹⁰⁶ In such cases a thickened pituitary stalk seen on MRI may be the only radiographic manifestation (Fig. 60.4).¹¹⁰ For most children, symptoms occur within 2 years of diagnosis and rarely, if ever, after 4 to 5 years.^{109, 111} Although most affected patients have complete absence of antidiuretic hormone, partial deficiency may occur. Progression from partial to complete DI may occur, and once complete DI has developed, it cannot be reversed. Whether systemic chemotherapy for LCH may prevent the development of DI is unclear. However, more rapid response to therapy and shorter disease duration corresponds to a decreased incidence of DI.⁸⁵ Reactivation of disease after complete resolution is associated with an increased risk of DI.⁸⁵

Neurodegenerative disease is the next most common CNS consequence of LCH after DI.¹¹² The typical MRI findings are diffuse, symmetrical signal changes of variable intensity in the basal ganglia or cerebellum (Fig. 60.8).^{113, 114} Patients with LCH-associated neurodegenerative disease demonstrate variable manifestations of disease. Some patients have no neurologic signs or symptoms, whereas others may have significant neurologic effects. Clinical signs may include tremor, ataxia, spasticity, dysarthria, and behavioral or psychiatric problems. The time course of disease progression is also variable, but neurologic deterioration may be severe and devastating. Histologic evaluation of neurodegenerative lesions show a T-cell mediated inflammatory process with tissue degeneration, and most importantly, absence of CD1a-positive cells.¹¹⁵

Growth retardation resulting from growth hormone (GH) deficiency is another complication of LCH.^{105, 108} GH deficiency occurs in approximately 10% of patients with LCH overall and up to 60% of patients with LCH-associated DI.^{84, 116} Loss of GH, along with deficiency of other anterior pituitary hormones, is usually due to involvement of the hypothalamus or anterior pituitary by Langerhans cells.¹¹⁶ GH replacement has been shown to be safe and effective in children with LCH and GH deficiency.¹¹⁷

Thyroid involvement by histiocytosis gives rise to goiter and may lead to hypothyroidism.¹⁰⁸ Obstruction of the upper airway by diffuse enlargement of the thyroid gland has been described.¹¹⁸ Most children with thyroid involvement have DI and other evidence of disseminated disease.¹⁰⁵

Enlargement of the liver, often associated with abnormal liver function, is observed in many children with the disseminated form of LCH.^{119, 120, 121} In some patients, liver involvement leads to portal cirrhosis or intrahepatic cholestasis.¹²¹ Tissue from liver biopsies obtained from children with hepatomegaly infrequently shows the infiltrates of Langerhans cells, eosinophils, and lymphocytes that are hallmarks of the disease in other organs. Instead, subtle changes in the portal triads are observed, including triaditis, bile duct proliferation, and fibrosis.¹²² Patients with triaditis alone at diagnosis are less likely to have abnormal liver function or progressive liver disease than those with fibrohistiocytic or cirrhotic changes. Persistent abnormality of liver function is a wellrecognized adverse prognostic indicator.¹²³

FIGURE 60.8. Axial magnetic resonance imaging scan showing diffuse bilateral signal abnormality in the cerebellum in a patient with neurodegenerative Langerhans cell histiocytosis.

Involvement of lymph nodes and spleen is often a feature of disseminated disease.²³ Lymph nodes may be involved because of contiguous bone or skin disease or as a result of widespread histiocytic dissemination. Splenomegaly is caused by portal hypertension or involvement of the spleen by large numbers of histiocytes. Curiously, Birbeck granules are rarely seen in otherwise characteristic Langerhans cells in the spleen and liver.^{41, 42}

Although not common, the lungs may be involved with disseminated histiocytosis.¹²⁴ As with other forms of disseminated disease, lung involvement occurs primarily in infants and young children. In contrast, primary pulmonary histiocytosis is principally a disease of young and middle-aged adults,^{125, 126, 127, 128, 129} although it does occur in children.^{130, 131} Smoking is often associated with pulmonary LCH.^{132, 133} Affected patients are without

P.1313

apparent multisystem disease at diagnosis; with further evaluation, however, some patients have asymptomatic bone lesions,¹³⁰ and as many as 10% subsequently develop DI.¹³⁴ Signs and symptoms of pulmonary involvement may be subtle or may include growth failure or weight loss, dyspnea, tachypnea, and hemoptysis. Recurrent pneumothoraces occur in as many as 20 to 25% of cases.¹³⁵ Lung involvement is characterized radiographically by diffuse micronodular densities with cyst formation, sometimes giving rise to a picture of "honeycomb lung." Lesions are usually prominent in the perihilar regions and the upper lung fields. Costophrenic angles are usually spared, and enlargement of hilar nodes is unusual. Permanent pulmonary sequelae often occur,¹³⁶ and reactivation in the lungs may be associated with smoking.¹³³

Bone marrow involvement by Langerhans cells has been described most often in infants with disseminated disease.^{23, 24, 137} It is characterized by anemia, neutropenia, and thrombocytopenia, occurring singly or together. Erythrophagocytosis may rarely be a factor in the pathogenesis of anemia.¹³⁸ Because bone marrow and splenic involvement often occur together, splenic sequestration of blood cells may further exaggerate the cytopenias of bone marrow involvement.

DIAGNOSIS

The clinical and radiographic features of LCH are distinctive enough to suggest the diagnosis in most patients. However, the diagnosis must be made pathologically, and for a definitive diagnosis, the presence of Birbeck granules or the presence of Langerin and/or CD1a on the surface of LCH cells must be demonstrated.¹³⁹

Assessment of the extent of disease is critical. To help standardize the workup and management of LCH patients, the Histiocyte Society has published guidelines on how to evaluate and follow patients.¹⁴⁰ A thorough physical examination is necessary to evaluate for hepatomegaly or splenomegaly, lymphadenopathy, and any bone or soft tissue masses. Bony lesions may be diagnosed by either bone scan or skeletal survey. Each modality has been shown to discover lesions missed by the other. However, radionuclide bone scan may miss osteolytic lesions that do not have any osteoblastic characteristics. This is particularly true for skull lesions.^{90, 91} Other studies required include a chest radiograph, complete blood count, assessment of liver function, and determination of renal concentrating ability. A bone marrow examination is required if cytopenias exist, and a high-resolution chest CT scan may be necessary if signs and symptoms suggest pulmonary involvement.¹³¹ Although not required to evaluate disease, some authors have recommended studies of T- and B-cell numbers, T-cell subsets, and lymphocyte function. New imaging modalities, including PET and octreotide scans, may be useful in LCH, but they require additional study.^{93, 141, 142}

TABLE 60.2 OUTCOME DATA

Group	No Reactivation or Progression	Progression	Reactivation	4-Year Event Free Survival Death (%)

From Jubran RF, Marachelian A, Dorey F, et al. Predictors of outcome in children with Langerhans cell histiocytosis. *Pediatr Blood Cancer* 2005;45:37-42, with permission.

Several staging or scoring systems have been proposed as having prognostic and therapeutic relevance. Most cite age (age younger than 2 years being a liability), extent of disease, and the function of involved organs as the important prognostic variables.^{23, 24, 143} An important distinction made by the Histiocyte Society and proven to be highly prognostic is whether "risk" organs are involved. "Risk" organs are the hematopoietic system defined as at least two cytopenias (with or without documented bone marrow involvement), spleen, liver, and lungs. The presence of "CNS-risk lesions" results in a higher risk of developing DI. CNS-risk lesions are those involving the craniofacial bones, particularly those around the eyes, ears, and oral cavity.⁸⁵ The Histiocyte Society also recognizes "Special Sites" as being bone lesions that are located in critical anatomic sites in which lesions may cause immediate morbidity. Examples include the odontoid peg and vertebral lesions with intraspinal soft tissue extension. Stratification for treatment is defined based on these parameters. Patients are divided into those with single-system LCH or multisystem disease. Patients with multisystem disease with or without risk organ involvement and those with single-system disease and either CNS-risk, multifocal bone lesion, or special site lesions are candidates for systemic therapy.

PROGNOSIS

For most patients with LCH, the prognosis is excellent. Although LCH may wax and wane over many years, most patients improve over time. However, patients with multisystem disease may experience organ failure, which can be fatal. Outcome by single bone, multiple bone, and multiple organ involvement are shown in Table 60.2.

Most patients with unifocal bone disease experience complete resolution of lesions with or without treatment. Progression of bone erosion and recurrences at new sites are the exception rather than the rule.¹⁴⁴ In a study of 48 patients with single bone involvement, the recurrence rate was 8% and no deaths were reported.⁷⁴ In contrast, disease that is multifocal at the time of diagnosis is often characterized by one or more recurrences after disease control.^{74, 80} Patients with multiple bone lesions, particularly those with skull involvement, have a much higher incidence of disease reactivation than those with single bone lesions.⁷⁴ In addition, most patients with multiple organ involvement will experience disease recurrence. In one large series, 72% of patients with multisystem disease who initially responded to treatment experienced recurrent LCH from 2 months to more than 5 years after cessation of therapy, and most recurrences were in previously uninvolved sites.⁷⁵ Young children, especially those younger than 2 years of age at diagnosis, are at particular risk for multiple relapses. However, in most patients the disease appears to eventually burn out.^{145, 146}

P.1314

Despite the favorable prognosis for most patients, mortality from disease progression can occur. Approximately one third of adults with pulmonary LCH die from the disease.¹²⁸ The highest incidence of mortality, however, is seen in children with involvement of the liver, lungs, hematopoietic system, or spleen at diagnosis ("risk" organs as defined by the Histiocyte Society).¹⁴⁰ A 5-year survival rate of only 25% has been reported in children with liver or spleen involvement at diagnosis.⁷⁵ In a series of 18 patients with "risk" organ involvement, 7 died after either disease progression or recurrence.⁷⁴ In contrast, in two separate studies, all patients 2 years of age or older without "risk" organ involvement survived.^{78, 146} After disease resolution, LCH survivors may be left with permanent complications, including DI, pulmonary difficulties, neurologic complications, orthopedic abnormalities, neuropsychological impairment, dental problems, chronic otitis, or hearing impairment.^{72, 84, 145} Patients with one or more reactivations after initial therapy are more likely to have long-term sequelae from LCH.¹⁴⁷

MANAGEMENT AND TREATMENT

Management is dictated by the likely natural history of the disease based on the location and extent of lesions and by the presence of specific organ involvement and/or dysfunction. Given that LCH tends to improve with time, most patients do not require treatment aimed at ablating the disease. In most patients, disease manifestations are reversed with therapy that is far less intensive than that used for neoplastic disease. As noted previously, multiple courses of treatment may be required for recurrences. DI is not ameliorated by chemotherapy. Although some authors describe reversal of DI with radiotherapy directed to the hypothalamus-pituitary region soon after the onset of symptoms,¹⁴⁸ the consensus is that radiotherapy, like chemotherapy, is without benefit in this situation.^{108, 149}

Treatment decisions should be based on the number of systems involved and on whether a particular lesion is likely to result in disability. Children with single-system disease, particularly if they have a solitary lesion of bone (e.g., eosinophilic granuloma of bone), may require no therapy other than curettage.¹⁴⁴ However, some patients have aggressive disease, warranting treatment with multiagent chemotherapy.¹²³ In addition, multiple courses of treatment may be required for recurrences. However, in contrast to neoplastic disease, patients with LCH recurrence can often be successfully re-treated with a previously received regimen. Sometimes, recurrence can be ameliorated with less intensive therapy than originally received. Rarely are aggressive approaches, such as bone marrow or liver transplantation, justified.

Because unifocal bone disease is associated with a uniformly excellent prognosis, therapy with potential late effects should be avoided. The surgical procedure required for diagnostic purposes often is definitively therapeutic as well. Lesions other than those for which curettage is performed for diagnostic purposes often heal spontaneously.¹⁵⁰ Lesions that progress or recur; those that threaten an important function, such as sight or hearing; and those that pose a risk of pathologic fracture or future disability may be treated effectively with low-dose radiotherapy. Doses of 600 to 1,000 cGy in three to five fractions effect local control in most patients.^{148, 149, 151} Lesions in weight-bearing sites, such as the neck of the femur, may require curettage and autologous bone grafting. Direct steroid injection into the lesion has been used¹⁵²; however, the benefit of this treatment has never been proven in a randomized fashion. Isolated histiocytosis of the skin in infants usually regresses spontaneously and does not require systemic therapy.^{5, 96, 153} Skin lesions in older children or adults may respond at least temporarily to radiation with ultraviolet light.¹⁵⁴

Systemic therapy is required for multisystem disease and for single-system disease in which multiple bones or CNS-risk bones are involved. Approximately 50% of patients requiring systemic therapy respond to corticosteroids alone.¹⁵⁵ Because of the toxicity of corticosteroids when used for more than brief periods, however, other chemotherapeutic agents are now the mainstay of management. Vinblastine, vincristine, 6-mercaptopurine, methotrexate, alkylating agents, anthracyclines, and etoposide, singly or in combinations, are effective in controlling LCH.¹⁴³ Patients with liver, lung, or bone marrow dysfunction as well as those at high risk for adverse CNS outcome are best treated with combination chemotherapy. In a clinical trial in which patients were stratified by risk, treatment included induction chemotherapy with vinblastine, etoposide, and prednisone followed by maintenance chemotherapy with etoposide, vinblastine, prednisone, 6-mercaptopurine, and methotrexate.¹²³ Two thirds of those patients with organ dysfunction achieved a complete remission, as did approximately 90% of those with either multisite bony disease or soft tissue disease without organ dysfunction.

The Histiocyte Society has conducted multinational randomized clinical trials in LCH.^{78, 156} In the first international trial (LCH I),⁷⁸ 143 patients were randomized to receive 24 weeks of vinblastine (6 mg/m² intravenously weekly) or etoposide (150 mg/m²/day intravenously for 3 days, every 3 weeks); all patients received a single dose of steroids. Both of those monotherapies were equivalent. Due to the risk of secondary leukemias with etoposide, subsequent studies have been built from the vinblastine arm. One robust finding in this study was that the response at 6 weeks was strongly prognostic, regardless of initial treatment. However, LCH I did not produce superior results compared to studies from the German/Austrian Group, DAK-HX 83 and DAL-HX 90.¹⁵⁷ Overall survival was similar, but a lower reactivation rate, longer reaction free interval, and fewer permanent disabilities were seen in the DAL studies compared to LCH I.

The Histiocyte Society's LCH II trial demonstrated that intensified treatment increased early response in patients younger than 2 years with multisystem disease and risk organ involvement.¹⁵⁶ The study showed that the addition of etoposide to a regimen of vinblastine, prednisone, and daily 6-mercaptopurine reduced the risk of mortality for these patients. The most recent LCH III trial evaluated the effect of adding methotrexate to the combination of vinblastine and prednisone for patients with "risk" organ involvement. Although data from that trial are pending, the current recommendation is that patients with multisystem disease should receive a 6-week course of therapy with weekly vinblastine and daily prednisone, followed by 12 months of maintenance therapy with vinblastine and prednisone pulses every 3 weeks with daily oral 6-mercaptopurine. Treatment should be similar for patients with multifocal bone and CNS-risk lesions, except that there is no proven benefit to 6-mercaptopurine.

Newer agents that have been evaluated for LCH that are refractory to standard therapy include cladribine (2-chlorodexoyadenosine). The early promise of cladribine reported in several small studies prompted further evaluation by the Histiocyte Society.^{158, 159, 161} In a Phase 2 study, cladribine showed benefit to patients with reactivation of disease in nonrisk organs.¹⁶² However, cladribine proved no more beneficial than standard therapy for patients with multisystem disease and risk organ involvement. The combination of cladribine with other agents such as cytarabine or etoposide may be more effective, but carries the risk of more pronounced bone marrow suppression and hematologic toxicity.¹⁶³ Other agents that have shown promise in small series include clofarabine, bisphosphonates, and etanercept.^{164, 165, 166, 167}

Etanercept inhibits TNF- α , which is highly expressed in Langerhans cells, lymphocytes, and macrophages of LCH lesions and promotes proliferation of Langerhans cells.^{168, 169}

Several patients with recurrent progressive LCH refractory to conventional therapy have benefited from allogeneic hematopoietic

P.1315

stem cell transplantation (HSCT).^{170, 171, 172, 173, 174, 175, 176} However, toxicity from HSCT in these patients has been an issue with high rates of transplant-related mortality. A few patients have undergone HSCT with reduced-intensity conditioning with less transplant-related morbidity and mortality.¹⁷⁷ The most effective conditioning regimens and appropriate timing of HSCT are yet to be determined.

Chapter 61

Pathology of Langerhans Cell Histiocytosis and Other Histiocytic Proliferations

Karen L. Chang

Lawrence M. Weiss

Langerhans cell histiocytosis and other dendritic and histiocytic neoplasms and related proliferations are uncommon diseases.¹ Dendritic cells, also known as classical dendritic cells, arise from the myeloid-derived common dendritic cell precursor and are divided by function and structure to include Langerhans cells, interdigitating dendritic cells, and follicular dendritic cells. Langerhans cells and interdigitating dendritic cells both show strong expression of S-100 protein and HLA-DR, with Langerhans cells positive for CD1a and langerin, and interdigitating dendritic cells negative for CD1a and langerin. Normal Langerhans cells reside primarily in the skin and migrate via lymphatics (as veiled cells) to the lymph nodes as they differentiate into interdigitating dendritic cells, which reside in the paracortical region of the lymph nodes. Langerhans cells are efficient antigen-processing presentation machines, whereas interdigitating dendritic cells interact closely with T-cells, leading to the initiation of strong cellular immunity. Follicular dendritic cells express CD21, CD35, and/or CD23, and not CD1a, langerin or S-100 protein. They are fixed cells that reside in lymphoid follicles, interacting

with follicular B cells in the formation and organization of the follicles. In addition, they trap and store antigen-antibody complexes and they are important in memory cell formation and affinity maturation of follicular B-cells. Plasmacytoid dendritic cells also arise from the common dendritic cell precursor and are the main source of α -interferon upon viral infection or CD154 stimulation. Plasmacytoid dendritic cells also play an important role in immune tolerance through immune regulation and/or depletion via the uptake of self-peptides captured by the uptake of apoptotic classic dendritic cells. They express CD123 and not S100, CD1a, or langerin. A subset of plasmacytoid dendritic cells has immunoglobulin rearrangements.

Histiocytes are noncirculating cells derived from a bone marrow stem cell known as monocyte/macrophage and dendritic cell precursor, which is the same stem cell that gives rise to the common dendritic cell precursor. Histiocytes are the tissue-based equivalent of monocytes and are normally resident in a variety of organs, including the spleen, lymph nodes, and bone marrow; liver (Kupffer cells); lung (alveolar macrophages); lamina propria of the gut; and brain (microglia). They express CD163 and CD68 (an antigenic marker of lysosomes). They play an important role in resistance to intracellular microorganisms and tumors through nonimmunologic mechanisms and in the recognition and clearance of apoptotic cells.

Each of these major dendritic and histiocytic cells has corresponding tumors, as summarized in Table 61.1 and discussed in further detail below.

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis is a neoplastic proliferation of Langerhans cells, albeit at perhaps a more immature state of maturation.² Langerhans cells are dendritic cells that are normally resident in the basal layer of the epidermis and are characterized by immunohistochemical expression of CD1a, S-100 protein, and langerin and the presence of Birbeck granules by ultrastructural examination. Three major syndromes of involvement are recognized.^{3, 4, 5} In the most common type, unifocal disease (formerly solitary eosinophilic granuloma), involvement of a single site, usually bone, is seen. This syndrome is seen primarily in adolescents and young adults. In multifocal unisystem disease (formerly many cases of Hand-Schuller-Christian disease), there is involvement of several sites within one organ system, almost always bone. This syndrome is seen primarily in children. In the least common multifocal multisystem disease (formerly many cases of Letterer-Siwe disease), multiple organs are involved, usually including the bones, skin, liver and spleen, and lymph nodes, often in a lymphoma-like distribution. These latter cases are usually seen in infants.

Langerhans cell histiocytosis represents a monoclonal proliferation, as revealed by molecular studies of the X-linked androgen receptor gene.⁶ There is no association with known viruses.⁷ Cytogenetic and other studies have shown abnormalities involving chromosomes 1p and 7.⁸ Recurrent mutations of the oncogene BRAF have been found in a large number of LCH cases, including the allegedly polyclonal pulmonary variant of LCH.⁹ Some investigators have theorized that immune dysfunction plays a role in the pathogenesis, although direct evidence is lacking. Neoplastic Langerhans cells may aberrantly express chemokines of immature dendritic cells, and abnormal reactions between Langerhans cells and macrophages may contribute to production of a cytokine "storm."^{10, 11}

Biopsy is essential to the diagnosis of Langerhans cell histiocytosis. The key to the diagnosis is the identification of neoplastic Langerhans cells. Langerhans cells are dendritic cells with characteristic grooved, folded, or indented nuclei, inconspicuous nucleoli, a relative bland chromatin pattern, and thin nuclear membranes¹² (Fig. 61.1). The degree of nuclear atypia or the mitotic rate in general does not correlate with outcome, with the exception that cases with frankly sarcomatous features probably represent rare cases of Langerhans cell sarcoma (see the section "Langerhans Cell Sarcoma"). The cytoplasm is usually moderately abundant and pale to intensely eosinophilic. Langerhans cells may be the only cell type, particularly as seen in cases of multifocal, multisystem disease, but most often they are found admixed in a characteristic cellular milieu that usually includes variable

P.1318

numbers of eosinophils, histiocytes, and neutrophils. Occasionally, eosinophilic microabscesses are seen. More mature lesions have greater numbers of histiocytes, which may be nonstimulated, epithelioid, or multinucleated and simulating osteoclasts. Late lesions tend to have variable numbers of foamy macrophages and plasma cells and are often associated with a significant degree of fibrosis. Ultrastructurally, neoplastic Langerhans cells have Birbeck granules, numerous lysosomes, small vesicles, and multivesicular bodies, and irregular cell membranes with an absence of cell junctions. Birbeck granules are specific to Langerhans cells and are usually "tennis racket"-shaped intracytoplasmic membranous bodies, with an osmiophilic core and a double outer sheath. The langerin antibody is an endocytic receptor associated

with the formation of Birbeck granules and thus is highly specific and sensitive and has in large part supplanted the need for electron microscopy studies.¹³

TABLE 61.1 MAJOR DENDRITIC AND HISTIOCYTIC CELLS AND THEIR TUMORS

Cell	Tumor	Major Phenotype
Langerhans cell	Langerhans cell histiocytosis/sarcoma	CD1a ⁺ , S-100 protein ⁺ , Langerin ⁺
Follicular dendritic cell	Follicular dendritic cell sarcoma	CD21 ⁺ , CD35 ⁺ , CD23 ⁺
Interdigitating dendritic cell	Interdigitating dendritic cell sarcoma	S-100 protein ⁺ , CD1a-
Plasmacytoid dendritic cell	Blastic plasmacytoid dendritic cell neoplasm	CD4 ⁺ , CD56 ⁺ , CD123 ⁺
Histiocyte	Histiocytic sarcoma	CD163 ⁺ , CD68 ⁺
Subset of sinusoidal histiocyte	Rosai-Dorfman disease	S-100 protein ⁺ , CD163 ⁺ , CD68 ⁺
Activated histiocyte	Hemophagocytic lymphohistiocytosis	CD163 ⁺ , CD68 ⁺

FIGURE 61.1. Langerhans cell histiocytosis. Histiocytic cells with frequent nuclear clefts are seen. Scattered eosinophils are present in the background.

Neoplastic Langerhans cells tend to have a similar (but not identical) phenotype as normal Langerhans cells, and are usually identified by expression of CD1a, langerin, and S-100 protein¹⁴ (Fig. 61.2). In addition, Langerhans cell histiocytosis expresses vimentin, HLA-DR, placental alkaline phosphatase (in contrast to normal Langerhans cells), and peanut agglutinin lectin. The tumor has been reported to be variably positive for CD45, CD68, CD163, CD4, and lysozyme; however, expression of these antigens probably represents positivity of the intimately admixed histiocytes. The Ki-67

index is usually low (<25%). Neoplastic and normal Langerhans cells are consistently negative for B- and T-lineage markers, CD30, CD34, and follicular dendritic cell markers CD21 and CD35. By enzyme histochemistry, normal and neoplastic Langerhans cells are positive for adenosine triphosphatase, α -D-mannosidase, α -naphthyl acetate esterase, α -naphthyl butyrate esterase, and acid phosphatase.¹⁵ There is no evidence of antigen-receptor gene rearrangements.

The differential diagnosis includes reactive proliferations of Langerhans cells, including dermatopathic lymphadenitis, so-called pulmonary Langerhans cell histiocytosis, and Langerhans cell histiocytosis-like proliferations associated with malignancy lymphoma. In dermatopathic lymphadenitis, the reactive Langerhans cells occur in the paracortex, in contrast to the sinusoidal or patchy pattern of lymph node involvement by Langerhans cell histiocytosis, and the proliferating Langerhans cells are accompanied by melanin-containing histiocytes and numerous interdigitating dendritic cells. So-called pulmonary Langerhans cell histiocytosis and Langerhans cell histiocytosis-like proliferations associated with malignant lymphoma are morphologically indistinguishable from Langerhans cell histiocytosis. Langerhans cell histiocytosis can be distinguished from most other histiocytic and dendritic disorders by their characteristic expression of CD1a, S-100 protein, and langerin.

FIGURE 61.2. Langerhans cell histiocytosis, S-100 protein stain (same case as Fig. 61.1). Nuclear staining of the Langerhans cells is seen.

LANGERHANS CELL SARCOMA

Langerhans cell sarcoma is an extremely rare neoplasm defined as a neoplastic proliferation of Langerhans cells that have overtly malignant cytologic features.^{16, 17, 18} It usually presents de novo but may also represent progression from typical Langerhans cell histiocytosis. There is a wide age range affected, and there may be a female predominance. Typically, multifocal multisystem disease is present. An aggressive behavior is seen, with an overall survival of ~50%.

Histologically, a proliferation of cytologically malignant histiocyte-like cells is seen (Fig. 61.3). The presence of occasional nuclear features characteristic of Langerhans cells may suggest the diagnosis. The mitotic rate is high, and the characteristic cellular milieu of Langerhans cell histiocytosis is not usually seen. Given this histologic picture, the diagnosis is usually established with the identification of the CD1a (which may be focal; Fig. 61.4) and S-100 protein, reactivities that are characteristic of Langerhans cells. The identification of Birbeck granules on ultrastructural examination is also

helpful in confirming the diagnosis. None of the cases reported to date have included langerin study. The Ki-67 index is usually much higher than that seen in typical Langerhans cell histiocytosis.

FOLLICULAR DENDRITIC CELL SARCOMA

Follicular dendritic cell sarcoma is a neoplasm of cells differentiating toward follicular dendritic cells. Normal follicular dendritic cells are the antigen-processing cells of the germinal center. Follicular dendritic cell sarcoma is a very rare neoplasm, occurring in a wide age range and even gender distribution.^{17, 19, 20, 21, 22} A subset of cases may occur in association with Castleman disease, and there may also be an association with schizophrenia.^{17, 22, 23} Most cases are not associated with known viruses, although a subset of cases, particularly those arising in liver or spleen, may be associated with Epstein-Barr virus (EBV).^{24, 25, 26} It most often presents in

P.1319

lymph nodes, but may also present in a variety of extranodal sites. Patients usually present with a slow-growing mass. Treatment usually consists of complete surgical excision, with or without adjuvant radiotherapy and/or chemotherapy. The tumor usually behaves in an indolent fashion, although local recurrence may occur in about one half of cases, and metastasis may occur in one fourth of cases.²⁷

FIGURE 61.3. Langerhans cell sarcoma. Although some of the nuclei have features of Langerhans cells, the nuclear atypia is striking. Note the presence of several mitotic figures, including atypical forms.

Histologically, one sees a spindle cell neoplasm, which may resemble a low-grade sarcoma (Fig. 61.5). The spindled cells may form fascicles and whorls, and there is characteristically an admixture of small mature lymphocytes, both amid the spindled cells or architecturally segregated into a second component, which may include secondary lymphoid follicles. The individual cells usually have bland spindled nuclei, although significant atypia may be seen in a minority of cases. The chromatin may vary from vesicular to granular and generally have small nucleoli. Occasional multinucleated cells may be seen. Ultrastructural studies show complex interdigitating cell processes with scattered mature desmosomes, typical of normal follicular dendritic cells, and an absence of Birbeck granules.

Immunohistochemical studies show the presence of phenotypic markers characteristic of normal follicular dendritic cells: expression of CD21, CD35, and/or CD23.¹⁷ They are also usually positive for vimentin, desmoplakin, and HLA-DR, variably positive for S-100 protein and CD68, and negative for keratin, CD45, langerin, and specific markers of B- and T-cell differentiation (although CD20 may occasionally be aberrantly expressed). A germline configuration of the antigen-receptor genes is found.

FIGURE 61.4. Langerhans cell sarcoma, CD1a (same case as Fig. 61.3). Membrane staining with CD1a is seen, characteristic of Langerhans cells.

FIGURE 61.5. Follicular dendritic cell sarcoma. A bland spindle cell proliferation is seen, with scattered mature lymphocytes.

The differential diagnosis includes other dendritic tumors as well as other sarcomas, carcinoma, and malignant melanoma. Other sarcomas and dendritic tumors lack CD21, CD35, and/or CD23, whereas carcinoma is keratin-positive and malignant melanoma expresses specific markers of melanocytic differentiation.

INTERDIGITATING DENDRITIC CELL SARCOMA

Interdigitating cell sarcoma is a tumor differentiating toward normal interdigitating dendritic cells.^{17, 22, 28, 29} Normal interdigitating dendritic cells are major antigen-processing cells, usually located in the lymph node paracortical region. Interdigitating dendritic cell tumor is a very rare neoplasm usually occurring in adults, equally in men and women. Tumors may present either primarily in lymph nodes or at extranodal sites. Patients usually present with a solitary mass, although systemic symptoms may be present. The clinical course varies from benign to rapidly progressive lethal disease. Some cases may be associated with B-cell lymphoma; in such occurrences, both entities have been shown to be clonally related.^{30, 31}

Interdigitating dendritic cell sarcoma usually shows a paracortical pattern of distribution, with residual follicles (Fig. 61.6). It may be comprised of spindled cells and has a close resemblance to follicular dendritic cell sarcoma, although the cells may be more rounded and occasionally simulate a diffuse large-cell lymphoma. Nuclear atypia may vary widely, as does the mitotic rate. Immunohistochemical studies usually show strong expression of S-100 protein, in the absence of specific markers of follicular dendritic cells (CD21, CD35, and/or CD23), the Langerhans cell markers CD1a and langerin, or B- and T-cell markers. CD45, CD163, and CD68 may be variably positive. There is a germline configuration of the antigen-receptor genes. Ultrastructural studies show an absence of Birbeck granules or well-formed desmosomes, although complex interdigitating cell processes are seen.

Immunohistochemical studies are necessary to distinguish interdigitating dendritic cell sarcoma from follicular dendritic

cell sarcoma (CD21-, CD35-, and/or CD23-positive), Langerhans cell histiocytosis (CD1a-positive and langerin-positive), malignant lymphoma (B-, T-, and/or CD30-positive), spindled carcinoma (keratin-positive), or malignant melanoma (which expresses HMB-45, MELAN-A, and/or melanoma-associated transcription factor).

FIGURE 61.6. Interdigitating dendritic cell sarcoma. The cells are epithelioid. This case showed strong nuclear staining for S-100 protein, yet was negative for CD1a.

OTHER RARE DENDRITIC CELL SARCOMAS

Other rare dendritic cell sarcomas described in the World Health Organization Classification of Hematopoietic and Lymphoid Tissues includes indeterminate cell tumor and fibroblastic reticular cell neoplasm. Indeterminate cell tumor is a CD1a-negative, S-100 protein-positive skin-based spindled cell tumor, which lacks Birbeck granules.^{19, 32, 33} The tumor comprises bland spindled cells, some of which show irregular grooves and clefts (Fig. 61.7). Ultrastructural studies do not show Birbeck granules, suggesting a transitional neoplasm between Langerhans cell histiocytosis and interdigitating dendritic cell sarcoma. Obviously, such hard-to-classify cases are extraordinarily rare, and not yet well characterized. Fibroblastic reticular cell neoplasms are also extremely rare.^{19, 34} They generally occur in the lymph node paracortex and have a spindled to histiocytic appearance, and express vimentin, actin, and smooth muscle actin (in a heterogeneous pattern), and not S-100, CD1a, langerin, CD45, or markers of lymphoid or follicular dendritic cells.

FIGURE 61.7. Indeterminate cell tumor. This cutaneous case showed positivity for CD1a and S-100 protein, yet Birbeck granules were not present on ultrastructural study.

BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM

Blastic plasmacytoid dendritic cell neoplasm (formerly, $CD4^+CD56^+$ hematodermic neoplasm or blastic NK-cell lymphoma) is a rare aggressive neoplasm that probably shows differentiation toward plasmacytoid dendritic cells (formerly known as plasmacytoid monocytes). Normal plasmacytoid dendritic cells are predendritic cells of the lymph node paracortex and are a major source of α -interferon in viral infection or CD154 stimulation.³⁵ The neoplasm consistently expresses CD123 (the interleukin-3 receptor), CD68, and CD4, and a subset of cells expresses CD56 (the neural cell adhesion molecule NCAM). There is no association with known viruses, including EBV.³⁶ Most patients with $CD4^+CD56^+$ hematodermic neoplasm are elderly and present with skin lesions.³⁷ Bone marrow, peripheral blood, and lymph nodes are commonly simultaneously involved. The disease is usually rapidly progressive, with the development of disseminated disease in most patients, although some cases localized to skin may have a good prognosis.

Histologically, one sees a diffuse monotonous infiltrate of medium-sized cells with fine, blastic-appearing chromatin, closely resembling a lymphoblastic neoplasm (Fig. 61.8). Immunohistochemical studies show a phenotype resembling normal plasmacytoid dendritic cells, with positivity for CD4, CD56, CD123, and CD68.³⁸ In addition, there is also consistent positivity for CD45, CD43, HLA-DR, CD62L, and CXCR3, and some cases show positivity for terminal deoxyribonucleotide transferase or CD34. Antigen-receptor genes are germline. The differential diagnosis includes lymphoblastic lymphoma and acute myeloid leukemia, both of which lack the characteristic $CD4^-$, $CD56^-$, $CD123^+$ -positive phenotype of $CD4^+CD56^+$ hematodermic neoplasm.

HISTIOCYTIC SARCOMA

Histiocytic sarcoma is a neoplastic proliferation of cells showing histologic, immunohistochemical, and molecular features of histiocytes.^{1, 17} By definition, there is the presence of one or more

P.1321

specific histiocytic markers and absence of specific B- and T-cell markers. The neoplasms are tissue-based, and neoplasms associated with monocytic leukemias are excluded.

FIGURE 61.8. Blastic plasmacytoid dendritic cell neoplasm. Note the uniform proliferation of cells with a blastic chromatin pattern.

Histiocytic sarcoma is a rare neoplasm, mostly commonly occurring in adults, although it has been reported in all ages.^{17, 39, 40, 41, 42} A subset of cases may be associated with mediastinal germ cell tumor, usually malignant teratoma, with or without yolk sac tumor.⁴³ Lymph nodes and skin are most commonly involved, although virtually any site may be affected, including liver, spleen, bone, and intestinal tract. The bone may show lytic lesions or diffuse marrow involvement, with the latter occasionally causing pancytopenia. Some patients may show a “systemic” pattern of spread, recalling the old term, “malignant histiocytosis.” Most patients present a high clinical stage. Histiocytic sarcoma is an aggressive neoplasm, generally with a poor response to therapy, with most patients dying of progressive disease.

Histologically, one usually sees a patternless diffuse infiltrate of large cells, with a close resemblance to diffuse large-cell lymphoma (Fig. 61.9). Occasionally, one sees a preferential or exclusively sinusoidal pattern of infiltration. The proliferating cells generally have irregularly shaped nuclei, sometimes eccentrically placed, often with multilobulation and occasionally with multinucleation. Nuclear atypia ranges from mild to severe. The chromatin pattern is usually vesicular, and nucleoli may vary from small to large. Cytoplasm is usually moderate to abundant and eosinophilic, and may show some spindling. There may be some cells with foamy cytoplasm. Cytophagocytosis, usually hemophagocytosis, may be present, but is not considered to be a defining feature.

Phenotyping studies are essential to distinguish histiocytic sarcoma from other malignancies. Histiocytic sarcoma shows expression of at least one specific histiocytic marker in the absence of specific B- and T-cell markers. Positive markers of histiocytic differentiation may include CD163, CD68, CD4, CD11c, CD14, and lysozyme (Fig. 61.10). Additional, albeit nonspecific, antigens expressed by the neoplastic cells of histiocytic sarcoma may include CD45 and HLA-DR. The myeloid markers CD34 and myeloperoxidase are negative, although CD33 is usually positive.⁴⁴ There may also be expression of S-100 protein, but CD1a, CD21, CD35, and langerin are negative. Antigen-receptor gene rearrangement studies show a germ

line configuration, with the exception of those with an association with B cell lymphoma, and there is no association with known viruses.

The most important differential diagnostic consideration is with malignant lymphoma. Histiocytic sarcoma is ~0.1% as frequent as malignant lymphoma, which can be identified by the presence of specific B- and T-cell markers and/or CD30. The malignancy most frequently confused with histiocytic sarcoma is anaplastic large-cell lymphoma, which often has a focal or preferential sinusoidal pattern of involvement and may be comprised of highly pleomorphic cells. In fact, most cases previously diagnosed as malignancy histiocytosis on histologic grounds alone probably represent anaplastic large-cell lymphoma, which may be distinguished from histiocytic sarcoma by the former's constant expression of CD30, with or without ALK staining.⁴⁵ Rarely, carcinomas and malignant melanoma may be confused with histiocytic sarcoma. Use of keratin and specific markers of melanocytic differentiation other than S-100 protein (such as HMB-45, melanocytic-associated transcription factor, and Melan-A) should identify these cases.

FIGURE 61.9. Histiocytic sarcoma. The nuclei appear lymphoid-like and closely resemble a diffuse large cell lymphoma.

FIGURE 61.10. Histiocytic sarcoma (same case as Fig. 61.9). CD163: strong positivity for CD163 is seen, consistent with a histiocytic lineage.

DISSEMINATED JUVENILE XANTHOGRANULOMA

Juvenile xanthogranulomata are protuberant cutaneous nodules that usually present in the head and neck of children.^{46, 47, 48} The lesions may measure up to 1 cm in diameter and may occasionally occur in the soft tissues or internal organs. An aggressive systemic form, known as disseminated juvenile xanthogranuloma, accounts for <5% of cases. This variant also most commonly affects children, although rarely adults are affected (Erdheim-Chester disease). The etiology of disseminated juvenile xanthogranuloma is unknown, but rare patients also have neurofibromatosis-1 and/or juvenile myelomonocytic leukemia. Of note, NF-1 and JMML are also associated with usual type juvenile xanthogranuloma.^{49, 50, 51} Pathologically, the lesions of disseminated juvenile xanthogranuloma are cellular, with a mixture of histiocytic, spindled, and giant cells.⁴⁷ Nuclear pleomorphism is not prominent. The tumor cells express factor XIIIa, fascin, CD163, and CD68, and do not express S-100 protein.

ROSAI-DORFMAN DISEASE

Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy) is a probably reactive disorder of as yet unknown etiology and whose proliferating cells may derive from a surfeit of sinusoidal macrophages.^{52, 53} Patients usually present with

P.1322

markedly enlarged, often bilateral, painless cervical lymph nodes. However, a wider variety of extranodal sites are involved in about one-half of cases, including skin, upper respiratory tract, bone, soft tissue, including orbit, and these extranodal sites may be the presenting or only site of disease.⁵⁴ Patients are generally young, presenting at a median age of 20 years, with no sex predilection, but a marked propensity for African Americans. There are usually a wide variety of laboratory abnormalities; including leukocytosis (neutrophilia), polyclonal hypergammaglobulinemia, and elevated

sedimentation rate. The clinical course is usually benign, although there may be persistence or recurrence of disease, and a small subset may be associated with immune dysfunction and have a poor outcome.⁵⁵

Involved lymph nodes are usually markedly enlarged and have a fibrotic lymph node capsule with massive dilation of the lymph node sinuses (Fig. 61.11). The sinuses show characteristic histiocytes, usually admixed with numerous plasma cells and the adjacent medullary cords also show numerous plasma cells. Extranodal sites usually show strikingly identical features, with dilated lymphatic sinuses, although surrounding fibrosis is usually more prominent. The characteristic histiocytes are very large with round nuclei that have a vesicular chromatin pattern, a delicate nuclear membrane, and one to several distinct nucleoli. Cytoplasm is abundant, amphiphilic to eosinophilic, and occasionally foamy. A distinctive feature is that the cytoplasm often contains numerous lymphocytes (lymphophagocytosis) or other cells (including neutrophils or erythrocytes).

Immunohistochemical studies show that the distinctive histiocytes are strongly positive for S-100 protein, CD163, CD68, CD11c, and CD14.^{56, 57, 58} They may also be focally positive for CD30 or, and more rarely, positive for CD1a. They are consistently negative for the follicular dendritic cell markers CD21 and CD35. Molecular studies show a germline configuration of the antigen-receptor genes, and the cells have been shown to be polyclonal by analyses of the X-linked androgen-receptor gene. There is no convincing evidence of an association with any known viruses.

The differential diagnosis includes sinus histiocytosis, Langerhans cell histiocytosis, hemophagocytic lymphohistiocytosis, and histiocytic sarcoma. The key to the diagnosis of Rosai-Dorfman disease is the recognition of the peculiar proliferating histiocytes, which contain a distinctive nucleus, and prominent lymphophagocytosis. Sinus histiocytosis lacks these peculiar cells, although it may show focal lymphophagocytosis.

FIGURE 61.11. Rosai-Dorfman disease. Note the peculiar histiocytes with abundant lymphophagocytosis, along with the accompanying infiltrate of mature plasma cells.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

Hemophagocytic lymphohistiocytosis is a clinicopathologic syndrome characterized by uncontrolled hyperinflammation caused by a variety of inherited or acquired immune deficiencies.⁵⁹ Most of the genetic defects involve defects in granulocyte-mediated cytotoxicity and NK-cell function.⁶⁰ Familial hemophagocytic lymphohistiocytosis usually presents within the first

year of life, with a symptom-free interval after birth typically seen.^{59, 61} EBV is the triggering agent in ~75% of cases of infection-associated hemophagocytic lymphohistiocytosis.⁶² The terminal stages of any malignancy, including malignant lymphoma, may be associated with hemophagocytic lymphohistiocytosis. However, EBV-associated T/NK neoplasms are particularly common, and the accompanying hemophagocytic syndromes may occur at an early stage and may even be the presenting symptom of the lymphoma.^{63, 64} Patients with hemophagocytic lymphohistiocytosis usually present with fever, hepatosplenomegaly, and cytopenias, and central nervous system symptoms are also common. Laboratory abnormalities include cytopenias of two or more cell lines, hypertriglyceridemia and/or hyperfibrinogenemia, and an increase in serum ferritin and soluble CD25. The prognosis is poor, with the immediate aim of therapy being to suppress the increased inflammatory response by immunosuppressive/immunomodulatory agents and cytotoxic drugs. Hematopoietic cell transplant has been curative in a selected group of patients with primary hemophagocytic lymphohistiocytosis.⁶⁵

Early in the disease course, biopsied lymph nodes may show a marked immunoblastic proliferation in the paracortex, with only minor hyperplasia of histiocytes noted in the sinuses. Later on, however, there is a massive infiltrating of the sinusoid by benign-appearing histiocytes. They show a normal histiocytic phenotype, with CD163 and CD68 positivity, and often show prominent hemo- and platelet phagocytosis (Fig. 61.12). There are also usually scattered to abundant plasma cells. The cortical and paracortical regions become comparatively diminished in size and stimulation. Finally, the lymph node may show lymphocyte depletion, with marked histiocytic hyperplasia with abundant phagocytosis in sinusoids. The hemophagocytic lymphohistiocytosis syndrome is usually established on clinical criteria, with lymph node biopsy performed to rule out coexisting malignant lymphoma.

FIGURE 61.12. Lymphohistiocytic hemophagocytosis, spleen. Note the prominent hemophagocytosis. This case was associated with Epstein-Barr infection.

Chapter 62

Infectious Mononucleosis and Other Epstein-Barr Virus-Related Disorders

Thomas G. Gross

Epstein-Barr virus (EBV) infects the majority of human individuals but usually results in subclinical infections. EBV has been etiologically linked to a wide spectrum of human disease, but it has been shown to be the etiologic agent in relatively few. Although EBV has been identified as the etiologic agent for infectious mononucleosis (IM), the diagnosis is predicated on the presence of a well-described constellation of clinical and laboratory features. EBV has been associated with Burkitt lymphoma (BL) and nasopharyngeal carcinoma (NPC), as well as many other human malignancies, such as non-Hodgkin lymphoma (NHL; B-cell, T-cell, and natural killer [NK]-cell phenotype), Hodgkin lymphoma (HL), leiomyosarcoma, gastric carcinoma, even hepatocellular carcinoma, and breast cancer. EBV has been associated with premalignant conditions or diseases with features of malignancy, such as oral hairy leukoplakia in human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) and lymphoproliferative disorders (LPDs) in patients with primary or secondary immunodeficiencies. EBV has been associated with several other nonmalignant disorders as well, such as hemophagocytic lymphohistiocytosis (HLH) and chronic active EBV infection (CAEBV), and even has been implicated in diseases such as multiple sclerosis and chronic fatigue syndrome. The role of EBV in the pathogenesis of these disorders remains to be fully understood. This chapter reviews the biology of EBV and IM in detail. The other diseases that have been associated with EBV infection are discussed, focusing on data pertaining to the role EBV may play in their pathogenesis.

HISTORICAL BACKGROUND

In the first decade of the 20th century, several cases of glandular enlargement, sore throat, and increased numbers of mononuclear cells on the blood smear were described by Turk,¹ Cabot, Marchant, and others.² These cases were sometimes reported as acute leukemia that apparently resulted in spontaneous remission and cure. In the 1920s, Sprunt and Evans³ classified these cases and six of their own as infectious mononucleosis (IM), emphasizing the peculiar blastlike cells present in the blood. In 1923, Downey et al. published a detailed morphologic description of these cells.⁴

In 1958, Denis Burkitt described an unusual, rapidly growing lymphoma in children of central Africa.⁵ In 1961, Dr. Burkitt gave a lecture at the Middlesex Hospital Medical School in London about the epidemiology of this lymphoma that now bears his name.⁶ A young doctor named Anthony Epstein was in attendance at this lecture and upon hearing the predilection of this tumor occurring in endemic malaria areas, he hypothesized a viral etiology for this tumor. For 3 years, Dr. Epstein and his colleagues were unsuccessful in finding viruses in the tumor tissue provided by Dr. Burkitt. However, in 1964, Dr. Epstein reported, along with Achong and Barr, the presence of viral particles in lymphoblasts cultured from tumor biopsies.⁷

The discovery of EBV as the etiologic cause of IM was the result of a very astute observation made in 1967.⁸ The Henles noted that blood taken from a laboratory technician who had recently contracted IM led to the spontaneous establishment of a lymphoid cell line containing characteristic EBV particles, whereas previous attempts to establish cell lines from this individual's blood had been unsuccessful. They also observed that sera obtained before the onset of IM were negative for an anti-EBV or heterophile titers, whereas after the onset of clinical IM, the anti-EBV and heterophile titers appeared and rose for a period of time. The Henles and associates studied the sera of a number of students from Yale University, where a prospective study of IM had been in progress for many years. In all instances of clinical IM, the anti-EBV and heterophile titers rose together from a negative baseline. Of even greater interest was the observation that the anti-EBV titer remained persistently elevated, in contrast to the transient nature of the heterophile response. Confirmation of EBV as the etiologic agent in the majority of cases of IM soon followed.^{9, 10, 11}

PATHOPHYSIOLOGY OF EPSTEIN-BARR VIRUS INFECTION

EBV is one of eight known human herpes viruses (HHVs) and is subgrouped into the γ -herpes virus subfamily. Immature virus particles that measure 75 to 80 nm can be found in both the nucleus and the cytoplasm of infected cells. Mature, fully infectious particles, with a diameter of 150 to 200 nm, are found only in the cytoplasm.¹² The infectious virus particle has three components: a nucleoid, a capsid, and an envelope. The doughnutshaped central core, or nucleoid, contains the viral DNA in linear form. Surrounding the nucleoid is the capsid, which is icosahedral and is made up of hollow, tubular protein subunits called capsomeres. Finally, the nucleocapsid (the capsid and the contained viral DNA) is enclosed in a protective envelope that is derived either from the nuclear membrane or from the outer membrane of the host cell. The envelope contains a number of viral antigens that are manufactured and inserted into the host cell membrane before the assembly of mature virus particles. The EBV genome (Fig. 62.1) is a double-stranded DNA molecule of approximately 173,000 base pairs (bp) organized into a series of unique coding regions (U1 to U5), divided by interval repeat regions (IR1 to IR4)

P.1325

and terminal repeat domains. The genome encodes approximately 100 proteins.^{13, 14} Figures 62.1 and 62.2 illustrate viral

genes encoded by the genome and are discussed in detail in the section, "Epstein-Barr Virus Infection." When EBV infects a cell, its linear genome circularizes to form an episome, an extrachromosomal element in the nucleus of the cell.^{13, 15, 16, 17}

FIGURE 62.1 Epstein-Barr virus (EBV) genome and its organization. Schematic representation of linear EBV DNA showing the general organization in a series of unique (U1 to U5), internal repeat (IR1 to IR4), and terminal repeat (TR) domains. The location of several EBV genes expressed during viral latency and replication is shown. EBER, EBV-encoded RNA; EBNA, EBV-determined nuclear antigen; gp, glycoprotein; LMP, latent membrane protein; ZEBRA, Z EBV replication activator. (From Tosato G, Tata K, Angiolillo AL, et al. Epstein-Barr virus as an agent of hematological disease. *Baillere Clin Hematol* 1995;8(1):165-199, with permission.)

Many variants have been reported, although the relevance to human disease pathogenesis is unclear. Two variants EBV-1 (A type) and EBV-2 (B type) exist, which are differentiated mainly by their differences in the EBV-determined nuclear antigens (EBNAs) 2, 3A, and 3C.^{13, 15, 18} Both types of EBV are found in most populations. The relationship between these different strains and specific diseases remains to be determined. Additional EBV variants with differences in EBNA-1 have been reported to be associated with specific EBV-affiliated diseases, such as BL, but the incidence of these variants has been shown to be similar in the general population of a particular geographic region.¹⁹ Furthermore, mutations (so-called 30-bp or 69-bp deletions) of latent membrane protein (LMP-1) have been reported to be highly associated with the development of HL, certain forms of T- and B-cell lymphoma, and NPC.^{20, 21, 22, 23} But again, when compared with EBV variants found in the geographic regions, there exists no difference between healthy individuals and those associated with tumors.^{23, 24} Therefore, caution must be exercised when attributing specific EBV viral strains to particular diseases in the absence of geographically matched control isolates.

Epstein-Barr Virus Infection

The only host that the virus infects naturally is the human, although lymphocytes from other species, namely New World primates (i.e., cottontop marmosets, owl monkeys, and tamarins), are infectible.^{25, 26} EBV has been found in a variety of human tissue types associated with disease (i.e., T lymphocytes, NK cells, HL, leiomyosarcoma, gastric carcinoma, hepatocellular carcinoma, and breast cancer).^{27, 28, 29, 30, 31, 32, 33} The mechanism of EBV infection in these tumors remains to be fully elucidated.

Infection of B lymphocytes begins with attachment of the virus envelope glycoprotein (gp) 350/220 to the complement receptor C3d, also known as CR2 or CD21.³⁴ For entry into B lymphocytes, a complex of three viral proteins (gH-gL-gp42) is required, and human leukocyte antigen (HLA) class II molecules serve as a coreceptor for gp42.³⁵ Epithelium of the oropharynx is a source of viral replication,³⁶ but it has been difficult to determine the mechanism of infection, inasmuch as these cells do not express CD21 or HLA class II molecules. Recent studies have demonstrated that during primary

infection, the majority of virions are not internalized after binding to B lymphocytes of the oropharyngeal tissue. And these B lymphocytes can form cellular conjugates with epithelial cells that allow for transfer of EBV virions into the epithelial cells.³⁷ The mechanism for EBV entry into other cell types (e.g., T cells, gastric mucosa, smooth muscle cells, etc.) may also be via direct contact with B cells that have bound virions with subsequent virion internalization. Infection of epithelium leads to the replication of the virus with the release of large quantities of viral particles containing three-part complexes (gH-gL-gp42) that favor infection of HLA class II and CD21-expressing cells (i.e., B lymphocytes located in the oropharyngeal lymphoid tissues of the Waldeyer ring).³⁵ These B lymphocytes may remain latently infected in the oropharynx, but if viral reactivation and replication occur, cellular lysis and death result, and the virus can be shed into the saliva. Virus contained in infectious saliva is produced by B lymphocytes of the oropharynx.^{38, 39} Salivary virus may then be transmitted to another host.

FIGURE 62.2 Epstein-Barr virus (EBV) gene transcription in the three forms of latency. The top panel shows the position of the exons on a linear map of the genome. The lower panel shows the direction of transcription from each promoter (arrows) and the splicing structure between the exons. Coding exons are shown in black and noncoding exons in white. EBER, EBV-encoded small RNA; EBNA, EBV-encoded nuclear antigen; LP, leader protein; LMP, latent membrane protein; TR, terminal repeat. (From Young LS, Dawson CW, Eliopoulos AG. The expression and function of Epstein-Barr virus encoded latent genes. *J Clin Pathol Mol Pathol* 2000;53:238-247.)

The mechanisms underlying viral replication are not completely understood as there exist no in vitro models that recapitulate viral replication in humans. Viral replication is initiated through oriLyt.⁴⁰ Two key early immediate genes are first transcribed, BRLF1 and BZLF-1, encoding Z EBV replication activator (ZEBRA) protein.^{13, 15, 41} These proteins then up-regulate the expression of early gene products essential for viral replication, including viral DNA polymerase and viral thymidine kinase. Late gene products follow, including viral capsid antigen (VCA), the major envelope glycoprotein (gp350), and the viral protein BCRF-1, which contains 70% homology to interleukin (IL)-10.^{13, 15, 42, 43} Complete viral replication results in the lysis and death of the host cell. Recently, it has been shown that viral proteins associated with type III latency (see below) are associated with viral replication.⁴⁴ What role this plays in B-cell transformation and immortalization remains to be determined.

Alternatively, infected B lymphocytes appear to undergo normal B-cell differentiation and disseminate throughout the body into secondary lymphatic organs (i.e., lymph nodes, spleen, and bone marrow).^{44, 45, 46, 47} Studies have demonstrated that the reservoir for latent EBV infection is a small percentage of postgerminal center, antigen-selected

resting memory B lymphocytes.⁴⁷ The number of latently infected B cells is approximately 10^{-5} to 10^{-6} of all B cells and remains stable for the majority of the life of the infected individual.^{46, 48}

P.1326

Latent infection is characterized by the expression of nine virally encoded proteins. Figures 62.1 and 62.2 illustrate the transcriptions of the nine latent proteins of EBV (EBNA-1, EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, EBNA leader protein [LP], LMP-1, LMP-2A, and LMP-2B).^{13, 15, 49} Two EBV-encoded RNAs (EBER-1 and EBER-2) are expressed abundantly in all EBV-infected cells and are valuable for making the diagnosis of EBV disease, but do not code for proteins and their function remains to be determined.¹³ In addition, the Bam HI-A rightward transcript (BART) is generally found in infected cells, but its function also remains to be fully delineated.⁵⁰

The state of latent infection is maintained by EBNA-1. The function of EBNA-1 is to bind to a nucleotide sequence called ori-P, part of the DNA origin of EBV replication, thereby allowing the viral genome to be maintained in the nucleus of the latently infected B cell.^{51, 52} By this mechanism, the EBV DNA is assured of being maintained in B cells that undergo replication.

EBNA-2 and LMP-1 appear to be required for B-cell immortalization.¹³ EBNA-2 transactivates the expression of LMP-1 and LMP-2.^{13, 53} EBNA-LP augments the ability of EBNA-2 to up-regulate LMP-1. LMP-1 and LMP-2 are associated with a cellular tyrosine kinase. The function of LMP-1 is similar to that of other members of the tumor necrosis factor (TNF) receptor family and is similar—but not identical—to that of CD40. LMP-1 interacts with TNF-receptor-associated factors and the TNF-receptor-associated death domain in infected cells and activates nuclear factor- κ B and c-Jun N-terminal kinase pathways, resulting in B-cell activation and proliferation.^{49, 54, 55, 56, 57} Additionally, LMP-1 expression also induces bcl-2 expression and can prevent apoptosis in B cells.⁵⁷ LMP-2 prevents viral reactivation by blocking tyrosine phosphorylation and promotes B-cell survival.⁵⁸ The EBNA-3 proteins regulate expression of certain cellular genes, including specific cellular receptors such as CD28, CD19, CD21, CD23, and CD30; T-cell co-stimulatory molecules CD80/CD86; adhesion molecules such as intercellular adhesion molecule-1, leukocyte factor antigen-1, and leukocyte factor antigen-3, and a member of the src oncogene family, c-fgr.^{15, 59}

Expression of EBV genes varies along the spectrum of EBV-associated diseases and often differs from in vitro immortalized B cells or normal human resting B cells infected by EBV.^{49, 53} The viral gene expression of viral latency is illustrated in Figure 62.2. Briefly, in type I latency- EBNA-1, EBER-1, and EBER-2 and BART are expressed. Type I latency is observed in BL and a portion of EBV-positive gastric carcinoma. Type II latency is characterized by the expression of EBNA-1, LMP-1, LMP-2A and B, EBER-1, and EBER-2 and is observed in NPC, and other EBV-positive lymphomas, such as T- or NK-cell NHL, and the Reed-Sternberg (RS) cells of HL. EBV-infected cells of LPD observed in immunodeficient patients resemble in vitro immortalized B cells and generally express all nine of the EBV-related latent proteins (type III latency). The site of EBV latency in seropositive healthy individuals, the resting memory B cells does not appear to express EBNA-1 but only LMP-2, EBER-1, and EBER-2 together with BART (type IV latency).⁶⁰

Immune Response to Epstein-Barr Virus Infection

Understanding the immune response to EBV infection is essential to comprehend the pathogenesis of EBV-related disease. EBV is a very potent immune stimulus. The immune system controls lymphoproliferation in the normal host and maintains a host/virus symbiosis. Figure 62.3 illustrates the delicate balance between the host T-cell immune response and control of B-cell proliferation of latently infected B cells. In a healthy individual, although only 10^{-5} to 10^{-6} B cells are latently infected with EBV, approximately 1% to 5% of all circulating CD8⁺ T cells are capable of reacting against EBV.^{48, 61, 62, 63} Initially, there is B-cell proliferation, producing both EBV-specific and -nonspecific antibodies. The number of these virus-containing B cells rises during the acute phase of the infection but never exceeds 0.03% to 0.1% of the circulating mononuclear cells.^{64, 65} A cellular immune response follows, which is composed primarily of an expansion of cytotoxic T lymphocytes (CTLs), with the vast majority being EBV-specific, although some are not EBV-specific.^{66, 67} Figure 62.4 illustrates the pathologic consequences of an abnormal CTL response to EBV infection. A deficient CTL response, either quantitative or qualitative, results in an EBV-driven B-cell proliferative process. The lack of an appropriate CTL response can also result in an aggressive, predominantly T-cell and histiocytic reaction that is not EBV-specific. This reaction is characterized by extensive infiltration of lymphoid and parenchymal organs with hemophagocytosis, and tissue destruction is often observed. If unchecked, this reaction can be rapidly fatal.^{68, 69}

EBV-Infected B Cells

EBV-CTL
1 – 5/100

FIGURE 62.3 Balance of immune control in Epstein-Barr virus (EBV) infections. CTL, cytotoxic T lymphocyte.

The humoral response to EBV is well characterized (Fig. 62.5).^{70, 71, 72, 73} VCA antibodies are the earliest to appear: first immunoglobulin M (IgM) and, later, IgG. IgM antibodies probably arise during the incubation period, peak with symptoms, and then decline rapidly.⁷³ IgA anti-VCA antibodies are seen in some patients and, like IgM anti-VCA antibodies, are gone within several weeks.^{74, 75} IgG anti-VCA antibodies reach a peak 2 to 3 weeks after their IgM predecessors and persist for life.^{74, 75} The majority of patients also have a transient response to the EBV early antigen (EA), peaking usually within a month of infection.⁷² Antibodies to EBNA may appear several weeks after the onset of the illness in some patients but, in general, take several months to appear, and titers rise slowly over 1 to 2 years and persist for life. The majority of normal individuals have detectable IgG to EBNA by 6 months after EBV infections, although it may take years to develop detectable anti-EBNA titers.⁷⁶ In young children, the anti-VCA and anti-EA responses may be much less intense, and anti-EBNA may take much longer to be seen.⁷⁷

An EBV-nonspecific humoral response also occurs with EBV infection. Paul et al.⁷⁸ first described this phenomenon in 1932 when they reported that the sera of patients with IM contained heterophil antibodies against sheep erythrocytes in concentrations far above normal. The use of heterophil antibodies in the diagnosis of IM is discussed in detail in the section, "Infectious Mononucleosis: Diagnosis." Many of these EBV-nonspecific antibodies function as autoantibodies and include cold reactive anti-i antibodies, Donath-Landsteiner cold hemolysins, and antibodies against smooth muscle, thyroid, and stomach.^{79, 80, 81, 82} In addition, antinuclear antibodies have been found in the sera of some patients,^{83, 84} as well as rheumatoid factors,⁸⁵ including anti-Gm antibodies,⁸⁶ anticardiolipin antibodies, and antiactin and anticytoskeletal antibodies.⁸⁷ The serum of some persons with IM may contain cryoglobulins.⁸⁸ Some of these autoantibodies have been reported to be monoclonal.⁸⁴

Although neutralizing antibodies produced after primary infection may play a role in thwarting the spread to additional B cells, EBV-specific antibodies are most useful for diagnosis,

P.1327

whereas the cellular response is the most important for control of EBV infections. NK cells and CD4⁺ T cells have been shown to play a role, but CD8⁺ memory cytotoxic T cells (EBV-CTLs) are the primary defense in controlling EBV infections.^{66, 67, 89, 90} The absolute number of NK cells may initially be increased, but a decrease in NK function is usually observed, returning to normal gradually over several weeks.⁹¹ Initially, these EBV-CTLs account for the majority of cells causing the lymphocytosis and the large, pleomorphic, atypical lymphocytes, or "Downey cells," characteristic of IM.^{66, 67, 90, 92} Of note, it has been shown that the amount of these T cells in the peripheral blood correlates with symptoms seen in IM, not the number of EBV-infected B cells or the viral load.⁹³ Not surprisingly, at first the majority of EBV-CTLs are reactive against lytic viral antigens. During lytic infection three EBV proteins, BNLF2A, BILF1, and BGLF5, function to lower HLA I surface expression, which in effect helps EBV-infected cells evade the immune system.⁹⁴ However, over time the number of EBV-CTLs reactive against latent viral antigens predominates.^{66, 67}

FIGURE 62.4 Immune response to Epstein-Barr virus (EBV) infection.

FIGURE 62.5 Laboratory tests I. Time course relationship between heterophil antibodies, various anti-Epstein-Barr virus antibodies, and the mean total and atypical lymphocyte counts. EA, early antigen; EBNA, Epstein-Barr nuclear antigen; D, diffuse component; Ig, immunoglobulin; VCA, viral capsid antigen.

This symbiosis of EBV and the infected host is maintained by interactions between viral gene expression in latently infected B cells and host EBV-CTL surveillance. The reservoir of viral latency is found among the resting memory B cells.^{46, 47} These resting memory B cells do not express high levels of adhesion molecules or T-cell co-stimulatory molecules, making them poor antigen-presenting cells. When these cells divide, EBNA-1 is expressed to ensure passage of viral DNA to progeny cells.⁵² Although CD4⁺ T-cell responses against EBNA-1 have been documented,⁹⁵ EBNA-1-specific cytotoxic T cells are not readily generated.^{96, 97} Thus, the reservoir of latent EBV infection is not recognized readily by the immune system.

Activated EBV-infected B cells express major histocompatibility complex class I antigens; various adhesion molecules make these proliferating EBV-infected B cells good antigen-presenting cells. Proliferating, latently infected B cells express all latent proteins, including EBNA-2, EBNA-3A, EBNA-3C, LMP-1, and LMP-2 (type III latency). These proliferating EBV-infected B cells are highly susceptible to cellular lysis by EBV-CTL and are eliminated during convalescence, whereas memory EBV-CTL provide lifetime immunosurveillance against EBV-driven B-cell proliferation. The immunodominant epitope of the EBV-CTL response is highly restricted by the HLA type of the individual.⁹⁸ For months after the expansion of EBV-infected B cells is controlled, virus is shed at high titers in the saliva,⁹⁹ indicating ongoing viral replication in infected B cells of the oropharynx.⁴⁶ Recent studies have demonstrated that EBV-CTL against latent viral antigens home more efficiently to lymphoid tissue of the oropharynx than EBV-CTL against lytic viral antigens.¹⁰⁰ This observation helps explain that the greatest risk of acquiring primary infection is salivary exposure from a recently infected person or a person in early convalescence, although infective virions can be found in the saliva of persons with a long latent infection.

INFECTIOUS MONONUCLEOSIS

Epidemiology

The typical clinical syndrome associated with IM occurs most commonly in young adults, the peak incidence being in persons between 17 and 25 years of age (Fig. 62.6).^{70, 101} Children often acquire immunity to EBV without developing the typical clinical manifestations of IM, for reasons still not understood.^{101, 102, 103} Because symptoms of EBV correlate with the CTL response,⁹³ this would suggest that young children generally respond with a less exuberant cellular response. The yearly conversion rate to EBV seropositivity among children in the United States is not known. Past studies suggest earlier conversion with lower socioeconomic status, i.e., 51% of Yale University freshmen and 86% of Marine recruits, had antibodies to EBV.^{12, 104} Authors of a British study concluded that 30% to 40% of children had been infected by their fifth year.¹⁰⁵ Generally speaking, the rate of seroconversion is high in developing countries, where standards of hygiene are relatively low compared to higher socioeconomic countries.^{10, 70} Under these circumstances, primary infection occurs in almost all children before 10 years of age, leaving few young adults susceptible to develop IM, and the observed incidence of IM in such countries is very low.^{10, 70} IM is sufficiently uncommon in individuals older than 30 years of age and is so rare in those older than 40 years of age that special care is needed when making the diagnosis in persons in their middle or late years. Nevertheless, well-documented cases of this illness in patients older than 40 years of age have been reported.^{105, 106, 107, 108} Complications such as protracted fever, jaundice, pleural effusion, and Guillain-Barré syndrome often dominate the clinical picture in these patients, detracting from the evidence that would allow the clinician to make the correct diagnosis.¹⁰⁷

IM is not as contagious as is commonly believed. It is rare for members of a patient's family, roommates of the same sex, and other close associates to develop symptoms of IM.^{109, 110} "Kissing disease," the colloquial term for IM, underscores the association of intimate kissing with IM.^{70, 99, 102, 111} Although oral shedding occurs throughout the life of a carrier, it peaks shortly after infection but often is readily detectable for 18 months or longer.^{99, 112, 113} Other modes of acquiring EBV infection include transplantation of organs or hematopoietic cells in which transmission to the transplant recipient is common.^{114, 115, 116, 117} Although it is not thought to occur frequently, there are anecdotal reports of transmission from blood transfusions,^{118, 119} in utero, or perinatally.^{120, 121} Although there are anecdotal reports of virus detected in cervical epithelium and semen, sexual transmission has never been demonstrated.¹²²

FIGURE 62.6 Age incidence. Age and sex of 82 patients with infectious mononucleosis at Johns Hopkins Hospital. Shaded columns, males; open columns, females.

Clinical Features

Many individuals have held that the manifestations of IM are protean and that many disorders may be simulated by this condition. IM is traditionally characterized by the clinical triad of fever, pharyngitis, and generalized adenopathy, with demonstration of an atypical lymphocytosis, defined as an absolute lymphocytosis with more than 50% lymphocytes and 10% or more atypical forms in the differential count, and the presence of heterophil antibodies.¹⁰² Usually, IM occurs only once in the lifetime of a host, although recurrences have been reported, and exacerbations of unresolved infection or transition to a chronic course may also occur. (See the section, “Chronic Active Epstein-Barr Virus Infections.”)

The signs and symptoms of IM are summarized in Table 62.1. The clinical course based on physical signs and symptoms is illustrated in Figures 62.7 and 62.8. In most young adults, the symptoms are fairly abrupt in onset, although close questioning frequently elicits vague complaints of lassitude and ill-being for several days before the onset of more pronounced symptoms. Most of the early symptoms are nonspecific. Myalgias do occur, but they are usually mild and are often confined to the neck and upper back. Excessive fatigue and general malaise may be accompanied by fever, sweating, and chills. Severe rigors rarely occur, and the patterns of fever are generally moderate and nonspecific. The fever is of no characteristic type. It may be transient and slight in degree, but in as many as one third of patients, it reaches a peak of 40°C. A secondary rise in temperature may occur after an initial drop to normal and may accompany the onset of glandular swelling or sore throat.

Anorexia is a common early symptom. Its intensity and duration are often linked to the severity of sore throat and dysphagia. The anorexia often persists for several weeks. Nausea is equally common and may be one of the earliest symptoms of IM, but

P.1329

vomiting is rare. Sore throat and dysphagia are among the most important manifestations of IM and may be the only symptoms in some patients. These symptoms usually develop gradually and subside in 1 to 2 weeks. For most patients, the symptoms of pharyngitis are mild, but occasionally, even taking sips of water may be painful.

TABLE 62.1 SYMPTOMS AND SIGNS OF INFECTIOUS MONONUCLEOSIS

Symptoms	%	Signs	%
Malaise and fatigue	90-100	Adenopathy	100
Sweats	80-95	Fever	80-95
Sore throat, dysphagia	80-85	Pharyngitis	65-85
Anorexia	50-80	Splenomegaly	50-60
Nausea	50-70	Bradycardia	35-50
Headache	40-70	Periorbital edema	25-40
Chills	40-60	Palatal exanthem	25-35
Cough (mild)	30-50	Liver or splenic tenderness	15-30
Myalgia	12-30	Hepatomegaly	15-25
Ocular muscle pain	10-20	Rhinitis	10-25
Chest pain	5-20	Jaundice	5-10
Arthralgia	5-10	Skin rash	3-6
Diarrhea or soft stools	5-10	Conjunctivitis	5
Photophobia	5-10	Pneumonitis	3
Abdominal pain	5		
Epistaxis	3

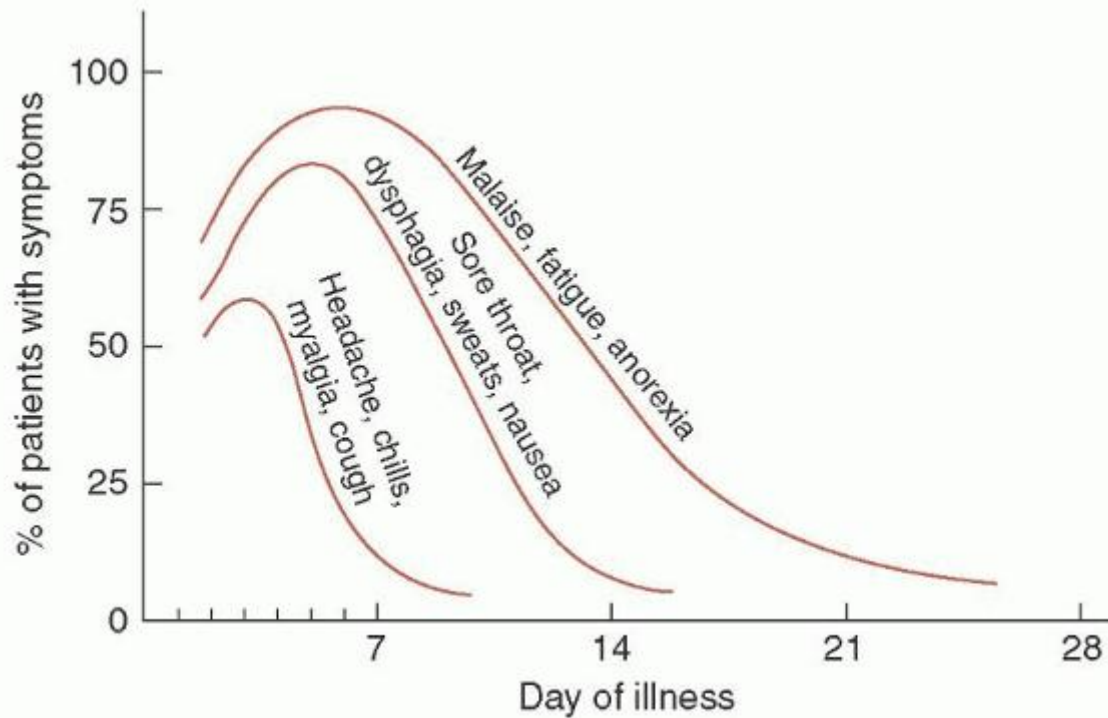

FIGURE 62.7 Major symptoms. Usual frequency and duration of major symptoms in young adults with infectious mononucleosis. (From Finch SC. Clinical symptoms and signs of infectious mononucleosis. In: Carter RL, Penman HG, eds. Infectious mononucleosis. Oxford: Blackwell Scientific, 1969.)

Lymph node enlargement is invariably present at some time.^{123, 124, 125} Adenopathy usually appears during the first week of illness and slowly resolves thereafter. Anterior and posterior cervical node enlargement is almost always present, and palpable axillary and inguinal nodes are common. Radiographically detectable hilar adenopathy is rare (<1%).¹²⁶ Although splenomegaly is expected, the spleen is palpable in only one half to three fourths of all patients, and massive splenomegaly is rare.¹²⁷ Hepatomegaly is detected in 15% to 25% of patients and is usually accompanied by percussion tenderness over the liver and discomfort on palpation. The course of hepatomegaly closely follows that of adenopathy and splenomegaly.¹²⁷ Pharyngeal inflammation usually appears in the first week and then subsides rapidly. In approximately 25% of patients, pharyngitis first occurs after the initial week of illness, and there are no pathognomonic features. It varies in intensity, but rarely, massive tonsillar and pharyngeal edema may cause virtually complete pharyngeal obstruction.¹²⁵ Severe cough is relatively rare, although mild cough is common.

FIGURE 62.8 Physical signs. Usual frequency and duration of major physical signs in young adults with infectious mononucleosis. (From Finch SC. Clinical symptoms and signs of infectious mononucleosis. In: Carter RL, Penman HG, eds. Infectious mononucleosis. Oxford: Blackwell Scientific, 1969.)

Headaches occur early, as well as photophobia, and ocular muscle pain can occur. Ocular manifestations occur in approximately one third of patients and include eyelid edema, conjunctivitis, dry eyes, keratitis, uveitis, choroiditis, retinitis, papillitis, and ophthalmoplegia.¹²⁸ Rashes are also common with primary EBV infection and may be the only symptom in young children.^{129, 130} Several observers have noted that patients experiencing IM are peculiarly prone to rashes when treated with ampicillin, which appear to be the result of vasculitis caused by circulating ampicillin-antibody complexes.^{131, 132, 133}

Laboratory Findings

Hematologic abnormalities in IM are observed in virtually all patients. The hematologic changes persist for a minimum of 2 weeks and usually persist for 1 to 2 months. One of the classic features of IM is the atypical lymphocytosis. The pleomorphism of the mononuclear cells found in the blood is usually striking. In addition to normal lymphocytes and monocytes, large mononuclear cells, or atypical lymphocytes, are observed in the blood (Fig. 62.9). Although nonspecific⁴ because they may be found in the blood of patients with a variety of conditions, including other viral infections,¹³⁴ they are a prominent feature of IM. The abnormal cells vary greatly in size and shape. They possess a nucleus that may be oval, kidney-shaped, or slightly lobulated and cytoplasm that most often is nongranular and vacuolated or foamy. The nuclear chromatin forms a coarse network of strands and masses and is not clearly differentiated from the parachromatin. The identity of these cells has been shown to be CD8⁺ T lymphocytes, as discussed previously (see the section, "Immune Response to Epstein-Barr Virus Infection"). The rapid proliferation of these activated T cells is responsible for the large numbers of atypical cells seen in the peripheral blood, whereas the proliferating B cells are primarily responsible for the generalized lymphadenopathy, hepatosplenomegaly, tonsillar and adenoidal changes, and the cellular infiltration seen in many parenchymal organs; this is discussed in detail in the section, "Infectious Mononucleosis: Histologic Findings."

Most patients with IM have slightly or moderately increased total white blood cell counts in the range of 10.0 to 20.0×10^9 cells/L, with approximately 15% of patients reaching levels in excess of 20.0×10^9 /L.^{111, 135, 136} The absolute lymphocyte count most often exceeds 5.0×10^9 cells/L; with atypical lymphocytes usually $>20\%$.¹¹¹ Lymphocytosis begins toward the end of the first week of illness and reaches a peak corresponding to symptoms, as does the total leukocyte count (Fig. 62.10). Leukopenia has also been observed and can be manifested as lymphopenia or granulocytopenia.¹³⁶ Most patients with IM have normal hemoglobin levels, and severe thrombocytopenia is rare, although mild depressions of platelet counts may be found in perhaps one half of patients.¹³⁷ Severe neutropenia and thrombocytopenia may be very ominous signs, as they are frequently seen in the hemophagocytic reactions (VAHS or EBV-HLH).

Nonhematologic abnormalities are also commonly observed in patients with IM. Many patients show mild to moderate abnormal liver function tests.¹³⁶ The reported incidence varies from 40% to 100%, depending on the severity of the disease, the time of testing, and the diligence with which the changes were sought. Reported enzyme changes include elevations of lactate dehydrogenase, alkaline phosphatase, glutamic pyruvate transaminase, phosphohexose isomerase, and aldolase, in roughly that order of frequency. Perhaps one third of patients have mild to moderate elevations of serum bilirubin values; levels above 8 mg/dl (135 μ mol/L) are exceedingly rare but have been reported.^{136, 138} Occasionally, proteinuria or hematuria is present, but renal function is usually unimpaired. When the patient is jaundiced, bile and increased concentrations of urobilinogen may be found. When

P.1330

lumbar puncture has been performed to evaluate patients with severe headaches, the cerebrospinal fluid (CSF) pressure may be elevated, and pleocytosis and increased levels of protein are often noted. The sugar content is normal. In a few patients, heterophil antibodies have even been demonstrated in the CSF.¹³⁹

FIGURE 62.9 Lymphocytes and cells of infectious mononucleosis. A: Large and small lymphocytes from the blood of normal subjects. B: Lymphocytes resembling plasma cells ("plasmacytoid" cells) in the blood of a patient with viral pneumonia. C: Somewhat atypical lymphocyte and plasmacytoid lymphocytes in blood. D: Lymphocytes from the blood of a patient with viral infection; azurophilic granules are clearly seen in one of the cells. E-J: Infectious mononucleosis; lymphocytes showing increasing levels of atypia. E: Downey type I. F,G: Downey type II. H-J: Downey type III. K: Lymphocytes from blood of patient with infectious mononucleosis.

FIGURE 62.10 Laboratory tests II. Major laboratory findings in adults with infectious mononucleosis. (From Finch SC. Clinical symptoms and signs of infectious mononucleosis. In: Carter RL, Penman HG, eds. Infectious mononucleosis. Oxford: Blackwell Scientific, 1969.)

Histologic Findings

The main pathologic feature of IM is a notable proliferative response within the reticuloendothelial system, especially by the lymph nodes and the spleen. It can be difficult to distinguish between malignant lymphoma and nonmalignant disease associated with EBV infection, especially in the immunodeficient patient population.⁶⁹ In summary, the histologic diagnosis of IM is one of suspicion rather than certainty.^{69, 140}

The lymph node architecture is generally intact^{141, 142} but may be distorted.^{140, 141, 142, 143} Other morphologic features mimicking lymphoma include extensive immunoblastic proliferation in sheets and nodules and significant cellular atypia.¹⁴¹ Clonality studies are often necessary to differentiate IM from malignant disease. The germinal centers are usually identifiable, but follicular prominence is diminished, probably because of the irregular and vaguely defined borders that result from the lymphocytic and reticuloendothelial hyperplasia of paracortical structures and, to a lesser extent, the medullary cords. This intense proliferative activity within the paracortical areas is in keeping with the characterization of atypical lymphocytes as T cells.¹⁴³ In addition, focal proliferations of macrophages are noted, as is, most characteristically, the presence of "typical" IM cells throughout the pulp, on the edges of germinal centers, and in the sinuses.¹⁴² RS-like cells^{140, 141, 143} are often observed in association with areas of necrosis.⁶⁹ Because the presence of EBV has been demonstrated in approximately 50% of HL specimens,^{144, 145, 146} the identification of

P.1331

the virus or EBV-determined antigens is not particularly helpful in the differential diagnosis of these two disorders.

The spleen is striking for infiltration of its fibromuscular structures by mononuclear cells.¹⁴⁷ Both the capsule and trabeculae are often thin and invaded by proliferating lymphocytes. This may explain the occurrence of splenic rupture in this disease. In vitro hybridization studies can be used to track the distribution pattern of cells carrying the viral genome.^{140, 148} Most labeled cells are found in the hyperplastic T-cell zones, the paracortical or interfollicular areas^{140, 148}; smaller numbers are found within the epithelioid venules, the lymph node sinuses, and, occasionally, the germinal centers and the mantle zone.¹⁴⁸ In the spleen, labeled cells are found mainly within pulp cords.¹⁴⁸ Most of the labeled cells are small lymphocytes, but occasional labeled blasts, dendritic cells, and macrophages can be identified.¹⁴⁸

The bone marrow may be cellular with generalized hyperplasia of erythroid, myeloid, and megakaryocytic elements.¹⁴⁹ With special techniques, sarcoidlike granulomas may also be demonstrated.^{149, 150, 151} In most instances, however, routine marrow aspiration reveals no abnormalities of note.

Diagnosis

The diagnosis of IM rests primarily on documentation of a primary EBV infection. Because EBV cannot be cultured, the humoral response to EBV infection, which has been discussed in the section, "Immune Response to Epstein-Barr Virus Infection," is the usual method to discern infection. In summary, a recent, primary EBV infection is characterized serologically by (a) a positive heterophil antibody titer; (b) high titers of anti-VCA antibodies, both IgM and IgG; (c) high titers of anti-EA antibodies; and (d) the absence of anti-EBNA-1 antibodies (Fig. 62.5). Convalescent sera demonstrate the disappearance of IgM anti-VCA antibodies and the appearance of anti-EBNA-1 antibodies.^{72, 73} At present, the diagnosis of IM is made by the presence of anti-IgM to EBV VCA. Rapid test systems using recombinant EBV antigens and enzymelinked immunosorbent or other assay technologies have been developed for use in clinical laboratories,^{152, 153} but false-positive tests, especially for anti-EBV IgM antibodies, can occur.¹⁵⁴

Because so many antibodies have been linked to the development of IM, elevation of Ig levels in association with this disease is not surprising.^{155, 156} Although this change is especially true for IgM, lesser elevations have also been seen in IgG and IgA. A general increase in titers of IgG antibodies and production of IgM antibodies against heterophile antigens and other infectious agents is common during the primary EBV infection^{157, 158} and must be taken into account when performing a diagnostic workup. Antibodies with recognized antigenic specificities make up only a small proportion of the total γ -globulins of the serum,^{155, 159} and the antigenic specificity of most of the increased γ -globulins remains undefined.

A serologic diagnostic test for IM has been available since Paul et al.⁷⁸ discovered that the sera of patients with IM contain agglutinins against sheep red cells. They called the antibody heterophil because it reacted with a heterologous antigen that obviously had not elicited its production. Historically, the heterophil antibody test was felt to be a sine qua non in the diagnosis of IM in adults. Investigators soon learned that the antibody reacted not only with sheep red cells, but also with beef and horse erythrocytes.^{157, 160, 161} The heterophil antibody is an IgM globulin,^{162, 163, 164} which, in some studies,¹⁶⁴ was shown to have λ light chains only. The Paul Bunnell (PB) antigen with which the heterophil antibody interacts is thermostable,^{160, 162} in contrast to the Forssman antigen. Its immunologically reactive sites appear to be carbohydrate in nature.¹⁶⁵ The carbohydrate nature of the antigen probably explains the observation that the antibody response is almost exclusively IgM. PB antigens are found also on cells other than heterologous erythrocytes.¹⁶² Of particular interest is the demonstration of PB-like antigens on murine T lymphocytes, Thy-1-positive murine lymphoma cells, and murine neutrophilic granulocytes.¹⁶² In addition, PB antigens have been demonstrated in various tissues of IM patients during the early stages of the disease,¹⁶² in cultures of some lymphoid cell lines,¹⁶⁶ in fresh BL tissues,¹⁶⁷ and in the spleens of some patients experiencing lymphoma or leukemia.¹⁶² The formation of PB antibodies by cultures of lymphocytes from IM patients also has been demonstrated.¹⁶⁸

Heterophil antibodies in titers of up to 1:28 are present in most normal persons and, occasionally, in titers of 1:56.¹⁶⁹ A study of more than 3,000 IM patients showed the following age distribution of PB antibodies: 5 to 9 years of age, 4%; 10 to 14 years of age, 8%; 15 to 24 years of age, 80%; 25 to 29 years of age, 3%; and older than 30 years of age, 5%.¹⁷⁰ For these reasons, the test for heterophil antibodies has been called "presumptive,"¹⁷¹ but in the presence of clinical and hematologic findings suggestive of IM and a titer of 1:256 or higher, the diagnosis of IM is likely. In patients with IM, positive heterophil reactions almost always appear during the first 2 weeks of the illness (Fig. 62.5). Highest titers usually are found during the second and third weeks. As a rule, positive reactions last 4 to 8 weeks, but they have been observed to persist for as short as 7 to 9 days or as long as 18 weeks.¹⁶⁹ The titer bears no relation to the severity of the disease or to the leukocyte changes. Although elevated heterophil antibody titers are quite common in EBV infection, occasionally patients with other disorders produce elevated levels.¹⁷²

Molecular diagnostic techniques are useful for the demonstration of EBV in tissues and body fluids. In situ hybridization techniques^{140, 148, 173} and the polymerase chain reaction (PCR)^{174, 175} are most commonly used. The use of quantitative EBV PCR has been evaluated for diagnostic and prognostic value in EBV-related diseases.^{176, 177} The detection of EBV DNA in peripheral blood or serum by PCR provides good evidence that the patient has been infected by EBV. However, interpretation of quantitative EBV DNA PCR or "viral load" results can be problematic, especially in the immunodeficient patient. Immunocompromised patients tend to have higher amounts of EBV DNA than normal healthy individuals with latent EBV infections. Also, different laboratories use different methods of detection, different specimens (blood vs. serum vs. mononuclear cells), and different measurements (copies per micrograms DNA vs. cells vs. ml of serum/blood).¹⁷⁷ It appears that the amount of EBV DNA detectable in the blood of a patient with EBV-related disease may be useful in

monitoring response to therapy in some diseases, but its value for diagnosis or prognosis still remains to be determined. The best method to diagnose EBV as an etiologic agent is tissue biopsy and in situ hybridization.

Differential Diagnosis

The diagnosis of IM usually is not difficult. In most instances, a young adult complains of malaise, fatigue, anorexia, and a sore throat and is found to have fever, adenopathy, pharyngitis, and splenomegaly. Appropriate changes in EBV titers will confirm the diagnosis. Much has been written about complications that can be devastating or even fatal, but serious complications in IM are rare, occurring in <1% of all diagnosed patients.¹²⁵ Therefore, signs of significant respiratory, cardiovascular, intestinal, urinary, or joint disease make considerations of other diagnoses mandatory.

The fever and general malaise can be seen in many infectious diseases including salmonella infections, listeriosis, brucellosis, subacute bacterial endocarditis, the lymphadenopathic form of toxoplasmosis, and malaria.⁶⁹ Generalized lymph node enlargement, including the postauricular and occipital nodes, is also characteristic of rubella.⁶⁹ The pharyngitis of IM must be differentiated from acute streptococcal pharyngitis, diphtheria, and acute viral pharyngitis of other types. β -Hemolytic streptococci are isolated relatively often from patients with classic IM.¹²³ Thus, a

P.1332

positive throat culture for streptococci does not make a search for an EBV infection unnecessary. In addition, a palatine exanthem may be present in patients with rubella, and atypical lymphocytes have been described in this condition. Drug fever and serum sicknesslike reactions may also suggest IM, because they often are characterized by fever, jaundice, lymph node enlargement, and atypical lymphocytes.⁶⁹ Lymphocytosis, absolute or relative, may be encountered in association with diseases other than IM. These disorders include tuberculosis, tularemia, pertussis, dengue, mumps, chickenpox, German measles, typhoid fever, infectious hepatitis, serum sickness, and various other allergic states. In association with some of these conditions, abnormal lymphocytes resembling those of IM have been observed, as mentioned previously. Leukocytosis due to small lymphocytes of normal appearance and not associated with splenomegaly, lymphadenopathy, or a positive heterophil titer is suggestive of some other acute infectious process.

The hematologist may be called on to differentiate IM from other more serious hematologic diseases, such as acute leukemia or lymphoma. Although many leukocytes of patients with IM appear abnormal, few contain nucleoli, and thrombocytopenia and anemia are rare in these patients. EBV serologies confirming primary infection can be very helpful. Bone marrow examination is rarely necessary to differentiate IM from acute leukemia. Nodal biopsy can be difficult at times to differentiate IM from a malignant process. (See the section, "Histologic Findings.") Patients who have had IM do not have a higher incidence of leukemia, but a few cases of concurrent IM and leukemia have been reported.^{178, 179, 180, 181}

A number of self-limiting diseases are associated with a peripheral blood picture that satisfies all of the morphologic criteria established for the diagnosis of IM; failure to recognize these illnesses can result in unnecessary lymph node or liver biopsies, bone marrow aspiration, or other irrelevant diagnostic tests. The most common causes include cytomegalovirus (CMV), rubella, hepatitis and adenoviruses, *Toxoplasma gondii*, trichinosis, HIV, and HHV6, as well as a number of bacterial infections, with CMV being the most common.^{182, 183, 184, 185, 186, 187, 188, 189}

When CMV-mononucleosis occurs, the illness can clinically be identical to IM with similar laboratory findings.¹⁸² The diagnosis is confirmed by demonstrating the presence of IgM antibodies to CMV in virtually all cases.^{123, 182} A few patients have been reported to present with evidence of simultaneous CMV and EBV infection.¹⁸¹

Complications

Unusual clinical patterns and serious complications are probably seen in no more than 1% of all patients.¹³⁸ Misconceptions about a higher incidence stem from the fact that most of the medical literature concerning IM deals with complications and from impressions of subspecialists who usually do not see patients with uncomplicated disease. The most frequently reported complications are listed in Tables 62.2 and 62.3.^{190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215}

Cardiac complications

Electrocardiography changes^{129, 243}

Pericarditis^{214, 215}

Myocarditis⁸⁰

Respiratory complications

Acute airway obstruction^{244, 245}

Pleural effusion^{247, 248, 249}

Parenchymal changes^{246, 247, 249}

Liver failure^{239, 250, 251, 252}

Pancreatitis^{253, 254}

Renal failure²⁵⁵

Hematologic complications are the most common. The incidence of hemolytic anemia may be as high as 3%.^{216, 217} Hemolysis usually is mild; in approximately 70% of the patients with hemolytic anemia, the reaction to the antiglobulin test (or Coombs test) is positive, and in approximately the same number, the titers of cold agglutinins are increased,²¹⁷ usually with anti-i specificity.²¹⁸ Occasionally, hemolysis has been attributed to Donath-Landsteiner cold hemolysins.^{219, 220} In summary, anti-i antibodies are extremely common, but hemolytic anemia is rare.^{218, 221, 222} Sometimes, however, no antibody of any kind is detectable. IM has been associated with accelerated hemolysis in patients with underlying hereditary spherocytosis,^{223, 224} elliptocytosis,²²⁵ or thalassemia,²²⁶ and in one patient, the onset of paroxysmal nocturnal hemoglobinuria coincided with the development of IM.²²⁷

Hematologic cytopenias are common. Although mild depression of the platelet count (100 to 140 $10^9/L$) may be found in perhaps one half of patients with IM,¹³⁷ thrombocytopenic purpura is a rare complication that is seen primarily in younger children.^{228, 229, 230} Thrombocytopenia occurring in acute IM has been attributed to increased destruction by an enlarged spleen or the production of platelet autoantibodies.^{231, 232} Immune thrombocytopenia preceding the development of severe aplastic anemia has been reported.²³³ Mild granulocytopenia is a common finding in patients with IM,²³³ but severe granulocytopenia is rare.^{233, 234, 235} When marrow examination has been performed, myeloid hyperplasia has been noted

with increased numbers of promyelocytes, but with depletion of more mature neutrophilic cells.^{234, 235} This picture is compatible with a proliferative response to an earlier marrow injury or peripheral destruction or increased use of granulocytes. Serious suppression of the entire marrow is rare.^{217, 236, 237} Fatal aplastic anemia has been noted after what appeared to be typical IM^{219, 238} but is more often related to hemophagocytic reactions (VAHS or EBV-HLH).²³⁹

P.1333

One of the most common reported complications is splenic rupture, which has led to death in several cases^{190, 191} but has been reported to occur with an incidence of 0.1% to 0.2% in North America. Of the 107 cases reported in the world literature up to 1978, only 18 were considered "spontaneous" by one reviewer.¹⁹² The diagnosis of a ruptured spleen should be entertained whenever a patient with IM has severe or even moderate pain below the left costal margin, especially if the pain is accompanied by radiation to the left shoulder and supraclavicular area, or has evidence of impending peripheral vascular collapse. Other signs include those characteristic of peritoneal irritation, abdominal tenderness, and shifting dullness if massive intra-abdominal bleeding has occurred. Frank rupture may be preceded by one or more episodes of subcapsular hemorrhage or minor capsular tears, which may be difficult to differentiate from rupture. Because potentially fatal bleeding may occur at any time, it is recommended that surgical intervention be pursued whenever the typical pain pattern is accompanied by signs of hemodynamic instability.^{190, 191} Delayed surgical intervention often is attributable to the misconception that abdominal pain is a common feature of the uncomplicated disease. Preservation of splenic function by surgical repair of the capsular tear (splenorrhaphy) or partial splenectomy has been recommended by some but is not generally recommended, as the altered splenic architecture in IM makes it unlikely that such interventions will be successful.^{190, 191}

Complications of almost all organ systems have been described in association with IM²⁴⁰ and are listed in Table 62.3. Neurologic manifestations are not infrequent in IM and may occur in 1% to 2% of patients.^{193, 194, 241} When serious neurologic complications occur, the mortality rate may be as high as 8% to 11%,²⁴² and, in addition, the incidence of serious residual damage may be as high as 12%.²⁴² Cardiac complications are rare, although electrocardiographic abnormalities may occur in approximately 10% of patients,^{129, 243} and fatal myocarditis has been reported in association with IM.⁸⁰ The most serious respiratory complication is acute airway obstruction, which usually is the result of extreme hyperplasia of the tonsils and other pharyngeal lymphatic tissue.^{244, 245} Pleural effusion and pulmonary parenchymal changes are exceedingly rare,^{246, 247, 248, 249} but occasional cases are characterized by extensive interstitial infiltrates (lymphoid interstitial pneumonitis), and severe respiratory insufficiency has been reported.²⁴⁷ Evidence for some degree of hepatic involvement is found in most patients but is usually mild; the necrosis and inflammatory exudate seen in association with infectious hepatitis are encountered only rarely.^{239, 250, 251, 252} Liver failure is rare^{239, 250} but can be a prominent feature in fatal cases of IM [fulminant infectious mononucleosis (FIM) or EBV-HLH],²⁵⁰ including those associated with subtle forms of immune deficiency.²⁵⁰ Acute pancreatitis has been associated with IM.^{253, 254} An association between IM and irreversible renal failure was postulated in one patient.²⁵⁵

Treatment

Most patients experiencing uncomplicated acute IM require only symptomatic therapy. Bed rest is recommended for patients with fever, malaise, and myalgias. Strenuous exercises, especially contact sports, should be avoided for at least 1 month or until resolution of splenomegaly. Nonsteroidal anti-inflammatory drugs, such as acetaminophen or ibuprofen, should be used to control pain, although in patients with severe hepatitis, these agents should be used judiciously. It has been suggested that aspirin may prolong convalescence.²⁵⁶ Aspirin also interferes with platelet function, potentially increasing the risk of bleeding in thrombocytopenic patients, and Reye syndrome has been reported in association with IM, albeit rarely.²⁰⁰ Antibiotics are of no value in uncomplicated IM, but many patients show culture or serologic evidence of a recent streptococcal infection,¹²³ and these should be treated with appropriate antibiotics. Ampicillin and amoxicillin should be avoided because they often cause a severe rash.^{123, 130, 132}

Corticosteroids have been used in cases of life-threatening complications such as airway obstruction, carditis, lymphoid interstitial pneumonitis, pleural effusions, or cerebral edema. Their efficacy is largely anecdotal and is presumably due to their anti-inflammatory and lympholytic properties. The cumulative results of several small, controlled clinical trials suggest that corticosteroids hasten the resolution of fever and tonsillopharyngeal symptoms but do not provide significant benefits in the therapy of lymphadenopathy or hepatosplenomegaly.^{15, 257, 258, 259, 260} Therefore, caution should be exercised when using corticosteroids.²⁶⁰ There are reports of encephalitis or myocarditis in association with steroid use in

IM,^{261, 263} and secondary bacterial and fungal infections can occur. However, in the face of severe complications, the use of steroids may well be indicated and necessary.

Several antiviral agents such as acyclovir, ganciclovir, zidovudine, foscarnet, and the interferons (IFNs) have been shown to inhibit the replication of EBV in vitro.²⁶² Only the linear form of the genome, not the latent circular form, is susceptible to inhibition. The efficacy of acyclovir in the therapy of uncomplicated IM has been assessed in several controlled trials.^{263, 264, 265, 266} In general, acyclovir reduces viral shedding during the time of therapy, but viral shedding resumed when therapy was discontinued.¹⁵ Clinical trials have documented few clinical benefits as measured by duration of illness and sore throat, weight loss, or absence from school or work, even when acyclovir was given in combination with steroids.^{259, 266} IFN- α has been used in a few patients experiencing persistent EBV infection with severe complications of interstitial pneumonitis, encephalitis, or genital ulcers, apparently with some success.²⁶⁷ Patients with IM-associated immune thrombocytopenia have responded to therapy with large doses of intravenously administered γ -globulin.²³² A viral protein vaccine has been developed that protects marmosets from developing LPD^{268, 269} but not from infection. Several groups are working on the development of EBV vaccines^{270, 271} Although these vaccines can induce a neutralizing antibody response they do not protect against primary infection or reduce the risk of developing clinical disease, i.e., IM.

Prognosis

Complete recovery occurs within 2 months in the majority of patients. Recurrences of IM are so rare that one must question whether the initial diagnosis or the diagnosis of recurrence is accurate. It is estimated that IM is fatal in as many as 1 in 3,000 cases, or approximately 50 cases annually in the United States.^{76, 272} Penman,²³⁹ in reviewing the world literature on IM, catalogued 87 fatalities attributed to the disease or its complications. Only 20 of these reports, however, contained adequate evidence for an unequivocal diagnosis. Of these 20 cases, 9 fatalities were related to be due to neurologic complications, 4 were related to respiratory failure from peripheral neuropathy of the Guillain-Barré type, and 5 were related to central respiratory paralysis; 3 were related to splenic rupture; and 3 were related to secondary infection. Other fatal complications included hepatic failure (two cases) and myocarditis (one case). In two cases, the cause of death was unrelated to IM. The majority of deaths associated with IM occur in patients who develop VAHS or EBV-HLH.^{76, 272}

A recent study has demonstrated that the severity and duration of the illness does not correlate with either control of viremia or rapidity of the antiviral humoral or cellular responses.²⁷³ Therefore, in the nearly 100 years since the first description of IM and the etiologic agent (i.e., Epstein-Barr virus) countless reports of describing the spectrum of potential complications have been published. But despite enormous numbers of studies to define the pathogenesis, it remains a mystery how and why EBV causes the symptoms of IM, and a therapy that reproducibly improves symptoms remains elusive.

P.1334

OTHER EPSTEIN-BARR VIRUS-RELATED DISEASES

Recently, methods for detecting infectious agents in human disease have become highly developed. Consequently, many ubiquitous infectious agents have been etiologically linked to certain human diseases (e.g., EBV infection has been associated with a wide spectrum of human diseases). Classically, EBV is associated with the development of human malignancies such as BL and NPC. EBV infection has also been associated with other human malignancies, such as NHL (B-cell, T-cell, and NK-cell phenotype), HL, gastric carcinoma, leiomyosarcoma, hepatocellular carcinoma, breast cancer, and LPDs associated with immunodeficiency. In addition, EBV infection has been associated with several nonmalignant, but potentially life-threatening human diseases, such as VAHS or EBV-HLH, and CAEBV, in which development of malignant lymphoma can occur. Also, some have linked EBV infection to chronic illnesses, such as chronic fatigue syndrome and most recently multiple sclerosis. Although association has been demonstrated, it remains controversial whether EBV is causative in these disorders (Table 62.4). The following discussion focuses on diagnosis of and evidence for the role of EBV in the pathogenesis of these diseases.

Chronic Active Epstein-Barr Virus Infection

EBV rarely causes recurrent or persistent symptomatic infections in apparently immunocompetent hosts. Diagnostic criteria for CAEBV have been proposed²⁷⁴ and consist of (a) evidence of severe, progressive EBV illness beginning as a primary EBV infection and lasting more than 6 months with anti-EBV titers of IgG anti-VCA 1:5120, anti-EA 1:640, or anti-EBNA<1:2, or all three; (b) histologic evidence of major organ involvement; and (c) increased amounts of EBV in peripheral

blood or affected tissues, or both. CAEBV is characterized by persistent or recurrent IM-like symptoms, such as recurrent fever, lymphadenopathy, and hepatosplenomegaly, and unusual anti-EBV antibody patterns.²⁷⁴ CAEBV occurs most commonly in patients who develop IM as older children or young adults.^{274, 275, 276} This entity may be more prevalent in Asia, as most of the published literature is from Japan. A cohort of 30 patients in Japan diagnosed with CAEBV presented with the following clinical manifestations: Fever (100%), liver dysfunction (90%), splenomegaly (90%), lymphadenopathy (50%), thrombocytopenia (50%), anemia (50%), hypersensitivity to mosquito bites (43%), calcification in the basal ganglia (18%), and oral ulcer (18%).²⁷⁵ CAEBV can be lethal, with 30 to 50% mortality within 5 years of diagnosis.^{28, 276} Life-threatening complications include the hemophagocytic syndrome (21%), coronary artery aneurysm (21%), hepatic failure (18%), malignant lymphoma (16%), and interstitial pneumonia (12%).²⁷⁶ The majority of deaths are due to hemophagocytic syndromes or hematologic malignancies, which may be of T-cell, B-cell, or NK-cell phenotype.^{28, 274, 276}

TABLE 62.4 DISEASES THAT HAVE BEEN ASSOCIATED WITH EPSTEIN-BARR VIRUS

Definite Etiologic Role	Strong Association	Etiologic Role Unclear	Controversial Association
Infectious mononucleosis	Burkitt lymphoma		Chronic fatigue syndrome
CAEBV	Nasopharyngeal carcinoma		Multiple sclerosis
EBV-HLH	Lymphoproliferative disease of immunodeficiency		Breast carcinoma
	Leiomyosarcoma of immunodeficiency		
	X-linked lymphoproliferative disease		
	Hodgkin disease		
	Nasal NK-/T-cell lymphoma		
	Gastric carcinoma		

CAEBV, chronic active Epstein-Barr virus infection; EBV, Epstein-Barr virus; HLH, hemophagocytic lymphohistiocytosis; NK, natural killer.

It is believed that cellular immunologic abnormalities are responsible for the development of CAEBV. In the peripheral blood of patients with CAEBV, high levels of EBV DNA have been found in CD4⁺ T cells and NK cells, but not in B cells.²⁷⁷ The significance of this finding in the pathogenesis of CAEBV and the mechanism of infection of these cells remain to be elucidated. This entity may overlap with severe or fulminant IM (FIM or EBV-HLH).^{68, 274, 277} Further studies are needed to differentiate between these enigmatic disorders and to determine the role of EBV infection in their pathogenesis.

A standard treatment approach to CAEBV has not been established. Most reports are anecdotal but include antiviral agents (acyclovir, ganciclovir, and vidarabine) and/or immunomodulating agents (IFN- α or IL-2).^{274, 275, 276, 277, 278, 279} Because immunochemotherapy (e.g., etoposide, corticosteroids, and cyclosporin A) has been effective in treating the EBV-hemophagocytic syndrome,^{280, 281} it has been used to control symptoms and treat hemophagocytic complications.²⁷⁴ Hematologic malignancies have been treated with standard NHL therapy,²⁷⁶ but curative therapy for the severely affected patient appears to require the replacement of the patient's immune system with a normally functioning immune system to control the EBV infection, for instance, by an allogeneic stem cell or marrow transplant^{275, 282} or by allogeneic adoptive T-cell therapy.²⁸³

CAEBV infections should be differentiated from the so-called chronic mononucleosis, or chronic fatigue syndrome. Due to the similar symptoms and reports of elevated anti-VCA and anti-EA titers, EBV has been suggested to be the etiologic agent in the chronic fatigue syndrome.²⁸⁴ In controlled studies, no specific EBV serologies have been found that differentiate chronic fatigue syndrome patients from controls.²⁸⁵ In a randomized, placebocontrolled trial of acyclovir, clinical improvement was seen as frequently with the placebo.²⁸⁶ Chronic fatigue syndrome has been associated with other infections (viral and bacterial) and, therefore, should not be considered a disease caused by EBV.^{285, 287}

Fulminant Infectious Mononucleosis or Epstein-Barr Virus-Associated Hemophagocytic Lymphohistiocytosis

The self-limited course of IM contrasts with the atypical responses that can occur in FIM, also called VAHS or EBV-associated HLH.⁶⁸ Death occurs in approximately 1 in 3,000 IM cases, or approximately 50 cases annually in the United States.^{76, 272} The median age at presentation of FIM/EBV-HLH is similar to that of uncomplicated IM (i.e., 13 years of age). Whereas FIM/EBV-HLH is the most common manifestation in males affected with X-linked lymphoproliferative disease

(XLP), it often occurs outside the context of XLP.^{68, 69, 272, 288, 289, 290} Outside the context of XLP, the male-to-female ratio is approximately 1:1.²⁷² VAHS has been associated with CMV, herpes simplex virus, and adenovirus, but EBV is the most common.^{68, 280} Clinically, FIM/EBV-HLH is indistinguishable from other types of VAHS, familial HLH, and the accelerated phase of Chédiak-Higashi disease or X-linked inhibitor of apoptosis (XIAP) or sometimes referred to as XLP2.^{68, 69, 280, 291} Because FIM/EBV-HLH is rare, a search for a heritable immune deficiency in family members is mandatory.

P.1335

Patients who progress to FIM/EBV-HLH initially present with the usual signs and symptoms of IM, but these symptoms usually rapidly progress in severity.²⁷² The EBV antibody responses vary considerably from completely lacking to unusually high; therefore, it may be difficult to differentiate FIM/EBV-HLH from other hemophagocytic syndromes, CAEBV, acute leukemia, other malignancies, or even overwhelming sepsis.^{68, 272} The course and progression of the disease are variable, ranging from multiorgan failure developing over hours to persistent or recurring symptoms of IM lasting for months. An atypical lymphocytosis usually is present at early stages of the disease, but patients subsequently develop severe persistent pancytopenia and/or hepatic dysfunction resulting in fulminant hepatitis and varying degrees of multiorgan failure.^{69, 272, 288, 289} The development of hepatic dysfunction, often with coagulation abnormalities secondary to liver failure or disseminated intravascular coagulation, and pancytopenia are ominous signs, as are other signs of hemophagocytic syndromes, such as hypofibrinogenemia and elevated triglyceride levels.^{68, 69, 280, 289, 292}

As discussed previously, EBV is a potent stimulus to the immune system, resulting in a massive EBV-specific and -nonspecific response of both the humoral and cellular immune systems (Fig. 62.4). In FIM/EBV-HLH, the EBV-nonspecific response, primarily the cellular immune response, is uncontrolled. FIM/EBV-HLH is characterized by extensive infiltration of parenchymal organs by lymphoid cells, primarily CD8⁺ cells in varying degrees of transformation and histiocytes with surprisingly few B cells.^{69, 292} The cells infected by EBV in FIM/EBV-HLH are usually T cells^{68, 277, 292} and are generally CD8⁺, as opposed to the CD4⁺ or NK cells observed in CAEBV.^{277, 292}

If this aggressive immune reaction proceeds unabated, all organs ultimately sustain extensive and irreparable damage.^{68, 69, 288, 290, 292} Early in the course of the disease, the bone marrow may be hypercellular with few infiltrating histiocytes; erythrophagocytosis is seen best in smears of marrow aspirates. The marrow later becomes hypocellular with varying numbers of infiltrating histiocytes.^{288, 290} Lymph nodes initially show an intense lymphoblastic proliferative response, again primarily T cells, but later, lymphoid depletion supervenes.^{69, 288, 290} Liver biopsies reveal active portal infiltration with lymphocytes and histiocytes, with occasional erythrophagocytosis in liver sinusoids.²⁵⁰ In the spleen, extensive necrosis of white pulp develops. Perivascular mononuclear cell infiltrates of the brain, mononuclear cell myocarditis, and interstitial nephritis also are observed.^{69, 272, 288, 289, 290, 293, 294} The thymus shows thymocyte depletion and necrosis of thymic epithelia.²⁹⁵ Increased serum levels of IL-2, IFN- γ , L-6, TNF- α , and soluble IL-2 receptors have been demonstrated.⁶⁸ The T cells that are activated in response to EBV are believed to be stimulated to produce proinflammatory cytokines (e.g., IL-2, IFN- γ , etc.), and it is believed this activates macrophages, which produce more proinflammatory cytokines, such as IL-6 and TNF- α , culminating in the phagocytosis, tissue destruction, and cellular depletion seen in FIM/EBV-HLH; death usually follows shortly thereafter due to multisystem organ failure.⁶⁸

Once FIM/EBV-HLH develops, therapy is difficult and often unsuccessful, with a median survival time of approximately 4 weeks.²⁹⁰ Antiviral drugs, Ig supplementation, IL-2, IFN- α , IFN- γ , plasmapheresis, corticosteroids, and most cytotoxic drugs have been ineffective.^{68, 76} The only therapy that has demonstrated consistent success in the treatment of FIM/EBV-HLH is with the early use of etoposide, which reduces the activity of stimulated macrophages *in vitro*.^{281, 296} The best results appear to be obtained with a combination of etoposide and concomitant immunosuppression with corticosteroids and cyclosporin A or tacrolimus (FK506).^{281, 297} Others have reported using rituximab (anti-CD20 monoclonal antibody) in combination with chemotherapy and immunotherapy.²⁹⁸ The rationale for this approach is that the reduction of EBV (+) B cells decreases immunogenic stimulus for the abnormal T-cell response. Therapy may have to be continued for 6 to 12 months. These patients are profoundly immunocompromised from their disease and the therapy. Therefore, a successful outcome is dependent on control of FIM/EBV-HLH symptoms as well as the prevention and successful treatment of life-threatening infectious complications. Even with remission of symptoms, recurrences are common and carry a poor prognosis. Curative therapy usually involves replacement of the patient's immune system with a normal immune system by allogeneic stem cell or marrow transplantation.^{289, 299, 300} With the advent of therapy with etoposide and immunomodulation therapy to "quiet" the disease and early intervention with allogeneic stem cell transplantation, the outcome has gone from <5% 1-year survival to approximately 50% 3- to 5-year survival.³⁰⁰

Epstein-Barr Virus-Associated Disorders in Immunodeficiency

In the mid-1970s, Purtilo et al. described XLP, in which affected males were thought to have a specific immunodeficiency to EBV, resulting in FIM, malignant lymphoma, hypogammaglobulinemia or agammaglobulinemia, or aplastic anemia.³⁰¹ Later, it was noted that patients with ataxia telangiectasia had high antibody titer responses against EBV-replicating antigens, and EBV genome positive malignant lymphomas were observed.^{302, 303} Similar antibody patterns and EBV-associated B-cell LPD (EBV-LPD) were also reported in patients with Wiskott-Aldrich syndrome.³⁰⁴ With more efficacious immunosuppression, EBV-LPD was also observed more frequently in recipients of organ and marrow transplants, whereas stopping or decreasing the dose of immunosuppressants sometimes resulted in the regression of EBV-LPD, suggesting that a deficiency of immunosurveillance is responsible for the development of EBV-LPD in such patients.³⁰⁵ In the late 1980s, an increased incidence of EBV-LPD, including BL, was reported in association with a growing number of patients with AIDS.³⁰⁶ In recent years, advances in the treatment of patients with immune disorders have resulted in longer survival, and the number of patients at risk of EBV-associated diseases has increased.

In LPD of immunodeficiency, EBV has been identified predominantly in the B-cell phenotypes, but EBV (+) T-cell LPD and HL can also be observed. However, not all LPD of immunodeficiency is EBV-associated. Even in XLP, where affected boys have a very aberrant immune response to EBV infection, many of the NHLs have been found to be EBV-negative.^{307, 308}

Primary Immunodeficiencies

As mentioned previously, the main immune defense against EBV-driven B-cell proliferation are EBV-CTL. Patients with primary immunodeficiencies often lack T-cell functions, which may manifest as insufficient EBV-CTL activity. Immunodeficiencies primarily affecting B cells or neutrophil function are not at increased risk of EBV-associated disease unless treated with T-cell immunosuppression.^{309, 310} There are numerous reports of the occurrence of EBV-LPD in patients with a primary immunodeficiency disease (e.g., ataxia telangiectasia, Wiskott-Aldrich syndrome, Chédiak-Higashi syndrome, severe combined immunodeficiency, and common variable immunodeficiency).³⁰⁷ Type III EBV latency is predominantly seen in these lymphomas,^{27, 307} suggesting a lack of appropriate EBV-CTL immunosurveillance (see the section, "Immune Response to Epstein-Barr Virus Infection"). In addition, relapses are common but may not represent failure to eradicate the original clone, instead indicating a new clonal proliferation.³¹¹ These data underscore the role of immunosurveillance in the pathogenesis of these malignancies.

The treatment is often difficult because of the underlying serious immunodeficiency and/or genetic susceptibility to

P.1336

chemotherapeutic agents. Antiviral therapy has had little effect in the treatment of EBV-LPD associated with immunodeficiency.^{309, 310, 312} Although complete remissions can be achieved with chemotherapy, immunodeficient patients with NHL have a far inferior outcome compared to those expected for immunocompetent children with NHL receiving similar therapy.^{310, 313, 314} These poor results are due to increased toxicity of chemotherapy, especially in defects of DNA repair such as ataxia telangiectasia patients, but infection-related deaths are also greatly increased compared to immunocompetent patients. Because recurrences can be of different clonal origin, successful treatment depends on controlling B-cell proliferation by developing appropriate EBV-CTL immunity. In the majority of cases, the only way to achieve this is allogeneic bone marrow transplantation (BMT).^{300, 309, 310, 315}

X-Linked Lymphoproliferative Disease

In 1974, there were two reports of maternally related boys dying of IM.^{316, 317} In 1975, Purtilo et al. described a kindred in which 6 of 18 boys died of an LPD associated with EBV infection.³¹⁷ XLP has also been called Duncan disease, after the original kindred, or Purtilo disease. XLP is a rare disorder, affecting an estimated 1 out of a million male individuals.²⁸⁹ Initially, three phenotypes were described in XLP patients, and these continue to characterize the majority of patients: FIM (or EBV-HLH), malignant lymphoma (LPD), and dysgammaglobulinemia.³¹⁷ Less commonly reported manifestations include disorders such as vasculitis, pulmonary lymphomatoid granulomatosis, and hematologic cytopenias, including aplastic anemia and pure red cell aplasia.^{289, 308} The "disease state" is capricious, as it may feature a single phenotype or two or more phenotypes, which may develop sequentially in susceptible individuals.^{289, 308}

Reflecting on the ubiquitous nature of EBV infection, FIM is the most common XLP phenotype, affecting approximately 50% of patients.^{289, 308} FIM is decidedly the most lethal of the XLP phenotypes; historically, most of the boys died within 1 month and historically only 7% of FIM patients survived.³⁰⁸ Treatment should be the same as for FIM or EBV-HLH as discussed previously. The median age of onset for XLP-associated FIM is 5 years of age, but the condition has occurred up to 40 years of age. The pathology and clinical findings of FIM associated with XLP are identical to those seen in patients

with EBV-HLH but without XLP, and have been discussed previously. It is interesting that over a third of XLP patients with evidence of current or prior EBV infection never develop FIM.³⁰⁸

Dysgammaglobulinemia is the second most common XLP phenotype, affecting approximately one fourth of boys.^{289, 308} Most boys manifesting this phenotype demonstrate global decreases of serum Ig levels. However, some have featured increased levels of IgM or IgA, or both, as well as variable deficiencies in IgG1 and IgG3 subclasses.³¹⁸ Although hypogammaglobulinemia often occurs after EBV infection, some XLP patients develop hypogammaglobulinemia without prior evidence of EBV infection.³⁰⁸ Mice with the XLP gene “knockout” can manifest progressive hypogammaglobulinemia and abnormalities in Ig switching.³¹⁹ The pathogenesis of dysgammaglobulinemia in XLP has not been delineated, but appears to be due to a defect in T-cell help and affects B-cell memory.

An LPD develops in approximately one fourth of XLP patients.^{289, 308} Most lymphomas are of B-cell phenotype and are characterized by Burkitt or diffuse large-cell histology.^{69, 320} Karyotypic analysis has not been extensively performed; however, the t(8;14) associated with classic BL is rare.^{321, 322} Approximately 10% of LPD are not of B-cell phenotype, including a small number of patients with HL or T-cell LPD.⁶⁹ As in other immunodeficiencies, the role of EBV in the LPD of XLP is unclear, inasmuch as approximately one half of the boys with LPD have had no evidence of prior EBV infection, and EBV is detectable in only 25% of tumor specimens.³⁰⁸

Distinct from the marrow depletion seen with FIM, a limited number (4%) of boys have developed isolated hematologic cytopenias.^{289, 308} Most manifest with suppression of two or more hematologic cell lines, although aplastic anemia and pure red cell aplasia have been observed.

Initially, it was thought that males affected with XLP only manifested symptoms after primary EBV infection. Although IM is, by definition, caused by EBV, other XLP phenotypes develop in EBV-seronegative patients.³⁰⁸ About 10% of affected boys will manifest symptoms of XLP before exposure to EBV.^{289, 308} There is no difference in the age of onset of clinical symptoms between males who have or have not been previously exposed to EBV.³⁰⁸ Therefore, prevention of EBV infection in boys with XLP does not avert clinical manifestations. In addition, whereas approximately 60% of the boys develop FIM after primary infection with EBV, others develop LPD, dysgammaglobulinemia, and hematologic cytopenias, and a few have no symptoms at all.³⁰⁸ These data suggest that the genetic defect in XLP is more global and not EBV-specific as once thought. There must be other genetic and/or environmental factors that influence the host susceptibility to EBV and are important in determining the clinical phenotype of XLP.

Now, the diagnosis can be made easily by identifying a mutated SH2D1A gene^{308, 323, 324, 325} or lack of the corresponding SLAM-associated protein (SAP) protein expression.³²⁶ Female carriers on average express SAP on only 50% of their lymphocytes, due to random X-chromosome inactivation,³²⁷ but do not develop overt clinical manifestations of XLP. Molecular analysis should be pursued in females at risk of being a carrier to provide accurate genetic counseling. Spontaneous mutations in SH2D1A in affected males where mothers do not have mutations have been reported.³²⁸

One might predict that mutations that delete the XLP gene or truncate the protein would be more likely to be associated with a severe phenotype, whereas missense mutations would occur preferentially in mildly affected patients. Attempts to correlate mutations of the SH2D1A gene and the clinical manifestations of XLP found that it was not uncommon to observe different phenotypes and severities with identical mutations, even within the same family.³⁰⁸ No significant differences were observed in the phenotypes or severity of disease based on the type (missense, nonsense, truncating) or localization of SH2D1A mutations. The age of onset of clinical manifestations of XLP varied considerably, from younger than 1 to 40 years of age, as did survival, but there was no correlation with the type of mutation. Therefore, genetic analysis does not predict the phenotype or severity of disease.³⁰⁸

The SH2D1A gene codes for a protein of 128 amino acid residues that consists of an SH2 domain and a 25-amino acid C-terminal tail.^{323, 324} SH2D1A is expressed throughout thymocyte development, as well as in CD4⁺ and CD8⁺ peripheral T cells, NK and NKT cells, but not on B cells.^{291, 325} SAP appears to function in the regulation of immune response by interacting with several proteins, including SLAM (signaling lymphocyte activating protein; CD150), also called SAP.³²⁴ SAP also has been demonstrated to interact with members of the CD2 superfamily of molecules, including CD2, CD48, CD583, CD84, Ly-9, and 2B4, and with a new family of RasGAP adapter proteins such as p62Dok (Dok [downstream of kinases]-1), p56Dok (Dok-2), and Dok-3.^{329, 330, 331, 332} The immunologic effects of SAP interactions with these proteins are under investigation but appear to be very important in NKT cell development and terminal B-cell differentiation.²⁹¹

Mice genetically deficient in Sh2d1 α (the murine homolog) expression have been generated.³³³ Consistent with human XLP, mutant animals are viable and fertile, transmit the gene defect in an X-linked Mendelian fashion, and display no significant defects in the number and phenotype of developing thymocytes or circulating T, B, or NK cells. After infection with lymphocytic

P.1337

choriomeningitis virus, Sh2d1 α -deficient mice recapitulate important aspects of the human disease. For example, these mice exhibit abnormal lymphocyte responses to a virus resulting in a large CD8⁺ cytotoxic T-cell response that is fatal to the mice.³³³ As mentioned previously, these mice also have defects in humoral responses and develop hypogammaglobulinemia over time.^{322, 333}

XLP is highly lethal, with historically 75% of patients dying by 10 years of age, although the oldest known survivor with XLP is over 50 years of age and has not required allogeneic transplantation.^{289, 308} Antiviral therapies, including acyclovir, ganciclovir, intravenous Ig, and IFN- α , have been used to treat primary EBV infection; none has been particularly effective.^{309, 334} The only therapy that has been consistently beneficial for males with FIM is etoposide and immunosuppression, as discussed previously.^{68, 297, 308} Several affected males have been treated successfully with anti-CD20 (rituximab) following primary infection with EBV but before they develop all the clinical signs and symptoms of FIM or EBV-HLH.²⁸⁸ With FIM or EBV-HLH, even with remissions, relapses are invariable. Therefore, an allogeneic BMT is recommended once the patient's condition is stabilized and a suitable donor has been identified.^{309, 310, 311, 315} As with EBV-HLH not associated with XLP, the outcome has improved from a <10% 1-year survival to perhaps half of the boys with FIM surviving with the early initiation of etoposide, immunosuppression, and allogeneic stem cell transplantation.^{300, 315} Patients with hypogammaglobulinemia require regular Ig supplementation to prevent bacterial and viral infections. However, Ig infusions do not offer the guarantee of protection from primary EBV infection in an EBV-seronegative patient.³⁰⁸ For patients with lymphoma or hematologic cytopenias, standard therapeutic protocols suffice. Although treatment can induce disease remissions, relapses and other XLP phenotypes invariably occur, and allogeneic BMT is recommended.^{309, 310, 311, 312, 313, 314, 315} With definitive diagnosis by genetic mutational analysis, BMT now can be performed before the appearance of clinical manifestations of the disease^{315, 335} and is recommended to prevent the life-threatening complications of the disease.

In 2006, another X-linked disorder that was characterized by EBV-HLH was described to be caused by deficiency in the BIRC4 gene.^{336, 337} Of note, BIRC4 resides in close proximity to the SH2D1A gene. Further studies demonstrated that these patients have defects in their antiapoptotic functions and the disorder has been named deficiency of the XIAP. Because XIAP patients frequently have problems with EBV-HLH, XIAP has also been called XLP2. However, unlike SAP which is limited to T, NK and NKT cells, XIAP is widely expressed on human tissue.²⁹¹ As the name suggests, the XIAP function is to inhibit apoptosis; therefore deficiency leads to increased sensitivity to apoptosis and hypogammaglobulinemia is observed in XIAP patients.²⁹¹ The immune mechanism for susceptibility to complications of EBV infection, including EBV-HLH is unclear, but XIAP patients do not have an increased incidence of lymphoma.²⁹¹ Therefore, it is best to differentiate XLP and XIAP as distinct clinical entities.

Secondary Immunodeficiencies

It is well recognized that patients infected with HIV, as well as transplant recipients, are at increased risk of developing LPD that are often associated with EBV. Rarely, elderly patients, malnourished patients, and those with cancer develop EBV-associated atypical lymphoproliferation.^{69, 312} Indeed, the World Health Organization (WHO) now recognizes a EBV-positive diffuse large B-cell lymphoma as a distinct entity.³³⁸ EBV-induced LPD have been reported in patients without severe immunodeficiency (e.g., individuals who received methotrexate as treatment for rheumatoid arthritis).³³⁹ Therefore, a high index of suspicion is warranted in any patient who may be immunosuppressed.

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

EBV has been found in several diseases associated with HIV infection, including oral hairy leukoplakia,^{340, 341} leiomyosarcoma,³³ and NHL.³⁴² Oral hairy leukoplakia is characterized by white raised plaques on the lateral surfaces of the tongue. EBV has been found in the lesions of oral hairy leukoplakia in HIV patients,^{342, 343} and these lesions have been reported to respond well to therapy with acyclovir.³⁴³ The EBV-associated leiomyomas and leiomyosarcomas account for 3% to 15% of all cancers in HIV-infected children.^{344, 345} For reasons that are not clear, leiomyomas and leiomyosarcomas do not appear to be increased in HIV-infected adults. Tumors can be found in the lung, brain, adrenal glands, and spleen.^{33, 346, 347, 348, 349, 350} How EBV gains access to smooth muscle cells and its pathogenic role in tumorigenesis remains unclear. The clinical course is highly variable, but aggressive treatment with highly active antiretroviral therapy (HAART) and primary excision of tumors, if feasible, are recommended in all patients, but chemotherapy and/or radiation are often required.

The clinical spectrum of HIV-related NHL typically includes systemic NHL, primary central nervous system (CNS) NHL, and pleural effusion lymphoma (PEL). Although EBV is detected in essentially all the primary CNS NHL³⁴⁹ and most PEL,³⁵⁰ only

approximately 50% to 60% of systemic HIV-related NHL have detectable EBV.³⁵¹ PEL is not typically associated with solid masses and is associated with HHV8, but most also have EBV present in tumor cells.³⁵⁰ The relative contribution of HHV8 and EBV in the pathogenesis of PEL is unclear. Following the introduction of HAART into clinical practice in the 1990s, there has been a dramatic effect on the incidence of AIDS-defining diseases. In the HAART era, there has been a decrease in primary CNS NHL and systemic diffuse large B-cell lymphoma; however, the incidence of BL has appeared to be unchanged.^{352, 353, 354} The outcome for patients with HIV and NHL has improved dramatically. There are some overlapping toxicities from HAART and cytotoxic agents; however, with the concurrent use of HAART and aggressive supportive care, HIV patients can now tolerate standard therapies for NHL with similar outcomes.³⁵⁵

Post-transplant Lymphoproliferative Disease

Figures 62.3 and 62.4 illustrate the importance of a qualitatively and quantitatively appropriate T-cell response in maintaining homeostasis and preventing EBV-driven B-cell proliferation. Therefore, with chronic immunosuppressive therapy following the transfer of EBV-infected B cells via blood, marrow, or organ grafts, complications due to EBV are frequently seen in transplant patients.

Post-transplant lymphoproliferative disease (PTLD) represents a spectrum of clinical and morphologic heterogeneous lymphoid proliferations.^{69, 309, 356, 357, 358, 359, 360} EBV LPD post-transplant may manifest as isolated hepatitis, lymphoid interstitial pneumonitis, or meningoencephalitis, or as an IM-like syndrome with peripheral adenopathy, fever, or hepatitis, or all three. Frequently, the definition of PTLD is limited to lymphomatous lesions (localized or diffuse) that are often extranodal (often in the allograft). Although less frequent, the most fulminant presentation of PTLD is a disseminated systemic disease that clinically resembles septic shock and histologically resembles FIM.

Histologically, EBV disease is quite heterogeneous as well. There have been several histologic classifications for PTLD over the years,^{356, 357, 358, 360} but the WHO has now proposed a classification, which includes (a) early lesions not considered PTLD and that are polymorphic hyperplasia, without disruption of the normal tissue architecture and often accompanied by more classic clinical signs and symptoms of IM; (b) polymorphic PTLD, where T-cell infiltration and disruption of normal tissue architecture are observed; and (c) monomorphic PTLD, which resembles

P.1338

intermediate- to high-grade NHL and tissue necrosis is more frequent.³³⁸ Distinguishing between a polyclonal and a monoclonal PTLD can be difficult as up to 50% of PTLDs do not express surface Ig.^{69, 338} Cytogenetic abnormalities are rare in PTLD, even with Burkitt histology, and abnormalities in genes observed in NHL (i.e., c-myc; N-, H-, and K-ras; p53; and bcl-2, etc.) are rare in PTLD.^{338, 358, 361}

The diagnosis of PTLD should be made by biopsy and evaluated by in situ hybridization with EBER probes or immunohistochemical staining for LMP-1, although LMP-1 staining is not as sensitive as EBER staining.³⁶² PTLD must be distinguished from the increased background number of EBV-positive cells in lymphoid tissue in the post-transplant patient, where up to 10 EBER-positive cells per high powered field (hpf) can be observed without PTLD compared to the nontransplant patient where 0 to 1 cell/hpf is normal.³⁶³ Perhaps the greatest difficulty in making the diagnosis of PTLD occurs in the proliferations that do not produce a mass lesion but have disseminated or infiltrative disease in solid organs. The diagnosis can sometimes be suspected upon examination of the peripheral blood, bone marrow, CSF, or other body fluids for the presence of plasmacytoid cells or large B cells. This type of PTLD is often first discovered at autopsy, with pre-mortem diagnosis being sepsis or graft-versus-host disease (GVHD).^{364, 365}

The majority of PTLD is CD20+,^{70, 369} but not all PTLD is of B-cell phenotype and not all are EBV positive. T-cell PTLD tends to occur late, often more than 10 years after transplantation.³⁶⁶ PTLD with HL phenotype can also occur but tends to occur later (i.e., >4 years post-transplant) and is generally EBV positive.³⁶⁷ The validity of the Hodgkin phenotype of PTLD has been questioned and it has been suggested that it may be a variant of polymorphic B-cell PTLD.³⁶⁸ The diagnosis of HL in the posttransplant patient should be reserved for disease where the RS cells are CD45(-) and/or CD15(+).³⁶⁸ The reason for the long latency in non-B-cell PTLD is unknown, but probably reflects a lesser role for EBV and/or deficient immunosurveillance in the pathogenesis.

More than 90% of early (<1 year post-transplant) PTLD is EBV positive, when EBV-CTL immunity is lowest,^{365, 369, 370} whereas late (>2 years post-transplant) PTLD are frequently EBV negative, can be of T-cell origin, and may have a poorer prognosis.^{366, 371, 372, 373, 374} The etiology of EBV-negative PTLD is not known, and no other virus has been identified as an etiologic agent. These late PTLD may be a different disease and appear more akin to LPD observed in other immunodeficient states (e.g., AIDS and primary immunodeficiencies), in which B-cell origin and EBV association are not universal.³⁷²

The risk factors for PTLD are well described and in general include anything that favors B-cell proliferation and/or suppresses T-cell activity. The reported incidence of PTLD ranges from 1% to 5% in low-risk procedures (e.g., renal, heart, liver, and non-T-cell-depleted bone marrow transplants) to >10% in the high-risk procedures (e.g., lung, small bowel, and T-cell-depleted bone marrow transplants).^{365, 369, 374} In children receiving a solid organ transplant, the effect of the type of allograft appears to be much less. This is likely due to the fact that age and EBV-seronegativity at the time of transplant are very strong risk factors.^{375, 376}

Successful treatment of PTLD necessitates controlling the B-cell proliferation and facilitating the development of an appropriate memory cytotoxic T-cell (EBV-CTL) response to maintain an asymptomatic state of viral latency (Figs. 62.3 and 62.4). Additional factors that contribute to the difficulty of treating these patients include increased toxicity from therapy, secondary infections, and the increased risk of organ rejection or GVHD due to the enhancement of alloreactive T-cell immunity. Surgery, radiotherapy, or both are effective in curing localized disease, but this benefits only a small percentage of patients.^{309, 312} The use of antiviral agents such as acyclovir or ganciclovir and/or intravenous Ig may reduce viral replication and thereby limit the number of infected B cells and may be useful in prophylaxis or preemptive therapy.^{312, 374, 375, 376, 377, 378} The efficacy of antiviral drugs in treating PTLD is controversial because they are seldom used without other interventions (e.g., reduction of immunosuppression); in addition, if viral replication, which is lytic to the infected B cells, is suppressed, B-cell proliferation could theoretically be enhanced.

The approach most widely used as initial therapy for PTLD is reduction of immunosuppression.^{312, 374} In some cases, this is sufficient for controlling the disease, especially in localized polymorphic cases or cases that present like IM. As opposed to PTLD after solid organ transplantation, reduction of immune suppression is rarely successful following BMT, because the major immunosuppression after BMT is from delayed EBV-CTL recovery, not suppression of EBV-CTL function. Patients who do not tolerate reduction of immunosuppression because of graft rejection or GVHD, or who do not respond to immunosuppression reduction, require more aggressive therapy and have a much poorer prognosis.^{309, 312, 374}

Anti-B-cell monoclonal antibodies have been used successfully, including anti-CD21 and anti-CD23³⁷⁹ and, more recently, anti-CD20.^{380, 381} Chemotherapy has also been used successfully for PTLD.^{382, 383} Chemotherapy is attractive because it kills proliferating B cells and is immunosuppressive enough to treat or prevent GVHD or organ rejection.^{382, 384} However, at conventional doses used in the treatment of NHL, post-transplant patients have more end-organ toxicity and susceptibility to infection, with as many as 35% of patients dying of toxicity caused by the therapy.³⁸³ A low-dose chemotherapy approach has been shown to be at least as effective in treating PTLD in children following organ transplant with little toxicity.³⁸⁴

Because the problem in most cases of PTLD is an inadequate number of EBV-CTL,^{370, 385} replacement of EBV-CTL is a logical therapeutic intervention. Infusion of donor lymphocytes has been demonstrated to be successful in the treatment of PTLD post-BMT.³⁸⁶ To avoid the GVHD and other associated toxicities with infusion of donor lymphocytes, ex vivo-generated EBV-specific CTL have been shown to be effective in treating and preventing PTLD post-BMT.³⁸⁷ The ex vivo generation of EBV-specific CTL takes several weeks^{387, 388, 389} and requires a high level of technology and cost. Therefore, due to the cost and regulatory oversight necessary to generate and administer the in vitro-generated EBV-CTL, this approach is not feasible for most centers. The use of adoptive T-cell therapy in an organ transplant recipient is more complex. First, cadaver organs are most widely used; therefore, donor lymphocytes are often not available. Second, as opposed to BMT, after organ transplant, the PTLD cells are usually of recipient origin, so the immunologic recognition, specificity, and efficacy of donor lymphocytes are uncertain. Third, the use of closely matched relatives' lymphocytes runs the risk of both rejection and GVHD. It has been shown that in organ transplant patients EBV-specific CTL can be given safely, and when given prophylactically no PTLD developed.³⁸⁹ However, despite detection of an increased number of EBV-specific CTL, EBV DNA levels in the peripheral blood decreased very little and the infused cells persisted only 2 to 6 months.³⁸⁹ EBV-specific CTL have been used to treat PTLD successfully following organ transplant, but again multiple infusions were required as the adoptively transferred EBV-specific CTL did not last.³⁸⁸ Although a logical and exciting therapeutic strategy, at present adoptive cellular therapy is not available for the majority of patients with PTLD.

Epstein-Barr Virus-Associated Malignancies

Burkitt Lymphoma

The neoplastic cells in BL have a mature germinal center B-cell phenotype as demonstrated by the expression of B-cell-associated

P.1339

antigens (CD19, 20, and 21) and the presence of surface Ig.⁹ Approximately 95% of endemic African BL are EBV positive, as

compared with 20% of sporadic BL occurring mainly in Europe and North America.^{9, 20, 390} Regardless of EBV status, BL is characterized by specific chromosomal translocations that involve chromosomes 8 and 14 (t[8;14]) in 70% of cases, or 8 and 22 (t[8;22]) and 8 and 2 (t[8;2]) in the remaining cases.^{390, 391, 392, 393} As a result, the MYC oncogene becomes juxtaposed to one of the Ig gene loci (i.e., chromosome 14 [heavy chain], chromosome 22 [λ -light chain], or chromosome 2 [κ -light chain]) and is constitutively expressed.^{391, 392, 393}

The role of EBV in the pathogenesis of BL remains to be fully defined. It has been hypothesized that chronic B-cell stimulation by EBV, HIV, and/or malaria^{6, 390, 393} plays a key role by enhancing the chances of a MYC translocation.^{6, 390, 393} The very restricted EBV viral gene expression of type I latency EBV gene expression (i.e., EBNA-1 and the EBERs only) seen in EBV-positive BL makes it difficult to explain the role of EBV in transformation of BL.^{13, 53, 394, 395} In vitro systems have demonstrated that latency III viral gene expression is incompatible with high c-myc expression and maintenance of BL cells,³⁹⁶ and that EBV gene expression, although not promoting cellular proliferation, inhibits apoptosis in MYC-expressing BL cells.³⁹⁷

Nasopharyngeal Carcinoma

NPC is another important EBV-associated malignant disorder. This tumor is mainly observed in Southeast Asia, Southern China, and a few other limited regions of the world.⁹ In these areas, NPC is one of the most frequent malignancies observed. A genetic predisposition appears to be a major factor in the development of this epithelial malignancy. The first generation of southern Chinese immigrants to the United States has an incidence of NPC that is approximately one half that of native Chinese, suggesting that both genetic and environmental factors contribute to the development of NPC.³⁹⁸ The evidence linking EBV to NPC is more compelling than with BL, with essentially all cases being EBV positive.³⁹⁹ The etiologic link between NPC and EBV was first suggested by serologic evidence, especially with anti-IgA antibodies directed against EA, present in high titers in NPC patients as compared with matched controls, IM patients, and BL patients.^{9, 400, 401} In fact, prospective screening for these IgA antibodies or quantitative PCR of EBV DNA in the serum has been useful in detecting preclinical NPC and in anticipating recurrences after therapy.^{402, 403}

Despite the universal association of EBV with NPC, the role EBV plays in the pathogenesis is unclear. The finding of monoclonal EBV found in precancerous lesions of NPC is noteworthy, as it suggests EBV infection takes place early in the pathogenesis and is essential in the development of NPC.^{404, 406} However, all attempts to transform nasopharyngeal epithelium with EBV in vitro have failed. As stated before, NPC tumor cells demonstrate type II viral latency gene expression (i.e., EBERs, EBNA-1, LMP-1 and LMP-2, and BARF1).³⁹⁹ It is hypothesized that because LMP-1 and BARF1 have effects on expression of cellular genes associated with proliferation, they are important in the pathogenesis of NPC.^{399, 405, 406} Other studies have identified genetic defects with presumed inactivation of tumor suppressor genes on chromosomes 3p, 9p, and 14q.⁴⁰⁷ For some time, environmental factors such as exposure to toxins contained in traditional Chinese medicines, including Euphorbia plant extracts, which induce EBV replication, and the ingestion of nitrosamines or other oncogenic substances in salted fish, have also been felt to play an important role in the development of NPC.⁹

Hodgkin Lymphoma

A pathologic link between EBV and HL has been suspected for some time on the basis of serologic studies that demonstrated unusually high titers of antibodies to VCA and EA, as well as the observation that individuals with high antibody titers to EBV have an increased risk of developing HL.^{408, 409, 410} The presence of EBV has been demonstrated conclusively within the RS cells and their mononuclear variants in 40% to 50% of HL specimens.^{28, 144, 145, 146} The virus appears to be monoclonal in any given individual, suggesting that infection occurred before the clonal expansion of RS cells.^{144, 411} EBV positivity is most frequent in mixed cellularity histology, followed by nodular sclerosing, whereas lymphocyte-predominant and lymphocyte-depleted types are usually negative.⁴¹² Again, as in NPC, the viral gene expression is latency type II.^{53, 145, 413}

What role EBV plays in HL also remains undetermined. A large epidemiologic study demonstrated that individuals who developed signs and symptoms of IM following primary infection had a 1 in a 1,000 chance of developing HL. This risk is small, but it was found to be statistically significant compared to the general population and to individuals who did not develop IM following primary infection.⁴¹⁴ In addition, the increased risk was only for developing EBV-positive HL.⁴¹⁴ It has recently been shown that in individuals who develop IM following primary EBV, a persistent deficit in their T cells to respond to IL-15 in vitro is prevalent, although this deficit was not found in individuals who did not develop IM following primary EBV infection.⁴¹⁵ LMP expression in RS cells occurs at very high levels,⁴¹⁶ which usually are immunogenic. It is hypothesized that individuals with IM have a lessened ability in immunosurveillance for EBV-induced lymphoproliferation, and this explains the increased incidence of EBV-positive HL in IM patients.⁴¹⁵ Inasmuch as only 1 in 1,000 individuals with IM ever develops HL, there must be other co-factors important in the pathogenesis.

T-cell Lymphoma

EBV genome-positive T-cell lymphoma was first described unexpectedly in three patients who had extraordinarily high IgG antibody titers to EBV-VCA and EBV-EA.⁴¹⁷ After this report, EBV genome-positive peripheral T-cell lymphoma had been increasingly reported mainly in Asian populations.⁴²⁶ Type II latency is predominantly shown in these malignancies.⁵³ The mechanism of EBV infection into human T cells still remains to be elucidated. CD21 expression has been reported on some T-cell lines^{418, 419}; however, in vitro experiments have failed to demonstrate continuous presence of EBV in such T-cell lines. Variable clinical manifestations are observed in patients with T-cell lymphoma. This may be in part due to cytokine production and cytotoxic functions that can be observed in these tumor cells. It is interesting that this type of lymphoma is often associated with severe CAEBV.^{274, 276} These malignancies are highly resistant to the standard therapies and the outcome is very poor despite aggressive therapy including transplantation.

Natural Killer-Cell Lymphoma/Leukemia

Patients with EBV genome-positive, CD3- NK-cell proliferations were initially reported by Japanese investigators.⁴²⁰ Type II latency is predominant in these malignancies as well.²³ NK-cell lymphoma/leukemia has often been associated with mosquito bite sensitivity⁴²¹ and CAEBV (see discussion in the section, "Chronic Active Epstein-Barr Virus Infection"). Midline granuloma, which is predominantly of T-/NK-cell origin, was first reported in Asia,⁴²² but now cases in North America and Europe have been shown to be EBV genome positive, with monoclonal viral episomes detected in virtually all tumor cells. In general, these malignancies have the same poor prognosis as EBV-positive T-cell malignancies.

Gastric Carcinoma

Gastric carcinoma is a leading cause of death due to cancer in Japan. Shibata and Weiss initially reported the presence of the EBV genome by in situ hybridization.²⁹ The incidence

P.1340

of the EBV genome in gastric carcinoma is 2% to 16% worldwide.^{29, 423, 424, 425} The viral gene expression pattern is unique. All EBV-positive gastric carcinomas express EBERs, EBNA-1, and BARF1 (BART) consistent with type I latency. However, some tumors express LMP-2A and/or lytic genes such as BZLF1 (ZEBRA protein).⁴²⁶

Miscellaneous Epstein-Barr Virus-Associated Human Disease

There are anecdotal reports of numerous human diseases that have been associated with EBV or that EBV DNA has been detected in pathologic tissues. The association of EBV to leiomyoma/leiomyosarcomas in immunodeficient children is strong, but the role in their pathogenesis is far from being understood.^{32, 33} Reports of EBV being detected in other malignancies include hepatocellular carcinoma,³⁰ lymphoepithelial carcinomas of the salivary glands, tonsillar carcinoma, parotid gland carcinoma, and thymoma (reviewed in Ref. 76). EBV has been found in breast carcinoma,³¹ but epidemiology studies have failed to demonstrate an association.⁴²⁷ One of the more intriguing associations is with multiple sclerosis (MS). There have been several epidemiology studies attempting to determine whether there is a link between the development of IM followed by MS. Published results are conflicting, but a recent meta-analysis suggested that an association does exist.⁴²⁸ Because EBV is so ubiquitous in the human population, associations of disease with EBV must be interpreted with caution.

Chapter 63

Primary Immunodeficiency Syndromes

Troy R. Torgerson

INTRODUCTION

The primary immunodeficiency disease (PIDD) are a group of clinical syndromes originally described in patients with marked susceptibility to particular types of infections. This group of disorders has now expanded to include more than 150 clinically defined entities that span the full spectrum of immune dysfunction ranging from virtually absent immune responses to overwhelming uncontrolled autoimmunity.¹ In this “genomic era” we have come to understand that the majority of immunodeficiency disorders are caused by defects in single genes. There are now approximately 200 known single gene defects associated with immune deficiency. It has also become evident that mutations in different genes can lead to a similar clinical phenotype. For example, defects in more than 20 different genes have now been associated with a clinical phenotype of severe combined immune deficiency (SCID).² This has led to an explosion in our understanding of the role of specific molecular pathways in the human immune system but has created some confusion when discussing the clinical syndromes themselves. Consequently, it has become the practice to refer to disorders by their molecular defect, either in combination with, or in lieu of, their clinical name or eponym (i.e., “ADA-deficiency” or “ADA-SCID” rather than “SCID”). This practice is followed here.

MAJOR COMPARTMENTS OF THE IMMUNE SYSTEM

To provide a framework for this overview of immunodeficiency, it is worthwhile to divide the immune system into four major compartments: complement, phagocytes, B cells and antibodies, and T cells. The complement and phagocyte compartments are part of the “innate” arm of the immune system, whereas the B-cell and T-cell compartments are components of the “adaptive” arm of the immune system (see Table 63.1). Many immunodeficiency disorders are caused by a defect in only one compartment of the immune system, whereas others are “combined” immunodeficiencies with defects in multiple compartments. In general, defects in each compartment of the immune system are associated with susceptibilities to particular types of infections. In addition, each specific immunodeficiency typically has unique features that differentiate it from other immunodeficiencies, often making it possible to identify the disorders based on clinical and laboratory findings (see Table 63.1).

TABLE 63.1 COMMON SYMPTOMS ASSOCIATED WITH DEFECTS IN EACH OF THE FOUR MAJOR IMMUNE COMPARTMENTS

Complement	Phagocytes	B Cells/Antibodies	T Cells
<ul style="list-style-type: none"> Invasive infections with encapsulated 	<ul style="list-style-type: none"> Skin and soft tissue 	<ul style="list-style-type: none"> Recurrent bacterial 	<ul style="list-style-type: none"> <i>Pneumocystis jiroveci</i> pneumonia

bacteria (<i>S. pneumoniae</i> , <i>H. influenzae</i> , etc.)	abscesses, boils, and lymphadenitis	sinopulmonary infections	• Recurrent, severe, or unusual viral infections (CMV, EBV, adenovirus, papillomavirus, etc.)
• Recurrent, invasive <i>Neisserial</i> infections	• Infections with Catalase ⁺ organisms (<i>S. aureus</i> , <i>Serratia</i> , <i>Aspergillus</i> , etc.)	• Unexplained bronchiectasis	• Invasive fungal or mycobacterial infections
• Hereditary angioedema	• Poor wound healing	• Chronic or recurrent gastroenteritis (giardia, cryptosporidium, enterovirus, etc.)	• GVHD (rash, abnormal LFTs, chronic diarrhea)
• Autoimmunity (lupus, glomerulonephritis)	• Chronic gingivitis and periodontal disease	• Echovirus encephalomyelitis	• Failure to thrive
• Familial hemolytic uremic syndrome (HUS)	• Mucosal ulcerations, colitis		
	• Delayed separation of the umbilical cord/omphalitis		

COMPLEMENT

The complement system consists of a series of proteins that are present in the plasma and become activated upon encountering pathogens. Activation of early complement components initiates a cascade of protein cleavage and activation events that ultimately leads to formation of the membrane attack complex (MAC) consisting of complement proteins C5, 6, 7, 8, and 9. A number of regulatory proteins including Factor H, Factor I, and membrane cofactor protein (MCP) control complement activation at the level of C3, thereby preventing inappropriate complement fixation. The complement cascade is activated via three major mechanisms: (1) the classical pathway, which is initiated by antigen/antibody complexes; (2) the alternative pathway, which is initiated directly by bacterial cell wall components; and (3) the lectin pathway, which is initiated by carbohydrate moieties present on bacteria.

Complement deficiencies make up only a small portion (~2%) of all primary immune deficiencies.³ Defective activation of the entire complement cascade can be caused by the absence or dysfunction of only 1 of more than 20 complement proteins. The proteins most often affected are C2, C3, and C4.⁴

Clinical Presentation

Patients with defects in the C1 esterase inhibitor have hereditary angioedema (HAE) in which allergic or mechanical stimuli can trigger massive, localized, severe attacks of edema that can be life-threatening if they involve the airway. Patients with deficiency of early complement components in the classical pathway (C1-C4) typically present with symptoms of autoimmunity (lupus or glomerulonephritis) or with recurrent invasive infections caused by encapsulated organisms (particularly *Streptococcus pneumoniae*). Patients with defects in the late complement components (C5-C9) that are involved in formation of the membrane attack complex typically present with recurrent or severe *Neisserial* infections.⁴ Patients with defects in complement regulatory proteins (Factor I, Factor H, and MCP) are at risk of developing familial hemolytic uremic syndrome and age-related macular degeneration (see Fig. 63.1).^{5, 6, 7}

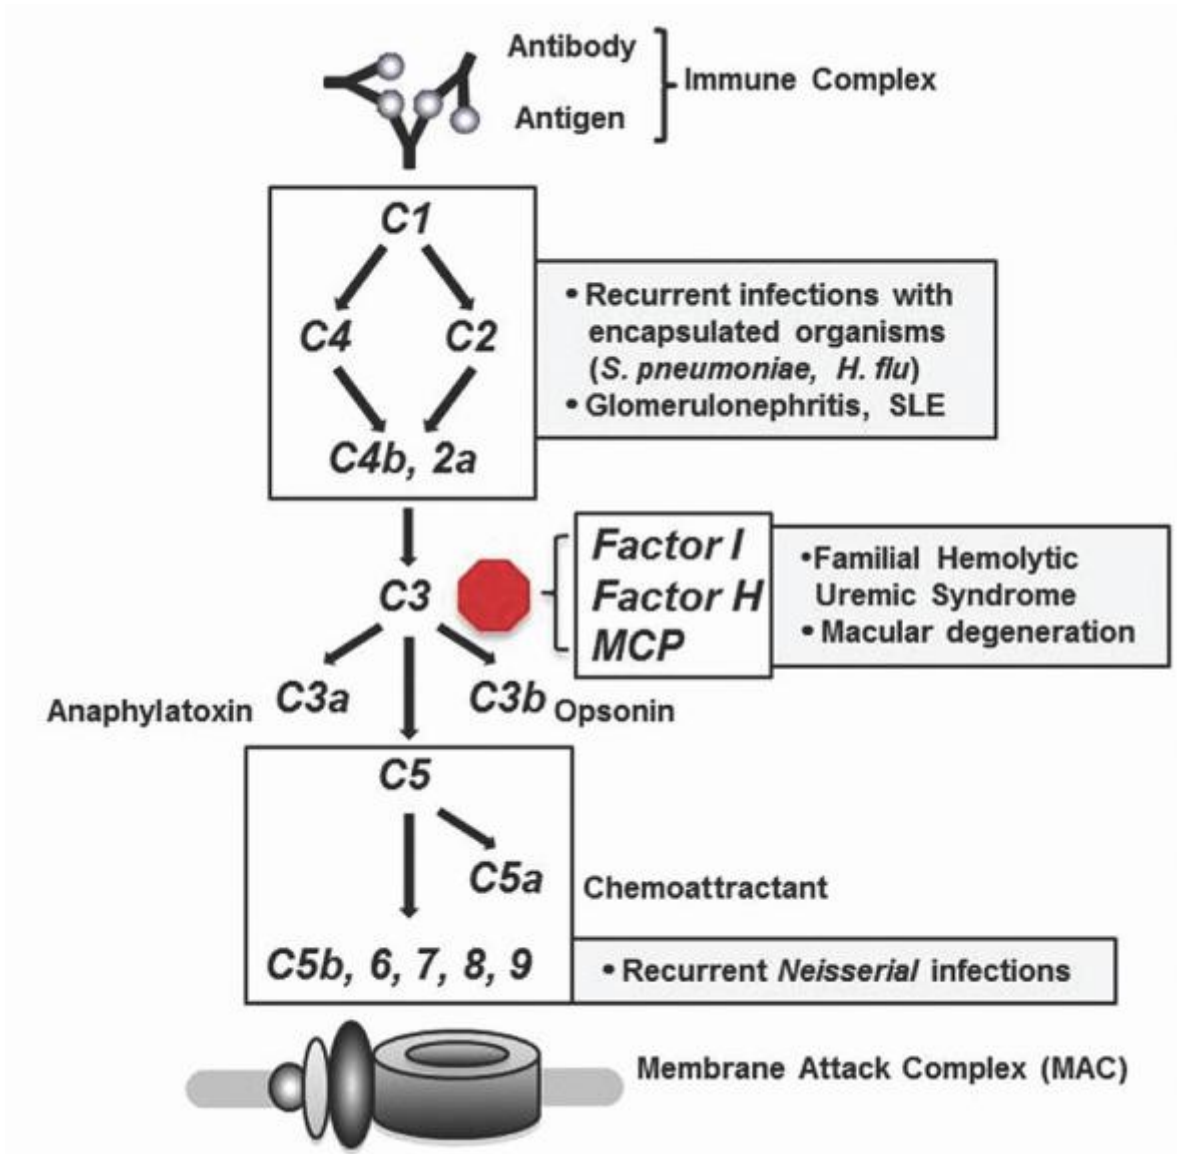

FIGURE 63.1. The classical complement pathway showing activation by immune complexes and ultimate formation of the membrane attack complex. Factor I, Factor H, and MCP (membrane cofactor protein) control complement activation primarily at the level of C3. Boxes indicate the clinical syndromes or infections that result from defects of the indicated complement proteins.

Specific Disorders

C1 Esterase Inhibitor Deficiency

Deficiency of C1 esterase inhibitor is the cause of HAE. Unlike many of the other early complement component deficiencies, absence of C1 esterase inhibitor does not lead to an increased risk for infection. Instead, this protein regulates the activity of kallikrein, blocking its ability to act on Factor XII and kininogen. As a consequence, minor irritants cause unabated production of bradykinin and other mediators of vascular permeability, leading to rapid swelling of the soft tissues (angioedema), severe abdominal pain, and at times, acute obstruction of the airway. Effective treatments are now available for HAE including purified C1 esterase inhibitor, a kallikrein inhibitor, and a bradykinin B2 receptor antagonist.^{8, 9, 10} Because of the expense of these agents, they are often administered at the beginning of an attack to abort symptoms rather than being administered prophylactically to prevent the onset of an attack.

C2 Deficiency

C2 deficiency is the most common complement component deficiency associated with susceptibility to infections, occurring in approximately 1 of 20,000 people. As indicated above, patients with early complement cascade defects (C1-C4) are susceptible to invasive infections with encapsulated organisms, *S. pneumoniae* being a particularly fulminant pathogen in these patients. The infectious susceptibility is compounded by functional antibody deficiency in some patients. In addition, patients with C1, C2, or C4 deficiency are at high risk of developing autoimmunity (lupus or glomerulonephritis). In the case of homozygous C2 deficiency, approximately 50% of patients develop lupus or glomerulonephritis.¹¹

Diagnosis

Screening for complement deficiency should be performed in patients with recurrent episodes of bacteremia, meningitis, or disseminated gonorrhea. Because more than 30% of patients with recurrent *Neisseria* infections have complement deficiency, it is imperative that prompt testing of the complement system be done in these individuals. The screening test of choice for complement deficiencies is the CH50 test, which measures functional complement activity in the plasma. The CH50 will only identify defects in the classical pathway, which is typically sufficient inasmuch as alternative pathway defects are exceedingly rare. If an alternative pathway defect is suspected, however, an analogous test (the AH50) can be performed. In order for the CH50 to give accurate results, the blood specimen needs to be handled carefully because complement is very heat labile. In general, it is recommended that any abnormal CH50 test should be repeated to confirm a complement deficiency. The CH50 is typically very low or absent in patients with a complement component deficiency. A CH50 result that is only moderately low is often seen in situations where the specimen was handled incorrectly or in patients with autoimmune disease such as lupus or mixed connective tissue disease. Once an abnormal CH50 test is confirmed, specialized testing to identify the specific complement component that is absent can be performed.

Treatment

Patients with complement deficiency are susceptible to fulminant sepsis and other deep-seated infections caused by encapsulated organisms. For this reason, patients should be given a letter or laminated card that they can keep with them at all times with contact information for their primary care physician and clinical immunologist, and a message indicating that they have a complement deficiency and there should be no delay in giving parenteral antibiotics should they be ill. For patients who live at a distance from skilled medical care, consideration should be given to providing a dose of parenteral antibiotic such as ceftriaxone that can be administered by the patient or a family member when they become ill, prior to a lengthy trip to the hospital. The efficacy of

P.1344

chronic prophylactic antibiotics to prevent infection in patients with complement deficiency is not well studied and remains a significant question in this group of disorders. In addition to preparing for and treating infections, patients should also be regularly screened for autoimmunity by history, physical exam (i.e., blood pressure monitoring), and laboratory testing including BUN, creatinine, and urinalysis to monitor for signs of glomerulonephritis inasmuch as this is a common autoimmune manifestation.

PHAGOCYTES

One of the major roles of phagocytic cells (neutrophils and macrophages) is to continuously survey the body for signs of infection. Upon sensing an infection, they migrate from the circulation into the tissues toward the site of the infection where they begin to ingest both opsonized and nonopsonized pathogens and debris. The ingested material is processed and fragments of digested proteins are loaded into class II MHC molecules that are presented at the cell surface where they can be recognized by cells of the adaptive immune system. Phagocytes that ingest pathogens and debris can either remain at the site of infection or migrate back to local draining lymph nodes to present antigen. Phagocytic disorders can occur in one of three ways: (1) a lack of phagocytes (congenital neutropenia); (2) defective phagocyte migration (leukocyte adhesion deficiency [LAD] and WHIM syndrome); and (3) inability of phagocytes to process or degrade organisms that have been ingested (chronic granulomatous disease [CGD]).

Clinical Presentation

Because of the role that phagocytes play in controlling bacterial and fungal pathogens, patients with phagocytic defects often present with infections and abscesses of skin, deep tissues, and organs caused by bacteria and fungi. Symptoms can include boils and/or cellulitis with or without pus, lymphadenitis, pneumonia, delayed shedding of the umbilical cord, hepatic abscesses, gastrointestinal disorders, gingivitis, and unexplained fever, malaise, and fatigue. The onset of symptoms of phagocytic cell disorders is typically in infancy or early childhood.

Specific Disorders

Severe Congenital Neutropenia

The congenital neutropenias are described in more detail elsewhere (Chapter 57) so are covered only briefly here. Mutations in five different genes have now been associated with severe congenital neutropenia (SCN): ELANE, which is inherited in an autosomal dominant manner, causes increased myeloid cell apoptosis and can present either with SCN or with a cyclic neutropenia phenotype; GFI1, which is also inherited in an autosomal dominant manner, causes defective myeloid cell differentiation; HAX1, which is inherited in an autosomal recessive manner, is associated with increased myeloid cell apoptosis, and is the cause of the classic “Kostmann” syndrome; G6PC3, which is inherited in an autosomal recessive manner, causes excessive myeloid cell apoptosis, and is associated with a variety of other congenital defects including cardiac, urogenital, endocrine, auditory, and facial anomalies; and WAS, in which specific activating mutations in the CDC42 binding domain are inherited in an X-linked recessive manner, leading to abnormal and dysregulated actin polymerization that causes defective neutrophil chemotaxis and increased apoptosis.¹²

In all cases, clinical management involves a heightened suspicion for infections and aggressive treatment if these arise. Treatment of acute infections may require antibiotics combined with G-CSF to increase neutrophil counts. Despite there being little evidence specifically in SCN supporting the use of prophylactic antibiotics, extrapolation from data in leukemic patients with neutropenia suggests a benefit so these are used in most patients. Prophylactic, long-term therapy with G-CSF is typically utilized only in those patients who have recurrent, severe bacterial infections in spite of antibiotic prophylaxis or in patients with fungal infections. Bone marrow transplantation is effective in SCN although there is little to no reported experience in those genetic disorders that are more rare such as G6PC3 deficiency.

Leukocyte Adhesion Deficiency

LAD is caused by the absence of functional adhesion receptors that are required for the migration of phagocytes from the circulation into the tissues. The characteristic clinical features of LAD include recurrent skin and soft tissue infections that often lead to development of deep ulcers despite there being highly elevated peripheral blood leukocyte counts. Interestingly, the inability of leukocytes to migrate to these sites of infection leads to an absence of pus in the lesions, which can be a useful diagnostic clue. Wound healing is also compromised and patients typically have marked gingivostomatitis. Three forms of LAD have been described: LAD-I, the most common form of LAD, is caused by mutations in the ITGB2 gene encoding the β 2-integrin CD18. Mutations cause an absence of the CD11/CD18 integrin complex on the surface of leukocytes, which can be readily discerned by flow cytometry. LAD-II is caused by mutations in the SLC35C1 gene encoding the GDP-fucose transporter. These mutations cause defective expression of Sialyl Lewis X (sLe^x), a fucose-containing ligand on neutrophils. sLe^x is the ligand for E- and P-selectins, which are expressed on the surface of cytokine-activated endothelial cells and allow neutrophil rolling. As a result of the fucose defect, all patients with LAD-II also have the rare Bombay blood group, which is a useful diagnostic test for suspected LAD-II. LAD-III is caused by mutations in the FERMT3 gene that encodes Kindlin-3, a coactivator that is required for activation and function of β 1-, β 2-, and β 3-integrins. Absence of functional Kindlin-3 leads to dysfunction of CD18 and causes an LAD phenotype (see LAD-I above). In addition, patients with LAD-III also have a Glanzmann-type bleeding disorder resulting from dysfunctional integrin-mediated aggregation of platelets.¹³

Patients with LAD-I and LAD-III typically present in childhood and often have a severe course with early mortality, whereas patients with LAD-II often have milder cases and may live into adulthood. Treatment of LAD can be more complicated than some of the other phagocytic disorders because in addition to treating infections aggressively with antibiotics, active soft tissue infections may require recurrent donor white cell infusions of functional neutrophils in order to clear the infection. The primary defects of LAD are intrinsic to hematopoietic cells, thus bone marrow transplantation can be curative.^{14, 15, 16}

WHIM Syndrome

WHIM syndrome (warts, hypogammaglobulinemia, recurrent bacterial infections, and myelokathexis [retention of neutrophils in the bone marrow]) is caused by autosomal dominant mutations in CXCR4, the receptor for the chemokine CXCL12 (SDF-1). Patients with WHIM typically present in childhood with recurrent bacterial otitis media, sinusitis, bronchitis, pneumonia, and cellulitis. The bacterial susceptibility is a result of the combination of hypogammaglobulinemia and neutropenia. In addition to bacterial infections, patients with WHIM have a particular susceptibility to papillomavirus infections, which can be severe and lead to early malignancy. The mechanisms that underlie the viral susceptibility are not entirely understood but are thought possibly to be intrinsic to the epithelial cells. In the hematopoietic system, CXCL12 causes homing of cells to the bone marrow and controls release of these cells from the marrow. Neutrophils and lymphocytes from patients

with WHIM have an increased chemotactic response to CXCL12, suggesting that the neutropenia and lymphopenia observed in WHIM are the result of inappropriate cell retention in the marrow.¹⁷ Treatment with G-CSF or GM-CSF can normalize the neutrophil counts although these often cause significant bone pain at the doses required.¹⁸ Recent studies using the CXCR4 antagonist plerixafor in adults with WHIM syndrome have shown promise for improving neutrophil counts by mobilizing neutrophils from the bone marrow.^{19, 20} Antibiotics and immunoglobulin replacement can significantly reduce the risk of bacterial infections. There is very little reported experience regarding bone marrow transplantation for WHIM although anecdotal evidence suggests that it may correct the neutropenia and hypogammaglobulinemia but may not alter the papillomavirus susceptibility.²¹

Chronic Granulomatous Disease

CGD is the most frequently diagnosed phagocytic cell immune defect. The most common form is X-linked, caused by mutations in the CYBB gene and accounting for approximately two thirds of all CGD patients. The remaining forms, caused by mutations in the CYBA, NCF1, NCF2, or NCF4 genes are all autosomal recessive. All mutations affect the formation or function of the NADPH oxidase complex, on neutrophil phagolysosomes. The NADPH oxidase is required to generate a burst of reactive oxygen species in response to phagocytosis of pathogens. Reactive oxygen species activate proteases in the phagolysosomes that destroy ingested bacteria. In CGD, the oxidative burst cannot be generated, leading to defective processing of ingested organisms and an inability to eliminate bacterial and fungal pathogens appropriately. Catalase-positive organisms including *Staphylococcus* species, *Aspergillus* species, *Burkholderia cepacia*, *Serratia marcescens*, and others are the most common pathogens. The most common types of infection at presentation are pneumonia, lymphadenitis, cellulitis, and hepatic abscesses (particularly with *Aspergillus* sp.). The most common cause of premature death is *Aspergillus* infection.²² In addition to the infectious susceptibilities of CGD, a substantial percentage of patients struggle with inflammatory complications that are common to this disorder including an inflammatory colitis that occurs in approximately 40%, hepatic dysfunction, gingivitis, and others.

Treatment of CGD revolves around aggressive management of acute infections followed by prophylaxis against future infections using a combination of daily antibiotic (typically trimethoprim-sulfamethoxazole), daily antifungal (typically itraconazole), and thrice-weekly Interferon- γ injections. This combination has dramatically improved outcomes in CGD; however, despite appropriate use of this regimen, some patients ultimately have increasing symptoms that lead to a decline in survival beginning in the late teens or early twenties. The prospects for long-term survival appear to be correlated with the amount of residual oxidative burst activity that can be generated by a particular patient's phagocytes.²³ This has led to a renewed interest in bone marrow transplantation for CGD, which has been quite successful in the modern era, likely due to improved antimicrobials and transplant-conditioning regimens with reduced toxicity. Many now recommend that for patients who have mutations that severely affect oxidative burst activity, bone marrow transplant should be considered preemptively, early in life before patients develop comorbidities.²⁴

Diagnosis

Assessment of patients for a possible phagocytic disorder requires that both the number and the function of phagocytes be evaluated. Numbers are easily evaluated using a complete blood count with differential. If there is a concern for cyclic neutropenia, neutrophil counts may need to be evaluated 3 times weekly for 3 to 4 weeks to identify the nadir.²⁵ Functional testing includes evaluation of CD11/CD18 integrin expression on myeloid cells by flow cytometry if the patient has symptoms suggestive of leukocyte adhesion deficiency. In cases of suspected CGD, evaluation of neutrophil oxidative burst function is essential. Traditionally this was done using nitroblue tetrazoleum (NBT) but is now performed using dihydrorhodamine (DHR), a reagent that permeates neutrophils and fluoresces when reduced by a normal neutrophil oxidative burst. Fluorescence is measured by flow cytometry. The DHR test is sensitive enough to differentiate most cases of X-linked CGD from autosomal recessive CGD, making it a particularly useful clinical assay.^{26, 27}

Treatment

As noted above, management of phagocytic disorders revolves around having a heightened suspicion for infections, aggressively treating acute infections using antibiotics and G-CSF as necessary, and developing a prophylaxis regimen that is both effective and reasonable from a patient standpoint. At times, patients continue to have recurrent or severe infections despite these efforts and require more definitive therapy. As indicated above, hematopoietic stem cell transplantation (HSCT) has been shown to be effective in many, but not all, phagocytic disorders. Gene therapy has been attempted for both X-linked CGD²⁸ and for LAD-1²⁹ but neither has been particularly successful thus far and at this point is considered to be experimental. Ongoing research to address the challenges of gene therapy that are unique to these two disorders is underway.

B CELLS/ANTIBODIES

The predominant role of B cells in the immune system is to make antibodies (immunoglobulins) in response to antigen challenge (pathogens, vaccines, etc.). The absence of functional antibodies causes susceptibility to bacterial and viral infections. Antibody deficiency can occur in one of three different ways: (1) hypogammaglobulinemia or low levels of one or more immunoglobulin classes (IgG, IgA, IgM, or IgE) occurring as a result of decreased antibody production, often associated with a specific single-gene defect; (2) hypogammaglobulinemia as a result of excessive antibody loss, typically through the kidneys as proteinuria or through the gut as protein-losing enteropathy; or (3) functional antibody deficiency, in which immunoglobulin levels are normal but the Ig lacks the quality required to bind and opsonize pathogens.

Clinical Presentation

Patients who lack sufficient levels of functional antibody present clinically with recurrent bacterial sinopulmonary infections (sinusitis, otitis media, bronchitis, and pneumonia). In addition, patients may develop bowel infections caused by microorganisms such as *Giardia* or *Cryptosporidium* that are often only modestly pathogenic to normal individuals. In addition to these symptoms, patients with certain antibody-deficiency disorders have characteristic clinical features that can provide clues to the specific diagnosis. These are covered below.

Specific Disorders

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA) is caused by mutations in the Bruton's tyrosine kinase (BTK) gene. BTK is a member of the Tec family of cytoplasmic tyrosine kinases and is required for the maturation of B-cell precursors in the bone marrow.³⁰ Mutations in BTK therefore cause an arrest of B-cell development at the pre-B-cell stage leading to virtual absence of circulating B cells in the peripheral

P.1346

blood. Mutations that only partially interfere with the enzymatic function of BTK have also been described and are associated with milder forms of the disease that only have defects in the generation of specific antibody responses.

XLA is typically suspected in male patients with recurrent bacterial sinopulmonary infections and <2% circulating CD19⁺ B cells. Other infections that occur relatively frequently in patients with XLA prior to the initiation of IgG replacement therapy include skin infections (furunculosis, pyoderma, and cellulitis) and sepsis. The diagnosis can be confirmed either by identifying a mutation in the BTK gene or by demonstrating absence of the BTK protein in monocytes or platelets. A positive family history suggestive of an X-linked recessive mode of inheritance increases the suspicion for XLA. It is uncommon for patients with XLA to develop symptoms in the first months of life because newborns are protected from most infections by transplacentally acquired maternal IgG. There are few distinguishing physical features of XLA that can provide clues to the diagnosis but absence of visible tonsils or adenoids (by X-ray or CT scan) is a useful clue.

In addition to the common sinopulmonary pathogens, patients with XLA are also susceptible to infections by particular opportunistic organisms that are more rare and fastidious, which can cause unusual clinical syndromes. For example, *Helicobacter cinaedi* can cause a syndrome of dermatomyositis and cellulitis that presents with cutaneous ulcerations, particularly on the lower legs.^{31, 32} The organism can sometimes be recovered from the blood but is fastidious and difficult to culture using usual methods. The ability to culture the organism and evaluate its antibiotic sensitivity is crucial in many cases because it is frequently resistant to various antibiotics. A combination of antibiotics is often needed to clear the infection effectively.³³ Similarly, *Mycoplasma* species, including *M. hominis*, can cause lung, abdominal, or bone infections that are remarkably hard to eradicate and *Ureaplasma urealyticum* infections are a rare cause of arthritis, urethritis, and pneumonia.³⁴

Prior to the widespread use of IgG supplementation in these patients, opportunistic viral infections, particularly with viruses that require an extracellular phase, were especially problematic. For example, echovirus encephalitis was estimated to be the cause of death in ~10% of boys with XLA in the 1970s but that number has fallen dramatically with aggressive use of IgG supplementation. There continue to be rare cases of echovirus encephalitis in patients with XLA, even in those on adequate IgG replacement therapy, but these are thought to be caused by viral strains for which there may not be high antibody titers in the particular IgG preparation being used.^{35, 36} Similarly, a mink astrovirus strain was recently identified by deep sequencing from the brain of an XLA patient who developed a neurodegenerative disorder as a teen.³⁷ Interestingly, he had lived next to a mink farm as a child but was started on immunosuppression early in his teens for inflammatory bowel disease, which may have allowed the virus to escape control. Lastly, infections with vaccine-strain poliovirus were pathogenic in undiagnosed patients with XLA who were immunized with the live-viral vaccine after

transplacentally acquired maternal antibody had waned. The shift from live attenuated to killed poliovirus for immunization has essentially eliminated new cases.

Hyperimmunoglobulin M Syndromes

Under normal circumstances, binding of antigen to cell surface IgM on naive B cells induces activation of the B-cell. The antigen that is bound to surface IgM on the B-cell is ingested, proteolytically digested, and antigenic peptide fragments are displayed on the B-cell surface in MHC Class II molecules. Antigen-specific T cells then engage the B-cell via MHC II/TCR interactions. Once engaged, the activated helper T-cell (Th) provides additional costimulatory signals to the B-cell that are critical to promote immunoglobulin class-switching from IgM to IgG, IgA, and IgE. The most important of these costimulatory signals comes via the interaction of CD40 ligand on activated T cells with CD40 on B cells. Additional costimulatory signals come from ICOS on activated T cells and ICOS ligand (B7-H2) on B cells. Activation of the B-cell through CD40 and cytokines that are secreted by the helper T-cell cause it to undergo class-switch recombination (CSR) during which the μ -heavy chain gene segment within the immunoglobulin gene, is replaced by either a γ , α , or ϵ gene segment. This is accomplished by nicking and double-strand breakage of the DNA in the immunoglobulin heavy-chain locus, which requires a series of enzymatic steps that involve activation-induced cytidine deaminase (AID), uracil DNA glycosylase (UNG), and others. Genetic defects that affect CD40 ligand (CD40L), CD40, AID, or UNG can therefore prevent class-switch recombination thus thwarting the B-cell's ability to make significant amounts of any antibody isotype in addition to IgM.

The overwhelming majority of patients with hyper-IgM syndrome have the X-linked form caused by X-linked recessive mutations in the CD40 ligand (CD40L/CD154), which is encoded by the CD40L gene on the X-chromosome.³⁸ CD40L and its receptor CD40 are members of the tumor necrosis factor (TNF) superfamily of ligands and receptors. In lymphocytes, CD40L is expressed only on activated T cells but is also expressed on platelets where its role is unknown. Affected boys may present with recurrent bacterial sinopulmonary infections caused by low IgG, IgA, and IgE, whereas IgM is normal or elevated. In addition to the usual bacterial pathogens, patients with CD40L mutations also demonstrate unique susceptibilities to fungal infections, particularly *Pneumocystis jiroveci* (PJ) that causes pneumonia, and to a protozoan, *Cryptosporidium parvum* (CP) that causes bowel infections. B lymphocytes are present, and T-cell numbers are generally normal. In almost all cases, the diagnosis can be made by using flow cytometry to evaluate the expression and function of the CD40L protein on activated T cells. Expression is evaluated using antibodies specific to the CD40L protein and the function is evaluated by measuring the binding of a CD40-Ig heavy chain fusion protein to the expressed CD40L. Gene sequencing can then be performed in order to identify a specific mutation.

The susceptibility to *Pneumocystis* and possibly other fungal pathogens has been somewhat of a puzzle because patients do not have other signs of a significant cellular immune defect such as severe or recurrent viral infections. Interestingly, the susceptibility to *Pneumocystis jiroveci* pneumonia (PJP) appears to go away in most patients by the age of 5. PJP is almost always diagnosed by staining bronchoalveolar lavage fluid for the presence of the organism. PJP can be readily prevented by prophylactic trimethoprim-sulfamethoxazole administration and active disease is amenable to treatment using higher doses of the same drug. Recent data have suggested that the fungal susceptibility in CD40L deficiency may be a result of defective CD40L signaling into dendritic cells and monocytes that express CD40.³⁹

C. parvum bowel infections are more difficult to diagnose and manage in patients with CD40L deficiency. CP may cause abdominal pain, bloating, diarrhea, malabsorption, and weight loss. It may require multiple stool samples to identify the oocysts and occasionally, the diagnosis can only be made on endoscopically obtained biopsy specimens. Treatment with paromomycin or nitazoxanide can clear the infection although prolonged courses are typically needed in hyper IgM patients and treatment failures are not uncommon. CP infections can result in chronic inflammation of the gut and biliary tree, which seems a likely contributor to the high incidence of bile duct cancers seen in these patients.^{40, 41}

Treatment involves the use of IgG replacement therapy combined with prophylactic antibiotics for prevention of PJP at least until the age of 5. The role of bone marrow transplantation for CD40L deficiency is still being evaluated. Even though a number of patients have undergone successful bone marrow

P.1347

transplantation, the role of BMT remains somewhat controversial in this disease although in patients with ongoing CP infection, the prognosis for the patients who develop bile duct disease is so poor that the risks of transplantation are well justified.^{42, 43}

CD40 deficiency is inherited as an autosomal recessive defect that has been described primarily in two cohorts from Italy and the Middle East. It results in a syndrome that is almost identical to CD40L deficiency in which both sexes are affected.

Homozygosity for a null mutation occurs, but heterozygosity is more common and can result in a partial phenotype because CD40 functions as a trimer (defects of even one chain of the trimer interfere with its function).⁴⁴

Autosomal recessive mutations in AID and UNG also cause a hyper-IgM phenotype but it tends to be milder than either CD40L or CD40 deficiency, likely because the defect is limited to B cells, whereas CD40L/CD40 signaling plays a role in other cell types including dendritic cells and monocytes.^{45, 46} Patients with AID or UNG typically live into adulthood and do not demonstrate the same susceptibility to PJP and CP bowel infections. Patients with mutations in AID do, however, have a significant propensity to develop autoimmunity affecting various organ systems. Patients are typically treated with IgG replacement therapy and antibiotics for acute infections. There are no reports of bone marrow transplantation for AID or UNG deficiency.

Common Variable Immunodeficiency Syndromes

Common variable immunodeficiency (CVID) is a heterogeneous disorder that is likely caused by a variety of molecular mechanisms that ultimately lead to a similar clinical phenotype. The European Society of Immunodeficiency (ESID) has proposed diagnostic criteria in an effort to standardize the diagnosis of CVID. These include: (1) plasma IgG levels that are less than 2 standard deviations below the mean for age combined with a "marked decrease" in either IgM or IgA; (2) age of onset of immunodeficiency >2 years of age; (3) absent isohemagglutinins or poor responses to vaccines; and (4) defined causes of hypogammaglobulinemia have been excluded.

The peak age of onset of CVID is in the second or third decade of life and 50% to 60% of patients have a clinical phenotype consisting almost exclusively of increased bacterial sinopulmonary infections. With IgG supplementation, this group of patients has a relatively benign course with long-term survival that is not unlike the normal population. The other half of patients have a complicated disease course with autoimmunity or lymphoproliferative disease that can involve the hematopoietic system, lungs, lymph nodes, liver, and bowel. The long-term outcome of this population is significantly worse, approaching only 40% survival over 40 years.⁴⁷

Among the disorders seen in this population, a granulomatous, lymphoproliferative, interstitial lung disease (GLILD) affects approximately 30% to 40% of patients.⁴⁸ This often presents with decreasing lung function that is manifested by cough, decreased exercise tolerance, and sometimes hypoxemia. Typical findings on chest CT scan include diffuse nodules within the lung, opacities that have a "ground glass" appearance, bronchial wall thickening, and sometimes bronchiectasis. Lung biopsy generally demonstrates a lymphocytic interstitial pneumonitis with noncaseating granulomas and a follicular bronchiolitis with lymphoid aggregates of both B and T cells. This pattern is sometimes mistaken for sarcoidosis although there are differences. Over time, this inflammatory process in the lungs will cause destruction of alveoli and will contribute to development of bronchiectasis. There continues to be some debate among providers about whether this process should be treated if the patient is not demonstrating pulmonary compromise. If left unchecked, however, there is evidence that irreversible damage and fibrosis develops in many patients. High-dose steroids are often used as first-line therapy to treat this process and in many cases they are effective but do not typically lead to a lasting remission on their own. A recent study using a combination of anti-CD20 monoclonal antibody (rituximab) therapy and azathioprine in a small cohort of CVID patients with GLILD demonstrated dramatic responses with a prolonged remission of disease in many patients.⁴⁹

In addition to pulmonary symptoms, gastrointestinal complaints are common in CVID, affecting 20% to 30% of patients.⁴⁷ Patients who develop disease demonstrate a hypertrophic lymphoproliferation of Peyer's patches that causes a nodular lymphoid hyperplasia in the bowel. This is associated with abdominal discomfort, diarrhea, malabsorption, and weight loss and can cause significant morbidity. A variety of approaches have been taken to treat this process but none have offered particularly dramatic results although nonabsorbable steroid preparations have shown some benefit with minimal side effects. A more troubling complication observed in 5% to 10% of patients is a hepatitis that can cause severe hepatic dysfunction with development of hepatosplenomegaly and ascites.⁴⁷ Infectious causes are almost never identified and liver biopsy demonstrates a nodular lymphoid hyperplasia in the liver parenchyma, not unlike that observed in the bowel. Liver disease is among the complications associated with a poor outcome.

Some 20% of subjects have additional clinical findings that are suggestive of autoimmunity/immune dysregulation including immune thrombocytopenia and hemolytic anemia, neuropathy, endocrinopathies, and skin disease. Skin involvement ranges from alopecia and vitiligo to psoriasis and granuloma annulare.^{50, 51}

In most cases of CVID, the molecular etiology of disease is unknown. There has, however, been some progress in identifying genetic defects associated with a CVID phenotype. The most common mutations identified are autosomal recessive defects in the transmembrane activator, calcium modulator, and cyclophilin ligand interactor (TACI), which are found in 7% to 10% of patients with CVID. Unfortunately, even in patients who have mutations that abrogate protein

expression, the penetrance of disease seems to be highly variable with individuals from one family harboring the same mutation, having either a CVID phenotype, a selective IgA deficiency phenotype, or no disease. This inability to correlate disease phenotype or prognosis with the presence of a TACI mutation has raised the question of whether TACI genotyping offers clinical value. In addition to TACI, autosomal recessive mutations in the genes encoding the Baff receptor (BAFFR), the inducible T-cell co-stimulator (ICOS), CD19, CD20, CD21, CD81, and the LPS-responsive vesicle trafficking, beach- and anchor-containing protein (LRBA) have been identified in rare patients with features of CVID. These mutations have provided insight into basic immune mechanisms in humans but explain only a handful of all patients with CVID.^{52, 53} Lastly, hypomorphic mutations in BTK (X-linked agammaglobulinemia), CD40L (X-linked hyper-IgM syndrome), SAP/SH2D1A (X-linked lymphoproliferative syndrome), and RAG1/RAG2 can be associated with a CVID-like phenotype and according to the diagnostic criteria for CVID, need to be excluded prior to making this diagnosis.⁵²

B-cell numbers in peripheral blood are typically normal but a subset of CVID patients have B-cell lymphopenia. In those patients with normal B-cell numbers, B-cell maturation, memory development, and immunoglobulin class-switching are often abnormal and can be assessed by detailed flow-cytometry-based immunophenotyping of B cells. Varying classification schemes have been proposed to subtype patients according to their B-cell phenotype and these subsets have been correlated with differences in risk for autoimmunity, and the like. B-cell immunophenotyping has therefore become a useful clinical tool in caring for patients with CVID. In addition to the humoral immune deficiency, many patients with CVID have impaired T-cell function with decreased CD4 or CD8 T cell numbers as well as abnormal T-cell proliferative responses in vitro to mitogens and antigens. Regulatory T-cell numbers and function have also been found to be decreased in patients with CVID.^{54, 55, 56, 57, 58}

P.1348

Selective Immunoglobulin A Deficiency

There are two isoforms of IgA that are made predominantly at mucosal surfaces where they play a critical role in neutralizing pathogens and maintaining mucosal integrity. Subjects >4 years of age with serum IgA levels consistently <7 mg/dl but normal IgG and IgM levels are considered selectively IgA deficient. Selective immunoglobulin A deficiency (SIgAD) can be difficult to diagnose in childhood because adult blood levels of IgA (50 to 200 mg/dl) are not usually attained until 12 years of age or older. The molecular mechanisms by which this occurs are largely unknown. Interestingly, despite low IgA, the frequency of cell-surface IgA-positive B cells is normal in patients with SIgAD. Up to 20% of IgA-deficient subjects have reduced levels of at least one IgG subclass: mostly IgG₂.

Selective IgA deficiency is the most common immunodeficiency with an incidence as high as 1 in 300 in blood bank studies. The majority (>50%) of patients with selective IgA-deficiency have no apparent symptoms that can be directly linked to their immune defect. In the patients who do have symptoms, they are typically more suggestive of immune dysregulation and autoimmunity (allergy, arthritis, diarrhea, celiac disease, etc.) than immune deficiency (sinusitis, otitis media, bronchitis, and pneumonia). In patients who are truly IgA deficient, sensitization to IgA itself can be a problem, leading to anaphylactic reactions during infusions of blood products including IVIg, red blood cells, platelets, and so on. This is, however, quite uncommon and can often be managed by pretreatment with benadryl, acetaminophen, and steroids before the start of the infusion.⁵⁹

Transient Hypogammaglobulinemia

Maternal IgG is actively transported across the placenta from mother to infant. The rate of transfer increases in the last month of pregnancy. Premature infants will therefore have low IgG levels but term newborns have IgG concentrations virtually equal to their mother's. Because the half-life of IgG is approximately 21 days, the levels of maternal immunoglobulin fall as the infant grows and the IgG is catabolized. For most term infants, the IgG level in the blood reaches a nadir between 200 to 400 mg/dl, typically between 3 and 4 months of age. As the infant's own immune system matures and begins to generate more IgG of its own, the immunoglobulin levels begin to rise again. There are, however, children whose IgG levels dip below 200 mg/dl and may remain low for a prolonged period of time before they begin to rise into the normal range again. Despite this, the response to protein antigen vaccines is often normal. This phenomenon is termed transient hypogammaglobulinemia of infancy (THI) and immunoglobulin levels typically return to normal by 2 to 6 years of age. There are almost no data about the mechanism by which THI occurs although it has been suggested that it may be the result of delayed B-cell maturation. This has, however, not been borne out by B-cell immunophenotyping studies.⁶⁰ The true incidence of THI is unknown because immunoglobulin levels are usually only requested if patients are having symptoms (i.e., recurrent infections). There is no consensus on how to manage THI although most would agree

that if patients are having frequent infections, they might require IgG supplementation until their own IgG levels normalize. One approach has been to immunize affected infants with killed vaccines and to start supplemental IgG therapy on those who make no significant antibody response. Infants who do respond to immunization with a protective specific antibody titer are usually safe with symptomatic management or with prophylactic antibiotics alone.

Immunodeficiency, Centromere Instability, and Facial Anomalies Syndrome

Immunodeficiency, centromere instability, and facial anomalies (ICF) syndrome is a complex syndrome that includes centromeric instability, a variable immune deficiency (often with normal B-cell counts), facial anomalies including hypertelorism, a flat nasal bridge, and low-set ears, and developmental delay. The immunoglobulin deficiency is variable but IgA, IgG, and/or IgM are frequently low. Lymphocyte proliferation can also be abnormal. The centromeric instability leads to chromosomal breaks, deletions, and multiradial chromosome junctions in activated lymphocytes that typically affect chromosomes 1, 9, and 16. ICF syndrome typically presents in childhood with recurrent bacterial sinopulmonary infections and patients generally require chronic IgG supplementation. The diagnosis is usually suspected in patients who have the facial phenotype and recurrent infections. ICF syndrome is caused by mutations in the DNMT3B gene, which encodes one of a family of DNA methyltransferases. Hypomethylation of the DNA is hypothesized to cause disease but the precise mechanism by which this generates the facial and immune phenotypes is unknown.^{61, 62} Evaluating the karyotype of activated peripheral blood lymphocytes can demonstrate the characteristic chromosomal abnormalities in chromosomes 1, 9, and 16, which can be highly suggestive of the diagnosis. Ultimately, sequencing of the DNMT3B gene can confirm a diagnosis of ICF syndrome.

Diagnosis

The diagnosis of antibody deficiency needs to evaluate both the quantity and the quality of the antibody response. Quantity is easily evaluated by measuring quantitative immunoglobulin levels (IgG, IgM, IgA, and IgE) in the blood and comparing these to the age-appropriate normal ranges. Evaluating the quality of the antibody response can be done by measuring specific antibody titers to vaccines that the patient has received. Generally, responses to both protein antigens (tetanus, diphtheria, hepatitis B, etc.) and carbohydrate antigens (23-valent unconjugated Pneumovax) need to be assessed to confirm normal antibody responses. Patients who respond appropriately to protein antigens but do not respond to carbohydrate antigens may have specific antibody deficiency and may require additional workup. Recent guidelines regarding the interpretation and use of diagnostic vaccination have recently been published.⁶³

In addition to evaluating antibody quantity and quality, it is essential to determine whether patients have normal B-cell numbers by evaluating lymphocyte subsets. The use of more detailed B-cell immunophenotyping to evaluate B-cell development, the presence of CD27⁺ memory B cells, and the ability of memory B cells to undergo immunoglobulin class switching has become standard-of-care in many clinics as it provides valuable diagnostic and prognostic information.⁶⁴

Flow cytometry testing to assess the expression of specific proteins that are defective in B-cell and antibody deficiency disorders including BTK, CD40 ligand, CD40, ICOS, CD27, BAFF receptor, and the like, can be performed in specialty laboratories and offer the ability to rapidly obtain a molecular diagnosis. This is typically supplemented by sequencing of specific genes.

Treatment

Immunoglobulin Replacement

In patients with antibody deficiency, replacement of IgG is critical to maintaining health and preventing long-term complications associated with recurrent infections. Immunoglobulin replacement therapy has been found to be effective when administered intravenously (IVIg), subcutaneously (SCIg), and intramuscularly (IMIg) and there are currently FDA-approved products that support administration via any of these routes. That said, because of significant discomfort associated with IMIg administration, this route is rarely used in the United States. Most patients are maintained on either IVIg or SCIg depending on patient preference and

P.1349

provider recommendations related to each patient's clinical need. Because the half-life of IgG in the circulation is ~21 days under normal circumstances, IVIg is typically administered every 3 to 4 weeks providing high peak levels followed by a decline over the ensuing weeks to a trough prior to the next infusion. In contrast, SCIg is typically administered 1 to 2 times per week in smaller doses providing a more "steady-state" level of IgG in the circulation. IgG products are prepared from the pooled plasma collected from thousands of healthy donors and therefore they contain a broad range of antibodies. A reasonable starting dose of either IVIg or SCIg is 400 to 500 mg/kg/month. This can be divided into the

number of doses required to administer the necessary monthly volume (IgG preparations range in concentration from 5 g/100cc (5%) to 20 g/100cc (20%)). In most patients, a trough IgG level of 600 mg/dl in the blood is a reasonable initial target but the dose can then be increased or decreased to achieve a trough IgG level that prevents both acute infections and development of progressive lung disease. There is evidence that at least for bacterial pneumonia, higher IgG trough levels are directly correlated with a decreased risk of infection.⁶⁵ Supplemental IgG is generally very effective at preventing lower respiratory tract infections (bronchitis and pneumonia), but the response of upper tract disease (particularly sinusitis) is more variable. Some patients have persistent sinus symptoms that can be a significant clinical problem despite IgG therapy. In these patients, the addition of prophylactic antibiotic therapy or increasing the frequency or dose of IgG infusions may be beneficial.

Side effects with IVIg therapy are relatively common, occurring in as many as 25% of treated patients.⁶⁶ Side effects include headaches, nausea, vomiting, chills, fatigue, fever, rash, and aseptic meningitis. These can often be managed by changing the IgG product being used, pretreating with benadryl, acetaminophen, and steroids (0.5 to 1 mg/kg) prior to infusion, or slowing the rate of infusion. Patients who have persistent symptoms despite these measures can often tolerate subcutaneous IgG supplementation (SCIg).

Prophylactic Antibiotics

It has been increasingly recognized that in many patients with antibody deficiency, replacement of IgG (even to normal levels), may not prevent all clinically significant infections. The addition of prophylactic antibiotics has been used as an adjunct to IgG therapy to try to improve control of infections and decrease morbidity. Unfortunately, to date, there have been no well-performed studies that argue strongly either for or against the use of prophylactic antibiotics to improve outcomes. Similarly, there have been virtually no studies that support a particular antibiotic regimen as being superior for prophylaxis. Many patients with antibody deficiency have evidence of bronchiectasis and chronic lung disease, therefore some providers, extrapolating from the lung transplant and cystic fibrosis literature, have utilized thrice weekly macrolide antibiotics as a prophylactic regimen in an attempt to prevent progression of lung pathology. Further studies are needed to clarify the role of prophylactic antibiotics and to define the optimal regimen.

T CELLS

Disorders characterized by the absence of T cells have been known for some time but the identification of several new genetic defects has expanded this group of disorders. Some are characterized by significant, generalized T-cell lymphopenia whereas others are characterized by the absence of specialized subsets of T cells.

Clinical Presentation

In general, absence of T cells causes susceptibility to unusual or severe infections caused by viruses including cytomegalovirus (CMV), Epstein-Barr virus (EBV), and adenoviruses, fungal infections caused by organisms such as *P. jiroveci* that commonly causes pneumonias in this group of patients, and mycobacteria such as *Bacilli Calmette-Guerin* (BCG) in areas of the world where this is used. In addition, patients with T-cell deficiencies frequently have symptoms of autoimmunity including diarrhea (secondary to autoimmune enteropathy), cytopenias (autoimmune hemolytic anemia [AIHA] and idiopathic thrombocytopenic purpura [ITP]), and hepatitis.

Specific Disorders

22q11.2 Deletion Syndrome (DiGeorge Syndrome)

Deletions within the 22q11.2 region of the long arm of chromosome 22 have been associated with various clinical syndromes including DiGeorge syndrome (DGS), velocardiofacial syndrome (VCFS), conotruncal anomaly face syndrome (CTFS), CATCH22 syndrome, and others. DiGeorge syndrome is the name most commonly associated with immune deficiency and thus is the focus of this discussion. Although DGS is a complex syndrome that has been associated with a wide array of symptoms, the diagnostic criteria proposed by the European Society of Immune Deficiency (ESID) are relatively straightforward. These propose that a diagnosis of DGS should be strongly considered in patients who have <500 CD3⁺ T cells/mm³ and any two of the following three characteristics: (1) conotruncal cardiac defect (truncus arteriosus, tetralogy of Fallot, interrupted aortic arch, or aberrant right subclavian); (2) hypocalcemia requiring therapy for >3 weeks; (3) deletion of chromosome 22q11.2. This chromosomal deletion syndrome occurs in approximately 1 in 4,000 to 5,000 births and causes haploinsufficiency of the genes encompassed in the deletion that can extend to include as much as 3 Mb of the chromosome.^{67, 68}

The characteristic T-cell lymphopenia of DiGeorge syndrome is thought to arise primarily from the absence of adequate thymic tissue and at times, the diagnosis is suspected when the cardiac surgeon correcting a congenital heart defect finds little or no thymic tissue in the mediastinum. Most affected infants have low, but not absent T cells and absolute counts

tend to improve over the first year of life. Both CD4⁺ and CD8⁺ T cells are low, however, CD8⁺ T-cell numbers tend to be more affected in most patients. Despite low T-cell counts, most patients do not have significant problems with recurrent or severe viral or fungal infections. Some patients may have recurrent candidiasis. Bacterial infections of the upper respiratory tract including otitis media and sinusitis do occur but may be related more to anatomical issues associated with the facial anomalies than to the immunodeficiency per se. Rare patients have severe T-cell lymphopenia with essentially no T cells and are termed “complete” DiGeorge. These patients may have a clinical phenotype similar to SCID.^{67, 68}

Other prominent clinical features include: hypocalcemia that can be severe and persistent due to parathyroid hypoplasia, dysmorphic facial features that include small low-set ears, hypertelorism, and micrognathia, renal anomalies including horseshoe kidney and a duplicated collecting system, and developmental delay including problems with speech acquisition, learning disabilities, and behavioral problems. Patients with DiGeorge syndrome have also been found to have an increased incidence of autoimmunity including cytopenias (particularly affecting red cells and platelets), juvenile idiopathic arthritis (JIA), and thyroiditis.

In symptomatic patients, the diagnosis of DiGeorge syndrome is typically made by confirming a deletion within the 22q11.2 region by fluorescence in situ hybridization (FISH) or by quantitative PCR for deletion of the TBX1 gene that lies within the deletion.⁶⁹ In approximately 10% of patients, deletion of this region cannot be detected despite the presence of classic clinical features.

Treatment of DiGeorge initially involves supportive care that may include cardiac support and calcium supplementation. In P.1350

patients with severe T-cell lymphopenia or evidence of decreased T-cell function, prophylaxis against PJP pneumonia and IgG supplementation may be utilized. Blood for these patients should be irradiated to prevent the risk of graft-versus-host disease. For those patients with the severe “complete” form of the syndrome, grafting of allogeneic thymus slices into the thigh muscle has proven to be successful in recovering the T-cell lymphopenia, improving T-cell responses to mitogens, and correcting the infectious susceptibility.^{70, 71} HSCT has been utilized in a handful of patients with mixed results.^{72, 73} In general, HSCT restores the T-cell counts and protects patients against further infection but in the absence of a thymus, the T-cell graft is thought to consist primarily of long-lived committed lymphoid progenitor T cells and not of cells derived from donor bone marrow stem cells. As a result, there is concern that the T-cell grafts may senesce over time, once again leaving the patient lymphopenic and susceptible to infection. There are currently no long-term therapies that can successfully correct the parathyroid defect.

Severe Combined Immune Deficiency

Made famous by *The Boy in the Plastic Bubble*, a 1976 made-for-TV movie starring John Travolta, SCID is among the most severe immunodeficiencies. It is now known that this category of diseases is made up of a variety of related disorders caused by mutations in more than 20 different genes. The one thing that is common to all forms of SCID is deficiency of one or more subsets of T cells. In many cases, there are no circulating T cells. Depending on the genetic defect, patients may also lack B cells and/or NK cells. This has led to the useful convention of defining cases of SCID by their cellular phenotype (i.e., T^{neg}B⁺NK⁺, T^{neg}B⁺NK^{neg}, T^{neg}B^{neg}NK⁺, T^{neg}B^{neg}NK^{neg}, etc.). The cellular phenotype suggests what the underlying genetic defect may be (see Table 63.2).² Because of the absence of functional T cells, patients with SCID typically come to medical attention because of severe or chronic viral infections, fungal infections, or autoimmunity. In the overwhelming majority of SCID cases, this leads to death in infancy or early childhood if patients do not undergo curative treatment such as HSCT or gene therapy. Unfortunately, the presence of infections makes HSCT or gene therapy much more complicated and substantially decreases the chances of survival. Because of this, efforts have been underway in the United States and other countries to perform screening of all newborns using dried blood spot cards obtained at birth to identify those who may have SCID. These efforts have led to the recognition that the incidence of SCID is approximately 1 in 40,000 live births in the United States.^{74, 75}

X-Linked Severe Combined Immunodeficiency

The X-linked form of SCID is the most common type, accounting for ~40% of all SCID cases. It occurs as a result of mutations in the IL2RG gene, encoding the γ receptor chain (γ c) utilized by a number of cytokine receptors including those for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 (see Fig. 63.2). In the absence of a functional γ c chain, cells are unable to respond to these cytokines. Because IL-2 and IL-7 are key growth factors for T cells, and IL-15 is the key growth factor for NK cells, patients with X-SCID lack T and NK cells but usually have normal numbers of B cells in their blood. The ability to make antibodies is nevertheless severely impaired due to the lack of T-cell help.

If not identified by newborn screening, infants with X-SCID typically present with severe infections. *P. jiroveci* pneumonia is common and often accompanied by severe viral infections with cytomegalovirus (CMV), EBV, respiratory syncytial virus (RSV), rotavirus, metapneumovirus, and others. Adenovirus is particularly lethal in SCID, causing not only pneumonitis but also a severe fulminant hepatitis. In countries where BCG is still used for vaccination, X-SCID patients may develop severe, systemic BCG-osis. Other symptoms that are frequently associated with X-SCID include diarrhea, failure to thrive, and candidiasis. The physical exam and associated studies offer few clues to the diagnosis of X-SCID other than a paucity of palpable lymph nodes and absence of a thymic shadow on a chest X-ray.

Flow cytometry testing to evaluate tyrosine phosphorylation of the STAT3 transcription factor in response to IL-21 stimulation can provide a rapid assessment of whether a patient may have an IL2RG or JAK3 defect (see below). Under normal circumstances, IL-21 stimulation of B cells causes rapid tyrosine phosphorylation in B cells that is absent in patients with IL2RG or JAK3 deficiency (see Fig. 63.2). The diagnosis is ultimately confirmed however by sequencing of the IL2RG gene.

HSCT has been the mainstay of therapy for X-SCID using a variety of pretransplant conditioning regimens. Some have strongly advocated the use of T-cell depleted grafts from one of the haploidentical parents because they are readily available but many patients transplanted using that approach have failed to obtain significant donor chimerism in the B-cell compartment, so have remained dependent on IgG supplementation posttransplant. X-SCID was also the first disorder successfully treated by gene therapy. Unfortunately, the retroviral gene therapy vector used to deliver the normal copy of the IL2RG gene had an unknown propensity to integrate within the T-cell oncogene LMO2, causing T-cell leukemias in a subset of treated patients.^{76, 77, 78} Further studies are underway using alternative viral vectors with the hope that these may have a better safety profile.

JAK3 Deficient Severe Combined Immune Deficiency

JAK3 is the tyrosine kinase immediately downstream of the common gamma chain (γ_c). It transduces signals from cytokine receptors to the STAT5 transcription factor and to other intracellular signaling molecules (see Fig. 63.2). Approximately 30 different mutations have been identified that impair JAK3 function to varying degrees. Those that are severe have a $T^{neg}B^+NK^{neg}$ cellular phenotype similar to mutations in IL2RG. Approximately one third of patients have milder mutations that allow some JAK3 function.^{79, 80} These patients can develop some T cells although the T cells that develop are functionally abnormal. The clinical presentation is similar to that observed in γ_c deficiency. Sequencing of the JAK3 gene is required to confirm the diagnosis.

Interleukin-7 Receptor, CD3 Components, and CD45-Deficient Severe Combined Immune Deficiency

Defects in the α -chain of the IL-7 receptor (IL7RA), CD3 subunits (γ, δ, ϵ), or CD45 can cause SCID with a $T^{neg}B^+NK^+$ phenotype. As noted above, IL-7 is one of the two key growth and differentiation factors for T cells. As a result, mutations in the IL-7 receptor α -chain (CD127) lead to selective T-cell deficiency but allow normal development of B and NK cells.

Similarly, absence of any of the CD3 subunits specifically affects the ability of T cells to develop because CD3 makes up an essential part of the T-cell receptor complex. The T-cell receptor, including CD3 subunits, assembles in the endoplasmic reticulum and Golgi complex before trafficking to the cell surface. If any of the receptor subunits are absent (including any of the CD3 chains), the receptor is recycled and never makes it to the outer cell membrane. As a result, cells are unable to receive the TCR stimulation needed as they traffic through the thymus and they die by "neglect." Because the number of T cells entering the thymus is normal, the CD3 defects are unusual among SCID disorders in that the size of the thymus is normal. Of the three known CD3 defects (γ, δ , and ϵ), CD3 γ deficiency may have a somewhat milder clinical phenotype that can present with moderate T-cell lymphopenia and recurrent pneumonia and otitis.

CD45 is a transmembrane tyrosine phosphatase present on most white blood cells. It regulates intracellular Src-family tyrosine kinases that are important for T-cell receptor function and

P.1351

activation. Autosomal recessive mutations of CD45 lead to T-cell deficiency and a SCID phenotype in affected infants.

TABLE 63.2 MOLECULAR DEFECTS ASSOCIATED WITH SPECIFIC CELLULAR PHENOTYPES IN SEVERE COMBINED IMMUNE DEFICIENCY (SCID)

Cellular Phenotype	Gene	Inheritance	Features
$T^{neg}B^{neg}NK^{neg}$			

• Adenosine deaminase deficiency	<i>ADA1</i>	AR	Costochondral abnormalities, neonatal hepatitis
• Purine nucleotide phosphorylase deficiency	<i>PNP</i>	AR	Progressive neurologic problems
• Reticular dysgenesis	<i>AK2</i>	AR	Also has deficiency of myeloid lineage cells, sensorineural deafness

T^{neg}B^{neg}NK⁺

• RAG1 deficiency	<i>RAG1</i>	AR	
• RAG2 deficiency	<i>RAG2</i>	AR	
• Artemis deficiency	<i>DCLRE1C</i>	AR	Radiosensitivity
• DNA-PKcs deficiency	<i>PRKDC</i>	AR	Radiosensitivity
• DNA ligase IV deficiency	<i>LIG4</i>	AR	Radiosensitivity, microcephaly, growth retardation
• Cernunnos/XLF deficiency	<i>NHEJ1</i>	AR	Radiosensitivity, microcephaly, growth retardation

T^{neg}B⁺NK^{neg}

• Common γ chain deficiency	<i>IL2RG</i>	XL	
• JAK3 deficiency	<i>JAK3</i>	AR	
• CD45	<i>PTPRC</i>	AR	Some NK cells may be present

T^{neg}B⁺NK⁺

• IL-7 receptor- α (CD127) deficiency	<i>IL7RA</i>	AR	
• DiGeorge syndrome	<i>22q11.2 del</i>	AD	Hypoparathyroidism, cardiac defects, dysmorphic facies
• CHARGE syndrome	<i>CHD7</i>	AD	Multiple anomalies make up the clinical complex of CHARGE syndrome
• CD3 δ deficiency	<i>CD3D</i>	AR	
• CD3 ϵ deficiency	<i>CD3E</i>	AR	
• CD3 γ deficiency	<i>CD3G</i>	AR	
• CD3 ζ deficiency	<i>CD3Z</i>	AR	
• P56lck deficiency	<i>LCK</i>	AR	
• Coronin-1A deficiency	<i>CORO1A</i>	AR	Lymphadenopathy

T⁺B⁺NK⁺

• MHC II deficiency	<i>CIITA</i>	AR	CD4 ⁺ T cells are typically decreased but not absent
	<i>RFXANK</i>	AR	
	<i>RFX5</i>	AR	
	<i>RFXAP</i>	AR	

• ORAI1 deficiency	<i>ORAI1</i>	AR	Myopathy, calcium flux defect in B and T cells so poor proliferation
• STIM1 deficiency	<i>STIM1</i>	AR	Myopathy, calcium flux defect in B and T cells so poor proliferation

AD, Autosomal dominant; AR, Autosomal recessive; XL, X-linked recessive.

Modified from Cossu F. Genetics of SCID. Ital J Pediatr 2010;36:76.

DNA Recombination and Repair Defects in Severe Combined Immune Deficiency

Rearrangement of the V, D, J, and constant regions of the T-cell receptor gene and the B-cell immunoglobulin gene requires that double-stranded breaks be made in the DNA and that these breaks then be repaired after removal of intervening chromosomal fragments. The recombinase activating genes RAG1 and RAG2 are expressed in T and B cells and play an essential role in creating the necessary double-stranded DNA breaks in the TCR and immunoglobulin loci. A large complex of proteins including Artemis (DCLRE1C), DNA-PKcs, Cernunnos/XLF (XRCC4-like factor), and DNA ligase IV (LIG4) then play a role in the repair of the DNA double-stranded breaks needed to create the final, recombined TCR or Ig locus. Inasmuch as productive rearrangement of the TCR or Ig locus is a necessary developmental step during T- and B-cell maturation, complete failure in one of these processes results in lymphopenia, with few if any T- or B cells

P.1352

in the blood, whereas generation of NK cells is generally unaffected. Because radiation induces double-strand breaks in DNA, cells from patients with mutations in any of the proteins involved in DNA repair (Artemis, DNA-PKcs, cernunnos, ligase IV) demonstrate decreased survival in vitro after radiation exposure (radiation-sensitivity). This can be a valuable diagnostic clue in making a diagnosis.

FIGURE 63.2. Interleukin-2 signaling. Under resting circumstances, the transcription factor STAT5 is present in the cytoplasm in a nonphosphorylated state. Upon binding of IL-2 to its receptor made up of α , β , and γ chains (1), the common γ chain is phosphorylated on tyrosine by the receptor-associated JAK3 kinase (2). STAT5 then binds to the phosphotyrosine residues on the receptor via its Src-homology 2 (SH2) domains, where it is also phosphorylated on key tyrosine residues by JAK3 (3). After undergoing a conformational change, the phosphorylated STAT5 dimer localizes to the nucleus where it binds DNA and mediates gene transcription. Mutations in the common IL-2 receptor γ chain or in JAK3 cause severe combined immunodeficiency (SCID).

Patients who have null mutations of any of these proteins have a clear $T^{\text{neg}}B^{\text{neg}}NK^+$ cell phenotype. There are, however, many mutations, particularly missense mutations or small inframe deletions that allow expression of a partially functional protein that can occasionally productively recombine a TCR or Ig gene locus. The cell in which this occurs is then able to

pass the developmental block and proliferate in an attempt to fill the lymphopenic void that is otherwise present in SCID. These forms of SCID are termed “leaky” because they allow a small number of T- (and occasionally B-) cells to “leak” past the developmental block. Omenn syndrome, originally described in leaky RAG1 or RAG2 mutants, is a clinical phenotype that results from this leaky form of SCID. Affected infants typically develop a desquamative erythroderma after birth that is associated with the presence of oligoclonal, activated T cells in the skin, hepatosplenomegaly, lymphadenopathy, eosinophilia, and elevated IgE. Some develop autoimmune enteropathy and cytopenias. Affected patients are typically treated with T-cell-directed immunosuppression such as cyclosporine or FK506, followed by bone marrow transplantation. Leaky forms of SCID have now been described in a number of SCID-associated molecular defects including RAG1, RAG2, Artemis, ligase IV, IL7RA, IL2RG, RMRP, and others.⁸¹

Adenosine Deaminase and Purine Nucleotide Phosphorylase Deficient Severe Combined Immune Deficiency

Adenosine deaminase (ADA) deficiency was the first molecularly defined immunodeficiency with discovery of patients with SCID who lacked the enzymatic activity of ADA in the peripheral blood in the early 1970s. ADA catalyzes the conversion of adenosine triphosphate (ATP), guanosine triphosphate (GTP), and their deoxy counterparts to adenosine diphosphate (ADP) and guanosinediphosphate (GDP). When enzyme activity is impaired or absent, intracellular levels of deoxy-ATP (dATP) rise to interfere with ribonucleotide reductase, such that DNA synthesis and repair are slowed and lymphocyte apoptosis is increased. Purine nucleotide phosphorylase (PNP) works farther down this same metabolic pathway to convert deoxyinosine to hypoxanthine. Mutations interfering with this function cause deoxy-GTP accumulation and the inhibition of ribonucleotide reductase and DNA synthesis. In both cases, affected infants typically have a T^{neg}B^{neg}NK^{neg/low} cellular phenotype due to the toxic nature of the accumulated metabolites on lymphocyte development. Patients typically present with severe or recurrent viral infections or recurrent sinopulmonary infections in the first year of life.

Both syndromes are associated with other, nonimmune symptoms including skeletal abnormalities and osseochondrosis dysplasia in ADA deficiency and neurologic deficits, developmental delay, and spasticity, in PNP deficiency. In both cases, the diagnosis can be made by detecting high levels of the toxic metabolites that build up in the peripheral blood in the absence of enzymatic activity. Sequencing of the ADA1 or PNP genes can be done to confirm the diagnosis. ADA deficiency accounts for 20% or more of autosomal-recessive SCID cases.

Aside from bone marrow transplantation, ADA deficient infants can be treated with polyethylene glycol-conjugated ADA, which is injected intramuscularly once per week. Treatment efficacy is gauged by measuring plasma ADA activity and red cell dATP levels. Enzyme treatment has the advantage of speed of response coupled with safety.^{82, 83} The treatment is very expensive and many treated patients develop antibodies to the bovine protein that may neutralize the effect of the enzyme. HSCT is effective in ADA deficiency but less so in PNP deficiency as it does not correct the neurologic deficits. Gene therapy for ADA deficiency has been quite successful and unlike X-linked SCID and WAS, there have been no reported cases of leukemia despite the retroviral gene therapy vector backbone being similar.⁸⁴

Zap-70 Deficient Severe Combined Immune Deficiency

Zap-70 is a tyrosine kinase that is downstream of CD3 in the T-cell receptor signaling pathway. Absence of functional enzyme results in a characteristic SCID phenotype with decreased CD4⁺ T cells but virtually absent CD8⁺ T cells. Immunoglobulin levels are often decreased and antibody responses to vaccination are typically absent because of the lack of effective T-cell help. The CD4⁺ T cells that are present do not respond to antigen or mitogen stimulation that utilizes the T-cell receptor but they do proliferate and make cytokines in response to phorbol and ionomycin stimulation, which mimics TCR stimulation by activating kinases and calcium flux through downstream mechanisms. Bone marrow transplantation is effective in this disorder.

Defects in Antigen Presentation by MHC I or MHC II

The class II MHC complex generally presents peptide antigen derived from ingested material (either by phagocytosis or via the B-cell antigen receptor). Defects that interfere with the assembly or cell-surface expression of the Class II MHC-peptide complex prevent effective antigen recognition by CD4⁺ T cells, resulting in a SCID syndrome that presents in infancy with chronic diarrhea, failure to thrive, and occasionally with autoimmune cytopenias. MHC II deficiency can result from defects in one of four

P.1353

DNA-binding proteins that regulate transcription of the MHC class II gene (CIITA, RFXANK, RFX5, and RFXAP). Founder mutations (particularly in RFXANK) that are common in the Mediterranean region have led to most affected patients

having some familial ties to this geographical area. Because MHC class II presentation of antigen is abnormal, CD4⁺ T-cell counts are often low whereas CD8 counts are normal. A rapid preliminary diagnosis can be made by evaluating peripheral blood cells for expression of the class II complex by flow cytometry, which will detect reduced expression. Some patients can have a mild disease course and can live well into adulthood with only supportive care although others with the same mutation (even in the same family) may have a more severe phenotype. Bone marrow transplantation for MHC II deficiency has been challenging with survival rates typically approaching approximately 50%. In addition, there is a high rate of severe graft-versus-host disease (GvHD) in these patients, possibly because thymic epithelial cells that play a role in positive and negative T-cell selection are not replaced by transplant and still do not express MHC II.⁸⁵

The class I MHC complex presents peptide antigens derived from intracellular proteins where proteolytically derived peptides are bound to the MHC I complex as it is generated and trafficked through the endoplasmic reticulum. Peptides that are generated in the cytosol are transported into the inner lumen of the endoplasmic reticulum by the peptide transporters TAP1 and TAP2. Mutations in either of these, or of Tapsin to which they bind, have been identified. TAP mutations are typically associated with recurrent viral infections, and recurrent sinusitis and bronchitis. The diagnosis is usually suspected when serologic typing for HLA Class I antigens fails to give interpretable results, but molecular typing indicates intact MHC DNA. CD8⁺ T-cell and NK-cell counts are frequently (but not uniformly) decreased in these patients. Other cell subsets are typically normal. Heterogeneity in the phenotype may reflect differences in the underlying mutation and in the gene affected. Some patients may survive into the third decade. The role of HSCT in MHC I deficiency is unclear.

Treatment of Severe Combined Immunodeficiency Syndromes

SCID was uniformly lethal in the first years of life until Good and colleagues successfully reconstituted an affected infant with a transplant of sibling bone marrow. Experience in subsequent years has shown that patients with B-cell-positive SCID (IL2RG, JAK3, IL7RA, etc.) readily reconstitute their T-cell deficiency but may not develop significant B-cell chimerism. The reasons for this are not entirely understood but various hypotheses have been put forward. From a practical standpoint, a lack of donor B-cell engraftment may lead to a chronic need for IgG replacement therapy even after transplant inasmuch as patients may not be able to mount sufficient antibody responses. Patients with B-cell-negative SCID are more likely to have successful donor engraftment of both T- and B-cell lineages and are more likely to recover full humoral immune function.

One of the most significant challenges in the treatment of SCID is that in the absence of a family history, most patients come to attention because of infections. These are most commonly PJP and severe viral infections (see above). PJP can be treated but may lead to lung damage, whereas the viral infections may or may not be controllable. In addition, many SCID infants have significant diarrhea and weight loss by the time they reach a transplant center. Together, these complications increase the risk of adverse outcomes during transplantation for SCID and have been the major impetus for adding SCID to state newborn screening panels. Initial management prior to transplant involves aggressive supportive care, antimicrobials to treat any intercurrent infections (bacterial, viral, and fungal), antimicrobial prophylaxis to prevent future infections, and IgG replacement therapy.

There is significant debate about the best pretransplant conditioning regimen for patients with SCID to balance safety and efficacy. In general, those patients that have a matched sibling donor receive no conditioning prior to receiving unmanipulated bone marrow. For other patients, a variety of conditioning regimens ranging from no conditioning to fully myeloablative regimens have been tried. Similarly, a range of manipulated and unmanipulated stem cell sources have been tried including matched bone marrow, matched peripheral blood, cord blood, and haploidentical. Last, a variety of prophylactic immunosuppressive regimens have been used in the early posttransplant period to limit GvHD and prevent graft rejection. Each option has advantages and disadvantages, which has led to the spectrum of transplant regimens that have been attempted for SCID. Current efforts are underway to assess which regimens offer the best outcomes and lowest risk.^{86, 87, 88, 89}

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia (CHH) is a complex disorder characterized by skeletal dysplasia with short limbs (metaphyseal chondrodysplasia), sparse hypoplastic hair, gastrointestinal problems, and a variable immunodeficiency. CHH is caused by mutations in the RMRP gene, which encodes the 267 base-pair RNA component of the RNase MRP complex that plays a role in processing of precursor ribosomal RNA. The mechanism by which autosomal recessive mutations in RMRP cause the clinical features of CHH is unknown. The largest populations of CHH patients have been identified among the Old Order Amish and Finnish populations. Virtually all patients with CHH have some degree of immunodeficiency that can range from a mild humoral defect with decreased vaccine responses to a SCID-like phenotype associated with progressive lymphopenia and severe infections with bacteria, viruses, and fungi. A leaky-SCID phenotype has also been described in

RMRP deficiency. The diagnosis of CHH can be made based on the clinical phenotype and confirmed by sequencing of the RMRP gene. The immunologic features of CHH can be corrected by HSCT but the other features persist.⁹⁰

Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-linked Syndrome

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) is a syndrome of regulatory T-cell deficiency. Natural regulatory T cells comprise a subset of CD4⁺ T cells that regulate immune responses and play a critical role in peripheral immune tolerance. IPEX syndrome is caused by mutations in the FOXP3 gene located on the X chromosome that encodes a key transcription factor that is required for the generation of functional regulatory T cells (Treg). In the absence of FOXP3, patients present with severe, early-onset, systemic autoimmunity that is the result of having decreased Treg cell function. Almost all patients with IPEX syndrome present with enteropathy within the first 6 months of life. The enteropathy is typically characterized by profuse watery diarrhea (often nonbloody) and villus atrophy. The majority of patients have an eczematous dermatitis that typically begins in the first months of life. An early onset endocrinopathy that is almost exclusively either thyroiditis or Type I diabetes is also developed by 60% to 70% of patients. The most consistent laboratory abnormality among patients is a significantly elevated serum IgE level. In addition to these characteristic clinical and lab features, patients also have a high incidence of other severe autoimmune disorders including: hemolytic anemia, thrombocytopenia, neutropenia, hepatitis, renal disease, and others.

Recognition of the clinical features of IPEX syndrome is the first step in diagnosing this disorder. Sequencing of the FOXP3 gene remains the gold standard for making a diagnosis of IPEX syndrome although sequencing needs to encompass noncoding

P.1354

areas of the gene including the upstream noncoding exon and the polyadenylation signal sequence in order to cover all regions in which pathogenic mutations have been identified.^{91, 92} Flow cytometry to measure FOXP3 protein expression and FOXP3⁺ Treg is a helpful adjunct to gene sequencing although only ~25% of patients have mutations that are predicted to abrogate FOXP3 protein expression completely. The remainder of patients have varying degrees of FOXP3⁺ Treg deficiency due to the fact that mutant FOXP3 may not support normal Treg development. As a result, flow cytometry by itself is not considered to be a sufficiently reliable screening test for IPEX syndrome.

Initial therapy for IPEX syndrome typically consists of aggressive supportive care (parenteral nutrition, insulin, thyroid hormone, etc.) combined with T-cell-directed immune suppression using agents such as tacrolimus, cyclosporine, or rapamycin. HSCT is currently the only curative therapy for IPEX syndrome. Early HSCT using a nonmyeloablative conditioning regimen prior to the onset of autoimmune-mediated organ damage usually leads to the best outcome and limits the adverse effects of therapy.^{93, 94} Because Tregs constitutively express the high-affinity IL-2 receptor, they have a selective growth advantage in vivo. As a result, complete donor engraftment in all hematopoietic lineages may not be necessary because preferential engraftment of donor Treg cells can be sufficient to control the disease.⁹⁵

OTHER COMPLEX OR COMBINED IMMUNODEFICIENCY DISORDERS

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is unique among immunodeficiency disorders because affected patients have both an infectious susceptibility and a bleeding disorder. The bleeding problems are caused by the platelets being small (mean platelet volume <5 fl), dysfunctional, and decreased in number (usually platelet counts <70,000/ μ l). Patients with WAS typically present in infancy with bloody diarrhea and/or bruising, recurrent upper respiratory tract infections, and eczema. The incidence of hematopoietic malignancies is high. IgE levels are often elevated. Serum IgG levels and T-cell counts are often normal in infancy but may decrease over time. Responses to vaccination, particularly with carbohydrate antigens such as Pneumovax are often abnormal.

WAS is caused by mutations in the WAS gene that is located on the short arm of the X chromosome. Inheritance is X-linked recessive. There is a distinct genotype/phenotype correlation of mutations in WAS: Mutations that destroy WAS protein (WASp) expression lead to the full syndrome of immunodeficiency and platelet dysfunction. Mutations that allow expression of a mutant WASp protein are typically associated with a milder X-linked thrombocytopenia (XLT) phenotype in which the platelet dysfunction persists but the immunodeficiency is very mild. Point mutations in the CDC42 binding domain of the WASp protein lead to a third phenotype of X-linked neutropenia (XLN) that is generally not accompanied by bleeding abnormalities.^{96, 97}

The WASp protein is expressed primarily in lymphoid and myeloid cells where it functions to nucleate actin polymerization in the cell. Patients with WAS therefore have problems with directed migration of neutrophils and with clustering and

signaling through T-cell and B-cell antigen receptors (this causes decreased signaling into the cell and abnormal proliferative responses). A diagnosis of WAS can be confirmed by demonstrating the absence of WASp protein in cells by flow cytometry or western blotting, or by identifying a mutation in the WAS gene.

Treatment of WAS initially involves supportive care including treatment of any acute infections and management of any bleeding episodes. In general, repeated platelet transfusions are avoided because of the concern that patients will become sensitized to a wide array of HLA types, which may increase the risk of complications during subsequent HSCT. Splenectomy can increase platelet counts, however, it also increases the risk that patients may die of sepsis with encapsulated organisms so there continues to be significant controversy surrounding the role of splenectomy in WAS. Patients with the full WAS phenotype should be evaluated for HSCT with matched related or unrelated donor bone marrow or cord blood.⁹⁸ Haploidentical transplants have proven risky in this disease and therefore are generally avoided. The role of HSCT in XLT remains controversial.⁹⁹ Some have advocated that the benefits for curing the bleeding problems are worth the risk if a matched sibling donor is available. Gene therapy has been successful in a small number of patients with WAS but as in the X-SCID gene therapy trials, some treated patients developed T-cell leukemias as a result of integration of the viral gene therapy vector near an oncogene.¹⁰⁰

Radiation Sensitive Disorders: Ataxia Telangiectasia and Nijmegen Breakage Syndrome

Ataxia telangiectasia (AT) is a disorder associated with progressive neurologic decline, immunodeficiency, and propensity to malignancy. It is caused by autosomal recessive mutations in the ATM gene that encodes a serine/threonine kinase that acts together with the NBS1 protein as one of the major sensors of double-stranded DNA breaks in the cell. ATM phosphorylates key proteins involved in the activation of the DNA damage repair checkpoint, leads to cell-cycle arrest, and then double-stranded DNA break repair. In the absence of functional ATM or NBS1, cells have a marked sensitivity to ionizing radiation. Because rearrangement of the TCR gene and the immunoglobulin gene loci also require double-stranded DNA break repair, these processes may be affected as well.

Patients with AT usually present in early childhood (most commonly between 2 and 5 years of age) with cerebellar ataxia that progresses to unsteady gait and over time, to choreoathetosis. Telangiectasias (small tufts of dilated blood vessels under the surface of the skin or mucus membranes) typically develop first on the conjunctivae and later are seen on the nose, ears, and shoulders. They can be an important diagnostic clue in a child with progressive ataxia. The majority of patients have immunoglobulin deficiency of varying degrees and can develop sinopulmonary symptoms and sepsis. The progressive neurodegeneration can compromise coughing, thus it is hard to determine whether respiratory infections occur more as a result of the immunodeficiency or the motor defects. Most affected individuals have elevated serum α -fetoprotein levels, which can be useful diagnostically. Malignancies are an important complication as a result of the DNA-repair defect. Acute T-cell leukemias are common and often demonstrate chromosomal translocations that affect the chromosomal regions involved in T-cell receptor gene rearrangements. B-cell lymphomas also occur and are usually associated with 11q22-23 chromosomal deletions. There is also an increase in the frequency of epithelial tumors in both homozygotes and ATM mutation carriers. Affected patients usually die in the second or third decade of life.

Other DNA repair defects that cause varying degrees of ataxia and/or mild mental retardation include an ataxialike syndrome caused by mutations in MRE11 and the Nijmegen breakage syndrome (NBS), caused by mutations in NBS1. In addition to an immunodeficiency like that observed in AT, patients with NBS have marked microcephaly, mild developmental delay/mental

P.1355

retardation, and a strong propensity to develop lymphomas. Another DNA repair defect, Bloom syndrome, caused by mutations in a DNA helicase (RecQ proteinlike-3), results in excess sister chromatid exchanges; it is associated principally with lymphomas and cancer. Multiple primary tumors occurring at an early age are common. Reduced growth in childhood results in a proportional dwarfism that, with cutaneous telangiectasias, is a useful physical sign. Inheritance is autosomal recessive, and the disease occurs with increased frequency in Ashkenazi Jewish populations. Chronic lung disease occurs and may be related to the low levels of IgA and IgM.¹⁰¹

Mammalian Susceptibility to Mycobacterial Disease

Under normal circumstances, intracellular pathogens such as mycobacteria induce production of IL-12 and IL-23 that play a role in driving maturation of naive T cells into activated T helper type 1 (Th1) cells that produce interferon- γ (IFN- γ). IFN- γ then acts on a variety of cells including phagocytes (neutrophils, monocytes, and dendritic cells) to induce a number of interferon-inducible genes. Multiple molecules in this signaling pathway have been found to be defective in patients with intact cellular immunity who have invasive, nontuberculous mycobacterial infections. Mutations in the genes encoding the

IL12 p40 subunit (IL12B), the IL-12 receptor β 1 chain (IL12RB1), the TYK2 tyrosine kinase that is associated with the IL-12 receptor and required for phosphorylation of the STAT4 transcription factor (TYK2), the IFN- γ receptor subunits (IFNGR1&IFNGR2), and the STAT1 transcription factor that is activated in response to IFN- γ (STAT1), and the mutations in this pathway are also associated with other infections including invasive salmonellosis and severe viral infections (STAT1). In addition to these genetic defects, patients with invasive mycobacterial disease have now been identified with neutralizing autoantibodies to IFN- γ . Together these discoveries demonstrate a major role for the IL-12/IL-23/IFN- γ axis in normal human immunity.¹⁰² For patients with the milder, autosomal dominant IFN- γ receptor defects, IL-12 p40 defects, IL-12 receptor defects, and TYK2 defects, antimicrobial therapy and IFN- γ treatment are often sufficient to treat invasive mycobacterial infections and to prevent future infections. For patients with the more severe, autosomal recessive IFN- γ receptor defects, IFN- γ supplementation provides no benefit and HSCT is warranted.^{103, 104}

Susceptibility to Hemophagocytic Lymphohistiocytosis and Severe Epstein-Barr Virus Infection

Several defects affecting intracellular trafficking of vesicles and granules are associated with susceptibility to hemophagocytic lymphohistiocytosis (HLH). This group includes some phenotypes that are quite distinctive including Chédiak-Higashi (CHS) and Griscelli (GS) syndromes, which are both associated with a partial oculocutaneous albinism. Patients with CHS have pyogenic infections and periodontitis; their neutrophils have reduced chemotaxis and contain giant inclusion bodies (lysosomes). Patients with GS also have neurologic defects ranging from developmental delay to fatal neurodegeneration. Their neutrophils are dysfunctional, but they lack the giant granules of CHS. In vitro tests show low natural killer cell and cytotoxic cell function. CHS, GS, and X-linked lymphoproliferative syndrome (XLP) share susceptibility for HLH, an accelerated inflammatory process that in the case of XLP may be triggered by EBV. The genes responsible for these syndromes are LYST, RAB27A, SH2D1A, and XIAP/BIRC4, respectively, whereas genes for a further group of proteins (Perforin, Munc 13-D, and Syntaxin 11) are associated with familial hemophagocytic lymphohistiocytosis.¹⁰⁵

Toll-like Receptors and Innate Signaling Pathway Defects

The Toll-like receptors are a family of at least 10 pattern recognition receptors that are expressed in varying combinations on a broad array of immune and nonimmune cells. They recognize particular types (patterns) of molecules derived from pathogens (e.g., bacterial lipopolysaccharide, flagellin, mannan, CpG dinucleotides, viral dsDNA, etc.). Triggering of Toll-like receptors activates intracellular signaling pathways, many of which converge on a common pathway utilizing the IRAK proteins and MyD88, which in turn activate the I κ B kinase complex (NEMO/I κ K α /I κ K β), ultimately leading to phosphorylation and degradation of I κ B α and activation of the NF- κ B transcription factor complex.

Mutations in TLR signaling pathways have now been associated with major infectious susceptibilities: mutations in IRAK4 and MyD88 have been identified in patients with susceptibility to invasive pyogenic bacterial infections including particularly *S. pneumoniae*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*. Interestingly, patients with IRAK4 or MyD88 deficiency tend to have problems with invasive pyogenic bacterial infections in childhood but these subside over time, presumably as a result of the adaptive immune response covering for this innate defect. Mutations in TLR3, TRIF, TRAF3, and UNC-93B have been identified in patients with susceptibility to herpesvirus encephalitis. Defects in NEMO and I κ B α also cause susceptibility to infections with pyogenic bacteria and mycobacteria and are associated with an anhydrotic ectodermal dysplasia phenotype. The severity of immunodeficiency and ectodermal dysplasia is quite variable and depends on the specific mutation that is present.¹⁰⁶

Chronic Mucocutaneous Candidiasis Syndromes

Chronic mucocutaneous candidiasis (CMC) is a clinical syndrome associated with chronic and recurrent candidal infections of mucosae, particularly oral and vaginal, together with nailbed infections but generally without systemic infection. CMC can occur in isolation or as part of a broader clinical syndrome such as in APECED (autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy). Recent discoveries have determined that in almost all cases, CMC is associated with abnormalities in development of Th17 effector T cells or with the production of, or responses to, the cytokine IL-17. These include autosomal recessive mutations in IL-17F or the IL-17 receptor α -subunit, dominant loss-of-function mutations in STAT3, and dominant gain-of-function mutations in STAT1.¹⁰⁷

Recently, the CMC associated with APECED was found to be the result of autoantibodies to IL-17 and IL-22.^{108, 109} APECED is caused by mutations in AIRE1, a nuclear protein that regulates the expression of self-antigens by thymic medullary epithelial cells where it plays a role in T-cell selection and maturation. Other features of this disorder include endocrinopathies (hypoparathyroidism, adrenal insufficiency, and diabetes), alopecia areata, nail dystrophy, and vitiligo.

Autoimmune Lymphoproliferative Syndrome

The clinical phenotype of autoimmune lymphoproliferative syndrome (ALPS) is characterized by massive lymphadenopathy and hepatosplenomegaly in most cases. In addition, patients have problems with recurrent episodes of autoimmune hemolytic

P.1356

anemia and thrombocytopenia. The defects that have been identified in patients with this group of disorders are all associated with abnormalities in lymphocyte apoptosis. These include FAS (CD95), Fas ligand (FASL), FADD, caspase 10 (CASP10), NRAS, and KRAS. Peripheral blood T- and B-cell counts are generally normal, but in almost all cases, there is an increased percentage of $\alpha\beta$ -TCR⁺ double-negative T cells that lack expression of both CD4 and CD8. A predisposition to developing lymphoid malignancies has been described in ALPS but is thought to be primarily in those patients who have mutations in the death domain of FAS. In addition to elevated double-negative T cells, patients with ALPS frequently have elevated levels of IL-10 and vitamin B12 in the blood, which can be valuable diagnostically in patients with suspected ALPS. Patients with mutations in caspase 8 (CASP8), were previously classified as ALPS but are now considered to have a unique syndrome that may include lymphadenopathy and splenomegaly, but recurrent respiratory tract infections and mucocutaneous herpesvirus infections are prominent, both unusual features in ALPS.^{110, 111}

Note: The laboratory evaluation for immunodeficiency should be individualized to each patient's clinical presentation.

A variety of immunosuppressive therapies have been tried in ALPS to control the recurrent autoimmune cytopenias and severe hepatosplenomegaly. Most of these were only modestly successful as was splenectomy. Recent studies have, however, demonstrated a dramatic response to rapamycin therapy in many patients with ALPS, often causing shrinkage of the lymph nodes and spleen back to their normal size.^{112, 113}

BASIC LABORATORY WORK-UP FOR IMMUNE DEFICIENCY

A basic laboratory work-up to screen for significant defects in each of the four major compartments of the immune system can be done by most practitioners prior to making a referral to a clinical immunologist for further detailed

evaluation. In simple terms, this work-up should include evaluation of numbers and function for each of the four immune system compartments. A recommended work-up using this approach is outlined in Table 63.3.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME

Human immunodeficiency virus (HIV) infection is a true pandemic, an infection that affects individuals in every country of the world.¹ A diagnosis of acquired immunodeficiency syndrome (AIDS) is made when a person with HIV infection progresses to develop severe immunodeficiency as demonstrated by a CD4 lymphocyte count of less than 200/ μ l or the development of specific AIDS-associated diseases.² The first cases of AIDS were described in 1981 in five young gay men in Los Angeles.³ Since the beginning of the HIV pandemic, an estimated 70 million people worldwide acquired HIV infection and over half of them died.¹ Currently, an estimated 34 million people are living with HIV infection, with over two thirds of them living in sub-Saharan Africa. There are an estimated 1.1 million people currently living with HIV infection in the United States.⁴ The development of effective antiretroviral treatment in 1996 changed the natural history and clinical course of HIV infection dramatically, with remarkable decreases in HIV-associated illnesses and deaths.⁵ In parallel, many of the hematologic complications of HIV infection also occur much less commonly today. Cytopenias due to HIV disease or its treatment occurred frequently in the past, but now are uncommon. Coagulation abnormalities occur occasionally. Hematologic malignancies remain an important challenge, even in the setting of effective HIV treatment. This chapter discusses HIV infection and the diagnosis and management of associated hematologic complications. A complete discussion of antiretroviral therapy and opportunistic diseases can be found elsewhere.^{6, 7, 8}

Background

HIV-1 was discovered by two independent groups in 1983 to 1984.⁹ A related virus, HIV-2, was discovered in 1986, but remains localized to Western Africa and countries with historic ties to Western African countries.¹⁰ HIV is transmitted most commonly worldwide by sexual contact and also by intravenous drug use, transfusion of infected blood or blood products, and perinatally from an infected mother to her child. HIV may be transmitted by infected blood, blood products, bloody fluids, or genital secretions, but not by saliva, sweat, urine, other nonbloody fluids, or feces. In the absence of HIV treatment, the time from initial HIV infection to the development of severe immunodeficiency and AIDS is approximately 10 years.¹¹ The U.S. Centers for Disease Control and Prevention define AIDS in individuals who are HIV-1 antibody positive with a CD4 cell count <200/ μ L (regardless of symptoms) or have one of ~25 AIDS-defining illnesses, including opportunistic infections and malignancies.² Effective antiretroviral therapy changes the natural history of the disease and prevents HIV disease progression and prolongs survival.

Pathophysiology

HIV-1 is a retrovirus with a genome that contains the structural genes gag, pol, and env that code for viral core proteins that control viral replication (e.g., HIV reverse transcriptase, HIV integrase, and HIV protease), as well as the envelope glycoproteins, gp 160, 120, and 41.¹² Additional regulatory genes, rev and tat, code for viral-specific proteins that control viral transcription and processing of viral messenger RNA. Other viral genes mediate infectivity and interactions with the host cell (nef, vif, vpr, vpu).

HIV entry is the first step in HIV-1 infection and consists of three substeps: CD4 receptor binding, co-receptor binding, and membrane fusion.¹³ In the first substep, the viral outer membrane glycoprotein, gp120, binds to the CD4 receptor on the surface of the target cell. Cells that express CD4 receptors include the CD4 lymphocyte, macrophages, and dendritic cells. Following binding of gp120 to the CD4 receptor, gp120 undergoes a conformational change and allows binding to a second co-receptor, the chemokine receptor, either CCR5 or CXCR4.¹⁴ Individuals who lack the gene that codes for the

CCR5 receptor are relatively resistant to HIV infection; individuals who are heterozygotes for this gene demonstrate a slower progression of HIV disease.¹⁵ Following binding to the co-receptor, gp120 undergoes a second conformational change that allows a second HIV membrane glycoprotein, gp41, to bind and attach to the cell surface and then allows the viral membrane to fuse with the host cell membrane.

After HIV entry, the contents of the viral particle, including viral RNA and viral proteins, are extruded into the cytoplasm of the target cell. Viral RNA is transcribed to complementary viral DNA by the viral specific enzyme, HIV reverse transcriptase. The viral DNA forms a double-stranded complex that migrates to the nucleus of the cell where the viral-specific protein HIV integrase inserts the viral DNA randomly into the host cell genome. An HIV-infected CD4 lymphocyte may enter a latency period that can extend to 70 years, constituting a long-lived viral reservoir.¹⁶ The latently infected cell may be activated, and then genomic DNA along with incorporated viral DNA is transcribed to viral RNA that is translated to viral proteins, including gag and pol gene products that assemble at the surface of the cell and then bud off into new viral particles. Post-budding, precursor viral proteins are cleaved by another viral-specific enzyme, HIV protease, in a step that is required for viral maturation and infectiousness.¹⁷ A single latently infected cell can produce hundreds to thousands of virions. When enough viral particles have budded off from an infected cell, the membrane becomes compromised and cell death occurs.

The characteristic decrease in CD4 lymphocytes over the course of untreated HIV disease occurs from a combination of increased apoptosis and decreased lymphopoiesis, although this is not completely understood.¹⁸ An estimated one million latently infected CD4 lymphocytes exist in an HIV-infected individual with controlled infection on antiretroviral therapy.¹⁹ Although the relative number of latently infected CD4 cells is small, apoptosis may occur in uninfected CD4 cells. Untreated HIV infection also was recognized early on to be associated with immune activation, CD8 cell dysfunction, B-cell dysfunction and impaired antibody production and general immune dysregulation.^{20, 21}

Diagnosis

The U.S. Centers for Disease Control currently recommend routine HIV testing for all individuals aged 13 to 64, not based on risk.²² Standard HIV testing detects HIV-1 antibody by using a screening test, a repeatedly positive enzyme-linked immunosorbent assay (ELISA), followed by a confirmatory test, a Western blot that demonstrates at least two among three major HIV-1-specific bands: p24, gp41, and gp120/160.²³ False-positive ELISA may occur because of the low specificity of the test. False-negative HIV antibody tests can occur due to the window period (4 to 6 weeks), the

P.1359

time between viral infection and the development of the detectable antibody response.

Newer rapid tests use a technology similar to the ELISA to detect HIV antibody in blood or oral fluids and results are available within 20 minutes. Although the rapid test is very specific (>99%) with a high positive predictive value (≥90%), a positive rapid test must be confirmed by a conventional confirmatory Western blot.²⁴ Some rapid tests are now CLIA-waived and may be performed in nonhealth care settings (e.g., street fairs, mobile vans or even self-administered at home) allowing more widespread testing.

Another method of HIV testing detects the virus directly, either the viral p24 antigen or HIV RNA, and reduces the window period: p24 antigen testing was added to the standard HIV antibody ELISA test, the so-called 4th generation ELISA test, to detect HIV infections earlier.²⁵ Nucleic-acid-based testing has been used both in individual cases and in blood bank screening programs.²⁶ Using these newer tests along with pre-transfusion screening, the risk of acquiring HIV infection through a blood transfusion in the United States is less than 1 per 1.5 million units transfused and is decreasing.²⁷

Clinical Features of Hiv-1 Infection

Acute HIV infection can present as a nonspecific illness characterized by fever, oral ulcers, and maculopapular rash²⁸; however, at least 50% of newly infected individuals may be completely asymptomatic. The clinical illness will subside over several weeks and then the patient enters an asymptomatic phase, often with nonspecific generalized lymphadenopathy, that may last years as the CD4 lymphocyte count gradually declines over time. HIV-related diseases occurring at higher CD4 counts (>300/ μ L) include those caused by more aggressive pathogens (e.g., tuberculosis, herpes zoster, and pneumococcal pneumonia) as well as Kaposi's sarcoma. As the CD4 cell count declines below 300, other HIV-related illnesses also occur, including oral hairy leukoplakia, oral thrush, and seborrheic dermatitis. As the CD4 cell count declines below 200, the case definition of AIDS is met and AIDS-defining illnesses may also occur including *Pneumocystis jirovecii* (formerly *carinii*) pneumonia, central nervous system (CNS) toxoplasmosis, and cryptococcal meningitis. Multiple opportunistic illnesses can occur simultaneously in a single patient.

Hematologic disorders such as leucopenia, anemia, immune and thrombotic thrombocytopenia, bone marrow failure, coagulation disorders including thrombosis, and malignancies all occurred commonly in HIV-infected individuals.^{29, 30} Some of these complications were due to viremia and immune dysregulation, and others were due to toxicity from HIV therapies.³¹ With the development of effective antiretroviral therapy, hematologic disorders and HIV-associated malignancies have decreased markedly.³²

Treatment

In the 1980s and early 1990s, the average life expectancy of a patient with AIDS was less than 1 year. Today, it is estimated that an individual diagnosed with HIV infection and appropriately managed with antiretroviral treatment will live close to the average life expectancy of the general population.³³ Antiretroviral therapy changes the natural history of HIV infection by inhibiting viral replication. Currently, there are 27 U.S. Food and Drug Administration-approved unique drugs for the treatment of HIV infection; combination regimens with 3 or more drugs are standard treatment. Current U.S. HIV treatment guidelines recommend starting antiretroviral therapy in all HIV-infected individuals, regardless of symptoms, HIV viral load, or CD4 cell count.⁶ The life cycle of the virus and the specific sites targeted by antiretroviral therapy are shown in Figure 64.1.

The oldest mechanistic classes of drugs are the HIV reverse transcriptase inhibitors of two kinds, the nucleoside analogs and the nonnucleoside analogs. The nucleoside analogs mimic the structures of the four DNA bases and when bound to the active site and incorporated into the elongating viral DNA, result in chain termination: adenosine analogs, didanosine (ddI) and tenofovir (TDF); cytosine analogs, emtricitabine (FTC), lamivudine (3TC), zalcitabine (ddC); guanine analog, abacavir (ABC); and thymidine analogs, stavudine (d4T) and zidovudine (AZT, ZDV). The nonnucleoside analogs also inhibit the HIV reverse transcriptase enzyme, but do so by binding a site remote to the active site and include delavirdine (DLV), efavirenz (EFV), etravirine (ETR), nevirapine (NVP), and rilpivirine (RPV).

In the mid-1990s, the third antiretroviral drug class was approved, the HIV protease inhibitors that target a step late in the viral life cycle. Following budding of the viral particles from the infected cell, viral precursor proteins must be chemically cleaved by the viral-specific enzyme, HIV protease. These compounds were the most potent known against HIV and when used in combination regimens resulted in suppression of HIV RNA levels and dramatic decreases in morbidity and mortality.⁵ The 10 approved protease inhibitors bind in the active site of the protease and block this cleavage: amprenavir (APV) and its prodrug fosamprenavir (FPV), atazanavir (ATV), darunavir (DRV), indinavir (IDV), lopinavir (LPV), nelfinavir (NFV), ritonavir (RTV), saquinavir (SQV), and tipranavir (TPV).

The three newer mechanistic classes of approved HIV drugs are two different HIV entry inhibitors and the HIV integrase inhibitors. The approved chemokine receptor antagonist is maraviroc (MVC) that binds to the host cell CCR5 receptor and prevents viral binding. The approved HIV fusion inhibitor is a small peptide, enfuvirtide (ENF, T-20) that targets the viral glycoprotein gp41 and prevents fusion of the viral and cellular membranes; as a

P.1360

peptide it requires twice-daily subcutaneous dosing and is used uncommonly. Raltegravir (RAL) and elvitegravir (EVG) inhibits the viral-specific enzyme HIV integrase that inserts the viral DNA into the host cell DNA.

FIGURE 64.1. The human immunodeficiency virus (HIV) life cycle, deciphered with the help of genomic analyses, is unusually complex in its details, but all viruses undergo the same basic steps to infect cells and reproduce. Points at which antiretrovirals act are marked.

Current treatment guidelines recommend four preferred combination antiretroviral regimens on the basis of potency, tolerability, and convenience⁶: (1) tenofovir/emtricitabine/efavirenz (co-formulated as a single pill taken once daily); (2) tenofovir/emtricitabine (co-formulated) + atazanavir and ritonavir (given as a low-dose pharmacologic booster; 3 pills once daily); (3) tenofovir/emtricitabine (co-formulated) + darunavir and ritonavir (booster; 3 pills once daily); and (4) tenofovir/emtricitabine (co-formulated) + raltegravir (3 pills divided twice daily). The goal of current HIV treatment is maximal virologic suppression; current virologic suppression rates on initial therapy regimens approach 90%. CD4 cell counts typically increase 100/ μL over baseline in the first weeks or months following initiation of therapy and then continue to increase at a slower rate.³⁴ The reconstituted CD4 cells generally are of the memory type (CD45RO⁺ or CD34RA⁺), with naïve cells increasing more slowly; thymic function also improves. Immune reconstitution may result in IRIS, the immune-related inflammatory syndrome that is usually managed symptomatically.³⁵ Appropriate increases in CD4 cell counts allow discontinuation of opportunistic maintenance therapy and prophylaxes. Specific immune-based

therapies, including interleukin-2, have failed to demonstrate additional clinical benefits and are not recommended currently.³⁶

An HIV-infected individual who is stable taking antiretroviral therapy will typically see the treating physician every 3 to 6 months to check for side effects and monitor the HIV RNA and CD4 cell count.⁶ In the case of virologic failure, drug resistance testing is performed and a new regimen selected on the basis of treatment history, drug resistance testing results, and available drug options. The goal is to construct a regimen with 2 to 3 fully active drugs and this will result in resuppression of HIV RNA in the majority of patients. HIV therapy currently is lifelong. Treatment interruptions are associated with clinical events³⁷ and should be avoided.

Several ongoing challenges remain in the management of HIV disease. Despite suppression of virologic replication, some patients experience ongoing inflammation and immune activation and this has been linked to nontraditional HIV illnesses such as cardiac, hepatic, renal, neurologic, and non-AIDS malignancies. In addition, despite dramatic improvements in life expectancy, cure of HIV disease remains elusive. The unique case of a man with HIV disease virologically controlled on antiretroviral therapy who developed acute myelogenous leukemia necessitating totalbody irradiation, cytotoxic chemotherapy, and bone marrow transplant from a donor with a deletion in the gene coding for the CCR5-receptor who ultimately experienced a course complicated by rejection and a second transplant is thought to be the only patient cured successfully of HIV disease.³⁸ Cure, or complete eradication of HIV, remains challenging because of the long-lived latently infected CD4 cell reservoir; much current research is focused on this goal.³⁹

HEMATOLOGIC COMPLICATIONS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Anemia

Anemia is the most frequent cytopenia observed in HIV-1 infection. Striking anemia with transfusion dependence was common early in the epidemic when high doses of zidovudine (ZDV) were in use, but severe depression of hemoglobin levels are now rarely observed, except in patients with advanced disease.⁴⁰ In several large multicenter studies, persistent anemia was associated with shorter survival, independent of the degree of immunosuppression.^{41, 42}

As in other persons, anemia occurs due to one of three major factors: either ineffective hematopoiesis; blood loss due to involvement of the intestines by infection such as cytomegalovirus (CMV) or Kaposi's sarcoma; or red blood cell destruction.

Red blood cell production can be affected by HIV itself due to cytokines that interfere with hematopoiesis,^{43, 44, 45} highly active antiretroviral therapy (HAART) and medications used to treat HIV-associated infections (Table 64.1 including high-dose trimethoprim-sulfamethoxazole (TMP-SMX) for *P. carinii* pneumonia and ganciclovir for CMV), HIV-associated cancers such as lymphomatous infiltration of the marrow, low erythropoietin, or HIV-associated hypogonadism.⁴⁶

The Effect of HAART on Anemia

Nucleoside analogs other than ZDV are not associated with anemia. Zidovudine is commonly associated with marrow toxicity, particularly with long-term administration. Use of lower ZDV doses in combination with other nonmyelosuppressive antiviral drugs (such as the protease inhibitors or other nucleoside analogs) has significantly decreased the frequency of anemia, although patients with advanced disease on doses of ZDV of <500 mg/day still demonstrate significantly decreased hemoglobin levels when compared to similarly immunosuppressed HIV-infected patients not taking the drug.⁴⁷ Although the mechanism responsible for ZDV-associated anemia, inhibition of thymidine kinase, and DNA chain termination should theoretically also affect cells of other lineages, neutropenia is less frequent a toxicity and thrombocytopenia is very uncommon. In contradistinction to zidovudine, protease inhibitors, such as indinavir, ritonavir, crixivan, and nelfinavir, alone or in combination with ZDV or other nucleoside

P.1361

analog, have little or no effect on hematopoiesis.^{31, 48} It is important to note that HAART itself improves anemia as shown in a single center retrospective series in the HAART era. HAART was associated with hemoglobin levels >140 g/L in 42% of patients, irrespective of use of zidovudine as part of HAART regimen, compared with 31% of patients who did not use HAART.⁴⁹

TABLE 64.1 HEMATOLOGIC TOXICITIES OF ANTIRETROVIRAL DRUGS

Medication	Type of Activity	Hematologic Toxicity
Zidovudine	Nucleoside analogs,	Anemia, neutropenia (dose dependent)

	antiviral	
Stavudine	Nucleoside analogs, antiviral	Anemia, neutropenia (dose dependent)
Ganciclovir	Cytomegalovirus infection	Leukopenia, thrombocytopenia
Trimethoprim/sulfamethoxazole	Antibiotic, <i>Pneumocystis pneumonia</i>	Dose-related neutropenia, anemia; methemoglobinemia especially in persons with G6PD deficiency
Primaquine	Antibiotic, <i>Pneumocystis pneumonia</i>	Rare agranulocytosis, thrombocytopenia; methemoglobinemia especially in G6PD deficiency
Pentamidine	<i>Pneumocystis pneumonia</i>	Infrequent anemia, leukopenia, thrombocytopenia
Sulfadiazine	Toxoplasmosis	Leukopenia in 40%; thrombocytopenia in 12%
Clindamycin/pyrimethamine	Toxoplasmosis	Cytopenias in 31%
Amphotericin B	Antifungal, cryptococcal meningitis	Anemia

G6PD, glucose-6-phosphate dehydrogenase.

Treatable causes of anemia include nutritional/vitamin deficiency, gastrointestinal losses, parvovirus B19 infection,^{50, 51} HIV related kidney disease, and low erythropoietin levels independent of normal renal function. In HIV infection, erythropoietin levels are low in some patients, in part because tumor necrosis factor- α (TNF- α) acts to block erythropoietin release in response to low hemoglobin levels.⁵² Patients with low erythropoietin levels respond better to its administration than do patients with normal or elevated levels of the hormone. In one meta-analysis, patients with erythropoietin levels below 500 IU/L demonstrated significant increases in hemoglobin levels, decreases in transfusion requirements, and improvement in quality of life, whereas replacement was ineffective in patients with high erythropoietin levels.⁵³

Some patients with HIV infection have significant anemia, requiring frequent transfusion. Clinical and experimental evidence suggests transfusion may be associated with substantial morbidity in HIV-infected patients. In one study, transfused patients with advanced disease had an increased incidence of CMV infection and death.⁵⁴ Laboratory data suggest transfusion may be associated with HIV viral activation. Allogeneic lymphocytes present in transfused blood components activate viral production by HIV-infected lymphocytes in vitro.⁵⁵ When quantitative polymerase chain reaction (PCR) was used to measure circulating HIV, viral load was increased in HIV-infected patients 5 days after transfusion.⁵⁶ However when leuko-depleted blood components were used, no significant differences in viremia or infectious complications occurred.⁵⁷

Red Blood Cell Destruction

Red blood cells can be destroyed in the setting of HIV infection through a variety of mechanisms. This includes autoimmune disease,⁵⁸ hemophagocytic syndrome, disseminated intravascular coagulation typically seen with infection or cancer, sulfa use in the setting of G6PD deficiency, or thrombotic thrombocytopenic purpura (TTP) (dealt with separately below). Drugs can also cause hemolysis.

Parvovirus is a rare, but treatable cause of anemia. Parvovirus affects erythroid lineage cells. In immunocompetent patients this is a self-limited infection, but is serious in patients who cannot clear the infection, or have other hemolytic problems. For parvovirus infection, commercial immune globulin infusion (400 mg/kg/day for 5 to 10 days) is almost always associated with marked improvement in hemoglobin levels with resolution of anemia.^{51, 59} HIV-infected patients frequently develop repeated episodes of B19 infection and need repeated treatments with intravenous immune globulin.⁶⁰

Thrombocytopenia

Thrombocytopenia occurs in the setting of HIV infection due to decreased production, increased destruction, or splenic sequestration secondary to other causes such as lymphoma or hepatitis C. Although mild to moderate thrombocytopenia is common in patients with HIV, it is rarely associated with bleeding. Thrombocytopenia is generally associated with decreased platelet survival, except in patients with advanced disease where bone marrow failure is more prominent.⁶¹ Opportunistic infection, splenomegaly, and fever all decrease platelet survival.

Autoimmune thrombocytopenia (ITP) is a feature of HIV infection and is a diagnosis of exclusion. Notably, patients can present in advance of other symptoms of HIV. Consequently, HIV should be ruled out in new cases of ITP. CD4⁺ lymphocyte counts in reported series of patients with HIV-ITP have averaged between 0.3 and 0.6 × 10⁹/L.

Although platelet-associated antibodies increase in prevalence with HIV disease progression, it is not clear if they play a major role in most patients. Technical difficulties in detecting platelet-associated antibody have led to a very high false-positive rate.⁶² Furthermore, for any condition (including sepsis and TTP) associated with platelet injury, antibody can be detected on the platelet surface. Specific platelet-associated antibody has nonetheless been carefully characterized in a limited number of patients. One study demonstrated that platelet-associated immune complexes are made up of antiplatelet integrin, glycoprotein IIIa (β3), antibody (Ab), and its anti-idiotypic blocking Ab.⁶³ Some of the antibodies also bound epitopes with homology to HIV-1 proteins nef, gag, env, and pol, suggesting molecular mimicry. The presence of this Ab was associated with thrombocytopenia and produced thrombocytopenia when infused into mice.⁶⁴ The associated platelet fragmentation was due to generation of the membrane-damaging peroxide and other reactive oxygen species. Antibodies to a cleavage product of talin, which can be generated by platelet activation or exposure to HIV-1 protease, have also been characterized. These may result from an immune response to talin-H, a neoantigen that may have been created by platelet fragmentation.⁶⁵

Defective megakaryocytopoiesis may also contribute to thrombocytopenia, particularly in patients with advanced disease. Megakaryocytes can be infected with certain strains of HIV, some of which can be cytopathic for the megakaryocytes.⁶⁶ In addition, megakaryocytes arising from HIV-1-infected CD34⁺ progenitor cells are defective in their ability to produce platelets.⁶⁷

Treatment

Generally, patients with modest thrombocytopenia (platelet count >50 × 10⁹/L) require no treatment. For others with clinically significant thrombocytopenia, short-term steroids produce rapid responses in 60% to 80% of patients. However, steroids are immunosuppressive and are associated with long-term infectious complications and can accelerate the development of Kaposi's sarcoma. HIV-specific antiretroviral therapy will result in improvements of platelet counts in most patients. Although most of the original work was done with ZDV, other antiretrovirals are effective. Both antiretroviral agents and steroids improve thrombocytopenia by increasing platelet production, without significantly affecting platelet survival.^{68, 69} Splenectomy will increase platelet counts in those not responding to antiretroviral therapy and does not appear to accelerate the underlying HIV disease.⁷⁰ Intravenous immune globulin also is effective but its high cost, limited availability, and short duration of action make this a less attractive treatment. Anti-Rh immune globulin has the advantages of wide availability and cheaper cost, but is also limited by its short duration of action⁷¹ and is associated with a mild hemolysis which can be clinically problematic in patients with pre-existing anemia, requiring transfusion prior to administration of anti-Rh immune globulin. Vincristine is effective when given monthly, although its administration is complicated by neuropathy. IL-11, a cytokine that promotes megakaryocyte maturation, is licensed for treatment of chemotherapy-related thrombocytopenia, but no studies have reported efficacy in HIV-infected patients. Rituximab is effective in some patients with idiopathic thrombocytopenic purpura (ITP) without HIV but has not been studied extensively in patients with HIV infection⁷² for this indication. Three newer treatments for ITP in the general population include the anti-B cell antibody rituximab, effective in 60% of patients, and the thrombopoietin mimetics, romiplostim and eltrombopag, each associated with a 60% to 85% response.⁷³ Remarkably, these drugs have not been systematically studied in HIV-associated ITP.

P.1362

Neutropenia

Mild neutropenia is relatively common in patients with HIV infection. Although generally not of clinical significance, a deficiency in bone marrow reserve may become clinically apparent when administration of cytotoxic chemotherapy or other marrowsuppressive drugs becomes necessary. In fact it is generally held that most cytotoxic chemotherapy requires prophylactic use of hematopoietic growth factors. Antineutrophil antibodies can frequently be seen,⁶² but their presence

does not correlate with the degree of neutropenia. Progenitor cell numbers are generally normal except in patients with advanced disease when they are modestly decreased.⁷⁴ Parenteral treatment with ganciclovir (GCV) or cytotoxic chemotherapy results in leukopenia in the majority of patients, frequently necessitating dose reduction and cytokine treatment.

Treatment

Neutropenic (absolute neutrophil count, $<1.0 \times 10^9/L$) HIV-positive patients may experience increased frequency of significant bacterial infections. In a case-controlled study, Tumbarello et al.⁷⁵ compared the neutrophil counts of groups of HIV-infected patients with and without bacteremia. An absolute neutrophil count of $<1.0 \times 10^9/L$ as present in 38% of bacteremic patients was compared with 19% of asymptomatic patients. A matched cohort study⁷⁶ found the frequency of bacteremia increased in neutropenic patients to 12.60 events per 100 patient months compared with 0.87 events per 100 patient months in the nonneutropenia controls. In another study of 1,645 patients with an absolute neutrophil count of $<0.5 \times 10^9/L$ the risk of Gramnegative infection increased eightfold.⁷⁷

A number of studies have looked at the effect of recombinant growth factors on the incidence of infection and number of hospitalizations. Granulocyte colony-stimulating factor (G-CSF) enhances the proliferation and differentiation of neutrophils and improves neutrophil function, whereas granulocyte-macrophage colony-stimulating factor (GM-CSF) stimulates the proliferation and differentiation of a variety of myeloid progenitor cells and inhibits migration of neutrophils, enhancing the function of mature neutrophils and macrophages.^{71, 78} G-CSF is the most widely used hematopoietic growth factor in HIV-infected patients, has fewer side effects, and increases the neutrophil count more rapidly. Although GM-CSF has been associated with an increase in HIV-1 replication in vitro, no consistent observation of acceleration of disease progression or increase in p24 antigen levels in patients receiving the drug has been demonstrated. G-CSF is primarily used to increase the tolerance of patients undergoing chemotherapy.

HIV-infected patients can also have a number of defects in neutrophil function. These include reduced L-selectin shedding and decreased H_2O_2 production⁷⁹ as well as defects in leukocyte migration, chemotaxis, and chemiluminescence during phagocytosis. These defects were more prominent in patients with advanced disease.⁸⁰ G-CSF and GM-CSF both improve leukocyte function in vitro. A number of studies have looked at potential benefits of these cytokines in animal models of immunosuppression. In a murine model of *Pneumocystis jiroveci* pneumonia, CD4⁺-depleted immunosuppressed mice that received G-CSF after experiential pulmonary infection with *P. jiroveci* demonstrated improved survival when compared with control mice receiving placebo. Similar benefits were demonstrated using mouse models of disseminated *Mycobacterium avium* infection, systemic candidiasis, and streptococcal pneumonia.⁸¹ No clinical study using either G-CSF or GM-CSF to enhance leukocyte function has been performed.

Lymphopenia

Increases in both CD4 and CD8 cell death and impairment in function are the sine qua non of HIV infection. IL-2 partially corrects the impaired lymphocyte proliferation and cytotoxicity seen in HIV infection in vitro. It also can partially block the enhanced tendency of lymphocytes obtained from HIV-infected patients to undergo programmed cell death (apoptosis).³⁸ In phase I trials of IL-2 in HIV-infected patients, it increased CD4 cell number and improved lymphocyte function.⁸² The development of a longacting polyethylene glycol-modified IL-2, which increases the half-life by 10- to 15-fold, allows for intermittent administration of the drug. Administration of doses of 1 to 5 million U/m², two to three times weekly, resulted in modest but sustained increases in CD4 counts and improvement in natural killer activity in a patient with CD4 counts $>0.4 \times 10^9/L$ ⁸³ in 3 to 6 months. Fever, rash, and capillary leak are the most common toxicities.⁸⁴ More recently, administration of very high doses of IL-2 (7.5 million IU twice daily to patients with early HIV infection) resulted in substantial increases in CD4 counts, compared with those seen in the group administered lower doses (1.5 million IU twice daily).⁸⁵ Of greater importance is the suggestion that intermittent administration of IL-2 in combination with HAART may lead to reduction in CD4⁺ T-lymphocyte cells that contain replication-competent HIV.⁸⁶ None of these approaches is currently standard of care.

Thrombotic Thrombocytopenic Purpura

TTP is more common among patients with HIV infection. HIV-1 infection has been reported to account for up to 30% of TTP/hemolytic-uremic syndrome.⁸⁷ The risk of microangiopathy has declined significantly after institution of HAART for unclear reasons.⁸⁸ Although no controlled studies comparing HIV-related TTP with classic TTP have been conducted, HIV-related TTP is generally thought to be associated with a milder course and a better response to therapy than classic TTP.⁸⁹

A number of different possible pathophysiologic mechanisms have been proposed. HIV can infect endothelial cells, and viral p24 antigen has been detected by immunochemical stain in splenic endothelial cells, spinal cord specimens, and bone marrow microvascular endothelial cells.⁹⁰ Whether infection results in vascular dysfunction has not been clearly

demonstrated. TNF- α and IL-1 β , two cytokines that are increased in HIV infection, could potentially lead to increases in endothelial expression of certain adhesion molecules, such as vascular cell adhesion molecule-1, intercellular adhesion molecule, and E-selectin, promoting localization of inflammatory cells to the endothelium with transmigration of lymphocytes through the endothelial wall. CMV, a virus that appeared to be associated with TTP in one large AIDS Clinical Treatment Group drug study, increases procoagulant activity in cultures of endothelial cells, potentially by binding and activating coagulation factor X/Xa.⁹¹ Endothelial cells from small vessels undergo apoptosis when exposed to plasma from patients with TTP.^{91, 92, 93} Recently, severe ADAMTS13 (a disintegrinlike and metalloprotease with thrombospondin type 1 repeats) deficiency has been reported in TTP unassociated with HIV.⁹⁴

Treatment

Although the treatment of choice of TTP is plasmapheresis or plasma exchange, successes with antiplatelet agents, vincristine, splenectomy, and plasma infusion have been reported.⁹⁵ In one study of HIV-TTP, most patients undergoing plasma exchange in addition to other therapies achieved a complete response.⁸⁹ Others have reported significant responses in patients receiving plasma infusions alone.⁹⁶ Plasma exchange may allow infusion of greater amounts of plasma to the individual. However, the success of infusion alone has important implications for those in the developing world where plasma exchange is not available.⁹⁶ Plasma exchange is currently recommended to replace 35 to 40 ml/kg per exchange using the lactate dehydrogenase (LDH) values and platelet counts to follow the course of the disease. A

P.1363

platelet count above $50 \times 10^9/L$ and a normalized LDH are general aims of effective therapy. Platelets should not be transfused because doing so may lead to thrombotic events.

Pathophysiology of Bone Marrow Suppression in Human Immunodeficiency Virus Infection

Diverse factors responsible for impaired hematopoiesis in HIV infection include suppression of the bone marrow by the virus or by viral proteins, immune dysregulation, actual infection of the bone marrow progenitor cells by HIV, and alteration of stromal cell elements. A number of studies demonstrate that CD34 cells have both HIV receptors necessary for infection (i.e., CD4 and the chemokine receptors CXCR4 or CCR5).⁹⁷ Chemokines are cytokines that induce chemotaxis. CD4 expression, as well as CXCR4 and CCR5 co-receptor expression, increases with maturation of the CD34 cell, and the expression of each correlates with potential infectability.⁹⁸ In addition, CXCR5 may be up-regulated by a number of different cytokines. Although it is clear that the CD34 cell can be infected by HIV under a number of conditions, it appears that bone marrow progenitor cells do not represent a significant reservoir of infection.⁹⁹ In one study, HIV was detected in CD34 cells in only 14% of HIV-infected patients recruited in the United States and in 36% of HIV-infected persons in Zaire.¹⁰⁰ When found, CD34 infection was present in those patients with far-advanced disease. Many investigators could not detect HIV infection in any stem cells.^{101, 102} In another study, purified CD34⁺ cells were infected in vitro and cultured on allogeneic stroma for extended periods of time.¹⁰³ A highly sensitive PCR failed to detect HIV-1 in the most primitive long-term colony-initiating cells (i.e., the secondary colonies generated from clonogenic cells harvested from stroma). Thus, it appears that although some committed progenitor cells can be infected with HIV-1 under some circumstances, the most immature stem cells appear not to be susceptible to HIV-1 infection.

The effects of HIV-1 on colony formation have been studied, either using bone marrow cells derived from HIV-1-infected patients^{101, 104} or after in vitro infection of hematopoietic cells from bone marrow of normal donors.^{67, 101} Results have been surprisingly divergent. Although the growth potential of committed bone marrow progenitor cells in methylcellulose cultures after challenge with HIV-1 appears to be diminished, normal growth frequently has also been reported.¹⁰¹ Similar disparity exists in the results of studies performed with patient bone marrow. Such differences may be related to techniques in assaying colony growth (total bone marrow vs. purified CD34⁺ cells), culture conditions (use of specific cytokines or growth factors), or patient selection. In some reports, inhibition of colony formation by virus was only observed in cultures of total bone marrow cells and not with isolated CD34⁺ cells.¹⁰⁵ Of interest is one report of abnormal progenitor cell function in HIV-negative infants born to infected mothers,¹⁰⁶ implying that direct infection was not necessary for marrow suppression.

Marrow stromal function has been examined in patients with HIV infection. Stromal cells from some HIV-1-infected patients may be infected by the virus, demonstrating the importance of stromal infection in causing dysregulation of hematopoiesis. In one study,¹⁰⁷ decreased colony formation has been observed when stroma infected in vitro was used to support growth of normal uninfected bone marrow progenitor cells. In another study, stroma obtained from HIV-infected patients supported growth of normal CD34⁺ cells equally as well as stroma obtained from normal uninfected controls.⁷⁴

Although the stem cell compartment appears to be relatively well preserved early in the disease, in patients with low CD4 counts and history of OIs, there is a modest reduction of long-term colony-initiating cell numbers.⁷⁴ However, the long-term colony-initiating cell numbers were far better preserved in this population than in patients with aplastic anemia with similar blood counts, implying that OIs; pharmacotherapy with antiparasitic, antimicrobial, antiviral, or cytotoxic agents; vitamin deficiencies; or poorly understood virally mediated immunomodulatory changes were the major contributors to bone marrow failure in patients with advanced HIV disease.

Inconsistencies in the results of experiments attempting to demonstrate the role of direct infection of HIV-1 on hematopoiesis have stimulated further search for pathophysiologic mechanisms of bone marrow suppression. Several cytokines that are released during the course of HIV-1 infection are potent inhibitors of hematopoiesis. Not only native virus and productive infection,^{105, 108} but also viral products, such as gp120, gp160, and viral tat proteins, induce the secretion of an array of cytokines, including TNF- α , lymphotoxin- β (TNF- β), and IL-6.¹⁰⁹ Perhaps the most prominent cytokine implicated in an array of pathophysiologic reactions in AIDS is TNF- α (or cachexin).^{110, 111} In addition to its effect on body metabolism and the immune system, TNF- α has inhibitory effects on hematopoiesis.¹¹² High levels of interferon- γ (IFN- γ) were not only associated with a poor prognosis in HIV-1 infection, but also correlated with the degree of anemia.¹¹³ Although disordered cytokine production by both lymphoid tissue and bone marrow clearly occurs in HIV-1 infection, it is difficult to determine its ultimate role in suppression of hematopoiesis. Many inhibitory cytokines are produced in greatest quantities early in the course of HIV-1 infection when marrow suppression is least, and their levels decline as the disease progresses (when marrow suppression becomes most marked). In addition, increased levels of stimulatory cytokines have been observed in HIV-1 infection, and many cytokines never reach significant levels in the circulation. Local production of growth factors in bone marrow may be more important than systemically secreted factors. In support of this hypothesis, one study of genetically engineered stromal cells, designed to produce low levels of IFN- γ constitutively, showed significant suppression of normal hematopoietic colony growth on IFN- γ stroma, which could only be replicated by addition of large amounts of exogenous IFN- γ to marrow grown on normal stroma.

Apoptosis of hematopoietic progenitor cells through the Fas-L/Fas-R pathway is a mechanism by which activated T-cells can kill virus-infected cells.¹¹⁴ It is likely that Fas-L and other cytokine products of activated T-cells contribute to the hematopoietic inhibition seen in HIV-1 infection. Increased levels of Fas-L have been reported in patients with AIDS, and triggering of Fas-R on hematopoietic cells results in apoptosis.

Bone Marrow Examination in Human Immunodeficiency Virus 1 Infection

The majority of bone marrow samples from HIV-1-infected patients will exhibit morphologic abnormalities, but most are nonspecific except in OI, in which the bone marrow examination provides valuable diagnostic information. Therefore, the bone marrow examination rarely yields substantial clinical information except in the diagnosis of concurrent *M. avium-intracellulare*, tuberculosis, or fungal infection or as part of staging for malignancy.

The histopathologic findings in the bone marrow of HIV-1-infected patients are varied. In one large study of 216 bone marrow examinations performed in 178 HIV-1-infected patients for evaluation of cytopenia, 69% of patients exhibited hypercellular marrow, 69% showed myelodysplastic changes, and 20% showed significant fibrosis; only 5% of the biopsies were hypocellular. Granulomas were found in 13% and lymphoid aggregates in 36% (but in other studies, in up to 50%) of specimens. Higher numbers of plasma cells and elevated numbers of eosinophils were also present, especially in conjunction with increased reticulum. Hyperplasia involving the granulocytic and erythrocytic lineages has been most commonly reported; the myeloid-to-erythroid ratio has varied from 2:1 to 5:1.⁹⁴

P.1364

Morphologic changes tend to be more pronounced in more immunosuppressed patients and increase in frequency as disease progresses. All lineages can be involved. Megaloblastic changes and ringed sideroblasts are frequent. Using the morphologic criteria established for primary myelodysplastic syndromes, dysplasia involving at least one lineage was diagnosed in 69% of patients. Dysplastic changes increase with disease progression. However, in one study, the numbers of erythroid precursors and the morphology of megakaryocytes clearly differentiated patients with AIDS from those with myelodysplastic syndrome.⁹⁶ The cumulative effects of drug toxicities, direct HIV-1 infection of marrow cells, and dysregulated cytokine production may be responsible for the morphologic changes that occur late in AIDS. However, the dysplastic changes in an individual lineage and specific cytopenias are not correlated.

Coagulation Abnormalities

A number of retrospective epidemiologic studies^{115, 116, 117, 118, 119, 120, 121, 122, 123, 124} have found that the incidence of thrombosis in HIV-infected patients was increased two- to tenfold over what would be expected in a healthy control population of the same age. However, except for isolated cases of protein S deficiency, no study has compared these patients to equally sick uninfected patients whose immobility, lymphedema, and hypoalbuminemia predispose them to hypercoagulability. Patients with HIV are more likely to develop antiphospholipid antibodies such as lupus anticoagulant (found in 1% of patients)¹²⁵ and antiphosphatidylcholine and anticardiolipin autoantibodies antibody (found in about 50% of patients with HIV infection)^{126, 127}; however, many of these studies were performed before HAART became standard of care. Apart from diagnostic problems related to a falsely elevated partial prothrombin time, these antibodies do not appear to be associated with an increased frequency of thrombosis, as they are in uninfected patients.^{128, 129}

Increased levels of complement-binding protein 4, which attaches to protein S and renders the protein inactive, can be detected in as many as 27% to 73% of patients. These patients demonstrate decreased functional protein S when a functional assay is used to measure activity. The risk of thrombosis in these patients is substantially increased. No clear guidelines are available for treatment or other protein-S-deficient patients, but most hematologists recommend anticoagulation for an undefined period of time for those with a history of unprovoked thrombosis.

ACQUIRED IMMUNODEFICIENCY SYNDROME-RELATED MALIGNANCIES

Cancer is the leading cause of death for HIV-1-infected persons on HAART. Twenty-five to forty percent of HIV-positive patients will develop a malignancy.^{32, 33, 130, 131, 132, 133, 134, 135, 136, 137} Although Kaposi sarcoma, aggressive B-cell lymphomas, and cervical cancer are said to be AIDS defining when occurring in the setting of HIV infection and occur more frequently in HIV infection, death from non-AIDS-defining cancers is more common. The development of malignancies is related to a number of factors, including immunosuppression and concurrent infections with other viruses such as human herpes virus 8 (HHV8) and Epstein-Barr virus (EBV), or the human papillomavirus, which foster malignant transformation. These viruses carry oncogenic proteins and cytokines that contribute to malignant pathogenesis. Additionally, HIV infection reduces the ability to clear the viral infection. The SMART study demonstrated that HAART interruptions in so-called drug conservation strategies increase the risk of cancer sixfold.¹³⁸

Although the incidence of KS and certain lymphomas has decreased after HAART was introduced, the frequency of other tumors such as cervical cancer has undergone little change. CNS lymphoma, although once accounting for 18% of AIDS-related lymphomas, now is extremely rare. Several new drugs and therapies have been developed for KS and AIDS-related lymphomas, and these treatments, plus the development of HAART, have contributed to improvements in morbidity and mortality. Given the introduction of HAART and our increased ability to treat infections effectively, the life span of patients with HIV has increased, eventually leading to substantial increases in individuals living with HIV-1.¹¹⁹ One analysis projected a median life expectancy of 75 years assuming a high rate of HIV diagnosis (median CD4 cell count at diagnosis, $0.432 \times 10^9/L$), and 71.5 years with a low diagnosis rate (diagnosis only when symptomatic, median CD4 cell count $0.14 \times 10^9/L$). Cumulative risks of death by 5 and 10 years after infection were 2.3% and 5.2%, respectively.¹³⁹ This makes treating malignancies more attractive than in the pre-HAART era. Although these malignancies also occur in the HIV-uninfected population, their presentation, as well as their appropriate treatment, is quite different in the HIV-infected patient.

ACQUIRED IMMUNODEFICIENCY SYNDROME-RELATED LYMPHOMA

Non-Hodgkin lymphoma (NHL) and Hodgkin lymphoma (HL) occur with increased frequency in patients infected with HIV.¹²⁵ Approximately 10% of HIV-positive people will develop NHL, and although the incidence has greatly reduced during HAART, it is still increased 25- to 150-fold compared to the general population.^{140, 141, 142, 143} These recent studies also demonstrate the duration and depth of the CD4 nadir and the duration of viremia increase the incidence of NHL. Decreased immune surveillance, B-cell dysregulation¹⁴⁴ and, in certain subtypes, infections with HHV8 and EBV, are also involved in the pathophysiology of the disorder.

A number of changes have occurred in the HIV-related lymphomas since widespread institution of HAART. The overall incidence of HIV-associated lymphomas has declined for NHL. This decrease has primarily affected lymphomas occurring at low CD4 counts, whereas NHL occurring at higher CD4 counts has been relatively unaffected.¹⁴⁵ Among patients with systemic, AIDS-related NHL, there has been decreased high-grade histology and improved survival.^{146, 147} Three types of lymphoma are now recognized as AIDS-defining by the CDC: Burkitt lymphoma, immunoblastic lymphoma which is a subtype of diffuse large B-cell lymphoma, and primary CNS lymphoma. The World Health Organization (WHO) more recently provided a classification system for the HIV-associated lymphomas (Table 64.2; Fig. 64.2). The frequency of NHL increases with the degree of immunosuppression, particularly for CNS lymphoma. Thus CNS lymphoma is rarely seen in developed countries where HAART is available, except in socioeconomic sectors where standard of care HIV therapy is not ubiquitous. In addition, patients with poorer virologic control on HAART suffer a significantly higher incidence of

lymphoma and worse outcomes following therapy.¹⁴⁸ Some studies have suggested genetic factors play a role in the development of NHL. One study demonstrated that HIV-infected patients who are heterozygous for the CCR5D32 deletion are less likely to develop lymphoma, whereas those with stromal-cell-derived factor-1 mutations are more likely to develop lymphoma.¹⁴⁹

For patients receiving combination chemotherapy, the optimal timing of HAART with combination chemotherapy is controversial.¹⁵⁰ Many oncologists continue antiretrovirals during chemotherapy, and some temporarily discontinue them, citing fears of drug-drug interactions and increased toxicities. The latter stance has been challenged by six randomized studies in infections showing immune reconstitution occurring within the first month of HAART leading to a decrease in infection mortality.¹⁵¹ This suggests that HAART discontinuation or deferment of initiation after a concurrent HIV and lymphoma diagnosis could be detrimental. Nonetheless, in a retrospective Italian study comparing toxicities between patients receiving CHOP (cyclophosphamide, doxorubicin,

P.1365

vincristine, and prednisone) plus HAART versus CHOP or a comparable regimen without HAART, the group receiving HAART experienced greater neurotoxicity and anemia but a decreased frequency of infection.¹⁵² The differences in favor of HAART may have been due to improvements in supportive care gained during the 1990s. Moreover, with an expansion of the panoply of HAART medications, it is now possible to avoid specific HAART components to minimize drug-drug interaction. However, no controlled clinical trial has yet been performed to assess the contribution of continuing HAART therapy to improvement in viral replication and lymphoma control.¹⁵³ It is unlikely that such a study will be conducted.

FIGURE 64.2. Human immunodeficiency virus (HIV)-associated lymphomas. A: HIV-associated Burkitt lymphoma. Tumor cells show plasmacytoid differentiation, which is often associated with positivity for HIV. B: Diffuse large B-cell lymphoma, immunoblastic variants. Lymphomas with this morphology often present in advanced AIDS. C: Primary effusion lymphoma, positive for human herpes virus 8/Kaposi sarcoma herpes virus. (Contributed by Dr. Elaine Jaffe, Chief Hematopathology Section and Acting Chief Laboratory of Pathology, National Cancer Institute.)

The three main pathologic types of HIV-NHL are the Burkitt and those with Burkitt features, diffuse large B-cell lymphomas, and primary effusion lymphomas (PELs). These differ in their clinical presentations, in their underlying pathogenesis, and in their response to therapy. The majority of HIV-related lymphomas are of B-cell origin. T-cell lymphomas are rare, as are PELs, which lack B-, T-, and hematopoietic cell markers. Burkitt and lymphomas with Burkitt features usually present with widespread disease and have a risk of CNS involvement. Other less common lymphomas include polymorphic lymphoproliferative disorders resembling post-transplant-associated lymphoproliferative disease and lymphomatoid granulomatosis.

The role of viruses in the pathophysiology of HIV-related lymphomas is dependent on subtype.¹⁵⁴ For example, CNS lymphomas are virtually always associated with EBV infection, and PEL is associated with HHV8 infection. EBV encodes for a number of cytokines promoting cell growth. AIDS-Burkitt is variably associated with EBV, but also contains activating mutations in the cMYC proto-oncogene, frequent inactivation of p53, as well as point mutations in BCL-6. One study showed that loss of EBV-specific CD8⁺ T-cells in subjects progressing to EBV-related NHL correlated with loss of CD4⁺ T cells and that these cells were better preserved in equally immunocompromised patients not developing lymphoma.¹⁵⁵

Patients with HIV-NHL frequently present with advanced stage III or IV disease. The majority will present with a rapidly growing mass or the development of systemic B symptoms (i.e., fever, night sweats, and unexplained weight loss). The clinical presentation is dependent on the site of involvement. Extranodal involvement including the bone marrow (25% to 40%), gastrointestinal tract (26%), and CNS (17% to 32%) is common.

P.1366

Leptomeningeal disease may be present and detected by flow cytometry only at a higher frequency than the immunocompetent population, where it is rare, with a surprising 22% among 51 newly diagnosed patients in one study in which 11 (22%) were detected by flow cytometry and only 1 by cytology.¹⁵⁶ Involvement of the small bowel and rectum is also prevalent, particularly in those with large cell histology. Several prognostic factors predict response to therapy and overall survival including CD4 count, Karnofsky performance, age, and LDH level.¹⁵⁷

TABLE 64.2 WORLD HEALTH ORGANIZATION CLASSIFICATION OF HUMAN IMMUNODEFICIENCY VIRUS (HIV)-ASSOCIATED LYMPHOMAS¹²⁵

1. Lymphomas that occur with reasonable frequency in the absence of HIV infection
 - a. Burkitt lymphoma
 - b. Diffuse large B-cell lymphoma
 - Centroblastic
 - Immunoblastic (includes primary central nervous system lymphoma)
 - c. Extranodal marginal zone B-cell lymphoma of the mucosa-associated lymphoid tissue^a
 - d. Peripheral T-cell lymphoma^a
 - e. Classic Hodgkin lymphoma
2. Unusual lymphoma occurring more specifically in HIV infection
 - a. Primary effusion lymphoma
 - b. Plasmablastic lymphoma
3. Lymphomas occurring in other immune deficiency states
 - a. Polymorphic B-cell lymphoma

^aOccur rarely in HIV.

From World Health Organization Classification of Tumours. Pathology and genetics: tumours of haematopoietic and lymphoid tissues. Lyon: IARC Press, 2001.

Clinical Manifestations

Therapy

Initially prior to HAART, patients with lymphoma were more debilitated and experienced significant toxicity associated with chemotherapy. Multiple trials focused on reduced-intensity chemotherapy, which generally resulted in shorter remission durations. Treatment of HIV lymphoma has changed radically after the institution of HAART and remission has been reported after institution of HAART alone. However, this is not the standard of care and most trials now focus on more intensive therapy.

The French Italian Cooperative Group recently tailored treatment to the level of pre-existing immunosuppression, examining low- versus high-dose therapy in patients with moderate and severe immunosuppression. Patients with CD4 counts over $0.2 \times 10^9/L$ received a dose-intensified regimen of ACVB (doxorubicin, cyclophosphamide, vindesine, bleomycin, methylprednisolone, methotrexate) versus standard CHOP because of evidence from previous trials of NHL unrelated to HIV showing that patients receiving an intensified regimen had more durable remissions.¹⁵⁸ Both groups of HIV-infected patients in this trial had comparable responses, but toxicity was better in the CHOP arm. Patients with one adverse prognostic factor were randomly assigned to CHOP or dose-reduced CHOP. High-risk patients were treated with dosereduced CHOP or vincristine plus prednisone. In the intermediaterisk group, standard-dose CHOP was superior to dose-reduced CHOP, but overall survival remained similar in the two groups. This risk-adapted approach has not been adapted universally due to the results of other trials.

A number of regimens administering chemotherapy by slow infusion appear effective without causing significant toxicity. Patients receiving cyclophosphamide, doxorubicin, and etoposide (CDE)¹⁵⁹ as an infusion had median survivals of 18.4 months. A multicenter phase II trial of infusional CDE in 48 systemic NHL patients not on HAART had only a 46% median survival at 8 months.¹⁶⁰ This infusion regimen has been combined with HAART with few problems other than increased mucositis in the HAART group.¹⁶¹

EPOCH (etoposide, prednisone vincristine, cyclophosphamide, and doxorubicin-cyclophosphamide dose adjusted to CD4 count) has produced responses of 79% in a preliminary study.¹⁶² Antiviral therapy was suspended during treatment in this protocol, for fear of concurrent toxicities, leading to transient increases in viral load and decreases in CD4 counts. A multicenter trial by the AIDS malignancy consortium investigated EPOCH with concurrent versus sequential rituximab and found the CR rate to be higher in the concurrent arm.¹⁶³ The vast majority of patients remained on HAART during treatment, challenging the earlier assertion that HAART must be suspended.

Anti-CD20 monoclonal antibody (rituximab) has become a ubiquitous component of B-cell NHL in the general population. Preliminary studies show that it can be added to EPOCH without evidence of added toxicity.¹⁶⁴ Rituximab administered with CDE and concomitant HAART has yielded 2-year survivals of 80%.¹⁶⁵ However, a randomized phase III study of CHOP with or without rituximab failed to demonstrate any added benefit of rituximab and suggested increased toxicity in those with a CD4 count less than $0.05 \times 10^9/L$.¹⁶⁶ In contrast, another study, rituximab adjunction to CHOP produced a complete response rate of 77% and a 2-year survival rate of 75% in patients with AIDS-related NHL, without increasing the risk of life-threatening infections.¹⁶⁷ The current standard of care is to use rituximab with attention to infection including hematopoietic growth factors and antibiotic prophylaxis in those at highest risk.

Primary Central Nervous System Lymphoma

Primary CNS NHL (PCNSL) typically affects the most immunocompromised with CD4⁺ lymphocyte counts $<0.05 \times 10^9/L$ and now is rarely seen in patients receiving HAART. Most are diffuse large B-cell lymphomas and are multifocal (reviewed in Ref. 168). Confusion, memory loss, lethargy, and focal neurologic findings are the most frequent presenting symptoms and signs. The response to therapy in patients with primary CNS lymphoma has been very disappointing. Palliation with steroids and whole-brain radiation (3,000 to 5,400 Gy) has response rates of 75% and treatment with high-dose methotrexate has reportedly given similar results, but the response duration is short with a median survival of 2 to 4 months regardless of CD4 count. A pilot study using only antivirals and immunomodulation was very promising with two of five patients treated remaining in complete remission at 28 months and 52 months, respectively, but closed early due to low accrual.¹⁶⁹

Primary Effusion Lymphoma

PEL comprises approximately 1% to 5% of AIDS-related lymphoma cases. Clinically, the disease is characterized by malignant effusions with the absence of nodal disease. Diagnosis is made by pericardiocentesis, thoracentesis, or paracentesis with cytologic examination of the fluid and immunohistochemical evaluation. PEL cells have pleomorphic morphology and lack expression of B-cell-associated genes, including surface immunoglobulin, although immunoglobulin gene rearrangements are usually positive, indicating a clonal B-cell origin. The gene expression profile of PEL cells suggests plasmablastic derivation.¹⁷⁰ The malignant clone is almost always found to be infected with HHV8, whereas concurrent infection with EBV is frequent. PEL may extend into tissues underlying the serous cavities, including the omentum, lymph nodes, mediastinum, and lung. In one study of 277 NHL

P.1367

patients, PEL was diagnosed in 11 patients (4%). Patients treated with doxorubicin, vincristine, and prednisone achieved a complete response rate of 42%. However, median survival time was only 6 months.¹⁷¹ The decision to undergo therapy should be based on the functional status of the patient, the degree of immunosuppression, and the likelihood that the quality of life would be improved. A report of antiviral therapy alone leading to sustained remission has been documented.¹⁷²

Burkitt Lymphoma

Burkitt lymphoma is highly overrepresented in patients living with HIV. Before the era of HAART, treatments were curtailed due to fears of prolonged and profound neutropenia associated with the intensive therapies that had become standard in the general population. One small retrospective¹⁷³ and one small prospective study¹⁷⁴ initially challenged the prevailing dogma and found that intensive therapies such as CODOX-M/IVAC or hyper-CVAD with methotrexate and high-dose cytarabine could be safely given with HAART with success rates of 80% to 90%. More recent publications have also suggested the same.^{175, 176} Another retrospective study has supported the use of R-EPOCH as more efficacious and less toxic.¹⁷⁷ A recently completed clinical trial by the AIDS Malignancy Consortium was designed to reduce toxicity while maintaining efficacy, and may confirm these results prospectively in a multicenter setting.¹⁷⁸ The NCI has also reported early results with EPOCH-rituximab in a prospective study.¹⁷⁹

Plasmablastic Lymphoma

Plasmablastic lymphoma is a very rare CD20 negative variant of HIV-associated NHL. It was originally described as almost exclusively associated with HIV and nearly always fatal in the pre-HAART era.¹⁸⁰ The sine qua non of stage I disease is a mass in the jaw, but disseminated disease including numerous bone lesions is common. A retrospective study suggested curability in the HAART era in both HIV-positive and HIV-negative patients.¹⁸¹ Optimal management will be difficult to define due to the rarity of the disease.

Hodgkin Lymphoma

Although HL is not considered an AIDS-defining illness, a marked increase is seen in HIV.^{182, 183, 184} Although risk of NHL has decreased with better therapy, the incidence of HL among patients with HIV infection has increased.^{182, 185} Unlike HL in HIV-uninfected patients, B symptoms are almost often present; mixed cellularity HL is the predominant pathologic subtype of disease; and advanced, extranodal disease is expected in the majority. One study showed 70% to 90% of patients present with B symptoms, and 74% to 96% of patients have advanced disease (stage III or IV) at the time of diagnosis with frequent involvement of extranodal sites (60%), including bone marrow, liver, and spleen involvement. Unlike those not infected with HIV, noncontiguous spread of disease is common and mediastinal involvement is far less. Bone marrow involvement occurs in 40% to 50% of patients and may be their first indication of the disease. Another characteristic distinguishing the HIV-associated HL from that not associated with HIV is the predominance of Reed-Sternberg cell-rich cases. AIDS-HL, like AIDS-NHL, is characterized by a high frequency of EBV infection when compared to HL in the HIV-negative population. The pathologic role of EBV in HL is evidenced by the Reed-Sternberg cell expression of EBV-transforming protein.

Treatment

Although standard multiagent chemotherapy may be curative in most HIV-negative patients with stage III or IV HL, the median survival for HIV-infected patients has been in the range of 1 to 2 years.¹⁸³ Response to standard chemotherapy ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) is lower than that of patients without HIV infection, but may be better in the HAART era. Poor tolerance to chemotherapy results in dose reduction or delay of chemotherapy, but this may be ameliorated by the use of GCSF. The median overall survival of patients is approximately 1.5 years.^{184, 186, 187} Because 85% to 95% of HL patients have widespread disease, no data exist on the impact of radiation therapy in

treatment of AIDS-HL. Recent studies in the HAART era include trials suggesting better outcomes. Currently an ongoing US intergroup study (S0816) is examining midtreatment risk adaption and regimen modification based on interim PET scan after cycle 2 of ABVD. The novel and highly potent brentuximab vedotin, an anti-CD30 antibody conjugated to an antitubulin drug approved for relapsed and refractory non-HIV Hodgkin has not yet been tested in the setting of HIV, but will be investigated in an upcoming AIDS Malignancy Consortium study of untreated advanced stage HIV-HL.

Transplantation for Hodgkin Lymphoma and Non-Hodgkin Lymphoma

Myeloablative autologous transplants have been performed in patients with both NHL and HL. The City of Hope reported the first prospective study of 12 patients with NHL beyond first complete remission.¹⁸⁸ Opportunistic infections were seen in three patients; transient increases in viral load were seen in seven (related to HAART noncompliance). Three patients died, including two with relapsed lymphoma, but all others were alive at 18.5 months. Another study included eight patients with relapsed or resistant lymphoma, four with HL, and four with NHL. Seven of eight continued HAART during transplant and seven engrafted successfully. Although six of seven patients engrafted, only four patients went into complete remission.¹⁸⁹ Another pilot of 16 patients with relapsed and refractory lymphoma reported 6/16 alive at a median of 8 months after secondline therapy, high-dose conditioning and autologous stem cell support.¹⁹⁰ The European Cooperative Study Group on AIDS and Tumors (GECAT) reported the largest study and the only one enrolling patients before second-line therapy with 27/50 going onto autologous transplant and a median overall survival of 33 in all 50 eligible patients.¹⁹¹ In addition, two retrospective case control studies have suggested no difference in outcome between HIV-positive and HIV-negative patients undergoing autologous transplant for the same indications.^{192, 193} The AIDS Malignancy Consortium and Bone Marrow Clinical Trials Network have partnered in an ongoing trial to demonstrate multicenter feasibility and study biologic correlates. Finally, gene therapy pilot studies are ongoing to test the feasibility of engineered hematopoietic stem cell HIV resistance at the time of transplant for malignancy.¹⁹⁴

Nonmyeloablative allogeneic transplantation has been used in patients with refractory disease and has produced short-term remissions (12 months), but was associated with little toxicity and few opportunistic infections.¹⁹⁵ A case has been reported of simultaneous treatment of acute myelogenous leukemia and eradication of HIV infection using a donor with homozygous CCR5 deletion, a receptor necessary for HIV infection. However, the rarity of this deletion makes this approach unique. The AIDS Malignancy Consortium and Bone Marrow Clinical Trials Network have recently opened an allogeneic transplant pilot study for HIV-infected patients with a wide variety of hematologic malignancies.

CONCLUSION

Patients with HIV infections are living longer and having better quality of life than ever before. Life expectancy can approach the general population. Treatment of HIV-infected patients with

P.1368

HAART has altered the natural history of HIV infection by decreasing the frequency of opportunistic infections and altering the expected frequency of hematologic complications and AIDS-related malignancies. Cytopenia, particularly anemia, is more common in advanced stages of HIV and results both from bone marrow failure and peripheral destruction. With the development and application of HAART, both AIDS-defining and non-AIDS-defining malignancies represent an ever-increasing cause of death in this population. Lymphomas are highly prevalent among HIV-infected patients, although CNS lymphoma is now very rare on HAART. Intensive curative therapies are now the norm except in patients with advanced AIDS. In the future, different strategies directed toward controlling the underlying inciting viral infections associated with malignancy (EBV, HHV8) and focusing on immune reconstitution in addition to standard chemotherapy may improve response rates and survival.
