spleen tyrosine kinase (SYK) on chromosome 9 was identified in 5 (17%) PTCL, NOS cases.⁵⁴⁵ Another translocation involving the multiple myeloma gene (MUM1)/ IFN-regulatory factor-4 (IRF4) gene locus with the TRA@ gene, t(6;14) (p25;q11.2) was found in two cases of PTCL, NOS and led to the recognition by FISH screening of non-TCR-related IRF4

translocations in ALK-negative ALCLs. A balanced translocation between DUSP22 phosphatase gene on 6p25.3 and FRA7H on 7q23 was subsequently found in both systemic and cutaneous ALCL.⁵⁴⁷

Image provided by Dr. Ron Arildsen, Vanderbilt University, Nashville, TN. C: There are aggregates of large B cells with open nuclear chromatin and nucleoli separated by fibrosis. Such fibrosis is characteristic of this lymphoma type. Images provided by Dr. Dan Arbor, Stanford University, Palo Alto, CA.

TABLE 88.13 MATURE (NONCUTANEOUS) T/NK LYMPHOMA/LEUKEMIA

- Nodal
 - Peripheral T cell lymphoma, not otherwise specified
 - Anaplastic large cell lymphoma
 - ALK-positive
 - ALK-negative
 - Angioimmunoblastic T cell lymphoma
- Extranodal
 - Nasal NK/T cell lymphoma
- Localized
 - Disseminated (nasal type)

Enteropathy type intestinal T cell lymphoma

Hepatosplenic T cell lymphoma

Subcutaneous panniculitis-like T cell lymphoma, $\alpha\beta$

Leukemia

T-prolymphocytic leukemia

Adult T cell lymphoma/leukemia

Large granular lymphocytic leukemia

Aggressive NK cell leukemia

ALK, anaplastic lymphoma kinase; NK, natural killer.

Although CHOP has been the mainstay of therapy for aggressive lymphomas, its results have been poor for most mature T/NK neoplasms.^{548, 549, 550} The response rates to CHOP have been inferior compared to B cell lymphomas, and there has been no ubiquitous monoclonal antibody similar to rituximab to improve survival. Adding agents to CHOP may slightly improve responses but is limited by increased toxicity. Adding etoposide to CHOP had modest improvement for only young patients, primarily with ALK-positive ALCL, in the combined analysis of trials by the German High-Grade Non-Hodgkin Lymphoma Study Group.⁵⁵¹ Escalating therapy, such as Mega-CHOEP or HyperCVAD, has not improved responses or survival.⁵⁵¹ Addition of alemtuzumab to CHOP led to increased infections so that its use is likely limited.⁵⁵² Using novel non-anthracycline-based regimens such as PEGS (cisplatin, etoposide, gemcitabine, solumedrol) have not improved survival.⁵⁵³

P.1854

How to incorporate newly approved agents such as pralatrexate, an antifolate, and romidepsin, a histone deacetylase inhibitor, into therapy is under investigation in PTCL. The response rate and toxicities in relapsed PTCL for pralatrexate was 29% (11% CR) with 22% mucositis and 18% to 32% cytopenias, and for romidepsin was 38% (18% CR) with 26% grade 3/4 neutropenia.^{554, 555} Because of the overall poor results with CHOP, stem cell transplant, both autologous and allogeneic, has been advocated in first remission in many patients with T/NK neoplasms although there is no randomized trial to prove its superiority.^{556, 557}

The WHO classification separates the mature T/NK neoplasms by site of involvement: nodal, extranodal, leukemic, and cutaneous. In the subsequent section, the focus is primarily on nodal and extranodal diseases followed by a brief description of the leukemias. Cutaneous T cell lymphomas are reviewed in Chapter 92.

Anaplastic Large Cell Lymphoma

Since the original description of Ki-1⁺ (CD30) ALCL by Stein in 1985, a type of ALCL has become a paradigm for the WHO classification for NHL.^{258, 558, 559} The first clinical description of ALCL was in a series by Kadin et al. in 6 children, all of whom had skin lesions.⁵⁶⁰ Subsequent studies recognized a common lymphoma (2% to 8% of NHL) with a wide morphologic spectrum, young median age, peripheral adenopathy with relative sparing of the mediastinum, frequent extranodal disease, and a good prognosis.^{258, 561, 562} In 1989, a proportion of ALCLs were associated with a specific chromosomal translocation;²⁵ and in 1994, Morris identified the genes involved in the t(2;5).²⁶

ALK rearrangements are present in 50% to 70% of CD30⁺ ALCL, and the t(2;5) occurs in approximately three-fourths of these patients.^{258, 563} Cytogenetic variants have been described with t(1;2)(q25;p23) as the most common.⁵⁶³

Immunocytochemical stain for the ALK protein is usually present in both cytoplasm and nuclei of the classic t(2;5)(p23;q35), while only in the cytoplasm of the variants.^{258, 312} Because the variants are of T or null cell origin and occur in a similar age group as the t(2;5), Falini proposed the term "ALKoma" for all patients expressing the ALK protein.³¹²

ALK expression subdivides ALCL into at least 3 clinical subtypes of ALCL: 1) ALK-positive systemic ALCL, 2) ALK-negative systemic ALCL, and 3) primary cutaneous ALCL (also, ALK-negative). ALK-positive ALCL occurs at a younger median age (15 to 30 years) than ALK-negative (45 to 65 years), has a male predominance (male:female = 2-6:1), and usually has advanced stage disease with frequent B symptoms (40% to 75%) and extranodal involvement (50% to 80%).^{258, 312, 313} Skin (21% to 35%) (Fig. 88.18), soft tissue (17%), and bone (8% to 17%) are common extranodal sites, while the gastrointestinal tract and central nervous system are rarely involved.²⁵⁸ Bone marrow involvement in ALK-positive ALCL is identified in 10% to

15% with hematoxylin and eosin stains, but up to 30% if immunohistochemistry stains are used to identify isolated ALCL cells.^{258, 564}

FIGURE 88.18. ALK-1 positive anaplastic large cell lymphoma (ALCL): Skin lesions can vary from nodules (A) in an axilla to ulcerations (B) in a popliteal fossa.

ALK-positive ALCL is more chemosensitive than ALK-negative ALCL with CR rates >75% for ALK-positive and 50% to 75% in ALK-negative.^{312, 313, 565, 566} Better responses have resulted in a twofold or higher increase in survival for ALK-positive ALCL (60% to 93% at 5 years) compared to ALK-negative ALCL (15% to 46%) in retrospective series (Fig. 88.19).^{312, 313, 542, 565, 567, 568, 569} A worse prognosis can be seen in ALK-positive patients with B symptoms, a high IPI, small cell variant histology, and expression of CD56 or survivin (a member of the inhibitor of apoptosis family).^{570, 571}

A problem comparing ALK-positive ALCL to ALK-negative ALCL is the fact that the latter represents a heterogeneous group of diseases. Translocations affecting 6p25.3 which target DUSP22 and/or IFD4 have been identified in a subset of ALK-negative ALCL with predominant skin involvement.⁵⁷² ALK-negative ALCL may be considered as secondary ALCL when it follows mycosis fungoides, lymphomatoid papulosis, or HL.²⁵⁸ Hodgkin-like ALCL is formally a provisional diagnosis of the WHO classification, but is probably a variant of HL.⁵⁷³ ALK-negative ALCL can rarely be of B cell origin, either with an aggressive course or in the setting of AIDS.^{258, 573} Differences in gene expression may further define ALCL with overexpression of genes encoding signal transduction and underexpression of transcription factor genes in ALK-positive compared to ALK-negative ALCL.^{574, 575}

Primary cutaneous ALCL is another ALK-negative ALCL, is part of the spectrum of CD30+ cutaneous lymphoproliferative disease, and clinically overlaps with lymphomatoid papulosis (Chapter 92).^{576, 577} It usually arises in the skin in an older patient (median age ~60 years) as an isolated reddish-violet tumor, which may be ulcerated. Less commonly, it may present as multiple nodules in a circumscribed area, or rarely with disseminated skin lesions. Treatment of localized lesions may be watchful waiting (because approximately one-quarter of patients regress), local excision ± radiation, or radiation alone.^{258, 577} Combination chemotherapy may be warranted with widespread skin disease or localized skin disease with adjacent nodal involvement, but these patients tend to relapse.^{577, 578}

Two proteins provide unique therapeutic targets in ALCL. Brentuximab vedotin (SGN-35; Adcetris, Seattle Genetics, Botnell, WA) is an antibody-drug complex that combines an anti-CD30 antibody with the antimicrotubule agent, monomethylauristatin E. In a phase II trial in 58 patients with relapsed/refractory ALCL, the ORR was 86% with 57% CR. The median duration of objective response was 12.6 months for all patients and 13.2 months for CR patients. Crizotinib (PR-02341066; Xalkori, Pfizer, San Diego, CA)

P.1855

is an oral small-molecule inhibitor of ALK tyrosine kinase that was first used in non-small cell lung cancer with a rearrangement involving ALK in 2% of cases. A phase I trial reported 7 CRs in 8 relapsed pediatric ALK-positive ALCL.⁵⁷⁹ A subsequent report confirmed CRs in adults.⁵⁸⁰ Both agents are being incorporated into phase III trials.⁵⁸¹

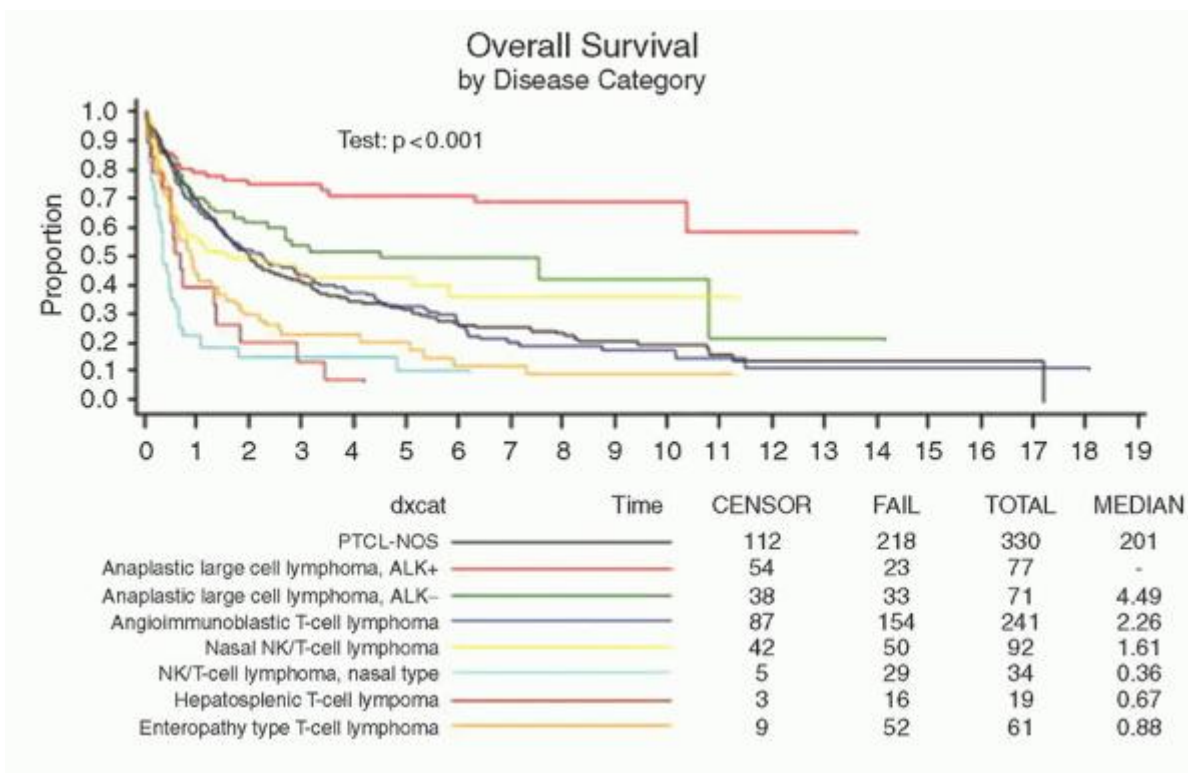

FIGURE 88.19. Overall survival for patients with aggressive peripheral T cell lymphoma by subtype according to the International Peripheral T Cell and NK/T Cell Lymphoma Study. From Armitage JO. The aggressive peripheral T cell lymphomas: 2012 update on diagnosis, risk stratification, and management. *Am J Hematol* 2012;87:511-519, with permission.

Nodal Peripheral T Cell Lymphoma

Problems in management of PTCL include the fact that, unlike B cell NHL, cell size does not correlate with prognosis, and there is sparse data regarding the impact of cytogenetics on diagnosis other than ALK expression in ALCL. The IPI does correlate with prognosis in PTCL-not otherwise specified (NOS), but only the low-risk (0,1) has prolonged survival over 45%.^{346, 5676, 568, 582} A new prognostic model has added bone marrow involvement to some of the IPI factors (age, PS LDH).³⁰⁷ Elevated levels of serological markers, nm23-H1 (involved in regulation of metastasis), IL-2 receptor, and soluble CD44 may enhance the IPI.⁵⁸³

PTCL-NOS represented the largest group (29.5%) in the international T cell Lymphoma Project.⁵⁸² The median age was 60 years with a male predominance. Most patients presented with nodal disease (87%) and had advanced stage (69%); extranodal involvement occurred in 49%. The 5-year OS was 32% and FFS was 20%.

Tumor-specific features under evaluation to assess prognosis include expression of cytotoxic molecules, Ki-67, TP53, chemokine receptors, and gene profiles.⁵⁸⁴ Cytotoxic molecules (CM), TIA-1, and granzyme B in PTCL-NOS, are associated with B symptoms, a higher IPI, an inferior CR rate, and a worse overall survival when compared to a CM-negative group.⁵⁸⁵ The proliferation-associated antigen, Ki67, was additive to IPI factors (age, PS, LDH) in a series of PTCL-NOS.⁵⁸⁶

Immunohistochemistry detection of TP53 overexpression was detected in a minority (29%) of nodal PTCL cases; was associated with Ki-67, BCL-2, and P-glycoprotein; and was a better predictor of poor survival than IPI.³²⁸ Preliminary data indicate chemokine receptor expression that distinguishes subsets of T helper cells, Th1 and Th2, and correlates with histology and prognosis.⁵⁸⁷

Gene expression profiles are under investigation as a method to subdivide PTCL.⁵⁸⁸ Three molecular profiles have been identified in PTCL-NOS: 1) Overexpression of genes with an aggressive course, including CYCLIN D2; 2) genes involved in T cell activation and apoptosis, NFKB1 and BCL-2; and 3) overexpression of genes in the interferon γ /JAK/STAT pathway.⁵⁸⁹ Another study reported that reduced expression of NF- κ B pathway genes had an inferior survival to those with increased NF- κ B expression.⁵⁹⁰ Two different profiles, a large group corresponding to activated CD4⁺ cells and a smaller group of CD8⁺ cells, also subdivided PTCL-NOS.⁵⁹¹

AILT is difficult to diagnose and treat because there may be the presence of both B and T clones, as well as EBV; and it has a variable clinical course with autoimmune features.^{543, 592, 593, 594} AITL was the second most common type (18.5%) in the IPTL usually occurs in the elderly (median age, 57 to 68 years) as a systemic disease with diffuse adenopathy (84% to 100%), B symptoms (52% to 86%), a pruritic rash (38% to 58%), arthritis (16% to 18%), eosinophilia (32% to 50%), and immunologic abnormalities (Coombs' positive hemolytic anemia [32% to 75%], cold agglutinins, cryoglobulinemia, polyclonal hypergammaglobulinemia [50% to 83%], antinuclear antibodies and rheumatoid factors). Most patients have extranodal disease and are advanced stage (68% to 94%).

There is clonal evolution over time in AILT and EBV may participate in lymphomagenesis.⁵⁹⁵ The cell of origin is a T-follicular helper cell (TFH); and there is cytoplasmic expression of the cytokine CXCL13.⁵⁹⁶ TCR gene rearrangements occur early in the course of AILT, indicating a clonal T cell population. Nearly all patients have EBV-positive B cells and approximately one-third have also had IG gene rearrangements.⁵⁹⁷ As with posttransplant lymphoproliferation but unlike other NHL, unrelated or oligoclonal clones are commonly found in AILT. The most common cytogenetic abnormalities are trisomy 3, trisomy 5, and an additional X chromosome, but patients who develop complex aberrant clones and structural abnormalities in the short arm of chromosome 1 progress rapidly.⁵⁹⁸ EBV can be identified in both B cells and T cells of AILT, and it may participate in the occasional B-immunoblastic lymphoma as well as the more common PTCL.^{592, 597, 599} Gene expression profile found overexpression of genes characteristic of TFH cells and genes deregulating vascular endothelial growth factor.^{600, 601}

AILT may spontaneously regress in up to 10% of patients; and it can respond to single agents, including steroids, cyclosporine, methotrexate, interferon, nucleoside analogs, bortezomib, denileukin diftitox, and rituximab. Combination chemotherapy is usually warranted once a diagnosis is made with a CR rate of 50% to 70% following anthracycline-based therapy, but patients have frequent and early relapses or deaths due to infections, with 5-year survival at 10% to 30%.^{543, 593}

P.1856

Extranodal T Cell and Natural Killer-Cell Lymphomas

Hepatosplenic γ/δ T cell lymphoma (HSTL) was first described in 1990 as an aggressive illness with B symptoms and organomegaly in young adult males.^{602, 603} Up to 20% of HSTLs arise in patients with solid organ transplants and Crohn disease.⁵⁴¹ The median age is 25 to 35 years with a male/female ratio of 9:1. Patients have splenomegaly (98%), hepatomegaly (80%), minimal to no lymphadenopathy, anemia (84%) and severe thrombocytopenia (85%).^{233, 604} The bone marrow is involved in 72% of patients and erythrophagocytosis may occur.⁶⁰⁴ Isochrome 7q, often associated with trisomy 8, is a common cytogenetic abnormality.⁶⁰⁵ Most patients are refractory to anthracycline-based therapy or have brief responses and have a median survival less than 1 year.^{233, 549, 604} There is an α/β variant with similar features and prognosis.⁶⁰⁶ A similar gene expression profile involving genes implicated in cytotoxic T and NK cell function is present in both γ/δ and α/β variants.⁶⁰⁷

Subcutaneous panniculitis-like T cell lymphoma (SPTL) presents with subcutaneous nodules, usually on the extremities, and is often associated with systemic symptoms and erythrophagocytosis.^{608, 609, 610} The 2008 WHO classification recognizes only the $\alpha\beta$ subtype as SPTL and distinguishes it from cutaneous $\gamma\delta$ T cell lymphoma, which may have a panniculitis-like presentation.⁶¹¹ The $\alpha\beta$ subtype occurs at a younger median age (36 years) with a female predominance. The skin lesions tend to be self-healing subcutaneous plaques and nodules without ulceration. Disseminated disease and hemophagocytosis (17%) are rare. These patients may be controlled with single agent steroids and/or methotrexate and have a 5-year OS of 82%.⁶¹¹ The $\gamma\delta$ type occurs in an older population (median age, 59 years) with a roughly equal male:female ratio. Skin lesions may involve the epidermis and ulcerate. B symptoms, nodal disease, and hemophagocytosis are associated with a poor prognosis and a 5-year OS of 11% despite combination chemotherapy.⁶¹¹

Enteropathy-associated T cell lymphoma (EATL) has an association with celiac disease but has occurred without it as well.^{612, 613, 614, 615, 616} There are two types of EATL.⁶¹⁶ Type 1 has a large cell or pleomorphic cytology, has chromosome 9q31.3 gain or 16q12.1 deletion, is associated with the HLA-DQ2 haplotype, is strongly associated with celiac disease, and is common in Europe. Type 2 is characterized by monomorphic cells often with CD56 expression, has chromosome 8q24 gain and less commonly 1q and 5q gains, is less associated with sprue, and is found in Asia. The median age is 50 to 64 years and males predominate in most series.^{614, 615} Abdominal pain and weight loss occur in over four-fifths of patients at presentation followed by diarrhea or vomiting in one-third of patients.⁶¹⁴ Small bowel obstruction or perforation is

common, and the diagnosis of EATL is usually made at laparotomy. Prognosis is poor, with median survival of 7.5 months and 1 year failure-free survival less than 20%.^{614, 615, 616}

Nasal and nasal-type NK/T lymphomas are characterized by angiocentric and angiodestructive proliferation; large granular lymphocyte morphology; CD2⁺, CD3⁻, CD16^{+/+}, CD56⁺, CD57⁻ phenotype; and an aggressive course.^{617, 618} Only 10% express surface CD3⁺ and have clonal TCR rearrangement and have a similar course.⁶¹⁸ EBV is consistently detected in tumor cells and elevated levels of EBV DNA in tumor tissue or serum have correlated with a poor prognosis.^{619, 620} NK neoplasms are prevalent in Asia and Latin America. Nasal NK/T lymphoma may present with facial swelling or midfacial destruction and was formerly called lethal midline granuloma or polymorphic reticulosis. The disease occurs more commonly in males with a median age of 50 to 55 years.^{617, 618}

FIGURE 88.20. Nasal NK/T lymphoma: Patient presented with facial edema, proptosis, and dysconjugate gaze (A) and an ulcerated lesion in the hard palate (B).

Nasal NK/T lymphoma is localized stage I/II in 80% of patients at diagnosis but can disseminate early to skin, gastrointestinal tract, testis, orbit, and CNS (Fig. 88.20). Although radiation alone can achieve CR in two-thirds of localized disease, local relapse occurs in half the patients and disseminated disease develops in one-quarter of patients.⁶¹⁷ Combined modality with early radiation and chemotherapy is recommended. Patients with disease confined to the nasal cavity, larynx, pharynx, or oral cavity had 54% 5-year survival compared to 20% ($P = 0.0068$) with more advanced disease.⁶²¹

Nasal-type NK/T cell lymphoma is essentially disseminated nasal disease without obvious nasal involvement.⁶²² Only one-fifth of patients have stage I disease.⁶²² Despite anthracycline therapy, median survival is less than 1 year. L-asparaginase has been shown to be effective as a single agent in patients who failed CHOP.⁶²³ Because of high expression in P-glycoprotein, regimens containing multidrug resistant-independent agents, such

P.1857

as SMILE (steroids, methotrexate, ifosfamide, L-asparaginase, etoposide) have been formulated to treat nasal-type NK/T cell lymphoma.⁶²⁴ Patients with cutaneous only involvement have a better survival.⁶²⁵ A disseminated, leukemic form is usually fatal within weeks.⁶²⁶

Mature T Cell and Natural Killer-Cell Leukemias

The differential diagnosis of CLL in Chapter 90 includes the mature T/NK leukemias. Large granular lymphocyte (LGL) leukemia was associated with chronic neutropenia in 1977, recognized as a clonal disorder in 1985, and classified into T (CD3⁺) and NK (CD3⁻) types in 1993 (Fig. 88.21A).^{204, 627, 628} The median age is 55 to 60 years, and there is an association with rheumatoid arthritis (20%) and autoimmune features.^{204, 629} Lymphocytosis is usually between 2 and 20 × 10⁹/L and mild splenomegaly (25% to 50%) may be present, but the usual clinical presentation is neutropenia or anemia. Recurrent infections are usually respiratory or mucocutaneous and occur in 15% to 56% of patients.²⁰⁴ Pure red cell aplasia, autoimmune hemolytic anemia, aplastic anemia, ITP, and MDS may occur in LGL leukemia. LGL cells express high levels of both FAS and FAS ligand, but the cells are resistant to FAS-mediated death due to STAT 3 activation which upregulates an antiapoptotic protein.^{629, 630} LGL leukemia is an indolent disease with median survival over 10 years.²⁰⁴ Immunosuppressant drugs which have been used in LGL leukemia include methotrexate, cyclosporine, prednisone, cyclophosphamide, nucleoside analogs, and alemtuzumab.^{204, 627, 631, 632}

FIGURE 88.21. Mature T/NK leukemias: A: T cell large granular lymphocytic leukemia: The lymphocytes are enlarged with dense nuclear chromatin and abundant cytoplasm with fine azurophilic granules. B: Natural killer/T cell leukemia: Three leukemic cells and one myelocyte are present. The leukemia cells have blastic, fine nuclear chromatin with irregular nuclei and basophilic cytoplasm. Some cases may show cytoplasmic granules. C: T cell prolymphocytic leukemia: The lymphocyte has clumped nuclear chromatin with irregular nuclear contours, sometimes referred to as “knobby cells.” Nucleoli may be inconspicuous, in contrast to B cell prolymphocytic leukemia, which has prominent nucleoli. D: Abnormal T lymphocyte in the peripheral blood of a patient with adult T cell leukemia. The cell is enlarged with a multilobated nucleus. These “flower cells” are usually easily found with this disorder. Images provided by Dr. Dan Arber, Stanford University, Palo Alto, CA.

Aggressive NK leukemia is a rare disorder more common in Asia, is associated with EBV, and represents the leukemic phase of nasal-type NK lymphoma (Fig. 88.21B).⁶³³⁻⁶³⁵ Patients are young (median age, 30 to 40 years) with slight male predominance and present with a fulminant illness characterized by B symptoms, diffuse adenopathy, organomegaly, and circulating LGL cells which can have a blastic appearance.^{634, 635} Patients are chemoresistant and have a median survival of less than 3 months.^{634, 635} Another neoplasm of possible NK cell lineage is myeloid/NK cell precursor acute leukemia.^{636, 637} Blastic plasmacytoid dendritic cell neoplasm, formerly mislabeled as CD4⁺/CD56⁺ hematodermic neoplasm or blastic NK

cell lymphoma, has a predilection for cutaneous involvement and probably should receive therapy for acute myeloid leukemia.⁶³⁸

T-prolymphocytic leukemia (T-PLL) represents approximately 2% of small lymphocytic leukemia in adults (Fig. 88.21C).⁶³⁹,⁶⁴⁰,⁶⁴¹ Median age is 57 to 69 years and the male:female ratio is 1.5:1.⁶⁴²,⁶⁴³ Patients usually have a marked lymphocytosis ($>100 \times 10^9/L$ in 75% of patients), splenomegaly (73%) and lymphadenopathy (53%); and approximately 20% of patients have

P.1858

skin infiltration.⁶³⁹,⁶⁴⁰,⁶⁴² Cell morphology is variable; the nuclei are irregular, include a “knobby” variant, and usually have prominent nucleoli; cytoplasmic protrusions are characteristic. Sixty per cent of patients are CD4⁺/CD8⁻; 25% coexpress CD4⁺/CD8⁺; and 15% are CD4⁻/CD8⁺.⁶³⁹,⁶⁴⁰,⁶⁴²

The most common cytogenetic abnormality occurring in 80% of patients is an inversion of chromosome 14 with break points in q11 and q32; 10% have a reciprocal translocation t(14;14) (q11;q32).⁶³⁹,⁶⁴⁴ These translocations juxtapose the locus of the TCR α/β gene with the TCL1 and TCL1b genes at 14q32.⁶⁴⁵ Deletions at 11q23, the locus for the ATM gene, and at 12p13, and abnormalities of chromosome 8 are other common cytogenetic findings in T-PLL.⁶³⁹,⁶⁴⁶

Response rates in T-PLL are 10% to 48% with few complete remissions utilizing chemotherapy, including CHOP or nucleoside analogs.⁶⁴²,⁶⁴³ Median survival is usually 1 year although up to one-third of patients can have an indolent phase.⁶⁴²,⁶⁴³,⁶⁴⁷ Alemtuzumab (Campath 1H) is the most active single agent in T-PLL with a 74% and 91% response rate in previously treated and untreated patients, respectively.⁶⁴¹,⁶⁴⁸ Preliminary data suggest the best survival occurs in patients treated with intravenous alemtuzumab followed by an allogeneic HCT. Nucleoside analogs, particularly pentostatin, can be effective in slow responders.⁶⁴¹

The clinical course of ATL, which follows infection by HTLV1, is variable and takes 4 basic forms: 1) acute (leukemic) (60%), 2) lymphoma (20%), 3) chronic (20%), and 4) smoldering (5%). The male to female ratio is 1.3-2.2:1, and the median age is 47 to 65 years.⁵⁹ The acute form is characterized by lymphadenopathy, organomegaly, skin lesions, elevated white count with multilobed lymphocytes, often referred to as “cloverleaf” or “flower” cells (Fig. 88.21D), hypercalcemia, elevated lactate dehydrogenase (LDH) level, and usually a rapidly fatal course. The cutaneous lesions have a diverse appearance, including papules, nodules, plaques, tumors, and ulcers. Histologically, dermal invasion predominates, although the lesions of ATL may resemble primary cutaneous T cell lymphoma with epidermotropism and Pautrier's microabscesses. Anemia and thrombocytopenia are infrequent findings because of a low degree of marrow infiltration. Central nervous system involvement may develop in as many as 10% of patients with ATL.⁶⁴⁹

Lymphoma is distinguished by prominent adenopathy without significant peripheral blood involvement. Primary extranodal lymphoma occurs in approximately 5% of lymphomatous presentations and has involved skin, Waldeyer's ring, gastrointestinal tract, sinuses, and pleura.⁶⁵⁰ The chronic type is associated with an increased white blood cell count and occasionally with slight adenopathy and organomegaly. Patients with smoldering ATL have few ATL cells (0.5% to 3%) in the peripheral blood, and may have skin lesions as well as slight adenopathy, organomegaly, and marrow infiltration. Chronic and/or smoldering ATL may evolve into an acute form after many years of indolent disease.⁶⁵¹

No consistent cytogenetic abnormality has been identified in ATL. The most common abnormalities are gains at chromosomes 14q, 7q, and 3p and losses at 6q and 13q.⁶⁵²,⁶⁵³ Aneuploidy, multiple chromosomal breaks, and loss of tumor suppressor genes are associated with an aggressive course.⁶⁵³,⁶⁵⁴

Despite combination chemotherapy, which can yield brief and low responses, median survivals in the acute and lymphomatous forms of ATL are usually less than 1 year.⁵⁹,⁶⁵⁵,⁶⁵⁶,⁶⁵⁷ Chemotherapy with a complex regimen, the LSG15 protocol, is marginally superior to CHOP and has higher response rates in the lymphoma form compared to acute.⁶⁵⁸ Overexpression of MDR (ABCB1) and TP53 contribute to chemoresistance.⁶⁵⁹,⁶⁶⁰ Poor performance status, high LDH, age above 40 years, tumor bulk, and hypercalcemia are adverse prognostic factors.⁶⁵⁵ The chronic and smoldering forms have a longer survival rate regardless of therapy. The major causes of death in ATL are opportunistic pulmonary infections and progressive disease, often in association with hypercalcemia.⁶⁶¹,⁶⁶²

Because of its chemoresistance and its HTLV-1 viral leukemogenesis, ATL has been a unique disease for investigating therapy. Interferon α (IFN) plus zidovudine (AZT) has had a higher response rate (67% to 92%) than chemotherapy regimens in ATLL.⁶⁶³ The current recommendation is to first initiate antiviral therapy for the acute, chronic, and smoldering forms.⁶⁵⁷ Others advocate debulking with chemotherapy followed by antiviral therapy or concomitant treatment, particularly for the lymphoma form. NF- κ B inhibition has been proposed as a therapeutic target in ATL. Arsenic

trioxide synergizes with IFN, has been shown to shut down the NF- κ B pathway, and has been effective in phase II trials.⁶⁶⁴ Conjugated and unconjugated monoclonal antibodies directed at the IL-2 receptor (CD25), CD52 (alemtuzumab), chemokine receptor 4 (KW-0761), and CD2 (Siplizumab) have activity in ATL and are being evaluated in conjunction with other therapy.

Allogeneic hematopoietic cell transplantation (alloHCT) was first reported as a curative option in ATL in 1996. Although the median survival with alloHCT (9.9 months in a review of 586 patients) does not appear superior to other therapy, the 3-year estimated overall survival of 36% suggests HCT may offer the best chance for long-term survival.⁶⁶⁵

Despite the new therapies under investigation in ATL, the ultimate goal is prevention of the disease. Avoiding breast-feeding in mothers infected with HTLV-1 can reduce infection in the newborn by 80%.⁵⁹ Other proposed methods to prevent ATL are antiretroviral therapy and a TAX-targeted vaccine.

THERAPY FOR LOCALIZED LARGE CELL LYMPHOMA

Localized disease is defined by either stage I or II disease which is nonbulky (no tumor mass \geq 10 cm; no mediastinal mass $>$ one-third the chest diameter). Radiation therapy alone has resulted in 20% to 85% cure rates for limited stage large cell lymphomas, with the best results in patients who have stage I disease after undergoing pathologic staging.^{18, 666} With clinical staging, cure rates with radiation alone have usually been less than 50%; therefore, most investigators are advocating chemotherapy, usually CHOP-type regimens, often followed by radiation, with cure rates of 70% to 90%.⁶⁶⁷ Using a stage-modified IPI for localized disease, patients with no adverse risk factors (stage I, age \leq 60, $<$ 2 performance status, normal LDH) have cure rates exceeding 90%.⁶⁶⁸

Clinical trials have addressed the issue of chemotherapy versus combined modality therapy in limited stage large cell lymphoma.⁶⁶⁹ In a SWOG study, patients with localized intermediate-or high-grade NHL were randomized to 3 cycles of CHOP followed by involved field radiation therapy (4,000 to 5,500 cGy) versus 8 cycles of CHOP.⁶⁷⁰ Better PFS (77% versus 64%, $P = 0.03$) and OS (82% versus 72%, $P = 0.02$) were observed in the combined modality arm and there was a trend toward increased toxicity, particularly cardiac, in the chemotherapy-only arm.⁶⁷⁰ A subsequent follow-up report, however, indicates no difference in survival between the two arms.⁶⁷¹ Other concerns of the SWOG study are that 8 cycles of CHOP is probably excessive for localized disease and that radiation will contribute to the risk of long-term toxicities.

An ECOG trial compared low-dose (30 Gy) radiotherapy (RT) with observation in limited stage aggressive lymphoma patients who had achieved CR after CHOP times 8 cycles, and assessed the impact of higher dose (40 Gy) RT in patients in PR.⁶⁷² The DFS at 6 years was significantly greater for CR patients who received RT (76% vs. 56%, $P = 0.05$), but there was no improvement in overall survival. Patients who received RT rarely relapsed in previously irradiated sites. PR patients had a 63% FFS at 6 years, indicating

P.1859

a role for the addition of RT. The efficacy of adding rituximab to CHOP chemotherapy followed by IFRT was evaluated in a SWOG study. The 4-year PFS and OS were 88% and 92%, respectively.⁶⁷³

Other randomized trials in children, as well as adults, have shown no benefit to combined modality over chemotherapy alone in limited stage patients.^{674, 675} A GELA trial compared 4 cycles of CHOP plus RT to 4 cycles of CHOP alone in patients over 60 years of age and found no difference in EFS or OS.⁶⁷⁵ Another GELA randomized trial compared an intensive regimen of ACVBP (doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone) to 3 cycles of CHOP followed by involved field RT for patients less than 60 years of age with limited stage disease. Although there was more toxicity in the ACVBP arm, there was superiority in both EFS (82% vs. 74%, $P < 0.001$) and OS (90% vs. 81%, $P = 0.001$) for the intensive regimen over the CHOP plus RT.⁶⁷⁶ The major improvement for ACVBP was in the patients with bulky stage II disease.

Thus, although short course chemotherapy (3 to 4 cycles) followed by RT is an accepted treatment for adults with localized large cell NHL, there is data to support chemotherapy alone for many patients. There may be more local relapses when RT is not used, but there are no differences in survival and there is likely to be fewer long-term toxicities with chemotherapy alone. A potential role for RT could be in patients who have a positive interim or postchemotherapy FDG-PET scan.⁶⁶⁹ In a series of 59 patients (83% with stage I/II disease), the 3-year PFS for patients with negative scans receiving chemotherapy alone ($n = 39$) and with positive scans receiving consolidative involved field RT ($n = 20$) were 97% and 90%, respectively.⁶⁷⁷

CHEMOTHERAPY

In the early 1970s, DeVita introduced a combination chemotherapy regimen, C-MOPP (cyclophosphamide replacing mechlorethamine, vincristine, procarbazine, and prednisone), which produced a CR rate in excess of 40% in patients with diffuse "histiocytic" lymphoma, a neoplasm generally equivalent to DLCL; approximately one-third of these patients were cured.^{678, 679} By the middle 1970s, doxorubicin had been added to cyclophosphamide, vincristine, and prednisone to produce the CHOP regimen, which produced CR rates of 50% to 60% and DFS of 30% to 40%.^{680, 681} CHOP is the most extensively studied and used regimen in the therapy of large cell lymphoma. The addition of rituximab has improved response and survival.⁶⁸² Clinical observations have been that rapid achievement of a CR was associated with a good prognosis^{680, 683} and that relapses after 2 years of DFS were rare. Further follow-up for large cell lymphoma, however, recorded relapses in 6% to 22% of patients after 2 years of CR.^{683, 684}

Subsequent regimens were developed in part on the concepts of Goldie and Coldman, who proposed that tumors develop drug resistance by spontaneous mutation soon after exposure to chemotherapy; and of Hryniuk and Bush, who proposed that increasing dose intensity could overcome drug resistance.^{342, 685, 686, 687, 688, 689, 690, 691, 692} The CR rates of third-generation regimens were 78% to 88% with DFS of 58% to 69% in studies primarily at single institutions.^{686, 692, 693, 694, 695} Many of these newer regimens had considerable toxicity when used initially, and were associated with mortality rates of 5% to 10%; however, the rate of toxic deaths decreased over time with more experience and with better patient selection.⁶⁸⁴ Many of the series in which these regimens were used involved favorable prognostic groups, including patients with limited stage disease and patients with a relatively young median age.

One of the most important clinical trials for lymphoma was performed by an intergroup (SWOG and ECOG) study which compared CHOP with 3 of the newer and reportedly more intensive regimens, m-BACOD (methotrexate, bleomycin, Adriamycin [doxorubicin], cyclophosphamide, Oncovin [vincristine], and dexamethasone), MACOP-B (methotrexate, bleomycin, Adriamycin, cyclophosphamide, Oncovin, and prednisone), and ProMACE-CytaBOM (prednisone, Matulane, Adriamycin, cyclophosphamide, etoposide/cytarabine, bleomycin, Oncovin, methotrexate).⁶⁹⁶ There were no differences in CR, PFS, or OS. The percentage of patients alive without progression at 3 years was 41% in the CHOP and MACOP-B groups and 46% in the m-BACOD and ProMACE-CytaBOM groups (Fig. 88.22). The estimated OS was 52% of the entire group: 50% for both ProMACE-CytaBOM and MACOP-B, 52% for m-BACOD, and 54% for CHOP (P = 0.90). There were also no differences in fatal toxicities among the regimens: CHOP (1%), ProMACE-CytaBOM (3%), m-BACOD (5%), and MACOP-B (6%)(P = 0.09).

FIGURE 88.22. Intergroup study comparing CHOP, M-BACOD, and ProMACE/CytaBOM in predominantly intermediate

grade Working Formulation (WF) lymphomas. There were no differences observed in time to treatment failure in the four groups. Updated and adapted from Fisher RI, Gaynor ER, Dahlborg S, et al. Comparison of a standard regimen (CHOP) with three intensive chemotherapy regimens for advanced non-Hodgkin's lymphoma. *N Engl J Med* 1993;328:1002-1006, with permission.

While the intergroup study reestablished CHOP as standard therapy for large cell lymphoma, it did not address the issue of dose intensity, and it did not emphasize how poorly these regimens do in patients with adverse prognostic factors. Although the newer regimens supposedly were more dose intensive than CHOP, there are few differences among the regimens with respect to the doses of the most active agents used (i.e., cyclophosphamide and doxorubicin). Although no differences were identified among the regimens in patients with adverse prognostic factors, none of them produced good results. Using these conventional regimens, CR rates of 55% and 44% and 5-year survivals of 43% and 26% were observed in the high-intermediate and high-risk groups, respectively, in the IPI (see section on Prognostic Factors).^{283, 697}

The intergroup trial was met with praise as well as disappointment because it indicated no improvement in survival for nearly two decades after the establishment of CHOP as an effective regimen. The first study to show an improvement in survival was a randomized GELA comparison of CHOP to rituximab plus CHOP (R-CHOP) in elderly patients (age 60 to 80 years) with DLBCL.²⁹⁹ The rate of CR/CRu was higher for R-CHOP compared to CHOP alone (75% versus 63%, $P = 0.005$). The 5-year EFS and OS were significantly higher in the R-CHOP arm: 47% versus 29%, $P < 0.001$; and 58% versus 45%, $P = 0.007$.^{299, 698} The results have held up at 10 years (Fig. 88.23).⁶⁹⁹ A similar intergroup trial reported a 3-year FFS of 53% for R-CHOP and 46% for CHOP ($P = 0.04$).⁷⁰⁰ A second randomization evaluated the role of maintenance rituximab (MR) and resulted in a 2-year FFS of 76% for MR compared to 61% for observation ($P = 0.009$); however, the major improvement was observed in patients who had not

P.1860

received rituximab with CHOP. The 2-year FFS after the second randomization for the 4 arms were: 77%, 79%, 74%, and 45% for R-CHOP, R-CHOP plus MR, CHOP+MR, and CHOP, respectively. Randomized trials in young patients have shown a superiority to the rituximab arm: 79% versus 59% 3-year EFS ($P < 0.0001$).⁷⁰¹ The addition of rituximab to CHOP may partially overcome the adverse prognosis associated with the nongerminal center (ABC) DLBCL.⁷⁰² New prognostic models evaluating biologic markers and/or gene expression are under investigation in the rituximab era, although reproducibility remains a concern.^{326, 703}

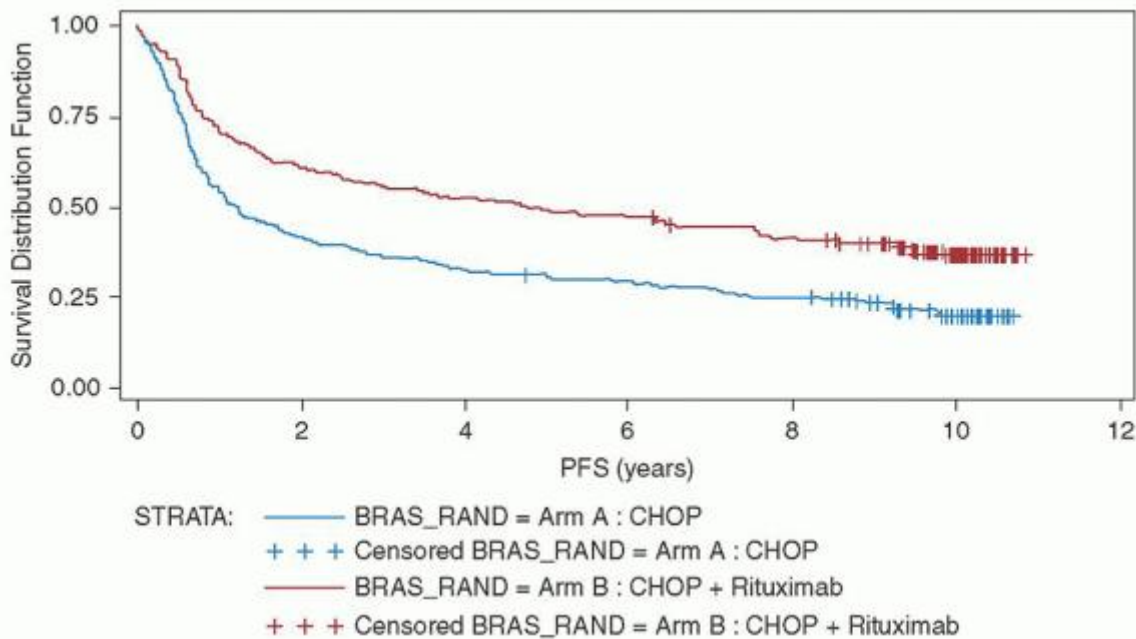

FIGURE 88.23. Progression-free survival (PFS) in elderly patients randomized between CHOP plus rituximab (R-CHOP) and CHOP. The 10-year PFS (median) was 36.5% (4.8 years, 95% CI: 23.7 to 7.6) for R-CHOP versus 20% (1.2 years, 95% CI: 9-1.8) for CHOP ($P < 0.0001$). From Coiffier B, Thieblemont C, Van Den Neste E, et al. Long-term outcome of patients in the LNH-98.5 trial, the first randomized study comparing rituximab-CHOP to standard CHOP chemotherapy in DLBCL patients:

a study by the Groupe d'Etudes des Lymphomes de l'Adulte. Blood 2010;116:2040-2045, with permission.

Strategies to improve response and survival in aggressive lymphomas have included using alternating non-cross-resistant regimens, infusional therapy, additional drugs, shorter intervals, modifiers of multidrug resistant genes, and dose intensification, including HCT. Phase II trials of non-cross-resistant regimens such as alternating triple therapy from M.D. Anderson, appeared to overcome adverse prognostic factors, but they were not compared to CHOP in phase III trials.^{704, 705} Similarly a continuous infusional regimen, EPOCH with dose adjustments (DA-EPOCH) based on an individual's drug clearance, had a CR rate in large B cell NHL of 92%, a 5-year PFS and OS of 70% and 73%, respectively, and overcame the IPI.⁵³⁶ Other phase II trials evaluating infusional therapy with or without modifiers of MDR (verapamil and quinine) have not shown an advantage over historical trials utilizing CHOP therapy.⁷⁰⁶ An intergroup trial is now comparing DA-EPOCH-R to R-CHOP.

German trials have evaluated whether biweekly CHOP (CHOP-14) with or without etoposide (CHOEP) was more effective than the same regimens given on a 21-day cycle. For elderly patients, aged 61 to 75 years, CHOP-14 was superior to CHOP-21 with 43.8% and 53.3% 5-year EFS and OS compared to 32.5% and 40.6%; and the CHOEP regimens were too toxic.⁷⁰⁷ Alternatively, for younger patients, aged 18 to 60 years, the CHOEP regimen had better CR (87.6% versus 79.4%, $P = 0.003$) and 5-year EFS (69.2% versus 57.6%; $P = 0.004$) than CHOP.⁷⁰⁸ There was no statistical advantage of CHOEP-14 over CHOEP-21. These trials were performed without rituximab which, if added, might lessen differences among the regimens. Randomized trials in the United Kingdom and France have compared R-CHOP 14 to R-CHOP 21 and have shown no differences in responses or survivals.^{709, 710}

Dose escalation has been advocated as a means to improve response and survival in aggressive lymphomas, but phase III clinical trials have yet to prove the efficacy of dose intensity. Increased doses of doxorubicin in the BACOP regimen failed to show improvement in response or survival when compared in a randomized trial to standard doses.⁷¹¹ In a small trial of 22 patients treated with high-dose CHOP, the CR rate was 86% with 69% PFS but short follow-up (median of 20 months).⁷¹² In a trial of 70 patients with intermediate- to high-grade lymphoma, a short course (8 weeks), dose intensive therapy, referred to as MEGA, produced an 81% CR rate and 52% 5-year FFS.⁷¹³ Another phase II trial evaluating double dose ProMACE-CytaBOM with growth factor support reported a CR of 69%, PFS of 58%, and OS at 73% at 4 years.⁷¹⁴ A dose-escalated trial known as MegaCHOEP with stem cell transplantation on the third and fourth cycles resulted in FTF of 62.1% and OS of 67.2% at 5 years.⁷¹⁵

In a phase III trial (LNH87-1) that compared a more intensive regimen, ACVBP (Adriamycin [doxorubicin], cyclophosphamide, vindesine, bleomycin, prednisone) to a standard regimen (m-BACOD) in a group of low-risk aggressive lymphoma patients, there were no differences in FFS and OS (65% and 75% in ACVBP, and 61% and 73% in m-BACOD).⁷¹⁶ In a multivariate analysis, ACVBP was associated with a better FFS in the patients with 2 or 3 age-adjusted IPI risk factors.⁷¹⁶ In another randomized trial, ACVBP was superior to CHOP plus RT for limited stage patients.⁶⁷⁶ ACVBP plus rituximab was also superior to R-CHOP in DLBCL patients <60 years with an IPI of 1. Three year EFS was 81% vs. 67% ($P = 0.0035$) and OS was 92% vs. 84% ($P = 0.0071$). Serious adverse events, particularly febrile neutropenia, were more common in R-ACVBP (42%) than in R-CHOP (15%).⁷¹⁷

Some investigators advocate early autologous HCT for selected DLBCL patients with poor prognostic factors, but large randomized trials have failed to consistently show a benefit for early transplantation.^{718, 719, 720, 721, 722, 723} R-CHOP is the standard regimen for DLBCL for adults in the United States. European trials and pediatric studies, however, have indicated a role for more intensive therapy based upon an increasing number of adverse features.^{715, 716, 724} And it is likely that there are patients with such poor survival at diagnosis who should be considered for either dose intensification or early transplantation. Ongoing trials continue to address the issues of dose intensity and transplantation as front-line therapy for aggressive NHL.^{725, 726}

P.1861

SALVAGE CHEMOTHERAPY

Chemotherapy regimens at relapse usually involve agents that are non-cross-resistant with, or at least different from, drugs used in initial therapy. Rituximab is usually added to the regimen as long as the lymphoma remains CD20-positive. For example, ifosfamide, an alkylating agent analog, produced a 29% response rate in phase II trials,⁷²⁷ and has been incorporated into salvage regimens. Investigators at MDACC have developed multiple effective protocols: MIME (methylguazone, ifosfamide, methotrexate, etoposide [VP-16]),⁷²⁸ DHAP (dexamethasone, high-dose cytarabine [ara-C], and cisplatin [Platinol]),⁷²⁹ ESHAP (etoposide, solumedrol [methylprednisone], high-dose cytarabine [ara-C], Platinol

[cisplatin]),⁷³⁰ MINE (mesna, ifosfamide, Novantrone [mitoxantrone], etoposide),⁷³¹ and MINT (mesna, ifosfamide, Novantrone [mitoxantrone], Taxol [paclitaxel]).⁷³² The CR and PR rates for a variety of histologic types were 24% and 36% for MIME; 31% and 24% for DHAP; 37% and 27% for etoposide, solumedrol (methylprednisolone), and high-dose cytarabine (ara-C) with or without cisplatin; and 26% and 20% for MINT. However, most of the responses were of short duration with median times to treatment failure usually less than 1 year. Combining regimens such as MINT-ESHAP or MINE-ESHAP has yielded response rates in the 49% to 69% range, but there are no obvious differences in outcome among the combinations.^{733, 734}

Various doses and schedules of ICE (ifosfamide, carboplatinum, etoposide) have been used in relapsed NHL and to mobilize peripheral blood stem cells prior to transplant.^{735, 736} The response rate to an ICE regimen developed at Memorial Sloan-Kettering Cancer Center was 66%, with 89% of these patients going on to transplantation.⁷³⁵ Patients who achieved a CR to ICE prior to transplantation had a superior OS to patients who had PR (65% versus 30%, $P = 0.003$).⁷³⁵ The addition of rituximab to an ICE regimen improved the CR rate from 27% on a previous study to 53%.⁷³⁷

A phase III trial, the Collaborative Trial in Relapsed Aggressive Lymphoma (CORAL) study, randomized R-ICE versus R-DHAP in patients with refractory or relapsed CD20⁺ DLBCL and found similar response rates (63.5% vs. 62.8%).⁷³⁸ Responding patients failed to mobilize after both regimens and only 50% of patients were able to undergo SCT. There was no difference in 3-year EFS (26% and 35%) or OS (47% and 51%) between the 2 regimens. EFS was adversely affected by initial relapse within 1 year from diagnosis, aIPI of 2 to 3, and prior rituximab treatment.

Based on the premise that prolonged exposure to therapy may be more effective than bolus, EPOCH was developed at the NCI and produced a 24% CR and 50% PR in relapsed/refractory NHL.⁷³⁹ With a median follow-up of 76 months, the OS and EFS were 17.5 and 7 months, respectively. In patients with chemosensitive disease with aggressive histologies, the EFS was 19% at 3 years⁷³⁹ (see section on "DA-EPOCH-R in Chemotherapy"). Investigators at Stanford University developed CEPP(B) (cyclophosphamide, etoposide, procarbazine, prednisone \pm bleomycin), which produced 34% CR and 22% PR in previously treated patients with intermediate- or high-grade histologies.⁷⁴⁰

In general, salvage chemotherapy regimens in DLBCL are utilized as a bridge to transplantations because prolonged survivals without transplant are less than 15%. Single agent therapy is rarely used in intermediate- to high-grade lymphoma except in phase I/II trials or as palliation. Because of significant activity in relapsed disease, some of the agents are being used in combination with other drugs earlier in the course of NHL.

Oxaliplatin, a third-generation platinum drug with no renal toxicity and minimal auditory damage, has a 40% response rate in refractory NHL and is used in salvage regimens.⁷⁴¹ Rituximab, dexamethasone, cytarabine, and oxaliplatin (R-DHAX) had an ORR of 75% (57% CR/CRu) in relapsed NHL, primarily DLBCL and FL.⁷⁴² Combining gemcitabine with oxaliplatin and rituximab (GEMOX-R) led to an ORR of 43% with 34% CR in refractory/relapsing DLBCL.⁷⁴³ Both regimens could be used in elderly patients and the best survivals were in patients who were able to go to transplant.

Doxorubicin-related compounds used as single agents and in combination chemotherapy for relapsed NHL include mitoxantrone,⁷³⁴ amsacrine,⁷⁴⁴ idarubicin,⁷⁴⁵ epirubicin,⁷⁴⁶ aclacinomycin,⁷⁴⁷ esorubicin,⁷⁴⁸ liposomal doxorubicin,⁷⁴⁹ and pixantrone.⁷⁵⁰ No drug has had an advantage over doxorubicin, although mitoxantrone produces less alopecia, mucositis, nausea, emesis, and possibly cardiotoxicity. Liposomal doxorubicin also appears to have less cardiotoxicity. CHOP was superior to CNOP (cyclophosphamide, mitoxantrone, vincristine, prednisone) in a randomized trial in elderly patients;⁷⁵¹ however, an argument has been made that the study did not compare equivalent doses of doxorubicin and mitoxantrone.⁷³⁴ A salvage regimen utilizing mitoxantrone, carboplatin, cytosine arabinoside, and methylprednisolone had a response rate of 70% (26% CR).⁷⁵²

Nucleoside analogs have primarily been used in indolent lymphomas, but gemcitabine, a pyrimidine antimetabolite, has had activity in relapsed aggressive lymphomas (see section on "GEMOX"). A response rate of 20% was observed in predominantly large B cell NHL, and higher responses have been observed in PTCL.^{753, 754} The ORRs in gemcitabine combination regimens with cisplatin and methylprednisolone, and with vinorelbine, have been 79% (21% CR) and 50% (14% CR), respectively.^{755, 756} The ORR of cisplatin, etoposide, gemcitabine, and methylprednisolone (PEGS) in PTCL was 39% (24% CR/CRu) with 2-year OS of 30% and PFS of 12%.⁵⁵³ The authors concluded that PEGS was not clearly superior to results for CHOP likely because of the inherent chemoresistance of PTCL, but PEGS could serve as a comparison for non-CHOP regimens in PTCL.

Vinca alkaloids with less neurotoxicity than vincristine have also been evaluated in NHL. Vincristine sulfate liposomes injection had a 25% ORR (5% CR/CRu) in refractory aggressive NHL with twice the dose intensity of standard vincristine.⁷⁵⁷ Infusional vinorelbine resulted in 25% response with a median PFS of 6 months in responders.⁷⁵⁸ Novel methods of drug

delivery including liposomal formulations, pegylation, different schedules of infusions, and oral formulations may also obtain responses in relapsed NHL.^{757, 759, 760}

Taxanes and camptothecins are agents with activity in solid tumors which are being evaluated in the therapy of NHL. Paclitaxel (Taxol) and docetaxel (Taxotere) are tubulin-binding taxanes which have produced responses in 13% to 23% of heavily treated patients.^{761, 762, 763, 764} Camptothecins, topoisomerase I inhibitors, including hycamptamine (Topotecan), irinotecan (Camptosar), and 9-aminocamptothecin (9-AC) have had responses of 25% to 35%.^{765, 766} Combinations of paclitaxel plus hycamptamine are synergistic, with a response rate of 48% and a median duration of 6 months.⁷⁶⁷

Bortezomib is a proteasome inhibitor that has shown activity in lymphoma, and response rates vary according to histologic subtypes.^{768, 769, 770} The best response rates (33% to 56%) have been reported in MCL, the only type of NHL for which bortezomib is approved. Bortezomib plus CHOP-R is in trials for previously untreated DLBCL and MCL and appears to overcome the poor prognosis of nongerminal DLBCL, possibly through inhibition of the NF-KB pathway.^{494, 769, 770, 771}

Understanding mechanisms of drug resistance is an area of investigation for the development of salvage regimens. Although the multidrug resistance (MDR/ABC1) gene and its gene product, P-glycoprotein, are expressed rarely in lymphomas at diagnosis, MDR expression often is detected in lymphoma cells at relapse. The MDR-inhibiting agents include verapamil, cyclosporine, and its analog valspodar (PSC-833), and their use in conjunction with chemotherapy has been inconsistent in patients with relapsed lymphomas.^{772, 773}

P.1862

NOVEL AGENTS

Relapse due to chemoresistance remains a major obstacle in improving survival for NHL. Targeting B and T cell receptors with monoclonal antibodies, both unconjugated and conjugated, is an ongoing area of investigation (see section on "Immunotherapy"). The PI3K/AKT/mTOR signaling pathway is critical in cancer development, and aberrant activation of the protein tyrosine kinases has led to the development of novel targeted therapy. Drugs under investigation target protein kinases, oncogenic signaling via the mammalian target of rapamycin complex (mTOR), and the tumor microenvironment (immune modulation) (Fig. 88.24).^{774, 775, 776}

B cell receptor (BCR) signaling can lead to activation of spleen tyrosine kinase (SYK) in B cell lymphomas. Fostamatinib, an oral SYK inhibitor, abrogates BCR signaling, inhibits MYC overexpression, and induces apoptosis. In a phase I/II trial of relapsed B-NHL (n = 68), the ORRs were: 22% for DLBCL, 10% for FL, 55% for SLL/CLL, and 11% for MCL.⁷⁷⁷ Side effects included fatigue (41%), diarrhea (41%), cytopenias (24% to 31%), and hypertension (24%).

Ibrutinib (PCI-32765) is an oral, irreversible inhibitor of Bruton tyrosine kinase (BTK) just downstream of SYK; and it inhibits the subsequent pathways, including MAPK, PI3K, and NF-κB signaling.⁷⁷⁸ In 26 elderly (median age, 71 years) CLL patients, 73% achieved a response (65% PR and 8% CR) and an additional 12% had a nodal response with lymphocytosis.⁷⁷⁹ One year PFS was 93%. Diarrhea, nausea, and fatigue were common (grade ≤2) side effects; 10% of patients had > grade 3 cytopenias or infections. In a phase IA study of 56 patients with relapsed B-NHL, the ORR was 62%, including 29% for DLBCL and 78% for MCL.⁷⁸⁰

CAL-101 (GS-1101) is an oral selective inhibitor of PI3K-δ and is active in CLL and other B cell NHL with little toxicity and minimal myelosuppression. In a phase I trial of 55 patients with relapsed B-NHL, PRs occurred in 62% for both indolent NHL and MCL but none in DLBCL.⁷⁸¹ Because CAL-101 inhibits microenvironment signals which can cause drug resistance and enhances cytotoxic agents, it is being investigated in combination regimens.⁷⁸² In 18 patients who received CAL-101 with rituximab or bendamustine, the ORRs were 91% in indolent B-NHL (n = 11) and 71% in CLL.⁷⁸³

Enzastaurin is an oral inhibitor of protein kinase C beta (PKCβ), an essential component of the vascular endothelial growth factor (VEGF) signaling pathway, which has been linked to a poor prognosis in DLBCL.⁷⁸⁴ In a phase II trial of 55 patients with relapsed/refractory DLBCL, 7% had a CR, 22% experienced FFP for ≥ 2 cycles, and 15% had FFP for ≥ 4 cycles.⁷⁸⁵ Toxicities were minimal with 4% grade 3 and there was no grade 3 or 4 neutropenia. In a randomized phase II trial of R-CHOP plus enzastaurin versus R-CHOP in high-intermediate or high IPI DLBCL, the CR rates were 36% vs. 26% and the 1 year PFS was 71% vs. 52% with similar toxicity profiles.⁷⁸⁶

FIGURE 88.24. Targeting B cells: This simplified schematic illustrates relationships between intermediates (see text) in the PI3K/AKT/mTOR pathway and shows points at which selected drugs inhibit B cell growth.

Rapamycin and the rapalogs (temsirolimus, everolimus, and deforolimus) are inhibitors of mTOR kinase, a mediator of growth signaling that follows the PI3K pathway and is activated by mutation or amplification of AKT (protein kinase B).^{774, 787} Temsirolimus has yielded ORR of 22% to 41% in MCL.⁷⁸⁷ In a phase III trial comparing temsirolimus to investigator's choice of therapy in relapsed/refractory MCL, the objective RR was higher for temsirolimus (22% vs. 2%) ($P = 0.0019$); and there was no statistical difference in median OS (12.8 vs. 9.7 months).⁷⁸⁸ The grade 3/4 toxicities were thrombocytopenia (59%), anemia (20%), neutropenia (15%), and asthenia (13%). In a phase II trial of everolimus for relapsed B-NHL, the ORR was 30% with no differences among DLBCL (30%), MCL (32%), and FL (38%).⁷⁸⁹

Immunomodulating drugs (IMiDs) have both immunomodulatory and antiangiogenic properties; they can stimulate T cell responses and dendritic cells to recruit natural killer cells and modify the cytokine microenvironment.⁷⁷⁴ Lenalidomide, an analog of thalidomide, has been extensively evaluated in CLL. Responses of 31% to 47% were observed in relapsed patients and 58% to 65% in previously untreated CLL.⁷⁹⁰ A tumor flare response (painful enlargement of nodes or spleen, fever, and rash) occurs in over half the patients in several series and may be lessened by slow dose escalation and the use of steroids.^{790, 791} Tumor lysis may occur in up to 5% of CLL patients treated with lenalidomide.⁷⁹⁰

Lenalidomide monotherapy has also been used in aggressive lymphomas. An ORR of 35% (12% CR/CRu) was observed in 49 relapsed/refractory B-NHL, including 19% for DLBCL and 53% for MCL.⁷⁹² Grade 4 cytopenias were 8.2%. In an international phase II trial, the ORR was similarly 35% (13% CR): 28% for DLBCL, 42% for MCL, 42% for FL-grade 3, and 45% for transformed lymphoma.⁷⁹³ The PFS was 3.7 months and the median duration of response for responders was 10.6 months. Grade 4 neutropenia and thrombocytopenia occurred in 17% and 6%, respectively. A higher response and improved survival with lenalidomide has been reported for the nongerminal center DLBCL compared to the germinal center type.⁷⁹⁴ An ORR of 30% has been reported in PTCL.⁷⁹⁵

P.1863

All of the above agents and many more are being investigated in combinations with each other, monoclonal antibodies, and chemotherapy. Trials should be designed with specific targets, pre-clinical evidence of synergism, and an awareness of the expense.

HIGHLY AGGRESSIVE LYMPHOMAS

BL and lymphoblastic lymphoma (LBL), usually of immature T cell origin, are rare NHLs in adults, each representing less than 3% of NHLs. Since NHL is more common in adults; the absolute number of highly aggressive lymphomas exceeds that in children. Because children are treated primarily on clinical trials unlike adults, at least in the United States, the main advances learned from pediatrics apply to the therapy of highly aggressive lymphoma in adults (Chapter 89). In brief, short course, dose intensive cyclophosphamide therapy is utilized in BL while therapy for ALL is the main approach to LBL. Both types of highly aggressive NHL require CNS prophylaxis, and have clinical overlap with adult ALL (Chapter 74).

Burkitt Lymphoma

BL has a bimodal peak between 0 and 15 years and a later peak over 60 years.⁷⁹⁶ SEER data indicates the median age is as high as 45 years with 30% over 60 years of age.⁷⁹⁷

BL is characterized by a high proliferative rate (Ki67 approaching 100%), a germinal center phenotype expressing CD10 and BCL6 and weak BCL2, and a MYC/8q24 translocation.⁷⁹⁸ B cell lymphoma unclassified with features intermediate between DLBCL and BL (BLU) tend to have slightly deviant morphology and not quite as high a proliferative rate as BL. MYC translocations occur in 30% to 50% of BLU, but there are usually more complex genetic abnormalities than BL, including "double hits" where there are BCL2 translocations or breakpoints in BCL6.⁵¹⁵

GEP is emerging as a technology to distinguish lymphomas with an intermediate morphology between DLBCL and BL. BL can be distinguished from DLBCL by a high level of MYC target genes, a subgroup of germinal center B genes, and a low level of expression of major-histocompatibility complex Class I genes and NF-κB target genes.⁷⁹⁹ Until GEP becomes more available, detecting MYC translocations by fluorescence in situ hybridization along with a high proliferative index can usually distinguish BL from DLBCL.⁸⁰⁰

In the United States, BL tends to occur in younger adults with more gastrointestinal presentations and less marrow involvement than BLU; but they clinically overlap, have a risk for spontaneous tumor lysis, and have been difficult to cure with conventional chemotherapy for adults. Intraabdominal presentations usually involve the small bowel and intraabdominal nodes and may mimic appendicitis or intussusception.⁸⁰¹ Surgery formerly played a role in staging and debulking disease, but now is reserved for the emergency acute abdomen. Early use of rasburicase and nephrology intervention should be considered in patients with elevated levels of LDH and uric acid. Bone marrow and CNS involvement have been reported in 30% to 38% and 13% to 17% of patients, respectively.⁸⁰¹

Short course, dose intensive regimens have improved results in BL/mature B-ALL.^{727, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815} Results vary in part due to differences in age, stage, number of HIV-positive patients, and intensity of therapy (Table 88.14). In general, the CR rates are in the range of greater than 80% and survival is approximately 50% for the older adult and in the range of 60% to 90% for young adults. CNS prophylaxis previously involved whole brain and occasionally spinal radiation, but can be accomplished by a combination of intravenous and intrathecal drugs (methotrexate and/or cytarabine). Radiation may still be utilized in patients who have documented CNS disease at diagnosis. Growth factors, either G- or GM-CSF, have decreased the length of myelosuppression and are a part of present-day regimens. Rituximab is incorporated into the regimens and appears to have improved outcome, but there are no comparative trials.⁸¹⁰ Relapses are usually confined to the first year after stopping therapy; there is no role for maintenance.

In pediatric and some adult trials, there is a prephase with low-dose cyclophosphamide- vincristin-steroids to debulk and to lessen tumor lysis, followed by intensive therapy stratified according to prognostic factors.⁸⁰³ Prephases are probably unnecessary in most patients, particularly with the use of rasburicase. Patients with limited stage disease often require only 2 to 3 cycles of therapy delivered over 2.5 to 4 months.⁸¹⁶ In a retrospective review of adults treated with the pediatric LMB protocols, the CR rate was 89% with a 3-year OS of 74%.⁸⁰³ The Magrath regimen of CODOX-m/IVAC has been administered to both children and adults and also utilizes risk stratification. The initial reports had a 4-year DFS of 84% but were in a young population with a median age of 25 years.⁷²⁷ Selected older patients are now given the more intensive regimens but tend to have more treatment-related deaths unless modifications are made.⁸¹⁷

Intensity of therapy in HIV patients with NHL was previously reduced due to risk of infections and poor survival; however, in the era of HAART and growth factor support, the CR rate with hyper-CVAD in HIV patients with BL/leukemia has reached 92% with a 2-year survival of 48%.⁸¹⁸ Myelosuppression can still be problematic in HIV patients and dose modifications may be required. There is a randomized trial indicating that rituximab does not improve survival if given with chemotherapy in HIV-related NHL.⁸¹⁹ The lack of improvement in the rituximab arm was attributed to increased infectious deaths in HIV patients with CD4(+) counts less than 50/mm³. Rituximab with concurrent infusional EPOCH achieved a high rate of complete response. At a median follow-up of 5 years the PFS and OS were 84% and 68%,

respectively.⁸²⁰ DA-EPOCH-R is also being used in non-HIV BL/BUL and may be particularly warranted in the elderly due to less toxicity.⁸¹⁵

Advanced stage patients with CNS or marrow involvement previously had survival less than 30% and were considered candidates for early transplantation;⁸²¹ however, with the present-day regimens, DFS is in the 40% to 80% range for BL/B-ALL, obviating the need for early transplantation in most adult patients.⁸²² At relapse, there is no standard therapy, and there is no clear advantage of allogeneic HCT over autologous, even though many centers favor the former.⁸²³ Transplantation is rarely successful for relapsed patients unless they are chemosensitive and in a second CR (see Chapter 104).

Lymphoblastic Lymphoma

T cell LBL is more common than B-LBL in adults, accounting for up to 90% of cases. T-LBL is seen primarily in adolescents and young adults with a predominance of men (2 to 3:1) who have a bimodal distribution (peaks at age 10 to 30 and 60 to 70 years).⁸²⁴ T-LBL presents with a mediastinal mass in 60% to 70% of cases.⁸²⁵ B cell LBL has a slight male predominance, a more even age distribution (median age ~39 years), and rarely has mediastinal or bone marrow involvement. Extranodal sites of disease are common in B-LBL and include skin, bone, and soft tissue.^{826 827}

The immature T cell origin of LBL was confirmed by the presence of the intranuclear enzyme, terminal deoxynucleotidyl transferase (TdT), which is not detected in the mature or peripheral T cell neoplasms. Although LBL expresses less TdT and tends to have a more mature phenotype than T-ALL, considerable overlap exists both biologically and clinically between these entities, and they are unified as precursor T cell lymphoblastic leukemia/lymphoma by the WHO classification.⁸²⁸

Multiple genes have been identified in the translocations associated with T-LBL/ALL. Approximately one-third of patients with T-LBL have translocations involving the loci of T cell receptor

P.1864

P.1865

genes, α and δ at 14q11.2, β at 7q35, and γ at 7p14-5, which produce high levels of transcription factor genes such as HOX11/TLX1, TAL1/SCL, TAL2, and LYL. GEP can subdivide T-LBL into subtypes with differing prognoses.^{829 830 831} Patients with HOX11 have a pattern of gene expression associated with the early cortical thymocyte and have a better prognosis than patients with TAL1 or LYL1 expression, which correlate with late cortical and early pro-T lymphocytes, respectively.⁸³² NOTCH1 is a transmembrane receptor and activating mutations occur in 50% to 60% of patients with childhood T-ALL.⁸³³ FBXW7 is a ubiquitin ligase that triggers ubiquitination and degradation by the proteasome. Inactivating mutations FBXW7 have been reported in 11% to 13% of patients. NOTCH1 and FBXW7 mutational status together identify a favorable group of lymphoblastic lymphoma.⁸³⁵ Rarely, T-LBL is associated with eosinophilia, myeloid malignancy, specific cytogenetic translocations t(8;13) (p11;q12), t(8;9)(p11;q32), or t(6;8)(q27;p11), and is known as 8p11 myeloproliferative disorder.⁸³⁶ Unusual cases of T cell LBL have been associated with prior epipodophyllotoxin chemotherapy and a cytogenetic translocation involving the MLL gene, t(11;19)(q23;p23).⁸³⁷

TABLE 88.14 CHEMOTHERAPY IN ADULTS WITH BURKITT LYMPHOMA

Author, Year	No. Median of Age Pts (Yrs)		HIV (%)	BM(%)	Therapy	Survival			Comments

BM, bone marrow involved; CALGB, Cancer and Leukemia Group B; CR, complete remission; CODOX, cyclophosphamide, vincristine, doxorubicin, high-dose methotrexate; D, liposomal cytarabine; DFS, disease-free survival; dm, dose-modified; EPOCH, etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin; M, methotrexate; GMALL, German Multicenter ALL; Hyper CVAD, cyclophosphamide, vincristine, Adriamycin (doxorubicin), dexamethasone alternated with high doses of methotrexate and cytarabine; HIV, human immunodeficiency virus; IVAC, ifosfamide, VP-16 (etoposide), Ara-C (cytarabine); LMB, Lymphoma Malins de Burkitt; R, rituximab.

Because LBL is rare in adults, only a few series have addressed therapy and some patients have received early transplantation, which compromises the assessment of the impact of chemotherapy.⁴⁵⁸ Studies in the 1980s indicated a CR rate of 53% to 95% using CHOP-like induction regimens and high CNS relapse (~40%) if CNS prophylaxis was not given.^{838, 839, 840} Using predominantly ALL-like regimens with a maintenance phase lasting 12 to 36 months results in 3- to 5-year survivals of 40% to 72%.^{838, 839, 840} Poor prognostic features included age (> 30 years), bone marrow involvement, elevated white-cell count (>50 × 10⁹/L), CNS disease, elevated LDH, and slow response.^{839, 840} Coleman reported a 5-year

survival of 94% in low-risk patients compared to 19% ($P < 0.001$) with high-risk features, defined by bone marrow or CNS disease or elevated LDH ($>1.5 \times$ normal).⁸⁴⁰ Short course, dose intensive regimens without maintenance have been tried in lymphoblastic lymphoma, but the relapses appear excessive and the numbers are too small to utilize this approach.⁸⁴¹

Controversial management issues for LBL include the optimal type of CNS prophylaxis, the role of radiation to the mediastinum, the type of maintenance therapy, and the role of transplantation. With present-day ALL regimens, the CR rates are 75% to 90%, with prolonged DFS of 40% to 70% of responders (Table 88.15).^{842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853} An option to consider for young adults is to utilize pediatric-based protocols which have had better EFS when compared to adult ALL protocols.⁸⁵⁴ A retrospective analysis comparing patients irradiated to those not irradiated showed less mediastinal relapse but no difference in FFP or OS.⁸⁵⁵ In the era of intensive ALL regimens, however, routine mediastinal radiation is no longer used in pediatrics and is probably not warranted in most adults. PET imaging may assess residual mediastinal disease, but it has not been well studied in LBL. Because of poor survival with chemotherapy in high-risk patients, there may be a role for early transplantation.⁸⁵¹

TABLE 88.15 CHEMOTHERAPY IN ADULTS WITH LYMPHOBLASTIC LYMPHOMA

Author, Year (Reference)	No. of Patients	Median Age (y)	Regimen	SCT in Overall			Survival by Risk Group

ALL, acute lymphoblastic leukemia; CR, complete response; GMALL, German Multicenter Acute Lymphoblastic Leukemia; HyperCVAD, cyclophosphamide, vincristine, doxorubicin, dexamethasone alternated with high-dose methotrexate and cytarabine followed by maintenance; LMT, Lymphoma Malignant T; NHL, non-Hodgkin lymphoma; SCT, stem cell transplant.

^a High risk defined by marrow involvement.

^b Transplant: 12 allo, 31 auto; auto had 55% vs. 24% RFS (3 year) for chemotherapy ($n = 34$) ($P = 0.065$).

^c Transplant: 4 allo, 25 auto.

^d CR rate up to 93% with radiation to 6 pts.

The most significant predictor of survival for patients undergoing HCT is the status of the disease at the time of transplant.^{853, 856, 857, 858, 859} The European Bone Marrow Transplantation Group retrospectively reviewed their experience in 214 patients with LBL who underwent autologous transplantation with 6-year DFS varying according to disease status: 63% in first CR, 31% in second CR, and 15% with resistant disease.⁸⁵³ Trials that evaluate HCT often fail to include intent to

treat analysis and result in a bias favoring the transplant arm. In a randomized trial comparing early autologous HCT to conventional chemotherapy,⁸⁵⁸ there was a trend favoring autoHCT (55% versus 24%, P = 0.065) but there was no improvement in OS.⁸⁵⁸ Only two-thirds of patients eligible for randomization were actually randomized.

The role of allogeneic transplant in LBL in first CR is even more controversial. In an International Bone Marrow Transplant Registry retrospective review of transplants for LBL, there were fewer relapses with allogeneic HCT compared to autologous HCT, but there was no survival advantage due to higher treatment-related mortality.⁸⁵⁹ Recent randomized trials in adult ALL, some of which include LBL, however, are favoring the allogeneic arm.^{860, 861}

Novel agents are being studied in relapsed LBL. Nelarabine, an analog of AraG, had an ORR of 55% in pediatric patients with T-ALL/LBL in first relapse and 27% in second relapse.⁸⁶² An ORR of 46% (36% CR) was reported for adults with relapsed/refractory T-ALL/LBL.⁸⁶³ Clofarabine, a nucleoside analog that

P.1866

inhibits ribonucleotide reductase, had an ORR of 30% (24% CR) in relapsed pediatric ALL and 17% in adult ALL.⁸⁶⁴ Clofarabine combined with cyclophosphamide and/or etoposide had a 31% CR rate in adults with relapsed ALL/LBL, but had 23% treatment-related deaths.⁸⁶⁵ The prevalent NOTCH1 mutations in T-ALL are targets for inhibition, and mutations of NUP214-ABL1, an activated tyrosine kinase in episomal DNA, present in 6% of T-ALL, may respond to tyrosine kinase inhibitors.⁸⁶⁶

MANAGEMENT OF EXTRANODAL LYMPHOMAS

Approximately one-third of NHLs arise from sites other than nodes, spleen, or bone marrow, and have occurred in almost every organ.⁸⁶⁷ There is geographic and ethnic variation for sites and types of extranodal lymphomas.⁸⁶⁸ The gastrointestinal tract accounts for up to one-third of extranodal NHL in the Western hemisphere.^{867, 869} If Waldeyer's ring and tonsils are included, head and neck localizations are the second most common site, accounting for one-fifth of cases. SEER data reports stomach, skin, intestine, and brain to be the most common sites of extranodal disease.³⁵ The sites of extranodal lymphoma reflect the homing mechanisms of lymphocytes and may depend upon antigen-driven lymphoproliferation. Management of extranodal lymphomas does not necessarily follow that of their nodal counterparts.⁸⁷⁰

TABLE 88.16 MANAGEMENT ISSUES FOR EXTRANODAL LYMPHOMAS

Site	Usual Pathology	Clinical Associations	Suggested Therapy ^a
Stomach	B cell MALToma	<i>Helicobacter pylori</i>	Antibiotic trial, serial endoscopy; other therapy if t(11;18), t(1;14), transformation or progressive disease
Intestine	Burkitt	Obstruction	High-dose cyclophosphamide combination chemotherapy ±surgery
Ileum	B cell MALToma	Malabsorption IgA heavy chain, Middle East	Antibiotics, steroids, ± combination chemotherapy
Immunoproliferative small intestinal disease	Peripheral T cell lymphoma	Celiac disease, West	Combination chemotherapy ± surgery; nutrition
Enteropathy-associated T cell lymphoma		Obstruction	
Waldeyer's ring	Large B cell	Other gastrointestinal disease	Combination chemotherapy or combined modality
Paranasal (sinus)	Large B cell	CNS disease	Combined modality, consider CNS prophylaxis
Nasal	Natural killer/T cell lymphoma	Epstein-Barr virus; angiocentric features,	Combined modality, consider CNS prophylaxis

Asia			
Salivary gland	B cell MALToma	Sjögren syndrome	Single agent and/or radiation
Thyroid	Large B cell, B cell MALToma	Hashimoto thyroiditis	Radiation or combined modality, depending on histology and stage
Lung	Small B cell, B cell MALToma		Single agent, surgery, or radiation
Orbital	Small B cell, B cell MALToma		Radiation
Primary CNS	Large B cell	Ocular involvement Leptomeningeal disease AIDS	Steroids, high-dose methotrexate ± radiation
Testis	Large B cell	Contralateral testicular disease, CNS disease, retroperitoneal spread	Orchiectomy, combination chemotherapy, radiation to contralateral testis, CNS prophylaxis
Breast	Large B cell	Pregnancy	Combination chemotherapy ± radiation
Ovary	Burkitt Large B cell	Bilateral disease	Combination chemotherapy
Bone	Large B cell		Combination chemotherapy ± radiation
Cutaneous	Mycosis Fungoides B cell MALTomas, primary cutaneous follicular lymphoma, primary cutaneous large B cell lymphoma		Skin-directed Radiation if stage IE Combined modality (see Chapter 92)

AIDS, acquired immunodeficiency syndrome; CNS, central nervous system; MALToma, lymphoma of mucosa-associated lymphoid tissue.

“Combined modality refers to combination chemotherapy and radiation. Combination chemotherapy refers to doxorubicin-based therapy. Rituximab is added to therapy of most B cell (CD20+) lymphomas.

Site(s) of involvement and histologic type are both important factors in the management of extranodal lymphomas (Table 88.16). It is important to determine whether the disease is localized or disseminated. The Ann Arbor staging system has been used with stage IE, representing localized extranodal lymphoma, and IIE, representing extranodal lymphoma with involvement of adjacent lymph nodes; a subclassification of IIE, which separates involvement into contiguous nodes (II₁E) and noncontiguous nodes (II₂E), has been used in gastric lymphomas; stages III and IV in extranodal lymphomas represent disseminated disease with little advantage in distinguishing the 2 stages. Extranodal lymphomas of the gastrointestinal tract, nasopharynx, and testes are generally more aggressive than those of the lung, orbit, or salivary gland. Therapy, however, depends not only on the site, but also on the histologic characteristics, immunophenotype, epidemiologic factors, size, and stage of the lymphoma.

The stomach accounts for approximately one-half of the gastrointestinal lymphomas; 60% of gastric lymphomas are aggressive, usually DLBCL, sometimes in conjunction with low grade histology, and 40% are indolent, usually of the MALT type. The

P.1867

recognition of MALTomas has led to unique therapeutic options. MALTomas were previously called pseudolymphomas, but the latter term is no longer valid because MALTomas are monoclonal, can be associated with a higher grade histology, and have cytogenetic abnormalities.^{107, 108, 109, 110, 871} Clinically, MALTomas are different from other indolent lymphomas in that they tend to remain localized, rarely disseminate, and respond favorably to local therapy.^{871, 872}

Management of gastric MALToma changed when antibiotic therapy for *H. pylori* resulted in regression of lymphoma.^{873, 874, 875, 876, 877} Ultrasound endoscopy and biopsies assist in determining the extent of disease and depth of invasion, which correlate with spread to regional lymph nodes and response to antibiotics.⁸⁷⁸ CR rates to antibiotics are over 80% when disease is confined to the mucosa and submucosa.⁸⁷⁶ Antibiotics are also curative in over half the patients with *H. pylori* associated gastric large B cell lymphoma, with either a mixed marginal zone/DLBCL or pure DLBCL.¹⁰¹ Infiltration of the muscularis propria or nodal extension and the presence of t(11;18) or t(1:14) predict poor response to antibiotics.^{875, 876, 879} Serial endoscopies are warranted to ensure eradication of *H. pylori* and gradual disappearance of the lymphoma over many months.^{873, 874, 875, 876} Follow-up endoscopy is recommended 2 months after antibiotic therapy and, subsequently, at least twice a year for 2 years.⁸⁷⁸ B cell clonality as detected by PCR may persist after histologic regression, but is of uncertain clinical significance.^{104, 880} If there is *H. pylori* negative or progressive disease, alternative therapies are usually effective and include radiation, rituximab, and/or single agent or combination chemotherapy.^{872, 881, 882}

With the recognition of MALToma and the effectiveness of other therapies, the role of surgery has diminished in the management of gastrointestinal lymphoma. While early studies advocated surgical resection in gastric and other intestinal lymphomas to cure localized disease, debulk, accurately stage, and/or prevent perforation,^{247, 883, 884} recent reports have achieved good results with either combination chemotherapy or combined modality without surgery, particularly for the aggressive histologies.⁸⁶⁹ While a partial or subtotal gastrectomy may be justified in rare cases, more extensive surgery, such as total gastrectomy, should not be routinely performed because of the increased morbidity and the curability with alternative therapies. In a series of 398 patients with localized primary gastric lymphoma (38% MZL and 49% DLBCL) who received radiation and/or chemotherapy, there was no difference in survival at 42 months for those treated with surgery (n = 63; 86% OS) compared to those without surgery (n = 335; 91% OS).⁸⁸⁵

Similar surgical issues pertain to intestinal lymphomas as to gastric lymphomas, particularly if they present with obstruction; however, they usually are less amenable to total resection.⁸⁸⁶ Other B cell tumors which can have unique gastrointestinal presentations are Burkitt in the ileocecal region, which is common in the Middle East,⁸⁸⁷ mantle cell lymphoma, which can present with lymphomatous polyposis,²⁵⁰ and FL in the duodenum.⁸⁸⁸ Immunoproliferative small intestinal disease (IPSID), also called alpha heavy chain disease or Mediterranean lymphoma, can be considered a subtype of B cell MALToma distinguished by its occurrence in older children and young adults (age range, 10 to 35 years) from low socioeconomic groups in the Middle East and North Africa and its association with the synthesis of an IgA heavy chain and *Campylobacter jejuni*.^{114, 889} Although the prognosis is usually considered poor in IPSID, a combination of antibiotics (tetracycline), steroids, and/or anthracycline-based chemotherapy, along with aggressive supportive care with hyperalimentation, can achieve complete remissions in two-thirds of patients, with survivals in over half the patients at 3.5 years.^{889, 890} A unique T cell lymphoma of the small intestine is EATL, which can be associated with celiac disease (type I), may require emergent surgery due to obstruction or perforation, and responds poorly to chemotherapy (see section on "Extranodal Peripheral T Cell Lymphoma").^{612, 891, 892}

Lymphomas involving Waldeyer's ring account for up to one-third of extranodal lymphomas and are second to gastric lymphoma as the most common extranodal site.⁸⁹³ Prognosis depends upon histology, which is usually a DLBCL, size of the tonsillar mass, and stage.⁸⁹⁴ Up to one-half of patients have advanced disease, and simultaneous involvement of the gastrointestinal tract is detected in 10% to 15% of patients with Waldeyer's ring lymphoma.^{895, 896} Because of the usual DLBCL histology and the advanced stage of many patients, chemotherapy plus rituximab, often in combination with radiation, is usually considered the therapy of choice.⁸⁹⁷ With combined modality therapy, 5-year PFS is 70% to 90% for clinical stage IE and 40% to 60% for stage IIE.^{898, 899, 900}

Lymphomas of the nasal cavity and paranasal sinuses often are evaluated in series that include Waldeyer's ring lymphomas, despite differences in presentation, diagnosis, and therapy. The primary lymphoma is often advanced in nasal lymphomas with invasion of adjacent bones and an increased risk for CNS involvement. Although uncommon, cervical

node involvement in nasal lymphomas is associated with a poor prognosis.⁸⁹⁸ Using the American Joint Committee TNM staging for carcinoma of the paranasal sinuses, patients with T 1 to 2 lesions had an 89% 5-year DFS compared to 25% for patients with T 3 to 4 lesions.⁸⁹⁸ DLBCL is the most common histology in the West; but in series from Asia, NK/T cell lymphomas predominate, present with nasal septal perforation or destruction, and are associated with EBV (see section on "Extranodal PTCL").^{617, 901} Concurrent chemoradiotherapy or novel chemotherapy using agents which bypass MDR is advocated for most nasal NK/T cell lymphoma.⁹⁰² The best therapeutic results in nasal lymphomas have tended to be in those series with combined modality therapy.^{901, 903} Adding CNS prophylaxis to combined modality therapy resulted in a 5-year OS of 47% and disease-specific survival of 62%.⁹⁰⁴

Although somewhat variable according to series, the majority of salivary gland lymphomas are indolent (MALToma) and localized, most often to the parotid, and have survivals following radiation therapy alone of 80% to 90% at 5 years and 50% to 70% at 10 years.^{188, 905, 906, 907} Most patients (approximately 80%) with thyroid lymphomas have localized stage IE or IIE disease, and the majority are DLBCL, sometimes with a MALToma component.^{908, 909} Approximately half of the patients have a history of HT.⁹¹⁰ A worse prognosis occurs with penetration of the thyroid capsule, tumor bulk, advanced stage, and intermediate- to high-grade histologic types. Because of the frequency of these factors, many have advocated combined modality therapy for thyroid lymphoma except in the patient with stage I MALToma, who can receive radiation alone.^{909, 910} Five-year OS for DLBCL of the thyroid ranges from 52% to 90%.^{906, 911} Five-year DFS for MALToma of the thyroid following radiation is 88% to 100%.⁹¹²

Most primary pulmonary lymphomas are small B lymphocytic with or without plasmacytic differentiation and are considered a part of the spectrum of MALTomas. Two previously diagnosed entities, pseudolymphoma and lymphocytic interstitial pneumonitis, likely represent MALTomas. Therapy options include rituximab; chemotherapy, either single agent or combination; surgical resection; and radiation. The prognosis is good with 94% OS at 5 years without reaching a median survival at 10 years; and there is no advantage for a specific type of therapy.^{274, 913, 914} Other pulmonary lymphomas are heterogeneous, and therapy depends upon pathology and extent of disease. A favorable prognosis has been reported for DLBCL without bulk disease and normal LDH.⁹¹⁵ Lymphomatoid granulomatosis (LYG) is a rare type of EBV lymphoproliferation of B cells which most commonly presents with lung lesions varying from nodules to necrotic cavitory lesions, and which can have associated CNS and skin lesions.⁹¹⁶ Therapy and prognosis depend upon grading with steroids and

P.1868

interferon used for grades 1/2 and chemotherapy plus rituximab for grade 3 lesions.

Orbital lymphomas usually involve small B lymphocytes with or without plasmacytic differentiation and need to be distinguished from benign lymphoid hyperplasia. Some are associated with *Chlamydia psittaci* and can respond to antibiotics (see section on "Prelymphomatous Conditions"). They tend to be localized (80%+), and 10% to 20% are bilateral. They respond to radiation, with survival of 75% to 95% at 5 years and 70% to 80% at 10 years.^{269, 917, 918} Large B cell lymphomas are less common, tend to involve the lacrimal gland or retro-orbital area, and are treated with (10 to 200) combined modality therapy plus rituximab.^{269, 919}

CNS lymphomas are predominantly DLBCL and are responsive to steroids, radiation, intrathecal or Ommaya reservoir therapy, and systemic chemotherapy which crosses the blood brain barrier.^{920, 921} Standard treatment historically for PCNSL was whole brain radiation therapy (WBRT) alone; and the prognosis was poor with survival less than 6 months in AIDS patients and 1 to 2 years in immunocompetent hosts.^{922, 923} However, recent data utilizing early chemotherapy, particularly high-dose methotrexate or cytosine arabinoside, usually followed by WBRT, have improved results in PCNSL with median survivals from 30 to 60 months.^{920, 924, 925, 926} Severe neurologic toxicity manifested as leukoencephalopathy secondary to radiation is common, particularly in the patient over 60 years of age, and trials with chemotherapy alone and deferred radiation are being conducted.^{266, 927, 928, 929} In a randomized trial of 551 patients with PCNSL, there was no difference in OS when WBRT was omitted from primary chemotherapy.⁹³⁰ Rituximab has poor penetration into the CNS, but it is being used in protocols with PCNSL and its role is yet to be determined.^{920, 931} Alkylating agents with good CNS penetration which are a part of chemotherapy combination include thiotepa, ifosfamide, nitrosoureas, procarbazine, and temozolomide.⁹²⁰ There may be a role for high-dose chemotherapy and autologous transplant for PCNSL in both the relapsed and upfront setting.^{932, 933}

Testicular lymphoma, representing approximately 5% of testicular neoplasms, is the most common testicular tumor beyond the age of 60 years and the most common bilateral testicular tumor.^{934, 935, 936} It is associated with involvement of the contralateral testis in 20% to 35% of patients, and with involvement of the skin, Waldeyer's ring, and CNS, each in

approximately 10% of patients. The predominant histologic type is DLBCL (80% to 90%). In early series, median survivals have been 1 to 2 years, and 5-year survivals have varied from 12% to 48%, depending in part upon the extent of disease.^{934, 935} Because of the poor prognosis and early systemic spread, anthracycline-based chemotherapy and rituximab are warranted, usually with radiation to the involved testis if unresected, as well as to the contralateral testis. Because of the CNS relapse rate of 15% to 31%, CNS prophylaxis should be considered.^{934, 937} In an international phase II trial of 53 patients treated with R-CHOP, usually with CNS prophylaxis and testicular radiation, the 5-year PFS and OS were 74% and 85%, respectively; CNS relapse was 6%.⁹³⁸ Breast lymphomas usually manifest as a rapidly enlarging mass, may be multiple, and involve the opposite breast in 10% to 20% of patients.^{273, 939, 940} The histologic type is variable, but the majority are DLBCL; low grade lesions with MALToma features and an association with lymphocytic lobulitis have been described.⁹⁴¹ Massive bilateral breast involvement with BL has been described in pregnant or lactating women, predominantly from Africa, and is characterized by rapid dissemination with ovarian and CNS disease.²⁷³ After simple biopsy and staging, radiation therapy can be considered for local control of low grade lesions, but combination chemotherapy plus rituximab is warranted for aggressive histologies.

Primary ovarian lymphomas are rare, except in countries where BL is endemic; however, the ovary is the most common site of female genital tract involvement by lymphoma.⁹⁴² Ovarian lymphomas may be associated with bilateral involvement in 20% to 50% of patients and have had a poor prognosis, with 5-year survival of less than 25%. Prognosis depends on the extent of disease and the histologic type. DLBCL is the most common type, followed by FL, all grades, and Burkitt. Combination chemotherapy plus rituximab is warranted in most patients because of aggressive histologies.

Primary bone lymphomas are usually DLBCL (85%+), and approximately one-third have more than one bone involved.²⁷¹ Prognosis depends on the bones involved, with the femur the best and the spine the worst, histologic type, stage, and the presence of soft tissue involvement.^{271, 943} Although combined modality has been recommended for aggressive histologies,^{944, 945} chemotherapy alone has been successful. Because radiologic abnormalities persist after chemotherapy, local radiation is often given to the entire bone with a boost to the tumor bed.⁹⁴⁶ For localized bone lymphoma treated with combined modality, FTF exceeds 80% at 5 years.⁹⁴⁷

Therapy of CTCL and the differential diagnosis of cutaneous lymphomas are addressed in Chapter 92. Local radiation therapy is often adequate for localized (IE) cutaneous MALToma or PCFCL, whereas multiple therapeutic options similar to other indolent lymphomas can be considered for advanced disease. Both the primary cutaneous MALToma, or marginal zone lymphoma (PCMZL), and PCFCL have a good prognosis with 5-year OS exceeding 90%.^{948, 949} The majority of PCMZL have multifocal skin lesions involving the trunk and extremities, and up to 50% will relapse within 5 years of their initial therapy, but will still have a good prognosis (5-year OS>90%).⁹⁴⁸ PCFCLs tend to involve the head and neck and lack BCL-2 expression and the BCL-2 gene rearrangement. Alternatively, BCL-2 expression is often present in PCBCL of the leg as opposed to other sites, is primarily seen in the elderly, and has a poor prognosis (5-year OS 43% to 63%) despite the use of rituximab and combined modality therapy.^{517, 949, 950, 951}

ROLE OF HEMATOPOIETIC CELL TRANSPLANTATION

Transplantation is addressed in Chapters 102 and 104 and has taken an expanded role in the therapy of NHL; its use has been noted in preceding sections on individual diseases. Outcomes depend upon disease state (type of lymphoma, remission status), patient factors (age, performance status), and source of stem cells, either autologous (auto) or allogeneic (allo). In 1978, Appelbaum reported long-term DFS in 3 of 9 patients with relapsed BL who underwent high-dose chemotherapy and autologous marrow transplantation.⁹⁵² Subsequent series reported a 5-year OS rate of 20% to 50% using autoSCT for relapsed NHL.^{953, 954, 956} In the rituximab and RIT era, the OS has improved to 40% to 70%, but is variable depending upon type of lymphoma, prognostic factors, and chemosensitivity.^{957, 958}

Patient selection determines outcome, with the best results achieved in patients who are either in first CR or have minimal residual disease before the transplant and have a good performance status. Transplants in first CR or in patients with indolent histologies are controversial. Patients with predominantly DLBCL who are in a sensitive relapse—i.e., they are responding to additional chemotherapy—have a 30% to 70% salvage rate with autoHCT, compared to 0% to 15% patients who are in a resistant relapse. There is no superior preparative regimen, which may include various chemotherapy agents with or without total body irradiation. Rituximab and/or RIT are being incorporated into preparative regimens to try to decrease relapses.^{957, 959} In a randomized trial comparing BEAM (carmustine, etoposide, cytarabine, and melphalan) plus rituximab vs. BEAM plus conventional tositumomab (Bexxar) followed by autoHCT, there was no difference in PFS, OS, or transplant relapsed mortality (TRM).⁹⁶⁰

AlloHCT has been used less than autoHCT because of higher mortality rates, cost, and/or lack of a donor. It was initially reserved for selected young patients (usually less than 50 years of age) with marrow involvement, highly aggressive lymphomas, or after relapse from an autoHCT. Early (day 100) mortality rates previously were 5% to 25% for autoHCT and 15% to 45% for alloHCT, but are now <5% and 5% to 15%, respectively. Relapse is the main reason for failure after autoHCT; and TRM, either regimen-related toxicity or graft-versus-host disease (GVHD), is the main problem with alloHCT. Donor availability has increased with the expansion of unrelated donor registries, the use of umbilical cord transplantation in adults, and immune suppression to allow the use of mismatched donors.

The development of reduced intensity conditioning (RIC) and nonmyeloablative (NMAC) regimens for alloHCT has led to less early mortality and to use in older patients.⁹⁵⁹ In a CIBMTR report of 396 alloHCT for DLBCL, there was higher 5-year non-relapse mortality (NRM) with myeloablative conditioning (MAC, n = 165) than RIC (n = 143) and NMAC (n = 88) regimens (56% vs. 47% vs. 36%; P = 0.007). Five-year relapse was lower in MAC than in RIC and NMAC (26% vs. 38% vs. 40%; P = 0.031).⁹⁶¹ There were no differences in GVHD 5-year PFS (15% to 25%) and OS (18% to 26%). Similar findings of less NRM and increased relapse were reported by the CIBMTR comparing RIC to MAC for alloHCT patients with relapsed FL.⁹⁶² Chemosensitivity and performance status were better predictors of outcome than intensity of conditioning and have led to a shift in favor of RIC/NMAC for FL. Using a NMAC regimen (fludarabine, cyclophosphamide, and high-dose rituximab), Khouri et al. reported a 5-year OS and PFS rate for FL of 85% and 83%, respectively, with a TRM of 14%; acute GVHD was 11% and chronic GVHD was 60%.⁹⁶³

Unresolved issues of HCT for NHL are the optimal timing and the type of transplant. There is agreement that HCT is warranted in relapsed patients with intermediate-grade histology based on the PARMA trial which randomized patients to transplantation versus chemotherapy (Fig. 88.25).⁹⁵³ Disagreement surrounds which, if any, poor prognostic factors could be used to select patients with NHL for early HCT. While several small series have had DFS over 75% in selected patients with aggressive histologies transplanted in initial PR or first CR,^{954, 955, 956} most studies comparing autoHCT to chemotherapy in first CR or in slow responders have shown no advantage to early transplantation.^{718, 719, 720, 964, 965, 966, 967, 968, 969} Retrospective analysis of trials and an occasional prospective trial indicate a survival advantage for HCT in patients with an age-adjusted IPI that is greater than or equal to 2 (high-intermediate or high);^{719, 968, 970} however, the majority of randomized trials have not supported early transplantation over chemotherapy.^{971, 972} Many centers still offer HCT in first CR for poor prognosis NHL, particularly MCL and PTCL (see sections on these diseases).

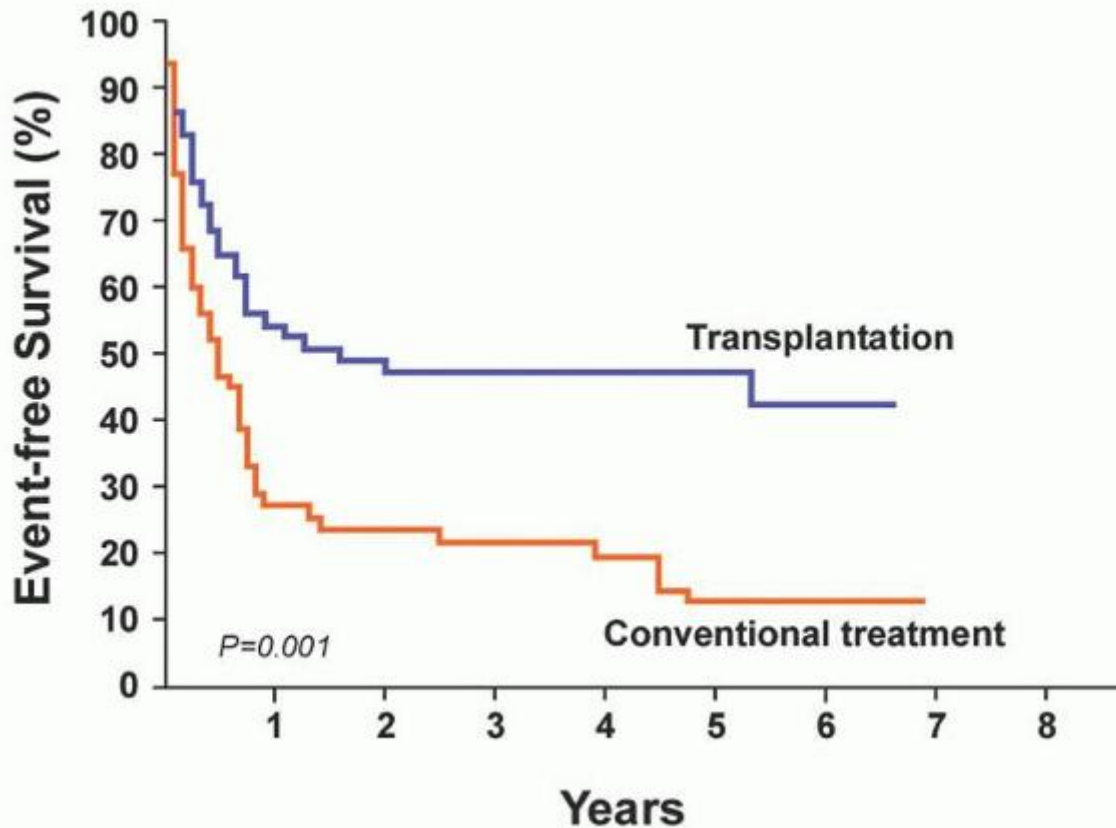

FIGURE 88.25. Kaplan-Meier curves for event-free survival of patients with relapsed intermediate to high grade lymphomas in the transplantation and conventional treatment groups. Data are based on an intention-to-treat analysis. From Philip T, Guglielmi C, Hagenbeck A, et al. Autologous bone marrow transplantation as compared with salvage chemotherapy in relapses of chemotherapy-sensitive non-Hodgkin's lymphoma. *N Engl J Med* 1995;333:1540-1545, with permission.

The use and timing of HCT and the role of purging are controversial in indolent lymphomas. Various techniques have been used for removal of tumor cells and include in vivo and in vitro monoclonal antibodies, metabolites of cytotoxic agents, and physical methods.⁹⁷³ There is evidence that indicates an advantage for successfully purging BCL2-positive clonal B cells in FL patients undergoing autoHCT.⁹⁷⁴ Prognostic models have been developed to select patients with indolent lymphomas for early HCT and include progressive disease within 1 year of initial therapy, extensive marrow involvement, multiple extranodal sites of disease, tumor bulk, transformation, and a high IPI.^{424, 975, 976, 977} Randomized trials comparing chemotherapy to chemotherapy followed by autoHCT are less common in FL than the aggressive histologies, predominantly DLBCL, but similarly have not shown an advantage to early HCT.^{975, 978} Long follow-up and randomized trials are required to determine the role of HCT and purging in indolent lymphomas.^{973, 975}

The optimal transplant strategy and stem cell source remain controversial. Peripheral blood stem cells have replaced bone marrow for autografting because of quicker engraftment, but have not consistently improved survival compared to marrow.⁹⁷⁹ Peripheral blood tends to also be used over marrow for allografts, but is associated with more chronic GVHD. As many as one-half of patients undergoing autologous peripheral stem cell collection mobilize malignant cells.^{979, 980} MDS and secondary AML are an increasingly recognized problem after autografts, with an actuarial incidence of 5% to 10% at 10 years. Prior exposure to radiation, 4 or more chemotherapy regimens, and difficulty harvesting stem cells have been associated with a higher risk of MDS/AML.^{981, 982, 983}

Some investigators have favored allografts because of fewer relapses, a graft-versus-lymphoma effect, a tumor free stem cell source, and less MDS/AML.^{984, 985, 986} The lack of an available donor and the toxicity of allograft transplantation keep the issue of optimal stem cell source unresolved; however, the availability of alternative donors and the use of nonmyeloablative regimens are expanding the role of alloHCT. Because of higher relapse rates in autografts, trials are evaluating pre- and posttransplant immunotherapy and radioimmunotherapy to eradicate minimal residual disease.^{960,}

^{987, 988, 989, 990} An emerging strategy is to utilize an autograft to achieve minimal residual disease followed by a RIC, or NMAC, allograft.^{991, 992}

SPECIAL AREAS

Therapy in the Elderly

Lymphomas steadily increase in number with aging as over half the new cases occur in people over 60 years of age.⁹⁹³ There is an expected increase in lymphomas solely based on the aging population, particularly in developed countries.⁹⁹⁴ The prognosis tends to be poor in the older patient; however, survival has improved for older patients with NHL in 2008 to 2012.⁹⁹⁵ Factors that contribute to poor prognosis in the elderly include poor performance status, reduced vital organ reserve, comorbid diseases, altered absorption or metabolism of drugs, decreased immunologic integrity, and biologic features of the lymphoma. Lymphomas in the elderly have more frequent extranodal presentations and more often have aggressive histologies. Unique presentations with a predilection for the elderly include primary CNS lymphoma,

P.1870

primary cutaneous DLBCL of the leg, EBV-positive DLBCL, and intravascular B cell lymphoma.

Randomized clinical trials comparing different regimens to doxorubicin-based therapy have shown inferior results.^{751, 996, 997, 998, 999} The randomized trials that favored CHOP plus rituximab over CHOP established a new standard for therapy of large B cell lymphoma in the elderly.^{299, 700} Physician biases and reduction of chemotherapy doses may contribute to an inferior prognosis in the elderly.^{1000, 1001} In a SWOG study with CHOP chemotherapy in which the dosage was reduced by 50% in patients over 65 years of age, CR rates declined with advancing age; however, in a small subset of patients over 65 years of age who did receive full doses, the CR rate approximated that of younger patients.¹⁰⁰² A relative dose intensity factor of CHOP-based therapy less than 70% is associated with poor long-term outcomes; however, dose reductions for patients over the age of 70 years (R-70%CHOP) and 80 years (R mini-CHOP) have not markedly compromised response or survival.^{1003, 1004} Elderly patients experience more frequent treatment-related toxicities even with dose reductions and greater utilization of supportive care.^{1005, 1006, 1007, 1008}

Novel regimens have been developed for the elderly patient, not only to lessen toxicity but also to maintain curability or control of NHL.^{1009, 1010, 1011, 1012} For patients who cannot tolerate anthracyclines, there are numerous alternatives, including bendamustine, gemcitabine, and etoposide, among others (see section on "Salvage Regimens"). Growth factors lessen the neutropenia of various regimens and allow the delivery of adequate doses on schedule.¹⁰¹⁰ Age is a continuum, with tolerance to therapy and survival worsening over 70 years of age; however, performance status is the best predictor of treatment-related death.¹⁰¹³ New clinical assessment tools, such as instrumental activities of daily living, may assist in determining a patient's ability to tolerate therapy.¹⁰⁰⁴ AutoHCT in the elderly (patients <70 years) can approach similar outcomes as observed in younger patients.¹⁰¹² With the use of RIC and NMAC regimens, alloHCT is being utilized in the eligible older patient. Elderly patients should not be excluded from clinical trials or curative therapy solely on the basis of age, but dose reductions or alternative drugs may be warranted in selected patients. Palliative care should be offered to those who are too frail or compromised to receive therapy.

Therapy in Pregnancy

Lymphoma is a rare event during pregnancy, but the estimated coincidence of NHL and HL in pregnancy is 1:1,000 to 1:6,000.¹⁰¹⁴ Therapy is based on histologic type and point of gestation at diagnosis.¹⁰¹⁵ Staging studies are limited because of concern for radiation exposure to the fetus. MRI can be used, although it is still recommended to avoid it in the first trimester. Ultrasonography and echocardiograms can provide useful information in the pregnant patient. Most women who develop NHL during pregnancy have aggressive histologies and advanced stage disease.¹⁰¹⁴ There is an unusually high incidence of breast, ovarian, uterine, and cervix involvement attributed to hormonal influences and increased blood flow to these organs.¹⁰¹⁴ Placental involvement is rare, and transmission to the fetus is so uncommon that it is reportable.¹⁰¹⁶

Patients with aggressive lymphomas who present in the first trimester should be considered for a therapeutic abortion unless the lymphoma is localized above the diaphragm and could be treated with involved field radiation plus abdominal shielding.¹⁰¹⁷ Radiation should be avoided until the third trimester, or not used at all, whereas combination chemotherapy can be given successfully in the second or third trimester. Although as a general rule chemotherapy is to be avoided in the first trimester, anthracyclines have been given without untoward effects to mother or fetus.¹⁰¹⁸ Rituximab with chemotherapy has been given to pregnant patients without evident harm to mother or fetus.¹⁰¹⁹ Early delivery (either by induction or caesarean section) can be considered either to avoid myelosuppression of mother and fetus or to initiate intensive chemotherapy. Complete staging should be done after delivery.

The prognosis for mothers has been relatively poor, with DFS of only 40% to 50%, probably because of both the aggressive histologies and the advanced stage.^{1014, 1016, 1017} Although indolent lymphomas constitute a minority of NHL in pregnancy, they generally can be observed until after delivery. If necessary, interferon can be used throughout pregnancy to control indolent hematologic disorders.¹⁰²⁰ Offspring who as fetuses received chemotherapy even in the first trimester have had normal growth and development and no increased risk of cancer.

Long-term Sequelae

The long-term complications of therapy in NHL are not as well described as those in HL, but they appear to be similar and depend on the therapy used, age of the patient, and comorbid illnesses.¹⁰²¹ These problems include endocrine disorders (infertility, hypothyroidism, panhypopituitarism, growth retardation), vital organ toxicity, psychosocial issues, and second neoplasms.^{1022, 1023} Radiation is the main cause of endocrine and neurological toxicities and secondary solid neoplasms.¹⁰²² Cardiotoxicity from anthracyclines is the most common chemotherapy-related toxicity and is usually manifested as congestive heart failure. Factors associated with increased cardiomyopathy include older age (>70 years), previous cardiac disease, hypertension, prior mediastinal radiation, and combination with other chemotherapy agents (e.g., cyclophosphamide). The cumulative incidence of cardiovascular disease in patients with NHL treated with anthracyclines was 12% at 5 years and 22% at 10 years.¹⁰²⁴ Cardiomyopathy can occur many years (15 to 20 years) after completion of therapy.¹⁰²⁵ Although previous studies suggested no increase in second neoplasms after therapy for NHL, the NCI's SEER Program identified an increased risk over time for AML; cancers of the bladder, kidney, and lung; malignant melanoma; and HL.^{1022, 1023} Up to 10% of NHL patients treated with standard chemotherapy regimens or autologous transplantation, particularly using total body irradiation, may develop MDS or AML within 10 years of their initial therapy.^{981, 983}

FUTURE DEVELOPMENTS

Advances in NHL will involve molecular techniques to refine diagnosis, classification, and therapy. The classification of lymphoma will improve with genomic profiling in conjunction with clinical and pathologic factors. The application of PCR to detect minimal residual disease may identify patients who should be followed more closely or receive additional therapy. The success of monoclonal antibody therapy in NHL has been remarkable; and the development of vaccines may be the ultimate goal of immunotherapy (Chapter 70). New agents are targeting both B and T cell receptors and protein signaling pathways critical to lymphomagenesis. The novel agents are synergistic with other chemotherapy and monoclonal antibodies and will require phase III trials to establish their place in the expanding list of treatments for NHL. Continued trials evaluating the role of dose intensification and the use of different types of transplantation are warranted in NHL.

Chapter 89

Non-Hodgkin Lymphoma in Children

John T. Sandlund, Jr.

Mihaela Onciu

INTRODUCTION

There have been significant clinical and laboratory advances over the last 25 years in our understanding of the non-Hodgkin lymphomas (NHLs) of childhood. These include the refinement of diagnosis and classification of clinically relevant histologic subtypes, the elucidation of various pathogenic mechanisms, and most importantly, improvements in therapy and supportive care which have resulted in improved event-free and overall survival rates. Increased attention to the reduction and elimination of late effects of therapy such as infertility, cardiotoxicity, and second cancers is another important hallmark of clinical research over recent years. These advances and future directions will be discussed in this chapter.

Malignant lymphomas, which comprise both Hodgkin lymphoma and NHL, are the third most common type of childhood cancer after acute lymphoblastic leukemia (ALL) and brain tumors.^{1, 2, 3, 4, 5, 6, 7} Among children <18 years of age, there is a slight predominance of Hodgkin lymphoma, whereas the reverse is true among those <15 years of age.^{3, 6}

It is important to note the distinction between the NHLs of adults and children.^{8, 9, 10} Children typically present with diffuse extranodal disease in contrast to adults, among whom primary nodal disease is more common. Additionally, the pediatric NHLs are typically high grade tumors,⁹ in contrast to the low- and intermediate-grade tumors which are predominant among adults. Age-related differences in the immune system and associated susceptibility to malignant transformation are possible contributing factors to these observed differences in histologic subtype.⁷

EPIDEMIOLOGY

There are at least 500 cases of newly diagnosed pediatric NHL in the United States each year.^{3, 4, 5} Although there is no clear peak age, the median age in one single institution review was 10 years (range, 7 months to 19 years).¹⁰ This disease occurs uncommonly in very young children (i.e., <3 years of age).^{2, 10} NHL is two to three times more common in boys than in girls, and more common in black children than in white children.^{2, 7} The reasons for these differences have yet to be elucidated.

There are geographical differences with respect to frequency and distribution of histologic subtypes of NHL in children.¹¹ For example, although NHL is very common in equatorial Africa, it is very rare in Japan.¹² Among the NHL cases observed in equatorial Africa, Burkitt lymphoma (BL) is the most common type observed. BL is also the most frequent histologic subtype encountered in northeastern Brazil and in some areas of the Middle East.¹³ In contrast, lymphoblastic lymphoma (LBL) is the predominant histologic subtype in southern India.¹³

BL is also of interest with respect to the geographical (i.e., endemic versus sporadic) variances that exist with respect to both clinical and biologic features.¹⁴ Those tumors, which arise in children from equatorial Africa ("endemic subtype"), are characterized clinically by frequent involvement of jaw, abdomen, paraspinal area, and orbit, and by a younger age at diagnosis.^{14, 15, 16} Those Burkitt tumors which arise in children from Western Europe and the United States ("sporadic subtype"), are in contrast characterized by frequent involvement of the abdomen, nasopharynx, and bone marrow and an older age at diagnosis.^{14, 15, 16} The breakpoint in the c-myc proto-oncogene and in the IG heavy chain (IGH) genes in BLs has also been reported to vary with respect to geography: in sporadic cases the breakpoints tend to occur within the MYC gene and the switch region of IGH gene, as compared to upstream of MYC and the VDJ region of IGH in endemic cases.^{14, 17}

An infectious agent was suspected to play a role in the pathogenesis of BL in equatorial Africa after it was noticed that the malaria belt overlapped with the lymphoma belt. Subsequently, EBV was shown to be associated with BL in this part of the world (i.e., equatorial Africa).^{14, 16} The association of EBV with BL has been shown, however, to vary with geography. EBV association occurs in approximately 85% of endemic cases, in contrast to the 15% association in Western Europe and the United States.^{14, 16} An intermediate degree of EBV association has been observed in other parts of the world, such as

northeastern Brazil.¹⁸ Although the evidence for a direct role for EBV in BL pathogenesis is relatively lacking, the circumstantial evidence is compelling. It was initially hypothesized that EBV, a B-cell mitogen, increases the target pool of cells that would be susceptible to a malignant transformation.¹⁴ This hypothesis is supported by the observation that the expression of the recombination activating gene (RAG) can be induced by EBV, and therefore potentially increases the chance that a chromosomal translocation may occur during IG gene rearrangement.¹⁹

Children with certain immunodeficiency conditions are at increased risk for the development of NHL.^{2, 7} Examples of specific populations at risk include those with congenital immunodeficiency disorders such as ataxia-telangiectasia (A-T),²⁰ X-linked lymphoproliferative syndrome (XLP), and Wiskott-Aldrich syndrome. It is important that these underlying conditions be recognized in children who present with NHL, so that appropriately designed therapy can be delivered. For example, in children with A-T, involved field irradiation and the use of radiomimetics such as bleomycin should be avoided, and the judicious use of x-rays is advised. Children with A-T are also at increased risk for the development of severe late onset hemorrhagic cystitis following the administration of alkylating agents such as cyclophosphamide and ifosfamide; therefore, vigorous hydration and administration of the uroprotectant mesna are recommended whenever these agents are delivered. Boys with XLP are at increased risk for the development of both B-cell lymphomas and fatal infectious mononucleosis, and are potential candidates for allogeneic bone marrow transplantation. Therefore, the diagnosis of XLP should be considered in any boy who presents with a B-cell lymphoma and whose brother has had either B-cell lymphoma or fatal infectious mononucleosis, or in any male who has had two primary B-cell lymphomas. There is also an increased risk for the development of NHL among children with acquired immunodeficiency conditions.²¹ Specific populations at risk include those with the acquired immunodeficiency syndrome (AIDS) and those on immunosuppressive therapy following bone marrow or organ transplantation.

PATHOLOGIC SPECIMEN EVALUATION

Most of the NHLs of childhood are very rapidly growing neoplasms. It is therefore imperative that the diagnosis be established as soon as possible so that appropriate therapy can be started. The diagnosis typically requires a comprehensive characterization of the tumor, including histologic, flow cytometric, cytogenetic,

P.1874

and molecular genetic studies. Ideally, larger fragments of tissue should be obtained by open biopsy of an involved site, but percutaneous image-guided needle biopsy has been increasingly used for diagnosis in the pediatric age group with good results.²² Bilateral bone marrow aspirates and biopsies should be considered before open biopsy, since this may allow the diagnosis to be established without a more invasive open biopsy. In patients who are not candidates for general anesthesia, such as those with a large anterior mediastinal mass, the diagnosis may be established by examination of pleural fluid obtained by thoracentesis or by parasternal core biopsy of the mass using local anesthesia with an anesthesiologist in attendance.²³

CLASSIFICATION

The most recent World Health Organization (WHO) Classification of Tumors of Haematopoietic and Lymphoid Tissues²⁴ designates NHLs, including those predominant in the pediatric age group, according to their clinical, morphologic, immunophenotypic, and genetic features, and also acknowledges difficulties in differentiating some of the clinically significant subtypes of B-cell lymphoma by introducing some borderline ("gray-zone") categories to encompass these issues. Table 89.1 summarizes the pediatric NHLs according to the WHO Classification 2008. Table 89.2 summarizes the main diagnostic immunophenotypic features of the most common subtypes of NHL encountered in this age group.

Lymphoblastic Lymphoma (T and B Lymphoblastic Lymphoma/Leukemia)

ALL and LBL are neoplasms of precursor B-cells or T-cells, characterized by immature (blastic) morphology and immunophenotype. At the pathologic and clinical levels, ALL and LBL appear to represent an overlapping continuum, with the distinction between these two processes being largely quantitative and arbitrary: cases involving at least 25% of the marrow cellularity are managed as ALL, while cases with less or no marrow involvement, are designated as LBL.^{25, 26, 27} More recent studies have identified important differences in gene expression profiles, adhesion molecule expression, and molecular pathways of T-ALL and T-LBL that explain at least partially their distinct dissemination patterns.^{28, 29, 30} T-LBL is the more common subtype and involves most often the mediastinum, lymph nodes, skin, bone, or soft tissues, and less commonly kidney, lung, or orbit. By contrast, the less common B-LBL more often presents in the lymph nodes, skin, bone, soft tissues, or breast, with mediastinal presentation being very uncommon.^{31, 32, 33, 34, 35} The most frequent location of skin lesions in children is the scalp.^{34, 35}

TABLE 89.1 SUBTYPES OF NON-HODGKIN LYMPHOMA ENCOUNTERED IN CHILDREN ACCORDING TO THE WORLD HEALTH ORGANIZATION (WHO) CLASSIFICATION (2008)*Precursor Lymphoid Neoplasms***B lymphoblastic lymphoma/leukemia****T lymphoblastic lymphoma/leukemia***Mature B-cell lymphomas***Burkitt lymphoma****Diffuse large B-cell lymphoma (DLBCL)****Primary mediastinal (thymic) large B-cell lymphoma**

B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and BL

B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma

Follicular lymphoma. Variant: Pediatric FL

Marginal zone lymphoma (nodal and extranodal/MALT lymphoma). Variant: Pediatric nodal marginal zone lymphoma

*Mature T and NK cell neoplasms***Anaplastic large cell lymphoma, ALK-positive****Peripheral T-cell lymphoma, NOS**

Hepatosplenic T-cell lymphoma

Extranodal NK/T cell lymphoma, nasal type

Subcutaneous panniculitis-like T-cell lymphoma

Primary cutaneous CD30 positive T-cell lymphoproliferative disorders

Mycosis fungoides

Hydroa vacciniforme-like lymphoma^a

The categories highlighted in bold represent entities common in children; the remainder are rare in this age group.

MALT, mucosa-associated lymphoid tissue; NK, natural killer; NOS, Not Otherwise Specified.

^a This type of lymphoma is limited to Asia, South and Central America, and Mexico.

Histologically, B- and T-LBLs show a diffuse growth pattern, with extensive replacement of the underlying normal tissue architecture by sheets of blastic cells. The malignant lymphoblasts are small to intermediate in size, with scant to moderate amounts of basophilic cytoplasm, finely dispersed nuclear chromatin, and small indistinct nucleoli (see Fig. 89.1). In some cases the nuclei may have markedly irregular or convoluted outlines, a feature more common in T-LBL. Mitotic figures may be numerous in some cases, correlating with the presence of a “starry sky” appearance imparted by scattered pale macrophages containing apoptotic nuclear debris. BL should be considered in the differential diagnosis of such cases.

Immunophenotypically, approximately 90% of LBLs are of T lineage and the remaining 10% of B lineage.^{36, 37, 38, 39, 40} Most T-LBLs resemble cortical thymocytes, a feature that may lead to difficulties in the differential diagnosis with thymoma and residual normal thymus in biopsy samples obtained from mediastinal and cervical lesions. They typically express CD1a, CD10, weak CD79a, BCL2, CD99, and the pan-T-cell antigens CD2, CD3 (mostly cytoplasmic), CD5, and CD7, although these markers may under- or overexpressed when compared to their normal counterparts. Similar to thymocytes, T-LBLs are often CD4⁺ and CD8⁺ and usually terminal deoxynucleotidyl transferase (TdT) positive, a marker that can be used to distinguish this neoplastic process from mature T-cell lymphomas.^{41, 46} Other immature T-cell markers, including CD34 and

HLA-DR are also coexpressed in these cases. A more frequent expression of T-cell receptor $\alpha\beta$ than $\gamma\delta$ has been reported in T-cell LBL as compared to precursor T-cell ALL.⁴⁷ Some LBLs may aberrantly express myeloid-associated antigens.^{37, 48, 49} Of note, CD45 expression, often used to differentiate blasts by flow cytometry, ranges from dim (“blast-like”) to strong (“mature lymphocyte-like”) in T-ALL/LBL. A subset of T-LBLs resemble late thymocytes. In these cases TdT expression may be absent. They also express strong surface CD3, lack expression of CD1a, CD10, CD34, and HLA-DR, and are CD4⁺ or CD8⁺, rendering distinction from mature T-NHL very difficult, especially in small needle biopsy samples. The mediastinal localization and blastic cell morphology are very helpful in such cases.

B-LBLs typically resemble normal progenitor B-cells found primarily in the bone marrow and in lower numbers in blood, lymph nodes, and tonsils.^{46, 50, 51} They express CD10, TdT, CD99, the B lineage antigens PAX-5 and CD79a, and may be negative or only weakly positive for the mature B-cell marker CD20. The neoplastic cells most often lack expression of surface Ig and light chain restriction. Most often they express cytoplasmic μ heavy chain without detectable κ or λ Ig light chains.^{38, 52, 53} Rare cases of B-LBL may express surface Ig with light chain restriction, associated with strong CD20 expression and without detectable TdT; in such cases BL should be considered in the differential diagnosis.^{39, 54} Of note, a significant proportion of pediatric B-ALL/LBL lack expression of CD45 (leukocyte common antigen), a marker often used to identify hematopoietic neoplasms in tissue

P.1875

sections. This feature, combined with the frequent expression of CD99 by these neoplasms may lead to an erroneous diagnosis of Ewing sarcoma, another CD99⁺ pediatric neoplasm with blastic morphology, unless other markers (e.g., PAX5, TdT) are included in the diagnostic immunohistochemistry panels.

TABLE 89.2 IMMUNOPHENOTYPIC FEATURES OF THE MOST COMMON PEDIATRIC NON-HODGKIN LYMPHOMAS

	TDT	CD20	CD79a	Ig	CD5	CD3	CD30	CD15	ALK	CTA	MUM1 ^b	BCL2	BCL6

ALCL, anaplastic large cell lymphoma; B-LBL, B lymphoblastic lymphoma; CTA, cytotoxic antigen (e.g., TIA-1, perforin); DLBCL, diffuse large B cell lymphoma; FL, follicular lymphoma; HSL; hepatosplenic lymphoma; MUM1, interferon regulatory factor-4 (IRF4); PMBL, mediastinal large B-cell lymphoma; PTCL, peripheral T cell lymphoma; T-LBL, T-lymphoblastic lymphoma.

^a cytoplasmic CD3.

^b cytoplasmic μ heavy chain only.

^c ALK restricted to the ALK+ DLBCL subtype.

Cytogenetic studies of pediatric LBLs are few and include small numbers of patients (Table 89.3).^{55, 56, 57} Additionally, some reports of the cytogenetic or molecular genetics of LBL include cases of ALL with extra-medullary spread. T-LBL and T-ALL share similar chromosomal abnormalities. Chromosome abnormalities of the T cell receptor are relatively common and include chromosome abnormalities at 7q34-36, 7p15, and 14q11.^{56, 57} The t(9;17) translocation appears more

commonly in T-LBL than T-ALL.^{56, 57} These patients often present with a mediastinal mass and have an aggressive disease course. The t(8;13)(p11;q11-14) has been described in rare cases of precursor T-LBL that present with myeloid hyperplasia and eosinophilia.^{58, 59, 60}

The t(10;11) (p13-14;q14-21) is an uncommon but recurring translocation associated with T-ALL, and T-LBL, where it correlates with expression of the γ/δ T-cell receptor by the neoplastic cells.^{61, 62, 63} Cytogenetic abnormalities have not been shown to be of prognostic significance in LBL. At the molecular level, B-LBLs and T-LBLs contain IG (IG) and T-cell receptor gene (TCR) rearrangements, respectively. The latter should not be used for lineage determination, as B-LBLs (like B-ALL) often contain TCR rearrangements, and T-LBLs may also harbor IG gene rearrangements.

FIGURE 89.1. Lymphoblastic lymphoma. Sheets of small lymphoid cells with fairly uniform chromatin without clearing and scant cytoplasm are present. They show little variation in size and many show mitotic activity.

Burkitt Lymphoma

The WHO Classification replaced “small noncleaved cell lymphoma” of the older NCI Working Formulation with BL (Table 89.1),^{9, 64, 65} and also combined under the same category the ALL-L3 of the French-American-British classification, which corresponded to cases of high-stage BL with leukemic dissemination.

BL is a mature B-cell lymphoma which resembles highly proliferative B-cells present in the follicular germinal center (GC). The biology of this lymphoma is characterized by translocations involving the MYC gene and leading to its overexpression and the typical high proliferation rate. Notably, however, MYC gene rearrangements are not unique to this subtype of mature B-cell lymphoma. Clinically, as described above (see section “Epidemiology”) there are three recognized variants of BL: endemic, sporadic, and immunodeficiency-associated, which appear to correlate with distinct profiles of clinical presentation, association with EBV, molecular lesions, and cytogenetic abnormalities. Histologically, BL may present as one of three patterns with no prognostic significance (classic, atypical, and plasmacytoid), previously recognized as disease variants and currently merged under the unique designation of BL. Regardless of the histologic variant, BL is characterized by a diffuse growth pattern that typically replaces extensively the normal underlying tissue architecture. Occasionally, BL cells may also be seen “colonizing” preexisting GCs adjacent to the main tumor or present in the lymph nodes, draining an area involved by diffuse BL. Frequent mitotic and apoptotic cells are present and reflect this lymphoma's high proliferative rate and apoptotic index,

respectively. Tingible body macrophages interspersed among the neoplastic cells impart a characteristic low-power microscopic "starry sky" appearance. The proliferation index, measured by immunohistochemical nuclear expression for Ki-67, typically approaches 100% of the tumor cells and is a requirement for the diagnosis of BL, regardless of the morphologic subtype, as an acceptable surrogate for the demonstration of MYC gene rearrangements. In the classic BL variant the neoplastic cells are monomorphous, medium-sized ("small noncleaved") with moderate amounts of basophilic cytoplasm (see Fig. 89.2).^{64, 65} The cells have round nuclei, clumped or condensed chromatin with clear parachromatin, and one to three nucleoli. When seen in Wrightstained cytologic preparations, BL cells have a characteristically deeply basophilic cytoplasm with prominent clear cytoplasmic vacuoles. In the atypical variant, the neoplastic cells are more pleomorphic, including large cells with centroblastic appearance and often prominent central nucleoli. The plasmacytoid BL cells, which are seen mostly in association with immunodeficiency, are more monomorphous, predominantly large, with eccentric nucleus, prominent nucleolus, and more abundant, IG-positive cytoplasm. BL cells retrieved from malignant pleural effusions often are larger and more pleomorphic than their tissue or blood counterparts.

TABLE 89.3 CLINICAL AND BIOLOGIC CHARACTERISTICS OF NON-HODGKIN LYMPHOMA IN CHILDREN

Subtype	Proportion of Cases (%) ^a	Phenotype	Primary Site	Translocation	Affected Genes
Burkitt	39	B cell	Abdomen or head and neck	t(8;14)(q24;q32) t(2;8)(p11;q24) t(8;22)(q24;q11)	<i>IGH - MYC</i> <i>IGL - MYC</i> <i>IGK - MYC</i>
Lymphoblastic	28	T-cell ^b	Mediastinum or head and neck	t(1;14)(p32;q11) t(11;14)(p13;q11) t(11;14)(p15;q11) t(10;14)(q24;q11) t(7;19)(q35;p13) t(8;14)(q24;q11) t(1;7)(p34;q34)	<i>TCRαδ - TAL1</i> <i>TCRαδ - LMO2</i> <i>TCRαδ - LMO1</i> <i>TCRαδ - TLX1</i> <i>TCRβ - LYL1</i> <i>TCRαδ - MYC</i> <i>TCRβ - LCK</i>
Large cell ^c	26	B cell, T cell	Mediastinum, abdomen, head and neck, or skin ^d	t(2;5)(p23;q35) ^d	<i>NPM-ALK</i>

Ig, IG; TCR, T cell receptor.

^a Proportion at St. Jude Children's Research Hospital; other histotypes account for approximately 7%.

^b B-cell-progenitor variants have also been described.

^c Includes DLBCL and its variants, ALCL and some types of peripheral T-cell lymphoma.

^d Primarily in T-ALCL.

FIGURE 89.2. Burkitt lymphoma. Sheets of medium-sized lymphocytes are present with fine chromatin and multiple nucleoli. In addition, there are scattered large histiocytes containing debris. These histiocytes give the “starry sky” appearance to the histology of BL.

Immunophenotypically, BLs have a mature GC-like profile. They express CD10, CD19, strong uniform CD20, CD22, CD79a, PAX5, BCL-6, and surface IG (IgM, or less commonly IgA or IgG), with IG light chain κ or λ restriction (Table 89.2).⁶⁶ They are typically negative for BCL2, CD34, and TDT. The latter two antigens are useful in the differential diagnosis with B-LBL, which is most often positive for these markers. CD21, the receptor for complement fragment Cd3 and the Epstein-Barr virus, is more frequently detected in the endemic than sporadic form.

Cytogenetically, all cases of BL harbor one of three chromosomal translocations which rearrange the MYC oncogene locus to regions controlled by regulatory components of the IGH or light chain (IGK or IGL) genes, leading to constitutively overexpressed MYC in the neoplastic B-cells (Table 89.3). These translocations include t(8;14)(q24;q32)/MYC-IGH (80% to 90% of the cases), t(2;8)(q11;q32)/IGL-MYC, and t(8;22)(q23;q11)/MYC-IGK. The translocations associated with BL are relatively easily detected by classical cytogenetic methods and more recently by fluorescent in situ hybridization of interphase nuclei.⁶⁷ In addition to these classic translocations, a significant proportion of pediatric BLs also contain other nonspecific but recurrent cytogenetic abnormalities, some of which may correlate with prognosis, at least in cases with high-stage presentation.⁶⁸

Diffuse Large B-cell Lymphoma

Diffuse Large B-Cell Lymphoma (DLBCL) is a mature B-cell neoplasm composed predominantly of large cells (i.e., nuclear size equal to or exceeding that of macrophage nuclei), with a diffuse growth pattern, and with a proliferation index typically less than that required for a diagnosis of BL (typically 90% or less). The neoplastic cells may have a predominantly centroblastic (>80% in children),⁶⁹ immunoblastic (<10% in children),⁶⁹ or anaplastic appearance, defining three morphologic variants with no known prognostic implications (see Fig. 89.3).⁶⁵ Tumors rich in T-lymphocytes and histocytes are defined as a distinct entity in the most recent WHO Classification as T-cell/histiocyte-rich large B-cell lymphoma.

FIGURE 89.3. Diffuse large B cell lymphoma. Sheets of variably sized large cells with prominent nucleoli and chromatin clearing. There is variation in cell size, in contrast to the more uniform cells of BL.

Immunophenotypically, DLBCLs express one or more pan-B-associated markers CD19, CD20, CD22, CD79a, and PAX5. Surface or cytoplasmic IG are expressed by 50% or more cases. Some cases may express CD5, CD10, BCL2, BCL6, IRF4/MUM1, and CD30 (Table 89.3). Gene expression profiling and immunohistochemical studies have defined subgroups with distinct biology in DLBCL. These groups do not currently determine therapy in children. The GC-like group, which is predominant in children⁶⁹ is characterized by a CD10^{+/+}, BCL6^{+/+}, IRF4/MUM1-immunophenotype, while the non-GC subtype is CD10⁻, BCL6^{+/+} and IRF4/MUM1⁺. Rare cases of anaplastic lymphoma kinase (ALK)-expressing DLBCL with plasmablastic features can be found among DLBCL of children.^{70, 71, 72} These have been included under the designation of ALK-positive large B-cell lymphoma in the WHO Classification 2008.²⁴

Cytogenetics of DLBCL often include complex karyotypes with recurrent, but nonspecific abnormalities. While in adults many of the GC-like cases contain the t(14;18) characteristic for follicular lymphoma (FL), this is not the case in pediatrics, perhaps due to the unique biology of FL in this age group (see below).⁶⁹ The rare ALK-positive cases may harbor the t(2;5) or t(2;17), resulting in ALK gene overexpression.^{70, 71, 72}

Primary Mediastinal (Thymic) Large B-cell Lymphoma

Primary mediastinal (thymic) large B-cell lymphoma (PMBL) is an uncommon subtype of diffuse large B-cell lymphoma (<10% of large cell lymphomas in children) thought to arise from noncirculating thymic medullary B-cells.^{65, 73, 74, 75, 76, 77, 78} The latter feature may explain the biologic behavior of this tumor, which never involves the bone marrow (prerequisite feature for a diagnosis of PMBL and exclusion of DLBCL with secondary mediastinal involvement). Patients present with signs and symptoms of a large mediastinal mass, frequently with extension into adjacent structures including lung, pericardium, chest wall, and superior vena cava. Extrathoracic extension at diagnosis is uncommon but with disease progression can include kidneys, brain, soft tissue, skin, and adrenal glands. In the pediatric age group, the presence of extrathoracic disease at presentation is an adverse prognostic feature.⁷⁶

Histologically, PMBL is characterized by a diffuse growth pattern and is composed of tumor cells that may range from medium-sized to large. They may have a centroblast-like appearance, may show lobated, “flower-like” nuclear outlines, or may have an anaplastic, Reed-Sternberg-like appearance. Often, they have abundant pale cytoplasm, with a “clear cell” appearance. The neoplastic cells are typically surrounded by thin to thick, dense fibrotic bands. Small benign-appearing lymphocytes and eosinophils may be present and add to the difficulty in differentiating PMBL from Hodgkin lymphoma.

Immunophenotypically, PMBL cells express CD45 and B-cell-associated antigens PAX5, CD19, CD20, CD22, and CD79a (Table 89.2), characteristically lack IG, and very often show variable degrees of CD30 expression,⁷⁹ as well as CD23 and IRF4/MUM1 positivity. Expression of CD10, BCL-6, and BCL2 is less common. Although not unique to PMBL, the expression of the myelin and lymphocyte protein (MAL) may be useful in differentiating it from other mature B-cell and post-thymic T-cell lymphomas.⁸⁰

Molecular studies uniformly reveal clonal IG gene rearrangements even if IG expression is not demonstrable by immunologic techniques. The lymphoma cells show mutated IG V region genes consistent with post-germinal center B-cells.^{81, 82} Uncommonly, evidence of clonal EBV genome may be present in the tumor cells. The relatively few cytogenetic studies reported show aneuploid tumor cells, often with gains of chromosome 9p or Xq.^{83, 84} The tumor cells may overexpress REL or MAL in a minority of cases.⁸⁵ BCL6, TP53, CDKN2A alterations and MYC rearrangements may be present.^{83, 84, 85, 86, 87}

Unclassifiable Large B-cell Lymphomas

The most recent WHO Classification has recognized the existence of some borderline B-cell lymphomas, where complete morphologic, immunophenotypic, and genetic characterization does not allow a clear distinction between clinically significant categories of aggressive B-cell NHL or between DLBCL and classical Hodgkin lymphoma. This recognition has led to the definition of two heterogeneous disease categories that are not to be applied for cases where sufficient information is not available for a definitive distinction. These rare cases do occur in the pediatric age group and, at the present time, it appears that they are best managed as aggressive B-cell lymphomas in these patients.

B-cell Lymphoma, Unclassifiable, with Features Intermediate between Diffuse Large B-cell Lymphoma and Burkitt Lymphoma

This is a heterogeneous category of mature B-cell lymphomas, often with morphologic features of both DLBCL and BL, but with intermediate biologic features: cases of DLBCL with a gene expression profile similar to BL, many of which harbor dual translocations involving MYC and BCL2 (“double-hit lymphomas”), correlating with a particularly poor outcome; cases of DLBCL with high proliferation rate and immunophenotype resembling BL, but lacking a detectable MYC translocation; or cases with morphology typical for BL, but atypical immunophenotype or genetic features. Some of these cases would have been classified as “Burkitt-like lymphoma” in previous classification systems.

B-cell Lymphoma, Unclassifiable, with Features Intermediate between Diffuse Large B-cell Lymphoma and Classical Hodgkin Lymphoma

This category has been introduced mainly to reflect a distinct group of B-cell lymphomas occurring in the mediastinum and showing features intermediate between PMBL and classical Hodgkin lymphoma (“gray-zone lymphomas”).⁸⁸ However, lymphomas with similar features have also been described in peripheral lymph nodes. Gene expression profiling studies P.1878

have suggested related molecular signatures for PMBL and classical Hodgkin lymphoma,^{89, 90, 91} offering a possible explanation for these phenotypically intermediate categories, although specific genomic studies of gray-zone lymphomas have not been reported.

Anaplastic Large Cell Lymphoma

Anaplastic large cell lymphomas (ALCLs) are mature T lineage lymphomas characterized by anaplastic morphology (large “hallmark” neoplastic cells with abundant cytoplasm, pleomorphic, often horseshoe-shaped nuclei) and strong uniform expression of CD30. The most recent WHO Classification has recognized two distinct biologic entities sharing these features: ALK-positive ALCL and ALK-negative ALCL. The vast majority of pediatric ALCLs are ALK-positive and therefore, the latter disease subtype will be referred to exclusively in the remainder of this chapter. In children, ALCL tends to involve lymph nodes and extranodal sites including skin, soft tissues, lungs, and bones.⁹² Approximately 20% to 25% of patients have bone marrow involvement at diagnosis that may not be obvious without ancillary studies.⁹³ Histologically, ALK expression by these lymphomas has allowed recognition of a wide spectrum of morphologic variants. These range from

classical (common) cases, where the anaplastic cells predominate, growing in diffuse sheets (see Fig. 89.4) or within sinusoidal lymph node space; to the small cell variant,^{65, 94} where the anaplastic cells are a minor component, admixed with predominantly small neoplastic cells; and the lymphohistiocytic variant,^{95, 96} containing a minority of “hallmark” cells surrounded by a reactive lymphohistiocytic population that forms the bulk of the tumor. The monomorphic variant, more common in children (author's unpublished observation) consists of sheets of monotonous immunoblastic cells with a high mitotic rate and “starry sky” appearance, mimicking BL. Rare cases have a sarcomatoid appearance, consisting of spindled CD3⁺/ALK⁺/CD30⁺ neoplastic cells. Although none of these variants appears to have prognostic implications, the small cell variant appears to be associated more often with systemic dissemination and leukemic peripheral blood involvement at presentation.^{97, 103}

Immunophenotypically, ALCLs express one or more T-cell-associated antigens including CD2, CD3, CD4, CD7, CD43, or CD45RO (Table 89.2).^{65, 104} T-cell antigens CD5 and CD8 are usually negative. Some cases lack demonstrable T-cell antigens but have evidence of TCR gene rearrangements.⁶⁵ Most ALCLs express cytoplasmic cytotoxic cell-associated proteins TIA-1, granzyme B, or perforin. A membranous and Golgi pattern of CD30 expression is characteristic of the neoplastic cells of ALCL.^{105, 107} The most intense reactivity to CD30 antibodies is seen in the large cells, whereas the smaller cells are weakly positive or more often negative. Most ALCLs are positive for the EMA (epithelial membrane antigen) with a pattern similar to CD30.¹⁰⁸ Myeloid-associated antigens (CD13, CD15, CD33) are often expressed by neoplastic cells, especially when analyzed by flow cytometry.¹⁰⁹ Expression of myeloid markers CD13 and CD33 appears to differentiate ALK+ ALCL from ALK- ALCL.¹¹⁰

FIGURE 89.4. Anaplastic large cell lymphoma. Heterogeneous population of large lymphocytes is present with clearing of the nuclear chromatin and moderately abundant pink cytoplasm. Some cells have irregular and horseshoe-shaped nuclei (“hallmark” cells).

Cytogenetically, the t(2;5)(p23;q35)/NPM-ALK translocation is demonstrable in over 75% of ALK+ ALCLs (Table 89.3).^{111, 112} Several other translocations involving the ALK gene have been described, including t(1;2)(q25;p23), t(2;3)(p23;q21), inv(2)(p23q35), t(2;22), t(2;17)(p23;q11), and t(2;19)(p23;p13).^{97, 113, 114, 115} All of these translocations lead to cytoplasmic overexpression and activation/phosphorylation of the ALK gene product as a result of dimerization of the gene partner-associated proteins. The NPM-ALK fusion is unique in that it is associated with both nuclear and cytoplasmic expression of

ALK, due to the unique nuclear localization properties of NPM (nucleophosmin). As a result ALCLs associated with this translocation show nuclear and cytoplasmic ALK expression, while all other tumors show cytoplasmic ALK only, allowing immunohistochemical staining for ALK to predict the underlying genetic lesion in these lymphomas.

Of note, ALK expression is not unique to ALCL, but has also been demonstrated in a large subset of inflammatory myofibroblastic tumors, a predominantly pediatric mesenchymal neoplasm that also harbors translocations involving ALK; as well as in other pediatric tumors, where alternative mechanisms of overexpression may be operative.^{116, 117, 118} Therefore, careful immunophenotypic characterization of ALK+ neoplasms should be performed to confirm the diagnosis of ALCL.

Uncommon Pediatric Lymphomas

While the lymphoblastic and large cell lymphomas detailed above represent the vast majority of pediatric NHLs, a small but significant proportion of lymphomas occurring in this age group consists of low-grade B-cell lymphomas and some subtypes of peripheral T-cell lymphoma (see Table 89.1). The diagnosis of these rare lymphomas in children is often delayed or initially interpreted as a reactive process or as one of the more common pediatric lymphomas.

Some of these neoplasms (including FL and marginal zone lymphoma [MZL]) appear to constitute distinct clinicopathologic entities in this age group and will be detailed below. Other rare lymphomas of children and adolescents include hepatosplenic T-cell lymphoma, mycosis fungoides,^{119, 120, 121, 122, 123, 124, 125, 126} panniculitis-like T-cell lymphoma,^{127, 128, 129} HTLV-1-associated leukemia/lymphoma,^{130, 131, 132} and natural killer (NK) lymphoma.^{129, 133, 134, 135} For the most part, the clinical and biologic features of these lymphomas in children resemble their adult counterparts. A detailed presentation of all of these lymphoma subtypes is beyond the scope of this chapter. Only hepatosplenic lymphoma will be discussed below, with an emphasis on the frequent bone marrow involvement at presentation and the importance in differential diagnosis with the more common pediatric leukemias.

Follicular Lymphoma

Follicular lymphoma (FL) is a neoplasm of follicular germinal center B-cells that retains a follicular or nodular growth pattern.

Children may develop FL pathologically and clinically similar to the adult disease, as well as FLs with unique clinicopathologic features, designated by the most recent WHO Classification as pediatric follicular lymphoma (P-FL). P-FL comprises <3% of all pediatric lymphomas,^{2, 136, 139, 140, 141} and usually presents with disease localized to lymph nodes of the head and neck area or

P.1879

testicles.^{140, 142, 143, 144, 145, 146} In striking contrast to adults, transformation to higher grade lymphoma is distinctly uncommon in P-FL, and the patients have prolonged remissions and high event-free survival rates, with or without therapy.^{138, 139, 140}

P-FL is characterized by a follicular growth pattern, often as large, irregular GCs with monotonous, predominantly centroblastic cells, similar to the grade 3 FL seen in adults.^{181, 183, 184, 186} Neoplastic cells of P-FL express CD10, CD19, CD20, CD22, CD79a, and BCL6; may be weakly positive or negative for surface IgM or IgG; and are negative for BCL2.^{65, 140, 141} P-FLs have BCL6 rearrangements but lack the t(14;18)(q32;q21), BCL2 rearrangements and P53 overexpression, despite their apparent high histologic grade (Table 89.3).^{142, 143, 144, 145} This is in contrast to the majority of adult FL, which express BCL-2 and have a t(14;18) that involves rearrangement of BCL2.⁶⁵ The distinction between classic FL and P-FL is important in the pediatric age group. In two separate studies of pediatric nontesticular FL, BCL2 expression was an important determinant of outcome,^{139, 140} with patients with BCL2+ lymphomas presenting with advanced disease stage or disease refractory to therapy; whereas children with BCL2 negative tumors (likely mostly P-FL cases) presented with stage I disease, achieved complete remission, and had no relapses.¹⁴⁰

Marginal Zone B-cell Lymphoma

MZL B-cell lymphoma is rarely diagnosed in the pediatric age group, with only a few reports available to date.^{141, 147, 148} As with adults, MZLs in children and young adults may be nodal or extranodal in their presentation. The extranodal MZLs of mucosa-associated tissue are also referred to as MALT lymphomas. Extranodal sites of presentation include salivary glands, lung, orbit, ocular adnexa, lip, breast, stomach, and sinonasal cavity. Gastric forms are associated with *H. pylori* infection. Nodal MZL is reportedly more frequent in males and presents usually with localized disease. Extranodal MZL also tends to be localized in these young patients and shows a slight male predominance. Most children with MZL do

exceptionally well with treatment. Both nodal and extranodal types demonstrate morphologic and immunophenotypic features similar to their adult counterparts. Morphologically, the marginal zone and interfollicular areas of the lymph node are infiltrated by a mixture of small lymphocytes, centrocyte-like cells, and monocytoid B-cells. A small number of immunoblastic cells may be present. Plasma cells and sometimes significant plasma cell differentiation may be present. Additionally, over two-thirds of pediatric nodal MZLs display disruption of residual normal follicles resembling progressive transformation of GCs, a feature that appears to be unique to MZLs in this age group. Immunophenotypically, the neoplastic cells express CD20, CD79a, IgD, and IgM; but not CD5, CD10, CD43, CD103, and cyclin D1.⁶⁵ Extranodal MZLs must be distinguished from benign marginal zone hyperplasias of tonsils or appendix with λ IG light chain restriction.¹⁴⁹

Hepatosplenic T-cell Lymphoma

Hepatosplenic T-cell lymphoma is an aggressive extranodal malignancy of cytotoxic T-cells usually of $\gamma\delta$ and less commonly $\alpha\beta$ T-cell receptor type.^{65, 150, 151, 152, 153, 154, 155} This rare lymphoma has a peak incidence in adolescents and young adults, with male predominance,^{65, 151} although a female predisposition is reported for $\alpha\beta$ hepatosplenic lymphomas.^{153, 154} A relatively high percentage of cases follow solid organ transplantation or immunosuppressive therapies for other conditions.^{156, 157, 158, 159} Patients typically present with enlarged spleens and livers, but no appreciable lymphadenopathy. Isolated thrombocytopenia is a common presentation. Circulating lymphoma cells are commonly present at diagnosis but may be difficult to distinguish from atypical lymphocytes. A more obvious leukemic phase may develop as the disease progresses.^{153, 154} Cases of $\alpha\beta$ hepatosplenic lymphoma are histologically, cytogenetically, and clinically similar to the $\gamma\delta$ form.¹⁵⁴

FIGURE 89.5. Hepatosplenic T cell lymphoma. Prominent hepatic sinusoidal infiltration by intermediate to large lymphoid cells with clumped chromatin and occasional nucleoli. Inset: Immunohistochemical staining for CD3 highlights a sinusoidal pattern of bone marrow infiltration.

In liver and spleen samples, the neoplastic cells are medium-sized to large, with scant to moderate amounts of cytoplasm and a predominantly sinusoidal location^{154, 155} (see Fig. 89.5). Azurophilic cytoplasmic granules have been described in a minority of cases. The nuclei may be round or convoluted with condensed chromatin and inconspicuous nucleoli. With disease progression, a blast cell transformation with large cells having prominent nucleoli may occur.^{156, 160, 161} This is the

most frequent lymphoma cell appearance in bone marrow samples from pediatric patients, and therefore it is an important consideration in the differential diagnosis with acute leukemias, especially of myeloid lineage. The bone marrow biopsy samples frequently show a characteristic sinusoidal infiltrate.^{154, 155, 161} Erythrophagocytosis may be evident.^{154, 155, 162, 163} The lymphoma cells have a fairly consistent immunophenotypic expression pattern of CD2⁺, CD3⁺, CD4⁻, CD8[±], CD5⁻, CD7⁺, CD16⁺, and CD56[±] (Table 89.2).^{65, 153, 164} The αβ hepatosplenic lymphomas have a similar immunophenotype except for a slightly more frequent expression of CD57.154 TCR βδ or less commonly TCR αβ proteins can be detected by flow cytometric analyses.^{150, 155} Cytotoxic granular protein TIA-1 is detected in most cases, whereas granzyme B or perforin are detected in only a minority of cases.^{153, 154, 162, 165, 166}

Cytogenetically, an isochromosome 7q, often with trisomy 8 and other random chromosomal abnormalities, is found in the majority of reported cases.^{154, 158, 160, 161, 167, 168, 169, 170}

CLINICAL FEATURES

The clinical presentation for children with NHL is quite varied (Tables 89.3 and 89.4).^{1, 2, 7} The primary sites of disease, which vary according to histologic subtype, are the primary determinants for the signs and symptoms observed. Children with advanced-stage T-LBL or mediastinal large B-cell lymphoma typically present with a mediastinal mass (Figs. 89.6 and 89.7), whereas children with BL typically present with abdominal disease (usually arising from the terminal ileum and often serving as a trigger point for an intussusception). By way of contrast, children with large cell lymphoma may present with primary involvement of either mediastinum or abdomen.

Those children presenting with an abdominal mass may have associated nausea, vomiting, and abdominal pain. Abdominal distension secondary to obstruction and associated ascites may be present on physical examination. Extension of the mass into the pelvis may result in ureteral compression and hydronephrosis. The presence of an anterior mediastinal mass may result in some

P.1880

degree of respiratory distress, ranging from slight cough to severe respiratory compromise, including arrest.⁷ The respiratory status may also be compromised by the presence of a pleural effusion. A mediastinal mass may obstruct venous return to the heart, resulting in a superior vena cava syndrome.⁷ This syndrome is characterized by swelling in the neck and shoulder region and prominent venous vasculature, a condition which may predispose the patient to the development of a deep venous thrombosis.

TABLE 89.4 STAGES OF NON-HODGKIN'S LYMPHOMA^a

Stage I

A single tumor (extranodal) or involvement of a single anatomical area (nodal), with the exclusion of the mediastinum and abdomen.

Stage II

A single tumor (extranodal) with regional node involvement.

Two or more nodal areas on the same side of the diaphragm.

Two single (extranodal) tumors, with or without regional node involvement on the same side of the diaphragm.

A primary gastrointestinal tract tumor (usually in the ileocecal area), with or without involvement of associated mesenteric nodes, that is completely resectable.

Stage III

Two single tumors (extranodal) on opposite sides of the diaphragm.

Two or more nodal areas above and below the diaphragm.

Any primary intrathoracic tumor (mediastinal, pleural, or thymic).

Extensive primary intraabdominal disease.

Any paraspinous or epidural tumor, whether or not other sites are involved.

Stage IV

Any of the above findings with initial involvement of the central nervous system, bone marrow, or both.

^aBased on the classification proposed by Murphy.

The degree of tumor burden at the time of diagnosis is quite variable. Some children present with isolated lymph node involvement, whereas others may present with more widespread disease (Fig. 89.8). Involvement of the bone marrow may be associated with pancytopenia, pallor, and bruising. Blurred vision, headache, or the presence of a cranial nerve palsy on physical examination may be present when the central nervous system is involved. Skin lesions may be present at the time of diagnosis in approximately 4% of children; however, this is usually associated with the CD30⁺, ALK⁺ anaplastic subtype of large cell lymphoma.^{171, 172} Involvement of bone may be associated with local swelling, pain, or limp. Boys may present with testicular enlargement secondary to tumor infiltration. Involvement of the ovary may be identified on diagnostic imaging studies.

MANAGEMENT

Initial workup and staging: Modern therapy for the NHLs of childhood is determined by both the histologic diagnosis and the disease stage. It is therefore imperative that an expeditious and comprehensive staging workup be performed after the diagnosis is established. This generally includes: computerized tomography of the neck, chest, abdomen, and pelvis; nuclear imaging; bilateral bone marrow aspirates and biopsies for cell count and differential, flow cytometry if the marrow is overtly involved, cytogenetics, and molecular pathology; lumbar puncture for cerebrospinal fluid cytology.^{2, 7} Over the past⁵ years there has been a change in the type of nuclear imaging studies done in the pediatric NHL staging workup. Historically, gallium and bone scans were considered part of the workup; however, positron emission tomography (PET) is becoming a more widely used staging modality for children with NHL.¹⁷³ Data on how PET compares to conventional gallium and bone scanning is lacking. Uniform criteria for the interpretation of PET findings in children both at diagnosis and in response evaluation are needed. In some large cooperative groups studies, PET is not used at all. Thus, it is important to know what imaging studies are being done for a staging workup when risk-adapted (e.g., stage-adjusted) protocol results are reported. A complete blood count with differential and chemistry panel including serum lactate dehydrogenase (LDH) should also be obtained. Upon completion of the above workup, patients are designated with a disease stage—usually according to the St. Jude system described by Murphy (Table 89.4).⁸ Those with stage I or II are considered to have limited-stage disease, whereas those with stage III or IV are considered to have advanced-stage disease.

Initial management: Upon expeditious completion of the diagnostic and staging workup, appropriate therapeutic options can be implemented. Before chemotherapy is started, however, a number of issues must be considered. Some children are at high risk for tumor lysis syndrome (TLS). This primarily includes children with advanced-stage BL and some children with LBL who have a large tumor burden at diagnosis, which may be reflected by an elevated serum LDH. Some of these children will have metabolic abnormalities with some degree of renal dysfunction at diagnosis, which only worsens once chemotherapy is started (e.g., hyperkalemia, hyperuricemia, hyperphosphatemia, etc.). Therefore, these children should have excellent intravenous access and vigorous hydration before starting chemotherapy. Hyperuricemia has historically been managed using hyperhydration coupled with allopurinol, a xanthine oxidase inhibitor. Uricolytics, such as uricozyme, which cleave uric acid to the more soluble and readily cleared allantoin, have been used for decades. A recombinant form of this drug, rasburicase, has been shown to be very effective and well tolerated with a reduced risk of associated allergic reaction.¹⁷⁴ The advantage of these agents is the precipitous drop in serum uric acid which negates the need for alkalinization, thus facilitating phosphorous excretion. Of note, a study of rasburicase in children at high risk for TLS demonstrated preservation of renal function with no significant associated hyperphosphatemia or hyperkalemia.¹⁷⁴

Therapy: There have been significant improvements in treatment outcome for children with newly diagnosed NHL over the past 25 years.¹ This has been largely accomplished through incremental refinements in sequential multicenter trials which feature both a stage- and histology- or immunophenotype-directed approach to treatment assignment. Two of the initial successful regimens for children with NHL were the multiagent LSA2L2 regimen^{175, 176, 177} designed for children with ALL, and the cyclophosphamide-based COMP regimen.¹⁷⁵ A randomized trial by the Children's Cancer Group (CCG) comparing these two approaches validated a stage- and histology-directed therapeutic approach to pediatric NHL.¹⁷⁵ Specifically, children with limited-stage disease did well regardless of the treatment arm. In contrast, among those with advancedstage disease, those with BL had a better outcome with COMP and those with LBL had a better outcome with LSA2L2; there was no clear therapeutic advantage with either approach for children with advanced-stage large cell lymphoma. Other trials validated and built on these observations.^{96, 178, 215}

Subsequent to the CCG trial comparing LSA2L2 and COMP, the dominant theme of most trials for children with limited-stage disease has been the reduction of treatment-related acute and late effects without compromising treatment outcome.^{180, 182, 183, 198, 201, 202} This has been attempted by shortening the duration of therapy, dose reduction of certain agents, and elimination of involved field irradiation. In the first of two sequential trials performed by the Pediatric Oncology Group (POG),¹⁸³ it was demonstrated that involved field irradiation could safely be eliminated from a 33-week treatment plan that featured three courses of cyclophosphamide, Adriamycin, vincristine, and prednisone (CHOP), followed by a 24-week maintenance phase of 6-mercaptopurine and low-dose methotrexate. In the subsequent trial it was shown that the 24-week maintenance phase could be safely eliminated for children with Burkitt or large cell lymphoma; however, for children with LBL the result was inferior.¹⁸³ Even with the 24-week maintenance phase, one-third of children with LBL experienced a recurrence; however, the majority were successfully salvaged, resulting in a similar overall survival to other histologic subtypes. Other groups have approached limitedstage LBL with a more intensive initial

treatment regimen.¹⁹⁷ For example, the French Society of Paediatric Oncology (SFOP) cooperative group trial treats children with LBL with the same regimen used for those with advanced-stage disease.¹⁹⁷ A somewhat intermediate intensity approach is currently being studied by the Children's Oncology Group (COG), in which patients with limited-stage LBL are receiving a regimen modeled after approaches used for low-risk ALL.

Treatment advances for children with advanced-stage disease have primarily focused on improving histology- and immunophenotype-directed treatment strategies (United States and Europe, respectively). Intensification of therapy, addition of new active agents, and refinement in risk-adapted therapy have all been credited with improvement in outcome.

Burkitt lymphoma: For children with advanced-stage BL, initial improvements in treatment outcome beyond that achieved with COMP were attained by the incorporation of high-dose methotrexate and cytarabine (Table 89.5). Two year event-free survival rates of approximately 80% for children with stage III BL were reported with the Total B regimen which featured 1 gram/m² methotrexate and sequentially escalating doses of continuous infusion cytarabine; for those with bone marrow involvement however, the outcome was inferior (approximately 20%).¹⁸¹ The POG modified the Total B approach in the PG8617 protocol by incorporating high-dose pulses of cytarabine and intensified intrathecal therapy; this resulted in an improved treatment outcome for children with stage IV disease.¹⁸⁵ The optimal duration of therapy was examined in other trials. For example, the French (SFOP)¹⁸⁶ demonstrated that the duration of therapy could be reduced to 4 months; Schwenn et al.¹⁹⁰ reported an excellent result with a 2-month regimen for those with stage III disease. Further advances in therapy were subsequently achieved by dose intensification of cyclophosphamide, methotrexate, and cytarabine and by the incorporation of new active agents (e.g., etoposide). The German Berlin-Frankfurt-Münster (BFM)²⁰¹ and SFOP¹⁸⁰ cooperative groups have reported encouraging results, using risk-directed treatment assignment based on clinical features such as stage, degree of surgical resection, tumor burden, degree of bone marrow involvement, and disease sites. For example, in the SFOP LMB-89 regimen,¹⁸⁰ Group A treatment is restricted to those who completely resected limited-stage disease, whereas Group C, which is the most intensive arm, comprises those who have greater than 70% marrow blasts or central nervous system

P.1882

disease. Group B is intermediate in intensity and is given to those with incompletely resected limited-stage disease, stage III, and those with <70% bone marrow replacement. Approximately 85% of children with advanced-stage B-cell lymphoma are cured with this approach. An international collaborative study (LMB-96) was conducted to determine whether the intensity of LMB-89 therapy could be safely reduced for patients with Group B and C therapy. Among Group B patients it was demonstrated that the avoidance of cyclophosphamide dose escalation in the second course of COPADM and deletion of a maintenance sequence could be safely implemented without compromising the outcome.²¹⁶ Among Group C patients however, reduction in therapy was associated with a poorer outcome.²¹⁷ The BFM cooperative group has also reported excellent results with a regimen that features high-dose methotrexate (5 g/m²), ifosfamide, doxorubicin, etoposide, cytarabine, vincristine, and steroids.²⁰¹ In their most recent trial, it was demonstrated that a 4-hour infusion of methotrexate resulted in a noninferior outcome compared to the 24-hour infusion; however, this was not found to be true for those with advanced-stage disease.²¹⁸ The current BFM study is examining a rituximab window phase to evaluate both activity and toxicity—responses to single agent rituximab were observed in some patients, and the toxicity profile was generally acceptable.²¹⁹

LBL: Strategies to improve the outcome for children with LBL have generally built on the results of the CCG trial, which demonstrated a superior result with an ALL-like treatment approach (i.e., LSA2L2). The incorporation of high-dose methotrexate has been featured in a number of successful treatment regimens (Table 89.6).^{197, 205, 206, 207} For example, the SFOP modified the LSA2L2 regimen by incorporating courses of high-dose methotrexate throughout the maintenance phase of therapy with an excellent treatment result.¹⁹⁷ The BFM cooperative group achieved an outstanding result (i.e., 5-year event-free survival rate of 90%) with an approach which featured a high-dose methotrexate consolidation phase (5 g/m² every other week for a total of 4 courses).²⁰⁵ The improved outcome with higher doses of methotrexate may be the result of higher levels of intracellular methotrexate polyglutamates achieved with dose escalation.²²⁰ The necessity of methotrexate in the treatment regimen has been questioned.²⁰⁷ In a randomized trial performed by the POG, it did not appear that high-dose methotrexate added to the treatment result for children with LBL in the setting of an anthracycline- and asparaginase-rich backbone^{207, 221} however; the result for children with T-ALL entered on this trial was inferior in the arm without high-dose methotrexate.²²¹ The COG recently completed a randomized trial which also examined the need for high-dose methotrexate in children with LBL. In this study, the arm featuring the incorporation of high-dose methotrexate was being compared to an arm which featured the incorporation of extended intrathecal therapy. Preliminary reports suggest no difference in the treatment arms, although the final analysis is pending. Improvements in treatment outcome have also been attributed to other interventions such as the incorporation of a delayed intensification phase²⁰⁵ (i.e., reinduction phase), L-asparaginase,²¹² and new active agents.¹⁹¹ A randomized trial performed by the POG demonstrated a survival advantage for those patients receiving additional doses of L-asparaginase. L-asparaginase is a featured component of the very successful Dana Farber approach. Anthracyclines are also commonly used in successful NHL treatment regimens. For example, they are a featured component in the POG 9404 regimen.^{207, 221} The use of epipodophyllotoxins in the treatment of LBL is more controversial. In this regard, etoposide was a featured agent in the successful NHL13 regimen²²²; however, their use in the POG T3 protocol was found to be associated with an increased rate of secondary AML.²¹²

It has been difficult to identify clinical features among children with LBL that are reliably predictive of outcome—that is, for whom novel or intensified therapy could be planned. However, the use of flow cytometric technology to measure disease extent at diagnosis (minimal disseminated disease, MDD) has identified higher risk patients. A study by Couston-Smith et al. demonstrated that the detection of MDD in the bone marrow of LBL patients at the time of diagnosis was predictive of outcome.²²³ Those with greater than or equal to 1% lymphoblasts in the marrow had a significantly inferior event-free survival compared to those with a lesser amount. Of interest, the level of disease detection in the peripheral blood was comparable to that found in the bone marrow, suggesting that disease response (minimal residual disease, MRD) could be followed with a peripheral blood test instead of bone marrow examination.²²³ This data regarding the prognostic significance of MDD at diagnosis is the basis for two ongoing clinical trials for advanced-stage T-cell LBL in the United States.

Large cell lymphoma: Determining the optimal treatment approach for children with advanced-stage large cell lymphoma has been more of a challenge for various reasons. The CCG randomized trial comparing COMP and LSA2L2 did not show an advantage to either approach for children with advanced-stage large cell lymphoma.¹⁷⁵ Further complicating the picture is the fact that historically, children with large cell lymphoma in the United States were treated on the basis of the histologic diagnosis (i.e., uniform therapy for all immunophenotypic subtypes), whereas in Europe, children with large cell lymphoma have been treated primarily according to immunophenotype (e.g., T-cell, B-cell, or CD30⁺ALCL).^{96, 196, 208, 224} With histology-directed therapy, the 5-year event-free survivals for children with advanced-stage disease have generally been in the range of 60% to 75%^{175, 178, 179, 188, 208, 210, 211} (Table 89.7). These results have largely been achieved using CHOP-based therapy (cyclophosphamide, Adriamycin, vincristine, and prednisone). During the past 15 years, the investigators in the United States have used an immunophenotype-directed approach for children with large cell lymphoma, in part because of the excellent results achieved in Europe using this strategy. For example, in France (SFOP), children with advanced-stage B-cell large cell lymphoma are treated according to a BL regimen (LMB89) with an excellent result (3-year event-free survival >80%). Most groups are now treating BL and B-cell large cell lymphoma similarly. The PMBL, however, have an inferior outcome with an approximate 70% event-free survival reported with modern therapy.²¹⁶

Preliminary results from protocols featuring dose-adjusted EPOCH-R in adults with PMBL been encouraging^{225, 226, 227} and have recently prompted the development of a protocol examining this approach in children.

CHOP, cyclophosphamide, Adriamycin, vincristine, and prednisone; EFS, event-free survival.

There are still quite varied approaches used for those children with CD30⁺ ALCL.^{96, 211, 224} In Europe, an immunophenotypedirected approach has been used. In the German BFM trials, children CD30⁺ ALCL have been treated with a B-cell approach (BL like) with an outstanding result (3-year event-free survival rate of approximately 80%).^{196, 224} The United Kingdom Children's Cancer Study Group studied the activity of a B-cell approach (NHL 9002), based on the very successful French LMB-89 B-cell protocol. In this UK study, children with stage II, III, and non-CNS+ stage IV ALCL treated with the Group B arm of the LMB-89 regimen achieved a 55% 5-year event-free survival rate.²¹³ It is unclear why this approach appeared to be inferior to the BFM B-cell approach; however, the BFM approach features more frequent use of alkylators. In SFOP trials, children with CD30⁺ ALCL have been entered on regimens specific for that subtype.⁹⁶ The HM 89 and HM 91 both feature an initial treatment phase (one course of COP followed by two courses of COPADM) based on their very successful B-cell protocol, LMB-89. The maintenance phases, however, were different from LMB-89: the HM 89 protocol

P.1884

featured alternating courses of VEM (etoposide, methotrexate, and cyclophosphamide) and VAD (vincristine, doxorubicin, and decadron), for a total of 8 courses; and the HM 91 regimen featured alternating courses of VEBP (vinblastine, etoposide, bleomycin, and prednisone) and Sequence 1 (vincristine, methotrexate, cyclophosphamide, and doxorubicin) for a total of 8 courses. The 3-year event-free survival for all stages treated with these two regimens was 66% (54% to 76%); however, among stage III and IV patients, the 3-year event-free survival was 55%.

In the United States, a histology-directed approach has historically been used to treat children with large cell lymphoma. The APO regimen is one of the most active regimens, and features an induction phase (doxorubicin, vincristine, prednisone, and intrathecal methotrexate) followed by sequential maintenance phases (doxorubicin, methotrexate, vincristine, prednisone, 6-mercaptopurine, and intrathecal methotrexate).^{193, 210, 211} A POG randomized trial which examined the potential benefit of adding intermediate-dose methotrexate and high-dose cytarabine to the APO regimen found no difference in outcome regardless of immunophenotype.²¹¹ Among the 86 patients with advanced-stage disease, a 4-year event-free survival and overall survival of 71.8% and 88.1%, respectively, were reported.

During the past decade, cooperative group trials in Europe and the United States built on the BFM B-cell and APO strategies, respectively. Both studies are examining the benefit of adding vinblastine, an agent which has activity as a single agent in multiply relapsed ALCL patients.²¹⁵ In the ALCL99 trial (BFM-based), the addition of vinblastine to the BFM backbone did not improve long-term event-free survival.²²⁸ Another observation in this trial was that the infusion of methotrexate could be changed from 1 gram/m² given over 24 hours with IT MTX to a 3-hour infusion of methotrexate at a dosage of 3 g/m² (without IT MTX), without compromising outcome.²²⁹ The shorter infusion was also associated with less toxicity. In this trial, various prognostic factors were examined. Interestingly, stage was not associated with prognosis²³⁰; however, those with a small cell variant or lymphohistiocytic histologic component had a poorer outcome

than children who lacked this subtype.²³¹ Preliminary results from the COG APO trial also indicated that the inclusion of vinblastine did not improve treatment outcome, although the final report is pending.

Relapse: Approximately 20% to 30% of children with NHL will have a treatment failure with frontline therapy as manifested by either recurrent or, less commonly, refractory disease.¹ The prognosis for children with recurrent or refractory NHL has generally been felt to be quite poor. Therefore, most oncologists consider either intensive or novel salvage chemotherapy regimens, followed by an intensification phase including either autologous or allogeneic hematopoietic stem cell transplantation (HSCT) in the majority of cases. However, the role of HSCT in this setting is somewhat controversial.²³²

There are a number of studies which feature HSCT.^{201, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243} For example, some children with BL who had a poor early response to therapy were successfully salvaged with high-dose intensive chemotherapy followed by autologous HSCT in European Cooperative Group trials.^{201, 236, 238, 239, 241} The Spanish Working Party for Bone Marrow Transplantation reported that 58% of the children who had either refractory/recurrent NHL, or high risk in first CR, were event-free survivors following HSCT.²³⁸ SFOP reported that 8 of 24 children with refractory or recurrent NHL were long-term disease-free survivors using HSCT.^{239, 243} In a St. Jude single institution review of 20 children with recurrent or refractory NHL, approximately 45% were survivors following HSCT.²⁴³ Published studies featuring HSCT for pediatric NHL are relatively small in number, and vary with respect to the type of HSCT (autologous versus allogeneic), salvage therapy, preparative regimen, and histologic subtype, making direct comparisons difficult.

The availability of novel and targeted therapies has made the histologic subtype of NHL a crucial factor in determining the appropriate initial salvage therapy, and in some cases the type of HSCT (i.e., allogeneic versus autologous) for those children who experience a failure following primary therapy.

- Various options can be considered for children with recurrent ALCL. Single agent vinblastine has been shown to be active even in children who have experienced multiple relapses. Of interest, some of these patients have experienced extended event-free survival after completing 1 to 2 years of therapy.²⁴⁴ Multiagent chemotherapy regimens have also been reported to be active and include the ICE regimen (ifosfamide, carboplatin, and etoposide)²⁴⁵ and the MIED regimen (methotrexate, ifosfamide, etoposide, and dexamethasone),²⁴⁶ with long-term event-free survival achieved with subsequent auto-HSCT in patients who are chemosensitive going into HSCT. The BFM reported prognostic factors for children with chemosensitive disease that went on to get an auto-HSCT; those with CD3⁺ tumors, or “relapse on therapy” had a poorer outcome.²⁴⁷ The BFM also published very promising results with the use of allo-HSCT for children with high-risk ALCL, suggesting a possible graft-versus-lymphoma effect.²⁴⁸
- One of the most commonly used regimens for children with recurrent CD20 mature B-cell lymphoma (e.g., BL, DLBCL) is the RICE regimen, which includes rituximab, ifosfamide, carboplatin, and etoposide. A COG study demonstrated activity of this regimen in patients with either BL or DLBCL with subsequent event-free survival following either auto-HSCT or allo-HSCT.²⁴⁹ A number of studies have suggested that autologous HSCT is beneficial in the management of children with BL who are poor early responders to initial therapy.^{201, 234, 239} It is less clear which approach is optimal for those children with BL who relapse in the bone marrow, although many would favor an allogeneic approach if a suitable donor is available.
- Children with recurrent T-cell LBL are generally managed with salvage regimens for recurrent T-ALL; if chemosensitive, they are generally managed with allo-HSCT, as auto-HSCT has not been found to be very effective.²⁵⁰

There is a spectrum of preparative regimens which have been studied in children with recurrent or refractory NHL.^{201, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243} Carmustine, etoposide, cytarabine, and melphalan (BEAM); and carmustine, cytarabine, cyclophosphamide, and thioguanine (BACT) are two of the earliest drug combinations used successfully.^{234, 235, 242} SFOP credited their excellent salvage rate in part to the inclusion of high-dose busulfan in the preparative regimen.²³⁹ Gordon et al.²³⁷ reported excellent results for children with recurrent peripheral T-cell lymphoma using a regimen that featured thiotepa. Additional prospective clinical trials which examine HSCT strategies in children with recurrent or refractory NHL are clearly needed; it has been suggested by one group that the potential graft-versus-lymphoma effect of the allogeneic HSCT approach be studied.²⁴¹

LONG-TERM SEQUELAE

Improvements in the cure rate for children with NHL have prompted investigators to more closely examine long-term treatment-related late effects. Areas of concern include second malignancies, second cancers, and fertility. Attempts to

reduce these unwanted sequelae include trials which have eliminated or reduced the doses of certain chemotherapeutic agents or involved field irradiation.

In the first of two sequential randomized trials for limited-stage NHL, the POG demonstrated that involved field irradiation could be safely eliminated without compromising the excellent treatment outcome.¹⁸³ The elimination of involved field irradiation was also shown to be possible without compromising outcomes in a

P.1885

St. Jude study of patients with advanced-stage disease.²⁵¹ Involved field irradiation of primary tumor masses is not used in most current NHL trials. However, cranial irradiation is considered in the management of children with LBL who present with overt involvement of the central nervous system. Historically, the use of cranial irradiation for CNS prophylaxis in children with LBL has been considered controversial; however, studies by the BFM²⁵² and St. Jude²²² have demonstrated that prophylactic cranial irradiation can be safely omitted from the treatment plan without compromising outcomes.

Alkylating agents such as cyclophosphamide and ifosfamide cause a dose-related depletion of germinal cells and tend to be more gonadotoxic in males. Studies suggest that fertility is generally maintained at a cumulative cyclophosphamide dose of $<4 \text{ g/m}^2$, whereas sterility is likely at doses greater than 7.5 g/m^2 .²⁵³ In this regard, various clinical trials have examined the possibility of eliminating or reducing the dose of cyclophosphamide in the treatment of certain NHL subtypes.²⁰⁹ For example, in the LMB-96 trial for children with high-grade mature B-cell lymphomas, it was demonstrated that escalation of the cyclophosphamide dosage in the second course of COPADM could be avoided in Group B patients without compromising the outcome.²¹⁶

Pediatric NHL trials have also been influenced by the desire to avoid or limit anthracycline-related cardiac toxicity. Although adults have been shown to tolerate cumulative Adriamycin doses of 550 mg/m^2 , children treated with lower cumulative doses have been shown to have clinically significant abnormalities in ventricular contractility.²⁵⁴ Factors which have been shown to be predictive of cardiac dysfunction include higher anthracycline dose intensity, cumulative anthracycline dose, female sex, younger age at time of treatment, combined modality therapy which includes mediastinal irradiation, and time interval since completion of therapy.^{255, 256} In addition to trials which attempt to reduce the cumulative dose of anthracyclines,¹⁸⁸ the study of cardioprotectants is also indicated.

FUTURE DIRECTIONS

Although significant progress has been made in the treatment of children with NHL, 25% to 30% continue to have refractory or recurrent disease. Treatment-related late effects are of additional concern. Thus, the continued goal and challenge for the pediatric oncologist is to develop more effective treatment approaches which are not associated with significant late effects. This will require further refinement in risk-adapted treatment planning, which will be made possible by the identification of additional prognostic biologic and clinical factors.

Various strategies may contribute to further improvement in treatment outcome, such as the development of new active agents or new schedules for the delivery of current agents. One of the most promising novel approaches is the use of immunotherapeutic agents such as rituximab for patients with $\text{CD}20^+$ B-cell lymphomas.^{257, 258, 259} In adults, the use of Rituxan has been shown to improve outcome for adults with DLBCL and FL. Pediatric trials which include rituximab for children with $\text{CD}20^+$ B-cell lymphomas are ongoing. The BFM recently reported on the activity and toxicity profile of rituximab given as window therapy before starting conventional therapy.²¹⁹ The COG performed two pilot studies which incorporated rituximab into Groups B and C of LMB-96 based therapy—preliminary results are promising, with final reports pending. Anti-CD30 (SGN30) has been shown to have activity in adults with $\text{CD}30^+$ ALCLs.²⁶⁰ A pediatric trial of SGN30 combined with ICE (ifosfamide, carboplatin, and etoposide) was recently completed, with results forthcoming. An antibody drug conjugate (i.e., SGN35) which links auristatin to anti-CD30 has been shown to be active in $\text{CD}30^+$ ALCL and Hodgkin lymphoma occurring in adults.^{261, 262, 263} Small molecule inhibitors, which have been shown to be active in adults with CML, may have a role in some types of childhood NHL; phase I studies are currently ongoing.^{264, 265} Crizotinib, a small molecule inhibitor of c-MET/ALK, has been shown to be active against ALCL in adults;²⁶⁶ pediatric trials are ongoing. Future plans for the use of targeted therapeutic agents, including immunotherapeutic agents and small molecule inhibitors, include their combination with conventional agents in the management of children with newly diagnosed ALCL.

The continued molecular characterization of chromosomal abnormalities associated with pediatric NHL may prove helpful in refining the classification of clinically relevant histologic subtypes,^{28, 267, 270} evaluating response to therapy, and developing novel therapeutic approaches which target the molecular lesion directly.

Chapter 90

Chronic Lymphocytic Leukemia

James B. Johnston

Matthew Seftel

Spencer B. Gibson

Chronic lymphocytic leukemia (CLL) is characterized by the accumulation of mature-appearing lymphocytes in the blood, marrow, lymph nodes, and spleen.^{1, 2, 3, 4} Small lymphocytic lymphoma (SLL) is the same disease, but primarily there is involvement of lymph nodes and spleen. Both CLL and SLL are antedated by monoclonal B-cell lymphocytosis (MBL) in which small numbers of CLL cells can be detected in the blood of asymptomatic individuals.^{1, 2, 3, 4} The CLL cells are monoclonal B lymphocytes that express CD19, CD5, and CD23 with weak or no expression of surface immunoglobulin (Ig), CD20, CD79b, and FMC7.^{1, 2, 3, 4} Recent evidence suggests that CLL cells have a similar gene expression profile as memory B-cells, and there is considerable heterogeneity in CLL in terms of cellular morphology, phenotype, biology, molecular genetics, and prognosis.^{1, 2, 3, 4, 5, 6, 7} The incidence of CLL varies throughout the world, being highest in North America

and rare in the Far East. In North America, CLL/SLL accounts for one-quarter of all leukemias, with the incidence reported by the Surveillance, Epidemiology and End Results (SEER) Program being 5.13/100,000 for the years 1993 to 2004.⁸ A total of 75% of cases were CLL and 25% SLL. However, the incidence is likely much higher, as many patients are diagnosed by flow cytometry and are not included in tumor registries.⁹ By combining data from flow cytometry and the cancer registry the incidence of CLL/SLL is 7.99/100,000, with the median age at diagnosis being 71.5 years.⁹ The median age at diagnosis is younger for males (70 years) than for females (73 years), with the male:female ratio being 1.3:1⁹ (Fig. 90.1). One third of patients are less than 65 years and 10% less than 50 years. Using SEER data, it has been shown that relative survival is poorest for those >80 years, and worse for men.¹⁰ Interestingly, the 10-year relative survival has increased over the last 20 years for all age groups except for those 80 years of age or older at the time of diagnosis (Fig. 90.2).¹⁰ Moreover, relative survival has improved for men, diminishing the difference previously seen between the sexes.

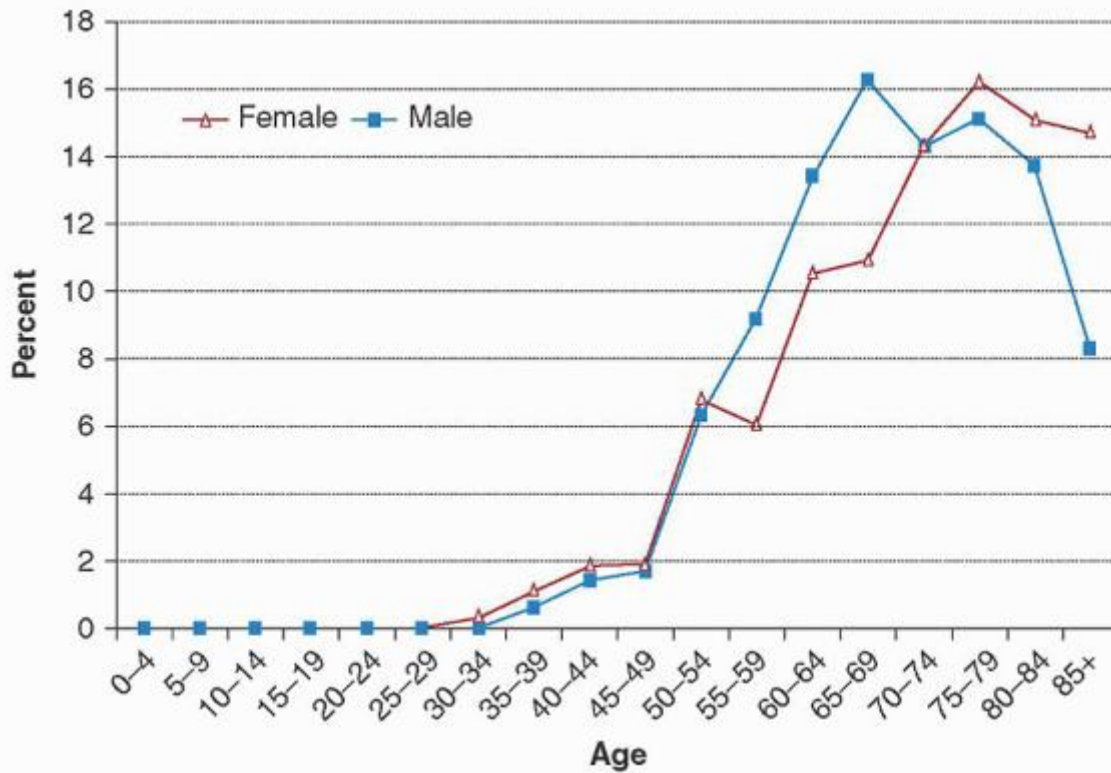

FIGURE 90.1. Age distribution of 351 males and 265 females diagnosed through the provincial cancer registry and a centralized flow cytometry facility in Manitoba over a 5-year period (1998 to 2003). The median age at diagnosis was 70 years for men and 73 years for women ($P = 0.0281$). Overall median age was 71.5 years. From Seftel MD, Demers AA, Banerji V, et al. High incidence of chronic lymphocytic leukemia (CLL) diagnosed by immunophenotyping: a population-based Canadian cohort. *Leuk Res* 2009;33:1463-1468, with permission.

Although the median age at diagnosis for CLL patients in the population is 71.5 years, it is 64 years in CLL clinics and as low as 58 years in specialized clinics.^{11, 12, 13} Thus, it is likely that many older patients are not being referred for assessment and therapy.

PATHOPHYSIOLOGY

Predisposing Factors Including Familial Chronic Lymphocytic Leukemia

Unlike other leukemias, there is no firm evidence linking an occupational exposure with an increased incidence of CLL.¹⁴ However, CLL patients have a higher incidence than normal individuals of having had an infection just prior to the diagnosis, suggesting a role for infection in the etiology of this disease.¹⁵ Moreover, a number of studies have demonstrated that about 20% of CLL patients have very similar (stereotypic) heavy-chain complementarity-determining region 3 (HCDR3) sequences in their B-cell receptors (BCR), and this affects mainly patients with an unmutated IgV_H gene (see section "Cell of Origin").^{2, 16, 17, 18, 19, 20} Moreover, approximately 1% of BCRs from both mutated and unmutated cases are identical.²⁰ Compared to normal B-cells in the elderly, there is skewing of IgV_H gene usage in CLL and the biologic features of the disease are reflected in the gene used and whether the HCDR3 is stereotypic.^{2, 16, 18, 19} These findings

suggest that a common antigen or an antigenlike element may be responsible for triggering this malignancy, perhaps an infective organism or an autoantigen.^{2, 16, 18, 19} Although patients with CLL have an increased risk of a prior diagnosis of pernicious anemia, they do not have an increased risk of other autoimmune diseases.^{4, 21} A recent study has shown that the BCRs from CLL cells, and not the BCRs from normal B-cells or other B-cell malignancies, can induce cell-autonomous signaling, which is dependent on the interaction

P.1889

of HCDR3 with internal epitopes on nearby BCRs.²⁰ As only specific HCDR3 structures may interact with the epitope and induce signaling, this may explain the high incidence of stereotypic HCDR3s. However, no obvious differences in signaling are seen between the BCRs of mutated or unmutated cases or whether the HCDR3 was stereotypic.

FIGURE 90.2. Ten-year relative survival curves of patients with chronic lymphocytic leukemia (CLL) by major age group. Period estimates for 1980 to 1984 (solid lines) and 2000 to 2004 (hatched lines). From, Brenner H, Gondos A, Pulte D. Trends in long-term survival of patients with chronic lymphocytic leukemia from the 1980s to the early 21st century. *Blood* 2008;111:4916-4921, with permission.

A family history of CLL or another lymphoproliferative disorder is a strong risk factor for CLL, and it is estimated that 1 in 10 patients with CLL has a family history of CLL or another lymphoproliferative disorder.^{14, 22} There is a thirtyfold increase in the risk of CLL in first-degree relatives of patients with CLL,^{22, 23, 24} and 13% to 18% of first-degree relatives have a peripheral blood CD5⁺ MBL.^{25, 26} However, whether individuals with these abnormal cells will eventually develop CLL is

presently unknown.²⁵ Patients with familial CLL are approximately 10 years younger than those with sporadic CLL,^{14, 23} and anticipation may occur in familial CLL, with affected children being 15 to 20 years younger than their parents at diagnosis.^{27, 28, 29, 30} However, other authors have not observed anticipation.¹⁴ There is no consistency in the clinical features of affected members with familial CLL and no difference in the clinical features of patients with familial CLL or sporadic CLL.^{14, 31} As discussed in the section on "Cell of Origin", there are two forms of sporadic CLL; those with somatic hypermutations of the IgV_H gene and those without. At the present time, it is unclear as to whether familial CLL differs from sporadic CLL with regard to the incidence of IgV_H gene mutations.^{32, 33}

The pattern of inheritance in familial CLL is unknown, but there is no linkage to HLA type.³⁴ Several recent studies have attempted to identify a susceptibility gene for familial CLL.^{35, 36} A 3.68 Mb minimal region has been identified at 13q21.33-q22.2, which has been found to be shared in four CLL families, including family members with CD5⁺ MBL.³⁷ These findings suggest that candidate genes at this and other sites may be involved in the pathogenesis of inherited CLL.¹⁴ It has been suggested that polymorphisms in the ataxia telangiectasia mutated (ATM) gene may pre-dispose individuals to develop

P.1890

CLL, but a recent study has discounted this hypothesis.³⁷ Patients with familial CLL have also been shown to have elevated plasma levels of B-lymphocyte stimulator (BLyS) and an increased frequency of a C→T polymorphism at -871 in the BLyS promoter.³⁸ Finally, in one CLL family, a single nucleotide polymorphism (SNP) in the promoter site of the death-associated protein kinase 1 (DAPK1) gene was observed in affected family members.³⁹ This polymorphism silenced this gene by binding the transcriptional regulator HOXB7.114. These results suggest that multiple abnormalities may be involved in the development of familial CLL.

Cell of Origin

There has been controversy as to the normal counterpart of the CLL cell.^{2, 19} As the CLL cell is CD5⁺, it was previously believed that the normal counterpart was the CD5⁺ B lymphocyte, which is present in the mantle zone of lymph nodes and in small numbers in the peripheral blood.⁴⁰ However, the CD5⁺ B lymphocyte lacks mutations of the IgV_H gene,⁴¹ whereas the CLL cell has undergone mutations in approximately 50% of cases.^{2, 19} Additional studies suggest that CLL cells with unmutated, as well as mutated, IgV_H have been antigen exposed.^{2, 19, 42} Firstly, surface immunophenotyping shows activation markers to be present in both mutated and unmutated cases.⁴² Secondly, there is a skewing toward specific IgV_H gene usage in CLL cells (IgV_{H1-69}, IgV_{H3-23}, IgV_{H3-7}, and IgV_{H4-34}) with some genes, for example, IgV_{H1-69} being more common in unmutated CLL and others, for example, IgV_{H4-34}, IgV_{H3-23}, and IgV_{H3-7} being more common in mutated cases.¹⁶ Thirdly, as discussed previously, 10% to 20% of patients have changes in their BCR, suggestive of antigen exposure.^{17, 18} Finally, gene expression studies indicate that both mutated and unmutated IgV_H CLL cells are memory B-cells.^{6, 7} The results of these studies indicate that the CLL cell is antigen-experienced, suggesting that the expressions of CD5 and CD23 on these cells are secondary changes, perhaps representing cell activation or nonspecific changes secondary to the malignancy. Thus, the cell of origin of the CLL cell may be the memory B-cell, regardless of whether there are mutations of the IgV_H gene. This would explain why all CLL cells are CD27⁺, which is typically a marker of the memory B-cell.⁴³ Although most normal CD27⁺ B-cells have IgV_H gene mutations, a small fraction does not.⁴⁴ Altered DNA methylation is observed in CLL and the methylation pattern in the unmutated IgV_H form of CLL is similar to a CD5⁺ naive B-cell form, whereas the mutated form is most similar to a memory B-cell.⁴⁵ Significant hypomethylation occurs in the production of the CLL cells, with many similar changes for the both the mutated and unmutated forms which may explain the similar gene expression profiles for both types of CLL. Based on the methylation patterns, a third form of CLL has been proposed, which is antigen-experienced but has lower levels of mutations than the IgV_H mutated form. The influence of DNA methylation on gene expression in CLL and how this can be altered is an area of great interest.^{45, 46}

FIGURE 90.3. Schematic presentation of human chronic lymphocytic leukemia (CLL) development based on the xenogeneic transplantation model. CLL human stem cells have accumulated genetic abnormalities that might play a role in amplified B-cell differentiation, and produce a high number of polyclonal B-cells carrying the same genetic aberrations. B-cell clones are selected, and expanded in response to B-cell receptors (BCR) signaling driven presumably by xenoantigens, simulating progression of monoclonal B cell lymphocytosis (MBL). Additional abnormalities such as aberrant karyotypes might play a role in progression from MBL into human CLL. This final step was not recapitulated in the xenograft model. From Kikushige Y, Ishikawa, Miyamoto T, et al. Self-renewing hematopoietic stem cell is the primary target in pathogenesis of human chronic lymphocytic leukemia. *Cancer Cell* 2011;20:246-259, with permission.

A recent study has demonstrated that the hematopoietic stem cell is abnormal in CLL having increased expression of early lymphoid transcription factors, such as IKAROS.⁴⁷ When CLL hematopoietic stem cells are transplanted into immunosuppressed mice there is an increased production of polyclonal B-cells including increased numbers of monoclonal or oligoclonal B-cells that are either CD5⁺ or CD5⁻, generally have mutated IgV_H and, as in CLL cells, preferentially used VH1, 3, and 4 similar to that seen with MBL (Fig. 90.3). However, the clonal cells have VDJ recombinations that are different from the original patient's cells. These clones do not have the typical genetic changes seen by fluorescence in situ hybridization (FISH) studies in CLL cells. These results indicate that the stem cells from CLL patients have the capacity to generate monoclonal B-cells and the authors speculate that a "second hit" is required for these clones to become CLL cells.

Abnormalities in Apoptosis

Although a defect in apoptosis typifies CLL, with the majority of cells being long-lived, noncycling, and in G₀, there is a small fraction of replicating cells in the lymph nodes and marrow that is responsible for disease progression.² Chemotherapeutic agents induce apoptosis, and defects in apoptosis may also be responsible for drug resistance.^{48, 49, 50} Considerable knowledge has been obtained regarding the apoptotic pathways, and the major steps are shown in Figure 90.4. Apoptosis occurs through the activation of caspases, which are cysteine proteases that cleave other caspases at aspartate acid residues, converting the inactive proforms to active enzymes. The downstream caspases, caspases 3, 6, and 7, cleave specific proteins leading to the typical morphologic changes of apoptosis. Apoptosis can be initiated through 2 main pathways, which interact and subsequently activate the same downstream caspases.

FIGURE 90.4. Apoptotic pathways in chronic lymphocytic leukemia.

Two Major Apoptotic Pathways

The intrinsic apoptotic pathway is typically initiated by DNA damage, which causes the up-regulation of TP53, an increase in the BAX:BCL2 ratio, and the release of cytochrome c from between the inner and outer mitochondrial membranes into the cytosol. Cytochrome c binds to and activates apoptosis-activating factor-1 (APAF1) in the cytosol in a process that requires deoxyadenosine triphosphate (dATP). The N-terminal of APAF1 binds to and causes the autoactivation of procaspase 9 and, subsequently, caspase 3.⁵¹ The cytochrome c/mitochondrial system is important for the activity of chemotherapy, and a deficiency in APAF1 can cause drug resistance,⁵² although whether the variable levels of APAF1 in CLL influence sensitivity to chemotherapy is unknown.⁵¹ As discussed later, the triphosphate derivatives of fludarabine and cladribine can substitute for dATP, and part of their cytotoxic activities is related to the binding of APAF1 and direct activation of caspases 9 and 3.^{53, 54, 55} SMAC/DIABLO is also released from the mitochondria along with cytochrome c and induces apoptosis by binding to the inhibitor of apoptosis (IAP) family of proteins, which normally inactivate a number of caspases, including caspase 3.⁵⁶

The extrinsic apoptotic pathway also plays a major role in apoptosis. There are presently 6 known death receptors (DRs), and these include the Tumor necrosis factor (TNF) receptor, FAS (APO-1 or CD95) and DR4/DR5 (receptors for TNF-related apoptosis-inducing ligand [TRAIL]). These receptors contain a cytosolic domain called the death domain, which recruits adaptor proteins such as FADD/MORT1 to the receptor complex after binding to ligand. The recruiter adaptor protein has a death domain end and a death effector domain (DED). Once bound to the TNF receptor, the DED binds to caspases 8 and 10, which then become activated by autoactivation.⁵¹ Apoptosis through this pathway is controlled by the presence of the receptor and a variety of inhibitors that can bind to the DED in place of the caspases. One of these inhibitors is FLICE inhibitory protein (FLIP), which is a homologue of procaspase 8 and contains 2 DED domains but lacks proteolytic activity.⁵⁷ It been reported that CLL cells have high levels of FLIP expression rendering the cells resistant to DR-induced apoptosis.⁵⁸

There is cross-talk between the intrinsic and extrinsic pathways. Thus, caspase 8 can activate Bid, which causes the release of cytochrome c from the mitochondria.^{50, 59} Alternatively, triggering of the intrinsic pathway in CLL cells by chemotherapy or irradiation can activate caspase 8,⁶⁰ possibly by activation of caspase 3.⁶¹

Apoptosis through the TNF receptors plays an important role in controlling lymphoid cell populations, and defects either in FAS ligand or the receptor result in the autoimmune lymphoproliferative syndrome (ALPS) with lymphadenopathy, splenomegaly, and an increase in the risk of subsequent autoimmune diseases and lymphomas. FAS is normally up-regulated in activated lymphocytes, and CLL cells are not sensitive to FAS ligand, even if FAS (CD95) is increased through the use of *Staphylococcus aureus* protein A from Cowan I plus interleukin (IL)-2, CD40 ligation, or through α - or γ -interferon.^{60, 61, 62, 63} DR4 and DR5 receptors are present on CLL cells, but the extent of sensitivity of these cells to TRAIL is controversial.^{57, 64} CLL cells secrete both TRAIL⁶⁵ and FAS ligand,^{60, 65} which may suppress normal T-cells and contribute to the immunosuppression seen with this disease.

Apart from the direct induction of apoptosis through the interaction with TNF ligands, the TNF receptors may play a role in the activity of chemotherapeutic agents. Chemotherapeutic

P.1892

agents may up-regulate receptors for FAS^{66, 67} or DR4/DR5,^{68, 69} which could prime the cells to physiologic levels of FAS ligand or TRAIL. However, although fludarabine and chlorambucil increase FAS messenger RNA levels in CLL cells in vitro, they do not affect the levels of FAS protein.⁶⁰ In contrast, irradiation does increase FAS protein levels, but none of these agents sensitizes CLL cells to FAS ligand.⁶⁰ Fludarabine and chlorambucil increase the messenger RNA and cell-surface protein expression levels of DR4/DR5 in CLL cells, and this sensitizes the cells to TRAIL.⁶⁴

Modulators of the Apoptotic Pathway in Chronic Lymphocytic Leukemia

The above pathways are modulated by a variety of proteins, which may be altered in CLL. The BCL2 family consists of approximately 20 members that can either promote or inhibit apoptosis. These proteins are located in the cell membrane, nuclear membrane, and mitochondrial membrane, and function by binding to other proteins or influencing cell permeability and the release of cytochrome c from the mitochondria. Some BCL2 family members (e.g., BAX, BCLXS, BAK, and BAD) promote apoptosis, whereas others (e.g., BCL2, BCL-xL, and MCL-1) inhibit apoptosis.^{70, 71, 72, 73, 74, 75, 76} In addition, another group (e.g., BAG1) can influence the activities of the other family members. CLL cells have high BCL2, BAX, and BAK levels but have low levels of BCLXL and BAD.^{70, 71, 72, 73, 74, 75, 76} The BCL2 overexpression is related to hypomethylation of DNA, rather than to a translocation, and may contribute to the longevity of the CLL cell.⁷⁰ CLL cells with high BCL2 levels have more prolonged in vitro survival than those with low levels, and decreasing BCL2 expression by antisense oligonucleotides can induce apoptosis.⁷⁰ Whether the BAX and BCL2 levels or the BAX:BCL2 ratios are predictive of drug sensitivity in CLL is controversial.^{71, 72, 73, 74, 75, 76} MCL1 protein levels are variable in CLL, and it has been suggested that patients with high levels are more resistant to chemotherapy.⁷⁴ An insertion of either 6 or 18 nucleotides in the promoter of MCL1 is found in CLL cells with a lower incidence in normal B cells.⁷⁷ An analysis of matched pairs of normal versus leukemia cell samples indicates that the MCL1 promoter insertions represent somatic alterations and not hereditary polymorphisms. This insertion is associated with higher levels of MCL1 protein and nonresponsiveness to chemotherapy.⁷⁷ However, other groups have not confirmed these findings and the importance of an insertion in the MCL1 promoter remains to be determined.⁷⁸ In addition, a guanine-to-adenosine substitution at position 125 (G125A) in the BAX promoter has been associated with decreased BAX expression, advanced disease, and drug resistance in CLL.⁷⁹

A number of other proteins play a role in apoptosis, and their expressions can be affected by the genetic changes in CLL, as discussed in the section on "Genomic Abnormalities." The tumor-suppressor gene, TP53, is a transcriptional activator and is located on chromosome 17p13.^{80, 81} TP53 protein is phosphorylated and stabilized after DNA damage, such as that produced by radiation or alkylating agents, through activation of ATM kinase and DNA-dependent kinase.⁸⁰ Cell cycle blockage at G¹ or G² may occur, allowing the cell to repair the damage before entering the S- or M-phase.⁸⁰ However, TP53 may also induce apoptosis, and this occurs preferentially in tumor cells, a feature that may explain the relative tumor specificity of anticancer agents.⁸¹ Mechanisms for TP53-induced apoptosis are through up-regulation in the expressions of the TRAIL DRs, DR4, and DR5, and increased expression of the proapoptotic BCL2 family members, BAX, NOXA, and PUMA.⁸² TP53 mutations are typically associated with deletions of the second allele (deletion 17p13), and mutations or TP53 gene deletions are observed in 10% to 15% of CLL patients (see section "Genomic Abnormalities"); these abnormalities are associated with high lymphocyte counts, drug resistance to anticancer agents in vitro and in vivo, and poor patient survival.^{2, 72, 73, 83, 84} In a longitudinal study of 181 patients, the percentage of leukemic cells with a TP53 mutation increased during the course of the disease, indicating that the mutation provides a survival advantage for the tumor cells.⁸³ The murine double minute-2 (MDM2) gene is located on chromosome 12 and is transactivated by TP53.⁸⁰ The MDM2 protein enhances the binding of TP53 to ubiquitin, and TP53 is subsequently degraded.⁸⁰ Thus, overexpression of MDM2 in cell lines reduces the capacity of TP53 to block the cell cycle in G¹ after irradiation and speculatively could also decrease TP53-induced apoptosis and produce drug resistance.⁷² However, although the MDM2 protein has been found to

be overexpressed in two-thirds of CLL cases, this does not correlate with disease stage, aggressiveness, or drug resistance.^{72, 85}

The ATM gene is located on chromosome 11q22-q23 and is responsible for phosphorylation and activation of p53 after DNA damage.^{80, 86} Approximately 10% to 20% of CLL patients have a mutation of ATM, and about half of these will have a defective response to irradiation, similar to that with a TP53 mutation, if all alleles are mutated or if one is mutated and the other lost because of a deletion of 11q22-23.^{86, 87} Approximately one third of patients with a mutated ATM have a deletion 11q22-23 and one third of those with a deletion 11q22-23 have a mutation on the other allele.^{86, 87}

Microenvironment

Overview

The microenvironment in the peripheral blood, spleen, lymph nodes, and marrow plays an important role in the biology of CLL. In the bone marrow and lymph nodes, follicular dendritic, stromal, and/or fibroblast cells interact with CLL cells whereas in the peripheral blood the interaction is with “nurselike” cells and T-cells.⁸⁸ Co-culture of CLL cells with “nurselike” or stromal cells decreases spontaneous apoptosis in the leukemia cells, promotes CLL cell proliferation, and confers drug resistance.^{89, 90, 91} This effect seems to require cell-cell contact and CLL cells interact with the microenvironment through activation of their cell surface receptors. The BCR plays a central role in CLL biology in the microenvironment through maintenance and expansion of the CLL cell clone. BCR signaling is controlled by intracellular tyrosine kinases such as spleen tyrosine kinase (Syk), and Bruton's tyrosine kinase (BTK; Fig. 90.5).^{92, 93, 94, 95, 96, 97} In addition, aberrantly expressed CD40L on CLL cells can interact with CD40 on microvascular endothelial cells which leads to the release of the TNF family members, BAFF (B-cell activating factor of the TNF family), and APRIL (a proliferation-inducing agent).⁹⁸ Receptors for BAFF and APRIL (BMCA, TAC1, and BAFF-R) are present on CLL cells and stimulation leads to increased survival and induction of the expression of CD40L on the CLL cells thus further potentiating the cycle. This exemplifies the cross-talk between CLL and stromal cells in the microenvironment. Adhesion molecules are also important for CLL cell survival. β 1 and β 2 integrins on CLL cells bind to CD54 and CD106 on stromal cells and this promotes cell survival.^{99, 100} Moreover, neutralizing antibodies against various integrins induces the CLL cells to undergo apoptosis.¹⁰¹ Caveolin-1 expression by CLL cells in lymph nodes may stimulate CLL proliferation and migration but also mediates immune synapses with autologous T lymphocytes which contributes to immune tolerance.¹⁰² Finally, CD44 on CLL cells is a receptor for hyaluronic acid and collagen, thus helping retain the cells in the microenvironment.¹⁰³

In addition to cell-cell contact, the extracellular milieu contains molecules such as growth factors, proteins, and lipids that contribute to CLL progression.⁸⁹ Stromal and CLL cells produce cytokines that may stimulate leukemia cell growth in an autocrine or paracrine fashion while inhibiting survival of normal lymphoid and marrow cells. This latter effect can lead to the

P.1893

immunosuppression and myelosuppression that typify this disease. In addition, the chemokine receptors CXCR4 and CXCR5 on CLL cells regulate CLL cell trafficking to the stromal cells (which produce the receptor ligands, CXCL12 and CXCL13, respectively) in the microenvironment where the CLL cells produce IL-6 and IL-8, which in turn provide signals for cell survival.^{11, 104} Upon BCR activation, CLL cells secrete cytokines such as CCL3 that attract additional accessory cells such as T-cells to join the CLL and stromal cells.¹⁰⁵ In addition to signaling, stromal cells also supply essential nutrients to the CLL cells. For example, CLL cells have limited capacity to transport cystine for glutathione synthesis due to low expression of Xc-transporter.¹⁰⁶ In contrast, stromal cells can effectively transport cystine and convert it to cysteine which can then be released into the microenvironment where the CLL cells take up the cysteine for GSH synthesis. CLL cells can also influence stromal cells signaling through microvesicles.¹⁰⁷ Microvesicles are released by CLL cells and can modulate the activity of the bone marrow stromal cells (BMSCs). The microvesicle can activate the AKT/mammalian target of rapamycin (mTOR)/p70S6K/hypoxia-inducible factor-1alpha axis in CLL-BMSCs with production of vascular endothelial growth factor (VEGF), a survival factor for CLL cells.^{107, 108} They can also transfer various messages to target cells that may be critical to disease progression. In the clinic, molecular targeting of the microenvironment through CXCR4 antagonists or BCR kinase inhibitors disrupts the interactions between CLL cells and the microenvironment.^{109, 110, 111} These chemotherapeutic agents have shown promising pre-clinical activities.

FIGURE 90.5. Molecular interactions in the chronic lymphocytic leukemia (CLL) microenvironment. Molecular interactions between CLL and stromal cells in the BM and/or lymphoid tissue microenvironments that are considered important for CLL-cell survival and proliferation, CLL-cell homing, and tissue retention. Contact between CLL cells and nurselike cells (NLCs) or bone marrow stromal cells (BMSCs) is established and maintained by chemokine receptors and adhesion molecules expressed on CLL cells. NLCs express the chemokines CXCL12 and CXCL13, whereas BMSCs predominantly express CXCL12. The chemokine receptors CXCR3 and CCR7 are additional chemokine receptors on CLL cells that are involved in lymphatic tissue homing. NLCs and BMSCs attract CLL cells via the G-protein-coupled chemokine receptors CXCR4 and CXCR5, which are expressed at high levels on CLL cells. Integrins, particularly VLA-4 integrins (CD49d), expressed on the surface of CLL cells cooperate with chemokine receptors in establishing cell-cell adhesion through respective ligands on the stromal cells (VCAM-1 and fibronectin). NLCs also express the TNF family members BAFF and APRIL, providing survival signals to CLL cells via corresponding receptors (BCMA, TACI, and BAFF-R). CD38 expression allows CLL cells to interact with CD31, the ligand for CD38 that is expressed by stromal and NLCs. Ligation of CD38 activates ZAP-70 and downstream survival pathways. Self- and/or environmental Ags are considered key factors in the activation and expansion of the CLL clone by activation of the BCR and its downstream kinases. Stimulation of the BCR complex (BCR and CD79a,b) induces downstream signaling by recruitment and activation of Syk, Btk, and PI3Ks. Finally, BCR stimulation and co-culture with NLCs also induces CLL cells to secrete chemokines (CCL3, CCL4, and CCL22) for the recruitment of immune cells (T-cells and monocytes) for cognate interactions. CD40L⁺ (CD154⁺) T-cells are preferentially found in CLL-proliferation centers, and can interact with CLL cells via CD40. From Burger JA. Nurture versus nature: the microenvironment in chronic lymphocytic leukemia. *Hematology (Am Soc Hematol Educ Program)* 2011;2011:96-103.

Cellular Features of the Microenvironment

BMSCs and other cells of the lymphatic tissue have intrinsic characteristics to support CLL cell functions.^{111, 112} Normal hematopoiesis depends upon BMSCs as the BMSCs provide attachment sites and growth signals for the hematopoietic precursors. In CLL the BMSCs create niches where CLL cells are nourished and protected from either spontaneous or chemotherapy-induced apoptosis. The CLL cells bind to BMSCs with high affinity which allows tight adhesion and migration of the CLL cells underneath the BMSCs. Both murine and human BMSCs have similar effects on CLL cell growth

and cell survival. BMSC are of mesenchymal origin and are similar to mesenchymal stromal cells in other tissues. Follicular dendritic cells (FDCs) are also found in lymphatic tissue and support CLL cell survival. These FDCs are being used to express CLL specific antigens and are under clinical investigation for the development of vaccines for CLL.¹¹³ The CLL cells also cross-talk with stromal cells through the CXCR4-CXCL12 and the CD40-C40L axis discussed in detail later.

Nurselike cells (NLC) are differentiated monocytes that are large, round, and adherent cells that bind to CLL cells mainly in P.1894

the peripheral blood system. However, NLCs can be found in the spleen and secondary lymphoid tissue.⁸⁹ There is diverse cross-talk between NLC and CLL cells. NLC express CXCL12, CXCL13, and CD31 plexin B1 BAFF and APRIL and vimentin.⁸⁸,¹¹² All these cell-surface markers interact with CLL receptors providing survival and proliferative signals.

T lymphocytes also interact with CLL cells. The number of circulating T-cells in CLL patients is often increased and this might be due to interactions with CLL cells. T-cells can either suppress or stimulate expansion of CLL cells. In the proliferation centers, T-cells co-localize suggesting that T-cells support the CLL proliferation.¹¹²,¹¹³ This is supported by evidence that CLL cells fail to proliferate in immunodeficient mice, demonstrating that activated CD4⁺ T-cells could be important for CLL proliferation.¹¹⁴

Survival Factors in the Microenvironment

B-cell receptor (BCR): The BCR is the most studied receptor in mature B-cells due to its important role in recognizing foreign antigens and activating B-cell proliferation and transformation into plasma cells. It has also been implicated in B-cell survival. In CLL cells, the BCR can be activated by binding to antigen-presenting cells, such as FDCs, and this promotes cell survival and protects the cells against drug-induced apoptosis.⁸⁸,⁹⁰ Activation of ZAP-70 through ligation of the BCR may play an important role in promoting cell survival in CLL.⁹³,⁹⁴,⁹⁵,⁹⁶ Overall, the protective effect of BCR activation against apoptosis has been related to increased expression of antiapoptotic BCL2 family members, especially MCL1.⁹⁷ Indeed, biopsies of CLL cells in the lymph nodes and bone marrow of CLL patients indicated that BCR activation signatures are found in CLL cells in these microenvironments.¹¹⁵ Inhibitors of the BCR-activated kinases including SYK, mTOR, phosphoinositide 3'-kinase (PI3K), and BTK, have been found to decrease CLL cell viability through modulation of the microenvironment.¹¹⁶,¹¹⁷,¹¹⁸,¹¹⁹ BCR pathway inhibitors appear to be highly active in refractory CLL, independent of the presence of poor prognostic markers, such as deletion 17p13.¹¹⁹ However, the extent of BCR activation in CLL remains controversial inasmuch as CLL cells are less responsive than naive B-cells to BCR activation.

Interleukins: CLL cells have receptors to various ILs and the levels of IL-4 and IL-8 are elevated in the blood of some patients. The addition of IL-4 and IL-8 to CLL cells protects them against spontaneous and drug-induced apoptosis.¹²⁰ A number of other IL (e.g., IL-1, IL-2, IL-6, and IL-8) can also prevent CLL cells from undergoing spontaneous apoptosis and these may be derived from the CLL cells (IL-1, -6, and -8), T cells (IL-2 and -4) or stromal cells.⁸⁸,¹²¹,¹²² CLL cells differ from normal CD19⁺ B-cells in producing the lymphoid stem cell growth factor, IL-7, suggesting that this cytokine might also be important in disease pathogenesis.¹²³ IL-7 does not itself induce proliferation or prevent apoptosis of CLL cells in vitro.¹²³ However, the prevention of apoptosis of CLL cells by co-culturing with endothelial cells appears to be related to the maintenance of intracellular IL-7 levels, which occurs by signaling through the cell-surface β 2-integrin.¹²³ Both IL-2 and IL-15 stimulate the proliferation of CLL but not normal B-cells.¹²⁴ Moreover, IL-2 is sequestered by the CLL cells and by the increased serum levels of the IL-2 receptor (TAC receptor) seen in this disease, preventing its interaction with normal lymphocytes.¹²⁵,¹²⁶ High levels of IL-6 have been shown to be a better prognostic marker than Ig mutation status in older CLL patients indicating the importance of ILs in disease progression.¹⁰⁴ This may also partly explain the immune dysfunction seen in CLL.

Tumor necrosis factor- α (TNF- α): CLL cells produce TNF- α in vitro.¹²⁷,¹²⁸ and TNF- α decreases apoptosis in these cells through the induction of BCL2 expression¹²⁷,¹²⁹,¹³⁰,¹³¹ In addition, TNF- α may induce the proliferation of CLL cells while suppressing the growth of normal lymphocytes and marrow cells.¹²⁷,¹²⁹,¹³⁰,¹³¹ The serum level of TNF- α is increased in most patients with CLL, and the highest levels are observed in those with advanced disease.¹³⁰ An increase in the serum levels of the soluble receptors for TNF- α has also been observed in CLL.¹³²

Transforming growth factor- β (TGF- β): TGF- β is secreted by CLL and marrow stromal cells.¹³³,¹³⁴ TGF- β inhibits DNA synthesis in both CLL and normal B-cells, although the degree of inhibition can be quite low in CLL as a result of the loss of TGF- β receptors.¹³⁵,¹³⁶ In contrast to normal B-cells, CLL cells are consistently resistant to apoptosis induced by TGF- β .¹³⁷

Adhesion molecule receptors: It has long been known that adhesion molecules on the cell surface are important for cell survival. For adherent cells, such as epithelial cells, removal of the cells from their attachments and resuspending the cells

in culture results in apoptosis, called anoikis.⁹⁹ Binding of adhesion molecules such as integrins can prevent anoikis suggesting that cell-cell contact is important in maintaining cell viability. Although CLL cells can be in suspension they do adhere to other cells in the marrow, lymph nodes, and peripheral blood and adhesion molecules play a role in protecting the leukemia cells against apoptosis.¹³⁸ As mentioned previously, β 1 and β 2 integrins and CD44 are also present on the CLL cell surface.^{99, 100, 103}

BMCA, TAC1, and BAFF-R: CLL cells express BAFF and APRIL along with their corresponding receptors BMCA, TAC1, and BAFF-R.¹³⁹ The addition of exogenous BAFF and APRIL to CLL cells prevents spontaneous and drug-induced apoptosis.¹⁴¹ These molecules are known factors in B-cell survival, differentiation, and apoptosis.¹³⁹ Conversely, the addition of a soluble form of the BMCA receptor or neutralizing antibodies against BAFF or APRIL results in increased apoptosis.¹⁴⁰ CLL cells secrete BAFF and APRIL and the plasma levels of APRIL are higher in CLL patients than in normal individuals.^{139, 140} In addition, antigen-presenting cells, such as dendritic cells, express high levels of BAFF and APRIL.¹⁴⁰ Because CLL cells have receptors for BAFF and APRIL, autocrine and paracrine survival signaling likely occurs in CLL.^{139, 140} This concept is supported by the fact that the ability of "nurselike" cells to provide survival signals to CLL cells is reduced by the presence of decoy receptors for BAFF and APRIL.¹³⁹

Vascular endothelial growth factor (VEGF) receptor: VEGF is an angiogenic factor that is involved in cell survival for many cancers.¹⁴¹ In CLL, VEGF protects the leukemic cells from both spontaneous and drug-induced apoptosis whereas apoptosis is increased by adding inhibitors to VEGF receptor kinase.^{142, 143} CLL cells express VEGF receptors 1 (VEGFR1) and 2 (VEGFR2) and increased protein levels of VEGFR2 are associated with elevated lymphocyte counts and advanced disease.^{143, 144} Furthermore, CLL cells secrete VEGF and the levels of VEGF are increased in the plasma of CLL patients.^{144, 145} The mechanism responsible for VEGF production by CLL cells is unclear but activation of CD40 by CD40 ligand (CD40L), which may be produced by CLL and other cells (see below) may be important for this activity.¹⁴²

CD40: CD40 is a glycoprotein of the TNF superfamily that is expressed on B-cell surfaces and is important for B-cell differentiation and function, whereas the CD40 ligand (CD40L) is expressed on activated T-cell surfaces. In addition to T-cells, NLC also express CD40L.¹⁴⁶ CD40L binds to normal B lymphocytes promoting proliferation and cell survival.¹⁴⁷ Similarly, stimulation of CD40 on CLL cells induces proliferation and the release of cytokines¹⁴⁸ and also prevents apoptosis induced by chemotherapy.^{149, 150} CLL cells may also release CD40L, and the level of ligand is high in the plasma of CLL patients.¹⁵¹ As CLL cells have both CD40 and CD40L, it has been suggested that the cell may stimulate its own growth and survival, perhaps through up-regulation of the antiapoptotic protein survivin (a member of the IAP family).^{147, 151, 152} In contrast to the CD40 survival function, increased CD40 expression may lead to better recognition by cytotoxic T-cells and increased CLL cell killing.¹⁵³ Moreover,

P.1895

co-stimulation of CD40 and FAS on CLL cells can increase apoptosis.¹⁵⁴ A novel therapeutic approach has thus been recently explored in which CLL cells are induced to secrete CD40L by a viral transfection strategy.¹⁵⁵

Stromal-derived growth factor-1 (SDF-1) receptor: SDF-1 is a chemokine that is normally secreted by stromal cells. The receptor for SDF-1 is CXCR4, which is expressed on CLL cells and the addition of SDF-1 protects CLL cells from spontaneous and drug-induced apoptosis.¹⁵⁶ Similarly, CLL cell survival is increased when the cells are co-cultured with stromal cells.¹⁵⁷ NLC can also express SDF-1 and the levels of SDF-1 are increased in the plasma, suggesting that this cytokine is probably important for CLL cell survival.¹⁵⁸

Basic fibroblast growth factor (bFGF) receptor: It has been demonstrated that the bFGF levels in the serum of CLL patients are elevated and that bFGF treatment of CLL cells prevents apoptosis through a decrease in TP53 expression and up-regulation of BCL2 expression.¹⁵⁹

NOTCH receptors. The Notch family consists of four receptors NOTCH 1 to 4 and five ligands, including Jagged1 and Jagged 2. All NOTCH receptors and ligands are constitutively expressed on CLL cells and on BMSCs.¹¹³ As discussed in detail later, NOTCH 1 gain-of-function mutations are detected in approximately 10% of CLL patients at diagnosis and the incidence increases with disease progression and the development of drug resistance. This is consistent with NOTCH signaling being involved in CLL survival and resistance to apoptosis. The microenvironment may also influence NOTCH signaling in CLL cells through integrins and chemokine receptor activation.¹¹³

Albumin: Albumin is the major protein in the blood and can decrease both spontaneous apoptosis and apoptosis induced by irradiation or chlorambucil in primary CLL cells in vitro.¹⁶⁰ This effect is related to the uptake of albumin into the CLL cells with activation of AKT protein kinase. In contrast, the protective effect of albumin against chlorambucil is not seen in normal B or T lymphocytes.

Lysophosphatidic acid (LPA): LPA is a soluble phospholipid with a wide range of biologic activities and can protect epithelial and fibroblast cell lines from apoptosis.¹⁶¹ Similar to albumin, LPA protects CLL cells, but not normal B-cells, from spontaneous and drug-induced apoptosis and this effect is mediated through the AKT kinase.¹⁶¹ Blockage of the LPA receptor or inactivation of AKT prevents the protective effect of LPA. As albumin allows for the solubilization of lipids in plasma it is possible that the protective effect of albumin is mediated through the carriage of LPA.¹⁶¹

Cell Survival Signaling Pathways in Chronic Lymphocytic Leukemia

The microenvironment influences survival responses primarily through receptor activation. This leads to activation of signal transduction pathways that regulate gene expression and BCL2 family member functions. These survival signaling pathways have overlapping functions and cross-talk with each other. The following is a brief description of the survival pathways in CLL.

The transcription factor nuclear factor- κ B (NF- κ B) plays an important role in suppressing apoptosis by inducing the expression of a variety of antiapoptotic genes.^{162, 163} NF- κ B is inactivated by I κ B, which binds NF- κ B and prevents its access to the nucleus; activation of NF- κ B occurs by the phosphorylation of I κ B, which leads to the coupling of I κ B with ubiquitin. This complex is degraded by a protease called the proteasome. The levels of NF- κ B are high in CLL and are increased further by stimulation with CD40 ligand, which plays an important role in preventing apoptosis and prolonging cell survival in CLL.¹⁶⁴ In addition, inactivation of the proteasome by inhibitors such as lactacystin, MG132, and bortezomib can induce death of CLL cells but not of normal lymphocytes.^{165, 166, 167} Cell death is mediated through the cytochrome c/mitochondrial pathway, and these agents may be useful in drug-resistant disease.^{165, 166, 167}

The protein kinase AKT is activated through phosphatidylinositol 3'-kinase and can suppress apoptosis by inactivating bad, caspase 9, and other proapoptotic proteins through phosphorylation.^{168, 169} In addition, AKT can activate NF- κ B and regulate the expression of antiapoptotic genes. This pathway is activated by autologous plasma in CLL, which may explain the relative resistance of these cells to spontaneous and drug-induced apoptosis when they are grown in plasma.¹⁶⁹ Overexpression of TCL1 in a transgenic mouse model leads to the expansion of B-cells which have similar characteristics as CLL cells.¹⁷⁰ The B-cells overexpressing TCL1 have increased levels of activated AKT, which may explain the enhanced survival of these cells.¹⁷¹

The mitogen-activated protein kinase (MAPK) signaling pathway is also activated in CLL cells. This pathway consists of extracellular regulated kinase (ERK), Jun N-terminal kinase (JNK), and p38 MAPK. BCR activation leads to ERK activation and up-regulation of BCL2 family members.¹⁷² During apoptosis, ERK activation is often suppressed.¹⁷³ p38 MAPK activation is elevated in CLL cells and plays a role in CLL survival mediated by human stromal cells.¹⁷⁴ In contrast, JNK activation is associated with increased apoptosis in CLL cells.

The JAK-STAT signaling pathway is an emerging pathway activated in CLL cells contributing to cell survival and drug resistance. In CLL, STAT3 is constitutively phosphorylated on serine 727 and is associated with increased transcriptional activation. STAT3 contributes to increased expression of antiapoptotic proteins such as X-linked apoptosis inhibiting protein (XIAP).^{175, 176, 177} STAT3 has also been shown to cross-talk with the NF- κ B in CLL cells increasing cell survival.¹⁷⁸ The JAK-STAT pathway is activated by growth factors such as VEGF.¹⁷⁹ These factors are found in the microenvironment indicating that the JAK-STAT pathway might be a good target for disrupting the CLL microenvironment.

Abnormalities in Cell Division

Although CLL cells in the peripheral blood are not dividing, the telomeres of these cells are shorter than in normal B-cells, suggesting that the leukemic cells have undergone more frequent cell divisions than normal B-cells.¹⁸⁰ Moreover, the telomeres in CLL cells with unmutated IgV_H genes have shorter telomeres than those cases with mutated IgV_H genes.¹⁸⁰ Using deuterated water (²H₂O) to label DNA, it has been estimated that 0.11% to 1.76% (median, 0.39%) of the CLL cells in patients are dividing each day, which is the same or greater than that observed in the B-cells from normal individuals.¹⁸¹ Although CLL cells in the peripheral blood are not dividing, cells in the "proliferation centers" in the lymph nodes or marrow are dividing, where, under the influence of CD4⁺ cells they express the proliferation markers, survivin and Ki67, and become CD38⁺.^{2, 14, 182, 183} Moreover, greater uptake of ²H₂O is observed in the CD38⁺ cell fraction as compared to the CD38⁻ cells confirming their role in cell proliferation.¹⁸⁴ Gene expression profiling has demonstrated that CLL cells in the lymph nodes have increased expression of genes related to BCR activation, as compared to cells from the peripheral blood.¹¹⁵ These changes include increased expression of phosphorylated Syk and NF- κ B and are less marked in marrow than in the lymph nodes. As predicted, the changes are greater in unmutated IgV_H cases than in mutated IgV_H cases and correlate with the rate of cell proliferation, as measured by Ki67.

Passage through the cell cycle is controlled by the interaction of the cyclins and the cyclin-dependent kinases (CDKs); the levels of the CDKs remain constant, whereas the levels of the five different cyclins fluctuate and activate the appropriate

CDK, leading the cell through the cycle (Fig. 90.6).¹⁸⁵ In addition, 2 classes of CDK inhibitors, the INK4 proteins and the Cip/Kip proteins, control the

P.1896

activity of the CDKs.¹⁸⁶ Normally, when quiescent cells enter the cell cycle, the D cyclins (D1, D2, and D3) in conjunction with CDKs 4 and 6 bring the cell into the S-phase. The D cyclin/CDK4/6 initiates phosphorylation of the retinoblastoma (Rb) protein, which is then further phosphorylated by cyclin E/CDK2. Another function of the D cyclins/CDK4 is the sequestration of the CIP/KIP inhibitors p27^{Kip1} and p21^{Cip1}, which normally inhibit the activity of cyclin E/CDK2. Although the majority of the peripheral blood CLL cells are quiescent and in G₀/G₁, the expression of cyclins D1, D2, and D3 are increased in these cells.^{187, 188, 189} Despite these findings, the Rb protein is not phosphorylated in unstimulated CLL cells¹⁹⁰; this may be related to overexpression of p27^{Kip1}, high levels of which are associated with high lymphocyte counts and poor patient survival.¹⁹¹ CDK1 (*cdc2*) is a serine/threonine kinase involved in G2-M phase transition and gene expression studies have shown that this gene is highly expressed in patients with del 11q22-23 cells.¹⁹²

TABLE 90.1 INCIDENCE OF GENOMIC ABNORMALITIES AND ASSOCIATED CLINICAL FEATURES IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Genomic Abnormality	Incidence (%)		Affected Genes	Clinical Features
	Classical Cytogenetics ^a	Fluorescence in Situ Hybridization ^b		
Normal	50 ^c	18	—	—
13q deletion	10	55	<i>Rb</i> , <i>MiR-15a</i> , <i>MiR-16-1</i>	Good prognosis
11q deletion	8	18	<i>ATM</i> <i>SF3B1</i>	Younger; bulky lymphadenopathy; poor prognosis
12q trisomy	13	16	<i>MDM2</i> <i>NOTCH1</i>	“Atypical” morphology; end-stage disease
17p deletion	4	7	<i>TP53</i>	CLL/PLL morphology; drug resistance; very poor prognosis
6q deletion	4	6	—	—

Cytogenetic findings and survival in B-cell chronic lymphocytic leukemia. Second IWCCLL compilation of data on 662 patients. *Leuk Lymphoma* 1991;5:21-25. Percentages refer to the number of cases with the abnormality compared to the total number of cases in which cytogenetic analysis was possible.

^b From Döhner H, Stilgenbauer S, Benner A, et al. Genomic aberrations and survival in chronic lymphocytic leukemia. *N Engl J Med* 2000;343:1910-1916.

^c In 50% of cases, clonal abnormalities were not obtained. As these studies were not carried out on purified chronic lymphocytic leukemia cells, some of the cases with normal cytogenetics reflect analysis of normal T-cells.

Genomic Abnormalities

Tremendous strides have been made in the analysis of the CLL genome, providing insight into pathogenesis and identifying genes that are important as markers of disease progression and drug resistance. Initial classical cytogenetic studies were carried out in the 1980s, but it was difficult to obtain metaphases in CLL.^{84, 193} When analysis was possible, clonal chromosomal abnormalities were detected in approximately 50% of cases,^{84, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206} and it is likely that the normal karyotyping in many of the remaining cases was due to analysis of contaminating normal T-cells. Of the 50% of cases with clonal abnormalities, one half had one clonal abnormality, and the remainder had 2 or 3 abnormal clones.¹⁹⁵ However, with the more recent use of the CD40 ligand, or a combination of IL-2 and CpG-oligodeoxynucleotides, to stimulate CLL cells, metaphases are now routinely obtained in over 90% of cases with aberrations detected in greater than 80% of samples.^{207, 208, 209}

Using FISH and comparative genomic hybridization (CGH) to analyze interphase cells (FISH) or isolated DNA (CGH), abnormalities are detected in over 80% of cases.^{84, 193} FISH is highly sensitive, but the specific abnormality to be studied needs to be known in advance, and this is therefore not a good technique to screen for new abnormalities. In contrast, CGH has been used to screen for chromosome gain or loss (i.e., aneuploidy, gene amplification, or deletions not detected by conventional cytogenetics).¹⁹³ More recently, new assays, including SNP and DNA sequencing have advanced our ability to detect genetic abnormalities.

Analysis by Conventional Cytogenetics

Using conventional cytogenetics, the International Working Party on Chromosomes in CLL reported in 1990 that clonal chromosomal abnormalities were obtained in 311 patients (51%) out of a total of 604 cytogenetically evaluable cases (Table 90.1).^{200, 201} The most common clonal abnormality was trisomy 12 (36%, or 19% of all evaluable cases), either by itself or in combination with other cytogenetic changes. Other frequently observed alterations included structural abnormalities of chromosome 13 (20%, or 10% of all cases) and of chromosome 14 (16%, or 8% of all cases).^{199, 200} The 13q abnormalities usually involved a 13q14

P.1897

deletion (site of the RB1 gene) or translocations with a breakpoint at chromosome 13q14. The 14q abnormalities included translocations from a variety of chromosomes, usually involving chromosome 11, suggesting that these patients had actually mantle cell lymphoma. Less than 5% of patients had an 11q22-q23 deletion. The abnormalities of chromosomes 12 and 13 occurred with equal frequency in cases with a single clonal abnormality and in patients having more than one clonal abnormality.^{195, 199} In contrast, abnormalities of chromosome 14 occurred primarily in patients having more than one clonal abnormality.^{195, 199} In general, patients with abnormal karyotyping had a worse prognosis than those with normal cytogenetics, and the outlook was poorest for those with multiple clonal abnormalities.^{196, 197, 198, 199, 200, 201, 202} In addition, the higher the percentage of cells at metaphase with a clonal chromosomal abnormality, the worse the prognosis. Of patients with a single clonal abnormality, those with trisomy 12 had the worst prognosis, and those with 13q+ had a similar survival as cases with normal karyotyping.^{199, 200} It is interesting that trisomy 12 was usually seen in those 15% of cases with CLL variants, either CLL/prolymphocytic leukemia (CLL/PLL) or "atypical" CLL, and this may explain the poor prognosis associated with these morphologic variants.^{202, 203, 204} When all patients were considered, regardless of the number of clones, those with chromosome 14 abnormalities had the worst prognosis.¹⁹⁹ As most of the chromosome 14 abnormality group had a t(11;14) (q13;q32), in retrospect, they likely had mantle cell lymphoma and not CLL.³ 11q22-q23 deletions have been detected in 13% of patients by karyotyping, and these patients had disease progression and poor survival.²⁰⁵

FIGURE 90.6. Control of the cell cycle. Both cyclins D2 and D3 are overexpressed in chronic lymphocytic leukemia cells, but the retinoblastoma (Rb) protein is not phosphorylated, perhaps related to overexpression of p27^{Kip1}. CDK, cyclin-dependent kinase.

Nowadays, metaphases may be obtained in over 90% of patients using either CD40 ligand or a combination of IL-2 and CpG-oligodeoxynucleotides with abnormalities being detected in over 80% of patients.^{207, 208, 209} These studies demonstrate that many more abnormalities can be detected using classical cytogenetics than seen with FISH alone and that both balanced and unbalanced translocations are observed.^{207, 208, 209} Mayr et al.²⁰⁸ observed translocations in one third of CLL patients, and half of these were balanced. The presence of these translocations was a poor prognostic feature and was independent of other prognostic factors for overall survival. Moreover, patients with 13q deletions and translocations had a poorer prognosis than patients with 13q deletions without translocations.

Analysis by Fluorescence in Situ Hybridization

A landmark study by Döhner et al.⁸⁴ in 2000 demonstrated the importance of FISH in CLL. In 325 patients, 268 (82%) had abnormalities, with deletion 13q14 being most frequent (55%), followed by deletion 11q22-23 (18%), trisomy 12q13 (16%), deletion 17p13 (7%), and deletion 6q21 (7%).⁸⁴ There was one abnormality in 175 (65%) patients, 67 (25%) patients had 2 aberrations, and 26 (10%) patients had more than 2 chromosomal changes. A hierarchical model categorized patients into 5 groups with different prognoses (Fig. 90.7). The median survival times for patients with a 17p13 deletion, an 11q22-q23 deletion, trisomy 12q, normal karyotype and a 13q deletion as the sole abnormality were 32, 79, 114, 111, and 133 months, respectively. Patients with 17p13 or 11q22-q23 deletions had the poorest survival, had more marked lymphadenopathy and splenomegaly, and were more likely to be symptomatic with night sweats and weight loss. Very similar results have been obtained in subsequent prospective studies.^{210, 211} The incidence of these specific abnormalities detected by FISH differed from the incidence with conventional cytogenetics in older studies, but similar incidences are now being observed where metaphases are being induced using CD40 ligand or a combination of IL-2 and CpG-oligodeoxynucleotides^{207, 208, 209} (Table 90.1). Patients with unmutated IgV_H are more likely to have deletions of 17p13 or 11q22-23 whereas patients with mutated IgV_H are more likely to have deletion 13q14.¹⁹³ The incidence of trisomy 12 is the same in patients with mutated or unmutated IgV_H.¹⁹³

FIGURE 90.7. Survival according to molecular genetic changes in chronic lymphocytic leukemia. From Döhner H, Stilgenbauer S, Benner A, et al. Genomic aberrations and survival in chronic lymphocytic leukemia. *N Engl J Med* 2000;343:1910-1916, with permission.

More recent evidence indicates that the prognosis with a 13q14 deletion depends on the extent of the deletion.^{212, 213} There are two anatomical landmarks for deletion 13q14: (a) the minimal deleted region (MDR) containing the deleted in leukemia (DLEU) 2 gene, microRNA (miR)-15A/16-1 cluster, and the first exon of the DLEU1 gene; and (b) the RB1 gene.²¹² Of patients with deletion 13q14, 60% had loss of MDR only and 40% also had loss of the RB1 gene. The prognosis is poorer if >70% nuclei have the deletion or if there is a concomitant loss of RB1.^{212, 213}

It has been recommended that all CLL patients should be routinely examined for an IGH translocation.^{214, 215} Of 1,032 patients at the Mayo Clinic with a presumptive diagnosis of CLL, 76 (7%) were found to have an IGH translocation, with 34 involving a translocation with cyclin D1, 18 a translocation with BCL2, and 6 a translocation with BCL3.²¹⁴ Upon review, half of the patients with translocations were found to have CLL and half had the leukemic phase of another lymphoid malignancy.

Trisomy 12 frequently occurs in “atypical” CLL or CLL/PLL.²⁰³ However, not all the “atypical” cells in an individual patient contain trisomy 12, indicating that the chromosomal abnormality is not responsible for the atypical morphology.^{201, 216} In addition, although trisomy 12 connotes aggressive disease, it is unclear whether the proportion of cells with trisomy 12 increases over time.^{201, 217} Half the patients with CLL/PLL have a TP53 mutation, suggesting a role for the gene in the pathogenesis of this variant.²¹⁸

Assessment of Genomic Complexity

Recent evidence has suggested that prognosis in CLL is closely linked to the complexity of genetic abnormalities, as well as to the specific defect.^{219, 220, 221, 222, 223, 224} The majority of patients using either CGH or SNP arrays will have 1 to 3 copy number abnormalities, and these techniques detect abnormalities not seen with FISH and demonstrate that increasing genomic complexity predicts poor prognosis. Moreover, although the presence of 11q21-22 and 17p13 deletions predict the presence of genomic complexity, genomic complexity can be present with

P.1898

low-risk FISH and is a useful independent prognostic predictor. Kay et al.²¹⁹ evaluated genomic complexity using CGH in patients commencing treatment with chemoimmunotherapy. Chromosome deletions were more common than gains and although abnormalities were typically seen in patients with high-risk FISH, complex abnormalities were also seen in patients with 13q deletions. Complex changes were associated with poor response to treatment. Similarly, Ouillette et al.²²³ have shown that increasing genomic complexity by SNP is an independent prognostic marker, predicting rapid disease progression, poor response to chemotherapy, and short survival. Genomic complexity has also been shown to correlate with resistance of the CLL cells to undergo apoptosis with radiation in vitro.²²²

Clonal Evolution

Chromosomal abnormalities may be identified in MBL and early CLL, with the likelihood of deletions of 11q22-23 and 17p13 increasing over time and with the development of drug resistance.^{2, 193} By FISH analysis, one-quarter of patients will have the development of new abnormalities after 5 years, particularly in patients who are ZAP-70 positive, CD38 positive, and those with unmutated IgV_H.²¹¹ Interestingly, patients with unmutated IgV_H have an increased risk of developing deletions of 11q22-q23 or 17p13, whereas those with mutated IgV_H develop deletions of 13q.²¹¹ The risk of developing new genetic abnormalities may be further increased by chemotherapy, as treatment with fludarabine increases the expression of TP53-dependent genes, thus increasing the risk of selecting 17p13 deleted cells.²²⁴ Indeed, 42% of fludarabine-resistant CLL patients have either TP53 mutations or deletions of 17p13.²²⁵

Whole Genome and Exome Sequencing

Several recent studies using whole genome and exome sequencing have identified important new mutations in CLL.^{226, 227, 228, 229} Nine genes are mutated at increased frequency with 4 being known to be important in CLL, TP53 (15%), ATM (9%), myeloid differentiation primary response gene 88 (MYD88; 10%), and NOTCH1 (4%). TP53 and ATM have been discussed in detail in other sections. MYD88 is an adaptor molecule of the IL-1 receptor-tolllike receptor signaling pathway and MYD88 mutations are associated with mutated IgV_H, deletion 13q14, and good prognosis.²²⁶ Stabilizing NOTCH1 mutations in exon 34 generate a stop codon, producing a shortened and more active isoform of the protein.²²⁷ NOTCH1 is one of 4 NOTCH receptor proteins activated by the Serrate/Jagged or Delta family expressed on neighboring cells and this results in release of the N-IC domain from NOTCH which in turn assembles a transcriptional complex that controls expression of a number of genes.²²⁹ Mutations of NOTCH1 occur in 8.3% of CLL cases at diagnosis, increase frequency with a Richter syndrome (RS) progression (31%), and drug resistance (20.8%).²²⁷ A number of subsequent studies have demonstrated that NOTCH1 mutations are associated with unmutated IgV_H, trisomy 12, and correlate with drug resistance, the development of RS, and poor survival.^{227, 229, 230, 231, 232, 233, 234}

Five genes with unestablished roles have also been identified in CLL and these include splicing factor 3b subunit 1 (SF3B1; 15%), ZMYM3, MAPK1, FBXW7, and DDX3X.²²⁶ SF3B1 is a component of one of the five small nuclear ribonucleoproteins (SnRNP) that form a complex and are involved in splicing messenger RNA. Mutations of SF3B1 are relatively common in CLL occurring in 15% to 17% of patients and the mutations cause aberrations in splicing activity. Mutations are associated with a deletion of 11q22-23 (36%), are a cause of fludarabine resistance, and are independent prognostic markers for survival.^{226, 234, 235}

Effects of Chromosome Changes on Gene Expression

Deletion 13q13

The most frequent structural abnormality in CLL is a deletion of 13q14 affecting 55% of cases.⁸⁴ Of these cases 76% are monoallelic and 24% biallelic, and deletions occur most commonly in patients who have mutated IgV_H disease.⁸⁴ The deleted region has been shown to involve the MDR, containing the DLEU2 gene and microRNA (miR)-15a/16-1.²³⁶ DLEU2 encodes a noncoding RNA, but its function is unknown, whereas miR-15a/16-1 inhibits proliferation and apoptosis.²³⁶ Using transgenic mice it has been demonstrated that deletion of miR-15a/16-1 alone can lead to MBL and CLL, which is related to increased cell proliferation as a result of the loss of miR-15a/16-1.^{237, 238} Moreover, as in CLL, many of these cases have a very similar CDR3, suggesting that a common antigen and/or autoantigen causes induction of the monoclonal

population. In addition, the disease is more aggressive if there is a concomitant deletion of DLEU2, suggesting that this element functions as a tumor-suppressor gene. In the clinical scenario, deletion 13q14 generally encompasses a much larger area than just MDR, with additional loss of a large area called the common deleted region (CDR) which contains DLEU1, DLEU7, and RNASEH2B.^{237, 238} Loss of this region, which is telomeric to MDR, results in more aggressive disease than for mice lacking MDR alone. This observation is similar to that in the clinical scenario where loss of RB1, which is centromeric to MDR, leads to more aggressive disease.^{212, 213} Thus, the effect of MDR deletion is potentiated by the loss of adjacent chromosomal material and the prognosis with a deletion 13q14 worsens with the extent of the deletion.

Deletion 11q22-q23

Deletion 11q22-23 occurs in approximately 20% of cases, is seen in younger patients, and is associated with marked lymphadenopathy, rapid disease progression, and poor survival.^{84, 239, 240, 241} The critical region for the deletion is a 3-Mb segment at 11q22.3-q23.1, and candidate genes in this region include radixin (RDX), which has homology to the neurofibromatosis-type 2 (NF2) tumor-suppressor gene and the ATM gene.²⁴⁰ The ATM protein is a protein kinase activated by DNA double-strand breaks and this leads to phosphorylation and activation of TP53. One third of patients with a deletion 11q22-23 have a mutation on the remaining ATM allele and this subgroup has a defective response to DNA damage with radiation or chemotherapy and a poorer overall survival (OS) than the group of patients with a deletion 11q22-23 and wildtype ATM on the other allele.^{37, 86, 87} Thus, the other two-thirds of patients must have an additional defect leading to their poor prognosis. Recently, 36% of patients with deletion 11q22-23 have been shown to have a mutation in SF3B1, an abnormality associated with drug resistance and poor survival.^{226, 235} Although CLL cells with a deletion 11q22-23 do not differ from other CLL cells in growth fraction, NF-κB expression, or response to mitogenic stimuli, they have reduced levels of a number of adhesion proteins, which may explain the marked lymphadenopathy observed in these cases.²⁴⁰ Complementary DNA microarray analysis has demonstrated that patients with a deletion of 11q22-11q23 have a distinct expression pattern, and overexpress genes involved in cell signaling, cycling, and apoptosis.^{192, 240, 241}

Deletion 17p13

Deletion 17p13 is usually associated with a mutation of TP53 on the other allele and these patients usually have aggressive and drug-resistant disease with poor survival.^{72, 73, 83, 84, 210} Further details regarding this abnormality are discussed later.

P.1899

Trisomy 12q13

Trisomy 12 occurs as a result of duplication of one homologue and is seen in 10% to 20% of CLL patients. Trisomy 12 is frequently associated with "atypical" CLL and CLL/PLL. Patient survival is only minimally affected when trisomy 12 is detected by FISH, whereas survival is shortened if trisomy 12 is detected by classical cytogenetics.^{84, 199, 200} 12q13-15 contains the MDM2 gene, and overexpression of MDM2 could simulate a TP53 mutation, as MDM2 binds and inactivates TP53.^{72, 84} However, although MDM2 is overexpressed in two-thirds of patients, the increase does not correlate with disease stage, aggressiveness, or drug resistance.⁸⁵

Translocations of 14q32

Translocation of 14q32 involving IGH occurs in 7% of patients with CLL and many of these cases turn out to have a different disorder.^{84, 193, 214} The t(11;14) (q13;q32) occurs typically in mantle cell lymphoma, and the rearrangement on chromosome 11 involves the BCL1 gene, a G¹ cyclin also called CCND1 or cyclin D1. A t(14;18) (q32;q21) translocation is seen commonly in follicular lymphomas, and this rearrangement juxtaposes the IGH locus on chromosome 14 to the 3' end of BCL2 on chromosome 18. This rearrangement causes overexpression of BCL2 in the follicular lymphomas with inhibition of apoptosis; although the levels of BCL2 in CLL are equivalent to those in follicular lymphomas, the overexpression in CLL is related to BCL2 gene hypomethylation.^{70, 71} The t(14;19) (q32;q13.1) is a rare event and involves the juxtapositioning of BCL3 on chromosome 19 with the Ig gene on chromosome 14. The candidate oncogene BCL3 is a member of the IκB family, and patients with this translocation have atypical morphology and progressive disease.²⁴²

CLINICAL FINDINGS

Most CLL patients in the general population are elderly (median age 71.5 years). As a result of referral bias the median age of patients seen in the specialist clinic is 64 years, with 20% to 25% of patients being <55 years old.^{11, 12, 243, 244} However,

the presenting features are similar regardless of age.^{243, 244} Nowadays, 70% to 80% of patients are diagnosed incidentally when they have a routine blood count and will have early-stage (Rai 0 or I) disease.²⁴⁵ Alternatively, lymphadenopathy, splenomegaly, or both may be detected during a regular physical examination. When symptomatic, the most frequent complaint is fatigue or a vague sense of being unwell. Less frequently, enlarged nodes or the development of an infection is the initial complaint, and the most frequent infections are bacterial pneumonias. Fever and weight loss are uncommon at presentation but may occur with advanced and drug-resistant disease.

Most symptomatic patients have enlarged lymph nodes, as well as splenomegaly. Enlargement of the cervical and supraclavicular nodes occurs more frequently than axillary or inguinal lymphadenopathy. The lymph nodes are usually discrete, freely movable, and nontender. Painful enlarged nodes usually indicate superimposed bacterial or viral infection. There is usually only mild to moderate enlargement of the spleen, and splenic infarction is uncommon. Less common manifestations are enlargement of the tonsils, abdominal masses due to mesenteric or retroperitoneal lymphadenopathy, and skin infiltration. Skin lesions in CLL may be caused by squamous and basal cell carcinomas which are thought to be related to immunosuppression (see section "Second Malignancies").²⁴⁶ Other common cutaneous manifestations include shingles and recalcitrant warts. Direct involvement of the skin by CLL typically affects the face and the features can be quite variable, from macules or papules, which may be vascular or to more extensive involvement that may simulate rhinophyma.²⁴⁷ Patients can also present with symptomatic anemia, which may be related to marrow replacement or, more rarely, to autoimmune hemolysis or aplasia. Alternatively, patients may have bruising or bleeding, most commonly related to thrombocytopenia and rarely to acquired von Willebrand disease, or factor VIII inhibitors. Rarely, patients may present with a paraneoplastic syndrome, such as nephrotic syndrome, paraneoplastic pemphigus, or angioedema (see section "Autoimmune Manifestations").

Peripheral Blood

The median lymphocyte count at diagnosis is 20 to 30 × 10⁹/L, and in most patients, there is a continuous increase in the lymphocyte count over time.^{13, 243, 244} In half the patients, it takes more than 12 months for the lymphocyte count to double; cyclic fluctuations of up to 50 × 10⁹/L can occur in the lymphocyte counts of untreated patients, and in others, the count may remain stable for years.²⁴⁴ The CLL cells are small to medium-sized lymphocytes with clumped chromatin, inconspicuous nucleoli, and a small ring of cytoplasm. Cytoplasmic inclusions occasionally may be observed in CLL cells and may be crystalline, globular, tubular, or rod-shaped.²⁴⁸ Smudge cells (basket cells or shadow cells of Gumprecht) are commonly seen in the peripheral blood smear in CLL, but not in other lymphoid disorders, and are caused by a decrease in the cellular content of vimentin, a cytoskeletal protein required for maintaining cell structure.^{249, 250} The number of smudge cells can vary from 1% to 75% (median 28%) and appears to be remarkably consistent in individual patients.²⁵⁰ One study suggests that patients with ≥30% smudge cells are more likely to have mutated IgV_H and have a better prognosis than those with <30% smudge cells.²⁵⁰ There can be variations in cell morphology, with some cells being PL, whereas others are larger with abundant cytoplasm, and some are plasmoid or cleaved.^{204, 251} The French/American/British classification system divides patients into 3 groups depending on the percentage of abnormal cells.²⁵¹ In classical CLL, >90% of cells are small, and when 11% to 54% of the cells are PL, it is termed CLL/PLL. When >15% of the lymphocytes are plasmoid or cleaved and <10% are PL, it is termed atypical CLL.^{203, 204, 251} Approximately 80% of patients have classical CLL, and 20% have CLL/PLL or atypical CLL. If ≥55% of the cells are PL, the patient has PLL.

Bone Marrow and Lymph Nodes

Marrow infiltration in CLL may be interstitial, nodular, mixed (nodular and interstitial), or diffuse, with mixed being the most common and nodular the least common.^{3, 252} Diffuse involvement, in which there is effacement of the fat spaces by tumor, carries the worst prognosis.^{3, 252} The marrow involvement is random and contrasts with follicular lymphomas, in which paratrabecular involvement is the rule. In contrast to marrow, involvement of the lymph node is diffuse. Proliferation centers with PL and paraimmunoblasts are typically seen in both marrow and lymph nodes.

Immunophenotyping

CLL can usually be readily differentiated from other disorders by immunophenotyping^{1, 2, 3, 253, 254, 255} (Table 90.2). The leukemic cells have the B-cell markers CD19, CD20 (low), CD43, and CD79b (low) and must be CD5⁺. In addition, the cells show clonal light chain restriction, weak expression of sIgM and sIgD, and are CD23⁺ and CD10⁻. The cells are also CD27⁺,⁴³ consistent with being memory B-cells.⁵ Alternatively, the presence of CD27, CD5, and CD23 could reflect the activated nature of the CLL cell.⁴² Matutes et al.^{254, 256} recommend 5 markers to differentiate CLL from other B-cell malignancies (Table 90.3). Typical CLL should be surface Ig (weak), CD5⁺, CD23⁺, CD79b or CD22 (weak), and FMC7⁻.

TABLE 90.2 IMMUNOPHENOTYPES OF CHRONIC LYMPHOCYTIC LEUKEMIA (CLL) AND OTHER CHRONIC B-CELL DISORDERS

-, not expressed; -/+, usually is not expressed; +/-, usually is expressed; + to +++, varying degrees of strength of expression; HCL, hairy cell leukemia; smIg, surface membrane Ig. Adapted from References 254-257.

One of the typical features of the CLL cell is the overexpression of membrane CD23, which is related to deregulation of NOTCH2 signaling and may play a role in the decreasing apoptosis.^{257, 258} The presence of CD23 is useful to differentiate CLL from mantle cell lymphoma, which is also CD5⁺.²⁵⁷ Cell surface CD23 undergoes spontaneous proteolysis, producing elevated serum levels of CD23, the level of which is a marker of disease stage and progression.²⁵⁷

The BCR complex is required for the proliferation of B-cells after immune stimulation and is a complex formed by sIg and Igα/Igβ (CD79a/CD79b). CLL cells lack CD79b, which is related to overexpression of an alternatively spliced form of the gene.²⁵⁹ The FMC7 antibody identifies an epitope of CD20 and usually strongly stains hairy cell leukemia and PLL; however, only 16% of CLL cases stain positively, presumably because CD20 is only weakly expressed in typical stable CLL.^{253, 260} In general, those patients who are FMC7⁺ have high levels of surface IgM, low expression of CD23, and poor prognosis.²⁵³ Although the myelomonocytic antigens (CD11b, CD13) may be expressed in multiple myeloma, acute lymphoblastic leukemia, and in the CD5- chronic lymphoid leukemias, they are not expressed in CLL.²⁶¹

TABLE 90.3 SCORING SYSTEM FOR DIAGNOSIS OF CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Marker	Marker Intensity	Score	Marker Intensity	Score
Surface Ig	Weak	1	Strong	0
CD5	+	1	-	0
CD23	+	1	-	0
CD22/CD79b	Weak	1	Strong	0
FMC7	-	1	+	0

+, present; -, absent.

Note: Diagnosis of chronic lymphocytic leukemia requires a score of 4 or 5.

From Matutes E, Polliack A. Morphological and immunophenotypic features of chronic lymphocytic leukemia. *Rev Clin Exp Hematol* 2000;4:22-47.

The CD5 antigen is most commonly associated with mature T-cells and is expressed weakly on thymocytes.^{2, 262} However, normal B-cells carrying the CD5 marker are located in the mantle zone of the lymph node, and small numbers of these cells are also present in the peripheral blood.²⁶² The CD5 molecule has been cloned and appears to be involved in the activation of T lymphocytes. The function of CD5 on the B-cell remains unknown, but its induction has been shown to be inhibited by the T-cell-derived cytokine IL-4. CD5⁺ B-cells can be stimulated to secrete anti-DNA antibodies and rheumatoid factors in vitro, and increased numbers are found in the peripheral blood of patients with rheumatoid arthritis, systemic lupus erythematosus, and Sjögren syndrome.²⁶² It has been suggested that the normal counterpart of the CLL cell is the CD5⁺ B-cell,¹⁹ although detailed immunophenotyping demonstrated significant differences between the two groups.²⁶³ Thus, the CD5⁺ B-cell appears to be a resting antigen-naïve cell, whereas the CLL cell is activated and antigen-experienced. Moreover, the specific activation marker expression pattern varies between cells that have IgV_H gene mutations and those that do not, with the unmutated group resembling B-cells at an earlier state of activation.⁴¹ Older studies suggested that about 5% of cases of CLL could be CD5⁻ and were more likely to be FMC7⁺, CD23⁻, CD11b⁺, and CD13⁺ and have a poor prognosis.²⁶¹ However, these CD5⁻ cases should be reclassified, as CD5⁺ is essential for the diagnosis of CLL.^{1, 3}

Surrogate Markers for IgV_H Mutational Status

Both CD38 and ZAP-70 have been evaluated as surrogate markers for IgV_H mutational status, as these can be measured readily by flow cytometry. To define the stage of maturation of the CLL cell, Damle et al.⁴² measured CD38 levels in CLL. Approximately 50% of patients had >30% CD38⁺ cells, and these patients had unmutated IgV_H and had a worse prognosis than those with <30% CD38⁺ cells. However, not all have found such a correlation.² CD38 acts as a receptor and enzyme and can produce cell replication and survival with a variety of signals.²⁶⁴ Activation of CD38⁺ cells, but not CD38⁻ cells, through sIgM induces apoptosis and through IgD prolongs cell survival and induces differentiation.²⁶⁴ In addition, recent evidence suggests that the replicating cells in CLL are the CD38⁺ cells and the number of CD38⁺ cells is higher

P.1901

in lymph nodes, likely reflecting the higher rate of cell proliferation at that site.^{115, 265} Although CD38 can be measured easily by flow cytometry there is disagreement about the number of cells that are required to define positivity, with values ranging from 5% to 30%.^{266, 267, 268} Moreover, the number of CD38 positive cells can vary over time.^{266, 267, 268}

ZAP-70 is a member of the Syk-ZAP-70 protein kinase family and is expressed in T and natural killer (NK) cells and is important in T-cell signaling.^{269, 270} However, recent evidence suggests that normal B-cells may also express ZAP-70, particularly when activated.^{269, 270} Gene expression studies in CLL have also demonstrated that cells with unmutated IgV_H have an increased expression of ZAP-70 whereas those with mutations have low levels.⁷ Subsequent studies have shown a 70% to 90% correlation between ZAP-70 expression and IgV_H mutational status, regardless of whether ZAP-70 was measured by flow cytometry (≥20% cells positive), Western blot analysis, or immunohistochemistry.^{271, 272, 273, 274} Kröber et al.²⁷⁵ have shown that discordant cases may have poor prognostic features including deletions of 17p13 or 11q22-q23, or IgV_H3-21 expression. ZAP-70 positivity also correlates moderately with CD38 positivity and the presence of poor-risk cytogenetics, that is, deletion 11q22-q23, deletion 17p13, and trisomy 12.^{275, 276} The poor prognosis associated with ZAP-70 positivity has been related to the magnified signaling by the BCR in ZAP-70-positive CLL cells.²⁷⁷ A major difficulty presently in the routine use of ZAP-70 is the variability in the assay as a result of the sensitivity of different antibodies and the use of different internal controls.^{266, 267, 268} Moreover, although initial studies suggested that ZAP-70 differed from CD38 in remaining stable during the disease course, more recent evidence indicates that ZAP-70 may also change over time.^{267, 268}

Immunoglobulin Production in Chronic Lymphocytic Leukemia

Apart from having either κ or λ light chains on the cell-surface membrane, clonality is confirmed by the presence of unique idiotypic specificities of the Igs produced by CLL cells²⁷⁸ and by IG gene rearrangements.^{2, 18} CLL cells have low to undetectable amounts of monoclonal polyreactive IgM autoantibodies, frequently of the rheumatoid factor type, on their surface.^{262, 263} Thus, the same monoclonal autoantibody produced by a leukemia cell may react with a variety of antigens (e.g., IgG, cardiolipin, histones, or single- or double-stranded DNA).²⁶² Surface and cytoplasmic Igs contain either κ or λ

light chains but never both. Most cells display a single heavy chain class, usually μ , although some display μ and δ . Less commonly, γ , α , or no heavy chain determinant is found. Although the CLL cell is believed to be frozen at a particular stage in maturation, up to 50% of CLL patients have IgM⁺ leukemia cells that are able to undergo isotype switching to IgA (usually) or to IgG.^{279, 280} Rearrangements of the IGH and IGL genes are seen in CLL and these remain constant over time.² Interestingly, the T-cell receptor β gene can be aberrantly re-arranged in 6% of CLL cases and this is associated with chromosome 6q deletions.^{281, 282}

CLL cells may secrete idiotypic IgM and in most cases can be induced by mitogens to secrete IgM that can react to a variety of autoantigens.^{283, 284} Using a sensitive immunoblotting technique, monoclonal proteins can be detected in the serum of virtually all patients although the light chain of the protein is only the same as that on the CLL in half the cases.²⁸⁵ These findings indicate that the monoclonal protein in many cases is not derived from the tumor cells. Serum electrophoresis detects a monoclonal protein in approximately 5% of CLL cases and an abnormal serum-free light chain ratio is observed in one third of patients.^{286, 287} The presence of an abnormal ratio correlates with advanced disease, markers of aggressive disease, and poor prognosis.²⁸⁷

Functional Immune Abnormalities

Patients with CLL are immunosuppressed, as a result of hypogammaglobulinemia, alterations in T-cell function and to abnormalities in complement activation and neutrophil/monocyte function.^{288, 289} Moreover, the immunosuppression is potentiated by chemotherapy or immunotherapy. As a result, about 50% of patients have recurrent infections, with sepsis being an important cause of death. Apart from typical bacterial infections, CLL patients are also susceptible to opportunistic infections, particularly if they have received nucleoside analogues, steroids, or monoclonal antibodies. The nucleoside analogues are highly toxic to T lymphocytes, whereas monoclonal antibodies may be cytotoxic to B-cells (e.g., rituximab) or to both B- and T-cells (alemtuzumab).

The CLL cell has no useful immune function and shows poor stimulatory activity in mixed lymphocyte culture²⁹⁰ and in response to B-cell mitogens, such as pokeweed mitogen, lipopolysaccharide, and the Epstein-Barr virus.^{291, 292} However, phorbol esters, *Staphylococcus aureus* protein A from Cowan I, anti- μ antibodies, anti-CD40, and loxoribine have been shown to be potent mitogens.^{293, 294} Moreover, these cells are poor antigen-presenting cells and, as discussed below, can interfere with normal B- and T-cell function.²⁹⁵

The risk of infection is closely related to the extent of hypogammaglobulinemia in CLL, and the severity increases with the duration and stage of disease.^{288, 289, 296} The Ig levels are all decreased, and within the IgG class, reduced levels of IgG2 and IgG4 correlate best with the risk of infection; however, the decline in IgA levels is the most important predictor of infection.^{296, 297} Interestingly, the correlation between Ig levels and infection rate is not absolute, and some patients with normal Ig will have repeated infections whereas others with hypogammaglobulinemia will remain infection-free.²⁸⁸ Patients with CLL have reduced primary and secondary responses to immunization.²⁸⁹ Although patients with higher levels of gammaglobulin usually show better responses than those with low levels, the responses of both groups are abnormal. The pathogenesis of the hypogammaglobulinemia is poorly understood. However, impaired B-cell function and regulatory abnormalities of T-cells (including the reversal of normal helper/suppressor cell ratios) probably play a role. In addition, CLL-derived NK-cells have been shown to suppress Ig secretion by normal B-cells in vitro.²⁹⁸

The absolute number of T-cells may be increased in untreated CLL, and there are marked abnormalities in the surface markers, including inversion of the T-helper to -suppressor cell ratio, suggesting perturbations in T-cell function.^{290, 299} In addition, the increase in the number of T-suppressor cells may correlate with the degree of hypogammaglobulinemia.³⁰⁰ The T-cells usually respond normally to mitogens, such as phytohemagglutinin, in vitro and produce IL-2 and γ -interferon.³⁰¹ However, there is decreased T-helper function with reduced reactivity to allogeneic and autologous B-cells.^{302, 303} Spontaneous and antibody-dependent cytotoxicities are reduced, suggesting an abnormality in the large granular lymphocyte population, including NK-cells.³⁰⁴

The cause of these abnormalities is unclear, but the increase in T-cells has been ascribed to stimulation by CLL cells or chronic infection, such as cytomegalovirus (CMV).^{289, 305, 306} Alternatively, the B-, T-, and NK-cell functions may be suppressed by means of immunosuppressive factors produced by CLL B-cells.^{307, 308} The gene expression profile of CD4⁺ and CD8⁺ cells are different in CLL patients as compared to normal individuals.³⁰⁷ However, the abnormal expression could be induced in CD4⁺ and CD8⁺ cells from normal individuals by co-culturing them with CLL cells.³⁰⁷ Similar studies showed that CLL cells could affect the ability of normal T-cells to form normal immunologic synapses.³⁰⁸ One potential candidate that could be causing these changes is TGF- β , which is secreted by CLL cells and marrow stromal cells in CLL, and has been shown to be a potent inhibitor of normal B- and

T-cells.^{133, 134, 135, 136, 137} In addition, CLL cells express both CD40 and the CD40L (CD154), and these cells decrease CD154 expression by normal T-cells with resultant effects on normal B-cell differentiation and isotype switching.³⁰⁹

The levels of different complement components are decreased in CLL, particularly in patients with advanced disease.³¹⁰ As well, multiple defects in neutrophil and monocyte function have been described in CLL, and these are associated with an increased risk of infection.^{288, 311}

Autoimmune Manifestations

Despite being immune deficient, CLL patients have an increased incidence of autoimmune cytopenias secondary to autoantibody formation.^{312, 313, 314, 315, 316, 317, 318} The immune cytopenias may be present before or at the time of diagnosis in one third and during the course of disease in two-thirds.³¹⁵ CLL is the most common cause of autoimmune hemolytic anemia (AIHA), causing 14% of cases, followed by systemic lupus erythematosus.³¹² Moreover, patients with AIHA have an increased incidence of MBL and subsequently developing CLL, but this is not true for patients with immune thrombocytopenia (ITP).^{314, 316} Overall, 4% to 10% of CLL patients develop AIHA, and this is usually associated with a warm-type antibody against the Rhesus system and a positive direct antiglobulin test (DAT).^{312, 313, 314, 315} Another 7% to 14% of cases may have a positive DAT without evidence of hemolysis. The incidence of this disorder is increased with male sex, older age, high lymphocyte count, advanced disease, and the presence of biologic markers of poor prognosis, such as high β 2-microglobulin, high ZAP-70, and unmutated IgV_H.^{314, 315, 317} The diagnosis of AIHA may be difficult in CLL, as multiple factors may produce anemia, a positive DAT can exist without hemolysis, and other diagnostic parameters may be influenced by the disease.^{314, 315, 317} Zent et al.³¹⁷ have thus developed diagnostic criteria for the diagnosis of AIHA in CLL and include (a) hemoglobin <100 g/L; (b) ≥ 1 marker of hemolysis, i.e., reticulocytosis, increased indirect bilirubin without liver disease, increased lactate dehydrogenase (LDH) without another cause or increased marrow erythropoiesis; (c) positive DAT/cold agglutinins or ≥ 2 markers of hemolysis, without evidence of hypersplenism or bleeding. When fludarabine was introduced, AIHA was seen relatively frequently leading investigators to believe that this was a unique complication of the drug. However, in the LRF CLL4 trial the incidence of AIHA was similar in previously untreated patients who received chlorambucil (12%) as compared to fludarabine (11%), and the incidence was lowest in patients treated with a combination of fludarabine plus cyclophosphamide (5%) indicating that cyclophosphamide has a protective effect.³¹⁸ The likelihood of developing AIHA was greater if the patient had a positive direct DAT before treatment, had advanced disease, or had a high β 2-microglobulin test.³¹⁸ The incidence of a positive DAT before treatment was 14% and approximately one third of patients receiving chlorambucil or fludarabine with a positive DAT developed AIHA. Conversely, the chance that a patient who was DAT-negative would develop AIHA was 7%. Thus, the high incidence of AIHA observed when fludarabine was first used was because patients receiving this drug usually had advanced and previously treated disease. The protective effect of cyclophosphamide has been confirmed in a subsequent study where the incidence of AIHA was 1%.³¹⁹ Although the addition of rituximab to chemotherapy would be expected to reduce the incidence of AIHA further, it is reported to occur in <1% to 6.5% of patients receiving FCR.^{210, 319} The impact of the development of immune cytopenias on survival has been recently evaluated in 2 studies, which have demonstrated that the prognosis of these patients is no worse than those without cytopenias.^{315, 317}

ITP occurs in <1% to 2% of patients, and the diagnosis is based on an increase in platelet size in the peripheral blood and an increase in megakaryocytes in the marrow, although the latter is often difficult to ascertain as the marrow usually is heavily infiltrated with CLL cells. ITP may be predicted if there is an isolated fall in platelets without splenomegaly as anemia usually precedes thrombocytopenia when cytopenia is caused by marrow replacement. Autoimmune neutropenia occurs rarely in CLL but should be considered if patients remain neutropenic following chemotherapy with recovery in the other blood counts. A bone marrow analysis will be required under these circumstances to assess marrow reserve. Red cell aplasia is also rare and is suspected when a patient develops isolated anemia with reticulocytopenia and none of the usual signs of hemolysis. A marrow shows a reduction in red cell precursors.

Several pieces of evidence indicate that the antibodies causing these cytopenias are produced by normal B-cells and not CLL cells. First, the antibodies are polyclonal and are usually IgG. Second, the autoimmune disorders may occur while the patient's disease is responding to therapy.^{312, 313, 314, 315} It has been suggested that CLL cells act as antigen-presenting cells for normal CD5⁺ or CD5⁻ antibody-producing B-cells and that antibody production is increased after inhibition of T-cells, either with advancement of disease or because of therapy.^{312, 313} Antigen presentation may occur in the spleen which is the major site of removal of senescent red cells and may be potentiated by T-cells through CD40L-CD40.^{313, 320} There is an association between AIHA in CLL and the expression by the leukemia cells of certain IgVH genes, for example, V1 family gene DP51p1.³²⁰ How this may influence the normal B-cell population to produce red cell antibodies is unknown. In

contrast, pure red cell aplasia is caused by a T-cell mechanism rather than the formation of autoantibodies, and these patients respond well to cyclosporine, a drug that affects T-cell function.^{313, 314, 321}

The above abnormalities are caused by normal B- or T-cells, however, antibodies produced by CLL cells can cause cold agglutinin disease, peripheral neuropathy, and paraneoplastic pemphigus.³¹³ Normal CD5⁺ B-cells can produce autoantibodies to IgG and single- and double-stranded DNA, as well as other autoantigens, and the number of these cells is increased in autoimmune disorders.²⁶² CLL cells can be induced to secrete IgM molecules that react with a comparable spectrum of antigens.^{264, 283, 318} Alternatively, IgM⁺ CLL cells can undergo isotype class-switching to IgG⁺ cells.^{278, 279}

In contrast, a number of other conditions may be caused by antibodies produced directly by the CLL cells.³¹³ Thus, the IgM antibody-producing cold agglutinin disease in CLL is produced by the CLL cells against the red cell I antigen and the CLL cells are typically IgV_{H4-21}.³²² Antibody produced by the CLL cells against myelin-associated glycoprotein (MAG) may also cause a poly-neuropathy.³¹³ Paraneoplastic pemphigus causes painful mouth ulcers, conjunctivitis, and pruritic blistering skin lesions.³²³ This disorder is diagnosed by distinct histologic changes in the skin and the presence of autoantibodies in the blood directed against cutaneous epitopes.^{323, 324} Acquired angioedema is associated with recurrent abdominal pain and is caused by consumption of the inhibitor of the first component of complement by tumor.³¹³ Glomerulonephritis, frequently with nephrotic syndrome, may occur secondary to deposition of intact monoclonal antibody or light chains in the kidney and remits with treatment of the CLL.^{313, 325} As opposed to the immune cytopenias, all of the above occur with CLL disease progression and resolve with treatment of the leukemia.

DIAGNOSIS

The International Workshop of Chronic Lymphocytic Leukemia (iwCLL) in 2008 changed the diagnosis of CLL to require a peripheral blood B-cell count of $\geq 5 \times 10^9/L$ and the presence of monoclonal (kappa or lambda) B-cells which have the P.1903

typical immunophenotype of CLL cells (CD19⁺, CD5⁺, CD23⁺, and decreased expression of surface Ig, CD20, and CD79b).¹ Using these markers a diagnostic scoring system for CLL has been developed and CLL may be considered “atypical” if there are variations in these markers (Table 90.3). The CLL cells are mature-appearing lymphocytes admixed with larger or atypical cells, PL, and cleaved cells. Having more than 55% PL is consistent with PLL. Individuals with a peripheral blood B-cell count of $< 5 \times 10^9/L$ and CLL cells in the blood have either SLL or MBL. These two disorders can be distinguished as MBL lacks lymphadenopathy or splenomegaly (by physical examination or CT scans;¹ Table 90.4).

TABLE 90.4 CHRONIC LYMPHOCYTIC LEUKEMIA AND VARIANTS

Marker	Monoclonal B-Cell Lymphocytosis (MBL)	Chronic Lymphocytic Leukemia (CLL)	Small Lymphocytic Lymphoma (SLL)
Peripheral blood B-cell count	$< 5 \times 10^9/L$	$\geq 5 \times 10^9/L$	$< 5 \times 10^9/L$
Enlarged lymph nodes or spleen ^a	No	Maybe	Yes

^a By physical examination.

From Hallek M, Cheson BD, Catovsky D, et al. Guidelines for the diagnosis and treatment of chronic lymphocytic leukemia: a report from the International Workshop on Chronic Lymphocytic Leukemia updating the National Cancer Institute-Working Group 1995 Guidelines. Blood 2008;111:5446-5456.

DIFFERENTIAL DIAGNOSIS

In most patients, the diagnosis of CLL is easily made after a careful review of the peripheral smear and immunophenotyping, although other conditions must be considered (Table 90.5). On occasion, immunohistochemistry or gene rearrangement studies are required to exclude other diagnoses.

Benign Causes

T-cell-Associated Causes

Chronic infections, such as tuberculosis or syphilis, may produce a lymphocytosis. A transient lymphocytosis may also be seen in viral illnesses, such as pertussis, CMV, or infectious mononucleosis. However, these are usually found in children or young adults and should be easily distinguished from CLL by the clinical features and the morphologic appearance of the cells.

B-cell-Associated Causes

Persistent polyclonal B-cell lymphocytosis is a rare and benign condition seen typically in middle-aged female smokers with a familial tendency.^{326, 327, 328} The lymphocytes are binucleated and have abundant cytoplasm. There is a polyclonal increase in Igs and a strong association with HLA-DR7, and an isochromosome 3q⁺ (i3)(q10) is observed in some cases.^{326, 327} These cells show IgV_H gene mutations and immunophenotypically are marginal zone lymphocytes.³²⁸ Delage et al.³²⁷ have demonstrated multiple BCL2/IGH gene rearrangements in this disease and described a family in which there was a high incidence of the gene rearrangements in first-degree relatives in association with a paternal HLA haplotype. These findings suggest that persistent polyclonal B-cell lymphocytosis can be a familial disorder and that the BCL2/IGH gene rearrangements may represent the first abnormality before B-cell expansion.³²⁷

Tropical splenomegaly syndrome or hyperreactive malarial splenomegaly occurs in countries with endemic malaria and may mimic CLL.^{329, 330} This disease is believed to be a disordered response to malarial antigens leading to overproduction of B-cells and is characterized by massive splenomegaly, an increase in IgM, and, in 10% of cases, an increase in the peripheral lymphocyte count. The disorder responds to antimalarial therapy, and this can be used to differentiate hyperreactive malarial splenomegaly from CLL.

Malignant Causes

Malignant disorders that may be confused with CLL are summarized here for comparative purposes and as an aid in differential diagnosis (Table 90.5). Before flow cytometry became routine, many patients were diagnosed as having CLL but in fact had other disorders³³¹ (Table 90.2). The most common malignancies to be confused with CLL are PLL and the leukemic phase of non-Hodgkin lymphomas. Morphologically, these disorders may appear similar to CLL.

B-cell-Associated Causes

Monoclonal B-cell lymphocytosis

In MBL there is a persistent increase in the number of monoclonal B-cells in the peripheral blood but the B-cell count remains $<5 \times 10^9/L$; there are three common variants, CLL-like MBL (CD5⁺, CD20 dim), atypical MBL (CD5⁺, "bright CD20," and CD5-MBL (Fig. 90.8).^{1, 332, 333} MBLs are found in 3.5% of adults older than 40 years of age with normal blood counts with the incidence increasing with age.^{334, 335} The incidence of MBL is even higher (13.5%) among healthy members of CLL families^{25, 26, 336} and in otherwise healthy people with a lymphocyte count $>4 \times 10^9/L$. A more recent study using 8-color flow cytometry detected MBL in up to 12% of healthy individuals with normal blood counts, suggesting

P.1904

that the incidence of the abnormality may be even higher depending on the sensitivity of the assay.³³⁷ Rather than having a continuous distribution of B-cell numbers in MBL there appears to be a bimodal distribution with a lower peak of 0.0001 to 0.010×10^9 clonal B-cells/L (detected when screening the healthy individuals, "population MBL") and a second peak of 0.05 to 0.5×10^9 clonal cells/L (detected when testing individuals for a slightly elevated lymphocyte count, "clinical MBL").³³⁸ Although the risk of patients with "population MBL" progressing to CLL is exceedingly low, these patients may harbor CLL-like genetic abnormalities, such as deletion 13q14, trisomy 12, or deletion 17p13, and have IgV_H gene mutations.^{339, 340} Moreover, there are multiple T-cell clones in half the cases, suggesting that the whole immune system is affected, perhaps related to chronic immune stimulation.³⁴⁰ Support for this concept has been the observation that multiple B-cell clones may also be observed in these individuals.^{334, 337} The difference between "clinical MBL" and low-count Rai stage 0 CLL appears quite arbitrary and 40% of patients diagnosed with CLL using the older criteria for CLL (lymphocyte count $>5 \times 10^9/L$) are now considered to have MBL.³⁴¹ Recent evidence indicates that the survival of CD38-"Clinical MBL" (79% patients, $<30\%$ cells positive) is no different from age- and sex-matched controls whereas the survival

of CD38⁺ "Clinical MBL" (21% patients, ≥30% cells positive) and Rai stage 0 patients is reduced.³⁴² Rawstron et al.³³⁶ have estimated that approximately 1% of the "Clinical MBL" cases will progress to CLL and require treatment each year.

TABLE 90.5 DIFFERENTIAL DIAGNOSIS OF CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Benign Causes

Bacterial (e.g., tuberculosis)

Viral (e.g., infectious mononucleosis)

T-Cell

Prolymphocytic leukemia

Adult T-cell leukemia/lymphoma

Sézary syndrome

Large granular lymphocytic (LGL) leukemia

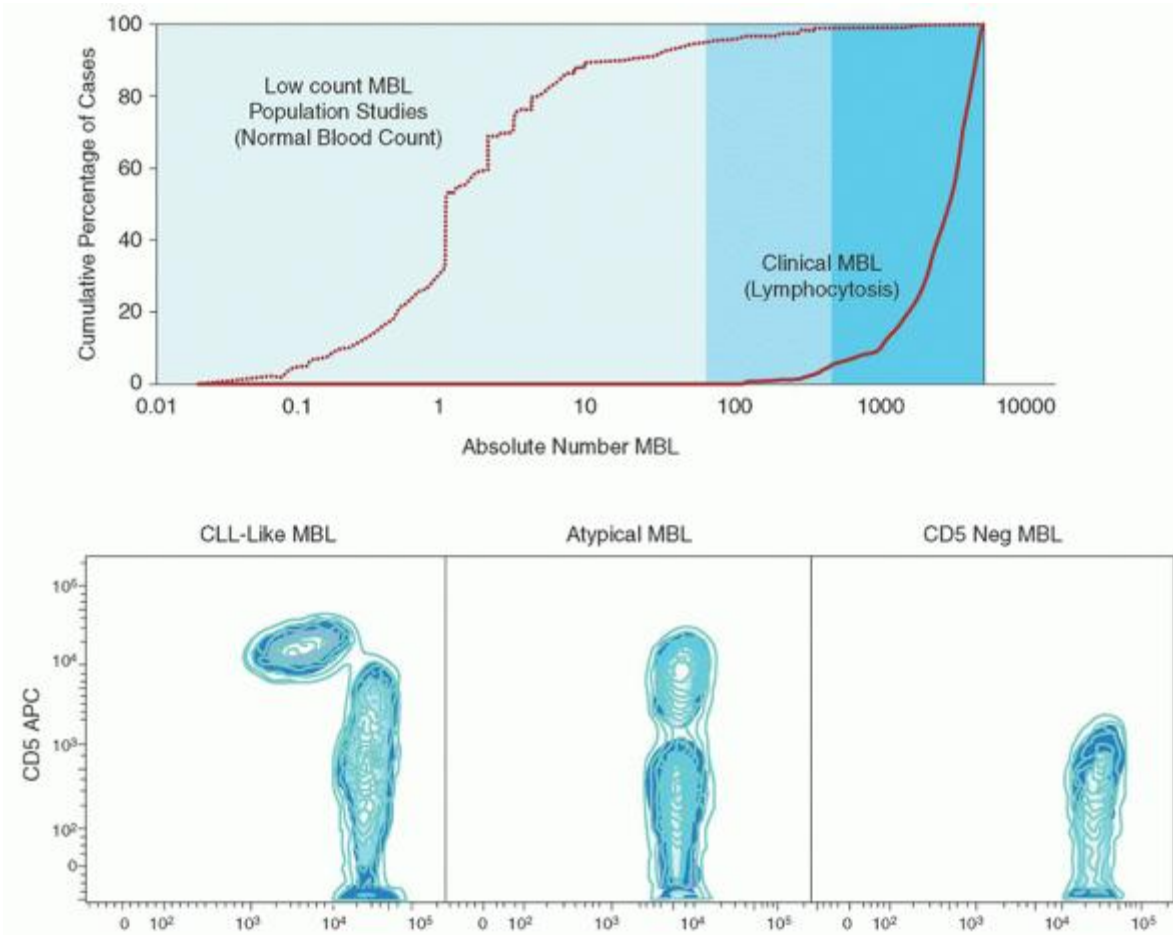

FIGURE 90.8. Role of absolute B-cell count in monoclonal B cell lymphocytosis (MBL) and immunophenotype patterns. The top panel shows the absolute number of B-cells as a cumulative function of the number of cases dividing low-count MBL (normal white blood cell count, absolute lymphocyte count) from clinical MBL (with lymphocytosis). The bottom panel from left to right shows the three major immunophenotypic patterns seen in MBL. From Marti GE. MBL: mostly benign lymphocytes, but... Blood 2011;118:6480-6481.

An ethical issue over MBL has been the possibility of unintentional transmission of this syndrome by blood transfusion or hematopoietic cell transplantation (HCT).^{337, 343} This issue is discussed further in the section on HCT for CLL.

B-cell Prolymphocytic Leukemia

B-cell PLL is characterized by larger, less mature-appearing cells than are seen in CLL, and the nucleus has condensed chromatin and prominent central nucleoli.^{344, 345} Patients with CLL/PLL have 11% to 54% PL, but in PLL ≥55% of the cells are PL.²⁵¹ PLL appearing de novo is an aggressive disease, and patients frequently are symptomatic with fever, weight P.1905

loss, or abdominal discomfort and are found to have massive splenomegaly, minimal lymphadenopathy, and resistance to therapy.^{344, 345} Leukocyte counts in excess of $150 \times 10^9/L$, consisting almost entirely of PL, are common, as are anemia and thrombocytopenia. The cells invariably have intense staining for surface membrane Ig, FMC7, CD20, and CD79b, whereas this may or may not occur with CLL/PLL.²⁵¹ One third of cases have a deletion of 11q23, one half a deletion of 13q14, and one half a mutation of TP53.^{346, 347} Although occasional patients may initially have stable disease, progression is the rule, and the median survival is 65 months.³⁴⁵

Leukemic Phase of Non-Hodgkin Lymphoma

The leukemic phase of non-Hodgkin lymphoma used to be referred to as lymphosarcoma cell leukemia and includes the leukemic phase of mantle cell lymphoma, follicular lymphoma, splenic lymphoma with villous lymphocytes (splenic marginal zone lymphoma), other marginal zone lymphomas, and, rarely, large-cell lymphomas. The lymphocytes in mantle

cell lymphoma are larger than those seen in CLL and have more cytoplasm; in contrast to CLL and the other disorders, there is variation in cell morphology, with some cells looking like classical CLL cells, others having irregular nuclei, and some looking like PL.^{348, 349} Two-thirds of patients have marrow involvement and one third have leukemic presentation.³⁴⁸ Patients with a leukemic picture have aggressive disease. The cells strongly express surface Ig and are CD19⁺, CD20⁺, CD5⁺, CD23⁻, CD10⁻, and FMC7⁺.³⁵⁰ These cells have the t(11;14)(q13;q32) and, by immunohistochemistry, stain strongly for cyclin D1. As the breakpoint for t(11;14)(q13;q32) covers a large area, polymerase chain reaction (PCR) using only one set of primers misses many cases, and Southern blot analysis or FISH may be required.^{350, 351} The leukemic phase of follicular lymphomas may be confused with CLL; usually, the cells are small, the nuclear chromatin is smooth and not clumped, there is almost no cytoplasm, and the nucleus is indented.³⁵² Occasionally, large cells are seen, and, when possible, a lymph node biopsy should be carried out to type the follicular lymphoma. The cells are identified by immunophenotyping and are CD19⁺, CD20⁺, FMC7⁺, CD23⁻, CD5⁻, and CD10⁺. The diagnosis can be confirmed by demonstrating a t(14;18)(q32;q21). Approximately 10% of peripheral B-cell lymphocytosis is caused by splenic marginal zone lymphoma; these cells have characteristic filamentous projections and, frequently, a nucleolus.^{351, 353} The cells are usually SIg⁺ (strong), CD19⁺, CD20⁺, CD23⁻, CD5⁻, CD79b⁺, and FMC7⁺. The other forms of marginal zone lymphomas (mucosa-associated lymphoid tissue and monocytoid B-cell lymphomas) and lymphoplasmacytic lymphomas may also rarely involve the marrow and peripheral blood.³

Hairy Cell Leukemia

In hairy cell leukemia (Chapter 91) the cells are of moderate size with eccentric oval nuclei and variable prominent nucleoli. The cells differ from CLL cells in being tartrate-resistant acid-phosphatase positive (TRAP+) and CD5⁻, CD11c⁺, CD25⁺, CD103⁺, and CD123⁺.³⁵⁴ In contrast to classical hairy cell leukemia, in which the lymphocyte count is usually low, the variant form of hairy cell leukemia has a higher lymphocyte count, but the cells have prominent nucleoli, are TRAP-, and are CD25⁻ and CD123⁻.³⁵⁵

T-cell-Associated Causes

The chronic T-cell disorders are much less common than the B-cell disorders but can be classified into 4 groups.²⁵¹

T-cell Prolymphocytic Leukemia

Formerly called T-cell CLL, T-cell PLL cells have a prominent nucleolus and the nucleus may be either round to oval in half the cases or irregular, often with convolutions.³⁴⁷ Splenomegaly is typically present, with lymphadenopathy in half the cases and skin involvement (nodules or a maculopapular rash) in 20%. Periorbital edema may also occur. Cells are CD3⁺, CD4⁺, CD7⁺, and CD8⁻, but in one-quarter of patients, the cells are both CD4⁺ and CD8⁺ or, more rarely, CD4⁻ and CD8⁺.³⁴⁷ Most patients (81%) achieve a complete remission (CR) with intravenous alemtuzumab with a median survival of 2 years.³⁴⁷

Adult T-cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma is most common in Asia and has a variety of clinical presentations.^{356, 357} Patients may present acutely with lymphadenopathy or hepatosplenomegaly, although skin involvement, lytic bone lesions, hypercalcemia, and involvement of other organs have been described. Alternatively, there may be a chronic form of the disease with peripheral lymphocytosis and skin involvement, which may either resolve entirely or develop into the acute form of the disease.³⁵⁷ A prognostic classification has been developed based on the proliferative capacity of the peripheral blood leukemic cells.³⁵⁸ The cells are usually CD4⁺ and are infected with human T-cell leukemia/lymphoma virus-1.

Sézary Syndrome

Sézary syndrome is the leukemic form of mycosis fungoides, and affected patients have diffuse skin involvement plus lymphadenopathy and splenomegaly, although peripheral lymphocytosis can occur in isolation.³⁵⁹ The cells are typically large with cerebriform nuclei, coarse chromatin, and inconspicuous nucleoli, and are usually CD4⁺.³⁵⁹ The diagnosis of Sézary's syndrome requires a peripheral blood Sézary cell count of $>1 \times 10^9/L$ or that $>20\%$ of the lymphocytes be identified as Sézary cells.³⁵⁹

Large Granular Lymphocytic Leukemia

Large granular lymphocytic (LGL) leukemia is characterized by moderate lymphocytosis (1 to $49 \times 10^9/L$) and the presence of cells that are bigger than CLL cells with abundant cytoplasm containing azurophilic granules.^{360, 361, 362} However, there is considerable variation, even within the same patient. In some cases, the lymphocytes may appear normal, and the granules may be coarse, fine, or absent.³⁶⁰ Large granular lymphocytes may be NK-cells that mediate nonmajor histocompatibility complex-restricted cytotoxicity or CD3⁺ T-cells that mediate nonmajor histocompatibility complex-

restricted cytotoxicity.³⁶⁰ T-LGL leukemia is the most common form, making up 85% of cases, and is associated with neutropenia (which may be cyclical), red cell aplasia, and rheumatoid arthritis (25%), but this is a distinct entity from Felty syndrome.³⁶⁰ It has been suggested that the neutropenia is related to the expression of FAS ligand by LGL cells.³⁶³ The usual immunophenotyping of T-LGL leukemia is CD3⁺, CD4⁻, CD8⁺, CD16⁺, CD56⁻, CD57⁺, and TCRαβ⁺; T-cell receptor gene rearrangement studies confirm T-cell monoclonicity. If therapy is required, responses may be observed with cyclosporin or methotrexate.³⁶⁴, ³⁶⁵ NK-LGL leukemia occurs most frequently in Japan and has an acute fulminant course with high fever, hepatosplenomegaly, and pancytopenia.³⁶¹ However, chronic NK-cell leukemia can occur, with a clinical course similar to that of T-LGL leukemia.³⁶² These cells are usually CD3⁻, CD4⁻, CD8⁻, CD16⁺, CD56⁺, and CD57⁻.³⁶⁰

INVESTIGATIONS AND STAGING

Investigations

A complete blood count, review of the peripheral smear, and immunophenotyping are required for diagnosis and prognosis in CLL. Recommended investigations have been published by the IWCLL and the European Medical Society of Oncology (EMSO).¹, ⁵

P.1906

These investigations depend on whether a patient is being seen in general practice or within the context of a clinical trial.

Standard Tests for General Practice

Physical Assessment

This includes measuring the bidimensional size of the largest nodes in the cervical, supraclavicular, axillary, inguinal, and femoral regions with measurement of the spleen and liver. The performance status should also be documented.

Laboratory Measurements

Complete blood count with white cell differential (including the percentage of PL) and reticulocyte count. DAT, routine plasma biochemistry [including renal/liver function tests, and LDH], serum protein electrophoresis and/or immunoelectrophoresis, and Ig levels.

Screening for hepatitis B and C, cytomegalovirus (CMV), and human immunodeficiency virus (HIV) should be carried out before treatment. Therapy for patients who are HIV-positive will need to be individualized depending on their condition and medications. Patients who have antibody to CMV will require monitoring and treatment if there is viral reactivation with alemtuzumab or allogeneic HCT.³⁶⁶ Patients who have hepatitis B antigenemia will require therapy with suppressive therapy (such as lamivudine) during chemotherapy in order to prevent viral reactivation.¹, ⁵

A number of prognostic markers may help in determining the rate of disease progression and overall prognosis in newly diagnosed patients and is discussed in detail below. FISH is recommended prior to therapy as the presence of certain abnormalities (deletion 17p13 or 11q22-23) can influence treatment.

Radiology

A baseline chest x-ray is useful to determine any pre-existing lung disease.

Additional Tests for Clinical Trials and Specific Clinical Situations

Laboratory Measurements

A marrow aspirate/biopsy may be useful: (a) to assess normal marrow reserve and to establish the cause of anemia and thrombocytopenia for patients with Rai stage III or IV disease; (b) to assess the cause of persistent cytopenias following chemotherapy, and (c) to assess cellularity and the extent/pattern of marrow infiltration, which is of prognostic value.²⁵²

Radiology

A meta-analysis has recently demonstrated that CT scans are not of value for routine management.³⁶⁷ Findings of the baseline CTs were not prognostically important and disease progression could be detected by clinical examination and blood counts. The presence of persistent radiologic disease following therapy predicted a shorter progression-free survival (PFS) and OS for patients treated with chemotherapy but was not of value when rituximab was added to chemotherapy, as in the German CLL8 study,²¹⁰ where FC (fludarabine/cyclophosphamide) was compared with FCR (fludarabine/cyclophosphamide/rituximab). Thus, the use of prognostic markers and the detection of minimal residual disease (MRD) following therapy are of greater value in CLL than CT scans. However, CT scan may be used: (a) in clinical trials; (b) to confirm a remission prior to hematopoietic cell transplant, where tumor burden is prognostically important,

and (c) to assess tumor burden prior to treatment with alemtuzumab. Patients with lymph nodes >5 cm respond poorly to alemtuzumab and require alternate therapy.³⁶⁷ PET scans are not useful for staging in CLL, as 18F-FDG uptake in CLL is low. However, they are useful to identify a suitable node for biopsy when determining whether new lymphadenopathy is related to disease progression, transformation, or a second malignancy.

Staging

Two staging systems are in general use, and are based on physical examination and results of a routine blood count.^{368, 369} The Rai staging system is generally used in North America, and the original system divided patients into 5 groups on the basis of lymphocytosis alone (peripheral blood lymphocyte count $\geq 15 \times 10^9/L$ and $\geq 40\%$ lymphocytes in the marrow), clinically apparent lymphadenopathy or splenomegaly, and the presence of anemia (hemoglobin <110 g/L) or thrombocytopenia (platelets $< 100 \times 10^9/L$; Table 90.6).³⁶⁸ A simplified 3-stage version of this scheme is now generally accepted (Table 90.6).¹ The Binet staging system is most frequently used in Europe,³⁶⁹ and staging is based on the number of involved areas, the level of hemoglobin, and the platelet count (Table 90.7). The diagnosis of CLL required a peripheral blood lymphocyte count of $\geq 4 \times 10^9/L$ with $\geq 40\%$ lymphocytes in the marrow. The 5 areas of involvement were 3 lymph node areas (cervical, axillary, and inguinal, whether unilateral or bilateral), the spleen, and the liver.

Several points should be emphasized about these staging systems:

- The staging is based on clinical examination and not on CT scans.
- The cause of cytopenia was not defined in the original descriptions of Rai stages III/IV or Binet stage C disease. A recent detailed study from the Mayo Clinic demonstrated that one-quarter of all CLL patients develop cytopenia, with 54% being due to marrow replacement by tumor, 18% due to immune cytopenias, and 28% due to other causes, for example, chemotherapy or uremia.³¹⁷ Recent studies have shown that the survival of patients with immune cytopenias is much better than those due to marrow replacement by tumor and likely not different to those without cytopenias.^{315, 317} It has thus been suggested that patients should be subclassified according to the cause of their cytopenia.

TABLE 90.6 RAI CLASSIFICATION SYSTEM FOR CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Stage	Modified Stage	Description	Median Survival (y)
0	Low-risk	Lymphocytosis ^a	>10
I	Intermediate-risk	Lymphocytosis + lymphadenopathy	7-9
II	Intermediate-risk	Lymphocytosis + splenomegaly ± lymphadenopathy	7-9
III	High-risk	Lymphocytosis + anemia ^a ± lymphadenopathy or splenomegaly	1.5-5
IV	High-risk	Lymphocytosis + thrombocytopenia ^a ± anemia, splenomegaly or lymphadenopathy	1.5-5

^aLymphocytosis, originally lymphocytes $>15 \times 10^9/L$ for >4 weeks; anemia, hemoglobin <110 g/L; and thrombocytopenia, platelets $< 100 \times 10^9/L$. TABLE 90.7 BINET CLASSIFICATION FOR CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Stage	Blood Counts	Involved Areas ^a	Median Survival (y)
A	Hb >100 g/L and platelets $> 100 \times 10^9/L$	<3	>10
B	Hb >100 g/L and platelets $> 100 \times 10^9/L$	≥ 3	7

C Hb <100 g/L, or platelets <100 × 10⁹/L, or Any number both 2-5

Hb, hemoglobin.

“The five areas of involvement include head and neck, axillae, groins, palpable spleen, and clinically enlarged liver.

Data from Binet JL, Auquier A, Dighiero G, et al. A new prognostic classification of chronic lymphocytic leukemia derived from a multivariate survival analysis. *Cancer* 1981;48:198-206, and Shanafelt TD. Predicting clinical outcome in CLL: how and why. *Hematology (Am Soc Hematol Educ Program)* 2009:421-429.

- The diagnosis of CLL in the original studies was not based on immunophenotyping, whereas nowadays the diagnosis of CLL depends on a peripheral blood B-cell count of ≥5 × 10⁹/L. Thus, a number of patients in the original studies likely had non-Hodgkin lymphomas with leukemic involvement. This might partly explain the poorer prognosis for patients with advanced stages, as compared with more recent observations. However, the relative survival of patients with confirmed CLL and stages Binet B/C disease has increased over the past 20 to 30 years, suggesting that the improved survival nowadays is related to improved therapy or supportive care.³⁷⁰

PROGNOSIS

CLL is a very heterogeneous disease, both in presentation and disease progression. The Rai or Binet clinical staging systems are simple and reliable prognostic measures. However, the prognostic value of these systems has been somewhat tempered, as there is variation in survival within each stage and the majority of patients are in Rai stage 0/I at diagnosis.²⁴⁵ Thus, 30% to 50% of patients with early-stage disease will require therapy in 1 to 4 years and have a median survival of 7 to 8 years whereas occasional patients may have a spontaneous remission.^{245, 371} This uncertainty about the future creates great anxiety for the patient and has led to tremendous efforts to develop reliable prognostic markers^{267, 268, 372} (Table 90.8). Stratification of patients into different risk groups will allow for a more rational approach to treatment options and will identify specific patient groups to be studied in clinical trials. Several general points about prognostic markers should be made. First, these markers have generally been evaluated in patients less than 65 years of age and their value in older patients is less certain.^{11, 12} Thus, although IgV_H status and FISH results are useful predictors of survival for younger patients they are less useful in those ≥75 years.^{11, 12} Second, the markers have been studied at the time of diagnosis and their utility throughout the disease course is less clear. The exception here is for FISH, which is usually carried out prior to treatments; new genetic abnormalities can develop during the disease course and the results of FISH are important for prognosis and influencing treatment decisions. Finally, a prognostic marker may be able to predict one aspect of the disease course, for example, time to first treatment, but may not be able to predict PFS or OS.

TABLE 90.8 PROGNOSTIC MARKERS IN CHRONIC LYMPHOCYtic LEUKEMIA (CLL)

Prognostic Marker	Better Prognosis	Worse Prognosis
Sex	Female	Male
Age	<70 y	>70 y
Plasma vitamin D level	High	Low
Rai stage	0, I, and II	III and IV
Lymphocyte count	<12 × 10 ⁹ /L	≥12 × 10 ⁹ /L
Lymphocyte doubling time	>12 mo	< 12 mo
Number of “smudge cells”	≥30%	<30%
β2-microglobulin level	Low	High
Flow cytometry: B-cell count CD38 ^a ZAP-70	<11 × 10 ⁹ /L <20% cells positive <20% cells positive	≥11 × 10 ⁹ /L ≥20% cells positive ≥20% cells positive
FISH	Deletion 13	Deletion 11q22-23 or 17p13

IgV_H mutation status

Mutated

Unmutated

^a The precise number of cells required for CD38 positivity varies according to the study.

Some prognostic markers, such as clinical staging, lymphocyte morphology and doubling time, CD38, serum LDH, β 2-microglobulin levels, and FISH are routinely available, but others are either experimental or only available at specialized centers. In the following section we review the most commonly used and new potentially important prognostic markers. Further details on other markers can be obtained in recent reviews.^{267, 268}

Rai and Binet Staging

The median survival of patients in the Rai staging low-risk group (~55% to 60%) who have an isolated lymphocytosis, is more than 10 years.^{267, 370, 373, 374, 375} Patients in the intermediate-risk group (~35% to 40%) have lymphadenopathy, splenomegaly, or both, and have a median survival of 7 to 9 years. Patients in the high-risk group (~5% to 10%) have anemia, thrombocytopenia, or both and a median survival of 1.5 to 5 years. Survival in the high-risk group depends on the cause of the cytopenia, being poorest

P.1908

in those with marrow failure due to CLL infiltration, whereas those with immune cytopenias have a good prognosis.^{315, 317} The median survival of patients with Binet stage A is >10 years, stage B is 7 years, and stage C is 2 to 5 years.³⁷⁵ Although both staging systems provide useful prognostic information, they do not correlate well with each other. Thus, there are more patients with Binet stage A as there are in the Rai low-risk groups, whereas the opposite is true for Binet stage B and Rai intermediate-risk groups.³⁷⁵

Age and Sex

Approximately 25% of CLL patients in the clinic are \leq 55 years, and the clinical features, prognostic markers, and staging at presentation are generally similar to older patients.^{12, 243, 244} Survival of both groups of patients is the same, although the proportion of deaths that can be directly attributed to CLL is greater for the younger age group.²⁴⁴ These results indicate that a subgroup of younger patients has aggressive disease and the risk of a Richter's transformation is fivefold higher in the younger age group.²⁴⁴ The male-to-female ratio for CLL is 1.3:1, and women are more likely to have early-stage disease. Regardless of stage and age, women have a better prognosis than men.^{376, 377} The mechanism(s) responsible for the improved survival in women is (are) unknown but has been related to an increased incidence of *IgV_H* mutated disease with good prognostic genetic markers in women.³⁷⁷ In addition, hormonal differences may be important as clinical responses have been observed in CLL when patients with co-existing prostate cancer were treated with estrogens.³⁷⁷

Lymphocyte Characteristics

Morphology

Approximately 20% of patients have atypical CLL or CLL/PLL, and these patients have a more advanced stage, a higher proliferative index, and a poorer prognosis.^{203, 204, 217, 254} These patients are also more likely to have trisomy 12 or deletion of 17p13 (TP53 mutation), to be CD38⁺, and to have unmutated *IgV_H*.^{204, 217, 284} However, in a multivariate analysis, aberrant cell morphology was found to be an independent prognostic marker.³⁷⁸ Patients with \geq 30% smudge cells have a better prognosis than those with <30% smudge cells.²⁵⁰

Number

Survival decreases with increasing B-cell or lymphocyte count at the time of diagnosis,^{341, 379} A B-cell count of $>11 \times 10^9/L$ predicts a shorter treatment-free survival and OS independent of CD38, ZAP-70, and *IgV_H* mutational status.³⁷⁹

Doubling Time

The lymphocyte doubling time (LDT) is a useful measure of disease aggressiveness. Indolent CLL is associated with a slow LDT, whereas patients with a LDT of <12 months have a significantly worse survival rate.^{380, 381} A recent study from Britain has demonstrated in 1,154 patients with Binet stage A disease that patients with a LDT of <12 months required treatment in 2.5 years and had a median survival of 12.6 years whereas those with a LDT of \geq 12 months required treatment in 18.6 years and had a median survival of 20.3 years.³⁸¹

Immunophenotyping

Variations in immunophenotyping, such as an increase in surface Igs, FMC7⁺, or increased intensity of CD20, may be associated with atypical morphology, trisomy 12, and poor prognosis.^{204, 253, 254, 382}

A number of studies have demonstrated the importance of CD38⁺ as a prognostic marker and this can be measured in either peripheral blood or marrow.^{266, 363, 381, 383, 384, 385} However, there is still controversy as to the number of cells required to denote positivity.^{247, 248} Initial studies suggest a correlation between the presence of an IgV_H gene mutation and CD38⁻ (<30% CD38⁺ cells), however, this has not been confirmed by others.^{266, 267} In all of these studies, CD38⁺ has been associated with shorter survival and correlates with increasing Rai stage, intrathoracic and abdominal lymphadenopathy, short doubling time, increased β2-microglobulin levels, and atypical morphology.^{383, 384, 385} Moreover, the CD38 status is useful to predict which patients within a particular clinical stage will progress.^{381, 384, 385} When followed over time, CD38⁻ patients may become CD38⁺, and this is associated with deletion of 17p13 (TP53 mutation) and disease progression.³⁷⁴

ZAP-70 is also a useful prognostic marker although further studies are required to standardize the assay and it is still unclear whether equivalent results are obtained on analyzing the marrow or peripheral blood.²⁶⁶ There is a 70% to 90% correlation between ZAP-70 expression and absence of IgV_H mutations, regardless of whether ZAP-70 is measured by flow cytometry (>20% cells positive), Western blot analysis, or immunohistochemistry.^{271, 272, 273, 274, 275} ZAP-70 positivity correlates moderately with CD38 positivity and the presence of poor-risk cytogenetics, that is, deletion 11q22-q23, deletion 17p13, and trisomy 12.²⁷⁵ Kröber et al.²⁷⁵ have also demonstrated that discordant cases may have poor prognostic features including deletions of 17p13 or 11q22-q23, or IgV_H3-21 expression. Thus, some patients with a mutated IgV_H3-21 gene express high levels of ZAP-70 and do poorly.^{271, 275} Alternatively, low ZAP-70 expression in some patients with unmutated IgV_H can correlate with the presence of deletions of 17p13 or 11q22-23.²⁷⁵ ZAP-70 positivity may be a stronger predictor for time to treatment (TTT), PFS, or OS than an unmutated IgV_H.^{273, 276} A comparison of the prognostic markers by the CLL Research Consortium has demonstrated that ZAP-70 is the most important marker for TTT.³⁸⁶ Thus, ZAP-70 positive patients had a median time from diagnosis to treatment of 2.6 years versus 8.4 years for ZAP-70 negative patients. The CD38 status did not add additional prognostic information but for ZAP-70 negative patients unmutated IgV_H patients had a median survival of 6.3 years versus 10 years for mutated IgV_H patients (Fig. 90.9). It is unclear why ZAP-70 positive CLL patients have a poor prognosis, although it has been related to the magnified signaling by the Ig cell receptor in ZAP-70 positive CLL cells.³⁸⁶

Alterations in T-cells are also prognostically important in CLL and a low CD4/CD8 ratio with a decreased number of NK-cells is observed in advanced disease with hypogammaglobulinemia.³⁸⁷

Molecular Genetics

FISH Studies

FISH has become a standard technique in CLL and patients with a deletion of 17p13 have a median survival of 2 to 3 years, compared with 6 to 7 years for those with a deletion of 11q22-23, 9 years for those with a trisomy 12 or normal FISH, and 11 years for those with a deletion of 13q14 alone.⁸⁴ The identification of deletions of 17p13 or 11q22-23 is particularly important as their presence can alter therapy and prognosis.^{2, 84, 210, 267, 388, 389}

The significance of a deletion 17p13 depends on when it is detected.^{390, 391} Thus, 4% to 5% of patients at diagnosis have a deletion of 17p13 and although half of these patients require treatment in 3 years one third will have stable disease.³⁹⁰ In contrast, at the time of first treatment, 10% patients have deletion 17p13 and these patients are resistant to chemotherapy with only one third surviving 3 years.²¹⁰ By the time patients are fludarabine-resistant, 33% will have a deletion of 17p13 and these patients have a very poor prognosis.²²⁵ Most patients with deletion 17p13 have a TP53 mutation on the other allele, however, patients may have a TP53 mutation without a deletion of 17p13.^{392, 393} Thus,

P.1909

fludarabine-resistant patients may have deletion 17p13 alone (~10%), deletion 17p13 with a TP53 mutation (~25%), or a TP53 mutation alone (~10%).^{225, 392, 393} Prognosis is equally poor in all groups leading to the suggestion that patients may require TP53 sequencing in addition to FISH studies.^{394, 395} The type of TP53 mutation is also important with mutations in the DNA binding domain portending a particularly poor prognosis.^{394, 395}

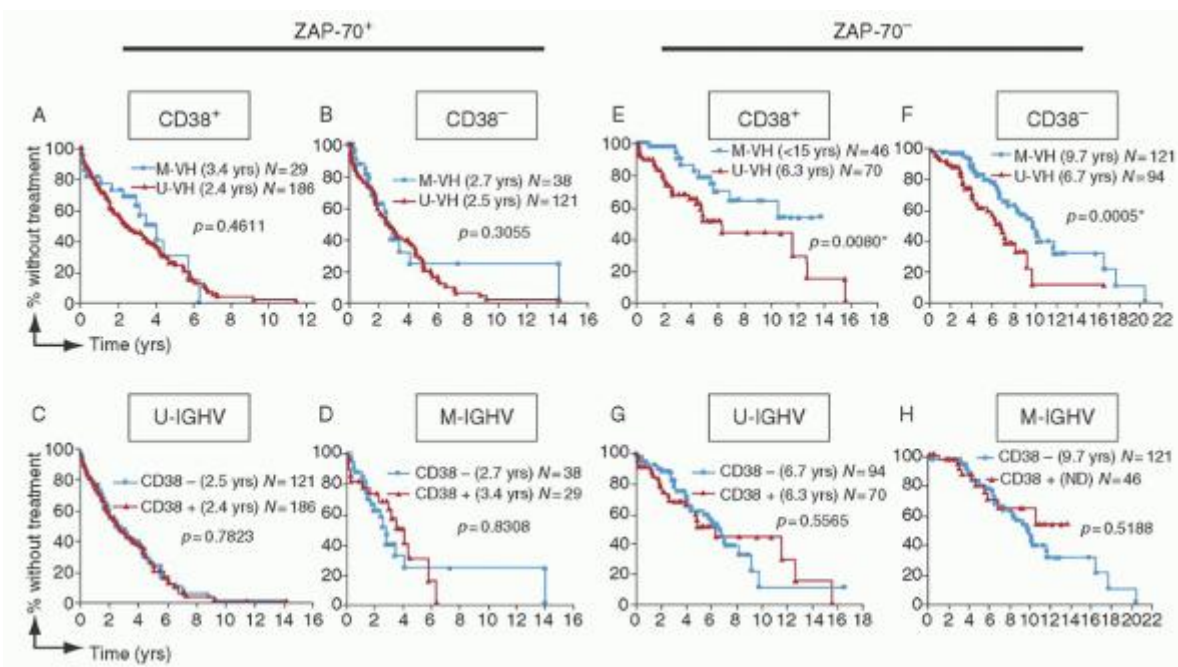

FIGURE 90.9. Relationship between ZAP-70 and CD38 or IGHV mutation status in defining the time from diagnosis to initial therapy. Kaplan-Meier curves depict the proportion of untreated CLL patients in the validation cohort (N = 705) from diagnosis to initial therapy. Panels A through D depict the time from diagnosis to initial treatment of patients who have CLL cells that express ZAP-70 (ZAP-70+), whereas panels E through H show the time from diagnosis to first treatment of patients with CLL cells that were ZAP-70 negative (ZAP-70⁻). Panels A and E or B and F show how IGHV mutation status can segregate cases that are CD38⁺ or CD38⁻, respectively. Panels C and G or D and H show how CD38 can segregate cases that use U-IGHV or M-IGHV, respectively. The P-values were determined using the log-rank test. The symbols represent the time at which patients were censored. From, Rassenti LZ, Jain S, Keating MJ, et al. Relative value of ZAP-70, CD38 and Ig mutation status in predicting aggressive disease in chronic lymphocytic leukemia. *Blood* 2008;112:1923-1930, with permission.

Patients with deletions of 11q22-23 typically are middle-aged men with bulky lymphadenopathy, and prognosis can be significantly improved with immunochemotherapy.^{210, 389} The addition of rituximab to fludarabine/cyclophosphamide (FCR) can improve the CR rate from 15% to 51% (p < 0.0001) and the OS at 3 years from 83% to 94% (p = 0.036).²¹⁰

Patients with trisomy 12 may have atypical morphology but the incidence does not correlate with stage and these patients respond well to chemotherapy.^{2, 210}

Mutations of the Immunoglobulin Gene and IgV_H3-21 Usage

Approximately 50% of patients with CLL have mutations of the IgV_H gene, and these patients generally have stable disease and normal cell morphology.^{2, 6, 7, 267, 268} In contrast, patients without IgV_H mutations are more likely to have atypical morphology, deletion of 11q22-23 and/or 17p13, and NOTCH1 mutations.^{2, 233} As a result, these patients generally have advanced disease, drug resistance, an increased risk of developing RS, and poor survival. Indeed, a recent large British study demonstrated that for Binet stage A patients the IgV_H mutational status was the most important prognostic indicator in a multivariate analysis.³⁸¹ The median TTT for patients with mutated IgV_H had not been reached and the median survival was 23.3 years, compared to a median TTT of 4.6 years and OS of 12.5 years in patients with unmutated IgV_H. The use of IgV_H3-21 has been associated with a poor prognosis, regardless of mutation status, perhaps related to overexpression of genes involved in transcription and cell cycle control.³⁹⁶

Telomere Length and Telomerase Activity

In CLL, the telomeres are generally shorter than in normal B-cells and are shortest in IgV_H unmutated cells.^{180, 397, 398, 399, 400} In response, telomerase may be increased, with activity being inversely related to telomere shortening. These abnormalities have been observed in patients with early-stage CLL with telomere shortening continuing to occur over time and being associated with telomere fusions and abnormal genetics, particularly deletions of 17p13 and 11q22-23.^{2, 398, 399, 400} Not surprisingly, increased telomerase and short telomeres have been associated with poor survival.³⁹⁸

NOTCH and SF1B3 Mutations

NOTCH1 and SF1B3 mutations have recently been identified as common and important prognostic markers in CLL and were discussed earlier.^{226, 227, 228, 229, 230, 231, 232, 233, 234, 235} Mutations in exon 34 of NOTCH1 is present in 4% to 10% of patients (usually unmutated IgV_H), but the incidence increases in patients with trisomy 12 (41.9%),²³² those with drug-resistant disease (20%),^{227, 233} and in those with Richter's syndrome (one third).^{227, 234} The NOTCH1 mutations decrease the rate of NOTCH1 protein clearance and thus increase the protein level and NOTCH1 activity.²⁰⁸ This results in increased NF-κB activity with cellular proliferation and increased cellular inhibitor of apoptosis protein 2 (c-IAP2) and X-linked inhibitor of apoptosis protein (XIAP) with

P.1910

decreased apoptosis.²³⁰ Interestingly, disruption of TP53 function is only observed in 10% of cases with a NOTCH1 mutation and thus NOTCH1 mutations are associated with non-TP53-mutated drug resistance.²³³ Mutations of SF3B1 occur in 15% to 17% of CLL patients and cause aberrations in splicing of a variety of mRNAs.^{226, 229, 234, 235} Mutations generally occur in patients with unmutated IgV_H, are associated with a deletion of 11q22-23 (36%), are a cause of fludarabine resistance, and are independent prognostic markers for survival.^{226, 234, 235}

MicroRNA Expression

Low levels of MiR-181b at diagnosis have been shown to predict disease progression, and the level of the MiR decreases over time in patients with progressive disease.⁴⁰¹ Both BCL2 and MCL1 are targets for MiR-181b and the levels of these antiapoptotic proteins increase as the level of MiR-181b falls.⁴⁰¹

Marrow Histology

Nodular and interstitial growth patterns in the marrow are associated with similar marrow tumor burdens and median survival times of 90 and 46 months, respectively, whereas diffuse infiltration or a "packed marrow" is associated with a greater marrow tumor burden and a median survival time of only 28 months.^{1, 252} Fibrosis of the marrow also indicates an aggressive clinical course.⁴⁰² Although the extent of lymphocyte involvement in the marrow is of prognostic importance, the marrow biopsy is preferable as it provides a more reproducible measure of lymphocyte infiltrate and can demonstrate the pattern of marrow involvement.⁴⁰³ However, it should be noted that other investigators have not found that the pattern of marrow involvement adds any additional prognostic information over clinical staging.⁴⁰⁴

The pattern of marrow involvement after chemotherapy is also prognostically important. Patients with persistent lymphoid nodules in the marrow after chemotherapy [nodular partial remission (nPR)] have persistent leukemia and have a shorter time to relapse compared to those in CR.⁴⁰⁵ However, the extent of involvement does not correlate with the rapidity of disease recurrence.⁴⁰⁶

Fludarabine resistance

One of the most important prognostic factors is fludarabine resistance. Patients who do not respond to fludarabine or relapse within 6 months of treatment have a median survival of 9 to 10 months with standard chemotherapy.^{407, 408}

Plasma Markers

Plasma LDH levels are a measure of cell turnover and increased levels are associated with the presence of other poor prognostic markers, such as high CD38 or ZAP-70, or the presence of deletion 17p13.²⁶⁸ Moreover, a sudden increase in LDH may indicate disease progression or the development of a RS.

Plasma β2-microglobulin is derived from the cell membrane of nucleated cells and is noncovalently linked to the α-chain of the class I major histocompatibility complex.²⁶⁸ Increased levels of β2-microglobulin have been shown to be a marker of poor prognosis predicting TTT, duration of response, and OS.^{11, 210, 409, 410, 411} It has been assumed that β2-microglobulin levels reflect tumor burden, however, β2-microglobulin levels remain a useful prognostic indicator in patients with similar low-bulk Binet stage A disease.^{409, 410} Moreover, the levels have been found to correlate very closely with the plasma levels of the inflammatory cytokines (IL-6, IL-8, and TNF-α), indicating that it reflects the cytokine milieu.¹¹ β-microglobulin is cleared by the kidneys and it has been suggested that its prognostic value can be increased by correcting for renal function.⁴¹¹

The plasma levels of the inflammatory cytokines may be increased in CLL and are important prognostic markers for survival, particularly in the elderly.^{11, 130, 412, 413, 414, 415} It is likely that many cell types secrete the cytokines which may act by increasing CLL cell adhesion in the microenvironment.¹¹ The chemokine, CCL3, has also been recently shown to have prognostic value in CLL.¹⁰⁵ CCL3 is secreted by CLL cells with BCR stimulation in the microenvironment and elevated plasma levels predict a short TTT.¹⁰⁵ Finally, Yan et al.⁴¹⁶ have measured 23 cytokines by a multiplex assay in 84 patients

and were able to identify 3 groups that showed clustering of different cytokines. Patients could be stratified into these groups to predict TTT and OS.

Two groups have recently demonstrated the importance of plasma vitamin D levels in CLL.^{417, 418} In one study from the Mayo Clinic, one third of patients had vitamin D deficiency.⁴¹⁷ The plasma level did not correlate with the season, and there was no correlation between age, sex, stage, lymphocyte count, nor other prognostic markers. However, patients with low levels had a shorter TTT and reduced OS. A subsequent study from Italy in untreated Binet stage A patients confirmed these results.⁴¹⁸ In both studies, TTT appeared inversely related to the vitamin D level. As the vitamin D receptor is highly expressed on CLL cells it has been suggested that vitamin D has a direct cytotoxic effect on CLL cells.^{417, 418}

Prognostic Index

Despite the ever-increasing number of prognostic markers there is conflicting evidence as to the value of these markers and whether combining markers will improve prognosis. Wierda et al.¹³ at the MD Anderson have developed a predictive model using generally available measurements. The value of this index in early-stage patients has been validated at the Mayo Clinic and in a large Swiss-Italian multicenter study.^{373, 374} Six factors were originally identified for the index (age, sex, Rai stage, lymphocyte counts, number of lymph node regions involved, and β 2-microglobulin level) with each factor being scored to generate a prognostic index.¹³ However, the subsequent studies did not find lymphocyte count to be of prognostic value, and the European study has simplified the index to include age, sex, Binet stage (which includes number of lymph node sites), and β 2-microglobulin.³⁷⁴ The MD Anderson have also subsequently developed a prognostic index incorporating clinical finding with IgV_H mutational status and the presence of deletions of 17p13 and 11q22-23.⁴¹⁹

TREATMENT

Therapy for CLL has undergone dramatic changes over the past 25 years. Previously, chlorambucil, or sometimes cyclophosphamide, was the agent of choice. Treatments were given intermittently to control blood counts, organomegaly, or symptoms. However, rigorous trials were never carried out to determine the optimum treatment dose or schedule for these agents. In the 1980s the nucleoside analogues were shown to have activity in CLL and the evaluation of these agents in clinical trials required increased precision in the diagnosis of CLL, standard indications for treatment, and definitions of response, including MRD. There was subsequently a re-evaluation of the role of chlorambucil in CLL and the development of combination therapies in CLL, using primarily alkylating agents and nucleoside analogues. Since that time there has been the development of monoclonal antibodies and exciting new agents which inhibit the BCR pathway. In the following sections we review each of these areas and provide a summary of the standard of care for CLL.

Indications for Treatment

The majority of patients with CLL present with Rai stages 0/I disease. They do not require treatment but do need careful monitoring for evidence of disease progression. Premature treatment

P.1911

may actually cause harm and initial studies with chlorambucil in patients with Rai 0 or Binet A disease showed a delay in disease progression but no improvement in survival and an increase in the incidence of epithelial tumors and acute leukemia.⁴²⁰ The indications for treatment are based on the following clinical findings.¹

- Rai stage 0-II disease in patients who are symptomatic (weight loss of >10% body weight in previous 6 months, extreme fatigue, night sweats or fevers of >100.5°F or 38°C for >2 weeks without evidence of infection), or have progressive anemia/thrombocytopenia or lymphocytosis (>50% increase over 2 months or doubling time <6 months)
- Rai stages III/IV to improve the hemoglobin level and/or platelet counts, although asymptomatic patients can be monitored and treatment initiated when there is clear evidence of disease progression
- Bulky or progressive lymphadenopathy (masses >10 cm in diameter) or splenomegaly (>6 cm below left costal margin)
- AIHA/ITP.

Response Criteria and Minimal Residual Disease

To facilitate comparisons of results obtained in clinical trials, the IWCLL¹ has established criteria for clinical responses in CLL, and the details of these definitions are outlined in Table 90.9. The presence of organomegaly in clinical practice is

based on clinical examination but CT scans are required for clinical trials. In the original NCI-WG definitions patients were considered to be in CR even if there were lymphoid nodules in the marrow, as these can occur normally. However, it was subsequently demonstrated that patients in CR achieved a shorter remission if there were nodules in the marrow, indicating that some of these nodules are malignant.⁴⁰⁵ Thus, patients with residual lymphoid nodules in the marrow are classified as having a nPR.

As therapy for CLL has become more effective, there has been interest in the prognostic value of MRD following treatment and in determining whether therapy should be aimed at eliminating MRD.^{421, 422, 423, 424} The optimum specific antibody combinations for detecting MRD were defined in 2007 as CD5/CD19 with CD20/CD38, CD81/CD22, and CD79b/CD43.⁴²³ Concordance between peripheral blood and marrow MRD was ~90% when assessed >3 months after treatment, and was poorer if testing was done <3 months after treatment, particularly if alemtuzumab was used. The detection sensitivity with flow cytometry was one CLL cell in 10,000 leukocytes and flow cytometry detection rates showed concordance with a real-time quantitative allele-specific oligonucleotide (R-ASO) Ig heavy chain gene (IgH) PCR assay, although the PCR assay was more sensitive. This flow cytometry assay was used to assess MRD following FCR or FC in the German CLL8 trial.⁴²⁴ MRD levels were lower in patients treated with FCR and for both treatment arms the reduction in MRD following therapy correlated with improvements in PFS and OS.⁴⁰⁶ This randomized study confirmed the prognostic importance of MRD measurements and the long-term benefit of achieving MRD negativity with therapy.

TABLE 90.9 CRITERIA FOR RESPONSE IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Parameter^a	Complete Response (CR)^b	Partial Response (PR)^c	Progressive Disease (PD)^d	Stable Disease (SD)^e
Symptoms	None	Any	Any	Not CR, PR or PD
Lymph nodes	<1.5 cm	Decrease ≥50%	New node or ≥50% increase	
Hepatomegaly/splenomegaly	None	Decrease ≥50%	Detected enlargement or ≥50% increase	
Lymphocytes	<4 × 10 ⁹ /L	Decrease ≥50% from baseline	Increase ≥50% over baseline	
Hemoglobin	>110 g/L	>110 g/L or ≥50% increase from baseline	Development of a cytopenia secondary to progressive CLL	
Neutrophils	>1.5 × 10 ⁹ /L	>1.5 × 10 ⁹ /L and/or		
Platelets	>100 × 10 ⁹ /L	>100 × 10 ⁹ /L or >50% increase		
Marrow	Normocellular <30% lymphocytes, no nodules	No marrow requirements for a PR		

^a In clinical trials CT scans of abdomen, pelvis, and thorax are desirable. Response should be by CT scan if abnormal before therapy.

^b Features should be maintained at least 2 months after completion of chemotherapy. If marrow hypocellular, repeat after 4 weeks or until peripheral blood counts have recovered (should be <6 months after chemotherapy). If nodules are present in marrow, do immunohistochemistry to confirm that they are monoclonal B-cells. If CLL nodules present, then is a “nodular PR”. If patient fulfills criteria for a CR but counts remain low as a result of chemotherapy, it is denoted CRi (CR with

incomplete marrow recovery).

^c For PR, require =50% decrease in lymphocytes, nodes, and liver/spleen with a recovery in one of the blood counts, as indicated, for >2 months.

^d If transformed to a more aggressive histology, such as Richter's syndrome.

^e From Hallek M, Cheson BD, Catovsky D et al. Guidelines for the diagnosis and treatment of chronic lymphocytic leukemia: a report from the International Workshop on Chronic Lymphocytic Leukemia updating the National Cancer Institute-Working Group 1995 Guidelines. *Blood* 2008;111(12):5446-5456.

Chemotherapy

Alkylating Agents

In the past, the standard treatment for CLL was the alkylating agent, chlorambucil, but nowadays this drug is generally only used in older and frail patients. The precise mechanism of action is unclear but it likely produces its antitumor effect by binding covalently with DNA, RNA, and cellular proteins.^{425, 426} Chlorambucil has been used in CLL for 60 years but the optimum treatment schedule and duration of therapy are still unclear. Traditionally, chlorambucil was administered continuously in a daily dosage of 0.1 mg/kg or intermittently as 0.4 mg/kg every 2 weeks, and these treatment schedules had equivalent efficacy, although the intermittent route produces less myelosuppression.^{427, 428} More recent studies have used chlorambucil administered in boluses, every 2 to 4 weeks (Table 90.10). Overall, the response rate with these regimens is 31% to 90%, with 4% to 60% of patients achieving a CR.^{429, 430, 431, 432, 433, 434, 435} The response rates have depended on dose intensity and criteria for remission. Although very high

P.1912

response rates have been reported by Jaksic et al.⁴³⁵ lower doses of chlorambucil are generally used. Cyclophosphamide differs little, if at all, from chlorambucil in its effectiveness in CLL.⁴³⁶ Cyclophosphamide may be given orally using 2 to 3 mg/kg/day or 20 mg/kg once every 2 to 3 weeks and it causes less myelosuppression than chlorambucil.

TABLE 90.10 RESPONSE RATES IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL) TO DIFFERENT CHLORAMBUCIL REGIMENS

Author	Chlorambucil Schedule	Total chlorambucil per month (mg) ^a	CR (%)	PR (%)	PFS (Months)
Rai (2000) ⁴²⁹	40 mg/m ² every 28 days (6-12 mo)	68	4	33	14
Hillmen (2007) ⁴³⁰	40 mg/m ² every 28 days (6-12 mo)	68	2	53	11.7
Eichorst (2009) ⁴³¹	0.4-0.8 (median 0.5) mg/kg days 1 and 15 (12 mo)	70	0	51	18
Knauf (2009) ⁴³²	0.8 mg/kg days 1 and 15 (6 mo)	112	2	29	8
Catovsky (2007) ⁴³³	10 mg/m ² , days 1-7, every 28 days (6-12 mo)	119	7	65	23

To improve response rates, alkylating agents have been combined with steroids or other agents. Monthly chlorambucil with prednisone increased the response rate (47%) and survival compared to daily chlorambucil plus prednisone (response rate, 37%) or prednisone alone (response rate, 11%).⁴²⁷ In a second study, the frequency of response and the number of patients alive at 2 years were higher when chlorambucil (6 mg/day) was combined with prednisone (30 mg/day) for 6 weeks than when chlorambucil was used alone; however, no difference in survival was demonstrated between the 2 groups.⁴³⁷ Steroids cause a re-distribution of the CLL cells and there is usually an increase in the peripheral lymphocyte count with the initiation of steroids. In practice, prednisone is frequently combined with chlorambucil or used prior to chlorambucil to produce a rapid decrease in lymph node/spleen size and reduce pancytopenia related to marrow packing.⁴³³ However, corticosteroids should be used sparingly as they do not increase survival and may produce significant side effects.

Nonrandomized studies initially reported excellent responses using intermittent cyclophosphamide, vincristine, and prednisone (COP) in patients with advanced CLL,^{438, 439} with approximately 44% of patients achieving a CR.⁴³⁸ However, a subsequent randomized study comparing COP to chlorambucil showed no difference in survival or disease progression at 9⁴⁴⁰ or 53⁴⁴¹ months. When COP was compared with chlorambucil and prednisone in untreated patients, the response and survival rates were identical.⁴⁴² In a similar study, a significantly higher response rate was observed using COP (59%) compared to chlorambucil and prednisone (31%), but the CR and OS rates were similar for both groups.⁴⁴³

The addition of low doses of doxorubicin to COP (CHOP) or CAP (cyclophosphamide, doxorubicin, and prednisone) or the use of multiple agents has been examined. The French Cooperative Group on CLL compared COP to CHOP in previously untreated patients with Binet stage C disease.⁴⁴⁴ The 3-year survival rates were 28% with COP and 71% with CHOP, and the median survival times were 22 and 62 months, respectively.⁴⁴⁵ However, these results are controversial, as no survival advantage has been observed when CHOP is compared with standard chlorambucil and prednisone.^{446, 447} Indeed, higher doses of chlorambucil (15 mg/day continuously) produced a statistically higher response rate than CHOP (89.5% vs. 75.0%) and an improved survival (median, 68 months vs. 47 months).⁴³⁵

Other combination regimens have been studied. In advanced or refractory disease the M2 program, consisting of cyclophosphamide, bischloroethylnitrosourea, melphalan, and prednisone, produced a CR rate of 17% and a PR rate of 44%.⁴⁴⁸ In addition, the median survivals were not significantly different from those achieved with less aggressive regimens. A CR rate of 30% was achieved in untreated patients.⁴⁴⁸ A combination protocol including prednisone, vincristine, cytosine arabinoside, cyclophosphamide, and doxorubicin (POACH) achieved response and survival rates not significantly different from those reported for chlorambucil and prednisone, with complete and overall response rates of 21% and 56%, respectively, for previously untreated patients and 6% and 21%, respectively, for previously treated patients.⁴⁴⁹ VAD (vincristine, doxorubicin, and dexamethasone) has been examined in relapsed or refractory CLL.⁴⁵⁰ No CRs were observed, and although 21% had a PR, 33% had progressive disease.

To determine whether aggressive multiagent therapy is better than standard chlorambucil (with or without prednisone) in CLL, a meta-analysis of 10 randomized studies involving 2,035 patients, mostly with Binet stage B and C disease, was carried out comparing chlorambucil with COP, CHOP, and chlorambucil/epirubicin.⁴⁵¹ This analysis did not reveal an improvement in survival by using an anthracycline-containing regimen compared to standard chlorambucil, demonstrating that more aggressive treatment approaches were not required to make an impact on survival.

Bendamustine has demonstrated high activity in CLL.^{432, 452} The drug was developed as an alkylating agent and has three components: (a) a 2-chloroethylamine alkylating group that is seen with the other nitrogen mustards; (b) a butyric side chain that is also contained in chlorambucil, and (c) a benzimidazole ring which is believed to contribute to the unique action of this agent.^{452, 453, 454} Bendamustine produces more extensive DNA cross-linking and breaks than other alkylators, activates a base-excision DNA repair pathway rather than O⁶-alkylguanine-DNA alkyltransferase repair used by chlorambucil and cyclophosphamide, is active against cell lines that are resistant to the nitrogen mustards, and may act through the induction of apoptosis and mitotic catastrophe.^{452, 453, 454} Bendamustine has been compared to chlorambucil in the first-line treatment of CLL (Table 90.11).^{432, 455} Bendamustine produced a higher CR rate, a threefold increase in PFS and time to next treatment (31.7 vs. 10.1 months) but no difference in survival. The quality of life was similar with both drugs and, not surprisingly, patients who were sensitive to either drug had an improved survival. However, adverse events were twofold

P.1913

more common with bendamustine and included skin rashes, marrow suppression, and nausea/vomiting.⁴³² As discussed later, bendamustine is now more typically administered with rituximab.

Nucleoside Analogues

The nucleoside analogues have demonstrated significant activity in the low-grade lymphoproliferative disorders.⁴⁵⁶ Pentostatin (2'-deoxycoformycin;dCF) is an inhibitor of adenosine deaminase, which is responsible for the deamination of deoxyadenosine and adenosine to deoxyinosine and inosine, respectively. After therapy with pentostatin, deoxyadenosine and adenosine accumulate in the plasma; after uptake into cells, deoxyadenosine is phosphorylated to deoxyadenosine monophosphate, deoxyadenosine diphosphate, and dATP, and this occurs preferentially in lymphocytes.⁴⁵⁷ The intracerebral accumulation of deoxyadenosine and adenosine likely causes nausea and vomiting, a major toxicity with this agent.⁴⁵⁸ Cladribine (2-chlorodeoxyadenosine; CdA) and F-ara-A are halogenated derivatives of deoxyadenosine that are resistant to degradation by adenosine deaminase. For clinical use, F-ara-A is administered as the more water-soluble monophosphate, F-ara-adenosine monophosphate (fludarabine); fludarabine is rapidly dephosphorylated in the plasma to F-ara-A.^{459, 460} Like deoxyadenosine, cladribine and F-ara-A are taken up into lymphocytes by a nucleoside transport system and accumulate in lymphocytes as their phosphorylated derivatives. A correlation has been found between the protein levels of the hNT2 transport protein and in vitro cytotoxicity.^{461, 462} The triphosphate derivatives of deoxyadenosine, cladribine, and F-ara-A can kill lymphocytes in three ways.^{52, 463} First, the triphosphate forms can trigger DNA breaks, which result in the release of cytochrome c from the mitochondria; the released cytochrome c interacts with Apaf-1 and dATP causing the activation of caspase 9 and, subsequently, apoptosis. Second, the increased levels of the triphosphates can enhance the effects of endogenous dATP on the apoptosome, inducing apoptosis. Finally, cladribine differs from the other two drugs in that it is phosphorylated by deoxyguanosine kinase in the mitochondria to CdATP, which is directly toxic to the mitochondria.

Pentostatin produces CR and PR rates of 16% to 25% in previously treated patients, with an additional 20% to 30% of patients exhibiting other forms of clinical improvement.^{464, 465} The standard dose is 4 mg/m² intravenously (IV) every other week.^{456, 465} Toxicities include infection, myelosuppression, nausea/vomiting, and pruritus.

Fludarabine has greater activity in CLL and is equally efficacious when administered orally or IV, although a higher dose is required when given orally.⁴⁶⁶ Using 25 to 30 mg/m² IV daily for 5 days, repeated monthly, the overall response rate is approximately 45% in previously treated patients, with the CR rate being 3% to 20%.^{467, 468, 469} In untreated patients, the response rate is approximately 70%, with the CR rate being 20% to 40%.^{429, 469, 470, 471} The main toxicities with fludarabine are myelosuppression and infections, particularly when patients have been previously treated with alkylating agents. Nausea, vomiting, and neuropathy rarely occur. In an attempt to reduce toxicity, fludarabine has been administered as 30 mg/m² IV daily for 3 days, repeated every 4 weeks.⁴⁷² Compared to the standard 5-day treatment schedule, the response rate was lower at 46% (CR, 10%), but there was a significant reduction in the infection rate and no difference in survival. The addition of prednisone does not improve the response rate over fludarabine used alone and significantly increases the risk of unusual infections (e.g., *Pneumocystis jirovecii* pneumonia and *Listeria monocytogenes* sepsis).⁴⁷³ Five major phase III studies have determined whether initial treatment with fludarabine could produce an increased remission rate compared with standard chemotherapy and whether this would translate into improved survival.^{429, 431, 433, 434, 469, 470} A summary of the results of these studies is in Table 90.11.

- In the European Cooperative Group study fludarabine was compared with CAP (cyclophosphamide, Adriamycin, prednisone).⁴⁶⁹ The responses with fludarabine were similar to those
P.1914
for CAP, but the duration of responses was significantly longer with fludarabine with a tendency toward a longer survival.
- In a French Cooperative Group study patients were randomized to CHOP, CAP, or fludarabine.⁴⁷⁰ The response rates were similar for CHOP and fludarabine, and both were better than CAP. However, time to relapse and survival rates were similar regardless of treatment.
- Three groups have compared fludarabine and chlorambucil, and although the doses of fludarabine were similar in all, the dose of chlorambucil was lowest in the North American Inter-Group CLB-9011 study (Table 90.11).⁴²⁹ In this study, there was a higher response rate, longer duration of response, and improved PFS in patients treated with fludarabine but no difference in OS. However, a follow-up analysis at 10 years showed a survival advantage for fludarabine.⁴⁷⁴ In the LRF CLL4 study from the United Kingdom, the response rates were higher for fludarabine than for chlorambucil, but there was no difference in PFS or OS.⁴³³ In the German CLL5 trial only patients >65 years were studied, and fludarabine produced a higher response rate compared to chlorambucil.⁴³¹ Again, there was no difference in PFS or OS.

In CLL, cladribine has been less extensively evaluated than fludarabine but the former probably has equivalent antitumor activity.^{434, 456, 475, 476, 477, 478, 479, 480} The drug is given in monthly cycles, in doses of 0.1 mg cladribine/kg/day by continuous infusion × 7 days,⁴⁷⁷ or 0.12 to 0.14 mg/kg/day over 2 hours × 5 days,^{475, 478} or 10 mg/m²/day orally × 5 days.⁴⁸² The results of studies with cladribine have varied greatly,^{434, 475, 476, 478} with response rates in previously treated patients varying from 48% to 72% and CR rates varying from 4% to 39%.^{456, 475} In previously untreated patients, approximately 80% of patients respond, and the CR rate varies from 10% to 45%.^{434, 456, 475, 479} In a multicenter study with patients randomized to receive initially either cladribine or chlorambucil, and resistant patients being switched to the other drug, cladribine produced a higher remission rate and more prolonged remissions than chlorambucil (Table 90.11).⁴³⁴ However, as with the randomized studies comparing fludarabine with alkylating agents, survival was similar whether the initial treatment was with cladribine or chlorambucil. The variation in the response rates to cladribine in previously treated patients may be related to the extent of prior therapy. In vitro studies have shown that cladribine is more myelosuppressive than fludarabine,⁴⁵⁹ and in the clinical setting, repeated treatments with cladribine can produce

prolonged thrombocytopenia.^{434, 475, 476, 477, 478, 479, 480} As is fludarabine, cladribine is very immunosuppressive, and infections are the major toxicity, particularly when cladribine is given in conjunction with prednisone.^{289, 434, 479}

Neither cladribine nor fludarabine causes the accumulation of adenosine, which likely explains the lack of nausea/vomiting observed with these agents when compared to pentostatin. However, all of these nucleoside analogues can produce neurotoxicity, and peripheral neuropathy is now being documented as a potential devastating toxicity.⁴⁸¹ The nucleoside analogues are all highly immunosuppressive, being both myelosuppressive and producing a marked fall in the CD4⁺ cell count, which may persist for years.⁴⁵⁶ Although initial studies demonstrated that the nucleoside analogues could trigger AIHAs, the frequency of this complication is no greater with the analogues than with other agents.^{433, 434} Graft-versus-host disease has been observed in patients being treated with nucleoside analogues who receive blood transfusions, and it has been recommended that these patients receive only irradiated blood products.⁴⁸² Reports have also indicated a higher incidence of acute myeloid leukemia (AML)/myelodysplasia in patients receiving nucleoside analogues,^{483, 484} and this risk may be further increased in patients receiving a combination of chlorambucil and fludarabine.⁴⁸⁴ Recent studies have demonstrated that fludarabine can be toxic to the lung, in addition to pre-disposing these patients to pneumonia.⁴⁸⁵ Once infections have been ruled out, the pulmonary toxicity syndrome often responds to steroids.⁴⁸⁵

TABLE 90.12 PHASE III STUDIES COMPARING FLUDARABINE AND FLUDARABINE/CYCLOPHOSPHAMIDE (FC) IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Reference	Treatment	Patient Number	CR (%)	PR (%)	PFS ^a	Survival
German CLL Study Group (2006) ⁴⁹³	Fludarabine	164	7	76	Median, 20 mo	3 y, 80.7%
	FC	164	24	70	Median, 48 mo	3 y, 80.3%

	FC	182	38	57	5 y, 36%	5 y, 54%
InterGroup Trial E2997 (2007) ⁴⁹⁴	Fludarabine	137	4.8	54.6	Median, 19.2 mo	2 y, 80%
	FC	141	23.4	50.4	Median, 31.6 mo	2 y, 79%

^a PFS, progression-free survival.

An *in vitro* study has demonstrated cross-resistance between fludarabine and cladribine in the leukemic cells of 90% of patients,⁴⁵⁹ and clinical studies have confirmed that patients resistant to fludarabine are unlikely to respond to cladribine, and vice versa.^{479, 486} In a clinical trial of 28 patients who were resistant to fludarabine, only 1 patient had a PR with cladribine.⁴⁸⁶ Thus, patients who are resistant to one of the nucleoside analogues should not be treated with another, particularly as such therapy increases the risk of infections secondary to myelosuppression and immunosuppression.

Combinations of Nucleoside Analogues with Alkylating Agents

To improve antitumor activity the nucleoside analogues have been combined with other agents. Combined therapy with steroids does not improve the antitumor effect and markedly increases the risk of infection.^{473, 478} *In vitro* studies have demonstrated that the nucleoside analogues can inhibit DNA repair, which explains the synergistic antitumor activity seen between these agents and irradiation or alkylating agents.^{487, 488, 489} Moreover, this effect is seen preferentially in CLL cells compared to normal marrow cells.⁴⁸⁸ Synergy has also been observed between fludarabine and cyclophosphamide in phase II clinical studies.^{490, 491, 492} O'Brien et al.⁴⁹⁰ combined fludarabine 30 mg/m² IV daily × 3 with cyclophosphamide 300, 350, or 500 mg/m² IV daily × 3 and demonstrated a 38% response rate in patients who were resistant to fludarabine alone. In previously untreated patients, more than 80% responded with a 35% CR. Moreover, the duration of response was longer than for fludarabine alone. Similar findings have been observed in 3 large randomized clinical trials^{433, 493, 494} (Table 90.12). The efficacy and toxicity of cladribine with cyclophosphamide is similar

P.1915

to that of FC in previously untreated patients.⁴⁹⁵ Pentostatin has also been combined with cyclophosphamide in one study.⁴⁹⁶ In 23 previously treated patients treated with pentostatin 4 mg/m² IV and cyclophosphamide 600 to 900 mg/m² IV repeated every 3 weeks × 6, 17 patients responded with 4 CRs and 13 PRs. It is important to note that 10 of 13 fludarabine-resistant patients responded with one CR. A concern with combining the nucleoside analogues with alkylating agents is an increased risk of myeloid leukemias, as may be the case when fludarabine and chlorambucil are combined.⁴⁸⁴

A recent systematic review has summarized all these studies.⁴⁹⁷ In brief, the addition of cyclophosphamide to a nucleoside analogue increases the response rates and PFS over single agents but this does not translate into improved survival, likely as a result of effective second-line therapies.

Steroids

As steroids kill CLL cells with a TP53 mutation,⁶⁸ they can be useful for palliation in patients resistant to alkylating agents and nucleoside analogues.⁴⁹⁸ However, as discussed later, nowadays they are usually combined with a monoclonal antibody. High-dose steroids, such as methylprednisolone at 1 gm/m²/day × 5 days, repeated monthly, can be helpful in advanced-stage patients, who are drug resistant and have bulky disease, marrow failure, or both.⁴⁹⁸ In 25 patients treated with methylprednisolone, with or without chemotherapy, the overall response rate was 77% with the median duration of response being 12 months (range, 7-23+). Of the 10 patients with p53 mutations, 5 responded to this therapy. The management of CLL patients maintained on steroids is discussed in the section “Systemic Complications Requiring Therapy.”

Monoclonal Antibodies

Anti-CD20

The cell-surface antigen CD20, plays an important role in the activation, proliferation, and differentiation of B-cells and antibodies to CD20 have transformed the therapy of the B-cell lymphoproliferative disorders.^{499, 500} The chimeric monoclonal antibody, rituximab, contains a human IgG1 Ig constant region and a murine variable region directed against CD20.^{499, 500} This agent was licensed for use in relapsed indolent lymphoma in 1997 by the US Food and Drug Administration (FDA) and since that time many variants of this antibody have been developed, with ofatumumab and GA101 being most studied in the clinic. Rituximab has shown significant activity against low-grade lymphomas, which have high surface concentrations of CD20, and is believed to exert its antitumor activity by complement-dependent cytotoxicity (CDC), antibody-dependent cell-mediated cytotoxicity (ADCC), or by the direct induction of apoptosis. An intact FcγR is required for ADCC and it has been suggested that polymorphisms in FcγRIIIa (CD16) may influence the response to rituximab.⁴⁹⁹ A variety of new anti-CD20 antibodies has been developed to enhance antitumor activity that are humanized, unlike rituximab which is chimeric. The anti-CD20 monoclonal antibodies are classified as type I or type II based on their ability to redistribute CD20 into lipid rafts that can influence antibody activity.⁴⁹⁹ Type I antibodies, exemplified by rituximab and ofatumumab, redistribute CD20 into lipid rafts and potentially activate complement. In contrast type II antibodies, as exemplified by tositumomab and GA101, induce programmed cell death that is independent of caspase activation and DNA breaks, and is not affected by BCL2.^{501, 502, 503} The ability to induce programmed cell death correlates with the induction of intercellular homotypic adhesion which alters the actin cytoskeleton causing permeabilization of the lysosome and the release of cathepsin B into the cytoplasm.^{501, 502, 503} Recent studies suggest that this leads to increased free radical formation from NADPH oxidases, which results in loss of plasma cell membrane and cell death.⁵⁰³ In animal models, the type II antibodies are more effective in clearing CD20 positive lymphocytes from blood and lymphoid organs.⁵⁰⁴

Using the standard rituximab regimen that is effective in follicular lymphomas (375 mg/m² IV weekly × 4), initial studies showed that rituximab had little activity in CLL (13% response rate), compared to a 50% response rate in the follicular lymphomas.⁵⁰⁵ This decreased activity was attributed to the low levels of CD20 on CLL cells and the high plasma CD20 levels observed in CLL; the high plasma CD20 levels are believed to divert rituximab from the cellular target and to reduce the half-life of the antibody.⁵⁰⁶ The plasma CD20 is believed to be derived from cell breakdown, and the level correlates with disease stage but not the lymphocyte count.⁵⁰⁶ However, 2 studies have shown that rituximab can rapidly, albeit transiently, reduce the peripheral lymphocyte counts of CLL patients.^{507, 508} The treatment had little effect on lymphadenopathy and did not normalize blood counts, and this discrepancy has been related to the fact that the CLL CD20 levels are lower in the nodes and marrow than in the peripheral blood.⁵⁰⁹ In an attempt to increase the effectiveness of rituximab in CLL, the dose of rituximab has been escalated, using either a weekly or thrice weekly schedule, and response rates of 36% to 45% have been achieved without a significantly higher toxicity than is observed with the standard schedule.^{510, 511} Of special interest is the observation that “shaving” or removal of CD20 and rituximab from the CLL surface by monocytes and macrophages results in the appearance of CLL cells in the circulation that have neither CD20 nor rituximab on their surface.⁵¹² This occurs primarily with high doses of rituximab, raising the question as to whether rituximab would be best administered using lower doses applied more frequently.⁵¹³

Rituximab can cause reactions (e.g., fevers/rigors, dyspnea, hypotension, and nausea/vomiting) as a result of the release of inflammatory cytokines (e.g., IL-6, IL-8, TNF-α, and γ-interferon) and this complication primarily occurs in patients with lymphocyte counts of greater than 50 × 10⁹/L.^{507, 508, 510, 511} The reactions usually occur with the first treatment, and the

likelihood of a reaction decreases with each subsequent treatment. Pretreatment with steroids and “stepped-up dosing” decreases the severity or likelihood of a reaction.⁵⁰⁸ More recently, the development of immune neutropenia has been observed after rituximab and usually resolves spontaneously in 1 to 3 weeks or in 3 to 5 days with G-CSF.⁵¹⁴

Rituximab has been administered with high-dose methylprednisolone for patients with high-risk disease including those with deletions of 17p13 and 11q22-23.^{515, 516} Approximately two-thirds of patients will respond with a median PFS of 1 year, and main side effects include hyperglycemia and fluid retention.

Ofatumumab is a fully human type I monoclonal antibody directed against a different epitope on CD20 that results in tighter binding and increased complement activation.^{499, 517} The pivotal study by Wierda et al.⁵¹⁸ showed a response rate of 58% in patients who were resistant to fludarabine and alemtuzumab (FA) and 47% in patients who were resistant to fludarabine with bulky (>5 cm) lymphadenopathy (BF). The median PFS and OS were 5.7 and 13.7 months for the FA group and 5.9 and 15.4 months for the BF group. The treatment schedule was with 8 weekly treatments followed by 4 monthly treatments. The first infusion was with 300 mg followed by 2,000 mg for all other infusions. Treatment was well tolerated and the FDA subsequently licensed ofatumumab for patients resistant to FA. A subsequent analysis indicated that rituximab-resistant patients had a similar response to ofatumumab as patients who were rituximab-naïve.⁵¹⁹ Ofatumumab has been administered with high-dose steroids with two-thirds of patients with fludarabine resistance and bulky lymphadenopathy responding.⁵²⁰ This included patients with deletions of 17p13, where the response to ofatumumab alone is 14%.⁵¹⁸

P.1916

GA101 (obinutuzumab) is a humanized type II antibody with a novel mechanism of action and is presently being evaluated against rituximab in a number of clinical trials for CLL.⁴⁹⁹

Anti-CD52

The monoclonal antibody, alemtuzumab (Campath-1H), is a humanized IgG1 antibody against CD52, with the antigen-binding site being of rodent origin; targets are B and T lymphocytes, NK-cells, monocytes and eosinophils with sparing of normal hematopoietic stem cells.^{521, 522} As with rituximab, alemtuzumab can kill tumor cells by CDC, ADCC, or the direct induction of apoptosis and has become an important agent for the treatment of fludarabine-resistant patients with deletions of 17p13 or 11q22-23.^{521, 522} In the pivotal CAM 211 multicenter study on 93 patients with fludarabine-resistant disease, patients were treated for 12 weeks with alemtuzumab.⁵²³ The CR rate was 2%, PR rate 31%, and 54% of patients had stabilization of their disease. Many patients with symptoms such as night sweats, fatigue, or weight loss had resolution of their symptoms. The median time to response was 1.5 months and median time to progression was 4.7 months for all patients and 9.5 months for responders. Median survival for all patients was 16 months and 32 months for responders. As an historical comparison, the median survival of fludarabine-resistant CLL patients is 10 months.⁵²³ Alemtuzumab was particularly efficacious at clearing the peripheral blood (first) and marrow/spleen (later) of CLL cells, but was less active against lymphadenopathy. Lymphadenopathy resolved in two-thirds of patients but no patient with nodes >5cm had complete resolution of lymphadenopathy. Unfortunately, patients had infusion-related toxicities (i.e., nausea/vomiting, fevers, rigors, and rash) with the initiation of treatment and there was an increased incidence of infections. Patients were maintained on prophylactic trimethoprim/sulphamethoxazole and famciclovir until 2 months after treatment was completed. Infections occurred in 55% of patients and CMV reactivation was the most common opportunistic infection. Because of the high risk of infections with alemtuzumab, especially in heavily pretreated patients, care must be used in patients who had previous infections or a poor performance status. To reduce the risk of CMV valganciclovir 450 mg twice a day has been recommended although 900 mg 3 times a week may also be effective and produce less myelosuppression.^{524, 525} Guidelines are available for the use of alemtuzumab, particularly with regard to prophylactic antibiotics and CMV monitoring.^{366, 522}

Alemtuzumab appears to have equivalent clinical activity when administered subcutaneously (sc), even though it takes longer to achieve a steady plasma concentration of antibody.^{526, 527} Thus, Stilgenbauer et al.⁵²⁶ were able to reproduce the results of the CAM 211 study using sc alemtuzumab. Of patients receiving sc alemtuzumab, 90% have local injection-site reactions, with erythema/edema, pruritus, and pain at the site of injection. However, the reactions disappear with continued treatments, usually within 2 weeks. During the initial 2 weeks, the local reactions can be controlled by ice-packing the injection site before the injection and for about 1 hour after the injection. Alemtuzumab has also been evaluated as front-line therapy in 2 studies.^{430, 528} Of 41 previously untreated CLL patients receiving sc alemtuzumab, 38 received more than 1 week of therapy, and in this group, the CR rate was 19% and the PR rate 68%.⁵²⁸ Consistent with

these findings, the CR and PR rates with alemtuzumab in the CAM 307 study were 22% and 61%, respectively.⁴³⁰ Following alemtuzumab therapy in previously untreated patients, the lymphocyte subtypes gradually recover, but remain at <25% baseline for >9 months following therapy.⁵²⁸ Despite this, infections were not a problem.

Because of its unique properties, there has been interest in evaluating alemtuzumab for the treatment of patients with resistant disease.^{225, 529} Of 36 fludarabine-resistant patients treated with alemtuzumab, 15 (42%) had TP53 mutations and/or deletions and 6 of the 15 (40%) responded to alemtuzumab.²²⁵ The median duration of response was 8 months (range, 3 to 17 months). When used as initial therapy in previously untreated patients, the response rates for 7 patients with a deletion of 17p13 was 64%.⁴³⁰ Alemtuzumab has also been administered following standard chemotherapy for the purpose of consolidation.^{530, 531, 532} In these studies the dose and duration of alemtuzumab ranged from 10 to 30 mg 3 times a week for 4 to 12 weeks. The CR and MRD-negative responses can be increased with this therapy and this is associated with a longer PFS. However, these positive effects are counterbalanced by an increased risk of infections and the development of Epstein-Barr positive large-cell lymphomas.^{530, 531, 532} Until further studies direct otherwise, the use of alemtuzumab in front-line therapy or for the purpose of consolidation should be confined to clinical trials.

Alemtuzumab has been combined with high-dose steroids in 17 untreated and 22 previously treated patients with a deletion of 17p13.⁵³³ The overall response rate and CR rate were 85% and 36%, respectively, with a median OS of 23.5 months demonstrating the effectiveness of the regimen in this high-risk group of patients. Side effects included hypokalemia, hyperglycemia, and infections. Two-thirds of patients needed granulocyte colony-stimulating factor for neutropenia, half needed (val)ganciclovir for CMV reactivation. Although grade 3 to 4 infection occurred in half the patients, this was age-related and only occurred in 29% of patients less than 60 years of age. Alemtuzumab has also been combined with rituximab in patients with molecular markers indicative of aggressive disease.⁵³⁴ Patients received alemtuzumab 30 mg subcutaneously 3 times a week for 4 weeks with rituximab 375 mg/m² weekly for 4 treatments. Of 30 patients, 90% responded with 37% CRs, and the median duration of response of responders was 14.4 months. Neutropenia was common and CMV reactivation occurred in 10%.

Anti-CD23

The anti-CD23 antibody, lumiliximab, has limited activity alone but results of a phase I/II study suggests that the addition of lumiliximab with FCR may increase the response rate without additional toxicity.⁵³⁵

Chemoimmunotherapy

Combinations with anti-CD20 Antibodies

Combinations with Rituximab

Synergy has been demonstrated between rituximab and chemotherapy *in vitro*, although the mechanisms underlying this phenomenon are unclear.^{536, 537, 538} Synergy may be related to effects of rituximab on the levels of antiapoptotic proteins, as rituximab reduces the cellular levels of BCL2 through inhibition of IL10 in lymphoma cell lines *in vitro*,⁵³⁷ and the levels of MCL1 and XIAP are decreased in the CLL cells of patients undergoing treatment with the antibody.⁵³⁹ Alternatively, fludarabine may down-regulate the expressions of CD46 and CD55 on the CLL cells, proteins that antagonize the effects of activated complement.⁵³⁸

Fludarabine has been combined with rituximab (FR) in the clinic.^{540, 541, 542, 543} In one study, 31 previously treated or untreated CLL patients received 4 monthly cycles of fludarabine (25 mg/m² IV daily × 5 days) combined with 4 monthly treatments with rituximab (375 mg/m² IV), the first 2 rituximab treatments given with the last 2 cycles of fludarabine.⁵⁴⁰ The CR rate was 33%, the PR rate was 55%, and treatment was well tolerated. Byrd et al.⁵⁴¹ compared concurrent versus sequential treatment with fludarabine and rituximab in untreated CLL patients (CALGB 9712). There were 51 patients who received 6 cycles of fludarabine followed by 4 weekly treatments with rituximab (sequential

P.1917

regimen), and 53 patients who received 6 cycles of concurrent fludarabine and rituximab followed by consolidation with 4 weekly treatments with rituximab. In the concurrent regimen, there were 47% CRs and 43% PRs, whereas the sequential regimen appeared less effective with 28% CR and 49% PR. Treatment was generally well tolerated; infusion-related toxicity, myelosuppression, and infections were the major toxicities. A follow-up analysis showed that both groups had a similar outcome with the combined median PFS being 42 months and the median OS being 85 months.⁵⁴³ A retrospective comparison has been made to patients treated with fludarabine alone (CALGB 9011).⁵⁴² The CR and PR rates in the CALGB 9011 study were 20% and 43%, respectively, and the CR and PR rates in the CALGB 9712 study (all patients) were 38% and 46%, respectively. The 2-year PFS and OS for patients receiving fludarabine were 45% and 81%, respectively, and for

patients receiving fludarabine with rituximab were significantly better at 67% and 93%, suggesting that the addition of rituximab in first-line therapy prolongs survival.

The MD Anderson Cancer Center developed the combined fludarabine with cyclophosphamide and rituximab (FCR) regimen using fludarabine 25 mg/m² and cyclophosphamide 250 mg/m² administered IV on days 1, 2, and 3 with rituximab 375 mg/m² IV on day 1 with the first course and then 500 mg/m² IV for courses 2 to 6. The treatments were given every 28 days for 6 cycles for the treatment of both untreated and previously treated patients (Table 90.13).^{544, 545, 546} In 224 previously untreated patients the CR, nPR, and PR rates were 72%, 10%, and 13%, respectively.⁵⁴⁵ A retrospective comparison among fludarabine, FC, and FCR also suggested that FCR increased OS, with OS at 6 years being 54%, 59%, and 77% for patients treated with fludarabine, fludarabine and cyclophosphamide/mitoxantrone, or FCR.⁵⁴⁵ The subsequent CLL8 prospective randomized phase 3 study from the German CLL Study Group confirmed these findings. FCR has subsequently become a standard first-line therapy for selected patients (Table 90.13). Previously untreated patients were randomized to FCR or FC using the MD Anderson treatment regimens. As FCR is an aggressive treatment regimen, patients were required to have an Eastern Cooperative Oncology Group (ECOG) performance status of 0 to 1, a cumulative illness rating scale (CIRS) of 6 or less, and a creatinine clearance of ≥70 ml/min. Prophylaxis with antivirals was not given and prophylaxis against *Pneumocystis jirovecii* only recommended for severe leukopenia lasting >7 days. Approximately one-quarter of patients in both the FC and FCR groups were unable to tolerate the full 6 cycles of therapy and drug dosages had to be reduced by >10% in 47% of patients on FCR and 27% of patients on FC. The CR and PR for FCR were 44% and 46% and for FC were 22% and 58% (p = <0.0001). The median PFS was 51.8 months with FCR and 32.8 months with FC (p < 0.001) whereas OS at 3 years was 87% with FCR and 83% with FC (p = 0.01) (Figs. 90.10 and 90.11). Although an improvement in CR rate was seen for all Binet stages with FCR, only Binet stage B showed an improvement in PFS and OS with chemoimmunotherapy. The response of patients with a deletion of 17p13 was equally poor for patients treated with FCR or FC, and although PFS was increased with FCR (11.3 vs. 6.5 months, p = 0.019) there was no improvement with survival. However, supporting a previous observation,³⁸⁸ FCR overcame the poor prognosis associated with FC in patients with a deletion 11q22-23, with an improved CR rate (51% vs. 15%, p = <0.0001), prolonged PFS at 3 years (64% vs. 32%, p = <0.0001), and increased OS at 3 years (94% vs. 83%). FCR caused more neutropenia than FC, and neutropenia and infections occurred more commonly in those >65 years. Deaths related to both regimens only occurred in 2% to 3% of patients, and it should be emphasized that these patients were carefully chosen according to performance status, comorbidities, and renal function. In addition, the median age of patients was only 61 years.

^a A, alemtuzumab; C, cyclophosphamide; F, fludarabine; FluCam, fludarabine/alemtuzumab; P, pentostatin; R, rituximab.

^b Median PFS was 32.8 mo with FC and 51.8 mo with FCR ($p < 0.001$). Overall survival at 37.7 months was 84.1% with FCR and 79.0% with FC ($p = 0.01$). Patients with Binet stage B disease primarily benefited from the addition of rituximab.

^c nPR and PR were combined.

^d High-risk patients with a $\beta 2$ -microglobulin of ≥ 4 mg/L and aged < 70 years.

^e Dose of pentostatin, 2 mg/m².

^f Dose of pentostatin, 4 mg/m².

The MD Anderson studies have demonstrated that about 20% of patients can have cytopenias lasting longer than 3 months following FCR and that 28% of patients whose blood counts have recovered following treatment can have a late cytopenia that usually occurs in the first year of remission.⁵⁴⁵ The incidence of immune cytopenias was reported to be 6.5% in the MD Anderson series with AIHA typically occurring between cycles 3 and 6 and most patients responding to standard therapies.³¹⁹ In contrast, in the CLL8 study, only 1% of patients developed immune cytopenias. In addition, the risk of serious or opportunistic infections at the MD Anderson was 10% and 4% in the first and second

P.1918

years of remission, respectively, with a relatively high incidence of shingles at these times. In addition, 4.5% of patients developed AML or myelodysplasia, with the median onset from the initiation of chemotherapy being 35 months (median, 3 to 118 months).⁵⁴⁷ Thus, although FCR is a highly effective therapy, there are significant toxicities and care must be taken in deciding which patients require, and/or can tolerate, this treatment. Patients with deletion 11q22-23 should receive FCR, if possible, Results of the CALGB 10404 study, comparing the front-line activities of FR and FCR in CLL, should help clinicians individualize treatment.⁵⁴³

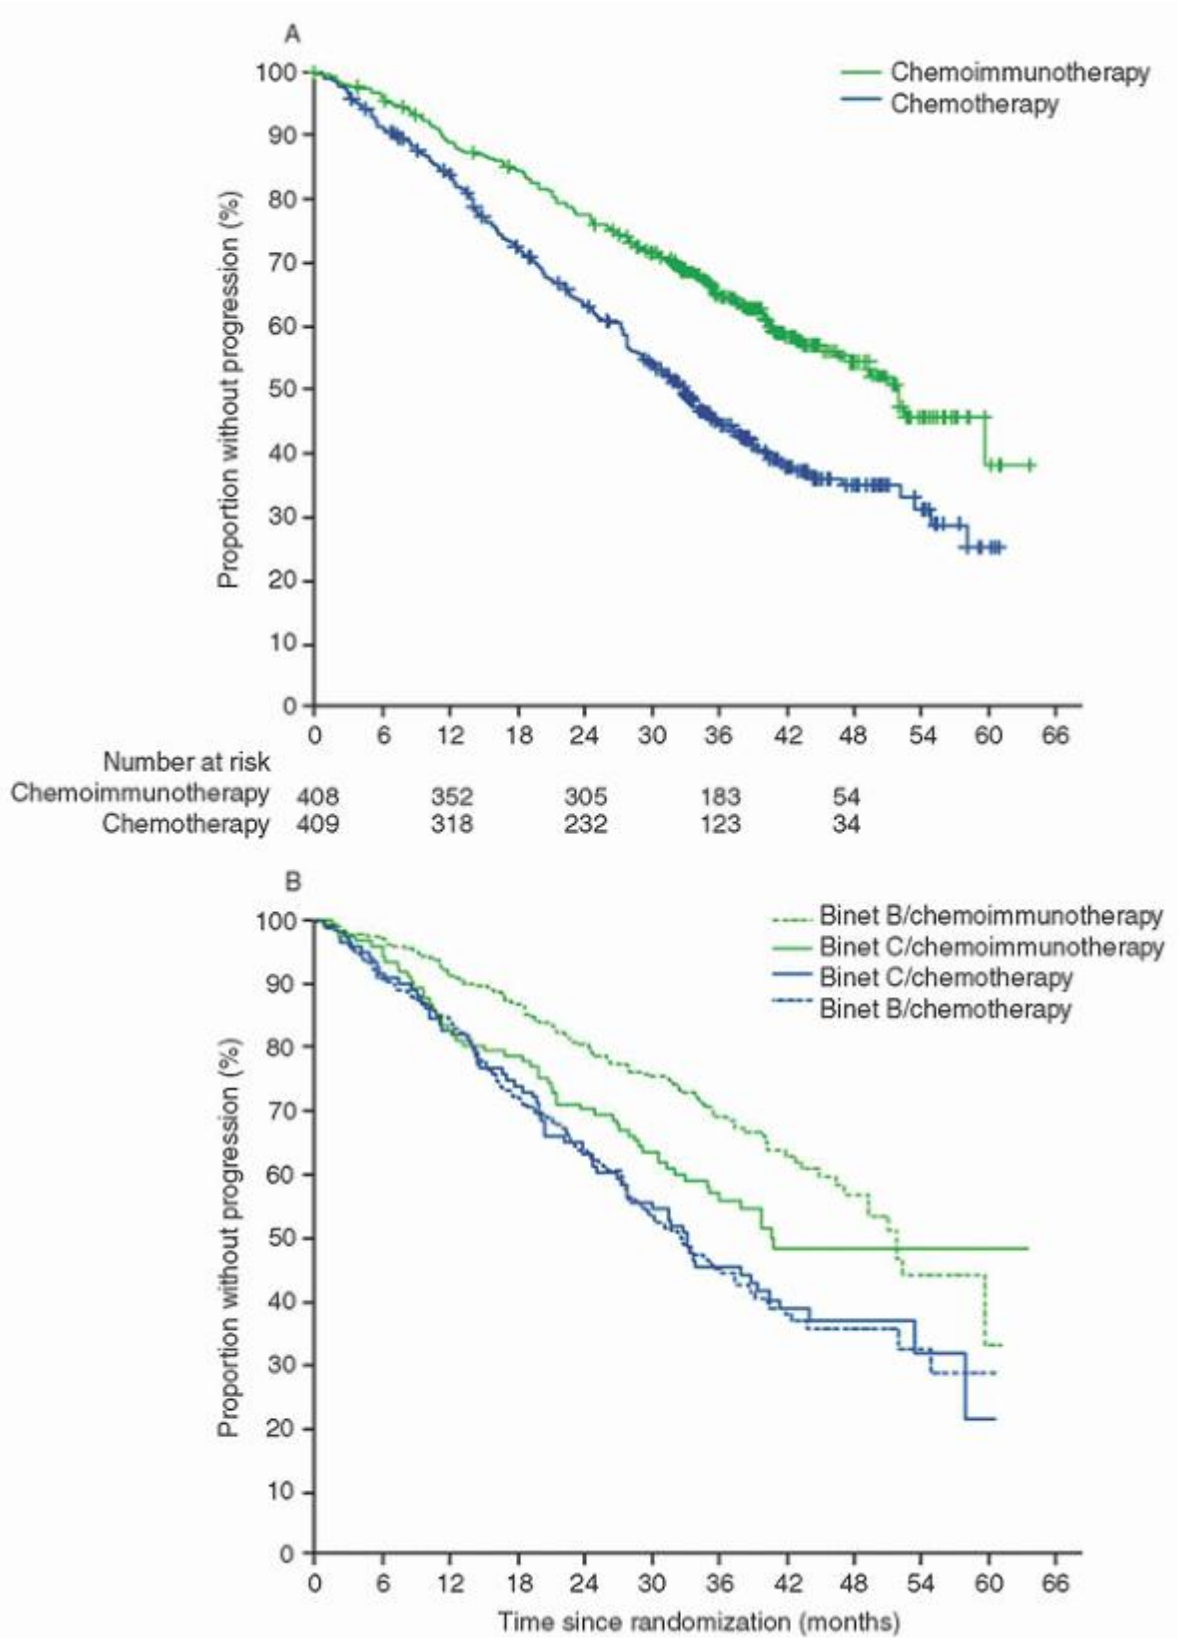

FIGURE 90.10. Progression-free survival in all patients and in patients with Binet stage B and C chronic lymphocytic leukemia. From Hallek M, Fischer K, Fingerle-Rowson G, et al. Addition of rituximab to fludarabine and cyclophosphamide in patients with chronic lymphocytic leukemia: a randomised, open-label, phase 3 trial. *Lancet* 2010;376:1164-1174.

To enhance activity, mitoxantrone has been added to the FCR regimen (R-FCM).⁵⁴⁸ In patients less than 70 years old, the response rate was 93% with 82% CR (46% MRD negative) with marrow suppression being the primary toxicity. Again, patients with high tumor burden, deletion 17p13, and high β 2-microglobulin levels did poorly. These patients received maintenance rituximab which will make it difficult to compare the effects on PFS and OS with the FCR studies where maintenance rituximab was not given.

Variations in FCR have been developed to reduce the significant myelosuppression of FCR. In one regimen, patients received 6 cycles of reduced doses of fludarabine and cyclophosphamide with increased doses of rituximab followed by maintenance rituximab every 3 months until relapse.⁵⁴⁹ This regimen decreased myelosuppression without compromising the response rate, but effects on survival are not yet known. Pentostatin has been substituted for fludarabine, as it is less myelotoxic.^{550, 551} Using pentostatin 2 mg/m² IV, cyclophosphamide 600 mg/m² IV, and rituximab 375 mg/m² IV, repeated every 3 weeks for 6 cycles the CR, nPR, and PR rates were 41%, 22%, and 28%, respectively, in 64 previously untreated patients.⁵⁵⁰ In contrast to FCR, patients >70 years of age appeared to do particularly well with

P.1919

this regimen having similar response rates and toxicities as seen with younger patients. The regimen appeared to be less myelotoxic than FCR and although patients with 11q22-23 deletions did as well as patients without high-risk cytogenetics, patients with deletions of 17p13 did not respond to PCR. Pentostatin and rituximab have been evaluated in 33 patients using a higher dose of pentostatin (4 mg/m²) than for PCR.⁵⁵¹ The CR was 27%, nPR 15%, and PR 33%, confirming the importance of additional cyclophosphamide to enhance response rate.

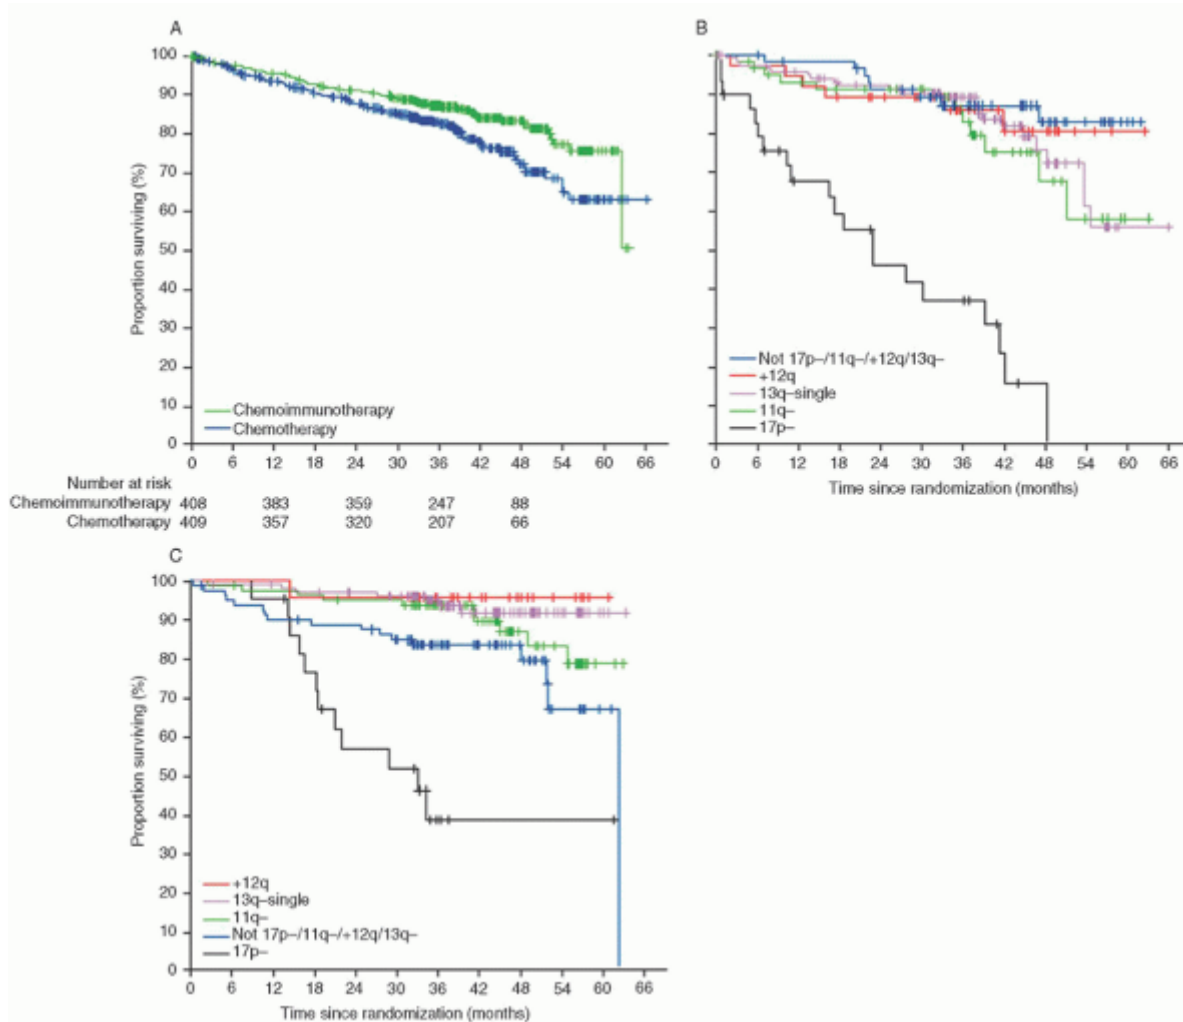

FIGURE 90.11. Overall survival in all patients (A), and in genetic subgroups of chemotherapy (B) and chemoimmunotherapy groups (C). Chemoimmunotherapy = fludarabine, cyclophosphamide, and rituximab. Chemotherapy = fludarabine and cyclophosphamide. From Hallek M, Fischer K, Fingerle-Rowson G, et al. Addition of

rituximab to fludarabine and cyclophosphamide in patients with chronic lymphocytic leukemia: a randomised, open-label, phase 3 trial. *Lancet* 2010;376:1164-1174.

Bendamustine has been combined with rituximab (BR) for 117 previously untreated CLL patients.⁵⁵² The CR was 23% and PR 65% with a median estimated event-free survival of 34 months. Marrow toxicity occurred in half the patients and although neutropenia appeared to be less than in the CLL8 study, there was a higher incidence of anemia and thrombocytopenia. Whether BR is better than FCR is being evaluated in the phase III German CLL10 study. Bendamustine/rituximab has also been evaluated in 78 previously treated CLL patients, of whom 22 were fludarabine-resistant and 14 had a deletion of 17p13.⁵⁵³ The CR, nPR, and PR rates were 9%, 3%, and 47%, respectively, and the median event-free survival was 14.7 months.

Combinations with Ofatumumab

Ofatumumab has been combined with fludarabine and cyclophosphamide (O-FC) for previously untreated CLL patients and has comparable activity to FCR.⁵⁵⁴

Combinations with anti-CD52 Antibody

Alemtuzumab may reverse drug resistance, as 1 CR and 4 PR were obtained in 6 fludarabine- and alemtuzumab-resistant CLL patients treated with a combination of FA.⁵⁵⁵ Sayala et al.⁵⁵⁶ administered alemtuzumab 30 mg sc 3 times a week with oral fludarabine 40 mg/m² for 3 consecutive days every 4 weeks to 17 fludarabine-resistant CLL patients who were not responding (NR) or had only a PR to alemtuzumab alone. Three patients responded

P.1920

(2 NR to a PR and 1 PR to a CR). Elter et al.⁵⁵⁷ administered FluCam (fludarabine 30 mg/m² IV with alemtuzumab 30 mg IV for 3 consecutive days every 4 weeks for 6 cycles) to 36 heavily pretreated patients. The CR and PR rates were 30% and 53% with the median time to progression being 13 months with an OS of 36 months. Of 9 fludarabine-refractory patients, 6 responded to FluCam. This combination was well tolerated and there were few infections. A subsequent study in previously treated patients who were sensitive to fludarabine or alemtuzumab (response to either agent had lasted >12 months) demonstrated improved survival when patients were treated with FluCam as compared to fludarabine.⁵⁵⁸ The CR and PR rates were 13% and 69% for FluCam and 4% and 71% for fludarabine, respectively. The PFS was significantly longer for FluCam (23.7 months vs. 16.5 months, $P = 0.0003$) and although the median OS was not reached for FluCam it was 52.9 months for fludarabine ($P = 0.021$). However, it is unclear how many of these patients had been treated with rituximab-containing regimens, and so the clinical applicability of the study is unclear. A small study using FluCam in elderly patients (median age 66 years) with deletions of 17p13 or p53 mutations showed that 6 of 7 patients achieved a CR and one a PR, with excellent tolerability.⁵⁵⁹ The likelihood of response diminished and the incidence of complications increased when previously treated patients received FluCam.

A clinical trial with alemtuzumab in combination with fludarabine and cyclophosphamide (FCCam) for relapsed or refractory CLL was discontinued because of myelotoxicity, infections, and a treatment-related mortality (TRM) of 9%.⁵⁶⁰ The response rate also did not appear to be as high as FluCam or FCR.⁵⁶⁰ In addition, a prospective phase III trial comparing FCR with FCCam in previously untreated patients showed that FCCam produced a lower response rate and was more toxic than FCR.⁵⁶¹

The MD Anderson has combined FCR with alemtuzumab (CFAR) both in previously untreated and treated patients.^{562, 563} In untreated patients <70 years and with a β 2-microglobulin ≥ 4 mg/dl, the CR, nPR, and PR rates were 70%, 3%, and 18%, respectively, with a median PFS of 38 months.⁵⁶² These results did not appear to be significantly better than expected with FCR. For heavily pretreated patients, the CR, nPR, and PR rates were 29%, 4%, and 33%, respectively, but the estimated PFS of 10.6 months and OS of 16.7 months was similar to that observed with FCR.⁵⁶³ Moreover, the infection rate was higher with CFAR. Thus, the addition of alemtuzumab to FCR appears to increase toxicity without significant benefit.

New Agents

A number of new agents are under development but only those agents already available for clinical use or hold promise are discussed (Fig. 90.12).⁵⁶⁴

CDK Inhibitors

Flavopiridol is one of a number of CDK inhibitors and is active in CLL, producing responses in 50% of resistant patients, including those with loss of TP53 function.⁵⁶⁵ Indeed, the drug is so effective that the major side effect is tumor lysis. The

mechanism of action of flavopiridol, and probably other CDK inhibitors, is likely through the inhibition of CDKs, the inhibition of transcription with a reduction in mcl-1 and XIAP, and the induction of endoplasmic reticulum stress.⁵⁶⁶

Inhibition of BCL2

A number of drugs have been developed to inhibit BCL2, which is increased in CLL. ABT-263 (Navitoclax) is a potent inhibitor of BCL2, BCLXL, and BCLW and potently induces cell death in CLL cells in vitro. In initial studies in heavily pretreated patients, one third of patients achieved a PR.⁵⁶⁴

Immune Modulation

Lenalidomide has multiple mechanisms of action in CLL affecting angiogenesis, cytokine levels, and the microenvironment. In refractory CLL, lenalidomide can produce responses in up to one third of patients with major toxicities including marrow suppression and tumor flare, which can be controlled with prednisone.⁵⁶⁷ Because of the risk of tumor lysis syndrome, it has been suggested to start lenalidomide using 2.5 mg/day with monthly escalations up to 20 mg/day.^{568, 569} The median dose achieved varies between 5 and 15 mg/day, depending on the extent of prior treatment and patient age.^{567, 568, 569, 570} The dose-limiting toxicity is marrow suppression although most patients have side effects with higher drug doses, including fatigue, bowel disturbance, and skin rash.^{567, 568, 569, 570} In previously untreated patients, approximately two-thirds of patients respond with up to 15% CRs.^{569, 570} In a study on patients >65 years, response depended on the drug dose with the median achieved being 5 mg/day.⁵⁷⁰ A total of 10% achieved a CR, 5% CR with residual cytopenias, 7% nodular PR, and 43% PR. Interestingly, serum Ig increased with lenalidomide and there was a fall in CCL3 and CCL4. However, the drug needs to be given continuously and patients with deletion 17p13 respond less well than other patients.⁵⁷⁰

Effectors of the Microenvironment

With the understanding of the importance of the BCR pathway for cell survival and proliferation in CLL, a number of drugs have been developed to inhibit different stages in the pathway and have recently been reviewed.^{110, 111} These include a SYK kinase inhibitor (fostamatinib); a Lyn/BTK inhibitor (dasatinib); and perhaps the two most exciting drugs, the PI3-kinase delta inhibitor, GS-1101 (formerly CAL-101) and the BTK inhibitor ibrutinib (PCI-32765).^{571, 572} In early studies these agents have demonstrated remarkable activity with little toxicity and there are a large number of ongoing studies evaluating these novel agents, either alone or in combination with standard therapies.

Treatment of Resistant Disease

The majority of CLL patients will initially respond to therapy resistance, however, they will eventually develop resistance, and these patients become progressively more difficult to treat.^{564, 573} The definition of drug resistance is a lack of response to treatment or relapse within 6 months and is based on the original definition by Keating et al.⁴⁰⁷ where the median survival of patients who were fludarabine-resistant was 10 months. However, nowadays, most patients will be treated initially with chemoimmunotherapy and may relapse 2 to 3 years later with refractory disease, where the time of relapse has just been postponed because of the more effective initial treatment. Thus, as opposed to "fludarabine-refractory" CLL, it is preferable to describe resistance as "refractory" CLL.⁵⁷³ As discussed in the section, "Molecular Genetics," approximately 45% of patients who are fludarabine-resistant have either deletions of 17p13 or p53 mutations, with the site of mutation influencing drug resistance.^{392, 393, 394, 395} Of the remaining 55% of cases approximately 20% will have a deletion of 11q22-23. Mutations of NOTCH1, SF3B1, and BIRC3 have also been associated with refractory disease.^{226, 227, 228, 229, 230, 231, 233, 392}

Thus, it has been suggested that CLL patients can be divided into three groups: (a) "highest-risk" where patients are unlikely to respond to chemotherapy, and these patients include those with a TP53 mutation/17p13 deletion, are resistant to fludarabine, or relapse within 2 years of FCR (approximately 20% (b)); (b) "high-risk" where patients are likely to relapse early after chemotherapy, and these include patients with a high β 2-microglobulin, deletion of 11q22-23 or unmutated IgV_H; and (c) "low-risk" where patients are untreated and have no TP53 mutations/deletions, no deletions

P.1921

of 11q22-23, mutated IgV_H, and low β 2-microglobulin.⁵⁷³ Patients in the highest-risk group should be considered for investigational agents, alemtuzumab, and allogeneic HCT. Patients in the high-risk group should receive FCR and an investigational agent to try to maintain the remission. Low-risk patients should be treated with FCR or an alternative regimen.^{573, 574}

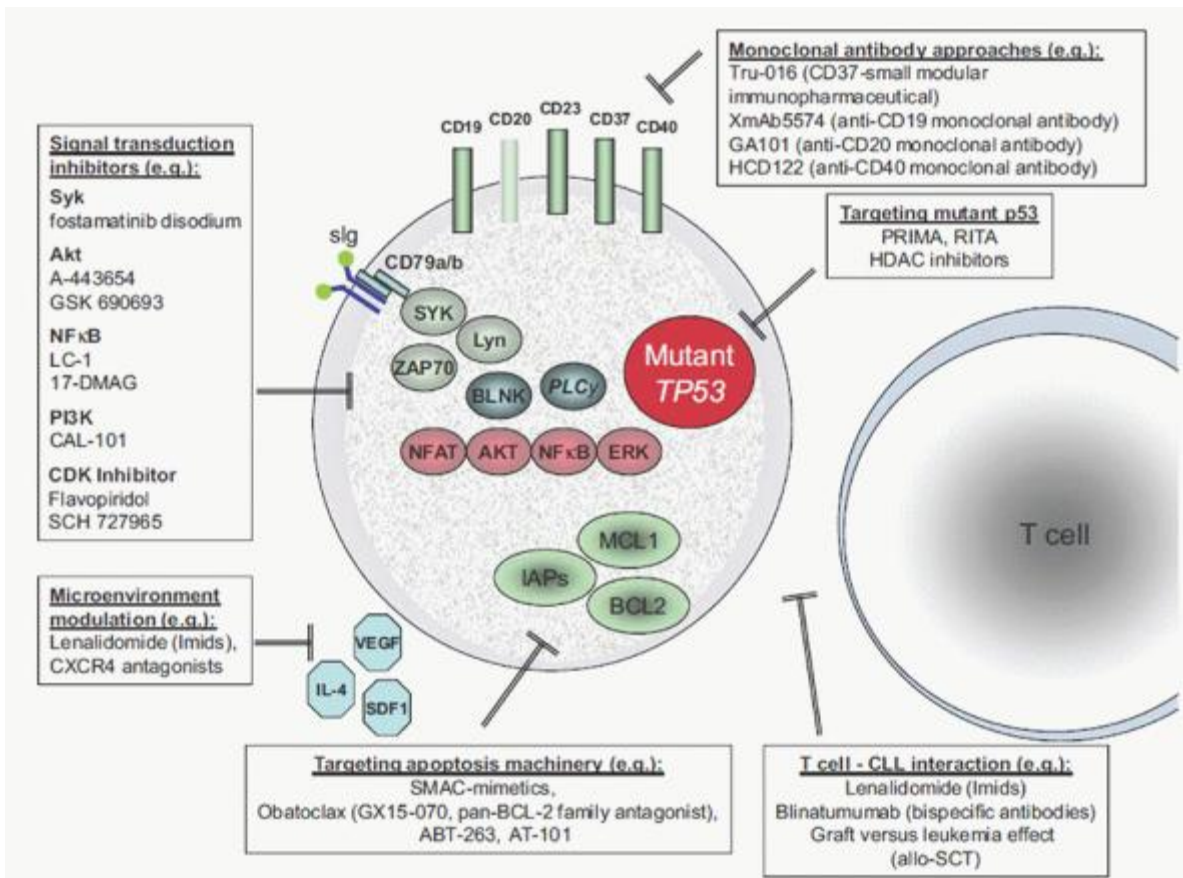

FIGURE 90.12. Selection of targets and novel agents in early clinical trials of CLL. There are multiple “biologic” therapeutic approaches in current clinical development in CLL. Signal transduction inhibition will often target the B-cell receptor cascade, which has been shown to be critical to CLL cell survival. A number of surface molecules of CLL cells can be targeted by antibodies. Different members of the apoptosis machinery are targets currently explored in clinical trials. Microenvironmental stimulation and T-cell interaction are of critical importance for CLL cell survival, and are being increasingly utilized for treatment strategies. There is ongoing interest in using mutant p53 as a “druggable” target, and a number of agents have been identified that may preferentially target mutant p53.³⁴ Improving efficacy in CLL with p53 pathway defects is likely to offer the greatest overall benefit. From Stilgenbauer S, and Zenz T. Understanding and managing ultra high-risk chronic lymphocytic leukemia. Hematology (Am Soc Hematol Educ Program) 2010;2010:481-488, with permission.

Hematopoietic Stem Cell Transplantation

Because CLL is not curable with standard therapy, HCT is worthy of consideration, particularly in younger patients who are more able to withstand this potentially arduous therapy. In addition, recent advances in the identification of clinical or biologic risk factors indicative of aggressive disease (i.e., fludarabine resistance, or deletions of 17p13) have permitted the recognition of patients who have a very poor prognosis with standard therapy and may benefit from HCT. As genomic abnormalities are known to develop over time in CLL, it is reasonable to consider early transplantation in these patients, before the development of drug resistance and even more aggressive disease. Detailed reviews have recently been published on the subject.^{575, 576, 577}

Autologous Transplantation and Cellular Therapy

The dose intensity of the preparative regimen is of critical importance for autologous HCT (autoHCT), as the intent of such myeloablative chemotherapy and/or radiotherapy is to eradicate residual CLL. This is followed by the reinfusion of autologous hematopoietic progenitor cells that are hopefully free of residual CLL cells. Until recently, autoHCT had been an attractive option in CLL, as the TRM of this procedure is relatively low and durable remissions were achievable.^{578, 579} However, subsequent randomized controlled trials demonstrated that autoHCT, when used as consolidation after first-line therapy, offers no survival advantage over observation⁵⁸⁰ or standard dose chemotherapy.⁵⁸¹ In addition, the German CLL study group compared the results of their single arm trial of autoHCT as first-line therapy for CLL to the outcomes in a

similar cohort of CLL patients who received first-line FCR. Survival was no better in the autoHCT cohort.⁵⁸² An additional concern with autoHCT is that of treatment-related myelodysplasia/acute myeloid leukemia (MDS/AML). The incidence of AML/MDS for CLL patients 5 years post-autoHCT is as high as 12.4%.⁵⁸³ Taken together, before autoHCT can be revisited as a therapeutic tool in CLL, new approaches are needed to

P.1922

improve methods of in vivo or ex vivo purging of CLL cells in the harvested autologous cells, the choice of conditioning regimens, post-autoHCT maintenance therapy, or the induction of an autologous graft-versus-CLL effect.

Chimeric Antigen Receptor Modified T-cells

The induction of autologous T-cells that are reactive against CLL cells represents a highly promising form of cellular therapy. This concept has led to early-phase clinical trials using chimeric antigen receptor modified T-cells (CARTs). Autologous T-cells are genetically modified to express chimeric antigen receptors, with T-cell specificity against the CD19 bearing B-cells found in CLL and other lymphoid malignancies.^{584, 585} These CLL-specific T-cells are then re-infused into recipients. Preliminary clinical results suggest that such therapy has the ability to achieve rapid and profound responses in heavily treated, chemorefractory CLL patients. However, despite their exciting potential, further data will be required before such strategies can be adopted into widespread clinical practice.

Allogeneic Transplantation

Whereas autoHCT primarily depends on dose intensity to eradicate CLL, allogeneic HCT (alloHCT) offers the added advantage of adoptive cellular immunotherapy. This probably explains the higher efficacy of this treatment, albeit at the cost of increased therapy-related toxicity. The difference in response between autoHCT and alloHCT is most likely due to the graft-versus-leukemia (GVL) effect. Specifically, CLL cells disappear with the onset of graft-versus-host disease, relapse risk increases with the use of T-cell-depleted grafts, and there are reports of favorable responses to donor lymphocyte infusions.^{586, 587, 588, 589}

In myeloablative alloHCT, the proposed benefit in preventing CLL relapse has been offset by relatively high treatment-related toxicities, with cumulative nonrelapse mortality approaching 50%.^{590, 591} However, the GVL effect associated with alloHCT has raised considerable interest in nonmyeloablative (NMA) or reduced-intensity conditioning (RIC) alloHCT. The principle of this approach is that the nonhematopoietic toxicity, profound pancytopenia, and opportunistic infections associated with intense myeloablative preparative regimens are avoided, and the beneficial GVL effect is retained. A pivotal European registry-based study demonstrated that in 73 heavily pretreated patients receiving NMA alloHCT, the cumulative TRM was relatively low at 19%. With a median follow-up of 22 months, the cumulative event-free and OS was 58% and 70%, respectively. In this study, only 1 patient relapsed after the 2-year post-transplant mark.^{575, 591} A retrospective comparison of these 73 NMA cases with 82 matched myeloablative HCT patients from the EBMT registry showed a significant reduction in TRM but an increased relapse incidence in the NMA population.⁵⁹¹ There was no significant difference between the 2 alloHCT modalities in terms of event-free and overall survival. Although NMA/RIC and conventional myeloablative alloHCT approaches have yet to be prospectively compared, the NMA/RIC strategy is probably at least as effective as the latter, and, in addition, allows the expansion of transplant eligibility criteria to older or more medically fragile or complex recipients. Current internationally accepted guidelines recommend NMA/RIC regimens for all CLL allograft recipients.⁵⁷⁵ A summary of recently updated studies in NMA/RIC alloHCT for CLL is provided in Table 90.14.

ATG, antithymocyte globulin; UD, antiCD52, alemtuzumab; B, busulfan; C, cyclophosphamide; F, Fludarabine; GVHD, graft-versus-host-disease; Mel, melphalan; N, number; NRM, nonrelapse mortality; OS, overall survival; R, rituximab; TBI, total body irradiation; UD, unrelated donor; y, year.

^a Alemtuzumab in 21 patients.

^b Not stated if acute or chronic.

^c Estimated from cumulative incidence curve.

^d The majority received FCR.

The best preparative regimen for use in NMA/RIC alloHCT is unknown. Several regimens have gained popularity, almost all of which include fludarabine in combination with alkylating agents (such as cyclophosphamide, melphalan, or busulphan), with or without anti-T-cell antibody therapy to augment recipient immune suppression. In the absence of controlled studies, preparative regimen choice should be individualized depending on patient (e.g., age, extent of CLL control pre-transplant, comorbidities) and donor variables (e.g., degree of HLA match), as well as familiarity of the transplant team with a specific regimen. The use of a partially matched donor generally requires the use of a regimen with heightened immune suppression, such as the addition of antithymocyte globulin.^{592, 593} The inclusion of alemtuzumab in the preparative regimen is more contentious, as its administration is thought to be associated with higher rates of post-transplant CLL relapse and poorer survival.^{592, 594} The reason for this is possibly related to the potent ability of alemtuzumab to reduce graft-versus-host disease, with a corresponding reduction in the graft-versus-tumor effect. The dose of alemtuzumab may be important in this regard, as lower doses may provide sufficient GVHD prophylaxis without excess risks of relapse or infection.⁵⁹⁵

P.1923

Traditionally, related donors have been the preferred source of donor cells for alloHCT. However, one concern in CLL is the high incidence of familial CLL.³³⁵ In addition, MBL is prevalent not only in relatives of CLL patients, but at substantial levels in the healthy adult population; estimates of MBL range from 0.14% to >20%, depending on the population studied.⁵⁹⁶ It is presently unknown what proportion of these patients will develop clinically relevant CLL. However, MBL is transferrable from donors to allogeneic transplant recipients.⁵⁹⁷ Consequently, it has been proposed that related donors be routinely screened for MBL and excluded from donation if found to have this syndrome.⁵⁹⁸ In the current era of high-resolution typing of unrelated donors, the prospect of more widespread use of unrelated donors is feasible, especially if histocompatible-related donors are unavailable or medically ineligible. The use of well-matched (at least 7/8 HLA allele compatibility) unrelated donor results in outcomes at least as favorable as those of related donor transplants.^{593, 599} To date, no published randomized studies have compared alloHCT to nontransplant-based therapy for CLL. However, there are data to suggest that alloHCT may overcome the poor prognostic impact of fludarabine-refractory CLL.⁵⁹² In addition, alloHCT may result in durable disease control and quite possibly cure in CLL patients with adverse cytogenetic markers (including 17p13 mutations).⁵⁹⁴ A case control study that compared RIC/NMA allografting with nontransplant controls that were matched for age and disease stage suggested that allografting may be superior to a nontransplant approach.⁶⁰⁰ Moreover, a decision analysis using a Markov model concluded that alloHCT remains the preferred approach for patients with relapsed or refractory CLL, even when accounting for the significant upfront costs and toxicity of the HCT.⁶⁰¹

Although there is increasing confidence in alloHCT for high-risk or relapsed CLL, controlled trials are required to address issues such as optimal patient selection, preparative and GVHD regimens, and, most important, whether this procedure is truly superior to modern nontransplant approaches. We recommend that CLL patients who are candidates for HCT be managed within the context of a clinical trial.

Radiotherapy

Radiation is rarely used for CLL nowadays, but for many decades irradiation of the spleen was the primary treatment for this disease;^{602, 603, 604, 605, 606, 607, 608} irradiation of the mediastinum,^{609, 610} extracorporeal irradiation of the blood,^{611, 612} TBI,^{613, 614, 615, 616, 617} and hemibody irradiation⁶¹⁸ may also reduce the peripheral blood lymphocyte counts and the size of lymph nodes, spleen, and liver.

Splenic irradiation has produced survival rates comparable to those achieved with chlorambucil or COP in Rai stage III and IV patients.⁶¹⁵ However, in general, splenic irradiation is reserved to treat patients with large painful spleens or those with cytopenias related to splenomegaly who are not medically fit for splenectomy. Although almost all patients experience a reduction in spleen size and relief from pain with irradiation, the effects on hemoglobin and platelets are more variable.^{604, 606} It is likely that differences in therapeutic effect are related to the extent of prior treatments, as untreated patients respond much better to irradiation than those who have previously undergone therapy.⁶⁰² High doses of splenic irradiation may cause neutropenia and thrombocytopenia, and it is thus recommended to initially use small fraction sizes (e.g., 0.25 to 0.50 Gy on alternate days, or 3 times per week).^{602, 603} The dose of irradiation is gradually increased according to response and toxicity, and the usual maximum cumulative dose is 5 to 10 Gy.

TBI has been given alone^{613, 614, 615} or in combination with chemotherapy.^{616, 617} Patients treated with TBI plus cyclophosphamide and prednisone had higher response rates than those treated with TBI alone.⁶¹⁶ Intermittent low doses of irradiation may also be effective.^{612, 614, 615} In one study, 48 patients with progressive disease received 5 to 10 rad TBI 3 to 5 times per week for a total of 100 to 400 rad.⁶¹⁴ A total of 88% of the patients responded, with one third achieving a CR, although mild anemia and thrombocytopenia persisted in some individuals. The regimen was generally well tolerated, although significant myelosuppression occurred, and rest periods of weeks to months were intermittently required to allow marrow recovery. The Ig levels returned to normal in most of the patients who achieved a CR.

Splenic irradiation can produce systemic effects with a decrease in lymphadenopathy and a reduction in lymphocyte count and can induce CRs.^{602, 608} The mechanism(s) underlying these phenomena is unclear, and many factors may be involved.⁶⁰² CLL cells are highly sensitive to ionizing radiation in vitro, and a correlation has been observed between the radiosensitivity of CLL cells in vitro and the patients' clinical response to radiation therapy.⁶¹⁹ However, irradiation may also produce its effects through the inhibition of CD8⁺ T-cells and the induction of cytokine release from CLL cells.^{602, 620} Finally, radiation of the spleen can produce a "radiotherapeutic splenectomy," thus decreasing "pooling" and improving normal blood counts.

Splenectomy

Splenectomy is primarily carried out in CLL for the treatment of AIHA or ITP but may also be useful for patients with massive painful splenomegaly or in whom the leukemia is predominantly confined to the spleen.^{621, 622, 623, 624, 625} In addition, splenectomy may be considered when cytopenias are believed to be due to hypersplenism and have not responded to chemotherapy.^{621, 622, 623, 624} Neal et al.⁶²⁴ noted an improvement in the hemoglobin and platelet counts in two-thirds of patients with advanced-stage CLL who underwent splenectomy, and the improvement was maintained during the 1-year follow-up. In this study, neither the spleen size nor the degree of marrow involvement was predictive of response, although others have observed a correlation between spleen size and the improvement in blood counts after splenectomy.⁶²¹ Approximately 50% of patients have post-operative infections, and half of these require antibiotics.⁶²¹ Moreover, the perioperative mortality from sepsis is 5% to 10%, but this is primarily in patients with advanced disease and poor performance status.⁶²¹ Thus, in selected patients with good performance status, splenectomy may increase the blood counts sufficiently to permit aggressive chemotherapy. In addition, more individuals may now be candidates for this procedure as laparoscopic splenectomies become routine.⁶²⁵ Patients should be immunized with pneumococcal, meningococcal, and hemophilus influenza vaccines about a month before splenectomy, although there will be variability among patients as to how well they can produce an antibody response.²⁸⁸

SYSTEMIC COMPLICATIONS REQUIRING THERAPY

Infection

Patients with CLL have an increased risk of infection, which is partly related to the effects of the disease and partly to the effects of chemotherapy. Although a number of immune abnormalities occur in CLL, the incidence of infection is most closely related to hypogammaglobulinemia which increases with disease stage and duration.^{288, 289, 626, 627} The risk of infections, particularly opportunistic ones, is increased by steroids, nucleoside analogues, and monoclonal antibodies. Patients treated with alkylating agents are primarily affected by bacterial infections, whereas those on fludarabine-based treatments can get other opportunistic infections, such as *Pneumocystis jirovecii*, CMV, herpes simplex, and varicella zoster. The addition of steroids markedly increases the risk of infections with fludarabine and should be avoided.

Patients with hypogammaglobulinemia and recurrent bacterial infections may be treated with intravenous Ig. High-dose Ig, 400 mg/kg IV every 3 weeks, reduces the incidence of bacterial infections by 50%, particularly those caused by *Streptococcus pneumoniae* and *Haemophilus influenzae*, but the total number of severe bacterial infections and nonbacterial infections is not reduced, and this treatment does not prolong survival.⁶²⁸ A subsequent study using this regimen showed that the reduction in infections did not improve the patients' quality of life or survival and that the treatment was not cost effective, because of the high doses of Ig infused.⁶²⁹ Lower doses of gammaglobulin may be as effective, for example, 250 mg/kg every 4 weeks or 10 g every 3 weeks.^{630, 631} Molica et al.⁶³² randomized CLL patients with an IgG of less than 6 g/L and a serious infection in the previous 6 months to 300 mg/kg gammaglobulin every 4 weeks or to observation. Patients receiving gammaglobulin had a reduced number of infections, but the effectiveness did not correlate with restoration of the IgG levels. Thus, it is recommended that selected patients with hypogammaglobulinemia and frequent bacterial infections may receive prophylactic Ig.^{289, 633}

Granulocyte-macrophage colony-stimulating factor can increase the neutrophil count and function in CLL, although whether this reduces the incidence of infections remains unclear.^{634, 635} However, the use of granulocyte colony-stimulating factor after fludarabine has been shown to reduce the risk of neutropenia and the incidence of pneumonia.⁶³⁶ In general, older patients with more advanced disease have greater risk of infection than younger patients, particularly if they have had prior therapy. Prophylactic antibiotics may be of benefit, particularly when patients are receiving nucleoside analogues, monoclonal antibodies, and steroids, and frequently, antibiotics are incorporated into the newer and more immunosuppressive regimens. Thus, patients may be maintained on trimethoprim-sulfamethoxazole (cotrimoxazole) to prevent *Pneumocystis jirovecii* pneumonia, acyclovir to prevent herpes viruses, valganciclovir to prevent both CMV, and fluconazole to prevent fungal infections. However, the use of these antibiotics varies widely and whether all patients should receive prophylactic antibiotics or only older patients or those with a history of shingles is still unclear.^{289, 633}

In general, vaccines are less effective in CLL because of impairment in the immune system.^{288, 633} However, it is still recommended to immunize these patients for pneumococcus and influenza, the latter annually. These patients should not receive live vaccines, and these include, typhoid, yellow fever, measles, mumps, rubella, BCG, and herpes zoster.^{288, 633}

Autoimmune Complications

As discussed previously, immune cytopenias are the commonest autoimmune complications occurring in 4.3% to 9.7% of patients with AIHA in about 7% of patients and <1% to 2% having ITP, red cell aplasia, or immune neutropenia.^{312, 313, 314, 633} The disorders are caused by the immune dysregulation in CLL, may be triggered by chemotherapy, and are treated with immunosuppressives. In contrast, other autoimmune disorders in CLL are caused by antibodies produced by the CLL cells, for example, cold agglutinin disease, and these will respond to treatment of the CLL. It is thus important to be constantly aware of the potential development of these disorders and to treat them appropriately.

The immune cytopenias are treated initially with steroids, using prednisone 1 mg/kg/day, and 75% of patients respond to this therapy.^{312, 633} A response may be seen within days, although it may take several weeks in some patients. Patients with AIHA should also be maintained on folic acid, 5 mg/day, and after the hemoglobin and reticulocyte counts have normalized (usually in 1 to 2 weeks), the prednisone can be tapered slowly over a period of 2 to 3 months. These patients should be watched for all the usual complications of prednisone, such as gastric irritation, diabetes mellitus, an increased risk of opportunistic infections, and osteoporosis. Thus, these patients may need to be maintained on an H₂-blocker or proton pump inhibitor, may require oral hypoglycemics/insulin, and should be maintained on prophylaxis against *Pneumocystis jirovecii* [e.g., trimethoprim-sulfamethoxazole (one double-strength tablet orally twice a day on Saturdays and Sundays, or one double-strength tablet 3 times a week)] if they are on steroids for longer than a few weeks.⁶³⁷ They are also at risk of other infections, such as oral candidiasis or herpetic infections and may require therapy or prophylactic antibiotics such as valganciclovir. Many of these patients are elderly, and the prolonged course of prednisone increases the risk of osteoporosis and vertebral collapse. Thus, patients should be maintained on bisphosphonates. The authors prefer an intravenous formulation to reduce the risk of the gastric irritation that may result from corticosteroids (e.g., pamidronate 30 mg IV every 3 months).⁶³⁸ It is important that patients with AIHA and dangerously low hemoglobins are transfused, because, despite theoretical concerns, these patients rarely have severe transfusion reactions.⁶³⁹ In addition, any infection should be treated promptly, as sepsis can inhibit the compensatory reticulocytosis and worsen the anemia.

If a more rapid response is required, or if the patient does not respond to prednisone within 7 to 10 days, 1 gram of methylprednisolone IV or intravenous Ig (0.4 g/kg/day × 5 days or 1 g/kg/day × 2 days) should be added.³¹⁴ This can

produce a rapid response, but the response is transient, and re-treatments are generally required every 3 to 4 weeks.³¹⁴,⁶⁴⁰ There is no standard therapy for patients who do not respond to this therapy or who cannot be weaned off prednisone without a relapse. Cyclosporin is a reasonable option and produces a major response in two-thirds of CLL patients with ITP or anemia and is highly effective in red cell aplasia.³¹⁴,⁶⁴¹,⁶⁴²,⁶⁴³ In one study using cyclosporin 300 mg/day, the median time to initial response was 3 weeks (range, 1 to 13 weeks), and the median time to best response was 10.5 weeks (range, 1 to 48 weeks).⁶⁴³ The median duration of response was 10 months (1+ to 39+ months), and some patients who had fludarabine-associated cytopenias were retreated effectively with fludarabine. Immune cytopenias also may be treated with other immunosuppressive drugs, such as 6-mercaptopurine or cyclophosphamide, although no controlled trials related to their use have been published.³¹⁴ Rituximab is also useful for the immune cytopenias, either alone⁶⁴⁴,⁶⁴⁵,⁶⁴⁶,⁶⁴⁷ or in combination with a cyclophosphamide-containing regimen when treatment of the underlying leukemia is also required.⁶⁴⁸,⁶⁴⁹,⁶⁵⁰ The response rate of 48 steroid-resistant CLL patients with immune cytopenias (AIHA 26, ITP 9, Evan syndrome 8, and red cell aplasia 5) receiving RCD (rituximab, cyclophosphamide, and dexamethasone) was 90% with the median duration of response being 24 months.⁶⁴⁹ There were 40% of these patients who had progressive disease at the time of treatment and all patients who relapsed with immune cytopenias had progression of their CLL. Further studies to prolong the duration of remission of the immune cytopenias will require better control of the underlying CLL. Good responses in small numbers of patients with CLL and AIHA have also been reported with alemtuzumab.⁶⁵¹

Splenectomy may also be a useful treatment for patients with AIHA, and the number of patients eligible for this procedure is increasing with the use of laparoscopic splenectomy.⁶²⁵ Splenic irradiation may be carried out in those who are not surgical candidates, but it may take up to 2 months to see a response; the responses last for approximately 1 year.³¹²,⁶⁰⁴

The thrombopoietin analogues, romiplostim, and eltrombopag, have also been shown to be effective in small numbers of CLL patients with refractory thrombocytopenia, although the drugs need to be given indefinitely.³¹⁴,⁶⁵²

P.1925

TRANSFORMATION OF CHRONIC LYMPHOCYTIC LEUKEMIA

Based on cytogenetic and molecular studies, it has been demonstrated that multiple clones may occur in CLL and that clonal evolution is a frequent occurrence.²⁰⁸,²¹⁷,²¹⁸,²¹⁹ The transformation of CLL to a high-grade non-Hodgkin lymphoma was originally described by Maurice Richter in 1928 (RS) and over time a Richter's transformation became synonymous with the development of diffuse large B-cell lymphoma, Hodgkin lymphoma, PLL, or acute leukemia in CLL.⁶⁵³ However, nowadays, RS or Richter's transformation is taken to reflect the development of diffuse large B-cell lymphoma in a patient with CLL or SLL.³,⁶⁵⁴,⁶⁵⁵ The likelihood of a second lymphoid malignancy is three- to fivefold higher in CLL than in the general population, is significantly increased by prior treatment with a purine nucleoside analogue, and almost half of these second malignancies are RS.⁶⁵⁶

In 75% of cases of RS the transformation is clonally related to the CLL and in 25% of cases is unrelated.²³⁴ By multivariate analysis the 4 most important factors predictive for a transformation are mutated NOTCH1, IgV_{H4-39} usage, trisomy 12/deletion 11q22-23/TP53 disruption, and CD38 positivity (≥30%).²³⁴ The risk of developing a clonally related RS is markedly increased if the patient has IgV_{H4-39} in addition to a NOTCH1 mutation (75% risk at 5 years) and least if the patient has neither (0% at 5 years).²³⁴ Of these lymphomas, 40% have a NOTCH1 mutation suggesting enrichment of CLL cells harboring the mutation over time.²²⁷ In contrast, patients who develop a clonally unrelated transformation generally have IgV_H mutated CLL.⁶⁵⁶

In contrast, NOTCH1 mutations are not involved in clonally unrelated RS.²³⁴ As discussed later, the clonally unrelated cases of RS in CLL behave as does de novo diffuse large B-cell lymphoma and may occur as a result of immunodeficiency or to an inherent predisposition to these malignancies.⁶⁵⁷ Finally, Epstein-Barr associated diffuse large B-cell lymphoma may develop in CLL following therapy with FA, and these tumors may resolve spontaneously.⁵³² Whether they are clonally related to the underlying CLL is not known.

RS occurs in 5% of patients with the median time to onset being 4 years, although patients can present with concomitant CLL and RS.⁶⁵⁴,⁶⁵⁵,⁶⁵⁸,⁶⁵⁹ The incidence of RS may actually be as high as 16.2% at 10 years, as many cases are probably misdiagnosed as having CLL progression.⁶⁶⁰ Patients with clonally related RS have a very poor prognosis and typically present with rapidly increasing lymphadenopathy or splenomegaly, fever, or weight loss, high LDH, and frequent extranodal involvement of kidneys, lungs, and the gastrointestinal tract. Preferably, the diagnosis should be made on a lymph node biopsy but in sick patients a needle aspirate of a node with cytology demonstrating large cells is sufficient.⁶⁵⁵ PET/CT scanning with ¹⁸F-FDG is a highly sensitive technique to detect a Richter's transformation and is useful in helping to

decide which node to biopsy.⁶⁶¹ However, hypermetabolism may also be seen with other transformations, with a co-existing solid tumor or infection, or with accelerated-phase CLL. The lymph node with accelerated-phase CLL shows increased numbers of proliferation centers, increased Ki67-positive CLL cells or PL, and no evidence of large-cell transformation.

Of 148 patients with RS at the MD Anderson, 135 received therapy using a variety of treatment regimens including R-CHOP (rituximab-cyclophosphamide, doxorubicin, vincristine, and prednisone).⁶⁵⁸ The addition of rituximab appeared to increase the response rate and for all patients the OR was 39% with 12% CR. For 7 patients in remission who underwent an allogeneic SCT the 3-year survival was 75%. Thus, although the OS was poor some patients did well and a RS prognostic score was thus developed based on performance status, LDH, platelet count, tumor size, and the number of prior treatments.⁶⁵⁸ However, the varying prognosis with RS likely depends on whether the tumors are clonally related or unrelated to the underlying CLL.⁶⁵⁹ Where the RS was clonally unrelated, the median survival was 62.5 months, no different from de novo diffuse large B-cell lymphoma, versus 14.2 months for clonally related RS. Patients with disruption of TP53, either through deletion or mutation, had a median survival of 9.4 months versus 47.1 months for patients with no disruption.

Occasionally, Hodgkin lymphoma develops in CLL, and is about 10% as common as RS.⁶⁶² As in RS, the Hodgkin's transformation occurs about 4 years after CLL is diagnosed with the mean age at diagnosis being 65.7 years versus a median age of 61 years for RS.⁶⁶² Histologically, there are 2 types of transformation. The type 1 transformation is characterized by scattered Reed-Sternberg cells in a field of typical CLL cells and the type 2 transformation shows Reed-Sternberg cells in a field of inflammatory cells, separate from the CLL cells.⁶⁶³ Most patients have advanced Rai stage disease at transformation and 70% of cases are mixed cellular or nodular sclerosing Hodgkin lymphoma.⁶⁶² As with RS, patients present with fever, lymphadenopathy, and weight loss.⁶⁶² One-quarter of patients achieve a CR with chemotherapy and one-quarter a PR, with a mean survival of 1.7 years (range, 0 to 14 years).⁶⁶² Patients who had previously received fludarabine for their CLL had a much poorer survival than patients who had not required treatment of their CLL. The cell of origin for the Reed-Sternberg cell in these patients has been debated, with some studies showing a clonal relationship to the underlying CLL cell, whereas others do not. However, whether the variation in response of these patients to chemotherapy is related to their clonal relationship to the underlying CLL is not yet known. In contrast to RS, Epstein-Barr viral infection is frequently seen in this transformation, but the exact role of the infection in this transformation is not yet known.

Polymphocytic transformation of CLL occurs slowly over several years with the gradual accumulation of increasing numbers of prolymphocytes [PLL/CLL] until there are $\geq 55\%$ prolymphocytes (PL).²⁵⁴ In general, this type of transformation occurs more frequently in patients with unmutated IgV_H and trisomy 12.²⁵⁴ The underlying genetic cause for the transformation is presently unknown, but MYC rearrangements have been described.⁶⁶⁴ Although most cases of PL in CLL represent a transformation of the CLL clone, cases of separate CLL and PL clones in the same patient have been described.⁶⁶⁵

Multiple myeloma may also develop in patients with CLL.^{666, 667} Some studies have suggested that the two diseases develop separately, whereas in others, multiple myeloma develops from the CLL clone. Acute leukemia occurs in less than 1% of CLL patients, and this contrasts with the almost invariable progression of patients with chronic myeloid leukemia to acute leukemia.⁶⁶⁸ Hairy cell leukemia is also more common in CLL.⁶⁵⁷ Of 31 cases of acute leukemia developing in patients with pre-existing CLL, 10 were lymphoblastic, 7 myeloblastic, and 1 plasmacytic; in 13 cases, the cell type was not identified.⁶⁶⁸ Both acute B- and T-cell lymphoblastic leukemias have been described in CLL,^{669, 670, 671, 672} and although this usually occurs after many years, the concomitant presentation of CLL and acute lymphoblastic leukemia also has been reported.⁶⁶⁹ In B-ALL, evidence of clonal evolution has been documented in some cases, whereas in T-cell cases, a common lymphoid progenitor precursor has been postulated as the source of both malignancies.^{669, 670, 671, 672}

SECOND MALIGNANCIES

Second malignancies are commonly found in the lymphoid malignancies, but are particularly common in CLL because of the significant immunosuppression seen in this disease.^{673, 674} Compared to the general population and patients with follicular lymphoma, the incidence of second malignancies is increased twofold, with

P.1926

the most common malignancies being squamous and basal cell carcinomas of the skin.^{674, 675, 676, 677, 678} Melanomas are also common, followed by cancers of the gastrointestinal tract, lung, breast, and prostate.^{674, 675, 676, 677, 678} Clinical features associated with an increased incidence of second malignancies include older age, male sex, a β 2-microglobulin >3

mg/dl, an increased LDH, and an elevated creatinine.⁶⁷⁵ In addition, these malignancies can be more aggressive than in patients without CLL, and an increased mortality is observed with skin cancers, melanomas, Merkel cell tumors, and lung cancer.^{674, 678, 679, 680, 681} The risk of developing AML or myelodysplasia with alkylating agents or nucleosides alone appears to be low, although the risk may increase if both are given together and the risk of developing AML/myelodysplasia with front-line FCR chemotherapy is 4.5% which occurs approximately 3 years following initiation of therapy.^{484, 547} This appears directly related to the potent myelosuppression seen with this regimen. Finally, patients with CLL may develop myeloproliferative disorders.⁶⁸²

Chronic myeloid leukemia, myelofibrosis, and essential thrombocythemia may also rarely occur in CLL. As second malignancies are a common cause of death in CLL, patients should be monitored for the development of new malignancies which should be promptly treated when identified.

SUMMARY OF THERAPY

The indications for treatment and the type of treatment will vary according to the patient's age and condition. If the patient is not participating in a clinical trial, the following are general guidelines.¹

- Patients with Rai stages 0-II usually do not require therapy unless there is evidence of significant disease progression or symptoms, for example, weight loss, night sweats, or fatigue.
- Patients with Rai stages III/IV disease frequently require treatment but this may be deferred until the patient is symptomatic or if there is disease progression.
- Other indications for treatment include AIHA/ITP and massive uncomfortable lymphadenopathy or splenomegaly.
- Patients with Rai stage III or IV disease may require a bone marrow aspirate and biopsy prior to chemotherapy to ensure that the anemia and/or thrombocytopenia are related to marrow infiltration.
- Prior to therapy, patients should have FISH analysis, a Coomb's test, and be screened for common viral pathogens, including hepatitis B and C, and CMV.
- Most treatment regimens include rituximab, and the standard initial therapy for patients with adequate performance status, comorbidity score, and renal status is FCR, particularly if the patient has a deletion 11q22-23. Other common regimens include FR and PCR, or chlorambucil with or without rituximab for the elderly and frail. Bendamustine with or without rituximab is also highly effective and is presently being compared with FCR in the German CLL10 study.
- Approximately half the patients who become refractory to the above regimens have a deletion 17p13 and treatment options for resistant patients include alemtuzumab alone, or high-dose steroids in combination with rituximab or alemtuzumab. Ofatumumab is used for patients who are refractory to alemtuzumab or with lymph nodes >5 cm, but is not very effective for patients with loss of p53 function.
- Prophylaxis against *Pneumocystis jirovecii* and herpes infections should be given to patients receiving nucleoside analogues, steroids, or alemtuzumab and continued for 6 months following therapy. The authors use trimethoprim-sulfamethoxazole (co-trimoxazole) 1 double strength twice a day on Saturdays and Sundays with valacyclovir 500 mg/day (or an equivalent). For patients allergic to trimethoprim-sulfamethoxazole, dapsone 100 mg 3 times a week or pentamidine by aerosol once a month may be used.
- Steroids should primarily be reserved to treat immune cytopenias and should be avoided, if possible, when patients are receiving chemotherapy. There is no evidence that steroids increase the response rate obtained with alkylating agents or nucleoside analogues alone, and they increase the risk of infection. However, if used judiciously, prednisone may be combined with chlorambucil to enhance marrow clearing of tumor and to reduce organomegaly.
- Patients with immune cytopenias or red cell aplasia should initially be treated with prednisone 1 mg/kg/day orally, but may also benefit from gammaglobulin, cyclosporine, cyclophosphamide, or rituximab. Patients who are going to receive a prolonged course of prednisone should be maintained on pamidronate 30 mg IV every 3 months, or an equivalent, to prevent osteoporosis and prophylactic antibiotics for *Pneumocystis jirovecii* and herpes infections.
- Radiotherapy is reserved for local lesions that are particularly bulky and troublesome and is used only when chemotherapy is not required for control of more disseminated disease. The lowest dose of radiotherapy capable

of shrinking the tumor mass should be used. Splenic irradiation may be helpful in patients who require a splenectomy but who are not surgical candidates. Radiotherapy is most useful in patients who have had little prior therapy.

- Splenectomy may be useful in patients with painful splenomegaly or who have cytopenias that are unresponsive to other therapies. Minimally invasive surgical techniques should be considered.
- Prophylactic gammaglobulin is useful in reducing the frequency of infections in patients with hypogammaglobulinemia and frequent bacterial infections. G-CSF and erythropoietin may be useful to maintain neutrophil counts and hemoglobin.
- Although not standard therapy, alloSCT may be considered for younger patients (<65 years) who have developed refractory disease.
- Most patients in CLL clinics will die from disease progression or transformation, infections, and second malignancies (skin, melanomas, and solid tumors). Thus, patients need to be monitored for these complications with each visit and second malignancies promptly treated.

Chapter 91

Hairy Cell Leukemia

James B. Johnston

Michael R. Grever

Hairy cell leukemia (HCL), or leukemic reticuloendotheliosis, is a chronic B-cell disorder that was initially described by Bouroncle et al. in 1958.¹ The disease is characterized by the presence of typical hairy cells in the peripheral blood and marrow, pancytopenia, and a variable degree of splenomegaly.^{1, 2, 3, 5, 6} The disease has always aroused interest, initially over the unique morphologic and clinical features of this disorder. The tumor cells are B-cells that typically express CD11c, CD25, CD103, and CD123, are usually IgVH-mutated and are unique memory B-cells in expressing multiple immunoglobulin (Ig) isotypes. More recently, it has been demonstrated that most hairy cells contain a mutated active form of the BRAF gene (V600E) which may be used as a diagnostic tool and a potential target for therapy. Most cases of HCL are very sensitive to interferon (IFN)- α and the nucleoside analogs pentostatin (2'-deoxycoformycin, dCF) and cladribine (2-chlorodeoxyadenosine CdA).^{5, 6} Less responsive patients generally respond to monoclonal antibodies, such as rituximab (against CD20) or to immunotoxin-labeled antibodies to CD22 or CD25. Prior to the development of these treatments the median survival for HCL patients was 4 years whereas now the survival of these patients is no different from an age- and sex-matched control population.

INCIDENCE AND ETIOLOGY

HCL is a rare disorder, accounting for 2% of all leukemias, and occurs more frequently in men, with an incidence in the United States of 2.9 per million per year for men and 0.6 per million per year for women.^{5, 7} The etiology of HCL is unknown. Several case-controlled studies have identified possible relationships to radiation exposure,^{7, 8} exposure to benzene,⁹ to farm animals, and to commercial herbicides and pesticides.^{9, 10} A familial predisposition is suggested by reports of the disorder in 15 families where HCL occurred among first-degree relatives. In these families, disease is usually associated with the following haplotypes; A2, B7, and Bw4/6; A1/3 and B7/8; A2, B51, and DR52/53.¹¹

PATHOGENESIS

Immunologic,^{12, 13, 14} molecular genetic,^{15, 16, 17, 18, 19, 20, 21} chromosomal,^{22, 23} and gene expression²⁴ studies have demonstrated that the hairy cell is of B-cell origin. Although some T-cell features have been reported,^{25, 26, 27, 28, 29, 30} including two cases in which the retrovirus human T-cell leukemia virus type II was isolated,^{31, 32} no instances of T-cell receptor gene rearrangements have been found. Fluctuations in the expression of T- and B-cell markers have been demonstrated both in vivo and under various in vitro culture conditions.^{33, 34, 35, 36} In most instances, the alteration noted was between a surface-immunoglobulin-positive (SIg⁺) CD2⁻ phenotype and a SIg⁻CD2⁺ phenotype. Other B-cell antigens, however, such as CD20, were retained, even with the loss of SIg and the appearance of CD2.³⁵

The cell of origin of the hairy cell has been a subject of much debate and has been discussed in several recent reviews.^{37, 38, 39} Gene expression profiling has demonstrated that the hairy cell is most similar to a memory B-cell, although it differs in that the hairy cell has increased expression of adhesion and chemokine receptor genes.²⁴ The profile is extremely homogeneous, quite different from other lymphoid malignancies, and the abnormal expression of specific genes explains the properties of this disease which include unique cell structure, marrow fibrosis, marrow suppression, and the tendency of tumor cells to home to spleen and marrow, rather than to lymph nodes. As hairy cells do not express CD27, which is normally expressed on memory B-cells, it has been suggested that the normal counterpart is a memory cell which lacks CD27 but has somatic mutations of the the IgVH genes.⁴⁰ However, the profile also demonstrated expression of many genes associated with macrophages suggesting that these cells are unique in having phagocytic properties.²⁴ Consistent with being a memory B-cell, the majority of cases with HCL show mutations of the variable chain of the Ig gene, demonstrating that the hairy cell has passed through the germinal center (Fig. 91.1).^{15, 16, 17, 18, 19, 20, 21, 41} However, 10% to 20% of cases have unmutated IgVH and in general these patients have very poor prognosis and are resistant to chemotherapy.^{17, 18} The IgVH gene usage is shown in Figure 91.2 and demonstrates that in classical HCL IgVH 3-23 (17%), 3-30 (8%), and 4-34 (7%) are most commonly used. IgVH 1-69, 3-11, 3-48, and 4-39 are each used in 5% of cases. The major difference between the HCL variant and classical HCL, is the usage of IgVH V4-34, which is present in 54% of variant cases but only 17% of classical cases.²⁰ The majority (94%) of IgVH4-34 cases are unmutated. As expected, the IgVH is more likely to be unmutated in the HCL variant (54%) as compared to classical HCL (17%). It is interesting that, as discussed later, patients with unmutated IgVH or those that use IgVH4-34 have more aggressive and drug-resistant disease.^{17, 18} The patterns of IgVH gene family usage and the incidence of IgVH mutations is different in HCL and chronic lymphocytic leukemia (CLL).²⁰ In CLL, the most commonly used IgVH genes are IgVH1-69, 3-21, 3-30, 4-34, and 1-02 and whereas most IgVH 1-69 cases are unmutated, most IgVH4-34 cases are mutated.⁴² Overall, approximately 60% of CLL cases have mutated IgVH and 40% are unmutated.

Hairy cells are unique in expressing multiple Ig isotypes that are related to RNA splicing. Thus, individual hairy cells may express IgG alone or in combination with IgM and/or IgD and/or IgA.^{15, 16, 41} Similarly, IgVH mutational analysis has demonstrated intraclonal variation in gene expression, both in the IgVH unmutated and mutated varieties. These studies have suggested that the hairy cell is in maturation arrest before deletional recombination within the heavy chain locus.

Cytogenetics

Cytogenetic studies have been difficult to carry out in HCL, because the number of circulating hairy cells is small, and attempts at marrow aspiration are usually unsuccessful. In addition, until recently it has been difficult to induce hairy cells to proliferate and to obtain hairy cells in metaphase. In early reports, the abnormalities observed in HCL tended to be nonclonal.^{43, 44} However, more recently, 15 of 19 patients were found to have an abnormal karyotype, and a 14q⁺ marker involving the breakpoint q32 at the Ig heavy chain locus was the most frequent clonal abnormality.²² Abnormalities involving the short arm of chromosome 12 have been observed in four patients.¹³ Haglund et al.⁴⁵ observed deletions and inversions in 67% of patients. Clonal abnormalities of chromosome 5 were found in 40% of cases (most commonly trisomy 5, pericentric inversions, and interstitial deletions involving 5q13). The frequency with which these abnormalities occur is unique and is not found in other B-cell malignancies. Abnormalities in 5q13 thus occur in one third of patients, and subsequent studies have identified three expressed sequences as candidates for a putative tumor-suppressor gene at 5q13.3.⁴⁶ Cytogenetic analysis has been carried out using monoclonal antibodies to CD40, because this

P.1930

appears to be the most effective way of inducing hairy cell proliferation.⁴⁷ This technique allowed cytogenetic analysis in 42 of 43 cases and demonstrated that clonal abnormalities were present in 19% of cases and involved numeric or structural abnormalities in chromosomes 5, 7, and 14. In contrast, abnormalities of chromosome 5 were not observed in the HCL variant, and translocations more frequently involved either chromosome 2 or 14.⁴⁸

FIGURE 91.1. The germinal center (GC) reaction is a key event in adaptive immunity to T-cell-dependent antigens. In lymph nodes and the spleen, antigen (Ag)-activated naive B-cells (immunoglobulin [Ig] M⁺/IgD⁺) are driven into primary follicles where, aided by T-cells, they undergo clonal expansion, form the GC, and displace nonproliferating naive B-cells to the periphery or mantle zone (shown in diagram). Within the GC, somatic hypermutation (SHM) mutates the Ig variable region of proliferating B-cells to increase their affinity for the stimulating Ag. Although most GC B-cells (GCB) acquire unfavorable mutations and die by apoptosis, a few improve their Ig affinity and are selected for further differentiation through interactions with T-cells and follicular dendritic cells (FDC). A proportion of these selected B-cells then undergo switch recombination of the Ig constant region, which changes the isotype and, consequently, the antibody-effector function. B-cells of the GC express BCL6, which is required for GC formation, and activation-induced cytidine deaminase (AID) which is essential for SHM and switch recombination. Finally, selected B-cells differentiate into memory B-cells (CD27⁺) or antibody-secreting plasma cells (CD138⁺). Follicular lymphoma (FL), Burkitt lymphoma (BL), and some diffuse large B-cell lymphomas (DLBCLs) are thought to derive from B-cells of the GC, mantle cell lymphoma (MCL) mainly from mantle-zone naive B-cells, B-cell chronic lymphocytic leukemia (B-CLL) and hairy-cell leukemia (HCL) from memory B-cells, and multiple myeloma (MM) from plasma cells. The majority of cases of CLL and HCL have undergone SHM, but a proportion have not and these cases have more aggressive disease. (From Tiacci E, Liso A, Piris M, and Falini B. Evolving concepts in the pathogenesis of hairy-cell leukaemia. *Nature Rev* 2006;6:437-448, with permission).

High-density genomewide DNA profiling in HCL showed that, in contrast with CLL, HCL has a remarkably stable genome.⁴⁹ Using a high-density single nucleotide polymorphism array, it has been shown that only 25% of patients had gross copy number abnormalities.⁴⁹ Alterations in the genes for FGF12 and FGF receptor were observed, and increased expression of these genes is typically observed in HCL, which is responsible for the marrow fibrosis seen in this disease.⁴⁹ Although a high incidence of TP53 mutations was initially reported in HCL, subsequent studies have suggested that this is uncommon and occurs primarily in patients with unmutated IgVH.^{17, 51, 52}

Oncogenes and Signal Transduction

To date, there has been little information regarding the role of oncogenes in HCL. It has been shown that CSF1R, which encodes the receptor for macrophage colony-stimulating factor and is normally expressed in macrophages/monocytes, is highly expressed in hairy cells.⁵³ The addition of macrophage colony-stimulating factor to hairy cells causes enhanced mobility of the cells, the extent of which depends on the underlying stratum, and this effect is mediated through alterations in the integrin $\alpha\beta4$.⁵⁴ More recently, it has been demonstrated that, compared with normal lymphocytes, hairy cells have markedly increased levels and activities of the protein tyrosine kinase pp60c-src, which is the product of the proto-oncogene CSK.⁵⁵ This increase was not observed in CLL cells and was unrelated to the amplification or structural

rearrangements of the gene.⁵⁵ Cyclin D1 messenger RNA and protein levels are increased in HCL, but the increase is less than is seen in mantle cell lymphoma and is not related to t^{11, 14} (q13;q32), which is typically observed in mantle cell lymphoma.^{56, 57} Finally, because of the high frequency of abnormalities of chromosome 5 in classic HCL, it has been suggested that a transforming oncogene might be located at 5q13.3.⁴⁶

Gene expression profiling identifies a unique homogeneous signature for HCL distinct from other B-cell malignancies. In HCL samples, decreased expression was noted for CXCR5, TNFRSF5, CD40, CD27, and CCR7, whereas increased expression was noted for GAS7, FGFR1, FGF2, FLT3, TIMP1, TIMP4, RECK, ANXA1,

P.1931

Syndecan3, Cyclin D1, IGF1R, and NUDT6.²⁴ The proposed effects of these changes on the pathophysiology of HCL are outlined in Table 91.1. More recently, a heterozygous mutation of GTG to GAG at codon 600 of the BRAF gene has been observed in typical HCL producing a V600E variant protein, in which glutamate substitutes for valine at position 600.^{58, 59, 60, 61, 62} BRAF is a serine-threonine kinase and the variant protein (V600E) demonstrates increased activity resulting in enhanced phosphorylation and activation of mitogen-activated protein-ERK kinase (MEK) and extracellular signal-regulated kinase (ERK), which increase cell survival and proliferation by increasing the expression cyclin D1 and decreasing p27.⁵⁸ The functionality of the variant protein was demonstrated in primary hairy cells by showing the presence of phosphorylated MEK and ERK in these cells, and demonstrating that the phosphorylation was decreased using the BRAF inhibitor, PLX-4720.⁵⁸ Initial studies suggested that all patients with classical HCL contained a V600E; however, a more recent study demonstrated that 82% of patients with classical HCL express BRAF, whereas the V4-34 subtype and HCL variant do not express BRAF.²¹ Thus, BRAF inhibitors may not be useful in the treatment of the aggressive V4-34 HCL subtype of the HCL variant.

FIGURE 91.2. Immunoglobulin (Ig) VH family and gene usage in hairy-cell leukemia (HCL). Number of IgV_H rearrangements in each family (A) and for genes used by more than one patient (B) for HCLc (black) and HCLv (gray). (From Arons E, Roth L, Sapolsky J, et al. Evidence of canonical somatic hypermutation in hairy cell leukemia. *Blood* 2011;117:4844-4851, with permission.)

It has also been demonstrated that the activities of MEK and ERK are increased in HCL through the epsilon form of protein kinase C (PKC ϵ), which in turn is activated by tyrosine nitration (Fig. 91.3).⁶³ Tyrosine nitration is produced by the high levels of reactive oxygen species (ROS) and nitric oxide (NO) in hairy cells.⁶³ In addition, apart from its role in cell survival, activated PKC ϵ is also involved in causing the unusual hairy cell structure by increasing the Rho guanosine triphosphatases

(GTPases), Rac1 and Cdc42.⁶³ The Rho GTPases are members of the Ras family of GTP-binding proteins and can either be active (GTP-bound) or inactive (GDP-bound).⁶³ The GTPases are important for actin structure within the cell and controlling cell shape. It has been shown that three groups of Rho GTPases, RhoA, Rac1, and Cdc42, are overexpressed in HCL and are responsible for the filamentous projections and growth of these cells.⁶⁴

P.1932

TABLE 91.1 MECHANISMS FOR HAIRY CELL LEUKEMIA FEATURES

Hairy Cell Feature	Mechanism
Hairy cell projections	Alteration of actin structure through up-regulation of the Rho GTPase Rac 1.
Prolonged survival of hairy cells	Autocrine stimulation by TNF- α , increased cellular levels of bcl-2.
Ability of hairy cell to phagocytose and expression of macrophage markers, for example, CD11c	Up-regulation of annexin1 mediates phagocytic function and c-Maf transcription factor for macrophage differentiation.
Marrow fibrosis and monocytopenia	Up-regulation of FGF2 which activates FGFR1 on the hairy cell producing fibronectin and TGF β , which causes the adjacent fibroblasts to secrete collagen. TNF- α and TGF- β cause marrow suppression and monocytopenia.
Infiltration of red pulp of spleen by hairy cells with the formation of "pseudosinususes"	Up-regulation of TIMP1, TIMP4, RECK inhibitors of matrix metalloproteinases.
Lack of lymph node involvement by hairy cells	Hairy cells lack L-selectin which is required for binding to venule endothelium and chemokine receptor 7 (CCR7) which is required for transendothelial migration.

GTPases, guanosine triphosphatases; TGF- β , transforming growth factor- β ; TNF- α , tumor necrosis factor.

Gene expression profiling of hairy cell leukemia reveals a phenotype related to memory B cells with altered expression of chemokine and adhesion receptors. *J Exp Med* 2004;199:59-68 and Cawley JC, Hawkins SF. The biology of hairy-cell leukaemia. *Curr Opin Hematol* 2010;17:341-349.

Cytokines

There has been great interest in the role of cytokines in the pathogenesis of HCL.^{37, 38, 39} Identified factors that may be involved include interleukin-2 (IL-2), tumor necrosis factor (TNF)- α , IL-4, IL-6, B-cell growth factor, IFN- α , transforming growth factor- β (TGF- β), and basic fibroblast growth factor (bFGF, FGF2).⁶⁵ Some of these factors may be produced by the hairy cells themselves or by normal T-cells.^{65, 66} T-cell clones have been shown to produce cytokines that stimulate the growth of hairy cells, but not normal B-cells; this effect is prevented by the addition of IFN- α .⁶⁶

A feature of classical HCL is the reactivity of the hairy cells with anti-Tac (CD25), which detects the α -chain of the IL-2 receptor.^{67, 68, 69, 70} Increased serum levels of IL-2 receptor have been found in untreated HCL patients, and there is evidence that the leukemic cells release the receptor.⁷⁰ The serum levels of IL-2 receptor correlate with the extent of disease and decrease after effective therapy with IFN- α .^{71, 72, 73} Paradoxically, even though the IL-2 receptor is present on

hairy cells, these cells do not respond to stimulation by IL-2, and IL-2 probably does not play a major role in the pathogenesis of HCL.⁶⁵

It has been demonstrated that TNF- α , but not TNF- β , stimulates the growth of hairy cells, whereas in CLL, both forms of TNF stimulate leukemic cell growth (Fig. 91.4).^{74, 75} Hairy cells can also produce TNF- α ,^{76, 77} and the serum level of TNF- α is increased in HCL, the level correlating with tumor burden.⁷⁷ The TNF- α receptor can also be detected in the serum of these patients, and the level of this receptor also decreases after treatment with IFN- α .^{78, 79} These findings suggest that TNF- α production by the hairy cells may play an important role in the pathogenesis of HCL by stimulating further growth of hairy cells and producing pancytopenia through the inhibition of normal marrow function.^{74, 76, 77}

FIGURE 91.3. Proposed pathways of constitutive signaling in hairy cells (HCs). This figure shows the schematic representation of the possible associations into two parallel pathways of active signaling components detected in HCs.

Protein kinase C (PKCε) plays a central role, controlling the activation of p60src, Rac1, and extracellular signal-regulated kinase (ERK). PKCε is itself activated through nitration of tyrosine residues by reactive oxygen species (ROS) and nitric oxide (NO) which are increased in HCLs. (From Slupsky JR, Kamiguti AS, Harris RJ, et al. Central role of protein kinase Cε in constitutive activation of ERK1/2 and Rac 1 in malignant cells in hairy cell leukemia. *Am J Pathol* 2007;170:745-754, with permission.) MEK, mitogen-activated protein-ERK kinase; MT, mitochondrial; NOX5, NADPH oxidase 5; iNOS, inducible nitric-oxide synthetase.

Hairy cells secrete low levels of IL-6, and the serum level of this cytokine is increased in HCL.^{65, 80} The production of IL-6 messenger RNA and IL-6 secretion is markedly increased by incubating HCL cells with TNF.⁸⁰ IL-6 antisense oligonucleotide can inhibit the effect of TNF on IL-6 secretion and DNA synthesis, suggesting that IL-6 mediates the activity of TNF in HCL.⁸⁰

Hairy cells also produce bFGF and TGF-β and express the bFGF receptor.^{81, 82} Adhesion of the hairy cells to hyaluronan via CD44 induces the secretion of bFGF, but not TGF-β.⁸¹ The secreted bFGF then feeds back on the hairy cell to secrete fibronectin, which is a major component of the marrow fibrosis in this disease. As the spleen does not have hyaluronic acid, this explains the lack of bFGF and fibrosis in this organ despite abundant hairy cells.⁸¹ TGF-β has been shown to be present in increased

P.1933

quantities in the plasma and marrow of patients with HCL, and this also contributes to the marrow fibrosis by inducing the production of collagen and reticulin by adjacent fibroblasts.⁸²

FIGURE 91.4. Immune suppression in hairy-cell leukemia (HCL). Immune suppression is a result of T-cell dysfunction and impaired hematopoiesis with pancytopenia, bone marrow fibrosis, and hypersplenism. T-cell activation, decreased numbers of memory T-cells, restricted T-cell repertoire, and opportunistic infections are the result of inappropriate activation and suppression of T-cell responses directly by cytokines produced by the neoplastic B-cells. Cytopenia with severe monocytopenia is caused by the secretion of tumor necrosis factor (TNF)-α by the hairy cells. TNF-α also has autocrine pro-survival effects on the tumor clone. Treatment of HCL with IFN-α is able to restore the abnormal T-cell repertoire and hematopoiesis by inhibiting cytokine (including TNF-α) mediated effects on the T-cells and tumor cell. Fibrosis is caused by production of fibroblast growth factor-2 (FGF-2) and overexpression of its receptor FGFR1. The FGF2-FGFR1 interaction increases with CD44v3 co-receptor and syndecan family members. FGFR1 signals secretion of autocrine fibronectin and of transforming growth factor-β (TGFβ) by hairy cells. TGFβ stimulates adjacent fibroblasts to produce fibronectin and collagen type III. (From Forconi F. Hairy cell leukaemia: biological and clinical overview from immunogenetic insights. *Haematol Oncol* 2011;29:55-66, with permission.)

CLINICAL FINDINGS

The median age in HCL is between 50 and 55 years (range, 22 to 85 years), with the male-to-female ratio being 4:1.^{1, 2, 3, 4, 5, 6, 83} Classically, these patients present with weakness and fatigue, and the symptoms can usually be related to pancytopenia and splenomegaly (Table 91.2).^{1, 2, 3, 4, 5, 6, 83} Ninety percent of patients have a palpable spleen, which may be massive, and one third of patients have hepatomegaly.^{1, 2, 3, 4, 5, 6, 83} Peripheral lymphadenopathy is uncommon,⁵ but with computed tomography scanning, significant abdominal lymphadenopathy may be observed.^{84, 85} The degree of abdominal lymphadenopathy correlates with the duration and extent of disease. The incidence at presentation is 17%, but increases to 56% at relapse after chemotherapy.⁸⁴ Less frequently, mediastinal node enlargement may also be observed.⁸⁶ Compared to 30 years ago, patients are now being diagnosed earlier and have less marked splenomegaly and anemia at presentation.⁶

Most patients have pancytopenia, the etiology of which is multifactorial but is primarily related to marrow failure and splenomegaly. Marrow failure is related to replacement of marrow by hairy cells and the associated reticulin fibrosis, and to the inhibition of myelopoiesis by cytokines, such as TNF- α , released by the hairy cells.^{37, 38, 39} Splenomegaly in HCL may produce pancytopenia by three mechanisms. First, the major factor responsible for the cytopenias is pooling (sequestration, margination) of normal peripheral blood cells in the enlarged spleen.^{87, 88, 89, 90, 91, 92} As much as 90% of the peripheral platelet mass,⁸⁸ 30% of the red cell mass,⁹¹ and 65% of the granulocytes⁸⁹ may pool in a massively enlarged spleen. In HCL, apparently because of the formation of blood-filled pseudosinuses by the hairy cells, a greater proportion of the peripheral red cell volume (as much as 48%) may be pooled in a massively enlarged spleen.⁹¹ A second mechanism responsible for cytopenias with splenomegaly is the increased destruction of cells in the spleen. Finally, an expanded plasma volume contributes to the appearance of cytopenia with splenomegaly; this is particularly true for the observed anemia.^{87, 90}

TABLE 91.2 HAIRY CELL LEUKEMIA: CLINICAL MANIFESTATIONS

Manifestation	Incidence (%)
Weakness, easy fatigue	80
Fever, sweats, weight loss, anorexia	20-35
Infection	20-30
Easy bruising, bleeding	20-30
Left upper quadrant abdominal discomfort	25
Autoimmune disorders	15-30
Splenomegaly	80-90
Hepatomegaly	30-40
Ecchymoses, petechiae	20-30

Infections

Prior to the development of effective treatments for HCL, infections were a major problem and the leading cause of death.^{83, 93, 94, 95, 96} Nowadays, approximately one third of patients will develop an infection during the course of their disease and two thirds of these will be serious.⁹⁶ Fever is rarely a manifestation of the underlying HCL; when present, it should prompt a careful search for an infectious process. Approximately 30% of patients present with infection, and 70% have either documented or suspected infections during the course of the disease.⁹³ Pyogenic infections account for ~50% of infectious episodes; Gram-negative and Gram-positive bacteria are identified with approximately equal frequency.^{83, 93} However, nonpyogenic infections occur in >30% of patients,^{83, 93} and infections can occur with unusual organisms such as atypical mycobacteria, including *Mycobacterium kansasii*, which is a unique feature of HCL, in comparison to other lymphoproliferative disorders.^{83, 94, 97} Other organisms include *Toxoplasma gondii*, *Legionella*, *Listeria monocytogenes*, and *Pneumocystis jirovecii*, as well as various fungi and viruses.^{83, 98, 99, 100}

The high infection rate can be ascribed primarily to neutropenia, although several other immune defects have been described. Monocytopenia is often a prominent feature,^{101, 102} and functional abnormalities of monocytes and granulocytes may occur.^{99, 101, 103, 104, 105} The defects in monocyte production and function may account for the unusual susceptibility of these patients to atypical mycobacterial and fungal infections.^{95, 96} The T-cells are also highly abnormal in

HCL, demonstrating an inversion in the CD4:CD8 ratio, and they have a poor antigen response which is likely related to absence of CD28.^{106, 107} Moreover, there is clonogenic expansion of CD8⁺ cytotoxic lymphocytes but the target for these cells has not yet been identified.¹⁰⁸ These abnormalities can resolve with IFN- α therapy, although it may take up to 2 years to see this effect.¹⁰⁹ A depressed helper to suppressor T-cell ratio associated with a decrease in the number of T-helper cells and an increase in the number of T-suppressor cells also has been demonstrated.¹⁰⁹ As expected, lymphocyte functional studies reveal impaired delayed-type hypersensitivity to recall antigens, as well as near-absent antibody-dependent cellular cytotoxicity.¹⁰⁶ In contrast to CLL, the serum Ig levels are normal.¹¹⁰

Autoimmune Disorders

Clinical manifestations secondary to various autoimmune disorders are being recognized with increasing frequency in patients

P.1934

with HCL.^{83, 111, 112, 113, 114, 115} In one series of patients, these complications were second only to infection as a cause of morbidity.^{83, 112} The onset may occur any time during the course of the disease and is not related to the tumor burden. Most frequently, patients present with arthritis, arthralgias, palpable purpura, or nodular skin lesions resulting from cutaneous vasculitis, and low-grade fever.^{83, 112, 114} Occasionally, patients may have involvement of the lung, liver, intestine, and kidney, with a clinical picture that resembles polyarteritis nodosa.^{83, 112, 113, 115} These patients often have fever, malaise, and weight loss, and a co-existent infection must be ruled out.^{83, 112} If skin lesions are present, the diagnosis can be confirmed by biopsy, which usually shows changes compatible with a diagnosis of polyarteritis nodosum or leukocytoclastic vasculitis; occasionally, a vasculitis related to the invasion of the vessel wall by hairy cells occurs; this may appear very similar to polyarteritis nodosa with the presence of aneurysms.¹¹⁴ In some organs, such as the lung, a granulomatous vasculitis may be found.¹¹² Angiography may reveal peripheral aneurysms.¹¹² Antinuclear antibodies, rheumatoid factor, immune complexes, and hepatitis B antigen are variably positive.¹¹¹ Cryoglobulinemia has been detected in some patients.^{116, 117} It has been postulated that the increased incidence of vasculitis in HCL may be related to infections with hepatitis B and other viruses, cross-reactivity of antibodies against hairy cells with epitopes on endothelial cells, and decreased clearance of immune complexes by the impaired immune system.¹¹⁴

These autoimmune manifestations may be self-limited, but if therapy is required, a short course of corticosteroids is usually effective.¹¹⁴ Remissions have also been observed after splenectomy, IFN- α , and pentostatin therapy.^{112, 114, 115}

Unusual Manifestations

Lytic Bone Lesions

Although the immunophenotypic profile of hairy cells closely resembles that of B-cells at a developmental stage just before terminal differentiation to plasma cells, lytic bone lesions are distinctly unusual (Table 91.3).^{118, 119, 120, 121} In some patients with osteolytic lesions, HCL and multiple myeloma were thought to coexist.^{122, 123} However, several patients with classic HCL and without any evidence of plasma cell proliferation have been reported to develop osteolytic lesions.^{119, 120, 121} These lesions have a predilection for the proximal femur and usually are associated with extensive bone marrow infiltration by hairy cells.^{120, 121} The lesions, as with those seen in association with multiple myeloma, respond well to radiotherapy. The administration of corticosteroids can produce prompt relief of bone pain.¹¹⁸

Skin Involvement

Cutaneous lesions referable to thrombocytopenia (ecchymoses, petechiae), infection, or vasculitis are common during the course of HCL, but lesions caused by infiltration of the skin by hairy cells are unusual.^{124, 125} In a retrospective review of 600 cases, skin lesions thought to be due to infiltration by hairy cells were reported in 8.0% of cases, but histopathologic verification was present in only 1.3%.¹²⁴ Infiltrative lesions usually are widely disseminated and consist of erythematous maculopapules. Biopsy shows the infiltrates to be perivascular, involving the dermis but not the epidermis.¹²⁶

Splenic Rupture

Surprisingly, even with massive splenomegaly, spontaneous splenic rupture is rare in HCL, occurring in ~2% of cases.^{1, 127}

Other Organ Dysfunction

Although hairy cell infiltration of multiple organs and tissues is a frequent finding at autopsy, clinically significant organ dysfunction is unusual.¹²⁸ Infiltration of connective tissue and fat surrounding organs is common.¹²⁸ Central nervous system involvement is unusual, and only a rare case of meningeal involvement has been documented.^{128, 129} Infection is by

far the most frequent cause for neurologic complications.¹²⁹ Pleural effusions, ascites, proteinlosing enteropathy, and spinal cord compression may occur rarely in HCL and result from tissue infiltration by hairy cells.¹¹⁸

LABORATORY FINDINGS

The relative incidence of the most characteristic laboratory findings is listed in Table 91.4. In a series of 725 cases studied by the Italian Cooperative Group, 80% of patients had pancytopenia at presentation, with one third of all patients having a hemoglobin level <8.5 g/dl, neutrophils <0.5 × 10⁹/L, and platelets <50 × 10⁹/L.⁶ A careful inspection of the peripheral blood smear demonstrates the presence of typical hairy cells in >85% of patients,^{1, 6} and in 13% of cases, there are >5 × 10⁹/L hairy cells.⁶ In Bouroncle's series of 82 patients, hairy cells accounted for ≥10% of the leukocytes in 80% of patients and ≥50% in 43% of patients.² The total leukocyte count was elevated in 20%, but in only 4% did the count exceed 50 × 10⁹/l.² Monocytopenia also typically occurs in active HCL.^{101, 102}

Abnormal liver function studies, usually with an isolated elevation of the serum alkaline phosphatase level, are obtained in 10% to 19% of individuals with HCL.⁴ The leukocyte alkaline phosphatase scores are high in most cases. The Ig levels are normal in HCL and monoclonal gammopathy is rare, occurring in 1% to 3% of patients.^{3, 4} It has been difficult to prove that the hairy cells are secreting the paraprotein¹³⁰; in other cases, the M band was thought to be related to a co-existing myeloma.^{120, 122, 123}

Hairy Cells

The characteristic morphologic appearance of hairy cells on a Wright-stained peripheral blood smear is the single most important diagnostic finding (Fig. 91.5).¹² Other B-cell disorders that may have hairy projections on the cells include B-cell prolymphocytic leukemia, atypical HCL, and splenic lymphoma with villous lymphocytes (SLVL), although careful analysis and flow cytometry can differentiate these disorders.¹³¹ Typical hairy cells are mononuclear with relatively abundant cytoplasm and a cell diameter in the range of 10 to 25 μm. The cytoplasm is pale blue-gray and agranular with a variable number of elongated (hairy) projections. The mechanism for the hairy cell villi has been related to up-regulation of the expression of the Rho GTPases in the hairy cells.⁶⁴ The nuclei are round, oval, reniform, or dumbbell-shaped with a nuclear chromatin pattern that is homogeneous and less clumped and lighter staining than that of normal mature lymphocytes

and those seen in classic CLL and prolymphocytic leukemia.^{6, 25, 131} A prominent nucleolus is rarely seen. On both transmission and scanning electron microscopy, the cytoplasmic projections appear as elongated slender microvilli or broad-based ruffles or pseudopods (Fig. 91.6).¹³² Other ultrastructural features include numerous mitochondria, polyribosomes, strands of rough endoplasmic reticulum, intermediate filaments, and some lysosomal granules.²⁵ In 50% of cases, cytoplasmic inclusions known as ribosome-lamellar complexes are found.^{6, 133} These complexes appear as rod-shaped structures under light microscopic analysis.¹³³ Although seen most frequently in individuals with HCL, they are not pathognomonic, having been reported in association with other chronic B-cell lymphoproliferative disorders, acute monocytic leukemia, and even nonhematologic neoplasms.¹³⁴ The characteristic filamentous projections can be seen readily in living hairy cells; using supravital dyes and phase-contrast microscopy, one can observe the cytoplasmic projections protruding and then retracting constantly.⁶

FIGURE 91.5. Hairy cells from a peripheral blood smear (light microscopy). Cells have abundant agranular cytoplasm with multiple cytoplasmic projections. Nucleus is round, oval, or reniform with light-staining homogeneous nuclear chromatin (Wright stain, $\times 1,500$).

A useful diagnostic test for HCL is the presence of acid phosphatase isoenzyme 5 in the cytoplasm of hairy cells, but this can also be positive in other disorders.^{6, 135, 136, 137, 138, 139} Cytochemical staining procedures demonstrate that this isoenzyme, unlike other acid phosphatase isoenzymes, is not inhibited by tartrate.^{135, 136, 137, 138, 139} The enzyme concentrates primarily in the Golgi area and nuclear membrane.¹³⁵ Even though a positive tartrate-resistant acid phosphatase (TRAP) stain is not pathognomonic for the diagnosis of HCL, it has stood the test of time as an important tool in the differential diagnosis of this disease.¹³⁷ The test is positive in more than 95% of cases.⁴ In one report,¹³⁷ the TRAP stain was positive in 76%, intermediate in 21%, and negative in only 3% of 29 patients with HCL. In contrast, in 37 patients with CLL and other lymphoproliferative disorders, the test was positive in only 3%, intermediate in 32%, and negative in 65%.¹³⁷ The TRAP stain can now be carried out on paraffin-embedded tissue using 9C5, a monoclonal antibody to TRAP.^{138, 139} The majority of cases of HCL are detected using this antibody, although only 50% of the cells stain positively.¹³⁹

Gene expression profiling has identified ANXA1 as one of the most up-regulated genes in HCL.²⁴ ANXA1 codes for annexin1, and is not expressed in normal B-cells. By using an immunocytochemical assay staining for the presence of annexin A1 on either paraffin-fixed bone marrow specimens or acetone-fixed cytopins of peripheral blood, 100% sensitivity and specificity has been shown in differentiating HCL from other B-cell malignancies, including variant HCL.¹⁴⁰ This is now considered one of the best tests.

More recently it has been shown that the majority of patients with classical HCL have GTG to GAG mutations at codon 600 of the BRAF gene, the (V600E) allowing glutamic acid to be substituted for valine at position 600 of the BRAF protein.^{58, 59, 60, 61, 62} A recent study by Kreitman et al²¹ has demonstrated that all classical HCL cases have the mutation apart from the aggressive and drug-resistant IgVH4-34 subtypes and the HCL variant. Several recent reports have described highly sensitive polymerase chain reaction (PCR) assays to detect the V600E mutation, which should be useful in the diagnosis of HCL and monitoring for minimal residual disease (MRD) following therapy.^{60, 61, 62}

Immunophenotyping has proved very useful in assisting in the diagnosis of HCL and in differentiating it from variants and other B-cell malignancies.^{1, 131, 141, 142, 143} Using flow cytometry, very small numbers of abnormal cells can be detected and the diagnosis of HCL can be made on the peripheral blood of the majority of patients. The hairy cells are monoclonal and, in contrast with most other lymphoid malignancies, cases with κ or λ expression are equally represented or there is a predominance of cases with κ expression.¹⁴² Table 91.5 shows the immunophenotype of typical HCL in comparison to other chronic B-cell disorders with which it can be confused. In HCL, the leukemia cells have Sig (IgM^{+/−}, IgG, IgD, or IgA) and B-cell-associated antigens (CD19, CD20, and CD22); typically, the cells are positive for CD25, the IL-2 receptor. CD11c (leu-M5), which reacts with the α subunit of p150/95, a member of the lymphocyte function-associated antigen subfamily of integrin molecules, is present on virtually all hairy cells, but it is also present on monocytes and neutrophils and on the cells of other lymphoid malignancies.^{6, 141} Several antibodies have been raised against hairy cells, although none is entirely specific for this leukemia. B-ly-7 reacts with a 144-kd antigen (mucosal lymphocyte antigen; CD103) on hairy cells and on a small number of normal lymphocytes, which have been postulated to be the normal hairy cell counterpart.¹⁴² Like

P.1936

B-ly 7, the antibodies HML-1, Ber-ACT8, and LF61 can also recognize CD103. Two further antibodies, RAB-1 and anti-HC2, are also relatively specific for hairy cells.⁶ CD123 (α chain of the IL-3 receptor) is present in 95% of cases with classical HCL and is only rarely detected in other chronic lymphoid malignancies.^{142, 143, 144} Hairy cells are also typically strongly FMC7 positive (an epitope of CD20), negative for CD79b (an epitope of B-cell receptor β chain), and CD27, CD10, and CD38 are rarely positive.¹⁴² In summary, the diagnostic immunophenotypic features for HCL are monoclonal B-cells that are positive for CD11c, CD25, CD103, and CD123.¹⁴²

FIGURE 91.6. Hairy cells from the peripheral blood (transmission electron microscopy). The characteristic and delicate cytoplasmic projections are striking. Nucleus is irregular in shape with marginated chromatin ($\times 11,000$).

These antibodies are primarily used on viable or frozen cells, but antibodies have also been developed that can recognize formalin-resistant hairy cell antigens. One of these is DBA.44, which is directed against CD72, strongly stains hairy cells fixed in formalin or Bouin solution, and has good sensitivity.^{143, 145} However, DBA.44 is not entirely specific for hairy cells and also stains mantle zone lymphocytes and a variety of low- and high-grade B-cell lymphomas. The specificity and sensitivity for the diagnosis of HCL by immunohistochemistry can be increased when DBA.44 staining is used in conjunction with the 9C5 antibody to detect TRAP and an anti-CD20 antibody to detect B-cells.^{139, 143}

Bone Marrow

More than 99% of patients have marrow infiltration by biopsy, although the occasional patient can have isolated involvement of the spleen.³ The pattern of bone marrow involvement on biopsy specimens is near to pathognomonic for

HCL (Fig. 91.7).^{146, 147, 148} Classically, the infiltration is diffuse and has a “honeycomb” appearance with the nucleus of each hairy cell surrounded by a halo of cytoplasm. The individual cells have been described as resembling a fried egg. This pattern of infiltration is quite different from that seen in other chronic lymphoproliferative disorders, such as CLL and lymphoplasmacytic lymphoma, where the lymphocyte nuclei closely approximate each other.^{146, 147, 148} In prolymphocytic leukemia, monocytoid B-cell lymphoma, marginal zone lymphoma, and large granular lymphocytic (LGL) leukemia, in which the malignant lymphocytes are about the size of hairy cells with a low nuclear-to-cytoplasmic ratio, the infiltrates are similar to those seen in HCL. Bone marrow involvement in systemic mast cell disease and even in some nonhematologic neoplasms, such as mesenchymal chondrosarcoma, also may mimic HCL.¹⁴⁹ The hairy cells may be more easily identified using immunohistochemistry with antibodies to CD20 (L26) or DBA.44.

<i>BRAF V600E</i> mutation	80-100%	0%	0%	0%

HCL, hairy cell leukemia; B-PLL, B-prolymphocytic leukemia; SLVL, splenic lymphoma with villous lymphocytes; SMZL, splenic marginal zone lymphoma.

^a Can be detected by cytochemistry or immunohistochemistry. Less frequently used nowadays.

^b It is the most specific marker to differentiate hairy cells from other lymphoid cells. However, it is expressed in myeloid and T-cells and thus not useful to detect residual disease.

Data from Swerdlow SH, Campo E, Harris NL, et al. WHO classification of tumours of haematopoietic and lymphoid tissues, vol. 2, 4th ed. WHO 2008; Matutes E. Immunophenotyping and differential diagnosis of hairy cell leukemia. *Hematol/Oncol Clin N Am* 2006;20:1051-1063. Cook JR. Splenic B-cell lymphomas/leukemias. *Surg Path* 2010;3:933-954, and Jones G, Parry-Jones N, Wilkins B, Else M, Catovsky D. Revised guidelines for the diagnosis and management of hairy cell leukaemia and hairy cell leukaemia variant. *Br J Haematol* 2011;156:186-195.

Silver staining demonstrates diffuse reticulin fibrosis, without a collagenous component; this likely explains the usual difficulty in obtaining a marrow by aspirate (“dry tap”). Recently, it has been demonstrated that this feature is related to the ability of hairy cells to synthesize fibronectin.¹⁵⁰ In addition, hairy cells contain the fibronectin receptor, very late antigen-5, and are able to assemble the fibronectin molecule into multimers.¹⁵⁰ In some patients, the bone marrow is not diffusely involved by hairy cells; instead, focal (patchy) or interstitial infiltrates are seen.^{146, 147, 148} The focal areas may be well-circumscribed nodules or they may have irregular borders. Extravasation of red cells into areas of involvement is

often present.¹⁴⁷ Islands of normal hematopoiesis, particularly erythroid islands, are common. Increased numbers of plasma cells, lymphocytes, and mast cells may also be seen.

The overall marrow cellularity is increased in 55% of patients and normal in 38% of patients.⁶ However, in 7% of cases, the cellularity is decreased; this can lead to the erroneous diagnosis of aplastic anemia or hypoplastic myelofibrosis.^{149, 151, 152} Patients with hypocellular marrows frequently do not have splenomegaly.

Spleen and Liver

The spleen is almost always involved in HCL, and the pattern of hairy cell involvement, as with that in the bone marrow, is nearly pathognomonic for HCL.^{124, 153, 154} The infiltrates are confined to the red pulp, and, unlike other lymphoproliferative disorders, the white pulp is not expanded and is actually atrophic. Although a variable degree of red pulp involvement is seen in association with all leukemias, it is not a feature of most lymphomas until a leukemic transformation occurs. Blood-filled pseudosinuses lined by hairy cells are a characteristic feature, and, despite monocytopenia, the number of histiocytes is increased in the red pulp. Infiltration of the liver occurs in both portal areas and sinuses.¹³¹ Pseudosinuses, some resembling hemangiomas, may be present.¹³¹

FIGURE 91.7. Bone marrow biopsy (plastic embedded) in hairy cell leukemia. Pattern of the infiltration gives a "honeycomb" appearance with the nucleus of each hairy cell surrounded by a halo of cytoplasm. Nuclei are bland and round, oval, or indented (hematoxylin and eosin, $\times 600$).

DIAGNOSIS

The diagnosis of HCL usually is not difficult.^{12, 13, 14, 5, 6} Most patients have splenomegaly in the absence of peripheral lymphadenopathy, and a variable degree of pancytopenia with severe monocytopenia. Typical hairy cells are evident in the peripheral blood on a routine smear or on a buffy coat in more than 90% of cases, and the suspected hairy cells should be TRAP positive and be monoclonal B-cells that are CD11c⁺, CD103⁺, and CD25⁺. The marrow aspirate is “dry,” and the bone biopsy should reveal the classic pattern of infiltration that may be diffuse, focal, or interstitial with increased reticulin and the cells staining positively for annexin A1. When hairy cells cannot be demonstrated in the peripheral blood, the bone marrow findings are critical for diagnosis. In addition to the typical bone marrow findings, immunophenotypic analysis may be helpful in identifying the leukemic cells (Table 91.5). Rarely, the diagnosis is confirmed only after splenectomy.

P.1938

DIFFERENTIAL DIAGNOSIS

Disorders to be considered in the differential diagnosis of HCL include lymphoid malignancies that present with splenomegaly in the absence of lymphadenopathy and are listed in Table 91.6.^{12, 131, 146} They can usually be easily separated by their clinical features, morphology, and immunophenotype (Table 91.5). The disorders most likely to be confused with hairy cell leukemia are the hairy cell variant, B-cell prolymphocytic leukemia, and splenic marginal zone lymphoma (SML)/SLVL.¹⁴⁶

The HCL variant makes up 10% to 20% of all HCL cases and was originally described as having morphologic features intermediate between hairy cells and prolymphocytes and nowadays is classified by the World Health Organization (WHO) as being a separate disease from classical HCL.^{12, 155, 156} However, there are other presentations of the HCL variant, including hybrid forms of HCL and prolymphocytic leukemia or CLL, a blastic form of HCL, and an HCL multilobular form.^{155, 156, 157, 158, 159, 160, 161} These patients have many of the clinical and laboratory features of typical HCL. The HCL variant differs from typical HCL in a number of ways^{155, 156}:

- Patients are older with a median age at diagnosis of 71 years.
- The peripheral leukocyte count is higher (often $>50 \times 10^9/L$).
- The hairy cells have a higher nuclear-to-cytoplasmic ratio with more condensed nuclear chromatin and more prominent nucleoli than in classic HCL.
- The cells are TRAP-, CD25-, and CD123-, are usually IgVH unmutated, frequently use the IgVH4-34 gene, and do not have the BRAF (V600E) mutation.
- The monocyte count is normal.
- The marrow can usually be aspirated and there is an interstitial pattern of infiltration in the marrow with variable fibrosis.
- The clinical course is aggressive with a poor response to therapy and the median survival is 9 years.

B-cell prolymphocytic leukemia may have a presentation very similar to that of HCL, with splenomegaly and minimal or no peripheral lymphadenopathy.¹⁶² Prolymphocytic leukemia can usually be distinguished from HCL in that the nuclear chromatin is more clumped than in hairy cells, the level of peripheral lymphocytosis is high, the TRAP stain is negative or only weakly positive, and expansion of the white pulp in the spleen is evident. Cells can be differentiated from hairy cells by tissue markers.¹⁴²

In SLVL, previously known as malignant lymphoma simulating leukemic reticuloendotheliosis¹⁶³ and now considered to be one of the SMZLs,¹² the white cell count is usually higher than in HCL, being 3 to $38 \times 10^9/L$.^{163, 164} Typically, these patients have prominent splenomegaly and no lymphadenopathy. The leukemia cell is smaller and frequently contains a nucleolus, and the villi are shorter, fewer, and more uneven than in a typical hairy cell and are frequently concentrated at one end of the cell. A small monoclonal band is found in the serum or urine in two thirds of patients and patients may develop a Coombs-positive autoimmune hemolytic anemia.¹⁶⁴ Marrow involvement is patchier without the “fried-egg” pattern or reticulin fibrosis; in the spleen, the white pulp is expanded, and there is a variable degree of red pulp expansion without pseudosinus formation.^{163, 164} Immunophenotyping can also assist in differentiating these cells from hairy cells.¹³ Although these cells have many markers similar to those of hairy cells, only 25% of cases are CD25⁺, and these do not have the other

classic markers for HCL (strong staining for CD11c, CD103, and CD123). In marginal zone B-cell lymphoma, the pattern of bone marrow infiltration also tends to be patchy or focal without reticulin fibrosis, but in the spleen, the infiltration is predominantly in the red pulp, such as occurs in HCL.¹²⁴ In nodal marginal zone lymphoma (monocytoid B-cell lymphoma), the infiltrates resemble those of HCL, but the clinical presentation is different.^{12, 13} These patients usually have peripheral lymphadenopathy without splenomegaly and a high incidence of extranodal involvement. Bone marrow involvement is less frequent and usually is paratrabecular; peripheral blood involvement is rare. In lymph nodes, the infiltration is interfollicular and sinusoidal, often with preservation of some lymph follicles, a finding similar to that seen in hairy cell involvement of lymph nodes.

TABLE 91.6 HAIRY CELL LEUKEMIA: DIFFERENTIAL DIAGNOSIS

Splenic marginal zone lymphomas/splenic lymphoma with villous lymphocytes

Hairy cell variant

B-cell prolymphocytic leukemia

Chronic lymphocytic leukemia/small lymphocytic lymphoma

Lymphoplasmacytoid lymphoma, including Waldenström macroglobulinemia

Mantle cell lymphoma

Myeloproliferative disorders

Malignant histiocytosis

Primary lymphoma of spleen

Monocytoid B-cell lymphoma

Large granular lymphocytic leukemia

Systemic mast cell disease

Patients with CLL/small lymphocytic lymphoma (SLL), lymphoplasmacytic lymphoma, primary splenic CLL, and mantle cell lymphoma can have the same clinical presentation as HCL, but the laboratory features are quite different.^{12, 131} The cytologic appearance of the malignant cells on Wright stain and the appearance and distribution of the infiltrates in the bone marrow, spleen, and lymph nodes distinguish these disorders from HCL. In CLL/SLL, the lymphocytes are small with scant cytoplasm and clumped nuclear chromatin. The bone marrow usually is diffusely involved in CLL, but a focal interstitial pattern may be evident early in the course of the disease. In SLL, the bone marrow may not be involved early in the course, and the pattern initially is more focal. Involved lymph nodes in SLL and CLL show diffuse infiltration with small mature lymphocytes that completely efface the nodal architecture. The spleen shows not only white pulp expansion, but also a variable degree of red pulp expansion. The malignant lymphocytes in CLL/SLL are CD5⁺ in contrast to hairy cells, which are CD5⁻. In the lymphoplasmacytic disorders, particularly Waldenström macroglobulinemia, splenomegaly, peripheral lymphadenopathy, and a variable degree of pancytopenia are a more common presentation. As with hairy cells, these malignant B-cells are CD5⁻, but they are CD103⁻ and usually CD11c⁻ and CD25⁻. In addition, the cytologic appearance (plasmacytoid lymphocytes) and the frequent presence of a serum IgM monoclonal spike distinguish them from HCL. Although mantle cell lymphoma is usually associated with generalized lymphadenopathy, splenomegaly may be a prominent feature. Again, this lymphoma can be differentiated from HCL by the cytologic appearance of the cells, immunophenotyping, and the pattern and nature of the infiltration in lymph nodes, spleen, and bone marrow. The malignant cells are small, mature lymphocytes with scant cytoplasm, a round or cleft nucleus, and clumped nuclear chromatin. The bone marrow may demonstrate diffuse or patchy involvement. Lymph nodes are diffusely infiltrated and often show expansion of the mantle zone with residual isolated benign-looking germinal centers. A similar pattern is seen in the expanded white pulp in the spleen with a variable degree of red pulp expansion.

Various myeloproliferative disorders present with splenomegaly without peripheral lymphadenopathy, but the diagnosis is established easily by bone marrow biopsy and the findings on a peripheral blood smear.

P.1939

Malignant histiocytosis occasionally is associated with splenomegaly as the predominant manifestation.¹⁶⁵ The characteristic cytologic and cytochemical features of the malignant histiocytes and the subsequent course of the disease make the process of differential diagnosis easy.

Rarely, a diagnosis cannot be made for a patient with symptomatic splenomegaly short of splenectomy; these patients may have primary lymphoma of the spleen¹⁶⁶ or, less commonly, primary splenic HCL.¹⁶⁷

LGL leukemia frequently presents with splenomegaly without peripheral lymphadenopathy.¹⁶⁸ The disease is characterized by the presence of cells that are bigger than CLL cells and have abundant cytoplasm containing azurophilic granules. LGLs may be CD3⁻ NK-cells that mediate nonmajor histocompatibility complex-restricted cytotoxicity, or they are CD3⁺ cells, that may be in vivo activated cytotoxic T-lymphocytes that mediate nonmajor histocompatibility complex-restricted cytotoxicity.¹⁶⁸ T-LGL leukemia is associated with neutropenia (which may be cyclical), red cell aplasia, and rheumatoid arthritis, but is a distinct entity from Felty syndrome.¹⁶⁸ The usual immunophenotype of T-LGL leukemia is CD3⁺, CD4⁻, CD8⁺, CD16⁺, CD56⁻, CD57⁺, and TCRαβ⁺. NK-LGL leukemia occurs most frequently in Japan and has an acute fulminant course with high fever, hepatosplenomegaly, and pancytopenia. However, chronic NK-LGL leukemia can occur with clinical features similar to those of T-LGL leukemia.¹⁶⁸ These cells are usually CD3⁻, CD4⁻, CD8⁻, CD16⁺, CD56⁺, and CD57⁻.

Systemic mast cell disease, in which splenomegaly may be a prominent feature, rarely presents a problem in differential diagnosis, except for the appearance of the mast cell infiltrates in tissue sections that can closely mimic HCL.¹⁶⁹

More recently, a condition called hairy B-cell lymphoproliferative disorder (HBLD) has been described in five patients from Japan.^{170, 171} All patients were middle-aged women who presented with clinical and laboratory features consistent with the HCL variant and had a polyclonal increase in IgG. However, the hairy cells were polyclonal. This condition is thus similar to persistent polyclonal B-cell lymphocytosis, a rare and benign condition seen typically in middle-aged female smokers with a familial tendency.^{172, 173, 174} The lymphocytes are binucleated and have abundant cytoplasm. There is a polyclonal increase in IgM and a strong association with HLA-DR7.¹⁷² However, HBLD differs from persistent polyclonal B-cell lymphocytosis in that the patients in HBLD are not smokers, there is a polyclonal increase in IgG in HBLD as opposed to the polyclonal increase in IgM seen with persistent polyclonal B-cell lymphocytosis, the cells in HBLD are not binucleated, are CD11c⁺, and there is no association with HLA-DR7 in HBLD. The disorder needs to be differentiated from the HCL-Japanese variant (HCL-JV) which is similar to the HCL variant in having splenomegaly, a high peripheral leukocyte count with hairy cells, and does not have the diagnostic markers of classical HCL (Table 91.5).¹⁵⁶ However, in contrast with the HCL variant, the clinical course of HCL-JV is indolent and similar to classical HCL.

TREATMENT

Although splenectomy used to be the standard treatment for HCL, therapy for this disease over the past quarter of a century has usually involved IFN-α, the nucleoside analogs, and rituximab.^{136, 175, 176} Splenectomy and IFN-α may still be used for HCL under specific circumstances, but the standard therapy consists of the nucleoside analogs pentostatin or cladribine, which produce complete and durable remissions in the majority of patients. More recently, it has been demonstrated that the monoclonal antibody rituximab, which is directed against CD20, and the immunotoxins LMB-2 and BL22, which are directed against CD25 and CD22, respectively, have significant activity against nucleoside-resistant HCL. As discussed, there has also been recent interest in combining the nucleoside analogs with rituximab. Defining the optimal strategy for this combination with respect to schedule of drug administration and numbers of doses of the monoclonal antibody will require additional investigation.

Splenectomy

Until the mid-1980s, the standard therapy for HCL was splenectomy.^{5, 177, 178, 179, 180} The variable degree of pancytopenia in all patients during the course of their disease is partly related to splenomegaly.^{80, 81, 82, 83} An enlarged spleen may be responsible for the development of peripheral cytopenias by one or more of three mechanisms: increased sequestration or pooling, increased rate of peripheral destruction, or dilution of the cellular elements in the peripheral blood by an expanded plasma volume.^{80, 81, 82, 83} Other clinical manifestations, such as hypermetabolism, weight loss, early satiety, and left upper quadrant abdominal discomfort, are also caused by splenomegaly. Occasionally, patients may achieve a complete remission (CR) with splenectomy, and these patients may have a pure "splenic" form of HCL.² Approximately two thirds of patients have a hematologic response to splenectomy; the procedure may also alleviate early satiety, weight loss, and abdominal discomfort.⁵ However, it is unclear whether this procedure prolongs survival, because all the studies are retrospective, and, because of the obvious clinical benefit of splenectomy, randomized prospective trials have not been carried out.⁵ Early studies, with small numbers of patients, demonstrated no overall improvement in survival for patients after splenectomy.^{177, 178} However, in a large, multicenter retrospective analysis of 391 patients, a highly significant survival advantage ($P < 0.0001$) was demonstrated for those patients who underwent splenectomy.¹⁷⁹ In the

multicenter analysis, CR, defined as a postsplenectomy hemoglobin >11 g/dl, neutrophils $>1 \times 10^9/L$, and platelets $>100 \times 10^9/L$, was achieved in 40% of patients.¹⁷⁹ An increase was noted in the hemoglobin in 92%, neutrophils in 84%, and platelets in 92% of patients.¹⁷⁹ Jansen et al.¹⁷⁹ also reported that patients with larger spleens responded better than those with smaller spleens, but this has been disputed.¹⁸⁰ The duration of response after splenectomy is variable, but some patients remain asymptomatic for years. Approximately one third, however, achieve only a minimal response or relapse within a few months. In an analysis of prognostic variables after splenectomy in 194 patients, the most important were bone marrow cellularity and the platelet count.¹⁸¹ Failure-free survival, defined as time from splenectomy to death or the need for more therapy, was significantly worse if the post-operative bone marrow cellularity was $\geq 85\%$ or the platelet count was $<60 \times 10^9/L$, or both.¹⁸¹

Although splenectomy is now rarely required in HCL, it may be of value for patients with splenic rupture, patients with the pure "splenic" form of the disease, and patients with splenomegaly and profound thrombocytopenia, having megakaryocytes in the marrow.⁵

Interferon- α

IFN- α , both the natural form and the two recombinant forms (IFN- $\alpha 2a$ and IFN- $\alpha 2b$), is effective in the treatment of HCL,^{182, 183, 184, 185, 186, 187, 188, 189, 190, 191} and a recent study has provided insight into the mechanism for this activity.¹⁹² IFN- α has been shown to induce apoptosis in nonadherent hairy cells; this is related to an increase in the production of TNF by the hairy cells associated with sensitization of the hairy cells to TNF- α .¹⁹² The sensitization is due to a decrease in the levels of inhibitors of apoptosis (IAPs) by IFN- α . It is interesting that IFN- α does not induce apoptosis in hairy cells adhering to vitronectin or fibronectin, because IFN- α does not affect the IAPs in adherent cells. The receptors for TNF- α are not changed by IFN- α . These results may explain why IFN- α can clear

P.1940

hairy cells rapidly from the bloodstream, but not from the tissues, in which the leukemic cells presumably are adherent.

A CR was defined as normalization of the peripheral blood counts (hemoglobin >120 g/L, platelets $>100 \times 10^9/L$, and neutrophils $>1.5 \times 10^9/L$) for at least 1 month with no morphologic evidence of hairy cells in the marrow or peripheral blood and resolution of organomegaly. A partial remission (PR) was defined as the normalization of peripheral blood counts and the persistence of $>5\%$ hairy cells in the marrow; however, treatment must have produced a $>50\%$ fall in the hairy cell infiltration in marrow. The aggregate results show that the overall response rate with IFN- α is $\sim 80\%$, with 13% having a CR and 69% having a PR.^{189, 190, 191} Responding patients have a reduced incidence of infections, even if they remain neutropenic.¹⁸⁷ The responses occur rapidly, regardless of whether the patients have previously had a splenectomy, with hairy cells disappearing from the peripheral blood within the first week; the platelet counts return to normal within 2 months, the hemoglobin level within 4 months, and the neutrophil counts within 4 to 6 months.^{182, 187} The percentage of hairy cells in the bone marrow decreases, but they rarely disappear completely, and the reticulin fibrosis persists.^{193, 194} Patients with CD5⁺ hairy cells¹⁹⁵ and HCL-variant patients¹⁴⁹ respond poorly to IFN- α .

The optimal dose schedule for IFN- α in HCL has yet to be established. In most series, the dose is 2 to 4×10^6 U/m² subcutaneously (SC) three to seven times weekly for 12 months. Higher doses do not appear to increase the response rate and are associated with more toxicity.^{186, 196} In addition, extending the treatment beyond 12 months does not improve the response rate, and the development of a chronic fatigue syndrome is more prevalent and severe.¹⁹⁷ Doses 1 log lower (2×10^5 U/m² three times weekly) show activity, but the response is inferior to that achieved with higher IFN- α doses.¹⁹⁸ However, the relapse rate is high (33% to 77%) after the discontinuation of IFN- α , usually 6 to 31 months after cessation of therapy.^{188, 199} It has been demonstrated that maintenance low-dose IFN- α (1×10^6 U, three times/week, or 3×10^6 U, once per week) can prolong remissions with minimal toxicity.^{191, 200, 201} In one study, patients received either no maintenance therapy or 1×10^6 U IFN- α three times/week; 37 of the 56 patients who did not receive maintenance therapy relapsed at a median time of 19 months, whereas none of the 28 patients receiving maintenance therapy relapsed, with the median follow-up time being 30 months.²⁰⁰ When patients relapse after IFN- α therapy, a further remission can generally be obtained with IFN- α ^{200, 201} or the nucleoside analogs.^{136, 175, 176} In addition, patients who relapse after therapy with the nucleoside analogs may respond to IFN- α , confirming the lack of cross-reactivity between these agents.²⁰²

Neutralizing anti-IFN antibodies appear to develop in one third of patients treated with IFN- $\alpha 2a$,²⁰³ but this does not occur with IFN- $\alpha 2b$.²⁰⁴ The clinical significance of these neutralizing antibodies and their role in the induction of resistance to therapy are controversial. In 51 patients with HCL treated with IFN- $\alpha 2a$, 31 (61%) developed antibodies after a median of 6 months of therapy, and in 16 of these, the antibodies neutralized the antiviral activity of recombinant IFN- $\alpha 2a$ in vitro but had no effect on natural IFN- α .²⁰³ It is interesting that six of the patients with antibodies were clinically resistant to

IFN- α , whereas none of the patients without antibodies were resistant. However, in a follow-up study, no further patients were noted to have developed antibodies, and antibodies to IFN could no longer be detected in patients who previously had antibodies, although they continued to receive IFN- α .²⁰⁵

Virtually all patients experience toxicity with IFN- α therapy, and the frequency and severity are dose- and age-related. Flu-like symptoms occur in most patients with the initiation of treatment; these symptoms can usually be controlled with acetaminophen or by reducing the IFN- α dosage, and symptoms usually resolve within 2 to 4 weeks. Less common symptoms include: nausea and vomiting; diarrhea; central nervous system manifestations, such as somnolence and confusion; cardiovascular disorders, including hypotension and tachycardia; and skin changes, such as rash and pruritus.¹⁹⁶ With high doses, leukopenia, thrombocytopenia, and anemia may occur, but this is rare with the doses of IFN- α used for HCL. A worsening of pre-existing autoimmune disorders, or the emergence of new autoimmune problems, has also been reported with IFN- α therapy; this appears to be related to the development of multiple autoantibodies.²⁰⁶ In most reports, patients developed thyroiditis, autoimmune thrombocytopenia, or anemia.^{207, 208} Kampmeier et al.²⁰⁹ reported an increased incidence of second malignancies in HCL patients treated with IFN. Of 69 patients treated with IFN- α 2b for 12 to 18 months, 13 (19%) developed second malignancies; this incidence was substantially higher than predicted. Six of the tumors were hematologic, and seven were adenocarcinomas. The tumors developed 17 to 105 months after the initiation of IFN- α . However, these results have not been confirmed, and no increase in the incidence of second malignancies was observed in 200 HCL patients in another study, of whom 147 had been treated with IFN- α .²¹⁰

Nucleoside Analogs

The nucleoside analogs pentostatin (pentostatin; Nipent, SuperGen, San Ramon, CA), cladribine (cladribine; Leustatin, Ortho Biotech, Raritan, NJ), and fludarabine (F-ara-A AMP; Fludara, Berlex Laboratories, Richmond, CA) have significant activity in the low-grade lymphoid malignancies (Fig. 91.8).^{136, 175, 176} Both pentostatin and cladribine have now replaced IFN- α as first-line therapy for HCL, and fludarabine is now one of the standard treatments for CLL.

After therapy with pentostatin, deoxyadenosine and adenosine accumulate in the plasma; after uptake into cells, deoxyadenosine is phosphorylated to deoxyadenosine monophosphate, deoxyadenosine diphosphate, and deoxyadenosine triphosphate (dATP); this occurs preferentially in lymphocytes.²¹¹ The intracerebral accumulation of deoxyadenosine and adenosine likely causes the nausea and vomiting that are a major toxicity of this agent.²¹² Cladribine and F-ara-A are halogenated derivatives of deoxyadenosine that are resistant to degradation by adenosine deaminase. For clinical use, F-ara-A is administered as the more water-soluble monophosphate, F-ara-AMP (fludarabine), which is rapidly dephosphorylated in the plasma to F-ara-A.^{213, 214} As with deoxyadenosine, cladribine and F-ara-A accumulate in lymphocytes as their phosphorylated derivatives and their mechanisms of action have been recently reviewed.^{215, 216, 217} These agents can kill lymphocytes in three ways (Figs 91.9 and 91.10).^{215, 216, 217} First, the triphosphate forms can trigger DNA breaks, which result in the release of cytochrome c from the mitochondria; the released cytochrome c interacts with Apaf-1 and dATP, causing the activation of caspase 9 and, subsequently, apoptosis. Second, the increased levels of triphosphates can enhance the effects of endogenous dATP on the apoptosome, inducing apoptosis. Finally, cladribine differs from deoxyadenosine and F-ara-A in that it is phosphorylated by deoxyguanosine kinase in the mitochondria to cdATP, which is directly toxic to the mitochondria.

Pentostatin is highly effective in HCL and produces a much higher rate of durable CR than is observed with IFN- α (Table 91.7).¹⁸⁹ Pentostatin has been administered in a variety of different doses and schedules for HCL, but regardless of the mode of administration, it produces responses in most patients. Of 960 patients in nine studies, the CR rate ranged from 44% to 89% (median, 76%), and the PR rate varied from 0% to 52% (median, 16%).^{189, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225} Patients who relapse after splenectomy or who are resistant to IFN- α also respond to pentostatin, with a median CR rate of 42% and a PR rate of 45%.^{225, 226, 227} In two large studies, the response rates to pentostatin were

P.1941

similar in untreated patients and in patients previously treated with IFN- α .^{189, 224} Moreover, these studies identified young age, initial high hemoglobin, high white cell count, and little or no splenomegaly as favorable prognostic features.^{189, 224} The most commonly used treatment regimen is pentostatin 4 mg/m² intravenously (IV) every second week; the average number of treatments to CR is 8 (range, 4 to 15).^{189, 220} The peripheral blood lymphocyte count falls rapidly after the initiation of treatment, with the hairy cell count decreasing by 50% to 95% in the first week.²²⁸ Concomitantly, there is a rapid increase in platelets followed by recovery of neutrophils and hemoglobin; the median time to documented peripheral and marrow CR is 4 months.²²⁸ In contrast to IFN- α , there is resolution of the marrow fibrosis after therapy with pentostatin.^{228, 229} Using immunophenotyping of peripheral blood or bone marrow, immunohistochemistry of the bone

biopsy, or gene rearrangement studies, one can detect MRD in HCL patients who are in morphologic CR after pentostatin, suggesting that pentostatin cannot entirely eliminate the hairy cell population.^{229, 230} In addition, relapses are observed after discontinuation of treatment without evidence of a plateau, although the duration of remissions is considerably longer than for IFN- α .^{189, 221, 231, 232, 233}

FIGURE 91.8. Structures of nucleoside analogs.

Several studies have evaluated the long-term outcome of patients treated with pentostatin^{223, 225, 232, 233, 234, 235, 236} (Table 91.8). The longest follow-up is of 188 patients followed for a median of 14 years with the relapse rates at 5, 10, and 15 years being 24%, 42%, and 47%, respectively.²³³ The likelihood of relapse depended on response and pre-treatment parameters with the longest remission being in those who achieved a CR and had a pre-treatment hemoglobin of >100 g/L and platelets $>100 \times 10^9$ /L, and the worst prognosis was in those who achieved a PR and were anemic and/or thrombocytopenic pre-treatment (Fig. 91.11).^{233, 234} For patients who remain in CR at 5 years the likelihood of remaining in CR by 15 years is 75%. For patients requiring another treatment, the likelihood of achieving a CR decreased but for those who did achieve a CR the prognosis was similar as for those with a first-time CR.^{233, 234}

In the Phase III intergroup study, patients were randomized to receive pentostatin, 4 mg/m^2 IV every 2 weeks, or IFN- α , 3×10^6 U SC three times per week.^{189, 236} Patients not responding to one treatment were switched to the other agent. There were 241 patients who received pentostatin and were followed for a median of 9.3 years; 154 received pentostatin as initial therapy, and 87 received pentostatin after failure with IFN- α . For all

P.1942

patients, the estimated 5- and 10-year survivals were 90% and 81%, similar to those predicted for the general population. The survival was similar whether patients were treated initially with pentostatin or were crossed over to pentostatin after

treatment with IFN- α (Fig. 91.12A). Patients younger than 55 years of age did significantly better than patients 55 years of age or older, and the 10-year survivals for the two groups were 93% and 68%, respectively (Fig. 91.12B). Similarly, in a large multicenter retrospective study from France, the estimated survivals at 5 and 10 years in 230 evaluable patients treated with pentostatin were both 89%.²²⁴ In that study, a hemoglobin level <100 g/L, a white cell count <2 $\times 10^9$ /L, and lymphadenopathy were associated with decreased survival.

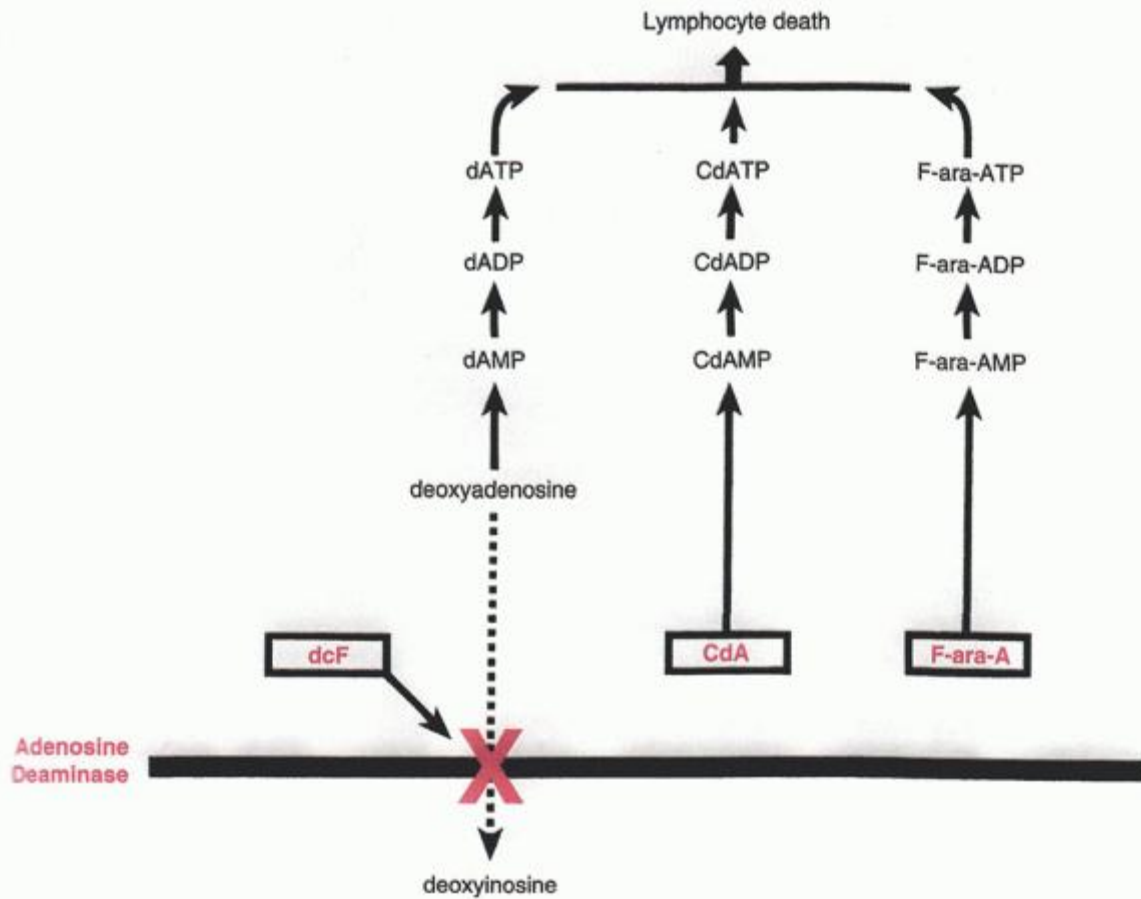

FIGURE 91.9. Metabolism of the nucleoside analogs. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; CdA, 2-chlorodeoxyadenosine; d, deoxy; dCF, 2'-deoxycoformycin.

Pentostatin is generally well tolerated, although nausea and vomiting and lethargy can occur.^{189, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225} Drug-induced neutropenia with fever commonly occurs with initiation of treatment and deaths from infection have occurred. However, for patients receiving 4 mg/m² pentostatin every 2 weeks, infections can be avoided by delaying the treatments if the white blood count is <1.5 $\times 10^9$ /L.²²⁰ Pentostatin decreases the number of T-cells to a greater extent than that of B-cells, and CD4⁺ cells are affected to a greater extent than CD8⁺ cells or NK-cells, whereas Ig levels are not affected.^{229, 237, 238, 239} The CD4⁺ and CD8⁺ cell counts fall to <0.2 $\times 10^9$ /L during therapy;^{229, 237, 238} after discontinuation of pentostatin, the CD4⁺ counts gradually recover and normalize in 3.0 to 49.5 months (median, 14.5 months).²²⁹ The CD8⁺ and B-cells recover at the same rate.^{229, 237, 238} Associated with the decrease in T-cells during therapy is an increase in the incidence of herpetic infections, which are easily treated with acyclovir, and there is a gradual decrease in the incidence after discontinuation of therapy.^{229, 237, 238} However, there is no increase in more unusual opportunistic infections, either during therapy or during long-term follow-up, and there is no evidence of a significant increase in second malignancies.^{233, 236} Although neurotoxicity is a problem with high doses of pentostatin,²⁴⁰ this is not observed with the doses used for HCL.

Cladribine appears to have activity equivalent to that of pentostatin in HCL, and has the advantage of rarely causing nausea and vomiting although it appears to be more myelosuppressive.^{233, 234, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253} In initial studies, cladribine was administered as 0.1 mg/kg/day by continuous infusion for 7 days, because in vitro studies indicated that a prolonged exposure to cladribine was required for cytotoxic effect.²⁴⁶ Response rates varied, with the CR ranging from 50% to 91% (median, 80%) and PR from 0% to 37% (median, 16%).^{241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253}

P.1943

As with pentostatin, there was a rapid recovery in blood counts, with the platelet count increasing almost immediately, followed by an increase in neutrophils and hemoglobin. Some patients achieved a CR with normal blood counts, whereas the marrows remained hypocellular.²⁵⁴ Technetium 99 m sulfur colloid scans have demonstrated increased uptake in the distal appendicular skeleton in some of these patients, suggesting abnormal areas of hematopoiesis.²⁵⁴ Although hairy cells may not be seen in the marrow 3 to 4 months after cladribine treatment, the leukemic cells can still be detected by immunostaining, using the monoclonal antibody, DBA.44,²⁵⁵ or by using the (PCR) with clonospecific probes for IGH genes.²⁵⁶ When marrows were intermittently examined by DBA.44 for 25 months after treatment with cladribine, there was no increase in the number of hairy cells in the marrow in most cases, suggesting stabilization of residual disease.²⁵⁵ However, others have suggested that the presence of residual disease is predictive of relapse.²⁵⁷ Because cladribine has not been compared with pentostatin in a randomized study, it is unknown whether one of these agents is superior in terms of toxicities and long-term outcomes (Table 91.8). However, in patients achieving a CR morphologically, Tallman et al.²⁵⁷ demonstrated with immunohistochemical stains that there is evidence of residual disease comparable to that observed after pentostatin. Moreover, Else et al.²³³ have recently carried out a retrospective analysis of patients treated either with pentostatin or cladribine at the Royal Marsden Hospital. The overall response rates and survivals were the same for both drugs. In a large, long-term study from the Scripps Clinic, 91% of patients achieved a CR with cladribine, and these 349 patients were followed for a median of 52 months (range, 1 to 134 months).²⁴⁸ Of these patients, 24% relapsed at a median time of 30 months (range, 7 to 85 months). The overall survival at 48 months was 96%. The same group has evaluated 207 patients followed for at least 7 years,²⁴⁹ and 37% relapsed with patients achieving a CR relapsing later (median 44 months [8 to 118 months]) than those who achieved PR (median 31 months [10 to 108]). Of 60 patients who received a second cycle of cladribine, 75% achieved a CR and 17% a PR. It is interesting that 19 of 358 patients treated at Scripps have remained in long-term remission after a single cycle of cladribine. The median time from cladribine was 16 years and 9 had no evidence of MRD, 7 had MRD, and 3 had morphologic evidence of HCL.²⁵³

FIGURE 91.10. Mechanism of action of the nucleoside analogs. CdA, 2-chlorodeoxyadenosine; dATP, deoxyadenosine triphosphate; dCF, 2'-deoxycoformycin. (Modified from Genini D, Adachi S, Chao Q, et al. Deoxyadenosine analogs induce programmed cell death in chronic lymphocytic leukemia cells by damaging the DNA and by directly affecting the mitochondria. *Blood* 2000;96:3537-3543, with permission.)

A number of patients who were resistant to pentostatin have obtained remissions with cladribine, suggesting a possible lack of cross-resistance between these agents.^{224, 258} This may be related to the additional action of cladribine on the mitochondria of the leukemia cells.^{215, 216} Likewise, some patients who have not achieved a CR with cladribine have also achieved durable remissions with pentostatin. Therefore, the overall response rates and relapse rates are comparable with either purine analog.

Cladribine can be toxic and was implicated as the cause of deaths in the National Cancer Institute group C Phase II study in P.1944

P.1945

1.1% of 979 patients.²⁴⁷ The major cladribine toxicity is marrow suppression; one third to one half of patients developed severe neutropenia with infections and often required prolonged blood support after therapy. This problem is not prevented by prophylactic antibiotics, and, although an infectious cause for the fever is not found in most cases, affected patients may require hospitalization for septic workup and antibiotics. The likelihood of this complication occurring increases with the severity of initial marrow involvement, and it has been suggested that these patients should initially be treated with IFN- α .²⁵⁹ Alternatively, to reduce the risk of infections, granulocyte colony-stimulating factor has been administered using 5 $\mu\text{g}/\text{kg}/\text{day}$ SC on days -3, -2, and -1 before a standard 7-day course of cladribine, and then after cladribine until the neutrophil count was $>2 \times 10^9/\text{L}$ for

P.1946

2 consecutive days.²⁶⁰ Although granulocyte colony-stimulating factor increased the neutrophil count before therapy and reduced the severity of neutropenia after cladribine, there was no decrease in the number of febrile episodes and the number of hospitalizations for antibiotics. An identical phenomenon is observed after treatment of HCL with pentostatin,^{218, 231} and it has been suggested that the fever is related to tumor lysis and the release of cytokines by the tumor.²⁴⁴ It is important to realize that patients with active infection were not eligible to participate in the initial cladribine trials. Thus, a patient with hairy cell leukemia who requires therapy, but has an active infection, presents a challenging dilemma. In general, it is important to try to treat any infection before administering a purine analog and if there is urgency in treating the leukemia initial therapy with IFN should be considered. Alternatively, pentostatin has been administered to patients with infection when therapy was essential and the incidence of febrile neutropenia may be less following pentostatin than seen with cladribine. The intermittent schedule of drug administration following pentostatin affords an opportunity to titrate the drug administration depending upon the neutrophil count. It is clear that the optimal management of patients with hairy cell leukemia with a concomitant active infection requires further investigation.

TABLE 91.7 RESPONSE RATES WITH DIFFERENT AGENTS AND TREATMENT SCHEDULES FOR HAIRY CELL LEUKEMIA

Agent	Author ^{Ref} (Year)	Dose and Schedule	Number of Patients	CR (%)	PR (%)
Interferon-α

FIGURE 91.11. Relapse-free survival after first-line purine analog therapy. Patients were separated by pre-treatment blood

counts and response to therapy. Relapse-free survival was longest in complete responders (CR) with hemoglobin (Hb) >100 g/L and platelet count >100 × 10⁹/L (CR + Hb and Plt higher) and shortest in partial responders with hemoglobin <10 g/dl and/or platelet count <100 × 10⁹/L (PR + Hb and/or Plt lower). (From Else M, Dearden CE, Mastutes E, et al. Long-term follow-up of 233 patients with hairy cell leukaemia, treated initially with pentostatin or cladribine, at a median of 16 years from diagnosis. *Br J Haematol* 2009;145:733-740, with permission.)

FIGURE 91.12. Long-term responses to treatment with the nucleoside analogs. A: Survival of patients treated initially with pentostatin or after crossover from interferon- α . Survival is similar in both groups ($p = 0.59$). Figure shows estimated distributions of overall survival (Kaplan-Meier estimates) from date of registration for 2'-deoxycoformycin (dCF) therapy, by phase of treatment. B: Overall survival by age of patients treated with dCF. Survival is significantly better for patients younger than 55 years of age ($p < 0.0001$). Figure shows estimated distributions of overall survival (Kaplan-Meier estimates) from date of registration for dCF therapy, by age at start of initial therapy. (From Flinn IW, Kopecky KJ, Foucar MK, et al. Long-term follow-up of remission duration, mortality, and second malignancies in hairy cell leukemia patients treated with pentostatin. *Blood* 2000;96:2981-2986, with permission.)

Cladribine also produces a profound fall in the CD4⁺ and CD8⁺ cell counts, and although CD8⁺ cell counts may recover within 3 months, the CD4⁺ count may take longer than 3 years to normalize.^{261, 262} Despite this, there have, to date, been no long-term problems with opportunistic infections after therapy with cladribine.^{239, 244} However, infections, sometimes opportunistic, do occur in some of these patients, and deaths have been reported.^{243, 263} More recently, Epstein-Barr virus, associated diffuse large B-cell non-Hodgkin's lymphoma, have been described in two patients shortly after completion of cladribine therapy.^{264, 265} Significant neurotoxicity has also been observed with cladribine and may involve the legs or arms.²⁴⁷ Transfusion-associated graft-versus-host disease has been observed with multiple cycles of cladribine or fludarabine in low-grade lymphomas and CLL,^{266, 267} but, to the authors' knowledge, this has not yet been observed in HCL.

There has been interest in investigating different modes of cladribine administration to simplify the treatment and minimize toxicity. Liliemark et al.²⁶⁸ demonstrated an identical "area under the curve" for drug concentration versus time using the same cladribine concentration given by continuous infusion, as a 2-hour infusion, or given orally using twice the IV dose. Similar responses have been obtained with cladribine in HCL using 0.1 mg/kg IV over 2 hours daily × 5²⁶⁹ or 0.1 mg/kg SC daily × 7^{270, 271} and when the drug was administered as 0.1 mg/kg/day by continuous infusion × 7. Weekly cladribine (e.g., 0.14 to 0.15 mg/kg/week IV × 5 to 6 weeks) appears to be as effective as the other schedules.^{272, 273, 274, 275, 276} However, although this regimen was initially felt to be associated with less marrow suppression and to be safer than conventional regimens, recent randomized studies demonstrated that the weekly regimen produced an equivalent incidence of infections and septic deaths as a standard regimen using 0.12 mg/kg over 2 hours daily × 5.^{275, 276}

Fludarabine has not yet been evaluated extensively in HCL. However, complete and partial responses have been observed in the few patients treated thus far.^{277, 278}

Monoclonal Antibodies

Monoclonal antibody therapy is an attractive option for HCL, because many patients have significant neutropenia at the time of diagnosis and the monoclonal antibodies should theoretically not worsen this problem. The chimeric monoclonal

antibody rituximab (Rituxan; Genentech, Inc., South San Francisco, and IDEC Pharmaceuticals, San Diego, CA) contains a human IgG1 Ig constant region and a murine variable region directed against the cell-surface CD20, an antigen that plays an important role in the activation, proliferation, and differentiation of B-cells.²⁷⁹ This agent has shown significant activity against the low-grade lymphomas, which have high surface concentrations of CD20, and is believed to exert its antitumor activity by complement-dependent cytotoxicity, antibody-dependent cell-mediated cytotoxicity, or the direct induction of apoptosis.^{279, 280, 281} Using rituximab, 375 mg/m² IV once per week for 4 weeks, response rates of 25% to 75% were observed with a variable number of CRs.^{283, 284, 285, 286, 287} This variation may be related to the extent of prior treatment as the poorest responses were observed in heavily pre-treated patients.²⁸⁴ A more prolonged duration of therapy may improve efficacy, and Nieva et al.²⁸⁴ have observed a response rate of 80% with 53% CRs in 15 patients with relapsed or refractory HCL using 8 weekly treatments with rituximab. Kreitman and Pastan^{288, 289, 290} have developed two immunotoxins directed against CD25 and CD22, which contain the modified light chains of the antibodies bound to a truncated form of the *Pseudomonas* exotoxin. The immunotoxin can kill the targeted cells through a variety of ways and the immune mechanisms utilized by rituximab are not required. BL22 is directed against CD22 and has undergone Phase I and II clinical trials, demonstrating a response rate of up to 72% with a CR rate of 47% in cladribine relapsed/resistant HCL patients.²⁹⁰ Some of these responses can last many years. Patients with small spleens were more likely to respond with not statistically significant relationship between prior response to cladribine and response to BL22. One unusual toxicity with this regimen is a reversible form of the hemolytic uremic syndrome, which occurs in about 10% of patients and appears unrelated to depletion of plasma ADADTS13.^{288, 289, 290} LMB-2 is a similar structured immunotoxin directed against CD25 which has also demonstrated activity in HCL.²⁸⁸

Repeated Treatments or Drug Combinations

As patients who achieve a CR appear to have a much longer remission than those who achieve a PR, attempts have been made to convert PR to a CR. The group at the Royal Marsden Hospital have demonstrated in 8 patients who achieved a PR with cladribine that a second course of treatment at 4 to 7 months led to a CR in 6 patients and the relapse-free survival was the same whether one or two cycles of therapy was required to achieve the CR.^{233, 234} An alternate approach has been to administer rituximab following chemotherapy to consolidate the remission. Thus, rituximab given 3 to 6 months following cladribine can increase the number of CRs without additional toxicity.²⁸⁶ More recently, 36 patients (5 with HCLv) have been treated with a standard dose of cladribine followed 1 month later by rituximab 375 mg/m² IV weekly for 8 weeks.²⁸⁷ All patients achieved a CR with 79% having a marrow clear of MRD; with a median follow-up time of 25 months (1 to 63 months), only 1 patient with HCLv has relapsed. Rituximab has also been co-administered with the nucleoside analogs with tolerable toxicity and high response rates.^{288, 291, 292}

Other Treatments

Because HCL is now so easily and effectively treated with the nucleoside analogs, IFN- α , or the monoclonal antibodies, other treatments have become redundant. However, for completeness and interest, they are reviewed briefly. Chlorambucil was previously used when the disease progressed after splenectomy.^{293, 294} Although some patients improved, the course in others was often worse, with more myelosuppression. The best results were reported by Golomb et al.,²⁹⁴ who administered chlorambucil, 4 mg orally/day for at least 6 months, to 24 postsplenectomy patients with progressive disease. A reduction in the number of circulating hairy cells and an increase in one or

P.1947

more of the normal peripheral blood cellular elements occurred in most patients. Six deaths occurred, and time to response was 6 months or longer. Other chemotherapeutic agents, either alone or in combination, have demonstrated some benefit, but the toxic effects were often severe.^{295, 296} These agents included doxorubicin;²⁹⁷ rubidazole;²⁹⁸ combinations of rubidazole, cytarabine, and cyclophosphamide; or cytarabine and cyclophosphamide.²⁹⁹ PRs also have been reported with androgens,^{300, 301} as well as with a combination of lithium carbonate and immunotherapy with Calmette-Guérin bacillus.³⁰² A transient increase in neutrophils can be obtained with granulocyte colony-stimulating factor and may be a useful adjunct to more definitive therapy.^{260, 303} Steroids are ineffective and increase the risk of infection.⁴

Bone Marrow Transplantation

One case of successful bone marrow transplantation from an identical twin has been reported.³⁰⁴

Leukapheresis

Clinical and hematologic improvements, lasting as long as 26 months, have been reported by using leukapheresis to reduce the number of hairy cells in the peripheral blood.^{305, 306} However, others have found the responses less predictable and more transient.³⁰⁷

Radiation Therapy

Low-dose radiotherapy to the spleen can produce transient clinical and hematologic improvements, but the response is slow and unpredictable.³⁰⁸ However, radiation therapy can be effective for the treatment of massive retroperitoneal lymphadenopathy and lytic bone lesions.³⁰⁹

Treatment of Hairy Cell Leukemia Variant

In contrast to classical HCL, the HCL variant is notoriously difficult to treat. Splenectomy has been reported to produce partial responses in approximately half the patients with improvements in the blood counts.^{155, 156, 157} Although response to the nucleoside analogs is generally poor, it is reasonable to treat these patients with a rituximab-nucleoside analog combination or to refer the patient for a clinical trial with a novel agent.^{143, 156, 287, 288, 289, 290, 291, 292}

SUMMARY

- Asymptomatic patients with HCL may not require treatment; however, it is generally recommended to start therapy, when the hemoglobin is <120 g/L, platelets $<100 \times 10^9$ /L or neutrophils $<1 \times 10^9$ /L or if there is evidence of disease progression.^{143, 175} Patients with active HCL are at risk of infection related to neutropenia, monocytopenia, and lymphocyte dysfunction, and this will resolve after a remission is obtained. Persistent lymphopenia and lymphocyte dysfunction may persist for many months following the use of a purine nucleoside analog. Concomitant use of rituximab may further deplete the lymphocytes. Although the value of prophylactic antibiotics in otherwise healthy patients is unclear, patients with prior infections may require prophylaxis for herpetic infections and *Pneumocystis jirovecii* until the lymphocytes are $\geq 1 \times 10^9$ /L.^{143, 176} In addition, it has been recommended by the British Guidelines that HCL patients who have been treated with a nucleoside analog should receive irradiated blood products for the rest of their lives, to prevent graft-versus-host disease.¹⁴³
- Our recommended approach to therapy is detailed in Figure 91.13. The standard therapy for HCL is with one of the nucleoside analogs, pentostatin or cladribine, which appear to have equal efficacy and produce CRs in the majority of patients. The survival of HCL patients nowadays is no different from age- and sex-matched controls. Cladribine appears to have similar efficacy as pentostatin and appears to have equal efficacy whether administered as 0.1 mg/kg/day $\times 7$, by continuous infusion, or as 0.14 mg/kg/day $\times 5$, as a 2-hour infusion or SC, or on a weekly schedule. Pentostatin is generally administered on a biweekly (4 mg/m² IV) basis. Because of the effectiveness of pentostatin and cladribine in HCL and the rarity of this disease, it is unlikely that there will be any prospective studies to compare the efficacy of these two agents and the different treatment regimens.

The major toxicity with the nucleoside analogs is myelosuppression and the risk of infections with initiation of treatment. As a result the authors prefer using pentostatin every other week or weekly cladribine with a blood count just prior to each treatment. For safety, the biweekly or weekly treatments are delayed until the neutrophil count is back to baseline or better. Both pentostatin and cladribine are excreted by the kidneys and the creatinine should be measured before each treatment and therapy only continued as long as renal function is not impaired. It has been suggested that 1.5 l of IV fluid be given with each pentostatin treatment.

Myelosuppression is most common in patients with severe marrow impairment; in such cases, it might be preferable to use IFN- α 3×10^6 units SC three times a week initially to obtain marrow clearing before treatment with a nucleoside analog. A morphologic CR can be obtained in $\sim 75\%$ of patients and a PR in 15% of cases, although residual hairy cells can invariably be detected by immunostaining, even with a morphologic CR. Remissions are prolonged, and most relapsing patients respond to a second cycle of therapy. It is unclear whether survival is longer for patients who achieve a CR or a PR. However, for patients who remain in CR for 5 years, the likelihood remaining in CR by 15 years is 75%.²³³ Response to cladribine and pentostatin is poorer for patients with the HCL variant and for those with bulky abdominal lymphadenopathy.³¹⁰ Prognosis for patients treated with pentostatin is worse for those older than 50 to 55 years of age and those with a hemoglobin level <100 g/L and white cell counts $<2 \times 10^9$ /L.^{224, 233, 236}

Patients should have a marrow test 6 months after starting cladribine or pentostatin and if there is residual disease, additional therapy with or without rituximab should be considered. The goal should be to strive for a CR, but to avoid excessive immunosuppressive and marrow toxicities remembering that long-term consequences (e.g., myelodysplasia or opportunistic infections) may result from excessive treatment.

3. IFN- α (3×10^6 U SC three times/week for 12 months) produces a lower response rate than the nucleoside analogs (8% CR and 74% PR), and relapses occur after discontinuation of the drug. However, IFN- α may be useful initially in patients with an active infection or severe neutropenia.
 4. Initial studies with the monoclonal antibodies against CD20, CD22, and CD25 suggest that these agents may be useful for the treatment of patients refractory to the nucleoside analogs, for patients with poor marrow reserve, and for patients with the HCL variant. Preliminary studies have also shown that concomitant or sequential therapy using rituximab with a nucleoside analog is highly effective therapy, and probably should be considered as initial therapy for the HCL variant.
 5. Two thirds of patients benefit from splenectomy, but a CR is rare. Splenectomy is required for patients who have a splenic
- P.1948

rupture and may be of value for patients with pure "splenic" HCL, as well as for patients who have severe thrombocytopenia with increased numbers of megakaryocytes in the marrow.

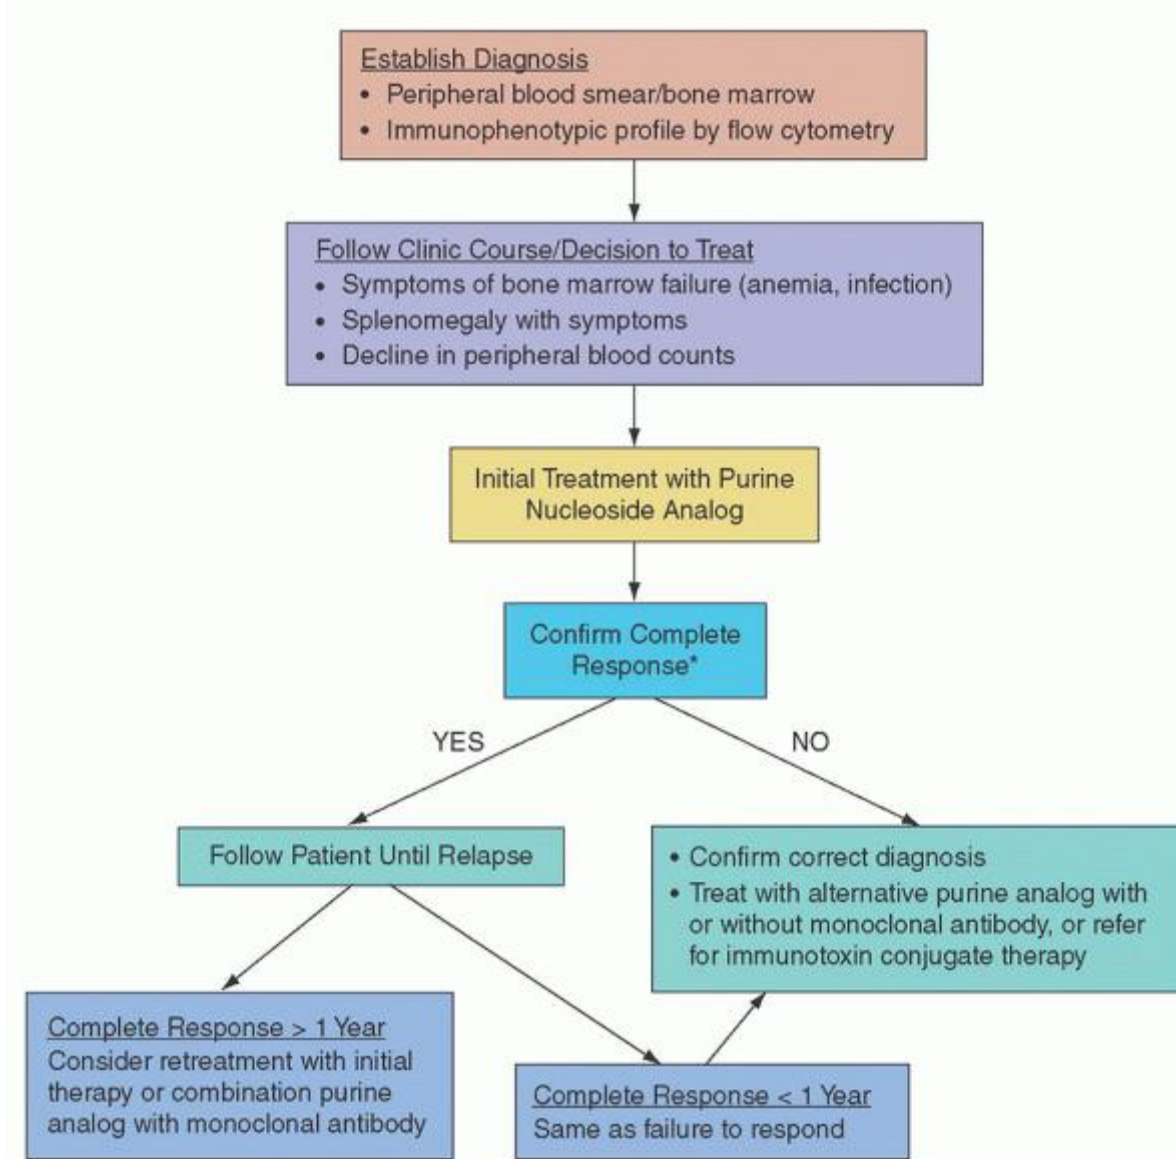

FIGURE 91.13. Recommended treatment schema for hairy cell leukemia (HCL). * Confirmation of a complete response: If patient is participating in a clinical trial, consider using flow cytometry or immunohistochemical stains on bone marrow to document minimal residual disease. It is difficult to require these added studies for patients being treated from a clinical

protocol. (From Grever MR. How I treat hairy cell leukemia. *Blood* 2010;115:21-28, with permission.)

SECOND MALIGNANCIES

There has been controversy as to whether patients with HCL have an increased incidence of malignancies and whether this may be related to therapy.^{210, 224, 236, 247, 248, 311, 312, 313, 314, 315, 316} Several studies have demonstrated an increased incidence of second tumors in HCL, and the incidence appears to be highest in the first 2 years after diagnosis. However, the increase may occur before the diagnosis of HCL, or concurrently, suggesting that these patients have an inherent tendency to develop second malignancies.^{210, 311, 312} Kampmeier et al.³¹² demonstrated that 19% of 69 patients observed for a median of 91 months after treatment with IFN- α developed a second malignancy, and the authors suggested that the increased incidence was related to the more prolonged survival of these immunocompromised patients rather than an effect of the IFN- α . However, it has been observed that the incidence of second malignancies is lower when patients are treated with pentostatin or cladribine than with IFN- α , suggesting that the second malignancies may be directly related to active HCL.³¹³ In 379 patients treated with cladribine, 22% developed a second malignancy (primarily solid tumors), a rate 2.03-fold higher than expected.²⁴⁹ Those patients who had had a malignancy before the diagnosis of HCL had a 3.7-fold increased risk of developing a second cancer compared with those who did not.²⁴⁹ However, Kurzrock et al.³¹⁴ observed a 7.4% incidence of second malignancies in 350 HCL patients after a mean follow-up of 7.1 years, and this incidence was not significantly greater than expected and was not influenced by treatment with IFN- α or the nucleoside analogs. Others have made similar observations.^{224, 236} In a large multicenter prospective crossover study with pentostatin and IFN- α and a median follow-up of 112 months, there was no increase in the number of second malignancies as compared with that of the control population.²³⁶ However, a large Surveillance, Epidemiology and End Results (SEER) population study of 3,104 HCL patients collected between 1973 and 2002 has demonstrated an increased incidence of Hodgkin lymphoma, non-Hodgkin lymphomas, and thyroid cancer in HCL, but the overall increase in cancer rates was small with the probability of a second cancer being 31.9% at 25 years.³¹⁶

PROGNOSIS

Before the availability of IFN- α and the nucleoside analogs, the median survival of HCL patients was 4.6 years for nonsplenectomized patients and 6.9 years for splenectomized patients.² However, the prognosis has improved markedly with present therapies, and the predicted 5- and 10-year survival rates for patients treated with the nucleoside analogs are now similar to those of the general population.^{233, 234, 236} However, long-term follow-up is required to determine the relapse rate, the percentage of patients who become resistant to the nucleoside analogs and, subsequently, the monoclonal antibodies, and whether there will be long-term complications from these treatments.

Chapter 92

Cutaneous T-Cell Lymphoma: Mycosis Fungoides and Sézary Syndrome

John A. Zic

Jeff P. Zwerner

Laura Y. McGirt

Claudio A. Mosse

John P. Greer

Cutaneous lymphomas are a heterogeneous group of non-Hodgkin lymphomas (NHLs) of T- and B-cell origin in which the skin is the primary organ of involvement. Primary cutaneous lymphomas usually present without signs of extracutaneous malignancy at onset of symptoms; they represent an entity distinct from nodal lymphomas with secondary cutaneous involvement. In 1975, Lutzner, Edelson, and associates introduced the term cutaneous T-cell lymphoma (CTCL) to describe the spectrum of skin-based lymphomas of T-cell origin including classical mycosis fungoides (MF) and Sézary syndrome (SS).^{1, 2} This chapter is a review of the history, epidemiology, clinicopathologic features, and therapy of these lymphomas.

HISTORICAL PERSPECTIVE AND PATHOPHYSIOLOGY

Clinical Description

The first clinical description of MF was provided in 1806 by Alibert, a French physician, who identified a 56-year-old man presenting with skin tumors resembling mushrooms after having had a desquamating rash over several months; the lesions waxed and waned for 5 years before the patient died with a “hectic” fever.³ In 1832 Alibert first used the term mycosis fungoïde in his treatise on diseases of the skin to describe the mushroomlike tumors.⁴ Bazin described the three “classical” cutaneous stages in 1870: (a) the premycotic stage, which can be localized or diffuse with superficial eczematous or erythematous lesions; (b) the infiltrative plaque stage; and (c) the tumor stage.⁵ The mycosis d'emblée variant, in which tumors develop rapidly without a preceding premycotic or plaque stage, was described by Vidal and Brocq in 1885.⁶ In the early 1890s, Besnier and Hallopeau described the erythrodermic variant, which later became known as Sézary syndrome.^{7, 8}

Histopathology

By the end of the 19th century, most authorities agreed that the small round cells infiltrating the epidermis and forming tumors were lymphoid in origin.⁹ Although the French authorities considered the disease lymphadenomatous in nature, the German, English, and American authorities were divided between sarcomatous and granulomatous (infectious) etiologies.^{9, 10}

The unique appearance of the cells involved in CTCL was identified in 1938 by Sézary and Bouvrain, who reported a triad of erythroderma, leukemia with circulating mononuclear cells that had convoluted nuclei, and adenopathy infiltrated with the same cells.¹¹ SS was recognized in the English literature by several groups in the 1950s, but it was not described in the United States medical literature until Taswell and Winkelmann at the Mayo Clinic in 1961.¹² In 1968, Lutzner and Jordan extended the light microscopic description of the Sézary cell by using electron microscopy to visualize the “serpentine” or cerebriform cell nucleus.¹³

Immunology

The 1970s witnessed the introduction of cellular immunology into the study of hematopoietic neoplasms, and in 1971 Crossen et al. confirmed the lymphocyte origin of SS.¹⁴ In 1973, Broome et al.¹⁵ and Brouet et al.¹⁶ identified the neoplastic cell as a T-cell, and Broder et al. demonstrated in 1976 that the cells are usually of the helper phenotype (CD4⁺).¹⁷

Studies performed in the early 1990s further characterized the circulating malignant T-cells in patients with SS as “memory” helper T-cells because of the expression of CD45RO⁺.¹⁸ In 1992, Vowels et al. detected a cytokine profile similar to that produced by murine Th2 cells from both stimulated peripheral blood mononuclear cells (PBMCs) and serum from patients with SS.¹⁹ Further studies identified a Th2 cytokine profile (interleukin [IL]-4, IL-5, IL-6, IL-10) to be present in the skin of patients with MF and SS.^{20, 21, 22} Increased levels of IL-4 and IL-5 produced by the malignant T-cell clone may account for the eosinophilia and increased levels of IgE and IgA in the serum of patients with advanced CTCL.²³ More recently, the Th17-associated proinflammatory cytokine, IL-17, has also been found to be up-regulated in MF skin lesions and appears to be activated through the Jak/Stat pathway.²⁴

Immunologic studies have addressed the pathogenesis of MF and SS by examining the complex interactions among malignant cerebriform T-cells, keratinocytes, Langerhans cells, and other immunomodulating cells.²⁴ Lymphocytes (malignant and inflammatory) that home to cutaneous sites differ from lymphocytes in noncutaneous infiltrates by expressing the cutaneous lymphocyte-associated antigen (CLA), which binds to the endothelial cell adhesion molecule E-selectin (ELAM-1), which is preferentially induced on cutaneous venules.²⁵ Both circulating and skin-based malignant T-cells from patients with MF have been shown to express CLA, which may explain how the cells preferentially home into the skin (Fig. 92.1).^{25, 26} In addition, CLA⁺ T cells selectively express CC chemokine receptor 4 (CCR4) and CCR10, whose ligands CCL17 (TARC) and CCL27 (CTAK) are generated by the lesional keratinocytes and also on the luminal surface of postcapillary venules in the skin.^{25, 26, 27, 28} Narducci et al. discovered that SS cells express a functionally active CXCR4 and that the ligand SDF-1 is abundantly produced in the skin, which represents the main destination of SS cell spreading.²⁹ SDF-1 is normally inactivated by proteolytic cleavage by the CD26/dipeptidylpeptidase IV (DPP-IV). The lack of CD26 from the cell surface is a hallmark of circulating SS cells. Additionally, it has been found that fibroblasts from lesional CTCL produce increased levels of the chemokine eotaxin, which is also expressed at increasingly higher levels as the disease advances.³⁰ The only receptor for eotaxin is CCR3, which is found on Th2 lymphocytes and eosinophils, and may further explain why we see an increase of Th2 polarity as CTCL progresses.³⁰ Another recent report suggests that low herpes virus entry mediator (HVEM) expression on dermal fibroblasts in advanced CTCL skin attenuates expression of Th1 chemokines, which may contribute to a shift to a Th2-dominant microenvironment as disease progresses.³¹

Within the skin, the specific epidermotropism of the malignant T-cell is partially explained by the discovery of increased expression of intercellular adhesion molecule-1 (ICAM-1 or CD54) by epidermal keratinocytes in early MF lesions. The binding of ICAM-1 to LFA-1 (lymphocyte function-associated protein or CD18) expressed by lymphocytes may explain the histologic finding of atypical lymphocytes nesting within the epidermis.³² Some authorities speculate that the expression of

P.1952

ICAM-1 by keratinocytes is induced by the release of interferon- γ (IFN- γ) from infiltrating CD8⁺ T-cells or natural killer (NK) cells responding to the malignant T-cell population within the dermis (Fig. 92.2).²³ Adhesion molecules other than ICAM-1/LFA-1 have been implicated in the phenomenon of epidermotropism and include E-cadherins, CD58/CD2, B7/CD28, CD49a (VLA-1), CD49c (VLA-3), and CD49f (VLA-6).²⁸ Soluble chemotactic factors may also play a role in the epidermotropism of MF. The expression of the CXC chemokine IP-10 (IFN- γ -inducible protein-10), which is chemotactic for CD4⁺ lymphocytes, has been shown to be markedly increased by basal and suprabasal keratinocytes in MF lesions.³³ Several studies suggest that in early MF, epidermal Langerhans cells convert to hyperstimulatory antigen-presenting cells (CD1a⁺, CD1b⁺, CD36⁺) with a high expression of Class II MHC molecules and adhesion molecules capable of activating tumor-infiltrating lymphocytes.²³

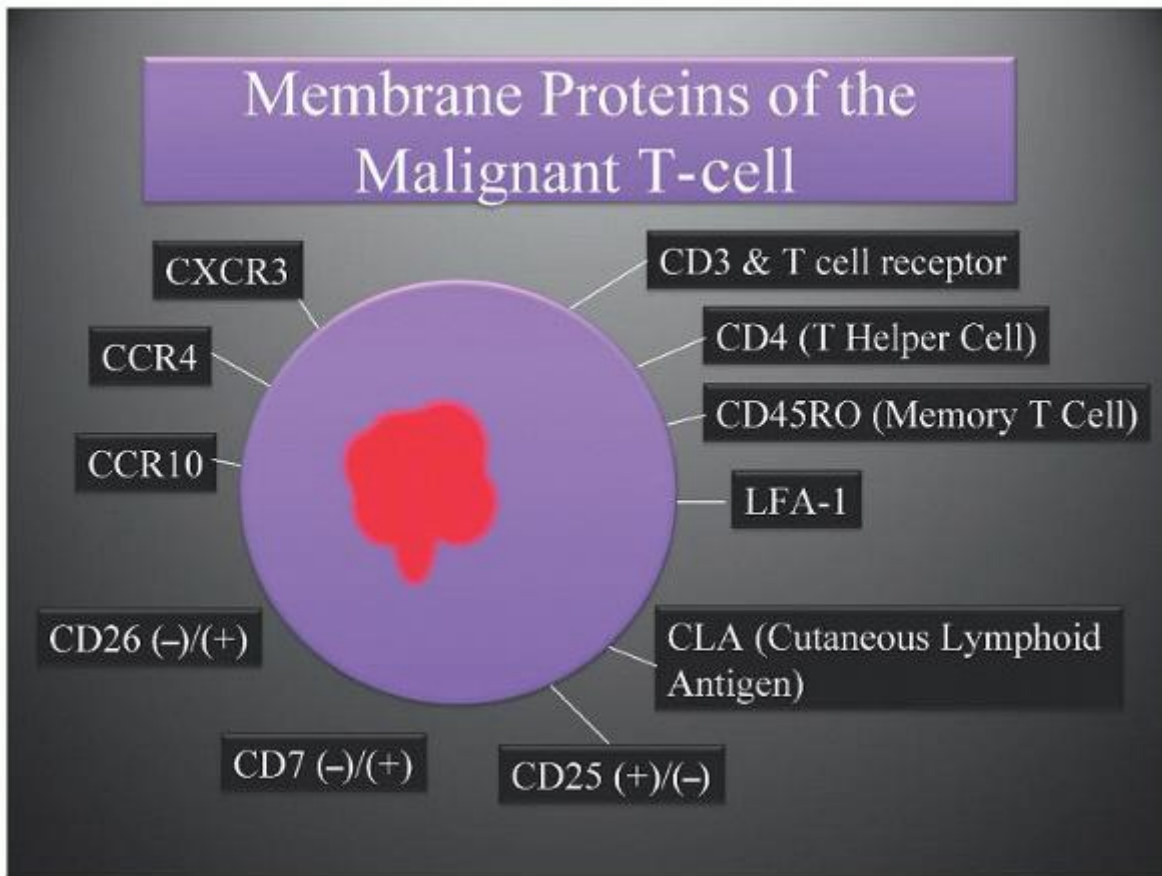

FIGURE 92.1. Membrane proteins of the malignant T-cell. The cutaneous lymphoid antigen (CLA) is a membrane protein expressed by a vast majority of T-cells found in inflamed skin including (CTCL). LFA-1 is a $\beta 2$ integrin expressed by all mature white blood cells.

FIGURE 92.2. Early (CTCL): mechanisms of epidermotropism. The release of interferon (IFN) γ by early, reactive CD8 cytotoxic T-cells or natural killer (NK)-cells leads to increased keratinocyte expression of intercellular adhesion molecule-1 (ICAM-1) and release of the CXC chemokine IP-10, which binds to the CXCR3 receptor, and may lead to nesting of CTCL cells within the epidermis.

FIGURE 92.3. Late cutaneous T-cell lymphoma (CTCL): loss of epidermotropism. As the clonal population of CTCL cells expands, more IL-4 is released which drives autocrine-induced proliferation of the CTCL cells and inhibition of CD8 cytotoxic T-cells and natural killer (NK)-cells. The impaired release of interferon (IFN) γ may lead to less ICAM-1 expression and decreased keratinocyte-CTCL cell adhesion. MF, mycosis fungoides.

More advanced lesions of MF, characterized clinically as tumors or generalized erythroderma, often demonstrate a loss of epidermotropism, with malignant T-cells infiltrating the deep dermis.²⁸ In 1989, Nickoloff et al. found markedly diminished ICAM-1 expression by keratinocytes in a patient with SS,³⁴ and similar findings in tumor-stage patients were reported by Vejlsgaard et al.³⁵ Rook et al.³⁶ have suggested that unknown mechanisms lead to an evasion of the host immune response, with subsequent expansion of the malignant clonal population and increased production of IL-4. Increased levels of IL-4 could inhibit the production of IFN- γ , leading to decreased ICAM-1 expression by keratinocytes and thus reduced binding of malignant T-cells within the epidermal compartment (Fig. 92.3).³⁶ In addition, CXCR3, a T-cell chemokine receptor, has been shown to be expressed by lymphocytes in early-stage MF but absent in cases of transformed MF, when epidermotropism is often absent.³⁷ Others have suggested that the expression of CCR7 by some peripheral blood Sézary cells may enhance their ability to home into lymph nodes.³⁸ Indeed, a recent study revealed a disparate chemokine receptor expression profile in leukemic CTCL cells as compared to CTCL cells isolated from lesional skin. The leukemic cells had strong expression of CCR7, L-selectin, and CCR4, whereas the cells from CTCL skin expressed CCR4 and CLA.³⁹ The results of these investigators suggest that SS is a malignancy of central memory T-cells and MF is a malignancy of skin-resident effector memory T-cells.³⁹

As the disease progresses, cell-mediated immunity, critical for tumor cell recognition and destruction, is slowly dismantled. IL-4 and IL-10 secreted by the malignant T-cell may inhibit Th1 cells responsible for coordinating cell-mediated immune functions.^{23, 40, 41} Also, the inhibition of IL-12 secretion from macrophages may diminish the cytokine's stimulatory effect on CD8-cytotoxic T-cells.²³ With Th1 cells, CD8-cytotoxic T-cells, macrophages, and NK cells partially disabled, the malignant clone can escape immune surveillance and proliferate.^{40, 41}

Molecular Genetics

Clonality in T-cell lymphoma was difficult to establish before the development of molecular genotyping methods in the 1980s. Initial evidence of clonality in MF/SS was provided by cytogenetic analysis.^{42, 43} Several of these early studies demonstrated the same abnormal clone in separate lesions from skin, peripheral blood, lymph nodes, and bone marrow.^{42, 43}

The identification of a defined cytogenetic abnormality would be a major advance in the diagnosis and our understanding of the pathogenesis of MF/SS. Unfortunately, to date, no such abnormality has been identified consistently in MF, with most reported findings being largely of a random nature.^{44, 45} Some of the specific chromosomal deletions and amplifications that have been identified in CTCL include 8q gains, 10q and 17p deletions,

P.1953

and 17q gains (isochromosome 17).^{46, 47, 48, 49, 50} Abnormalities in chromosome 10 have been correlated with progression to tumor stage, including loss of heterozygosity on 10q and microsatellite instability.⁵¹ Salgado et al. demonstrated through comparative genomic hybridization oligonucleotide array that in tumor-stage MF, loss of 9p21.3 (encodes CDKN2A and CDKN2B) and 10q26qter, and gain of 8q.24.21 were associated with decreased survival.⁵² Additionally, p16INK4a, a protein coded at the 9p21 locus, has been shown to be silenced in tumor-stage MF.⁵³ Microsatellite instability was detected in 16 of 56 patients with CTCL that may be a consequence of hMLH1 promoter hypermethylation and may prevent transcription in a subset of patients.⁵⁴ van Doorn and colleagues reported that the malignant T-cells of patients with CTCL display widespread promoter hypermethylation associated with inactivation of several tumor-suppressor genes involved in DNA repair (MGMT, MLH1), cell-cycle (CHFR), and apoptosis signaling pathways.⁵⁵ Recently, comparative transcriptome analysis was performed on tissue from patients with early-stage MF and benign dermatoses that identified increased expression of the TOX protein in MF. TOX is strongly expressed in thymic tissue but is normally silenced in mature CD4⁺ T-cells.⁵⁶ It may prove to be useful as an immunohistochemical diagnostic marker.

Overexpression of the tumor-suppressor gene TP53 has been detected in some cases of high-grade CTCL such as cutaneous anaplastic large-cell lymphoma (ALCL), but rarely in low-grade CTCL.⁵⁷ Infrequent FAS mutations, but no BAX or TP53 mutations, were discovered in a study of 44 patients with early MF.⁵⁷ Aberrant expression of the BCL-2 gene, which normally codes for an inner mitochondrial membrane protein, can suppress apoptosis, an important pathogenic mechanism in lymphomas. Although Dummer and colleagues detected BCL-2 expression in 22 of 26 MF cases; it was also present in 5 of 6 cases of benign inflammatory dermatoses.⁵⁸ A cDNA microarray study of 29 cases of MF and 11 cases of inflammatory dermatoses revealed a signature of 27 genes implicated in the tumorigenesis of MF, including tumor necrosis factor receptor-dependent apoptosis regulators, STAT4, CD40L, and other oncogenes and apoptosis inhibitors.⁵⁹ Loss of SHP-1 tyrosine phosphatase expression appears to correlate with the advanced stages of CTCL.⁶⁰ The epigenetic silencing of SHP-1 is induced by an activated phosphorylated (p)-STAT3 transcription factor in cooperation with DNA methyltransferase 1, the key member of the epigenetic gene silencing machinery.⁶⁰ JUNB amplification leads to enhanced Th2 cell function, a hallmark of the malignant T-cell in CTCL. Mao and colleagues reported the amplification and overexpression of JUNB in tissue from patients with CTCL.⁶¹ Recently, mutations involving the RAS pathway have been identified in a minority of CTCL.⁶²

The small, single-strand, noncoding RNAs, known as microRNAs (miRNAs), have been found to be differentially expressed in MF/CTCL.^{63, 64} A CTCL miRNA signature (miR-155, miR-203, and miR-205) has been identified in a recent study and is capable of distinguishing between CTCL and benign inflammatory dermatoses with 95% accuracy.⁶⁴ It has also been demonstrated that there is a loss of miR-223 and miR-342 in SS versus normal CD4⁺ T-cells and that the reduced miR-342 leads to inhibition of apoptosis in CTCL cells.⁶⁵

In 1985 Aisenberg et al. and Weiss et al. independently described Southern blot analysis techniques using probes for the β chain of the T-cell receptor (TCR) to establish clonality in T-cell lymphoproliferative disorders.^{66, 67} Because earlier cytogenetic studies suggested that CTCL arises from a single malignant clone of mature T-cells,⁴² the presence of TCR β -chain rearrangement in pathologically suspicious tissue has been considered strong evidence for the diagnosis of CTCL.⁶⁸ However, in early lesions of MF (patch stage), when the number of infiltrating malignant T-cells is minimal, the Southern blot technique fails to detect clonal T-cell populations consistently. Other limitations of the Southern blot technique include its necessity for large amounts of preserved DNA, as well as its extensive time and labor requirement.⁶⁹ Therefore, the detection sensitivity of Southern blotting of DNA derived from skin biopsy specimens of early lesions is too low and may fail as a diagnostic test when the clinical and histologic diagnosis is most difficult.⁷⁰

More sensitive techniques involving polymerase chain reaction (PCR) have been developed to evaluate clonality in CTCL and related skin diseases and are now considered the methods of choice.^{71, 72} The PCR is an *in vitro* imitation of the enzymatic DNA repair and replication that takes place in all proliferating cells, but it amplifies short specific lengths of DNA of the order of 10⁹ to 10¹² and therefore permits the use of very small amounts of starting DNA. Although the vast majority of CTCL express the α/β TCR heterodimer, most labs using the PCR technique take advantage of the fact that all α/β TCR-positive T-cells also contain at least one rearranged allele of the TCR γ -chain gene.⁷³ The γ gene contains a very limited number of clinically significant V segments (8) and C regions (2), making it possible to use specific primers for all

known TCR γ V segments.⁷⁴ It is estimated that this PCR-based technique in combination with high-resolution nondenaturing polyacrylamide gel electrophoresis is 10 to 50 times more sensitive than conventional Southern blot analysis in the detection of small T-cell clones.⁷² Several studies have shown a sensitivity of 90% to 95% using the PCR technique, indicating that up to 10% of cases of CTCL may show no TCR rearrangement even with this sensitive technique.^{71, 75, 76} Given that some TCR β rearrangements may be missed with conventional TCR γ primers, there are those who recommend use of both TCR γ and TCR β primers.⁷⁷ It is important to note that clonality does not indicate malignancy, as suggested by one study in which 25% of tissue from patients with lichen planus, a benign dermatosis, were found to have TCR gene rearrangements using the PCR technique.⁷⁵

In the late 1990s, a European consortium of 45 laboratories (BIOMED-2 Concerted Action BMH4-CT98-3936) was initiated with the aim to establish a highly reliable standard in PCR-based clonality testing, for B-cell as well as for T-cell malignancies.⁷⁸ Because of the higher speed, efficiency, and sensitivity of the BIOMED-2 multiplex PCR protocol, it can reliably replace Southern blot analysis in clonality diagnostics in routine laboratory settings.⁷⁹ Expertise with clonality diagnostics and knowledge about the biology of TCR gene recombination are essential for correct interpretation of TCR clonality data.⁷⁸ Patel and colleagues recently showed that combining TCR- γ primers with TCR- β primers significantly improved the sensitivity of TCR gene analysis, to 94%.⁸⁰ Yang et al. used the strategy of multiple PCR/heteroduplex analysis for TCR- γ gene rearrangement combined with a laser-capture microdissection proteinase K approach to increase the detection rate of clonal TCR- γ gene rearrangement in early MF cases.⁸¹ This approach could provide strong evidence to confirm the diagnosis of early MF when the diagnosis can be most challenging.

EPIDEMIOLOGY

The incidence of the primary CTCLs has risen dramatically and consistently since 1973.⁸² Based on data from the Surveillance, Epidemiology, and End Results (SEER) Program of nine cancer registries, the incidence of CTCL in the United States increased from 2.8 to 6.3 to 9.6 cases per 1 million population in the periods 1973 to 1977, 1988 to 1992, and 1998 to 2002, respectively.⁸² During the period 1973 to 2002, the overall annual age-adjusted incidence of CTCL for the original nine SEER registries was 6.4 per million persons, representing 4% of all reported NHLs.⁸² Bradford et al. reported an age-adjusted CTCL incidence of 7.7 per million persons from 2004 to 2005.⁸³ Because the number of patients with early-stage MF often is not reported to tumor registries, the actual incidence may be higher. In one study, missed

P.1954

cases were estimated to constitute 17% of MF.⁸⁴ Thus, using the most recent incidence rate, the incidence of new cases of CTCL in the United States in the first decade of the 21st century is almost 3,000 cases per year. The incidence of MF increases with advancing age, and the median age is usually between 60 and 70 years, with an incidence rate of 24.6 per million for persons 70 to 79 years of age and a peak around 80 years of age.^{82, 83} It is rare in patients <30 years of age. However, in the 1990s there emerged several reports of children and adolescents affected with MF and SS.^{85, 86, 87} One study found that 4% to 5% of patients with MF had onset of their eruption before 20 years of age,⁸⁷ whereas the more recent epidemiologic study by Criscione and Weinstock showed only 1% of cases of CTCL to be in the <20 years age group.⁸² A study from the International Childhood Registry of Cutaneous Lymphoma found the mean age of onset and diagnosis of pediatric cutaneous lymphoma to be 7.5 years (± 3.8 years) and 9.9 years (± 3.4 years), respectively.⁸⁸

Blacks are more likely to develop MF compared to whites, 9.0 to 10.0 versus 6.1 to 8.1 per million incidence rates, with the greatest racial differences seen among the younger patient populations.^{82, 83} Both Asian/Pacific Islanders and Hispanic whites have an incidence rate of 5.1 per million.⁸³ Men are significantly more likely to develop CTCL than women, with an age-adjusted incidence rate almost twice that of women.^{82, 83} The epidemiologic study by Criscione and Weinstock found the incidence rates of CTCL to be correlated with high physician density, high family income, high percentage of population with a bachelor's degree or higher, and high home values, suggesting that increased detection of CTCL may play a role in the increased incidence rates since 1973.⁸²

The etiology of MF/SS remains unknown, but genetic, environmental, and infectious agents have been implicated as possible factors in triggering lymphocyte activation and/or lymphocyte transformation.^{89, 90} A recent study found that not only did the antioxidative effects of wine consumption fail to protect against the development of MF, but patients who consume >24 g of alcohol per day demonstrated a higher incidence of MF than matched controls (adjusted odds ratio 3.02, 95% confidence interval 1.34 to 6.79).⁹¹ Also significant was that the alcohol effect remained constant regardless of beverage type.

Rare familial clusters of CTCL cases have been reported,⁹² and an increased incidence has been noted in patients with certain histocompatibility antigens.^{93, 94} A rare case of transformed CTCL developing in a husband and wife suggested a

common environmental or infectious exposure in the etiology of their disease.⁹⁵ Early reports implicated an increased risk of developing CTCL in people employed in a manufacturing occupation, particularly those related to petrochemicals, textiles, or metals, or in farming, with exposure to pesticides or herbicides.⁹⁶ However, two case-control studies have failed to confirm these observations.^{97, 98} Results of other studies have suggested that patients with MF have increased contact allergies, but Whittemore et al. were unable to substantiate the association in a case-control clinical study.⁹⁸

Human retroviruses have been suggested as possible etiologic agents in CTCL. HTLV-I was described initially in a CTCL patient who had an aggressive clinical course; however, this disease was later identified as adult T-cell leukemia/lymphoma (ATL), which is endemic to Japan, the Caribbean, and other areas of the world but can have cutaneous lesions similar to CTCL (see ATL in Chapter 88).⁹⁹ Serologic findings for HTLV-I/II in patients with CTCL are negative in the vast majority of patients.^{100, 101, 102} In support of the association of HTLV-I/II and MF, virus particles indistinguishable from HTLV-I have been identified using electron microscopy on immortalized MF cells,¹⁰³ and combined PCR/Southern blot analyses have demonstrated HTLV pol, tax, and/or rex sequences in PBMC lysate extracts and lesional skin from patients with MF/SS.^{100, 104, 105, 106} Further support of a potential HTLV-1/CTCL association was suggested after inoculation of immunosuppressed rats with PBMC extracts from patients with MF/SS. A novel anti-HTLV-I antibody was detected in the serum of 29% of the animals, whereas PBMC from healthy controls did not elicit an anti-HTLV-1 antibody response. These findings lend further support to the role of HTLV-1 as being at least a co-factor in the pathogenesis of CTCL.¹⁰⁷ Based on these studies, some authors contend that the strongest evidence of an etiologic/pathogenic factor for CTCL relates to the presence of a defective or variant HTLV-I virus.^{70, 104} Other authorities,^{101, 102, 108, 109} however, disagree, citing seven series that found no proviral HTLV-I sequences in 332 CTCL patients^{101, 110, 111, 112, 113, 114, 115} and four studies that detected the proviral sequences in 10% of 176 patients.^{116, 117, 118, 119} Future development of advanced molecular techniques should eliminate the difficulty of establishing with certainty the presence or absence of HTLV-I proviral sequences in patients with CTCL.^{108, 120} More recently, there have been studies evaluating the presence of HHV-8 and the Merkel cell polyoma virus, but neither of these infectious agents has been significantly identified.^{121, 122} A separate group evaluated MF skin samples for the presence of multiple infectious agents (HTLV, Epstein-Barr virus, and *Borrelia burgdorferi*) and found that 21/83 MF samples had two or more infectious agents identified as compared to 1/83 healthy controls.¹²³

CLINICAL PRESENTATION

MF usually evolves over a long period, so patients often have a long premycotic or pre-malignant phase with eczematous skin eruptions between 4 and 10 years before a histologic diagnosis is established.⁷⁰ The differential diagnosis during this period includes chronic eczematous, atopic or contact dermatitis, which may evolve slowly into eruptions clinically suggestive of parapsoriasis en plaque, poikiloderma atrophicum vasculare, or other benign papulosquamous skin diseases.¹²⁴ Failure of the lesions to respond to standard topical therapy may be an early clue of a different diagnosis. However, initial lesions occasionally appear to improve following topical steroid application, which masks early recognition of the underlying malignancy.¹²⁵ Because of the difficulty in diagnosis in the premycotic phase of MF, careful follow-up with serial skin biopsies is warranted in patients with suspect lesions (see section "Diagnostic Evaluation").

The earliest diagnostic phase of MF is the patch phase, characterized by persistent scaly macules and patches that vary in size, shape, and color, tend to involve sun-protected sites, and are occasionally associated with pruritus (Fig. 92.4A).^{5, 124, 126} Early MF patches and plaques, unlike other eczematous eruptions, are usually asymptomatic. Other, less common early skin findings in MF include poikiloderma,¹²⁷ hypopigmentation,¹²⁸ hyperpigmentation (Fig. 92.4B), alopecia, pruritus alone,^{129, 130, 131} and porokeratosis-like lesions.¹³² Recently, several cases of "invisible MF" were described. Afflicted patients presented only with persistent, generalized pruritus and no clinical eruption.^{129, 130, 131} Random biopsies of "normal" skin confirmed the diagnosis of MF.

Plaques are sharply demarcated, scaly, elevated lesions that may have annular, arcuate, or serpiginous borders (Fig. 92.4C). Plaques with thick scale can mimic psoriasis or nummular eczema, whereas annular lesions with central clearing may be confused with tinea corporis.¹²⁴ Ultraviolet radiation occasionally induces regression of patches and plaques, further delaying correct diagnosis. Prominent involvement of the palms and/or soles may result in hyperkeratosis, fissuring, or frank keratoderma (Fig. 92.4D).¹³³

The tumor phase is heralded by the onset of dome-shaped, deep red to violaceous nodules emerging in areas of uninvolved skin or in pre-existing plaques.¹²⁴ The tumors may ulcerate and become secondarily infected (Fig. 92.4E), and there is a predilection for the body folds and face, where dermal

thickening, coalescing plaques, and tumors may result in characteristic “leonine facies” (Fig. 92.4F). The tumor stage is more clinically aggressive than the patch and plaque stages, and may be associated with histologic transformation to a large cell process with a vertical growth phase (see section “Histopathology and Prognosis”).¹²⁴ Rarely, patients with MF will present initially with tumors without the preceding patch and plaque phases (the MF d'emblée variant).^{6, 134} It is very common for more advanced patients to have patches, plaques, and/or tumors present simultaneously on different areas of their skin.⁷⁰

FIGURE 92.4. The cutaneous phases of mycosis fungoides. A: Early patch-stage lesions in a sun-protected region. B: Hyperpigmented diffuse patches on the back of a dark-skinned patient. C: Scattered thin and thick plaques on the back. D: Early keratoderma of the sole. E: Ulcerated tumor within a plaque on the posterior leg. F: Coalescing nodules and tumors with dermal thickening forming “leonine facies” in this patient with transformed cutaneous T-cell lymphoma (CTCL). See text for full description.

Generalized erythroderma may develop as the initial presenting sign of MF/SS or may accompany plaques and tumors.⁷⁰ In SS, the leukemic variant of CTCL, erythroderma, and circulating tumor cells (Sézary cells) in the peripheral blood may be

accompanied by generalized lymphadenopathy, splenomegaly, keratoderma, vitiligo-like hypopigmented patches,¹³⁵ alopecia,

P.1956

ectropion, nail dystrophy, and ankle edema.¹³⁶ Intense pruritus and cutaneous pain are common in SS, and when the palms and soles are affected with scaling and fissuring, walking and manual dexterity become difficult.¹³⁶

CLASSIFICATION OF CUTANEOUS T-CELL LYMPHOMAS

The term cutaneous T-cell lymphoma or CTCL is a general term that encompasses a variety of diseases, including MF and SS. In addition, there are other cutaneous T-cell lymphoproliferative disorders that appear to be specific entities with unique clinical, histologic, and prognostic features. In an effort to recognize the separate disease processes, a new classification of primary cutaneous lymphomas was formulated jointly by the World Health Organization (WHO) and the European Organisation for Research and Treatment of Cancer (EORTC) in 2005 (Table 92.1).¹³⁷ The most recent WHO classification of tumors of hematopoietic and lymphoid tissues presented in 2008 essentially mirrors, with a few exceptions, the 2005 WHO-EORTC classification scheme.^{138, 139} MF is the most common subtype, accounting for almost 50% of all CTCL, and this term should be used only for patients with the classic presentation of patches and plaques with slow progression as described by Alibert and Bazin.¹³⁷ The WHO-EORTC classification recognizes three variants of MF and the T-cell lymphoproliferative disorder lymphomatoid papulosis (LyP) as a distinct subtype of CTCL for the first time. The following sections focus on the histopathology and immunopathology of MF, SS, and the other types of primary CTCLs.

TABLE 92.1 WHO-EORTC CLASSIFICATION OF CUTANEOUS LYMPHOMA

Cutaneous T-cell Lymphomas

Mycosis fungoides^a

Variants of MF:

Folliculotropic mycosis fungoides^a

Pagetoid reticulosis^a

Subtype of MF:

Granulomatous slack skin^a

Sézary syndrome^b

CD30⁺ lymphoproliferative disorders of the skin

Lymphomatoid papulosis^a

Primary cutaneous anaplastic large-cell lymphoma^a

Subcutaneous panniculitis-like T-cell lymphoma^a

Primary cutaneous T-cell lymphoma, unspecified^c

Provisional entities:

Primary cutaneous epidermotropic CD8⁺ T-cell lymphoma (provisional)^b

Cutaneous $\gamma\delta$ -positive T-cell lymphoma (provisional)^b

Primary cutaneous CD4⁺ small/medium-sized pleomorphic T-cell lymphoma^a

Extranodal NK-/T-cell lymphoma, nasal type^{b, d}

Adult T-cell leukemia/lymphoma^d

Cutaneous B-cell Lymphomas

Primary cutaneous marginal zone B-cell lymphoma (MALT-type)^a

Primary cutaneous follicle center lymphoma^a

Follicular, follicular and diffuse, diffuse growth patterns

Primary cutaneous diffuse large B-cell lymphoma, leg type^e

Primary cutaneous diffuse large B-cell lymphoma, other^e

Intravascular large B-cell lymphoma^{d, e}

Precursor Hematologic Neoplasm

Blastic plasmacytoid dendritic cell neoplasm (previously CD4⁺/CD56⁺ hematodermic neoplasm)

EORTC, European Organization for Research and Treatment of Cancer; MALT, mucosal associated lymphoid tissue; MF, mycosis fungoides; NK, natural killer WHO, World Health Organization.

^a Indolent (5-year disease-specific survival >75%).

^b Aggressive (5-year disease-specific survival <25%) clinical behavior.

^c Aggressive (5-year disease-specific survival <25%) clinical behavior (excluding provisional entities).

^d Typically, an extracutaneous lymphoma with skin as a secondary site.

^e Intermediate (5-year disease-specific survival 25% to 75%).

Modified from Willemze R, Jaffe ES, Burg G, et al. WHO-EORTC classification for cutaneous lymphomas. *Blood* 2005;105:3768-3785.

DIAGNOSTIC EVALUATION

Tissue Handling

Skin biopsies for diagnosis of MF/SS must be properly handled to maximize the diagnostic information obtained. These studies include routine histology, immunophenotyping, and molecular genotyping. Communication between the clinical staff, dermatologists, and pathologists is essential to ensure that the appropriate types of biopsies are done and are properly handled. In general, 6-mm punch biopsies are recommended. Multiple biopsies from different skin lesions may be necessary to establish a definitive diagnosis of MF/SS, particularly in early-patch-stage lesions. Topical steroids may blunt many of the histologic features of MF/SS and should be discontinued for 2 to 3 weeks prior to biopsy. A careful drug history should be taken prior to biopsy, because certain drug eruptions can closely mimic early MF, particularly phenytoin and other anticonvulsants.¹⁴⁰ Although advancements in immunohistochemical protocols and molecular diagnostics allow most studies to be performed on formalin-fixed tissue, optimally skin biopsies for possible CTCL should be sent to the pathology or dermatopathology lab fresh, on saline-soaked gauze or in tissue culture media such as RPMI. These biopsies can then be divided for the various diagnostic studies. Punch biopsies can be divided into halves, one half for routine histology and the other half for immunophenotyping and/or molecular diagnostic studies. Sections for routine histology should be fixed in a good nuclear fixative such as B5 to facilitate evaluation of nuclear morphology and recognition of characteristic cerebriform cells. If it is a large biopsy of a cutaneous tumor or a lymph node biopsy, it may provide adequate tissue to prepare cell suspensions for immunophenotyping by flow cytometry and for cytogenetic studies. The tissue for immunophenotyping by flow cytometry should be promptly delivered to the appropriate laboratory in cell culture media. Tissue for molecular studies should be snap-frozen in liquid nitrogen and stored at -70°C. For leukemic infiltrates, cytochemical stains can be performed on air-dried touch imprints from freshly cut surfaces. A small sliver of the biopsy can be shaved off and fixed in glutaraldehyde for electron microscopy if needed. Lymph nodes should be worked up as previously described.¹⁴¹

Histopathology

Cutaneous Features of Mycosis Fungoides/Sézary Syndrome

In general, the histologic diagnosis of MF/SS in skin biopsies is based on criteria similar to those used for the diagnosis of other lymphoid neoplasms, including the presence of an infiltrative or destructive growth pattern and cytologic atypia. The distribution of the infiltrate within the skin biopsy is also important (Fig. 92.5A). The characteristic atypical

lymphocytes in MF and SS are dysplastic cerebriform T-cells with enlarged hyperchromatic nuclei and complex nuclear folding. Demonstration of cerebriform nuclear

P.1957

folding requires good fixation (such as B5 fixation), thin (4- μ m) sections, and examination under 100 \times oil immersion. Others have used special methods such as 1- μ m sections of plastic-embedded tissue, electron microscopy, or nuclear morphometry.¹⁴² Diagnostic criteria for cutaneous involvement by MF are best illustrated in plaque-stage lesions (Fig. 92.5B,C). The essential criteria for diagnosis are (a) a bandlike lymphocytic infiltrate in the superficial papillary dermis, (b) epidermotropism, and (c) atypical cerebriform T-cells in the dermal and epidermal infiltrates.^{143, 144} Pautrier microabscesses (Fig. 92.5D) are characteristic of MF but are often absent in patch-stage lesions, erythroderma, and nonepidermotropic tumors. Diagnosing early-patch-stage lesions is often difficult. In a morphologic study of >700 early-patch-stage lesions by Massone et al., the histologic features most helpful for diagnosing MF were (a) epidermotropism, particularly with a basilar lymphocytosis (23%) or with "haloed" lymphocytes (40%); (b) a dermal lymphocytic infiltrate that is bandlike (30%) or patchy lichenoid (66%); and (c) interface dermatitis (59%).¹⁴⁵ Large convoluted lymphocytes in the epidermis were found only in 9% of cases, and Pautrier microabscesses were found in 19%. The authors noted that although these cytologic changes are highly specific, the architectural abnormalities (infiltrate, epidermotropism) were more sensitive in diagnosing MF, as has also been suggested by others.¹⁴⁶ Earlier studies have shown similar criteria as being valuable in diagnosing MF "haloed" epidermotropic cerebriform T-cells along the basal layer of the epidermis, disproportionate epidermotropism (intraepidermal lymphocytes without accompanying spongiosis), and medium to large cerebriform cells in the epidermis and clustered in the dermis.^{143, 147, 148} Several studies have pointed to the association of papillary dermal fibrosis with MF/SS; however, at least one study found that in a carefully selected population of early, untreated MF patients this finding argued against a lymphoma diagnosis.¹⁴⁹

FIGURE 92.5. A: Mycosis fungoides (MF), patch stage. A bandlike lymphocytic infiltrate occupies the superficial papillary dermis with single-cell epidermotropism by atypical, "haloed" cerebriform T-cells, preferentially involving the basal layer (hematoxylin and eosin, $\times 50$). B: MF, plaque stage. A bandlike lymphocytic infiltrate occupies the papillary dermis with

epidermotropism by atypical cerebriform T-cells, focally forming small Pautrier microabscesses (hematoxylin and eosin, $\times 25$). C: MF, thick plaque. A dense bandlike lymphocytic infiltrate fills the papillary dermis and extends into the reticular dermis. Prominent epidermotropism by atypical, enlarged cerebriform T-cells creates large Pautrier microabscesses (hematoxylin and eosin, $\times 25$). D: MF, Pautrier microabscess. High magnification of a Pautrier microabscess shows characteristic small to medium cerebriform T-cells with highly convoluted nuclear folding. The Pautrier microabscess recapitulates normal interactions between components of the skin-associated lymphoid tissue, i.e., cutaneous T-cells, Langerhans histiocytes (2 cells with large pale nuclei in the center), and keratinocytes (hematoxylin and eosin, $\times 500$).

Spongiosis should be minimal in relationship to epidermotropism in MF and SS. Biopsies with prominent spongiosis must be differentiated from eczematous or spongiotic dermatitis. Microvesiculation and Langerhans cell microabscesses are rarely present in MF/SS and would point toward a spongiotic process. Eosinophils and plasma cells are often present in early patch- and plaque-stage MF, and represent a nonspecific reactive component.

P.1958

It is important to understand that a definitive diagnosis of MF may not be possible in some early-patch-stage lesions. Multiple biopsies of separate skin lesions, immunophenotyping, and TCR gene rearrangement studies may help confirm the diagnosis in difficult cases. Even these ancillary studies may be inconclusive in early lesions. The reported range of sensitivity of T-cell clonality detection is large, with some studies reporting as few as 20% of early-patch-stage lesions being clonal¹⁵⁰ to as many as 71%.¹⁵¹ Likely, this variability reflects variability in density of infiltrate in early lesions, variability in source material for DNA extraction (frozen vs. paraffin), and variability of the clonality assay [Southern blot vs. PCR vs. denaturing gel electrophoresis vs. capillary electrophoresis]. In later plaque- and tumor-stage lesions, T-cell clonality can typically be detected in $>90\%$ of cases.^{151, 152} Recently, a PCR-based clonality protocol has been proposed and validated (BIOMED-2) in an attempt to provide some degree of standardization.^{77, 153} In addition, several techniques have been advocated, such as comparing clonality studies from disparate clinical lesions and using complementary clonality studies (TCR β and TCR γ) that may increase the specificity and sensitivity of the molecular studies.^{154, 155} Despite these advancements, however, a lack of demonstrated clonality in a histologically or clinically suspicious lesion should not prevent a diagnosis of CTCL. Likewise, the presence of a clonal population does not equate with malignancy as many benign dermatoses may demonstrate clonality.¹⁵⁶

Tumor-stage MF is characterized histologically by a dense dermal infiltrate involving the papillary and reticular dermis, often with extension into the subcutis. In contrast to patch- and plaque-stage lesions, MF tumors are often nonepidermotropic and may spare the dermal—epidermal interface. Furthermore, the malignant T-cells in tumor-stage MF often display various degrees of histologic transformation, with medium and large pleomorphic cells, immunoblastic large cells, and anaplastic large cells.^{157, 158} The diagnosis of malignancy in the tumor stage is rarely in question, but recognition of MF origin for tumors with large-cell transformation may be obscured by their resemblance to other NHLs. A careful search for dysplastic cerebriform T-cells and residual foci of epidermal infiltration near the edges of tumors often provides histologic evidence of MF origin in difficult cases.¹⁵⁷ Previous or concurrent biopsies of earlier-stage MF lesions may also help confirm the diagnosis in these cases.

Generalized exfoliative erythroderma is characteristic of SS but may also occur in MF.¹⁵⁹ Cutaneous biopsies of erythroderma in MF/SS often lack many of the hallmark features found in patch/plaque MF, such as epidermotropism and lymphocytes aligned along the basement membrane.¹⁶⁰ In fact, in one study, up to 17% of skin biopsies of patients with established SS were considered nondiagnostic because of insufficient epidermotropism.¹⁶¹ Evaluation of the peripheral blood for circulating tumor cells and/or molecular analysis of the skin and peripheral blood for a clonal rearrangement of the TCR may help establish the diagnosis of MF/SS in cases for which skin biopsies are histologically suspicious, but nondiagnostic. In addition, the finding of identical clonal populations in the skin and peripheral blood is very supportive of a lymphoma diagnosis.¹⁶²

Large-cell Transformation of Mycosis Fungoides/Sézary Syndrome

Approximately 20% of low-grade MF and SS undergo secondary transformation to high-grade large-cell lymphoma with a predominance ($>25\%$) of large transformed lymphocytes (Fig. 92.6).¹⁵⁷ Secondary large-cell transformation of MF/SS may resemble immunoblastic large-cell lymphoma, pleomorphic large-cell lymphoma, or ALCL.^{157, 163} It has been shown that secondary large-cell lymphoma is immunophenotypically and clonally related to earlier MF/SS biopsies taken prior to transformation.¹⁶⁴ Cutaneous large-cell transformation usually occurs late in tumor-stage lesions, but it can occasionally be seen in plaques or erythrodermic MF and may be present in the initial diagnostic biopsy (mycosis d'emblée variant).

Lymph nodes are the most common site of extracutaneous large-cell transformation, but it may also occur in other extracutaneous sites. Approximately 50% of secondarily transformed large-cell lymphomas express CD30.¹⁶⁵ In MF patients with large-cell transformation the absence of CD30 expression has been associated with a reduced disease-specific survival.¹⁶⁶ It is important to distinguish secondary large-cell transformation of MF/SS from unrelated primary cutaneous large-cell lymphoma, LyP, and secondary cutaneous involvement by systemic large-cell lymphoma because of prognostic differences.¹⁶⁷ This is particularly true for secondary CD30⁺ large-cell lymphoma resulting from transformation of MF/SS, which has a poor prognosis, in contrast to primary cutaneous CD30⁺ ALCL and LyP, both of which have a favorable prognosis.^{168, 169} Differentiating these entities is often impossible on histologic grounds alone and requires close collaboration between the clinician and pathologist to establish the correct diagnosis in the WHO-EORTC classification scheme.

FIGURE 92.6. Large-cell transformation of mycosis fungoides (MF). This represents secondary transformation of low-grade MF to high-grade immunoblastic large-cell lymphoma. This tumor is composed of sheets of large transformed cells or immunoblasts with round to oval nuclei, dispersed chromatin, and prominent nucleoli. Several mitoses are present (hematoxylin and eosin, $\times 500$).

Extracutaneous Mycosis Fungoides/Sézary Syndrome

Extracutaneous dissemination is generally considered to be a late occurrence in MF/SS because the disease is clinically limited to the skin for prolonged periods of time in most patients. Using more sensitive techniques such as cytogenetics, electron microscopy, and immunophenotypic studies, extracutaneous disease has been found in nearly 90% of MF/SS patients at initial staging in one case series.¹⁷⁰ There is evidence that nodal involvement as detected with highly sensitive molecular techniques can segregate otherwise low-stage patients into high-risk and low-risk groups;¹⁷¹ however, assessment of regional lymph nodes is not standard practice in early-stage MF patients. Although autopsy studies have histologically documented widespread extracutaneous disease in most patients,¹⁷² most series were performed several decades ago, when detection of early disease was difficult.

Extracutaneous MF/SS has histologic features that are usually similar to those seen in the skin. Dysplastic cerebriform T-cells are the most helpful diagnostic feature for recognition as extracutaneous disease. Almost every organ has been involved by MF/SS in autopsy series, but the most frequent sites are the lymph

nodes, liver, spleen, and lungs, which may be involved in >50% of more advanced cases.¹⁷² Other common sites include kidney, bone marrow, thyroid, heart, pancreas, gastrointestinal tract, and central nervous system. Lymph nodes represent the most frequent site of extracutaneous disease in pathologic staging studies; up to 50% of lymph nodes are positive by light microscopy at initial staging.¹⁷³ Several series from the 1980s found visceral involvement present in ~15% of initial staging liver and bone marrow biopsies.^{157, 173, 174} When staging laparotomies were routinely performed in the past, ~30% of spleens were microscopically involved by MF/SS.¹⁷⁵ Extracutaneous CTCL, particularly visceral disease, is strongly associated with advanced-stage skin disease (tumors and erythroderma) and SS.¹⁷⁴ Because tumor-stage MF and generalized erythroderma are frequently nonepidermotropic, it has been suggested that loss of epidermotropism may play an important role in systemic dissemination.

Lymph Node Pathology

With up to 50% of staging lymph node biopsies being microscopically involved by MF/SS, lymph nodes are the earliest and most common site of extracutaneous dissemination.¹⁷³ Nevertheless, the ISCL guidelines only recommend excision of lymph nodes if they are either >1.5 cm in greatest transverse diameter or are palpably irregular, firm, or fixed lymph nodes regardless of size.¹⁷⁶ Partially effaced nodes often have an interfollicular pattern with preservation of reactive follicular centers, but eventually most lymph nodes become completely effaced. As lymph nodes become progressively infiltrated, the cerebriform T-cells tend to become larger and more pleomorphic, with increased numbers of large transformed cells.¹⁷⁷ Over 35% of positive nodes will show complete large-cell transformation with pleomorphic, immunoblastic, or anaplastic large-cell morphology.^{157, 177, 178} In contrast to MF, lymph nodes from patients with SS tend to be effaced by more monomorphic infiltrates of small to medium cerebriform T-cells,¹⁷⁹ but may also undergo large-cell transformation in some cases.^{157, 165}

Bone Marrow Involvement

The bone marrow in MF and SS is generally thought to be spared until late in the course of the disease, including in patients with large numbers of circulating Sézary cells.^{70, 170} Early studies suggested that antemortem marrow involvement occurred in <3% of MF/SS patients,¹⁷⁰ yet the marrow was involved in nearly 50% of patients at autopsy in several series from the 1970s.^{172, 180} Marrow involvement typically manifests as nonparatrabeular lymphoid aggregates with cerebriform lymphocytes. Molecular studies have shown that in patients with a defined clonal T-cell rearrangement in the skin, approximately 20% will have an identical T-cell clone detected in their blood or bone marrow. Moreover, all patients with bone marrow involvement by molecular studies had blood involvement as well, but only 76% of patients with blood involvement had bone marrow involvement.¹⁸¹ Sibaud et al. were unable to demonstrate that bone marrow involvement was associated with a worse prognosis in a multivariate analysis of their data; however, blood involvement was an independent variable for disease progression. In patients with SS, subtle small interstitial clusters of Sézary cells have been identified in up to 90% of cases, suggesting that most patients with circulating Sézary cells have early systemic dissemination of disease.¹⁷⁴ Detection of these subtle interstitial infiltrates of Sézary cells requires careful examination under oil immersion (100×) to identify the cells with abnormal cerebriform nuclear folds. Identification can be facilitated with immunoperoxidase studies for T-cell markers such as CD3, CD4, and CD7. Flow cytometry using a broad array of T-cell markers including CD3, CD4, CD8, CD7, and CD26 is also useful for detecting marrow involvement.

Other Extracutaneous Sites

Splenic and hepatic involvement by MF and SS is common and can be staged using imaging criteria rather than by invasive methods.¹⁸² Liver involvement in initial staging procedures has been found in 8% to 16% of cases.¹⁷³ Disseminated MF and SS tend to form nodular infiltrates of atypical cerebriform T-cells within the portal tracts or hepatic lobules. Cerebriform T-cells within the hepatic sinusoids without formation of focal aggregates are not considered diagnostic of liver involvement in the presence of peripheral blood involvement. Splenic infiltration was documented in 31% of staging laparotomies in one series.¹⁷⁵ The atypical cerebriform T-cells usually infiltrate the red pulp diffusely, but they may home to the periarteriolar lymphocyte sheath.¹⁸⁰ Splenic rupture has been reported in a rare case with massive splenic involvement by CTCL.¹⁸³

All other suspected sites of visceral involvement should be confirmed by biopsy if possible. Antemortem pulmonary manifestations of MF and SS are generally uncommon but may occasionally present clinically as interstitial or nodular pulmonary infiltrates.¹⁸⁴ However, the lungs are frequently involved by MF/SS at autopsy.¹⁷² Infiltrates of atypical cerebriform T-cells usually spread along the alveolar septae with preservation of the alveolar architecture. In some cases, the infiltrates may also fill alveolar spaces.

Blood Involvement

The ISCL has defined three stages of blood involvement for MF/SS.¹⁷⁶ Patients with B2 peripheral blood involvement have $>1,000$ Sézary cells/ mm^3 , where the Sézary cells are distinguished by their large nuclear size ($>15 \mu\text{m}$) and high nuclear contour index (Fig. 92.7).¹⁸⁵ In one study, increased large Sézary cells correlated significantly with poorer survival.¹⁸⁶ However, size criteria alone would fail to recognize the small Sézary cell variant, which is similar in size to a normal resting lymphocyte. Because of the inherent difficulties in diagnosing peripheral blood involvement by MF/SS on peripheral smear review, additional technologies are now used including flow cytometry and molecular studies such as PCR. The ISCL considers a positive clonal TCR rearrangement in the blood coupled with either a CD4:CD8 ratio $>10:1$ or abnormal immunophenotype by flow cytometry ($\text{CD4}^+\text{CD7}^-$ or $\text{CD4}^+\text{CD26}^-$) as adequate evidence to constitute a positive peripheral blood for staging purposes.¹⁸⁵ It has been shown that patients with B2 blood involvement have a statistically worse survival than those with B1 or B0 staging.¹⁸⁶ ISCL B0 is defined as no increase in Sézary cells ($<5\%$ of peripheral blood lymphocytes). B0 cases with molecular detection of T-cell clonality (B0b) have a worse prognosis than

P.1960

molecularly negative (B0a) cases even when the histologic criteria for blood involvement have not been met.^{162, 187, 188} In fact, T-cell clonality in the peripheral blood even in the absence of increased lymphocytes by morphology or flow cytometry (B0b) has been shown to convey a worse overall survival (OS), disease-specific survival and risk of disease progression.¹⁸⁹ B1 stage is defined as the group of patients who fail to meet criteria for B2 or B1. These patients have $>5\%$ atypical T-cells but do not otherwise reach the criteria for B2 involvement. These patients can also be split into B1a molecular clone negative and B1b molecular clone positive cases. Although T-cell clonality is required for diagnosis of B2 stage, the presence of molecularly defined T-cell clones in elderly patients or in patients with other lymphoproliferative disorders is not uncommon^{151, 190, 191} requiring therefore correlation with the clonality of the cutaneous infiltrate or association with MF-associated immunophenotypic abnormalities (increased CD4:CD8 ratio, loss of CD7 or CD26 on CD4 T cells).

FIGURE 92.7. Sézary syndrome. The peripheral blood shows lymphocytosis. Most lymphocytes are Sézary cells with enlarged, highly convoluted nuclei and scant cytoplasm (hematoxylin and eosin, $\times 250$).

Immunophenotyping Studies

T-cell origin of the neoplastic cells in MF and SS is well established as a memory T-cell that expresses CLA, the cutaneous lymphoid antigen homing receptor.¹⁹² The vast majority are derived from T-helper cells that express CD4 and other T-cell-

associated antigens including CD2, CD3, CD5, CD45RO, and $\alpha\beta$ TCRs (Fig. 92.8).¹⁹³ However, a small number of CD8⁺ CTCL¹⁹⁴ have been reported as well as $\gamma\delta$ CTCL.^{195, 196} Of note, clinical presentation and behavior are crucial in distinguishing the CD8⁺ MF variant from the more aggressive primary cutaneous aggressive epidermotropic CD8⁺ cytotoxic T-cell lymphoma described in the updated WHO-EORTC nomenclature as a provisional subtype of peripheral CTCL. Furthermore, it is likely that most $\gamma\delta$ CTCL would be classified as cutaneous $\gamma\delta$ T-cell lymphoma (CGDTCL) in the WHO-EORTC scheme.^{137, 194, 197} Activation-associated (HLA-DR, CD25, CD30, CD38) and proliferation-associated (CD71, Ki-67) antigens are also frequently expressed in MF/SS, particularly in advanced stages.¹⁵⁷

Aberrant T-antigen expression is often seen in MF and SS, particularly advanced plaque- or tumor-stage lesions, and can be used to help differentiate reactive dermatitis from MF/SS.¹⁹⁸ Often, flow cytometry is used to assess antigen expression on the T-cells present in circulation or directly from involved skin biopsies. Aberrant T-cell phenotypes are defined as diminished or absent expression of pan-T-cell antigens (CD2, CD3, or CD5), absent T-subset antigen expression (CD4⁻ CD8⁺), or co-expression of T-subset antigens (CD4⁺ CD8⁺). Diminished or absent CD7 expression is one of the most common aberrant T-cell phenotypes in tissue sections of MF and SS.¹⁹⁸ However, the isolated findings of loss of CD7 expression must be considered in the context of other clinical, histologic, and immunophenotypic findings in that expanded populations of CD7-negative T-cells can also be seen in benign dermatitides.¹⁹³ More recently, several studies have shown that the loss of CD26 (dipeptidyl-aminopeptidase IV) expression is a characteristic feature of circulating Sézary cells that is likely more sensitive than loss of CD7 expression.^{199, 200, 201} Nevertheless, when considered as a group, loss of any major T-cell antigen (CD2, CD5, CD3, CD4, or CD7) is as or more sensitive a marker for SS and MF than loss of CD26.²⁰²

FIGURE 92.8. Frozen section immunohistochemistry of a cutaneous plaque in a patient with MF shows a marked predominance of CD4⁺ T-helper cells within Pautrier microabscesses and within the dermis. CD8 is essentially negative (Diaminobenzidinehematoxylin, $\times 50$). MF, mycosis fungoides.

For histologic diagnosis of cutaneous lymphomas, immunohistochemistry can reliably differentiate among T-cell lymphomas, B-cell lymphomas, and Hodgkin disease. The most widely used paraffin-reactive T-cell antibodies include CD2, CD3, CD4, CD5, CD7, CD8, CD30, CD43, CD45RO, β F1, and TCR $\alpha\beta$. Although immunohistochemistry for CD7 can be helpful in evaluating early MF biopsies, loss of CD7 can be seen in a wide variety of reactive benign conditions requiring correlation with clinical, histologic, other immunophenotypic and molecular findings.^{203, 204} NK-cell or cytotoxic lymphocyte markers (CD56, granzyme B, perforin, and TIA-1) can be used as well if non-MF NK-/T-cell lymphomas are in

the differential. CD20, CD79a, CD5, CD10, BCL-6, BCL-2, κ , λ , MUM1, and CD138 are the most widely used B-cell paraffin-reactive antibodies. When used in panels, these antibodies allow subclassification of most cutaneous lymphomas.

DIFFERENTIAL DIAGNOSIS

The clinicopathologic differential diagnosis for MF/SS includes several forms of benign dermatitis, other primary low-grade CTCLs, and secondary cutaneous involvement by disseminated lymphomas or leukemias (Table 92.2). Differentiation of these mimickers from CTCL often requires careful correlation of clinical, histopathologic, immunophenotypic, and genotypic characteristics, and may require multiple or serial biopsies. The following discussion describes methods to differentiate MF/SS from similar benign conditions, indolent CTCL, and other primary CTCLs.

To assist clinicians with the diagnosis of early MF, Pimpinelli et al. proposed an algorithm using clinical, histopathologic, molecular biologic, and immunopathologic criteria in which a total of 4 points from any of the four categories was necessary to make the diagnosis of early MF.¹²⁶ The scoring system would allow, for example, a patient with persistent patches in nonsun-exposed areas with size/shape variation (2 points) and histologic findings of a superficial lymphocytic infiltrate, epidermotropism without spongiosis, and lymphocyte atypia (2 points) to meet criteria for early MF diagnosis without any immunostains or T-cell-receptor gene rearrangement analysis of the skin tissue.

Benign Conditions

Benign inflammatory skin lesions are most likely to be confused with early patch-stage MF. In general, these conditions have clinical presentations and courses that are different from MF, lack enlarged atypical cerebriform T-cells, and lack epidermotropism that is disproportionately increased in relationship to spongiosis. However, in difficult cases, immunophenotypic analysis and gene rearrangement studies may be necessary to look for aberrant T-cell phenotypes or clonal TCR gene rearrangements. The benign inflammatory dermatoses that most closely resemble CTCL include small and LPP, PVA, pityriasis lichenoides, pigmented purpuric eruption, lichenoid keratosis, benign erythroderma, contact dermatitis, persistent arthropod bite reactions, drug eruptions, LyP, and actinic reticuloid (AR).²⁰⁵

Despite the name, the chronic skin diseases under the term parapsoriasis are unrelated to the much more common skin P.1961

disease psoriasis. Most dermatologists separate parapsoriasis into one of two types. The benign subtype is known as small plaque parapsoriasis, digitate dermatosis, or chronic superficial dermatitis. The other type is considered pre-malignant and is most often called LPP or parapsoriasis en plaques (having in the past been called pre-reticulotic poikiloderma).^{206, 207} LPP is clinically indistinguishable from patch-stage MF.¹²⁶ However, the patches of MF tend to be fixed whereas the patches of LPP tend to wane in the summer and flare in the winter. Because of clinical and histologic overlap, some authorities consider LPP to be an early stage of MF.²⁰⁸ Others consider LPP to be a latent form of MF²⁰⁹ because ~10% of patients eventually develop overt MF.²¹⁰ A retrospective review documented a higher rate of evolution to MF in 12 of 36 (33%) patients with LPP.²¹¹ This view is supported by the demonstration of clonal TCR gene rearrangement in 50% of LPP biopsies.⁷³ Furthermore, demonstration of clonal TCR gene rearrangements in small plaque or digitate parapsoriasis has suggested that this may be an abortive form of MF.^{212, 213} Histologically, the lymphoid infiltrate of LPP is perivascular and less dense with less epidermotropism than in MF; Pautrier microabscesses are not seen in LPP. Furthermore, cytologically atypical cerebriform T-cells with highly convoluted nuclei are inconspicuous or absent in LPP. However, immunophenotypic analysis is usually not helpful for differentiating LPP from patch-stage MF as both have a predominance of CD4⁺ helper cells with absent CD7 and CD62L expression.¹²⁷ One study found the presence of HECA-452 immunostaining higher in MF than LPP, which may be helpful in distinguishing the two diseases and predicting which cases of LPP may evolve into MF.²¹⁴

TABLE 92.2 BENIGN AND MALIGNANT CONDITIONS THAT CAN MIMIC MF AND SÉZARY SYNDROME

Benign Conditions

Small and large plaque parapsoriasis

Poikiloderma vasculare atrophicans

Pityriasis lichenoides et varioliformis acuta

Benign erythroderma

Chronic spongiotic dermatitis

Contact dermatitis

Drug eruption

Arthropod bites

Actinic reticuloid

Follicular mucinosis

CD30⁺ Lymphoproliferative Disorders

Lymphomatoid papulosis

Primary cutaneous anaplastic large-cell lymphoma

Other Primary Cutaneous T-Cell Lymphomas

Pagetoid reticulosis

Folliculotropic mycosis fungoides

Granulomatous slack skin

Subcutaneous panniculitis-like T-cell lymphoma

Primary cutaneous $\gamma\delta$ + T-cell lymphoma

Primary cutaneous CD8+ T-cell lymphoma

Primary cutaneous pleomorphic small/medium-sized CTCL

Primary Cutaneous B-Cell Lymphomas

Primary cutaneous follicle center lymphoma

Primary cutaneous marginal zone lymphoma

Primary cutaneous large B-cell lymphoma

Intravascular large B-cell lymphoma

Secondary Lymphoma/Leukemia

Leukemia cutis

Extramedullary myeloid tumor

Adult T-cell leukemia/lymphoma

Peripheral T-cell lymphoma

Hodgkin lymphoma

CTCL, cutaneous T-cell lymphoma

PVA can also present similarly to early MF, so much so, that most experts believe PVA to be a rare variant of MF.^{215, 216, 217} The macules and patches of PVA show the poikilodermatous features of hypopigmentation, hyperpigmentation, atrophy, and telangiectasias. PVA macules/patches tend also to be localized to sun-protected sites, most commonly appearing on the buttocks, breasts, and flexural areas. And, like LPP, some clinicians believe that PVA may potentially precede or co-exist with MF.¹²⁵ Histologically, PVA is characterized by an atrophic epidermis, chronic, ill-defined inflammatory changes and dilated capillaries. Often, lymphoid cells form a bandlike pattern in the superficial dermis, with only rare epidermotropism.^{215, 216, 217}

Pityriasis lichenoides is considered a spectrum of diseases including an acute and a chronic form: pityriasis lichenoides et varioliformis acuta (PLEVA) and pityriasis lichenoides chronica (PLC), respectively. Many patients demonstrate lesions of both forms during their disease course. PLEVA, also known as Mucha-Habermann disease, is a benign cutaneous disorder characterized by recurrent, self-healing papulonecrotic lesions that may resemble LyP, which is discussed later.²¹⁸ PLC, which is a benign eruption with lymphocytic infiltrates of the skin, presents as a persistent, erythematous, papular

eruption with scale.²¹⁹ Biopsies may show slightly atypical cerebriform T-cells with some epidermotropism, but vacuolar degeneration of the epidermal basilar layer, necrotic keratinocytes, and dermal hemorrhage in PLEVA distinguish it from MF. The lymphoid infiltrate is composed predominantly of CD8⁺ cells as opposed to the typical CD4⁺ phenotype of MF.²²⁰ The histology of PLC is similar to PLEVA, although the findings are muted with only focal basal vacuolar change and limited lymphocytic exocytosis. The intraepidermal lymphocytes tend to be CD4⁺, which further complicates the distinction from early MF. As in PLEVA, the lymphocytes lack significant cytologic atypia. Some consider pityriasis lichenoides to be a T-cell lymphoproliferative disorder or a form of indolent cutaneous T-cell dyscrasia related to LyP, and clonal TCR gene rearrangement has been demonstrated.^{221, 222, 223, 224} Although cases of patients with pityriasis lichenoides progressing to MF have been described, this is definitely a rare event.^{220, 224, 225}

Pigmented purpuric dermatoses (PPD) are a group of chronic and benign skin disorders categorized by rupture of the small capillaries in the superficial papillary dermis. Clinically, patients present with petechiae and bronze discoloration of the skin on the lower extremities.²²⁶ Histologically, there is a superficial perivascular infiltrate that may be dense and lichenoid in nature. Dermal hemorrhage and hemosiderin deposition is present to varying degrees. Lymphocytic exocytosis is often present, however, cytologic atypia and intraepidermal lymphocytic microabscesses are generally absent. Immunohistochemical and molecular studies are typically not helpful in differentiating PPD from MF. Lichen aureus, a rare type of PPD, can mimic MF both clinically and histologically and progress to MF in very rare cases.²²⁷ One study showed that of 43 cases of PPD, 21 showed a clonal population of T-cells. Only 40% of the cases with demonstrated clonality, however, had clinical and pathologic features consistent with MF. In addition, loss of CD7 was frequently observed in both

P.1962

the polyclonal and monoclonal groups.²²⁸ Other studies have documented the frequent occurrence of T-cell clonality in cases of PPD that fail to develop disease typical of MF.²²⁹ The presence of extensive PPD-like skin disease, especially when present outside the lower extremities, should raise the suspicion of MF regardless of the histologic features.

Lymphomatoid keratosis is a benign epithelial skin neoplasm related to an inflamed seborrheic keratosis or lichenoid keratosis. Patients generally demonstrate scattered small hyperkeratotic plaques on the trunk and are biopsied to rule out the possibility of a nonmelanoma skin cancer. The histologic features can be indistinguishable from MF with a lichenoid infiltrate and extensive lymphocytic exocytosis. Additionally, clonal populations of T-cells have been detected.²³⁰ The presence of epidermotropic CD20⁺ B-cells is suggestive of a lymphomatoid keratosis; however, clinicopathologic correlation is paramount in arriving at the correct diagnosis.²³¹

Erythroderma may occur in a variety of benign dermatologic disorders including psoriasis, pityriasis rubra pilaris, eczematous dermatitis, seborrheic dermatitis, severe contact dermatitis, and drug eruptions.^{232, 233} These patients may also have circulating cerebriform cells and lymphadenopathy, further complicating the diagnosis. Erythroderma secondary to drug reactions, especially anticonvulsants such as phenytoin, can be particularly difficult to distinguish from MF/SS because of the presence of convoluted cerebriform T-cells and the formation of Pautrier microabscesses.¹⁴⁰ Several studies have compared the histologic features of erythrodermic MF/SS with other causes of reactive erythroderma. Although not present in all cases, Pautrier microabscesses and a dense, often lichenoid, dermal lymphocytic infiltrate were more commonly associated with erythrodermic MF/SS.^{234, 235, 236} Differentiation of benign erythroderma from erythrodermic CTCL can usually be accomplished through careful evaluation of the history, skin biopsy of the more typical lesions of the underlying disease, and molecular genetic analysis of both skin and blood.^{235, 236} Numerous eosinophils favor a drug reaction. Aberrant T phenotypes or clonal TCR gene rearrangements are usually not present in benign erythroderma.

Subacute or chronic spongiotic dermatitis and interface dermatitis resulting from contact dermatitis, drug eruption, and persistent arthropod bite reaction may have atypical cerebriform T-cells with epidermotropism and Pautrier-like microabscesses mimicking MF.²⁰⁵ Caution should be exercised in interpretation of epidermotropism associated with significant spongiosis, especially microvesiculation, which is only rarely observed in MF.¹⁴³ The Pautrier-like microabscesses seen in spongiotic processes typically have a flask shape and are composed of Langerhans cells and keratinocytes. Immunophenotyping may be helpful in this differential diagnosis because cutaneous T-cell pseudolymphomas rarely show aberrant loss of CD2, CD3, or CD5 expression, especially a combination of these markers.²⁰⁵ CD7 and CD62L (Leu 8) are not as helpful as their expression is commonly lost in both MF and reactive dermatoses.²⁰⁵ Typically, T-cell-predominant pseudolymphomas are characterized by perivascular, "sleevelike" infiltrates around vessels in the dermis, with accompanying plasma cells, eosinophils, and macrophages. The T-cells are typically a mixture of CD4⁺ and CD8⁺ cells as opposed to the CD4⁺-predominant population characteristic of most cases of MF. The

utility of gene rearrangement studies in this setting is unclear as clonal TCR gene rearrangements have been reported in some cutaneous T-cell pseudolymphomas.^{237, 238, 239} The following drugs have been implicated as causing pseudolymphoma: alprazolam, amitriptyline, atenolol, carbamazepine, cefixime, chlorpromazine, cimetidine, clarithromycin, clonazepam, clonidine, cotrimoxazole, cyclosporine, desipramine, diltiazem, doxepin, fluoxetine, furosemide, gemfibrozil, gold, lamotrigine, lithium, lorazepam, losartan, methotrexate, nizatidine, perphenazine, phenytoin, ranitidine, sulfamethoxazole, sulfasalazine, and thioridazine.²⁴⁰

B-cell-predominant pseudolymphomas are notable for reactive follicle formation with tingible-body macrophages, centroblasts, and centrocytes in the germinal centers surrounded by distinct mantle zones. There are polyclonal plasma cells, a mix of CD4⁺ and CD8⁺ T-cells and often eosinophils in the accompanying inflammatory infiltrate.^{241, 242} CD21⁺ follicular dendritic cells (DCs) can be found in the follicles as well.

AR is a severe form of photosensitive dermatitis that may closely mimic MF or SS clinically and histologically when fully developed.^{243, 244, 245} AR is a chronic persistent eruption that can be induced by a broad spectrum of light wavelengths (ultraviolet A [UVA], UVB, and visible wavelengths of light).²⁴³ The skin lesions are typically plaques and papules on the sun-exposed areas of the face and hands, but may extend to covered areas or even become generalized erythroderma.²⁴⁶ In contrast to MF, epidermotropism is not prominent, but small Pautrier microabscesses may be found in some cases. Severe cases of erythrodermic AR may have generalized lymphadenopathy and circulating Sézary cells mimicking SS. Preferential involvement of sun-exposed areas, absence of large dysplastic cerebriform T-cells, and a CD8⁺ phenotype help distinguish AR from MF/SS. AR does not appear to be associated with progression to malignant lymphoma, and clonal TCR rearrangements have not been reported.²⁴⁵

CD30⁺ Lymphoproliferative Diseases

The differential diagnosis for suspected MF also includes a variety of related conditions, which are equally concerning for their malignant or pre-malignant clinical course. LyP and primary cutaneous ALCL (pcALCL) are both characterized by the presence of CD30⁺ T-cells; together, they represent the poles of a continuous disease spectrum. Both LyP and pcALCL are now considered subtypes of the CTCLs.¹³⁷ There is no clear-cut boundary between the diseases, however, and many patients fall into a borderline category when definitive diagnosis is not possible based on the current clinicopathologic features.

LyP is a CD30 (Ki-1)-positive T-cell lymphoproliferative disorder characterized by chronically recurring, self-healing crops of mildly pruritic papulonodular lesions that are clinically benign but histologically malignant.²⁴⁷ LyP initially presents with crops of erythematous papules that wax and wane, becoming hemorrhagic and necrotic before undergoing spontaneous regression with scar formation. Individual lesions range from 2 mm to 2 cm in diameter (usually <1 cm) and have an average duration of 5 weeks, ranging from 2 weeks to 6 months.²⁴⁸ LyP is classically divided into three histologic types, type A, type B, and type C. More recently a fourth histologic presentation, termed LyP type D, has been described.²⁴⁹ Any of the histologic types may occur simultaneously in the same patient or during the course of the disease and the individual histologic type provides no prognostic significance.²⁵⁰ LyP type A, the most common type, is characterized by a polymorphous infiltrate of eosinophils, neutrophils, and scattered anaplastic large transformed lymphocytes and binucleate Reed-Sternberg-like cells (Fig. 92.9).^{251, 252} LyP type B is characterized by small to medium cerebriform T-cells resembling MF. LyP type C is characterized by sheets of large, anaplastic CD30⁺ cells and can be histologically identical to pcALCL but follows a waxing and waning clinical course. The atypical cells in LyP types A, B, and C are typically CD4⁺. LyP type D is characterized by an extensively epidermotropic population of cytologically atypical CD8⁺ lymphocytes in a pattern that is nearly identical to that observed in primary cutaneous aggressive epidermotropic CD8⁺ cytotoxic T-cell lymphoma (see below).^{249, 253, 254} The atypical cells in all of the types often have clonal rearrangement of the T-cell-receptor gene, and absent or diminished expression of pan-T-cell antigens.²⁵⁵ However, CD30 expression differs among the types; the large transformed cells in types A, C, and D are CD30⁺, similar to CD30⁺ ALCL, whereas the atypical cerebriform T-cells in type

P.1963

B LyP typically do not express CD30.²⁵⁶ Vonderheid and Kadin have suggested that the papular variant of MF and type B LyP are the same entity²⁵⁶ although Kodama and colleagues point to the lack of spontaneous resolution of papules in papular MF.²⁵⁷ Clinical behavior of LyP is usually benign; however, overt lymphoma has been documented in ~10% to 25% of patients, usually MF, pcALCL, or Hodgkin lymphoma.^{248, 258} The cumulative risk for the development of another lymphoma in patients with LyP over 15 years of disease may be as high as 80%.²⁵⁹ A retrospective review of 31 patients with LyP over a 27-year span identified 60% who developed a co-existing lymphoma.²⁵⁸ No clinical, histologic,

immunophenotypic, or molecular genetic features have been identified that can predict which patients will develop lymphoma, but two studies suggest that malignant transformation is more strongly associated with type A than with type B LyP.²⁵⁶ Onset of LyP at a younger age may be associated with increased cumulative risk for overt lymphoma and therefore all LyP patients should be closely monitored throughout their lives.^{221, 259, 260} The benign or malignant nature of LyP is controversial, but the WHO-EORTC considers LyP to be a latent or low-grade stage of the primary cutaneous CD30⁺ lymphoproliferative disorders that are considered to be malignancies.^{137, 261} Its clinical, histologic, and immunophenotypic similarities to pcALCL, aberrant T-cell-antigen expression, clonal TCR gene rearrangements, and increased risk for transformation to malignant lymphoma support this view.

FIGURE 92.9. Lymphomatoid papulosis, type A. Anaplastic large cells with abundant cytoplasm, reniform nuclei, and prominent nucleoli are scattered among small lymphocytes and eosinophils. Note occasional binucleate Reed-Sternberg-like cells (hematoxylin and eosin, $\times 250$). The large cells were strongly positive for CD30 (not shown).

Differentiation of primary cutaneous ALCL from LyP and secondary CD30⁺ LCL resulting from large-cell transformation of MF/SS is important because of differences in prognosis and therapy.^{137, 261} pcALCL has a good prognosis and can be effectively managed with local excision and/or radiation therapy,²⁶² whereas secondary CD30⁺ LCL due to large-cell transformation of MF/SS has a very poor prognosis requiring systemic therapy that often includes aggressive combination chemotherapy.^{167, 263} LyP also has an excellent prognosis and can often be managed with no therapy, topical chemotherapy, phototherapy, and low-dose methotrexate without the need for aggressive therapy.^{264, 265} Furthermore, pcALCL must be differentiated from secondary cutaneous involvement by extracutaneous ALCL.^{266, 267} Primary nodal ALCL and secondary cutaneous involvement by extracutaneous ALCL are more aggressive than pcALCL.^{266, 267} In malignant cells, the presence of anaplastic lymphoma kinase-1 protein (ALK-1) from the t(2;5) (p23;q35) chromosomal translocation favors primary nodal ALCL.²⁶⁸ A thorough dermatologic examination, history, and staging for extracutaneous disease are necessary to exclude secondary large-cell transformation of low-grade MF or secondary cutaneous involvement by extracutaneous lymphoma before a case is accepted as pcALCL. pcALCL is differentiated from LyP type A by cohesive sheets or $>75\%$ CD30⁺ large transformed cells, fewer admixed neutrophils and eosinophils, a diffuse infiltrate that extends into the deep dermis versus a more superficial wedge-shaped infiltrate, larger solitary or localized nodules or tumors instead of crops of papules, and higher frequency of persistent or progressive cutaneous lesions with less frequent or incomplete spontaneous regression.^{263, 268, 269} Recently it has been shown that translocations in the interferon regulatory factor-4 (IRF4) gene are specifically associated with pcALCL and may be used to differentiate it from the other previously mentioned entities.²⁷⁰ Other aspects of ALCL are discussed in more detail in Chapter 88.

Other Primary Cutaneous T-cell Lymphomas

Using the WHO-EORTC classification for cutaneous lymphomas as a guide, other primary CTCLs need to be considered in patients with atypical lymphocytic infiltrates of the skin.^{137, 139, 271} These lymphomas include: three variants of MF (pagetoid reticulosis [PR], granulomatous slack skin [GSS] disease, and folliculotropic MF); subcutaneous panniculitic T-cell lymphoma; extranodal NK-/T-cell lymphoma, nasal type; and primary cutaneous peripheral T-cell lymphomas (PTCLs), unspecified, which include: (a) primary cutaneous aggressive epidermotropic CD8⁺ T-cell lymphoma, (b) CGDTCL, and (c) primary cutaneous CD4⁺ small/medium-sized pleomorphic T-cell lymphoma.

PR and folliculotropic MF are variants of MF implying minor clinicopathologic differences from classical MF, whereas GSS is a subtype of MF with more significant differences from classical MF.²⁷² As in classical MF, these diseases are low-grade clonal T-cell lymphomas that generally follow a benign course but may behave aggressively over time. PR is a rare epidermotropic variant of MF that usually presents as localized, hyperkeratotic, verrucous plaques on the hands or feet (Woringer-Kolopp disease)²⁷³ but may also present with disseminated cutaneous plaques (Ketrion-Goodman disease).²⁷⁴ Given its more aggressive clinical course, Ketrion-Goodman disease would currently be better classified as tumor-stage MF, CGDTCL, or aggressive epidermotropic CD8⁺ CTCL.^{137, 275, 276} PR may mimic a more unusual variant of MF localized to the palms and soles known as MF palmaris et plantaris.²⁷⁷ Skin biopsies of PR show pagetoid epidermotropism by enlarged, atypical cerebriform T-cells, with relative sparing of the dermis (Fig. 92.10). The malignant cells in PR may be CD8⁺ or, less commonly, CD4⁺ and rarely, CD4⁺CD8⁻.²⁷⁸ In contrast to conventional MF and SS, there is often co-expression of CD30⁺. Although the original classification of PR allowed for $\gamma\delta$ TCR expression of the neoplastic cells, these cases are best classified

P.1964

as CGDTCL according to the WHO-EORTC guidelines. Clonal TCR gene rearrangement and aberrant T-cell-antigen expression support classification of PR as a form of CTCL;²⁷⁹ however, PR has a clinically benign course, with only rare reports of cutaneous dissemination of localized PR.²⁷⁶ Further studies are needed to confirm whether phenotypic differences in PR have clinical relevance. Local excision or radiation therapy is generally adequate treatment for PR, especially the localized form.

FIGURE 92.10. Pagetoid reticulosis. Note the pronounced pagetoid pattern of epidermotropism by enlarged, atypical cerebriform T-cells (hematoxylin and eosin, $\times 50$).

Folliculotropic or follicular MF (FMF) is another uncommon variant of CTCL first reported in 1985 with preferential perifollicular and folliculotropic infiltration by atypical cerebriform T-cells with minimal or absent epidermotropism and mucin (Fig. 92.11).^{280, 281, 282} The follicles may show plugging, cystic dilatation, and mucinous degeneration, as seen with mucin stains such as Alcian blue. Folliculotropic cerebriform T-cells are CD4⁺^{282, 283} and may express an aberrant T-cell phenotype with loss of CD7 and other T-cell antigens.²⁸² Differential up-regulation of ICAM-1 (CD54) on follicular epithelium instead of epidermal keratinocytes has been implicated in the folliculotropic homing pattern of folliculotropic MF.²⁸² Lymph node involvement and large cell transformation have also been described.²⁸² Folliculotropic MF, whether or not exhibiting follicular mucinosis, has shown a more aggressive course than classic MF.^{189, 284} Approximately 7% of reported cases have demonstrated rapid lymph node involvement.^{285, 286} In a large series of patients with FMF (n = 51), the disease-specific survival was 68% at 5 years and 26% at 10 years.²⁸⁶ This poor prognosis has been confirmed by other studies as well.^{166, 287} Agar and colleagues completed an outcome analysis on 1,502 patients with MF/SS concluding that folliculotropic MF was one of several independent predictors of poor survival and increased risk of disease progression.¹⁸⁹

Follicular mucinosis is frequently associated with folliculotropic MF and less commonly with classical MF. This variant of MF must be differentiated from idiopathic follicular mucinosis or alopecia mucinosa.^{288, 289} In general, no single clinicopathologic feature can differentiate follicular mucinosis associated with MF from alopecia mucinosa.^{288, 289, 290} Alopecia mucinosa tends to occur in younger patients with fewer lesions localized to the head and neck as opposed to the more general distribution commonly seen in MF-associated cases. Histologically, alopecia mucinosa tends to have fewer atypical cerebriform T-cells, less epidermotropism and/or lymphocytic infiltration of follicular epithelium, and a normal CD4/CD8 ratio. In follicular mucinosis associated with MF the infiltrate tends to be denser and cytologically atypical with a CD4⁺-predominant immunophenotype.²⁸⁸ Clonal TCR gene rearrangement can be detected in many cases of alopecia mucinosa thus limiting its usefulness in the differentiation from MF.^{290, 291} In support of this, a long-term follow-up study of seven patients with follicular mucinosis concluded that despite the presence of a clonal TCR gene rearrangement, there was no evidence of progression to CTCL in any patient.²⁹²

FIGURE 92.11. Folliculotropic mycosis fungoides with follicular mucinosis. Note the preferential pattern of perifollicular infiltration by atypical cerebriform T-cells with prominent folliculotropism forming small Pautrier microabscesses. Also note the bluish pools of mucin within the hair follicles (hematoxylin and eosin, $\times 25$).

GSS disease is a rare but distinctive subtype of MF that begins with patches and plaques that steadily progress to characteristic pendulous, erythematous skin folds in the axillae and groin.^{293, 294, 295, 296, 297, 298} Several authors stress the importance of distinguishing the mature lesions of GSS from the histologic variant of granulomatous MF, which can be differentiated quantitatively, not qualitatively.^{293, 298} GSS has histologic features of MF including superficial papillary dermal and epidermotropic infiltrates of atypical cerebriform T-cells, but it also exhibits expansive infiltration into the deep dermis and subcutis with extensive elastolysis and a prominent granulomatous reaction with Langerhans-type multinucleated giant cells (Fig. 92.12). These multinucleated giant cells are histiocytic in origin with 20 to 30 nuclei,

frequently show emperipolesis and elastophagocytosis, and express CD68 and CD1a.^{293, 299, 300} Similar to MF, GSS is a clonal proliferation of CD4⁺ T-helper cells that frequently lack expression of CD7 and CD62L. GSS usually remains localized to the skin, although hypercalcemia, lymph node involvement, and fatal systemic dissemination have been reported.^{295, 296, 297, 298, 301, 302} It is important to note that in contrast to other CTCL variants, patients with GSS have an increased incidence of Hodgkin lymphoma at a frequency between 25% to 50%.^{293, 302, 303}

FIGURE 92.12. Granulomatous slack skin. This variant of mycosis fungoides (MF) shows a deep lymphocytic infiltrate with dermal edema, disruption of elastic fibers, and numerous foreign body giant cells (hematoxylin and eosin, $\times 10$).

Subcutaneous panniculitis-like T-cell lymphoma (SPTL) presents as tender erythematous nodules or subcutaneous palpable masses, mostly on the legs, trunk, arms, or face. Histologically, this lesion is confined to the subcutis and does not typically

P.1965

extend to the dermis or epidermis.^{304, 305} Classically, T-cells ranging from small and inconspicuous to large and transformed cells with hyperchromatic nuclei rim individual fat cells.^{306, 307} There is necrosis, karyorrhexis, and cytophagocytosis by the histiocytes that are found interspersed in the lesional tissue. As the name implies, this lymphoma is similar in histology to a lobular panniculitis and, in fact, many patients present with a history of previously biopsied panniculitis. In addition, there is some clinical and histologic overlap with lupus panniculitis and many patients with SPTL will present with or develop evidence of concomitant systemic lupus erythematosus.^{308, 309, 310} By immunohistochemistry, the neoplastic T-cells express $\alpha\beta$ TCR, CD3, CD8, and cytotoxic granule proteins, although CD56 and CD30 are rarely detected.^{304, 306, 307, 311, 312} Historically SPTL had been associated with a very poor prognosis often secondary to an aggressive hemophagocytic syndrome (HPS). The more recent WHO-EORTC classifications divided these cases into SPTL with an $\alpha\beta$ phenotype and CGDTCL based both on immunohistologic features and clinical behavior. SPTL with an $\alpha\beta$ phenotype are CD4⁺, CD8⁺, CD56⁻, and β F1⁺; are limited to the subcutaneous fat; are uncommonly associated with a HPS; and have a favorable prognosis (5-year OS 82%). CGDTCL is generally CD4⁻, CD8⁻, CD56[±], and β F1⁻; tends to involve the epidermis with resulting ulceration; is commonly associated with HPS; and has a dire prognosis (5-year OS 11%).³¹³ Repeat biopsies may be necessary to confirm the diagnosis of SPTL. Once confirmed, early induction of combination chemotherapy with or without radiotherapy may yield remission and prevent the development of HPS.^{314, 315, 316} (For further discussion of SPTL, see Chapter 88.)

Primary cutaneous T-cell neoplasias that do not fit into the other categories of CTCL are diagnosed as primary cutaneous PTCL, unspecified, in the WHO-EORTC classification system. This large category includes three provisional entities that are considered separately here. First, CGDTCL is characterized clinically by disseminated plaques and ulceronecrotic nodules that frequently also involve mucosal sites. The different clinicopathologic presentations may resemble MF, PR, PTCL, unspecified, and SPTL.^{307, 317, 318, 319} Patients presenting with nodules/tumors/plaques localized predominantly to the extremities should alert the clinician to CGDTCL. One series found all 23 of their patients with CGDTCL to have nodules or tumors on the extremities, with less than half exhibiting concurrent truncal lesions.³¹⁹ Most reports suggest that CGDTCL is aggressive and poorly responsive to therapy. Whether these lesions are primary to the mucosa or the skin, the prognosis is universally poor,³²⁰ except in rare cases.³²¹ As mentioned previously, CGDTCL includes subcutaneous lesions previously considered to be $\gamma\delta$ variants of SPTL, which is associated with a potentially very aggressive HPS.^{241, 319} There are reports of a more indolent subcutaneous form of CGDTCL associated with atypical lymphocytic lobular panniculitis³²¹ that may be difficult to distinguish without clinical correlation. Histologically, the neoplastic clone of CGDTCL is a mature, activated $\gamma\delta$ T-cell with a cytotoxic phenotype. The subcutis, dermis, or epidermis may be involved by medium- to large-sized cells with irregular nuclei and clumped chromatin. Basal vacuolar interface change and interface dermatitis is common. The background tissue shows apoptosis and necrosis with occasional angioinvasion. Often, one patient may show different histologic patterns at different sites. In contrast to $\alpha\beta$ ⁺ MF and SS, the neoplastic $\gamma\delta$ ⁺ T-cells are typically negative for both CD4 and CD8, with rare CD8⁺ cases.^{318, 319} Immunohistochemically, these neoplastic $\gamma\delta$ T-cells express CD3, CD2, CD43, and CD45RO.³²² The T-cells also express cytotoxic granule proteins such as TIA-1, perforin, and granzyme B.³⁰⁴ Due to the lack of a reliable antibody that could detect either the γ or δ TCR in formalin-fixed tissue, identifying $\gamma\delta$ T-cells has historically been deduced from the lack of CD4, CD8, and TCR β F1 staining. Recently a protocol using commercially available antibodies directed against epitopes on the γ and δ TCR has been described.³²³

Primary cutaneous aggressive epidermotropic CD8⁺ cytotoxic T-cell lymphoma (PC8TCL) is a second provisional entity in the primary cutaneous PTCL, unspecified, group. As the name implies, this tumor is comprised of epidermotropic CD8⁺ T-cells with an aggressive clinical course.^{324, 325} Patients with this aggressive variant usually present with widespread eruptive ulcerative plaques. Mucosal and genital involvement is common. The disease course is often complicated by spread to the central nervous system, lung, and testis.³²⁴ Of note, the lymph nodes are rarely involved. Histologically, there is a pagetoid pattern or occasionally a linear distribution of T-cells in an atrophic or acanthotic epidermis. Spongiosis may accompany the intraepidermal lymphocytes.³²⁴ Angioinvasion with adnexal destruction are common findings. Immunohistochemically, the neoplastic cells express CD3, CD8, CD45RA, and cytotoxic granule proteins such as perforin, granzyme B, and TIA-1.¹⁹⁴ CD2 and CD5 expression are often lost, but CD7 expression is retained, a pattern that is generally the reverse of what is typically observed in MF.³²⁶ PC8TCL must clinically and histologically be differentiated from CD8 MF, PR, and Type D LyP, all of which tend to follow an indolent course.^{194, 254, 327} Nofal and colleagues have recently proposed diagnostic criteria for PC8TCL that must include these constant features:³²⁴ (1) clinical: a history of onset within weeks to months of an aggressively behaving eruption of widespread papules, plaques, and tumors, that often ulcerate, without any precursor lesions; (2) histopathologic: epidermotropism, often prominent with a nodular or diffuse infiltrates of pleomorphic T-cells; (3) immunohistochemical: CD8⁺, CD4⁻ staining pleomorphic T-cells. PC8TCL

patients have a poor prognosis with a median survival of 32 months.^{324, 326} This is further exemplified by an average 5-year survival of 18% as compared with 88% in the more indolent MF.¹³⁷

The third provisional entity classified as a primary cutaneous PTCL is primary cutaneous CD4⁺ small-/medium-sized pleomorphic T-cell lymphoma. Primary cutaneous CD4⁺ small-/medium-sized pleomorphic T-cell lymphoma typically presents as a solitary plaque or tumor on the trunk or head and neck without preceding erythematous patches or plaques more typical of MF.³²⁸ Uncommonly, the papulonodules, tumors, or deep plaques of primary cutaneous CD4⁺ small-/medium-sized pleomorphic T-cell lymphoma can be multiple.^{328, 329} Histologically, there is a nodular or diffuse infiltrate of small- or medium-sized pleomorphic lymphocytes in the dermis, with minimal or no epidermotropism and without cerebriform nuclei. The infiltrate can extend deeply into the dermis and subcutis and can include histiocytes, plasma cells, and eosinophils. Large atypical lymphocytes should comprise <30% of total cellularity. There have been rare cases with granulomatous features that may be confusing for GSS, yet GSS typically presents with more epidermotropism and shows some cerebriform cells.^{328, 330} The neoplastic T-cells are by definition CD4⁺ and also express CD3 and $\alpha\beta$ TCR, but are negative for CD8, CD30, and cytotoxic proteins, and they can show loss of pan-T-cell markers. Several recent studies have shown that the neoplastic cells express the markers PD-1, CXCL13, and BCL-6 consistent with derivation from follicular T-helper cells.^{331, 332, 333} The prognosis is usually excellent; a 5-year survival rate has been reported as 60% to 80% in several series.^{328, 329, 334}

Other Hematopoietic Neoplasms with Similar Cutaneous Presentations

Other lymphomas and hematopoietic tumors that may involve the skin include HTLV-1⁺ ATL (Fig. 92.13), extranodal NK-/T-cell lymphoma, Hodgkin lymphoma, cutaneous B-cell lymphomas, and leukemia cutis or extramedullary myeloid tumor (EMT) (including granulocytic sarcoma and monoblastic sarcoma). Peripheral T-cell and NK/T-cell lymphomas are discussed in Chapters 88 and 89. Hodgkin lymphoma is discussed in Chapters 91 and 92. Cutaneous B-cell lymphoma, leukemia cutis, and EMTs are discussed in the following section.

P.1966

FIGURE 92.13. HTLV-1 (+) adult T-cell leukemia/lymphoma. Cutaneous involvement by HTLV-1 (+) adult T-cell leukemia/lymphoma showing epidermotropism and formation of a Pautrier microabscess (hematoxylin and eosin, $\times 50$). HTLV-1, human T-cell lymphotropic virus type-I

Primary cutaneous B-cell lymphomas are uncommon (incidence of 3.1 per million person-years), and must be differentiated from secondary cutaneous involvement by systemic B-cell lymphoma and cutaneous lymphoid hyperplasia of B-cell type.⁸³ The primary cutaneous B-cell lymphomas include: primary cutaneous follicle center lymphoma (PCFCL); primary cutaneous marginal zone B-cell lymphoma (PCMZL); primary cutaneous diffuse large B-cell lymphoma (PCLBCL), leg type; and primary cutaneous large B-cell lymphoma, other.^{137, 335} Other systemic B-cell lymphomas may involve the skin, including intravascular large B-cell lymphoma, lymphomatoid granulomatosis, chronic lymphocytic leukemia/small-cell lymphoid neoplasm, mantle cell lymphoma, and Burkitt lymphoma.^{137, 261} Cutaneous B-cell lymphomas usually present as single or multiple violaceous nodules on the head and neck or trunk and tend to infiltrate the deeper portions of the dermis, sparing the epidermis (“bottom-heavy”). PCFCLs are the most common cutaneous B-cell lymphomas. PCFCLs may have a nodular or a nodular and diffuse growth pattern and more frequently have a predominance of large noncleaved cells³³⁶ than their nodal counterparts (Fig. 92.14). The Mann-Berard grading system used for nodal follicular lymphomas is not predictive in PCFCL. In fact, in contrast to the aggressive behavior of nodal large-cell follicular lymphomas, primary cutaneous large-cell follicular lymphomas tend to be localized, follow an indolent course, and can often be managed with local excision, radiation therapy, and more recently rituximab.^{335, 337, 338, 339, 340} However, careful staging must be performed to exclude extracutaneous lymphoma before a case is classified as primary cutaneous B-cell lymphoma. Typically, nodal follicular lymphomas express BCL-2 and are characterized by the chromosomal translocation t(14;18). PCFCLs, on the other hand, rarely show characteristic chromosomal translocations and BCL-2 is uncommonly expressed (Table 92.3).^{341, 342}

FIGURE 92.14. Primary cutaneous follicle center lymphoma. Note the back-to-back nodular pattern. The infiltrate extends from the superficial reticular dermis to the superficial subcutis in a “bottom-heavy” pattern sparing the papillary dermis and epidermis (hematoxylin and eosin, $\times 2$).

PCMZL is an indolent lymphoma characterized clinically by small purple-pink irregular plaques on the trunk, in contrast to PCFCL, in which the violaceous nodules are usually confined to the head and neck.³⁴³ Histologically, PCMZL is characterized by small, monocytoid, or lymphoplasmacytoid B-cells. Rarely, the infiltrate may be predominantly plasmacytic, and in instances where there is no evidence of systemic disease, these lesions are still considered part of the spectrum of PCMZL. The infiltrates range from nodular to diffuse. Reactive germinal centers may serve as foci for the nodular infiltrate of neoplastic marginalzone cells. The neoplastic cells typically express CD20 and CD79 and BCL-2 but are negative for CD5, CD10, and BCL-6, the last two markers helping to distinguish it from PCFCL.^{343, 344} The presence of large clusters of CD123 plasmacytoid DCs has also been proposed as a differentiating feature of PCMZL from the other primary cutaneous B-cell lymphomas.³⁴⁵ The chromosomal translocation t(14;18) (q32;q21) leading to the fusion of IGH and MALT1 genes as well as

the t(3;14) (p14;q32) fusing the IGH and FOXP1 genes have rarely been reported in PCMZLs.³⁴⁶ Similar to diffuse large B-cell lymphoma, a recent study identified aberrant somatic hypermutation in PCMZL, which leads to genomic instability.³⁴⁷

PCLBCL, leg type, typically presents in the elderly (average age of onset, 78 years) with rapidly growing reddish to violaceous nodules and tumors on the lower legs, but they can occur at any cutaneous site.^{348, 349, 350, 351} Histologically, the lesion is composed of immunoblasts and centroblasts without the admixed centrocytes that are more often seen in PCFCL. The infiltrate rarely involves the epidermis but can extend into the deep dermis and subcutaneous tissue. Because PCLBCL has a poor prognosis compared to the more indolent course of PCFCL, it is important to be able to distinguish these two entities.^{348, 349, 350, 351} As noted earlier, PCFCL and also PCLBCL can have a purely diffuse infiltrate with many centroblasts and immunoblasts, yet PCFCL will also contain centrocytes whereas PCLBCL, leg type, will not. By immunohistochemistry, PCFCL expresses CD10 and BCL-6 and only expresses BCL-2 or MUM1/IRF4 in a minority population, whereas PCLBCL diffusely expresses BCL-2, MUM1/IRF4, and IgM, but does not express CD10 and only rarely expresses BCL-6.^{344, 350, 351, 352, 353} Gene chip expression profiling has shown that PCLBCL has an activated B-cell genotype, whereas PCFCL has more of a germinal center B-cell genotype.³⁵⁴ A further study evaluating apoptosis-related genes identified a strong cellular cytotoxic immune response in PCFCL, whereas PCLBCL, leg type, had constitutive activation of the intrinsic mediated apoptosis pathway and downstream inhibition of apoptosis.³⁵⁵

PCLBCL, other, is a WHO-EORTC classification that includes those B-cell lymphomas that do not conform to the PCFCL or PCLBCL, leg type, criteria. This category includes large B-cell lymphoma subtypes such as anaplastic, plasmablastic, T-cell/histiocyte-rich, and intravascular large B-cell lymphoma.^{356, 357, 358, 359, 360, 361, 362} Although these entities can present initially as cutaneous lesions, they often represent cutaneous involvement by a systemic lymphoma. Of note, some cases of intravascular large B-cell lymphoma appear to be confined exclusively to the venules, capillaries, and arterioles of the skin, without systemic involvement.³⁶² These rare cases have a better prognosis (56% 3-year OS vs. 22%) than their systemic counterparts.³⁶² More detailed discussion of the other systemic B-cell lymphomas is in Chapter 88.

P.1967

TABLE 92.3 IMMUNOHISTOCHEMISTRY PATTERN OF THE PRIMARY CUTANEOUS B-CELL LYMPHOMAS (CBCL)

CBCL Type	BCL-2	BCL-6	CD10	CD20	Ig	MUM1/IRF4
PCFCL	- (10% +)	+	+ follicular pattern; - diffuse pattern	+	-	- (10% +)
Secondary FCCL	+	+	+	+	+	-
PCMZL	+	-	-	+	+	+ on associated plasma cells
PCLBL, Leg type	++	rarely	-	+	+IgM	++

FCCL, follicle center cell lymphoma; PCFCL, primary cutaneous follicle center lymphoma; PCLBL, primary cutaneous large B-cell lymphoma; PCMZL, primary cutaneous marginal zone lymphoma.

Leukemia cutis and EMT are cutaneous infiltrates of myeloblasts and immature myeloid precursors that are often difficult to differentiate from cutaneous lymphoma. EMT, also known as granulocytic sarcoma or chloroma, is an extramedullary tumor composed of immature granulocytic precursor cells. The most common sites of presentation are bone, periosteum, soft tissue, lymph node, skin, and, infrequently, small intestine. The tumor may develop during the course of acute myeloid leukemia, chronic myeloid leukemia, or other myelodysplastic disorders.^{363, 364} EMT usually presents as nodules or tumors that are often solitary, whereas leukemia cutis presents with multiple skin lesions with a varied clinical appearance, including papules, nodules, plaques, palpable purpura, or ulcers.³⁶⁴ Histologically, EMT and leukemia cutis tend to infiltrate between collagen bundles and fat spaces in an interstitial pattern (Fig. 92.15). Cytologically, the myeloblasts of EMT and leukemia cutis are medium-sized cells with finely dispersed chromatin, small or inconspicuous nucleoli, and scant cytoplasm. Occasionally, eosinophilic or neutrophilic granules may point to the cells' myeloid lineage. In difficult cases, immunohistochemistry, flow cytometry, and cytochemical stains will usually confirm the diagnosis and exclude lymphoma.³⁶⁵ CD68, CD43, and lysozyme, although not lineage-specific for monocytes or macrophages, have been shown to be the most sensitive markers for detecting myeloid leukemia cutis.^{366, 367} Nearly half of the cases may be

myeloperoxidase negative; however, a recent study looking at 173 skin biopsies of myeloid leukemia cutis demonstrated a 100% diagnostic accuracy utilizing CD68, CD33, and MPO.³⁶⁸ If the patient has systemic leukemia, comparing the immunohistochemical profile of the cutaneous infiltrate with that from the peripheral blood or bone marrow can be helpful. It must be kept in mind, however, that many of the immunophenotypic markers used in defining blastic cells in the blood or bone marrow (CD117 and CD34) are often negative in the cutaneous infiltrates.³⁵³ Myeloperoxidase, Sudan black B, and chloroacetate esterase cytochemical stains can be used to confirm myeloid differentiation if air-dried touch imprints are available.

FIGURE 92.15. Leukemia cutis. Clusters of myeloblasts with fine chromatin and scant cytoplasm infiltrate between collagen bundles in the reticular dermis (hematoxylin and eosin, $\times 250$).

STAGING

In 1979, a staging system for CTCL was proposed by an international panel of experts who devised a tumor-node-metastasis (TNM) system.³⁶⁹ In the original TNM staging system, peripheral blood involvement with $>5\%$ atypical circulating cells was indicated by a separate peripheral blood stage B1 (vs. B0) and did not affect the clinical stage designation. Two large series have shown that blood involvement is more commonly seen in higher-stage disease, with 0% to 12% of patients with plaques only, 16% to 27% of patients with tumors, and $>90\%$ with erythroderma, demonstrating peripheral blood involvement.^{173, 370} More recently, Vonderheid et al. have shown that blood involvement has distinct prognostic implications.³⁷¹

In 2007 the ISCL/EORTC recommended revisions to the MF Cooperative Group classification and staging system for CTCL.¹⁷⁶ These revisions are made to incorporate advances related to tumor cell biology, diagnostic techniques, and prognostic variables pertaining exclusively to MF and SS as opposed to non-MF/SS CTCLs (Table 92.4). Stage I refers to patients with patches and plaques without adenopathy and is divided into stage IA for patients with $<10\%$ body surface area (BSA) involvement (T1) and stage IB for more generalized patches and plaques (T2). Stage II has two unique categories: stage IIA patients have patches/plaques with palpable adenopathy (histology negative), whereas stage IIB patients have tumors (nodules $>1\text{cm}$ in size) with or without palpable adenopathy (histology negative). Patients with erythroderma are placed into stage III with or without palpable adenopathy (histology negative). Stage IV patients have evidence of CTCL beyond the skin. Stage IVA₁ reflects significant blood involvement. Patients with stage IVA₂ have nodal involvement without visceral disease and stage IVB reflects patients with visceral disease. The lymph node staging includes N1 for dermatopathic lymph nodes (NCI grades 0 to 2), N2 for NCI grade 3 lymph nodes, and N3 for NCI grade 4 lymph nodes (Table 92.5). New to the ISCL/EORTC staging system is B2 staging for high blood tumor burden (Table 92.4),

B0 for <5% Sézary cells, and B1 blood stage for >5% Sézary cells when criteria for B2 are not met. For the first time, the blood stage is factored into the clinical stage to create a TNMB matrix. Changes also include the creation of clinical stages IIIA (T4N0-2M0B0), IIIB (T4N0-2M0B1), IVA₁ (T1-4N0-2M0B2), and IVA₂ (T1-4N3M0B0-2).¹⁷⁶

Staging procedures recommended by the international panel in 1979 included lymph node biopsy of a nonpalpable lymph node in patients without adenopathy, and liver and bone marrow biopsies for advanced stages (II, III, IV).³⁷² These procedures may be considered in patients in clinical trials but are rarely helpful in those patients with limited skin disease and no

P.1968

lymphadenopathy.¹⁸² Because invasive tests such as liver biopsy or staging laparotomy have added little diagnostic information for patients with early and advanced-stage disease,^{175, 373, 374} these staging studies are not recommended by the recent consensus conference.¹⁷⁶ Table 92.6 outlines staging procedures for MF/SS adapted from the ISCL/EORTC guidelines.¹⁷⁶ All patients should have a complete physical examination with special attention to skin and lymph nodes. Careful mapping of skin involvement and/or total-body photographs are recommended to document the initial extent of disease at diagnosis and to assess response to treatment.³⁷⁵ Laboratory studies should include serum comprehensive metabolic panel, lactate dehydrogenase, and complete blood count with manual differential. In addition, peripheral blood should be examined for abnormal lymphocytes by either a Sézary cell count (number per microliter) and/or flow cytometry with attention to CD4⁺/CD8⁺ ratio and CD4⁺/CD7⁻ or CD4⁺/CD26⁻ gated populations if indicated. TCR gene rearrangement of peripheral blood is also recommended, including an attempt to correlate a positive finding with any clone in the skin. A recent study showed no significant benefit to performing bone marrow biopsies for staging purposes.¹⁸¹ They may be helpful in working up unexplained hematologic abnormalities.

TABLE 92.4 2007 ISCL/EORTC STAGING OF MYCOSIS FUNGOIDES/SÉZARY SYNDROME

Stage	Clinical-Pathologic Features
T Skin Stage	
T1	Patches/plaques <10% BSA
T2	Patches/plaques >10% BSA
T3	At least one tumor nodule >1 cm in diameter
T4	Confluence of erythema (erythroderma) covering >80% BSA
N Lymph Node Stage	
N0	No clinically abnormal peripheral lymph nodes (pLNs)
N1	Clinically abnormal pLNs with NCI grade 1 or 2 pathology
N2	Clinically abnormal pLNs with NCI grade 3 pathology
N3	Clinically abnormal pLNs with NCI grade 4 pathology
Nx	Clinically abnormal pLNs with no histologic confirmation
M Visceral Stage	
M0	No visceral involvement
M1	Visceral involvement
B Blood Stage	
B0	Sézary cell count ≤5% lymphocytes
B1	Sézary cell count >5% lymphocytes when B2 criteria are not met
B2	T-cell clone in blood + >1,000 Sézary cells/μl, OR 2 of 3: CD4/CD8 ratio >10, or CD4 ⁺ CD7 ⁻ >40% lymphocytes, or CD4 ⁺ CD26 ⁻ >30%

lymphocytes
AND lymphocytes or CD4 or CD3 count must be elevated.

TABLE 92.5 NCI VA GRADING SCHEME FOR LYMPH NODE HISTOLOGY IN CTCL

Grade	Histopathologic Features
LN-1	DL with occasional CTC
LN-2	DL with CTC singly or in small clusters (<6 cells)
LN-3	DL with numerous CTC, singly or in large clusters (>15 cells)
LN-4	Partial or complete effacement by MF/SS ± DL

CTC, cerebriform T-cells; CTCL, cutaneous T-cell lymphoma; DL, dermatopathic lymphadenopathy; LN, lymph node; MF, mycosis fungoides; NCI, National Cancer Institute; SS, Sézary syndrome; VA, Veterans Affairs. Modified from Sausville EA, Eddy JL, Makuch RW, et al. Histopathologic staging at initial diagnosis of mycosis fungoides and the Sézary syndrome. Definition of three distinctive prognostic groups. *Ann Intern Med* 1988;109:372-382.

Imaging

The role of diagnostic imaging in the initial staging of CTCL has been examined by several authors.^{376, 377, 378, 379} Kulin et al. studied the results of gallium citrate Ga-67 scintigraphy, liver-spleen scans, lymphangiography, and computed tomography

(CT) used in the initial staging of 62 CTCL patients (85% with stage I or II disease) and found that none of the results added significantly to the information obtained from physical examination and routinely performed lymph node biopsy (73% of 62).³⁷⁷ In contrast, a study of 63 CTCL patients (78% with stage I or II disease) who had staging body CT scans found positive findings in 18 (29%) patients, one half of whom had clinically unsuspected advanced-stage disease.³⁷⁶ Eight of these 18 patients had biopsies, with 5 of 8 confirming extracutaneous CTCL. Of the 38 patients with stage I disease, however, only 2 had positive findings on CT scan.³⁷⁶ Another retrospective study of 33 CTCL patients (70% with stage I or II disease) who had CT scans found that 3 of the 20 patients with initial clinical stage I disease were staged higher on the basis of CT findings as stage II.³⁷⁸ Subsequent lymph node biopsies confirmed extracutaneous disease in all three patients (stage IVA). In summary, pelvic, abdominal, and thoracic CT scans have a low yield in patients without palpable adenopathy (stage I) and are not necessary for staging these patients. The highest yield of CT scans appears to be in cases of non-MF/SS CTCL (nonepidermotropic, transformed CTCL, ALCL) and stage III disease (erythroderma), in contrast to stage II and IV patients, in whom CT findings often do not change treatment or stage.³⁷⁶ Therefore, staging CT scans of the chest, abdomen, and pelvis are recommended for patients with generalized plaques, erythroderma, tumors, palpable lymph nodes, or blood involvement.¹⁷⁶

TABLE 92.6 RECOMMENDED INITIAL STAGING EVALUATION OF MYCOSIS FUNGOIDES/SÉZARY SYNDROME**Evaluation and Studies****Skin**

Physical exam	Identify primary skin lesion (patches, plaques, tumors, erythroderma) and % BSA involved.
Skin biopsy	Punch biopsy of thickest or oldest skin lesions (>1 skin biopsy)
Immunophenotyping	CD2, CD3, CD4, CD5, CD7, CD8, CD20, CD30.
Molecular genetics	T-cell receptor rearrangement analysis if needed.

Lymph Nodes

Physical exam	Identify abnormal peripheral lymph nodes ≥ 1.5 cm or irregular.
Radiologic tests	CT scans of chest, abdomen, pelvis except in stage IA or limited IB. PET scans may be helpful to identify which LN to biopsy.
LN biopsy	Complete LN biopsy preferred over core LN biopsy or FNA.
Immunophenotyping	CD2, CD3, CD4, CD5, CD7, CD8, CD20, CD30.
Molecular genetics	T-cell receptor rearrangement analysis if needed.

Viscera

Physical exam	Identify abnormal liver, spleen, or other organs.
Radiologic tests	CT scans of chest, abdomen, pelvis except in stage IA or limited IB. PET scans may be helpful to identify visceral abnormalities.
Liver biopsy	Not indicated, unless involvement would change management.
Spleen biopsy	Not indicated, unless involvement would change management.
Bone marrow biopsy	Not indicated, unless abnormalities would change management.
Other biopsies	Not indicated, unless involvement would change management.
Immunophenotyping	CD2, CD3, CD4, CD5, CD7, CD8, CD20, CD30.
Molecular genetics	T-cell receptor rearrangement analysis if needed.

Blood

Chemistries	Comprehensive panel including liver enzymes, lactate dehydrogenase, HTLV-1 serology if indicated.
-------------	---

Blood cells	Complete blood count and manual Sézary cell count/differential.
Immunophenotyping	Flow cytometry for absolute count and %: CD2, CD3, CD4, CD5, CD7, CD8, CD20, CD26 (if available), CD30. Also include CD4/CD8 ratio, CD4 ⁺ CD7 ⁻ , CD4 ⁺ CD26 ⁻ (if available).
Molecular genetics	T-cell receptor rearrangement analysis.

BSA, body surface area; CT, computed tomography; FNA, fine-needle aspiration; HTLV-1, human T-lymphotropic virus-1; LN, lymph node; PET, positron emission tomography.

Revisions to the staging and classification of mycosis fungoides and Sézary syndrome: a proposal of the International Society for Cutaneous Lymphomas (ISCL) and the Cutaneous Lymphoma Task Force of the European Organization of Research and Treatment of Cancer (EORTC). *Blood* 2007;110:1713-1722.

P.1970

Positron emission tomography (PET) may provide an alternative staging and response-assessment tool for patients with CTCL. A recent study evaluated 13 patients with MF and SS at risk for secondary lymph node involvement using integrated PET/CT followed by excisional biopsy of the lymph nodes.³⁸⁰ Two of seven patients with LN4 effaced lymph nodes had nodes <1.5 cm on CT scan and would have been assigned a N0 classification without the use of integrated PET/CT. The intensity of PET activity correlated roughly with lymph node histologic grade but did not reach statistical significance because of the small sample size. Feeney and colleagues recently evaluated the FDG PET/CT findings in patients with a variety of T-cell lymphomas noting a significant difference in the mean maximum standardized uptake value (SUV) in patients with MF with transformation (SUV, 11.3) compared with patients with MF without transformation (SUV, 3.82; $\pi < 0.05$).³⁸¹ Additional studies need to be performed to evaluate the role of CT/PET in the staging of patients with MF/SS.

Lymph Nodes

Although the presence of palpable nodes has prognostic value, lymph node histology is even more important in staging and assessing prognosis, not only at diagnosis but also later in the course of the disease. Enlarged lymph nodes from MF/SS patients either show dermatopathic lymphadenopathy or involvement by MF/SS. Sausville et al. described a system of grading lymph nodes in CTCL patients (NCI VA classification) that correlated well with prognosis: LN1, a few atypical cerebriform T-cells; LN2, dermatopathic lymphadenopathy with small clusters (<6 cells) of atypical cerebriform T-cells; LN3, dermatopathic lymphadenopathy with large clusters (>6 cells) of atypical cerebriform T-cells; and LN4, partial or complete effacement of lymph node architecture.¹⁷³ Although clusters of atypical cerebriform T-cells are present in grades LN2 and LN3, lymph node architecture is preserved. Only LN4 lymph nodes are considered involved with CTCL (histology positive) for purposes of the TNM staging system (Table 92.4). The NCI VA classification has been criticized because of the nonspecificity of grades LN1-3 and because lymph nodes from patients with unrelated diseases can show similar findings, and many consider LN3 lymph nodes to be histologically borderline.^{163, 382}

The ISCL/EORTC consensus staging system for lymph nodes distinguishes stage N3 lymph nodes that show effacement of nodal architecture (grade LN4) from stage N2 lymph nodes that contain clusters of atypical lymphocytes (>6 cells) that do not efface architecture (grade LN3). ISCL/EORTC stage N1 lymph nodes may show dermatopathic lymphadenopathy, or small clusters of atypical lymphocytes (3 to 6 cells) that do not distort nodal architecture (grade LN1-2). In general, there is good correlation between histologic and molecular evaluation of lymph nodes for involvement by MF/SS. Three studies have shown that most histologically negative lymph nodes (LN1-2) do not show T-cell-receptor gene rearrangements, whereas ~90% or more histologically involved LNs (LN4) do show clonal T-cell-receptor gene rearrangements by Southern blot analysis.^{383, 384, 385} All three studies also showed a mixture of clonal and polyclonal populations in histologically borderline cases (LN3 or histologically equivalent to LN3). Although not statistically significant in all studies, histologically borderline cases that have a positive TCR gene rearrangement tend to have a poorer prognosis, similar to cases with histologically involved lymph nodes (LN4).³⁸⁴

Fine-needle aspiration of lymph nodes to assess for involvement by MF/SS has been evaluated in a limited number of patients, with good correlation between cytologic grade of the FNA specimen and histologic classification of the lymph node biopsy.^{382, 386} However, as with other types of lymphomas, there is an inherent risk of sampling only low-grade

involvement and missing a focal area of transformation to a large-cell lymphoma. Therefore, excisional biopsy of peripheral lymph nodes >1.5 cm in diameter is recommended, with preference for the largest lymph node draining the involved skin area or, if available, the lymph node with the highest SUV from PET scan data.¹⁷⁶

Peripheral Blood

The 1979 Committee on Staging and Classification of CTCLs defined peripheral blood involvement by MF/SS as >5% peripheral blood lymphocytes with Sézary cell morphology (Fig. 92.7);³⁷² however, this criterion is not uniformly agreed on. Because Sézary cells can be seen in the peripheral blood of patients with benign dermatitis or erythroderma, investigators have suggested that other criteria be used to define peripheral blood involvement.^{176, 371} The 2007 ISCL/EORTC staging criteria of peripheral blood involvement includes B2 staging for high blood tumor burden and B1 blood stage for low blood tumor burden (>5% Sézary cells) when criteria for B2 are not met. More specifically, B2 is defined as clonal TCR rearrangement in the blood and one or more of the following: (a) absolute Sézary cell count of 1,000 cells/ μ l or more, (b) CD4/CD8 ratio of 10 or more due to an increase in CD3⁺ or CD4⁺ cells by flow cytometry, (c) increase in CD4⁺ cells with an aberrant phenotype: \geq 40% CD4⁺/CD7⁻, or \geq 30% CD4⁺/CD26⁻ as suggested by Vonderheid and Bernengo.³⁸⁷

As discussed earlier, aberrant phenotypes include the absence of T-cell markers such as CD2, CD3, CD5, CD7, and CD26, which are usually expressed on normal T-cells, or co-expression or absence of both CD4 and CD8. A CD4:CD8 ratio of >10:1 or an aberrant phenotype constitutes an abnormal population. Because decreased CD7 expression on T-cells has been seen in patients with benign skin conditions, the ISCL recommends that 40% or more of the CD4⁺ T cells lack CD7 for it to be considered significant.¹⁷⁶ PCR of peripheral blood has been shown to detect a clonal population of T-cells in approximately one third of patients with stage I to II disease and a majority of patients with stage III to IV disease.^{187, 388} In addition, loss of CD26 expression on circulating CD4⁺ T-cells has been reported in most cases of MF and SS.^{199, 200, 389} Therefore, gating of CD4⁺CD26⁻ T-cells may provide a more sensitive way to use flow cytometry to evaluate peripheral blood for involvement by MF/SS.^{29, 38, 235, 390} A recent study of CD27 expression in peripheral blood T-cells showed a significantly higher expression of the CD4⁺CD27⁺CD45RA⁻ central memory T-cell subset in patients with SS as compared to patients with idiopathic erythroderma patients who showed increased CD4⁺CD27⁻CD45RA⁺ effector memory T-cell levels.³⁹¹

Bone Marrow

Studies of bone marrow involvement in MF patients at initial staging found disease in 2% to 22% of patients.¹⁷⁴ Histologic findings in involved marrows include clusters of CD3⁺ atypical lymphocytes with cerebriform nuclei and occasional large dysplastic cells.¹⁷⁴ Bone marrow involvement by MF is more common in higher-stage disease and correlates with a poorer prognosis; however, when other factors such as skin stage and visceral involvement were considered, bone marrow involvement was not shown to be an adverse prognostic factor.³⁹² These findings were supported by a recent study that evaluated the prognostic significance of histologic and molecular evidence of bone marrow involvement at the time of diagnosis. This study also showed a correlation between histologic or molecular bone marrow involvement and clinical stage of disease, but bone marrow involvement failed to be an independent prognostic indicator.¹⁸¹ Therefore, despite being considered in initial staging of non-MF/SS lymphoma patients, routine staging bone marrow biopsies in patients with MF are not currently recommended. The recent ISCL/EORTC consensus conference recommended performing bone marrow biopsies only in patients with B2 blood involvement or unexplained hematologic abnormalities.¹⁷⁶

P.1971

PROGNOSIS

Prognosis correlates with the extent of skin disease and status of the lymph nodes, blood, and visceral involvement. MF behaves in a manner similar to other low-grade or indolent NHLs, with prolonged survival despite recurrent relapses (see Chapter 88). Zackheim et al. assessed relative (observed/expected) long-term survival among the four skin stages. Stage and survival data for 489 patients with CTCL was extracted from a University of California, San Francisco, CTCL registry dated 1957 to 1994 and compared to a control group matched for age, sex, race, and geographic variables. Using the control group to generate expected survival values, researchers found a relative survival at 10 years for each group as follows: 100% for T1, 67% for T2, 40% for T3, and 41% for T4.³⁹³

The TNM staging system has correlated well with prognosis, demonstrating the following 5-year survival rates: 95% for stage I, 76% for stage II, 45% for stage III, and 51% for stage IV.³⁹⁴ Utilizing the newest staging criteria from the

ISCL/EORTC, the 5-year survival rates are similar: 94% for stage IA, 84% for stage IB, 78% for stage IIA, 47% for stage IIB, 47% for stage IIIA, 40% for stage IIIB, 37% for stage IVA₁, 18% for stage IVA₂, and 18% for stage IVB.¹⁸⁹ Data from a retrospective cohort analysis suggest that the long-term (30-year) survival of patients with stage IA (limited patch/plaque) MF is similar to the expected survival of a matched control population.^{389, 393} Therefore, it is unlikely that stage IA MF will affect the life expectancy of afflicted patients.

Kim et al. performed a retrospective cohort analysis of 525 patients with MF/SS at Stanford University from 1958 through 1999.³⁸⁹ In the multivariate analysis, patient age, T classification, and the presence of extracutaneous disease were the most important independent factors. The risk for disease progression to a more advanced TNM or B classification, worse clinical stage, the development of extracutaneous disease, or death due to MF correlated with the severity of the initial T classification. None of the patients had T1 disease when their extracutaneous disease was detected.³⁸⁹

Using histology to differentiate between patch and plaque predominance within stage T2, one study found plaque predominance to influence relative survival negatively.³⁹⁵ A retrospective analysis by Sausville et al. of 152 consecutively staged patients at the NCI identified skin stage (T3, T4 vs. T1, T2) and visceral involvement as the most significant independent predictors of survival with palpable adenopathy and lymph node histopathology classification showing marginal significance using multivariate analysis.¹⁷³ Three prognostic groups were identified, with the most favorable, low-risk group having limited skin disease without visceral or blood involvement (TNM stages IA, IB, IIA) and the least favorable, high-risk group demonstrating effaced lymph nodes (NCI VA LN4, TNM stage IVA) or visceral involvement (TNM stage IVB).^{173, 396} The intermediate-risk group included all other patients (TNM stages IIB, III) and stage IVA patients with grade LN3 lymph node histopathology. Several reports suggest that patients with dermatopathic or early lymph node involvement with TCR gene rearrangement have a worse prognosis than similar patients without evidence of gene rearrangement.^{171, 383, 384, 397}

A study of 57 patients demonstrated serum LDH to reflect tumor burden in erythrodermic CTCL, with levels being inversely related to hematologic stage and survival.³⁹⁸ This same study used a univariate model, which found lymph node stage and hematologic stage to predict survival. Upon multivariate assessment, however, only lymph node stage served as an important prognostic indicator of survival.

A more recent study that retrospectively analyzed 1,502 MF/SS patients with the revised ISCL/EORTC staging for CTCL found a significant difference in survival between those with patch-only disease (T1a/T2a) versus patch and plaque disease (T1b/T2b).¹⁸⁹ Multivariate analysis revealed that advanced T stage, the presence of a peripheral blood tumor clone without Sézary cells (B0b), increased LDH, and folliculotropic MF were associated with both decreased survival and increased risk of disease progression.¹⁸⁹

The same analysis showed that large-cell transformation was predictive only of increased risk of disease progression, and male sex, increasing age, and poikilodermatous MF were associated with decreased survival.¹⁸⁹ In a retrospective analysis of 100 patients with transformed MF, Benner et al. identified decreased overall and disease-specific survival in those with folliculotropic MF and those lacking CD30.¹⁶⁶ They developed a "prognostic index" for those with transformed MF based upon the following four negative prognostic factors: CD30 negativity, generalized skin lesions, extracutaneous transformation, and folliculotropic MF. There was a significant decrease in survival in those with 2+ negative prognostic factors versus those with 0 to 1.¹⁶⁶

Patients with SS have a relatively poor prognosis, with a median survival of ~3 to 4 years.^{136, 389, 399} In a series of 29 patients with SS, features linked with a bad prognosis included fast evolution of the disease (from symptoms onset up to diagnosis) ($p = 0.0274$), raised levels of serum lactate dehydrogenase ($p = 0.0379$), and β 2-microglobulin ($p = 0.0151$), the latter being the most important prognostic factor.³⁹⁹ Some of these findings were confirmed in another series of 28 patients with SS in whom the detrimental prognostic value of increasing age and LDH level, and the identification of the EBV genome in the skin, were reported.⁴⁰⁰

The prognosis for patients with extracutaneous disease is poor, with median survivals between 1 and 2.5 years.⁴⁰¹ Virtually all patients with extracutaneous disease die of CTCL, compared to nearly one third of patients with generalized plaques and a majority of patients with tumors or erythroderma without visceral involvement.^{375, 402} Very few patients with limited plaques (T1) actually die of MF, with most deaths due to cardiovascular events or other malignancies.^{375, 389, 393} Overall, illnesses attributed directly to CTCL or indirectly implicated via CTCL-related complications contribute up to a mere 19% of deaths in CTCL patients.³⁹⁴ More recently, Agar et al. found that 26% died due to their cutaneous lymphoma.¹⁸⁹ Overall, the bulk of patients with CTCL do not die from their malignancy.^{401, 403} Second malignancies other than skin cancers include NHL, HD, colon cancer, and lung cancer.⁴⁰⁴ Infection remains the most common cause of death in patients who succumb to CTCL, with *Staphylococcus aureus* and *Pseudomonas aeruginosa* being the most common

pathogens infecting the skin, leading to bacteremia and sepsis.^{402, 403} Visceral involvement with CTCL may lead to organ failure and ultimately death.

THERAPY

The mainstay of treatment of CTCL has been control of the cutaneous manifestations of disease with topical therapies in the hope of preventing spread to extracutaneous sites. However, because of the risk of progression to extracutaneous sites and worsening cutaneous symptoms, systemic agents alone or in combination with topical therapies have been studied to control more advanced disease. Therapy in MF/SS is based on the extent of disease, age, performance status, potential for remission, availability of treatments, efficacy, and treatment toxicity.^{405, 406} Because MF usually behaves as a low-grade or indolent lymphoma, controversial issues have involved the timing, selection, and intensity of systemic therapy. Unfortunately, there are few randomized clinical trials comparing the efficacy of the numerous therapeutic options available for patients with MF/SS. The following discussion summarizes the efficacy and toxicity of each therapy, and relates these parameters to disease stage (Fig. 92.16).

P.1972

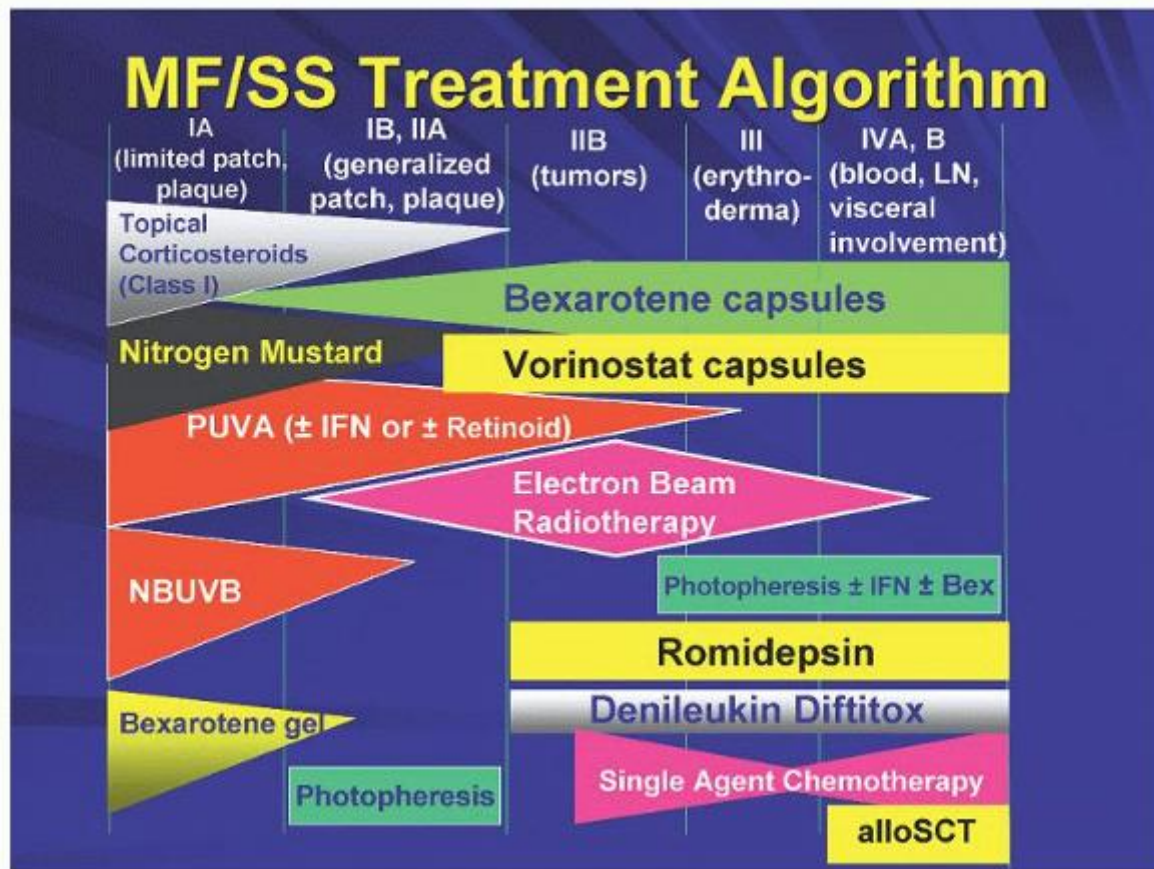

FIGURE 92.16. Cutaneous T-cell lymphoma (CTCL) treatment algorithm. alloSCT, allogeneic stem cell transplant; Bex, bexarotene capsules; IFN, interferon; LN, lymph node; MF/SS, mycosis fungoides/ Sézary syndrome; NBUVB, narrow beam ultraviolet B phototherapy; PUVA, psoralen + ultraviolet A phototherapy. Note that single-agent chemotherapeutic agents with impressive benefit/risk ratios include pegylated liposomal doxorubicin, gemcitabine, and pralatrexate.

Topical Chemotherapy

Mechlorethamine hydrochloride, or nitrogen mustard (HN2), was introduced in 1947 as the first topical agent to demonstrate activity in treating MF⁴⁰⁷ and remains one of the major therapies of choice for early-stage MF. In 1942, HN2 became the first chemotherapy agent to be infused into a human being for the treatment of cancer.⁴⁰⁸ HN2 is an alkylating agent that undergoes rapid degradation to an active ethylenimonium ion that has high antimitotic activity and a brief half-

life.⁴⁰¹ Several studies have suggested that the mode of action of HN2 may involve induction of G₂ arrest,⁴⁰⁹ gene-specific DNA cross-links,^{410, 411} and blockage of transcription factor-binding sites.⁴¹² Some investigators have suggested that immunogenic properties of HN2 demonstrated by its propensity to induce delayed-type hypersensitivity contribute to its antineoplastic activity.⁴¹³ Topical HN2 may be prepared in a variety of ways; initial studies involved dissolving HN2 in water to reach a concentration of 10 to 20 mg/dl,⁴¹⁴ whereas more recently HN2 has been suspended in an emollient such as Aquaphor or a gel at concentrations of 0.01% and 0.02%.^{415, 416} Topical HN2 is usually applied once daily to the entire skin surface with relative sparing of the eyelids, genitalia, rectum, lips, and intertriginous areas. The length of treatment is variable but usually involves daily applications until the patient achieves a complete or significant clearing of skin lesions, followed by a maintenance regimen of daily or every-other-day applications for a period of 6 months to 2 years. No author has advocated a maintenance regimen of indefinite HN2 applications. Recently, Kim et al. found that longer maintenance regimens had no impact on the relapse rate in patients treated with topical HN2.⁴¹⁷ Treatment may be intensified for localized lesions by increasing either the concentration or frequency of application.

The response rate of topical HN2 is related to the morphology (patch/plaque vs. tumor) and extent of disease (T1 vs. T2). Several large series with >100 patients have been reported.^{417, 418, 419} It is difficult to compare overall response rates among these studies because of differences in the clinical stages treated, adjunctive therapies, and staging systems. The percentage of patients with early-stage MF achieving an initial complete response (CR) ranged from 64%⁴¹⁸ to 75%⁴¹⁹ in stage I disease. Including more advanced stages, the complete response ranged from 37% in stage I/IIA disease to 50% in stage I to III disease.⁴¹⁷ The median time to achieve CR is shorter for stage I patients than for those with more advanced stages.^{417, 418} Vonderheid et al. found a durable CR to HN2 lasting more than 8 years occurring in 34 of 324 (10%) patients with early-stage MF,⁴¹⁹ and Kim et al. demonstrated that freedom-from-progression rates at 10 years were 85% and 83% for T1 and T2 patients, respectively.⁴¹⁷ Relapse is common, as Kim et al. observed relapses in 42% of 107 patients after an initial CR, all of which occurred within 5 years, and disease progression to a higher skin stage has been recently reported in 12% and 17% of T1 and T2 patients, respectively.⁴¹⁷ However, among patients who had an initial response to HN2 and relapsed, 67% achieved a CR after receiving HN2 salvage therapy. In summary, HN2 is effective in achieving an initial response in early-stage disease. Relapse occurs frequently but can often be treated with a second course of therapy.

The side effects of topical HN2 include local allergic reactions, xerosis, hyperpigmentation, and secondary cutaneous cancers.⁴¹³ Immediate hypersensitivity reactions manifesting as urticaria are rare but do occur in ~5% of patients using topical HN2 and necessitate discontinuing treatment to avoid a potentially life-threatening anaphylactic reaction.^{413, 420, 421} Delayed-type hypersensitivity reactions (allergic contact dermatitis) manifesting as erythematous eczematous patches occur in up to 64% of patients treated with aqueous HN2^{418, 419, 422} but occur less frequently (<10%) with the ointment-based preparation.⁴¹⁷ Some investigators have suggested that the delayed-type hypersensitivity reaction to topical HN2 may have a beneficial effect in clearing MF lesions⁴¹³ and advocate topical desensitization^{414, 418, 423} rather than discontinuation of the HN2 when delayed-type hypersensitivity reactions occur.⁴¹³ Despite this, discontinuation of the medication can occur in up to 19% of patients.⁴²² Hyperpigmentation of the skin, especially in sites of MF involvement, occur commonly in patients using topical HN2, and patients should be reassured that the hyperpigmentation will resolve spontaneously within several months.⁴¹³

In their study of 331 patients treated with HN2, Vonderheid et al. calculated an 8.6-fold (n = 31, 9%) and 1.8-fold (n = 27, 8%) increased risk for the development of squamous cell carcinoma (SCC) and basal cell carcinoma (BCC) of the skin, respectively, when compared to the general US population.⁴¹⁹ In contrast, Kim et al. found BCC or SCC skin neoplasms in only 8 of 203 (4%) CTCL patients treated initially with HN2.⁴¹⁷ Melanoma occurred in 1 patient in the Kim et al. cohort. This patient had Fitzpatrick skin type 1 and had had a previous BCC.⁴¹⁷ Because HN2 is a known radiomimetic agent, its carcinogenic potential may be amplified with the simultaneous use of other agents, most notably ultraviolet therapy.^{413, 424} To help minimize this risk, patients using HN2 should adhere to strict protection from sun exposure. The risk of environmental contamination from topical HN2 appears to be minimal, as there are no epidemiologic data of increased malignancy in family members of treated patients; however, treatment assistants should wear latex gloves and wash accidentally exposed skin thoroughly.^{425, 426}

Topical carmustine (BCNU), a nitrosourea compound that causes DNA damage through alkylation at an O6 site of guanine and interstrand cross-linkage, is also used to treat early-stage MF, although experience is more limited than with topical HN2.^{427, 428} The use of topical nitrosoureas for the treatment of MF was first reported in 1972.⁴²⁹ Patients mix a 5-ml (10-mg) aliquot of a 0.2% alcoholic stock solution with 60 cc of tap water and apply the solution to only the involved areas of MF.⁴¹³ Applications are repeated daily for no more than 8 to 10 weeks at a time. Zackheim et al. reported a CR in 86% of T1 stage patients and 48% of T2 patients treated with BCNU solution.⁴²⁷ In their follow-up report of 188 early-stage MF patients treated with topical BCNU, 91% of stage T1 patients and 62% of stage T2 patients had not failed treatment after

36 months, and 5-year survivals were 97% and 80%, respectively.⁴¹³ Very recently, a phase 1 clinical trial evaluating the use of topical carmustine and intravenous

P.1973

O6-benzylguanine was reported.⁴²⁸ Given the likelihood of a potentiating effect from the two therapies, O6-benzylguanine and systemic carmustine have been used to treat solid tumors. The therapeutic combination, now utilizing topical carmustine was initiated in 21 patients with refractory early-stage MF (IA-IIA). The minimal toxic effect was seen at the 40-mg dose of carmustine, and there was also a 76% overall clinical response noted.⁴²⁸ Side effects from carmustine include erythema and skin tenderness in a great majority of patients, telangiectasia following less common severe cutaneous reactions, allergic cutaneous reactions (<10%), and mild leukopenia (4%).⁴²⁸

Phototherapy

Psoralen photochemotherapy was introduced in 1974 for refractory psoriasis⁴³⁰ and has been used extensively in the early stages of CTCL. Psoralen and ultraviolet A light therapy (PUVA) involves the ingestion of 8-methoxypsoralen (8-MOP), a photosensitizing compound, which is activated after exposure to ultraviolet A (UVA) light (320- to 400-nm wavelength). More recently, 5-methoxypsoralen has been used as the photosensitizing agent in PUVA, and early studies indicated similar efficacy.⁴³¹ Because of the similar efficacy of narrow-band ultraviolet B (NBUBV) phototherapy as compared to PUVA phototherapy in the treatment of psoriasis, the availability of UVA light boxes in dermatology offices is diminishing. Psoralen intercalates with DNA and, after UVA exposure, forms mono- or bifunctional adducts to pyrimidine bases and cross-links between strands of DNA. In addition to interfering with DNA synthesis and the subsequent death of neoplastic T-cells,⁴³² PUVA may have other effects, including a direct cytotoxic effect, immunomodulation,⁴³³ and the induction of apoptosis in peripheral blood lymphocytes.⁴³⁴

Approximately 1 to 2 hours after ingesting 8-MOP, patients are exposed to increasing doses of UVA light, initially in the range of 1.5 to 3.0 J/cm² based on the patient's skin type (I to VI) determined from skin color and sun sensitivity or, less commonly, based on the direct measurement of a patient's minimal phototoxic dose.⁴³² Treatments are given at a frequency of two to three times per week until complete clearing occurs, followed by a maintenance regimen with increasing intervals between treatments over 2 to 7 months.^{432, 435} Some authors recommend a once-monthly treatment indefinitely to decrease recurrences,⁴³⁵ whereas others discontinue PUVA treatments in stage I patients after the maintenance regimen.⁴³⁶ In a small study, the number of patients in the relapse versus the nonrelapse group receiving maintenance therapy was the same.⁴³⁷ Therefore, the risk of increased cumulative UVA dose in patients treated with maintenance therapy must be balanced against the potential side effects.

In their combined analysis of five recent studies^{435, 436, 438, 439, 440} reflecting the response of 244 CTCL patients to PUVA, Herrmann et al. reported the following complete response rates for each stage: IA, 54/60 (90%); IB, 88/116 (76%); IIA, 7/9 (78%); IIB, 16/27 (59%); III, 11/18 (61%); IVA, 4/10 (40%); IVB, 0/4 (0%).⁴³² Median time to complete response was 3 months in the study of Herrmann et al.⁴³⁵ Patients with early-stage disease readily respond to PUVA, but relapse among complete responders is common, affecting ~31%, 56%, and 71% of stage IA, IB, and IIA patients, respectively.⁴³⁵ In a retrospective review of 104 patients with early-stage MF treated with PUVA, Querfeld et al. reported a 63% CR rate, although 50% relapsed on maintenance PUVA therapy.⁴³⁷ Even higher relapse rates were seen in erythrodermic patients treated with PUVA alone. Tumor-stage (IIB) patients usually require localized radiation therapy or systemic chemotherapy to achieve a significant response and PUVA should play only an adjunctive role. Approximately one third of relapsing stage IA patients will achieve a second long-lasting disease-free remission with re-initiation of PUVA, whereas ~22% of stage IB patients can be expected to do the same.^{432, 435} Hermann et al. reported the same 5- and 10-year survival rates of 89%, 78%, and 100% for stages IA (n = 19), IB (n = 49), and IIA (n = 6) patients, respectively, and a 5-year survival rate of 80% for stage III (n = 6) patients.⁴³⁵ In an attempt to minimize side effects, Weber et al. evaluated 16 patients who received bath PUVA. Patients were treated with 30 ml of 0.5% alcoholic 8-MOP in 150 l of water; all 16 patients achieved a CR.⁴⁴¹

Acute side effects of PUVA include delayed (24 hours) burning and erythema (10%), pruritus (7%), nausea due to psoralen (4%), and reactivation of herpes simplex (2%).⁴³² The photosensitivity due to psoralen may last up to 24 hours, and patients should wear protective clothing and sunscreens to prevent sunburn. Potential complications to long-term PUVA therapy include cataract formation, nonmelanoma skin cancer (8% to 10%), benign solar lentigos (4%), actinic keratoses, keratoacanthomas (3%), and vitiligo (2%).^{432, 435} Because of the potential of PUVA to induce cataracts, patients are instructed to wear ultraviolet light-blocking eyeglasses for 24 hours. BCC and SCC of the skin can be expected to occur in 8% to 10% of patients receiving PUVA after several years, with a clear predominance of SCC, unlike the general population.^{432, 435}

Wide-band ultraviolet B phototherapy (WBUVB) (280- to 320-nm wavelength) has also been used effectively to treat stage I CTCL patients,^{442, 443} but has largely been replaced by NBUVB phototherapy.⁴⁴⁴ Resnik and Vonderheid reported the 15-year follow-up results of 31 patients with MF (68% stage IA, 29% stage IB, one patient stage IIA) treated with alternate-day home ultraviolet B phototherapy using a commercially available cabinet of Westinghouse FS40 lamps for 3 to 12 months beyond the date of initial remission (median = 5 months).⁴⁴³ Overall, 23 of 31 (74%) patients achieved a CR, and available long-term follow-up data from 19 complete responders showed that 7 of 19 had a median disease-free sustained remission of >94 months. Ramsay et al. reported similar results in 37 patients (32 with CTCL, 5 with parapsoriasis en plaques), most of whom (73%) had received home UVB therapy, the rest receiving WBUVB phototherapy in an outpatient setting.⁴⁴² None of the 4 patients with infiltrated plaques responded, whereas 25 of 30 (83%) patients with erythematous patches achieved a CR, with 5 (20%) relapses and a median CR duration of 22 months.⁴⁴² Although burning and erythema may occur, adverse effects from UVB phototherapy are minimal.⁴³² No cutaneous SCC tumors and four BCC tumors were noted in the previous studies.^{442, 443}

More recently, studies have emerged on the effectiveness of NBUVB phototherapy (311 to 312-nm wavelength). NBUVB was first introduced in 1984 with the Philip TL-01 lamp as the optimal wavelength for antipsoriatic activity.⁴⁴⁵ NBUVB treatment has a lower carcinogenic potential and is associated with less erythema than PUVA and broad-band UVB (BBUVB), respectively.^{446, 447, 448} One in vitro study, however, reported cyclobutane pyrimidine dimer (CPD) formation, a sign of carcinogenicity, following a minimum erythema dose by NBUVB was significantly higher than that following 1 MED by WBUVB, whereas the formation of (6-4) photoproducts and 8-oxoG following WBUVB was significantly higher than those following NBUVB exposure. These results suggest that CPD formation is closely related to higher carcinogenic characteristics of NBUVB.⁴⁴⁹ In the initial clinical report, Clark et al. reported a CR in 6 of 8 patients with MF treated with NBUVB.⁴⁵⁰ Since that time, several larger studies have emerged. Gathers et al. evaluated 24 patients with stage IA/IB disease. A total of 13 (54%) achieved a CR, 7 (29%) achieved a PR, and 4 (17%) had no response. In the 4 patients who achieved a CR and discontinued therapy, the average time to relapse was 12.5 weeks.⁴⁵¹ In two comparative studies of NBUVB to PUVA in stage IA/IB disease, no difference in CR rates was observed in patients receiving NBUVB or PUVA.^{452, 453} Pavlotsky et al. conducted a retrospective analysis of patients with stage IA/IB disease receiving NBUVB and WBUVB. CR was seen in 84% and 89% of stage

P.1974

1A patients receiving NBUVB and WBUVB, respectively. The CR dropped to 78% and 44% in patients with stage IB disease. Once maintenance therapy was stopped, 65% were relapse-free at 27 weeks. The study found no difference in relapse rates regardless of use of maintenance therapy.⁴⁵⁴ Other recent small series of patients with early-stage MF treated with NBUVB therapy have been reported, with CR rates of 57% to 100% (for patch-stage disease) and relapse rates of ~50%.^{446, 455, 456, 457} Side effects of NBUVB therapy were minor and did not require discontinuation of therapy. Gathers et al. report erythema in 42% of patients and pruritus in 29% of patients.⁴⁵¹ Permanent tan freckles (lentiginos) and white macules (idiopathic guttate hypomelanosis) have also been reported recently as side effects of NBUVB.^{458, 459, 460} In early MF, there is no statistically significant difference between the response to oral PUVA and NBUVB.⁴⁶¹ NBUVB is a safe and effective treatment for stage IA/IB MF, especially patch-stage disease. In addition, several studies have confirmed the safety of NBUVB in children as opposed to PUVA phototherapy which should be avoided.^{462, 463, 464}

Retinoids

Retinoids are a class of pharmaceuticals whose structure and function resemble vitamin A and its metabolites. Vitamin A and its analogs, the retinoids, have antiproliferative activity, may induce cellular maturation, and probably modulate immune response.⁴⁶⁵ Isotretinoin (13-cis-retinoic acid) and etretinate, a monoaromatic retinoid compound no longer available, have demonstrated similar efficacy in the treatment of CTCL.⁴⁶⁶ Three clinical trials have demonstrated overall objective clinical responses in 66 of 113 patients (58%) treated with isotretinoin or etretinate and a CR in 19%.^{466, 467, 468} Median duration of response, however, has ranged from 3 to >8 months.⁴⁶⁸ Etretinate is no longer available and has largely been replaced with its metabolite, acitretin, because of its superior safety profile. Acitretin may reduce the thick palmoplantar keratoderma of advanced MF or SS.⁴⁶⁵

In 1999 the FDA approved the use of bexarotene capsules, a novel retinoid, for the treatment of CTCL. Unlike isotretinoin and acitretin, which bind to nuclear retinoic acid receptor (RAR), bexarotene binds to and activates the nuclear retinoid X receptor RXR and is therefore referred to as a "rexinoid." RXRs are unique in that they form heterodimers with a vast array of nuclear receptors including the RARs, liver X receptors (LXR), and peroxisome proliferator activator receptors.^{469, 470} The ultimate antiproliferative effect is mediated, in part, by the induction of apoptosis and expression of adhesion molecules.^{471, 472} Two multicenter clinical trials established the optimal dose of 300 mg/m²/day, with an overall response

rate of 45%.^{473, 474} Higher response rates were seen in patients with higher initial doses (up to 650 mg/m²), but side effects of hypertriglyceridemia were dose-limiting. Subsequent pancreatitis occurred in 4 of the 152 patients enrolled in the two clinical trials.^{473, 474} The advanced-stage CTCL trial showed a relapse rate of 36% but an impressive median duration of response of 299 days.⁴⁷³

Talpur et al. recently summarized the experience of treating 70 patients with CTCL using bexarotene capsules as monotherapy and combined with other modalities.⁴⁷⁵ Many of the patients participated in the two pivotal clinical trials. The overall response rate seen in the monotherapy group (n = 54) was 48%, in contrast to the 69% response rate in the combination-therapy group. Bexarotene was safely added to photopheresis (extracorporeal photochemotherapy [ECP]), ECP/IFN, IFN/PUVA, and ECP/IFN/PUVA. Adverse effects were similar between the clinical trials and included hypertriglyceridemia (87%), central hypothyroidism requiring thyroid supplementation (80%),⁴⁷⁶ neutropenia (41%), skin peeling (43%), hypercholesterolemia (20%), and pancreatitis (3%). Of the monotherapy group, 78% (n = 54) and 100% of the combination-therapy group (n = 16) required at least one lipid-lowering agent (LLA). Of the 10 patients with diabetes, 3 had hypertriglyceridemia that could not be controlled with an LLA.⁴⁷⁵ In this series, atorvastatin and fenofibrate were the LLAs of choice. It is interesting that 9 of 10 (90%) patients on bexarotene monotherapy taking two LLAs responded, which was significantly higher than those groups on one or no LLA (p = 0.0001). The explanation for this finding is not clear, but using two LLAs may allow patients to maintain maximum doses of bexarotene.⁴⁷⁵ Vigilance should be exercised when combining atorvastatin and fenofibrate to monitor for rhabdomyolysis. Gemfibrozil and drugs that inhibit the CYP 3A4 enzyme are contraindicated with bexarotene, to avoid elevated drug levels and worsened side effects. Although patients taking bexarotene are at increased risk for elevated triglycerides, elevated LDL, and decreased HDL, there are no reports to date indicating an increased risk of cardiac events. Several animal studies have shown that bexarotene may have a favorable pharmacologic effect on atherosclerosis despite the induction of hypertriglyceridemia via LXR,⁴⁷⁷ due to a beneficial action on intestinal absorption and macrophage efflux,⁴⁷⁸ inhibition of the initial inflammatory response that precedes the atherogenic process by targeting different steps of the mononuclear recruitment cascade,⁴⁶⁹ and protective effects against H2O2-induced apoptosis in H9c2 rat ventricular cells through antioxidant and mitochondria-protective mechanisms.⁴⁷⁹

Bexarotene is also available as a 1% gel. The gel formulation is most helpful in early-stage patients (IA) without prior therapies. In a phase I/II multicenter trial, bexarotene 1% gel was applied to lesional skin with increasing frequency, once daily the first week and twice daily the second week, with a goal of four times daily if tolerated.⁴⁸⁰ Patients achieved an overall response rate of 63% and a clinical CR of 21%. Median projected time to onset of response was 20.1 weeks (range, 4.0 to 86.0 weeks), and the estimated median response duration from the start of therapy was 99 weeks.⁴⁸⁰ The most common side effect was irritation (retinoid "paint splatter" dermatitis) at the sites of application, which might make it difficult to assess response to the drug. The study was followed by a phase III study that included patients with stages IA/B and IIA disease. The overall response rate was 44% according to the Physicians Global Assessment. Similar to the previous study, the median time to response was 142 days (range, 28 to 505 days), and the relapse rate in responding patients was 26%. The most frequent adverse response was irritant dermatitis, which occurred more frequently in patients applying the drug more frequently.⁴⁸¹ Overall, topical bexarotene is a moderately effective and well-tolerated treatment for early-stage MF most often used for refractory patches or thin plaques. The retinoid dermatitis may obscure evaluation of the patches of MF so patients should be instructed to avoid enlarging the original treatment area and to stop applying the gel 1 to 2 weeks before clinical evaluation.

Interferon

IFNs are glycoproteins, naturally occurring or synthesized by recombinant DNA technology. These agents act as immunomodulators with both cytostatic and antiviral activity.⁴⁸² Although three classes, IFN- α , IFN- β , and IFN- γ , are described, the α -IFNs have been most extensively studied in MF and SS, and their efficacy was first reported by Bunn et al. in 1984.⁴⁸³ The exact mechanism of action of IFN in MF and SS is unknown. IFN may act to inhibit IL-4 and IL-5 production by normal and aberrant T-cells in patients with SS, induce myelomonocytic My7 antigen (CD13) in epidermal basal cells,⁴⁸⁴ induce the ds-RNA-dependent enzyme 2'5'-oligoadenylate synthetase leading to cleavage of cellular RNAs, and phosphorylate eIF-2, a peptide elongation initiation factor that blocks protein synthesis.⁴⁸² The pharmacokinetics of IFN delivered via the intramuscular and subcutaneous routes are equivalent, allowing patients the opportunity to self-administer the drug subcutaneously.

P.1975

The phase II National Cancer Institute (NCI) trial reported by Bunn et al. in 1984 used high doses of recombinant IFN- α 2a (50×10^6 U/m² = 50 MU/m² subcutaneously three times per week) in 20 heavily pretreated MF patients and demonstrated an objective response in 45%, including 3 patients (15%) who achieved a CR.^{485, 486} Treatment of MF and SS with IFN- α has been reported in >200 patients and the results have been summarized.⁴⁸² The overall response rate for IFN- α alone was 52%, with a 17% CR among 207 MF and SS patients, summarized by Bunn et al.⁴⁸⁷ Over three quarters of the patients received IFN- α 2a, which is no longer available in the United States, although there were no apparent differences in clinical efficacy between IFN- α 2a and IFN- α 2b (Intron-A, Schering-Plough Research Institute).^{482, 487} However, interpretation of pooled data is complicated by variations in initial dose, target dose, frequency, and length of therapy among study centers.⁴⁸² A trial evaluating PUVA and IFN- α 2a versus PUVA and IFN- α 2b in CTCL patients demonstrated increased myelosuppression and liver toxicity, but also reduced constitutional effects, reduced study drop-out, and increased overall response (89% versus 50%) in the IFN- α 2b arm.⁴⁸⁸ There are conflicting reports regarding the impact of clinical stage on the likelihood of response to systemic IFN- α .^{482, 489, 490} In their study of 51 MF and SS patients, Jumbou et al. found that patients with early disease (stages I and II) demonstrated a higher response rate to IFN- α than those with advanced disease.⁴⁹¹

In an attempt to define the optimal dose of IFN- α in CTCL, a randomized study from Duke and Northwestern Universities was designed comparing low-dose (3 MU/day) to escalating doses (up to 36 MU/day); however, because of slow patient accrual, the proposed study was terminated.⁴⁸⁹ For the 22 patients evaluated, the objective response rate was 64% and was greater, although not statistically significant, for those receiving high doses (11 of 14) than for those receiving low doses (3 of 8), in part because of late responses in unresponsive patients who crossed over into the higher-dose arm.^{487, 489} Of interest, two of the three CR patients were induced by the low-dose regimen, suggesting that patients could achieve a CR with 3 MU daily of IFN- α 2a.^{482, 489} An intermediate daily dose of 18 MU of IFN- α 2a for 3 months followed by the same dose three times a week resulted in an impressive 80% objective response rate (27% CR, 53% PR) in 15 CTCL patients reported by Tura et al.⁴⁹²

Daily dosing of IFN- α 2a for an induction period of several months was used by all of the larger studies of IFN-treated CTCL patients,^{490, 493} whereas many fewer patients have been studied using an initial three times a week schedule.^{494, 495, 496} Nonetheless, some authorities⁴⁸⁷ recommend an optimal dose of 3 MU of IFN- α 2a three times a week, based in part on randomized dose studies in B-cell indolent NHL showing no benefit of higher-dose IFN with respect to response rate or duration.⁴⁹⁷ Maximum daily dosing is dependent on several patient factors but, in general, should not exceed 15 M.⁴⁹⁸ Two to five months is generally necessary to obtain an objective response with IFN, but a complete or maximal response can take much longer.^{482, 490} Treatment is generally continued for ~1 year after a CR to prevent the high potential for relapse when treatment is discontinued before clearing.⁴⁸² Three studies have reported a median duration of response to IFN- α as follows: 6 months,⁴⁸⁵ 8 months,⁴⁹³ and 14 months.⁴⁹⁰ Olsen et al. noted a mean duration of PR while on therapy of 7.9 months (range, 2.1 to 26.5 months) and durations of CR off therapy ranging from 4 to 28 months.⁴⁸² Two NCI phase II trials combined IFN- α 2a with the adenosine analogs DCF and fludarabine to treat CTCL and demonstrated no clear advantage over either drug alone.⁴⁹⁹ The numerous side effects associated with IFN have led to dose reductions in 50% to 86% of patients in some studies.^{489, 492}

Besides producing anti-IFN antibodies, patients with MF can also exhibit decreased responsiveness to IFN through acquired resistance to IFN- α -induced gene expression. Specifically, a resistant CTCL cell line exhibits disrupted signal transduction in a pathway that is normally activated by IFN- α when therapeutic. In particular, STAT1 expression is reduced in these cells, which interrupts the JAK/STAT signaling pathway.⁵⁰⁰

Recombinant IFN- γ and IFN- β have been studied in many fewer CTCL patients, as they appear to offer no major advantage over IFN- α .^{501, 502, 503} IFN- β has reportedly shown little effectiveness in treating CTCL,⁵⁰¹ and IFN- γ has been linked with more intense and frequent side effects than IFN- α .⁴⁸² Interestingly, it has been demonstrated in vitro that the combination of IFN- γ and a Tolllike receptor (TLR) 7/8 agonist increases natural-killer-cell cytotoxic activity against CTCL cell lines.⁵⁰⁴ This combination of the two therapies led to an increase in IL-12 and IFN- α levels which was regulated through the IRF8.⁵⁰⁴

Electron Beam Radiotherapy and Photon Beam Irradiation

Radiation was one of the earliest effective treatments for MF, first reported in 1902.⁵⁰⁵ In 1953, Trump et al. were first to suggest using accelerated electrons for treatment.⁵⁰⁶ Modern total-skin electron beam radiotherapy (TSEBRT) is among the most effective and well-studied therapies for MF.^{200, 507, 508} The total skin surface can be treated by linear accelerator, generated electron beams that are scattered by a penetrable plate at the collimator site.⁵⁰⁹ The usual depth of penetration is <10 mm and is proportional to the energy of the electrons generated, allowing effective dosing to the skin and adnexal structures without internal organ toxicity.⁵⁰⁷ The most common technique uses a dual fixed-angle 6-field or rotation methods with 4- to 9-MeV electrons, with total doses in the range of 2,400 to 3,600 cGy over an 8- to 10-week

period.^{507, 510} With this technique, relatively lower doses are delivered to the scalp, soles, and areas of self-shielding such as the ventral penis, perineum, upper medial thighs, perianal skin, inframammary folds, and folds under any pannus.⁵⁰⁷ Only the eyes are routinely shielded, and unless there is involvement of the head and neck, a scalp shield is used after a dose of 2,500 to 2,600 cGy has been delivered, to decrease the degree of alopecia.⁵⁰⁷

The hands, forearms, ankles, and dorsal penis may receive doses >100%, and shielding all of these structures for part of TSEBRT is not uncommon.⁵⁰⁷ The long-term results of 561 MF patients treated at Stanford University and Hamilton Regional Cancer Centre from the mid-1950s to 1993 with TSEBRT alone were summarized by Jones et al.⁵⁰⁷ Over 80% of stage IA patients can be expected to achieve a CR after TSEBRT, with 40% to 60% remaining relapse-free at 5 years.⁵⁰⁷ Two more recent studies showed similar CR rates, ranging from 80% to 90% for IA and IB disease.^{511, 512} Less encouraging were the relapse-free rates, at 2.5 years for stages IB (35% to 40%), IIA (21% to 37%), IIB (7% to 26%), and III (10% to 23%).⁵⁰⁷ However, most patients who relapse with what is usually minimal disease will re-enter remission with other topical therapies.⁵⁰⁷ In these studies, a new diagnosis of MF, low stage, lack of blood involvement, and intensity of TSEB were independently associated with progression-free survival (PFS).^{507, 511} TSEBRT was less effective in advanced-stage disease (II to IV), with a CR rate of 60%.⁵¹¹ Another report suggests that prognosis for tumor-stage patients with <10% skin involvement treated with TSEBRT is significantly better than for patients with >10% involvement.⁵¹³

Acute cutaneous side effects, peaking 1 to 2 weeks after TSEBRT, include erythema, edema, dry or moist desquamation, tenderness, and rare blister formation that is most severe at sites of disease.^{507, 514} Total-body alopecia and loss of nails will occur in all unshielded patients, but the skin appendages will normally regrow within 6 months.⁵⁰⁷ During the first year, heat intolerance may develop as a result of the suppression of sweat gland production, which may be permanent.^{403, 515} Patients with erythroderma (T4) may experience more severe acute side effects

P.1976

from TSEBRT; however, radiation may be effective in stage III, especially with no blood involvement.⁵¹⁶ When there is blood, lymph node, or visceral involvement in patients with erythroderma, combined-modality therapies, in particular photopheresis, should be explored.^{516, 517} Chronic cutaneous side effects most commonly include xerosis, superficial atrophy, telangiectasia, and dyspigmentation.^{507, 515} The role of TSEBRT in the development of secondary cutaneous malignancies has not been clearly established, as most patients have received a variety of therapies that could contribute to the development of skin cancer.⁵⁰⁷

Several studies have evaluated the response and toxicity of multiple courses of TSEBRT for CTCL, with similar results.^{512, 518, 519, 520} Wilson et al.⁵¹⁸ reported on 14 CTCL patients, 5 receiving three courses of TSEBRT and 9 patients who received two courses. The total median dose was 5,700 cGy (range, 4,500 to 8,200 cGy) with 86% (n = 12) achieving a CR after the second course of therapy (median relapse-free interval, 11.5 months) and 3 of 5 (60%) achieving a CR after a third course (limited follow-up).⁵¹⁸

Because of the toxicities of TSEBRT and the effectiveness of topical therapies, most authorities recommend using TSEBRT for patients with progressive disease, those failing topical therapies, or patients with extensive, deeply infiltrated plaques and tumors.^{511, 521} Because of the high relapse rates after TSEBRT, post-treatment with nitrogen mustard, PUVA, or photopheresis have been studied to maintain remissions.^{511, 517, 522} A recent retrospective study of patients with MF that received TSEBRT (n = 180, T2 and T3 skin stage) from Stanford University found no difference in outcomes between those that received adjunctive topical nitrogen mustard to prevent relapse and those patients that did not.⁵²⁰

Small-field megavoltage photon beam irradiation can be applied as palliation to either deep-seated cutaneous lesions in the tumor phase or for extracutaneous disease.⁵²³ Nearly all cutaneous lesions respond completely, with the risk of relapse (up to 45%) being inversely proportional to the dose, and with recurrence usually developing within 2 years of treatment.

Photopheresis or Extracorporeal Photochemotherapy

Because of the development of resistance to conventional chemotherapy and radiation and the high potential for relapse in advanced-stage patients, new modalities to treat CTCL have been developed. Leukapheresis, which had been used in patients with high Sézary cell counts,⁵²⁴ was the forerunner for a new adaptation of PUVA called extracorporeal photochemotherapy (ECP) or photopheresis. In the original protocol, patients ingested 8-MOP prior to undergoing fractionation of their blood. A leukocyte-enriched blood fraction was then isolated and exposed to UVA in an extracorporeal system, which photoactivated the psoralen.⁵²⁵ The photopheresis procedure currently performed uses liquid 8-MOP injected directly into the collection bag containing the enriched white blood cell fraction to achieve a

concentration of 340 ng/ml within the collection bag. All treated and untreated blood products were then returned to the patient.

In 1987, Edelson et al. were the first to report responses in 27 of 37 patients (64%) with resistant CTCL treated with ECP, including 8 of 10 patients with lymph node involvement and 24 of 29 patients with erythroderma. However, patients with extensive plaques or tumors did not respond as well (3 of 8 patients).⁵²⁵

The immunomodulatory mechanism underlying patient response to ECP is still under debate. However, evidence currently supports the following two simultaneous and synergistic processes occurring during ECP: induction of apoptosis in malignant T-cells, and a mass conversion of blood monocytes to DCs.^{434, 526, 527} Animal studies demonstrate that ECP induces a CD8⁺ T-cell response against expanded clones of pathogenic T-cells,⁵²⁸ as well as an increased synthesis of class I MHC molecules on murine T-cell lymphoma cells.⁵²⁹ Recent in vitro studies using family-specific monoclonal antibodies and magnetic bead technology demonstrated a tumor-specific cytolytic CD8⁺ T-cell response to distinctive Class I surface peptides on CTCL tumor cells of four patients with advanced disease. These results suggest that reduced Class I expression of relevant tumor antigen epitopes may limit the extent of CD8⁺ T-cell-mediated cytotoxicity.⁵³⁰ In support of this hypothesis, investigators have found a favorable response to correlate with the following two scenarios at the onset of ECP: normal or near-normal numbers of CD8⁺ peripheral blood T-cells⁵³¹ and a lower CD4/CD8 ratio in the peripheral blood.⁵³²

Other investigators have found that ECP and in vitro PUVA induce apoptosis in peripheral blood lymphocytes but not in monocytes.⁴³⁴ The apoptosis induction mechanism remains unknown, but may be explained by the observation that a significant amount of tumor necrosis factor- α (TNF- α), which mediates various antitumor effects, is produced by macrophages following ECP.⁵³³ Berger et al. identified monocytes transitioning to immature DCs during overnight incubation in gas-permeable bags of ECP-treated WBCs from five patients with intractable CTCL.⁵³⁴ Both the initial leukapheresis step as well as the subsequent passage through the narrow photoactivation plate initiated and contributed to monocytes-to-DC differentiation.^{534, 535} Edelson proposed that the innumerable encounters of monocytes with the plastic surface of the photoactivation plate activated the cells to begin differentiation to immature DCs.⁵²⁶ An immature DC can engulf an apoptotic T-cell and present tumor antigen via MHC Class I molecules, which stimulates a potent antitumor CD8 T-cell response.^{526, 527, 534, 535, 536}

Treatment of CTCL with ECP has been reported in >400 patients and has been recently summarized.⁵³⁷ The majority of CTCL patients treated with ECP have exhibited generalized erythroderma (skin stage T4), a finding most likely due to the encouraging preliminary study results of Edelson et al.⁵³⁷ A combined analysis of >400 patients treated with ECP and adjunctive therapies showed an overall response rate for all stages of CTCL of 55.7% (244 of 438), with 17.6% (77 of 438) achieving a complete response.⁵³⁷ Efficacy in treating certain clinical stages (IB, IIA, III, and IVA) and skin stages (T2 and T4) of MF and SS is favorable, although randomized trials comparing ECP to other standard therapies are needed. Combined analysis of five North American series^{525, 538, 539, 540, 541, 542} of ECP-treated CTCL patients (N = 157) demonstrates an objective response (>25% improvement of skin lesions) in 67 of 111 stage T4 patients (60%), with ~20% achieving a CR. A long-term follow-up study of the original 29 erythrodermic CTCL patients in the report of Edelson et al.⁵²⁵ demonstrated a median survival of 60 months, which compared favorably to historical controls.⁵³² Many authorities recommend that ECP be considered the first line of treatment for erythrodermic-stage patients.^{543, 544, 545} However, other authorities differ in their opinions regarding the role of ECP in the treatment of CTCL, stating that the data have been inconsistent and the need for prospective randomized studies.^{546, 547, 548}

Preliminary and long-term follow-up studies by Zic et al. on 20 refractory CTCL patients treated with ECP and adjunctive therapies demonstrated an objective response (>50% clearing of skin lesions) in 9 of 14 (64%) early-stage T2 patients, with CR in 4.^{538, 549} Talpur and colleagues reported the results of a prospective study of 19 patients with MF stages IA, IB, and IIA who were treated with photopheresis administered 2 days every 4 weeks for 6 months.⁵⁵⁰ Patients with partial responses by skin weighted assessment continued for an additional 6 months and nonresponders added oral bexarotene and/or IFN- α . The overall response rate was 42% and the authors concluded that ECP is effective for patients with early-stage MF alone or in combination with biologic response modifiers with low toxicity and improved quality of life.⁵⁵⁰ Observations by other investigators question

P.1977

the use of ECP to treat stage IB patients when less expensive and more widely accessible therapies are available.^{551, 552, 553} ECP is well tolerated, with few complications or adverse effects.^{537, 545} Uncommon adverse reactions are usually vascular-related and include the fluid-responsive hypotension and venipuncture-site hematomas.⁵⁴⁹ Rarely, adverse reactions have

included exacerbation of congestive heart failure or arrhythmias,⁵⁴³ superficial thrombophlebitis,⁵⁴³ catheter-related sepsis,⁵⁵⁴ herpes infections,⁵⁴³ disseminated fungal infection,⁵⁴³ and a single episode of hemolysis.⁵³⁸

Several studies have focused on the effects of combining ECP with systemic chemotherapy, PUVA, IFN and other cytokines,^{555, 556, 557, 558} radiation therapy, bexarotene with and without IFN,^{559, 560} and nitrogen mustard. Recently, Raphael and colleagues summarized their experience treating 98 patients with SS with at least 3 months of photopheresis and one or more systemic immunostimulatory agents (IFN- α , oral retinoids, IFN- γ , granulocyte-macrophage colony-stimulating factor).⁵⁶¹ A total of 73 patients (75%) responded (30% CR, 45% PR) and a lower CD4/CD8 ratio, a higher percentage of monocytes, and lower numbers of circulating abnormal T-cells at baseline were the strongest predictive factors for complete response compared with nonresponse.⁵⁶¹ A much smaller cohort of patients with SS (n = 12) showed a lower response rate of 42% and the parameters that correlated best with response were number of Sézary cells, CD4/CD8 ratio, and white blood cell count.⁵⁶² McGirt and colleagues found increased eosinophils and decreased percentages of Sézary cells were associated with a favorable clinical response to ECP, but they were not able to identify the predictors of ECP response within the first 3 months of treatment.⁵⁶³

Systemic Chemotherapy

Single agent and combination chemotherapy are reserved for patients who have advanced stage (IIb-IVb), relapsed or refractory disease or are part of a clinical trial.⁵⁶⁴ Treatments that maintain or augment the immune response, such as IFN, bexarotene, and ECP may be preferable over chemotherapy which is immunosuppressive. Sequential use of single agents should be considered over combinations inasmuch as CTCL is chronic and the clinical goals are control of the disease, amelioration of pruritus, and prevention of skin breakdown; however, combination chemotherapy may be warranted if the disease is progressive, extensive, or in stage IV.^{565, 566} There is no consensus about the optimal combination of agents.⁵⁶⁴

Previously, single agents used for MF/SS were the same as those used in all types of NHL and included oral corticosteroids, alkylating agents, methotrexate, doxorubicin, bleomycin, vinka alkaloids, cisplatin, and etoposide, and resulted in an objective response in a majority of patients with CR rates ranging from 15% to 20%.^{559, 567} However, median relapse-free intervals were usually short and lasted less than 6 months with a range from 3 to 22 months.⁵⁶⁷ Daily or pulse chlorambucil with a steroid has been used to successfully treat SS.^{568, 569} In two retrospective series using weekly low-dose oral methotrexate, Zackheim et al. reported a 33% response rate (12% CR) in T2 skin disease and a 55% response rate (41% CR) in erythrodermic CTCL with time to progression and OS of 15 months and 31 months, respectively.^{570, 571}

Novel chemotherapy agents have been evaluated for therapy of CTCL and include nucleoside analogs, liposomal doxorubicin, histone deacetylase inhibitors, the antifolate pralatrexate, the proteasome inhibitor bortezomib, and a novel alkylating agent, temozolomide. In a phase II trial of gemcitabine, a pyrimidine antimetabolite, in refractory patients, Zinzani et al. reported a 70% ORR, including 10% CR and a median response duration of 8 months.⁵⁷² Gemcitabine was given at a dose of 1,200 mg/m² on days 1, 8, and 15 of a 28-day cycle for a total of three courses. One to two cycles were sufficient to induce tumor reduction in 83% of patients with stage IIB MF. Side effects with gemcitabine included neutropenia (34%), thrombocytopenia (25%), cutaneous hyperpigmentation (17%), and elevated liver enzymes (13%).⁵⁷² Duvic et al. demonstrated a similar response rate (68%) and side-effect profile in another phase II trial, with dosing 1,000 mg/m² on days 1, 8, and 15 for 6 cycles.⁵⁷³ Marchi et al. reported a 78% ORR, including 22% CR, in previously untreated patients.⁵⁷⁴ Isolated cases of cardiotoxicity, including atrial fibrillation, myocardial infarction, and congestive heart failure; and of pulmonary toxicity suggest that patients with CTCL may be prone to unusual, nonhematopoietic side effects of gemcitabine.⁵⁷⁵

The purine nucleoside analogs, 2-deoxycoformycin (DCF or pentostatin), 2 chlorodeoxyadenosine (2CdA or cladribine), and fludarabine monophosphate (FAMP) have activity in CTCL.^{576, 577} DCF inhibits adenosine deaminase, preventing the transformation from adenosine to inosine, which is found in high concentrations of T lymphocytes. Accumulation of metabolites blocks DNA synthesis by inhibiting ribonucleotide reductase. Dosing of DCF has varied among studies and yields an ORR of 33% to 71% with approximately one third of the responses being CR.⁵⁷⁸ The median time to progression ranges from 1.3 to 8.3 months, and there appears to be a better response in SS than in MF.^{578, 579, 580} The most common side effects are granulocytopenia, renal insufficiency, and prolonged CD4 lymphopenia. A combination study of DCF with high-dose IFN resulted in an ORR of 41% with a median PFS of 13.1 months.⁵⁸¹

2CdA is a chlorinated purine analog that is activated by phosphorylation and accumulates in lymphocytes with high deoxycytidine kinase, resulting in DNA strand breaks and cell death. 2-CdA was initially given by continuous infusion over 5 to 7 days and resulted in an ORR of 28% to 41% with a median duration of response of 4 to 5 months in pretreated

patients.^{577, 582, 583} Toxicity included leukopenia (62%) with grade 3 or 4 neutropenia (24%), thrombocytopenia (33%), and infections (62%) of both bacterial and opportunistic types.⁵⁸²

FAMP is activated by phosphorylation and inhibits DNA repair to induce cell death in lymphocytes. The ORR of FAMP as a single agent in relapsed CTCL has been 19% to 29.5%;^{584, 585} however, response rates improved in small series when FAMP was combined with IFN (51%), cyclophosphamide (42%), or ECP (63%).^{499, 585, 586} The median PFS for IFN and ECP were 5.9 months and 13 months, respectively.^{499, 585} Grade 3 or 4 cytopenias occurred in 60% of FAMP+IFN but only 5% of FAMP+ECP.

Forodesine is a selective purine nucleoside phosphorylase inhibitor and causes increased levels of deoxyguanosine and deoxyguanosine triphosphate, which inhibit T-cell proliferation.^{587, 588} In a phase I intravenous trial of 13 patients with CTCL, there were 4 responses (3 CR, 1 PR) and 6 with stable disease (SD). In a phase I/II trial using an oral formulation at 80 mg/m² once daily, the objective response rate was 53.6% (2 CR, 13 PR and 22 SD).⁵⁸⁹ Forodesine was well tolerated with primarily mild (grade 1 or 2) side effects, including nausea, dizziness, headache, peripheral edema, and fatigue.

Altering a drug's vehicle can improve its efficacy and lower its toxicity, as evidenced by the pegylated liposomal preparation of doxorubicin.⁵⁹⁰ In an open clinical trial, 10 patients with relapsing CTCL were treated with pegylated liposomal doxorubicin at a dosage of 20 mg/m² once a month, with an upper limit of 400 mg or 8 infusions.⁵⁹¹ A total of 60% of patients experienced a CR, 10% PR, and 10% SD following this monotherapy. These results were supported by a retrospective review of 34 patients using doses of 20 to 40 mg/m² every 2 to 4 week.⁵⁹² They demonstrated an overall response rate of 88% (44% CR + CRu [patients who achieved a CR defined by clinical criteria only with no biopsy] and 44% PR), an OS of 17.8 months and event-free survival of 12 months. Adverse events were reported in 41% of patients with 17% grade 3/4, including only one with palmar-plantar erythrodysesthesias.

P.1978

Histone deacetylase (HDAC) inhibitors (HDI) were discovered serendipitously to have activity in T-cell lymphomas in phase I trials by Piekarz et al. at the NCI and by O'Connor et al. at Memorial Sloan Kettering Cancer Center (MSKCC).^{593, 594} HDI cause histone hyperacetylation, alter chromatin structure, and modulate gene expression.⁵⁹⁵ They also acetylate nonhistone proteins such as p53 and down-modulate cytokines such as IL-10, both of which contribute to apoptosis of cancer cells.^{595, 596, 597} HDI can be divided into 6 groups based on their chemical structures, and it is unknown whether pan-HDAC inhibition (HDACi) or more selective HDACi is better in treating malignancies.⁵⁹⁸ Two HDI have been approved for therapy in relapsed CTCL, vorinostat (Zolinza, Merck & Co, Whitehouse Station, NJ, suberoylanilide hydroxamic acid [SAHA]), a relatively nonselective inhibitor of HDAC, and romidepsin (Istodax, formerly depsipeptide, Celgene Corp, Summit, NJ), a specific inhibitor of class I HDAC enzymes.⁵⁹⁶

Vorinostat was approved for the treatment of relapsed CTCL in October 2006. The maximum tolerated daily oral doses of vorinostat were determined to be 400 mg. In a phase II trial of 33 heavily treated patients with CTCL (median number of prior systemic therapy = 5), Duvic et al. reported an ORR of 24% (all PR) and an additional 33% had SD, pruritus relief, or both.⁵⁹⁹ In a multicenter phase II trial in 74 patients treated with at least two previous systemic therapies, the ORR was similar at 29.7%.⁶⁰⁰ The median time to progression was 4.9 months and 9.8 months for responders with stage IIB-IVB disease. The adverse effects for the two phase II trials were diarrhea (49% to 60%), fatigue (46% to 78%), nausea (43% to 60%), thrombocytopenia (22% to 54%), and dysgeusia (24% to 51%). Grade 3/4 adverse events were thrombocytopenia (5% to 19%), dehydration (1% to 8%), and pulmonary embolism (5%).^{599, 600} Cardiac complications have been reported including QT prolongation.⁶⁰¹ Vorinostat is being evaluated in combinations with bexarotene, bortezomib, and lenalidomide.^{595, 602}

Romidepsin achieved orphan drug status in 2007 and was approved for the treatment of relapsed CTCL in November 2009.^{603, 604} It is a natural product and a stable prodrug that is converted into its active form by a glutathione-mediated step. Thus, a benefit of romidepsin lies in its ability to counteract glutathione-mediated drug resistance.^{593, 605} In two phase II trials in relapsed CTCL patients (n = 71 and 96), the ORRs were 34% in both, including 6% CR in both and the median durations were 13.7 and 15.4 months.^{606, 607} Both studies used the same dose and schedule derived from the NCI phase I study: 14 mg/m² as a 4-hour infusion once weekly times 3 out of 4 weeks.

Most of the adverse events with romidepsin were mild (grade 1 or 2) and were gastrointestinal symptoms or fatigue. Adverse events (all grades) were nausea (52% to 54%), fatigue (41% to 42%), emesis (19% to 26%), anorexia (20% to 21%), diarrhea (8% to 14%), and ageusia (13% to 19%). Grade 3/4 cytopenias were more pronounced in the NCI study: neutropenia (14%), lymphopenia (21%), thrombocytopenia (6%),⁶⁰⁸ and anemia (6%).⁶⁰⁶ There was concern that HDI,

including romidepsin, would have significant prolongation of the QT interval and risk of arrhythmia, but the studies found minimal risk; however, antiemetics which prolong QT should be limited and the potassium and magnesium levels should be normalized before romidepsin infusion.

The potential to alter the expression of a more focused, disease-related subset of genes and to limit adverse effects has prompted the development of isoform-specific HDAC inhibitors in various stages of study.^{597, 609} Belinostat is an intravenous hydroxamic acid with an ORR of 14% in CTCL and 25% in PTCL.^{610, 611, 612, 613} Panobinostat is a hydroxamic acid with both intravenous and oral formulations and had a 60% ORR in a study of 10 patients with CTCL;⁶¹⁴ however, a larger study of 95 patients reported only 16% ORR.⁶¹⁵ Clinically relevant QTc prolongation is not associated with current dose schedules of panobinostat.⁶¹⁶

Pralatrexate (Foloty; Allos Therapeutics Inc.) is a novel antifolate with a high affinity for the reduced folate carrier-1 which is overexpressed in neoplastic cells. Pralatrexate inhibits dihydrofolate reductase, an enzyme involved in the synthesis of deoxythymidine and the purine DNA nucleotides, and promotes apoptosis. Pralatrexate received approval in September 2009 for relapsed or refractory PTCL at a dose of 30 mg/m² weekly for 6 of 7 weeks.⁶¹⁷ A de-escalation trial identified an effective dose of 15 mg/m² weekly for 3 of 4 weeks in patients with relapsed CTCL.⁶¹⁸ The ORR was 45% (13/29: 1 CR, 12 PR); 73% of responses were continuing at 6 months by Kaplan-Meier estimate. The main toxicities were mild except for mucositis (48% all grades, 17% grade 3). To reduce mucositis, vitamin B12 and folate supplementation are started before therapy with pralatrexate. Ongoing trials are investigating combination therapies that incorporate pralatrexate. Although in vitro studies suggested synergy with sequential gemcitabine, the toxicities, primarily marrow suppression, were excessive.^{619, 620} Pralatrexate is synergistic with bortezomib in both in vitro and in vivo models of T-cell malignancies.⁶²¹

Bortezomib (Velcade; Millennium Pharmaceuticals, Boston, MA); a proteasome inhibitor, down-regulates NF-κB activation and causes apoptosis of CTCL cell lines.⁶²² In a phase II trial of 12 relapsed patients (10 MF, 2 PTCLU with skin involvement), the ORR was 67% (2CR, 6PR) and all responses were durable, lasting from 7 to >14 months.⁶²³ There were no grade 4 toxicities, and the grade 3 toxicities were neutropenia (n = 2), thrombocytopenia (n = 2), and sensory neuropathy (n = 2). Bortezomib is synergistic with other agents. A phase I trial of bortezomib, gemcitabine, and liposomal doxorubicin reported a PR in 6 of 7 relapsed CTCL patients.⁶²⁴ The combination of bortezomib with the HDAC inhibitor, vorinostat, induced apoptosis in CTCL and was associated with an up-regulation of cell cycle regulating proteins p21 and p27, an increased expression of phosphorylated p38, and a suppression of vascular endothelial growth factor by tumor cells.⁶²⁵

Temozolomide, an oral derivative of dacarbazine that causes DNA damage by methylating nucleotide bases, has demonstrated some efficacy in the treatment of CTCL. This alkylating agent produces O6-alkylguanine adducts, which are deactivated by O6-alkylguanine-DNA alkyltransferase (AGT), a DNA repair enzyme often found in tumor cells. Dolan et al. found that patients with MF demonstrated lower than expected levels of AGT in tumor cells, thus emphasizing temozolomide's potential therapeutic efficacy in this specific malignancy.⁶²⁶ In a phase II trial, 9 patients were treated with 150 mg/m² of temozolomide orally for 5 days for the first 4-week cycle and then 200 mg/m² of temozolomide for 5 days for the second and third 4-week cycles. A total response rate of 33% was observed with 2 patients developing grade 3 hematopoietic toxicities.⁶²⁷ In a larger trial of 26 relapsed patients using the 200 mg/m² dosing schedule, the ORR was 27% (2CR, 5 PR); the median disease-free survival (DFS) and OS were 4 and 24 months, respectively.⁶²⁸ The response did not correlate with levels of AGT. The most common grade 1/2 toxicities were gastrointestinal and treatment was stopped in three patients due to grade 3 thrombocytopenia, lymphopenia, and skin reaction.

Combination chemotherapy regimens tend to be reserved for relapsed, aggressive, and advanced-stage MF/SS. Responses occur in the 40% to 89% range but are brief with PFS in the 5 to 9 month range.^{629, 630, 631} In a phase II trial of EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin) in 15 refractory patients with CTCL, including 4 ALCL, the ORR was 80% (4 CR, 8 PR); the median PFS was 8.0 months and the median OS was 13.5 months.⁶³¹ Infectious complications, including staphylococcal bacteremia related to open skin lesions, are a significant problem for patients receiving combination chemotherapy.

P.1979

Combined-modality Therapy

Because there is no single therapy for CTCL that can consistently induce long-lasting remissions, various combinations of therapeutic modalities have been studied. The results of several small studies suggested that better survival could be

achieved by combining TSEBRT with chemotherapy.^{632, 633} Hallahan et al. evaluated TSEBRT followed by combination chemotherapy for 21 patients with tumor-stage CTCL demonstrating an objective response in 19 (90%) with a median duration of remission of 12 months, but all patients relapsed within 25 months.⁶³² Two nonrandomized studies suggested a benefit for early-stage CTCL patients who receive TSEBRT followed by chemotherapy.^{633, 634}

Following TSEBT, subsequent PUVA therapy appears to aid in maintaining remission status in patients with CTCL. A significant benefit in DFS but no statistically significant improvement in OS was observed. However, prospective, randomized data are needed to confirm these results. Incidentally, PUVA has also demonstrated effectiveness as a salvage therapy after TSEBT in early-stage patients with recurrence, with acceptable toxicity.⁶³⁵

The most significant study to evaluate the role of combined-modality therapy was that of Kaye et al. at the NCI who compared TSEBRT and combination chemotherapy (cyclophosphamide, doxorubicin, etoposide, and vincristine) to conservative topical therapy (beginning with topical HN2 followed sequentially, if needed, by PUVA, TSEBRT, and combination chemotherapy) in a randomized trial of 103 patients with MF.⁶³⁶ Although the rate of CR was significantly increased in the combined-modality arm (38% vs. 10%, $p = 0.032$), toxicity was greater and no significant difference was noted between the groups in disease-free or OS (Fig. 9.17). Thus, this study indicated that, similar to other low-grade lymphomas, early aggressive therapy in MF does not have a major impact on survival.

A nonrandomized study from Yale University compared relapse-free survival (RFS) and OS between CTCL patients who achieved a CR following TSEBRT, with subsequent treatment consisting of either adjuvant chemotherapy (cyclophosphamide and doxorubicin; $n = 77$), photopheresis ($n = 11$), or no adjuvant therapy ($n = 43$).⁶³⁷ Adjuvant therapy was also offered to 32 patients who achieved a "good PR" to TSEBRT. The statistical analysis found no appreciable impact on RFS among the patients receiving adjuvant chemotherapy or photopheresis when compared to patients receiving no adjuvant therapy. However, a marginally significant ($p < 0.06$) improvement on OS was demonstrated when stage T3/T4 patients treated with adjuvant photopheresis ($n = 7$) were compared to stage T3/T4 patients receiving no adjuvant therapy ($n = 22$).⁶³⁷

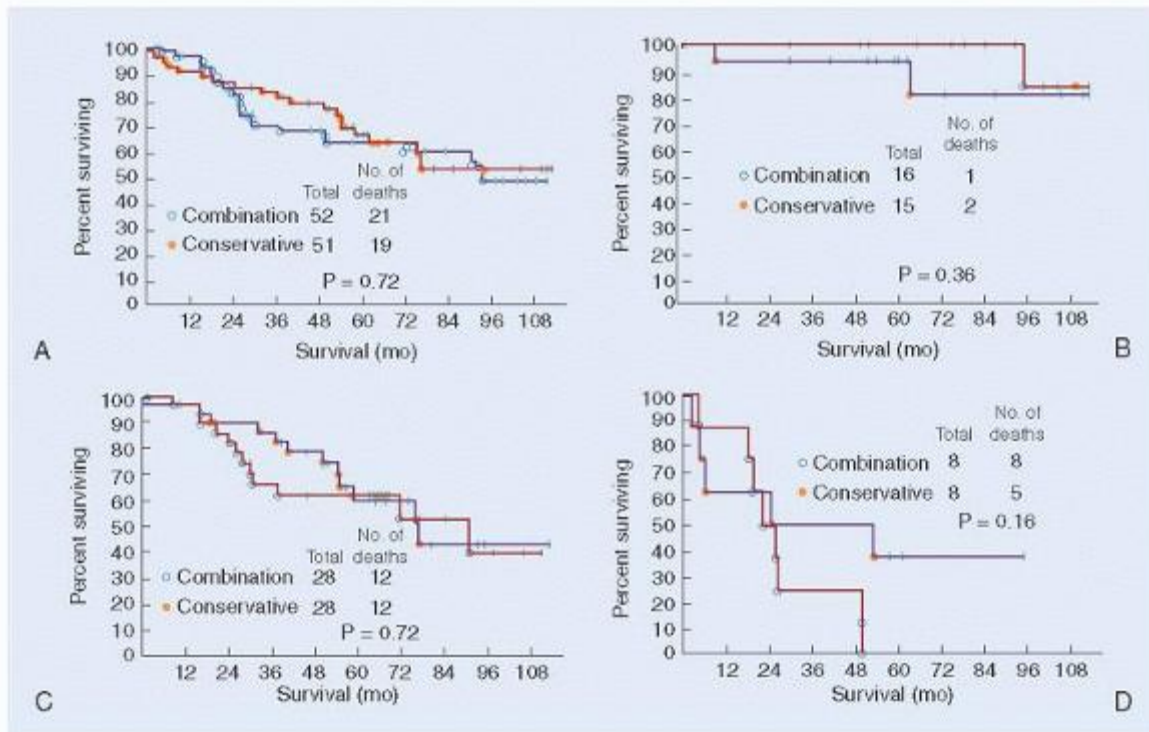

FIGURE 9.17. Survival curves from randomized study at the National Cancer Institute comparing intensive combined therapy. A: Overall survival. B: Survival among low-risk patients (stage IA, IB, or IIB). C: Survival among intermediate-risk patients (stage IIB, III, or IVA). D: Survival among high-risk patients (stage IVB). (From Kaye FJ, et al. A randomized trial comparing combination electron beam radiation and chemotherapy with topical therapy in the initial treatment of mycosis fungoides. *N Engl J Med* 1989;321:1784, with permission.)

Retinoids and IFN- α have been combined to treat CTCL in several open studies.^{638, 639, 640} Combined analysis of the results of 102 reported patients treated with retinoids and IFN- α showed that approximately 60% of patients respond and 10% achieve a CR similar to the response for IFN- α alone.⁴⁸⁷ PUVA therapy has been combined with systemic retinoids to treat CTCL in two studies.⁶⁴¹ demonstrating response rates similar to PUVA alone. Bexarotene has been combined with ECP, PUVA phototherapy, and IFN- α in several patients with potential beneficial effects, as well as no increased toxicity.^{475, 642}

The combination of PUVA and IFN- α is well tolerated and generates impressive complete response rates.^{643, 644, 645} In the combined analysis of the phase I and phase II trials of IFN- α and PUVA for CTCL at Northwestern University, 39 CTCL patients (Stage IB, n = 14; IIA, n = 5; IIB, n = 6; III, n = 8; IVA, n = 5; IVB, n = 1) received intramuscular or subcutaneous IFN- α 2a three times a week at initial intermediate doses (6MU, n = 3; 12MU to 18MU, n = 13; 21MU to 30MU, n = 23) with subsequent dose reduction in 19 patients due to apparent toxicity.⁶⁴³ IFN- α was continued for the planned 2-year period in only 10 of 39 patients (26%) with 8 patients receiving 4 or less months of IFN- α due to tumor progression, toxic effects, or patient request. PUVA was initiated three times per week and tapered to 1 monthly treatment indefinitely for patients achieving a CR. The overall objective response rate was 90% with 24 patients (62%) achieving a pathologically confirmed CR, 15 of whom had early-stage disease (Stage IB/IIA). A total of 19 patients (54%) relapsed demonstrating a median duration of response of 28 months (range, 1 to 64 months). Median survival for the entire cohort was 62 months with mean survivals for stage I/II and stage III/IV patients of 55 and 35 months, respectively.⁶⁴³ Thus, although patients respond impressively, a majority of patients will relapse despite maintenance PUVA and experience nontrivial toxicities at higher doses of IFN. The overall impact on survival of combined PUVA and IFN- α has yet to be determined.

A prospective phase II trial examined escalating doses of IFN- α 2a combined with PUVA in 63 symptomatic patients representing all stages of MF and SS.⁶⁴⁵ A total of 51 patients achieved a CR (74.6%) or PR (6%), with a median response duration of 32 months. The 5-year OS rate was 91% and included 17 patients with advanced disease.⁶⁴⁵

Rupoli et al. completed a multicenter prospective phase II clinical study on 89 patients with early-stage IA to IIA MF treated for 14 months with low-dose IFN- α 2b (6 to 18 MU/wk) and PUVA.⁶⁴⁶ Complete remission (CR) was achieved in 84% and an overall response rate in 98% of cases. Long-term CR was associated with high epidermal CD1a⁺ dendritic-cell density (P = 0.030) and high CD8⁺ lymphoid T-cell density was associated with a lower relapse rate (P = 0.002).⁶⁴⁶

Stadler and colleagues completed a prospective randomized multicenter trial to compare IFN plus PUVA and IFN plus acitretin in stage I and II patients with CTCL (n = 82 evaluable patients).⁶⁴⁷ IFN- α 2a was administered subcutaneously at 9 MU three times weekly and combined with either PUVA at an initial interval of five times weekly, or with acitretin up to 50 mg daily. IFN- α + PUVA (n = 40) was significantly superior to the IFN + acitretin (n = 42), as marked by a 70% complete remission rate in the former, versus a 38.1% complete remission rate in the latter.⁶⁴⁷ A recent report appeared to suggest that elevated levels of the cutaneous T-cell attracting chemokine CTACK/CCL27 in skin and sera after combined PUVA and IFN- α 2b therapy might be correlated with risk of recurrence.²⁶ Reports have emerged of the successful combination of low-dose bexarotene and phototherapy. Narrow-band UVB phototherapy has been combined with oral bexarotene with success in one recent case.⁶⁴⁸

P.1980

The successful combination of low-dose bexarotene with PUVA phototherapy has also been reported.^{475, 642, 649, 650, 651, 652, 653, 654}

Immunotherapy

Over the past decade, researchers have developed immunotherapies to correct abnormalities in the immune response, and cellular growth and differentiation pathways in patients with CTCL. As described in previous sections, recombinant forms of natural cytokines such as IFNs and immunomodulation with photopheresis have shown promise in the treatment of CTCL, with tolerable toxicity profiles and reasonable efficacy. This section focuses on other cytokines and monoclonal antibody therapies for the treatment of CTCL.

Fusion toxin therapy takes advantage of the preferential expression of specific receptors on the surface of malignant cells. Recombinant fusion of a plant or bacterial toxin gene to a specific receptor ligand can guide the toxin gene to the target cell, where it can be internalized via receptor-mediated endocytosis and translocated into a toxic moiety in the cytosol.⁶⁵⁵ The interleukin-2 receptor (IL-2R) is present in low-, medium-, and high-affinity forms. The high-affinity form of IL-2R is a three-subunit peptide, and one of the three subunits contains CD25. The high-affinity IL-2R has been a specific target that is commonly present on cells in ATLL,⁶⁵⁶ and on mature, activated T-cells. Approximately 60% of patients with CTCL will show expression of IL-2R on their mature T-cells, but there is both interpatient and inpatient variability of expression.⁶⁵⁷

DAB486IL2 and DAB389IL2 were the first fusion toxins to be used in clinical trials and are composed of the nucleotide sequence of the enzymatically active and the membrane translocating domains of diphtheria toxin conjugated to the amino acid sequence of human IL-2.^{655, 658, 659} In a phase II trial of DAB486IL2 reported by Foss et al.,⁶⁶⁰ 3 of 14 CTCL patients demonstrated an objective response (1 patient with a PR and 2 patients with slightly less than 50% improvement). The authors observed that IL-2R expression was necessary, but not sufficient, to predict response. DAB389IL2 (denileukin diftitox), a second-generation molecule, replaced DAB486IL2 because it showed a more favorable pharmacokinetic profile.

A pivotal phase III trial evaluated the safety, efficacy, and pharmacokinetics of two dose levels of denileukin diftitox.⁶⁶¹ This randomized, blinded, parallel-grouped study focused on the use of denileukin diftitox in the treatment of 71 patients with persistent or recurrent stage IB to IVA CTCL. For study inclusion, patients had to have detectable CD25 on $\geq 25\%$ of their tissue biopsy lymphocytes via immunoperoxidase assay. Following therapy, 30% of patients experienced an objective response (20% PR and 10% CR), 32% experienced SD, and 3% demonstrated progressive disease. Both 9- and 18- $\mu\text{g}/\text{kg}/\text{day}$ doses were compared, and showed similar tolerability and no evidence of cumulative toxicity. No statistically significant difference was found between the two dosing regimens with respect to response rate and duration of response (median 6.9 months, range 2.7 to 46.1 + months).⁶⁶¹ Upon stratification with respect to disease stage, 18 $\mu\text{g}/\text{kg}/\text{day}$ of denileukin diftitox proved more effective in treating stage IIB patients (36% OR) than the lower dose (23% OR).⁶⁶¹ Denileukin diftitox was approved by the FDA in 1999 for the treatment of patients with persistent or recurrent CTCL whose malignant cells express the CD25 component of the IL-2 receptor. A phase III, placebo-controlled trial, again evaluating the two dosing regimens of 9- and 18- $\mu\text{g}/\text{kg}/\text{day}$ doses was performed with 144, CD25 CTCL patients of any stage.⁶⁶² The overall response rate was higher in the 18- $\mu\text{g}/\text{kg}/\text{day}$ group as compared to the 9- $\mu\text{g}/\text{kg}/\text{day}$ group (49.1% vs. 37.8%) and both were higher than placebo (15.9%).⁶⁶² There was also increased estimated PFS in the 18- $\mu\text{g}/\text{kg}/\text{day}$ group versus the 9 $\mu\text{g}/\text{kg}/\text{day}$ group (32.4 months vs. 26.5 months), but the adverse events were similar for both dosing arms.⁶⁶² Not surprisingly, the placebo group had significantly fewer adverse events and reduced PFS.

The effectiveness of denileukin diftitox in patients with $<20\%$ of their lymphocyte population expressing CD25 has not been determined, but a study of 24 patients treated without prior knowledge of their CD25 status showed a significant difference in patients achieving a partial response when patients with high CD25 expression were compared to patients with intermediate to minimal CD25 expression. In this study, no patient experienced a complete response, and the side-effect profile was similar to that of previous studies.⁶⁶³

Another small phase III study focused on the use of steroid pre-medication to improve the tolerability of denileukin diftitox. Fifteen CTCL patients received prednisone or dexamethasone immediately prior to each dose of denileukin diftitox, which was administered at two dose levels (9 or 18 $\mu\text{g}/\text{kg}/\text{day}$) for 5 consecutive days, every 3 weeks. This cycle was repeated up to eight times. Following therapy, a significant decrease in the incidence of acute hypersensitivity reactions was noted, and a 60% response rate was observed. These findings prompted the authors to conclude that steroid pre-medication not only made denileukin diftitox more tolerable, it also performed this task without compromising clinical response.⁶⁶⁴

Side effects of denileukin diftitox have included reversible elevated hepatic transaminases (61% total, 15% with grade 3 or 4) and flu-like symptoms (fever/chills, nausea/vomiting, and arthralgias/myalgias) seen in 92% of patients in the pivotal trial. A delayed vascular leak syndrome (hypoalbuminemia, edema, and hypotension) was seen in 25% of patients in the same patient population. Increasing hydration may decrease the incidence of vascular leak syndrome, but this theory currently lacks supporting data. Acute hypersensitivity reactions during infusion may show as dyspnea, back pain, chest pain, and hypotension. As noted above, pre-treatment of these patients with steroids make acute hypersensitivity reactions less likely. Bone marrow suppression or secondary immunosuppressive effects have not been noted as significant adverse events related to denileukin diftitox.^{655, 661} Infections were seen in 56% of subjects. However, 80% of these infections were typical in patients with advanced-stage or heavily pretreated CTCL and were thus not attributed to therapy.⁶⁶¹

Alemtuzumab (CAMPATH-1H), a monoclonal antibody directed against CD52, has been studied in the treatment of advanced, low-grade NHLs, including CTCL. This humanized antibody targets T and B lymphocytes, and it appears to have a predilection for circulating cells, relatively sparing those localized within lymph nodes.^{665, 666} Two small phase II studies evaluated the safety and efficacy of alemtuzumab in stage IIB to IV disease. Kennedy et al. reported a 38% overall response rate, and Lundin reported a 55% overall response rate. Both studies used 30 mg twice weekly dosing. The time to progression and the time to treatment failure were short in both studies, at <4 and 12 months, respectively.^{667, 668} A more recent open-label trial from Querfeld et al. treated 19 erythrodermic CTCL patients with escalating IV doses of alemtuzumab up to a maximum of 30 mg, three times weekly, for 4 weeks, followed by 8 weeks of subcutaneous

administration.⁶⁶⁹ The overall response rate was 84%, with 47% having a complete response. Similar to previous studies, the median PFS was 6 months. Significant side effects occurred, including grade 3 to 4 cytopenias and severe infections.⁶⁶⁹ There are also reports of cardiac toxicity in several patients that resolved with the discontinuation of treatment,⁶⁷⁰ however, Lundin et al. did not experience any adverse cardiac events in their study patients.⁶⁷¹ The side-effect profile for CAMPATH-1H includes significant neutropenia with subsequent increased susceptibility to opportunistic infections and bacterial septicemia, thus limiting its utility in the treatment of advanced-stage patients with compromised immune systems.^{667, 668, 672, 673} Although subcutaneous low-dose alemtuzumab shows promise in the setting of SS, larger clinical trials

P.1981

are needed to clarify the role of alemtuzumab in the treatment of CTCL.^{136, 673, 674, 675, 676}

Another monoclonal antibody that targets CD4 (zanolimumab) has undergone phase II trials in CTCL patients. Kim et al. reported the use of zanolimumab in 47 treatment-refractory CTCL patients.⁶⁷⁷ Seventeen weekly infusions at a dose of either 280, 560, or 980 mg were utilized. An objective response was seen in 15 of the 41 patients (36.6%), but evaluation of the two higher dosing regimens had an objective response of 56% with a median response of 81 weeks.⁶⁷⁷

An antibody to CD30 (SGN30) had minimal activity until it was conjugated to a cytotoxic drug monomethyl auristatin E (MMAE). Brentuximab vedotin (SGN35; Adcetris, Seattle Genetics) is an antibody-drug conjugate that consists of three components: a chimeric immunoglobulin G1 mAb cAC10 specific for human CD30, the microtubule disrupting agent MMAE, and a protease cleavable covalent linker that attaches the antibody to MMAE.⁶⁷⁸ Brentuximab vedotin was approved by the FDA in August 2011 for relapsed patients with Hodgkin lymphoma or systemic ALCL. A phase II trial in 58 patients with relapsed ALCL (72% ALK-negative) reported an objective response in 86% of patients including 57% CR and 29% PR.⁶⁷⁹ The median durations of overall response and CR were 12.6 months and 13.2 months, respectively. Grade 3 or 4 adverse events were neutropenia (21%), thrombocytopenia (14%), and peripheral sensory neuropathy (12%).

CCR4 is expressed on tumor cells from most patients who have ATLL, which is relatively resistant to chemotherapy. KW-0761 is humanized anti-CCR4 monoclonal antibody, which enhances antibody-dependent cellular cytotoxicity. In a phase II trial of 26 patients with relapsed CCR4-positive ATL, the overall response rate was 50%, including 31% CR.⁶⁸⁰ Median PFS and OS were 5.2 and 13.7 months, respectively. Adverse events were manageable in fusion reactions (89%) and skin rashes (63%). Clinical trials are investigating KW-0761 in CTCL.

In addition to monoclonal antibodies, there have been efforts to harness the patients' own immune system to enhance the cytotoxic antitumor response. Utilizing TLRs, and additional cytokines to stimulate NK cells, *in vitro* studies have shown increased cellular death in CTCL lines.⁵⁰⁴ A phase I trial initially evaluated the use of a TLR9 agonist in treatment-refractory CTCL patients (Stage IB-IVA), using a dose escalation ranging from 0.08 to 0.36 mg/kg in 24 weekly subcutaneous injections.⁶⁸¹ Common side effects included rigors, cytopenias, and pyrexia, among others. Although the trial was not designed to evaluate for efficacy, they did identify a 32% overall response rate, of which most lasted for the duration of the study (24 weeks).⁶⁸¹ More recently, a phase I/II study combined an intratumoral injection of a TLR9 agonist with radiation (to enhance tumor immunogenicity) in a cohort of 15 MF patients (stage IA-IVA) who had failed at least one standard therapy.⁶⁸² They again found a 33% overall response rate and the therapy was well tolerated with mild injection site reaction or flu-like symptoms.⁶⁸²

Hematopoietic Stem Cell Transplantation

Inasmuch as patients with advanced CTCL have a poor prognosis with only a small chance of sustained remission, treatments as invasive as hematopoietic stem cell transplantation (HSCT) have been increasingly explored using various donor sources, donor sites, and therapeutic conditioning regimens. See Chapters 102 and 104 for a full discussion of HSCT.

Autologous stem cell transplant (autoSCT) has an advantage over allogeneic SCT (alloSCT) with a lower treatment-related mortality, but has a disadvantage with a higher relapse rate. AutoSCT has been done in a small number of heavily pretreated CTCL patients, but relapses have occurred quickly in the majority of patients.^{683, 684, 685} In a report of six patients, five achieved a CR, but three relapsed within 100 days and two remained in CR at 12 months.⁶⁸³ Using T-depletion and CD34⁺ stem cell selection in nine patients with tumor stage or more advanced MF, Olavarria et al. reported CR in eight patients, but seven relapsed at a median of 7 months (range, 2 to 14 months), one died of sepsis and one remained in CR at 10 months.⁶⁸⁵ Four of the relapsed patients had a less aggressive disease course and responded to conventional therapy. Most experts agree that autoSCT offers little advantage for patients with CTCL due to the high rate of relapse and the increased risk of infectious complications.

In the era of alternative donors and reduced intensity conditioning (RIC), alloSCT is more readily available, but it remains controversial in CTCL due to the indolent course, an increasing number of novel therapies, and the risk and expense of alloSCT. An advantage of alloSCT is an apparent graft-versus-tumor effect. Molina et al. obtained a CR in all eight patients receiving alloSCT (4 matched related donor [MRD] and 4 matched unrelated donor [MUD]).⁶⁸⁶ The clonal T-cell population originally found in six patients became undetectable within 60 days post-SCT and had not recurred within a mean follow-up of 56 months. One patient died of respiratory syncytial viral pneumonia at day +34, and a second patient expired from graft-versus-host disease at 16 months. Six patients remained in remission at a median of 53 months (range, 33 to 108 months).

European investigators, retrospectively, analyzed 60 patients (36 MF, 24 SS; median age = 46.5 years [range, 22 to 66 years]) who underwent alloSCT (45 MRD; 15 MUD); 44 received RIC regimens, and 25 underwent T-cell depletion.⁶⁸⁷ The PFS was 42% and 34% and the OS was 66% and 53% at 1 and 3 years, respectively. Nonrelapse mortality was 20% at 1 year. A total of 26 patients relapsed (REL) at a median of 3.8 months (range, 1 to 37 months) and the incidence of relapse was 47% at 3 years. There were 17 REL patients who received donor lymphocyte infusions (DLI) and 10 achieved either a CR (8; 47%) or PR (2; 12%). RIC and MRD SCT had better survival than myeloablative and MUD SCT, respectively.⁶⁸⁷

Duvic et al. reported the MD Anderson experience in 19 patients with advanced CTCL (median age = 50 years; range, 21 to 63 years) who received total skin EBRT prior to a RIC alloSCT (12 MRD; 7 MUD).⁶⁸⁸ Of 18 evaluable patients 7 experienced relapse or progression in the skin at a median of 50 days (range; 28 to 718 days). Of 8 that experienced relapse in the skin, 5 regained CR with reduced immunosuppression of DLI. Two-year PFS was 53% and OS was 79%. Of the 19 patients 11 (58%) were in CR at a median follow-up of 1.7 years (range, 0.8 to 7.9 years).

More studies are required to define the role of SCT in the treatment of advanced CTCL. An expanding donor pool, including umbilical cord and mismatched family; the decreased mortality of RIC, and improvements in supportive care are increasing the applicability of alloSCT for hematologic cancers. Based on preliminary findings in a limited number of patients, alloSCT warrants further study in CTCL.

SUMMARY AND FUTURE INVESTIGATIONS

Molecular studies are unraveling the complex interactions of cytokines, adhesion molecules, and the immune system responsible for the pathogenesis of CTCL and are continuing to provide insight for novel approaches to treatment. As with other indolent lymphomas, an array of therapies can produce responses in CTCL, but are generally not curative. In contrast to other lymphomas, however, is the high degree of efficacy of topical treatments (NM, TSEBRT, NBUVB, and PUVA phototherapies) for patients with early-stage MF/SS. Because CTCL is not cured by systemic chemotherapy, initial management of early-stage disease should include skin-directed therapy.⁶⁸⁹ Ongoing clinical trials may define the roles of systemic therapy in managing more advanced-stage patients including combinations of skin-directed therapies, chemotherapy

Chapter 93

Hodgkin Lymphoma in Adults

David S. Morgan

Kristie A. Blum

Hodgkin lymphoma (HL) is a lymphoproliferative malignancy that accounts for only 1% of newly diagnosed malignancies in the United States; however, the disease's importance to the field of medical oncology is out of proportion to its clinical incidence. From an historical point of view, HL was the first cancer in which the curative potential of combination chemotherapy was demonstrated. Second, because affected patients are often young, there is a great potential for adding years of productive life by giving curative therapy. Third, because patients with HL are often cured, HL serves as a clinical laboratory for investigating the late effects of cancer therapy.

HL usually presents as solitary or generalized lymphadenopathy and most commonly occurs in young adults, although persons in any age group may be affected. The disease tends to spread in a contiguous fashion, and most patients present with disease limited to the lymph nodes or to the lymph nodes and spleen. Even patients with advanced disease have a reasonable chance of cure. Overall, cure can be achieved in approximately 80% of patients with HL. Treatment of limited disease often incorporates radiation therapy and combination chemotherapy, whereas treatment of advanced disease is generally limited to combination chemotherapy alone.

The evaluation of data and conclusions from clinical trials in HL requires certain caveats. The first issue is that salvage therapy for relapsed HL patients has a relatively high rate of cure. This fortunate fact can complicate the interpretation of trials of initial therapy for HL. In contrast to the situation in many other areas of oncology where salvage therapies

generally do not lead to cures, progression-free survival (PFS) in HL trials must not be used as a surrogate marker for overall survival (OS). Conversely, because late complications, including malignancy, can compromise the long-term efficacy of treatments that appear superior in the short run, therapies that produce superior PFS at 5 years may not be associated with superior OS at 15 years. In some situations, then, treatment plans with built-in contingencies may be appropriate. As an example, consider two hypothetical treatment strategies: treatment A is moderately effective but nontoxic, and failures can be salvaged effectively with treatment X. The alternate treatment, B, is very effective but failures are only rarely salvaged with treatment Y. The combination of the (less-effective) treatment A and salvage with X if needed may lead to superior long-term results as opposed to starting out with the (more effective) treatment B and salvage with treatment Y. This may be especially true if one considers short- and long-term toxicities of treatment. When considering initial therapy for patients with HL, one must realize that valid alternatives exist in addition to what may be considered the “best therapy” based on short-term observations, and that individualized approaches may be appropriate to accommodate individual risks, especially for long-term toxicity.¹

EARLY HISTORY

In 1832, Thomas Hodgkin presented a paper entitled, “On Some Morbid Appearances of the Absorbent Glands and Spleen.”² His report was an autopsy description of seven patients, and the major original thesis presented in the paper was that the entity he was describing was a primary process involving the lymph glands and spleen rather than a reactive inflammatory condition. In 1856, Samuel Wilks published a series of cases involving enlargement of the lymph glands³ and noted Hodgkin's original description. In 1865, Wilks wrote, “Cases of Enlargement of the Lymphatic Glands and Spleen (or Hodgkin's Disease) with Remarks,” updating and extending his findings.⁴ Thus, Thomas Hodgkin's name became linked to the disorder. Of note, some of the cases included in Hodgkin's initial report were cases of tuberculous lymphadenopathy and non-Hodgkin lymphoma.

After these gross pathologic descriptions, the first microscopic description of HL was reported by Langhans⁵ in 1872. This report was followed by independent reports by Sternberg in 1898⁶ and by Reed in 1902⁷ describing the characteristic giant cells that came to be known as (RS) cells. At the time of these early reports, all comments regarding the cause of HL were purely speculative. Not surprisingly, these early authors were divided over whether HL represented an infectious disease, an inflammatory disorder, or a malignancy involving the lymph glands.

EPIDEMIOLOGY AND ETIOLOGY

It is estimated that 9,060 new cases of HL will be diagnosed in 2012.⁸ The male-to-female ratio is 1.2:1.⁸ In most economically developed countries, there is a bimodal age distribution, with one peak occurring in the third decade of life and the second, smaller, peak occurring after age 50 years.⁹ The occurrence of HL in patients between the ages of 15 and 39 has been positively associated with increased maternal education, decreased numbers of siblings and playmates, and single-family dwellings in childhood.¹⁰ In less economically developed countries, HL is less common but affects children, most of whom are boys; mixed cellularity HL and lymphocyte-depleted HL are more commonly seen.¹¹ These data have been interpreted as supporting the hypothesis that HL is caused by an infectious agent, and it has been postulated that malignancy is more likely to occur when exposure to the agent in question is delayed until late adolescence or early adulthood.^{11, 12, 13, 14}

Epstein-Barr virus (EBV) has been proposed as contributing to the development of some cases of HL, and the circumstantial evidence is considerable. The incidence of HL is elevated among patients with a history of EBV infection.^{15, 16, 17} EBV has been associated with other related malignancies, including Burkitt lymphoma and lymphomas developing in immunocompromised patients. Using modern molecular biology techniques, EBV genome fragments have been found in RS cells from approximately 40% of patients with HL,^{18, 19, 20} more commonly in cases of mixed cellularity HL.²³ In addition, the EBV DNA associated with RS cells in HL has been shown to be monoclonal, establishing that EBV preceded the development of HL.^{18, 19} Interestingly, prognosis appears to be better in HL that is EBV-positive, as compared to cases that are EBV-negative.^{21, 22, 23}

HL occurring in early childhood or in older adults is more likely to be EBV-associated than are cases of HL occurring in young adults.²⁴ However, in an important 2003 study, 38,555 patients with documented EBV-positive infectious mononucleosis were followed for an extensive period.²⁵ In this selected population, 29 cases of HL developed and 16 (55%) were positive for EBV. The risk of EBV-positive HL was increased by a factor of 4 as compared to patients who never had documented EBV-positive infectious mononucleosis; the median latency for HL after EBV infection was 4.1 years. There was no increase of EBV-negative HL in this population. These data do not prove causality: the data are equally compatible with the theory that EBV predisposes

patients to the development of HL. If there is a causal role for EBV, additional factors must be required for the development of HL.

The idea that HL may represent an uncommon host response to a common agent has received additional support in a study of monozygotic and dizygotic twins. Monozygotic twins, who would be expected to have similar immune responses, had a 99-fold increased risk of being concordant for having HL, supporting a role for genetic susceptibility or abnormal immune response, or both, in the etiology of HL.²⁶ The incidence of HL in patients with the acquired immunodeficiency syndrome or with human immunodeficiency virus infection is elevated over the incidence in the general population (although not to the extent of the increase in the incidence of non-Hodgkin lymphoma), perhaps lending further plausibility to the concept that HL represents a disordered immune response to antigens.^{27, 28} An increased incidence of HL has been noted in recipients of allogeneic bone marrow transplants.²⁹ In addition, a patient has been reported with reversible methotrexate-associated lymphoproliferative disorder that eventually evolved into HL.³⁰

HISTOPATHOLOGY

The diagnosis of HL requires biopsy of an involved lymph node or, rarely, of an involved extranodal site (Chapter 86). It is important to note that inflammatory nodes may be interspersed among nodes harboring HL. In general, a larger node with more abnormal features on imaging is a better target for biopsy than a smaller, perhaps more accessible, node. Inguinal nodes, although generally fairly easily biopsied, are often enlarged from current or past inflammation, and biopsy may be misleading. A fine needle aspiration (FNA) should generally be considered an inferior diagnostic approach and will only rarely yield a firm diagnosis; most diagnoses will require an excisional lymph node biopsy (although occasionally a diagnosis can be made on generous core biopsy). Flow cytometry is noninformative in HL, as the majority of cells in a specimen reflect the inflammatory background, with the malignant RS cells being relatively rare. This fact can occasionally falsely reassure a clinician who gets a flow cytometry result of “reactive” and a nondiagnostic FNA on a patient with unexplained adenopathy; the correct response is to go on to an excisional biopsy. Fortunately for clinicians, concordance between pathologists regarding the diagnosis of HL is high, often exceeding 90%.³¹

HL can be confused with atypical inflammatory reactions that can occur in some patients with infectious mononucleosis³² or in patients receiving phenytoin.³³ Among the lymphomas, HL is sometimes mistaken at the histologic level for anaplastic large cell lymphoma, mediastinal large cell lymphoma, or T-cell-rich B-cell lymphoma. Correct classification can usually be achieved using immunohistochemistry and cytogenetic techniques. Recently identified and listed as a provisional entity in the World Health Organizations classification was:³⁴ “B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classical Hodgkin lymphoma (cHL),” also known as “Grey Zone Lymphoma.”^{35, 36}

Pathologically, HL is distinguished from other lymphomas by the presence of large binucleated or multinucleated cells (RS cells) generally surrounded by a benign reactive response consisting of lymphocytes, histiocytes, granulocytes, eosinophils, and plasma cells. RS cells are large cells with abundant cytoplasm and generally contain two or more nuclei and two or more inclusionlike nucleoli. Molecular evidence (clonal immunoglobulin rearrangements) has shown that the cell of origin for RS cells is a germinal center or post-germinal center B-cell. The RS cell does not express the common B-cell transcription factors and thus its B-cell phenotype (including the B-cell receptor) because of down-regulation and because of epigenetic silencing.^{37, 38} Commonly such nonfunctional B-cells would undergo apoptosis, and activation of several antiapoptotic pathways (including the nuclear factor [NF]- κ B pathway)³⁹ has been proposed as mechanisms for the molecular pathogenesis of HL. The molecular mechanisms involved in the development of HL have been the subject of several reviews,^{40, 41} and further discussion of these intracellular pathways is beyond the scope of this clinical chapter.

Variant forms of RS cells exist, especially in the nodular sclerosis subtype of HL and the nodular form of lymphocyte-predominant HL (LPHL). RS cells are not specific for HL and have been noted in cases of infectious mononucleosis⁴² and other malignancies including lymphoma, carcinomas, and sarcomas.⁴³ Therefore, RS cells are not sufficient to establish the diagnosis of HL because that diagnosis depends on the presence of both the characteristic RS cells and the characteristic cellular environment in which the RS cells are found. In addition to the histologic criteria, immunostaining, the RS cells or variants in classical HL should be positive for CD15 (85%) and CD30 (100%), and negative for most pan-B-cell and pan-T-cell antigens. If a B-cell antigen is present, it is usually CD20 and it is variable in intensity.^{44, 45}

The subclassification of HL depends in large part on the ratio of neoplastic to reactive cells and their orientation. The current subtype classification stems from the classification of Lukes and Butler,⁴⁶ as modified at the Rye Conference in 1966.⁴⁷ These investigators described RS cell and their variants (Fig. 86.16), one of which they called the L and H cell, (“lymphocytic and histiocytic” because of the associated background) seen primarily in the LPHL. Later these multilobated

cells were referred to as “popcorn cells.”⁴⁸ It was later shown through immunohistochemistry studies that classic RS cells and L and H cells were distinct, with RS cells or variants of other subtypes of HL being CD30 and usually CD15 positive and negative for pan-B-cell markers (Fig. 86.17), and with the L and H cells of LPHL being CD20 pos and CD30 and CD15 negative (Fig. 86.23). Likewise it is now clear on clinical, immunophenotyping, and gene expression profiling grounds that LPHL is a clinicopathologic entity distinct from the other types of HL.^{49, 50, 51, 52} Thus the current WHO classification³⁴ distinguishes cHL from LPHL.

cHL is comprised of four subtypes: nodular sclerosis HL, mixed cellularity HL, lymphocyte-rich classical HL (LRCHL), and lymphocyte-depleted HL. In the past, the subtype of HL was felt to give the clinician valuable prognostic information; however, it is now recognized that the histologic subtype co-varies with stage, and that much of the reported differences in prognosis previously attributed to histologic subtypes may be attributed to stage. When patients are stratified by stage and receive equivalent therapy, differences attributable to histologic subtype are either trivial or nonexistent.^{53, 54, 55, 56}

The incidence of HL cases with respect to histologic subtype is shown in Table 93.1. The data are taken from one large tumor registry⁵⁷ and three large series of referred patients,^{31, 58, 59} and are subject to biases in the selection process. However, the general agreement among the series suggests that this is a fairly reliable estimate regarding the relative incidence of the subtypes of HL.

In nodular sclerosis HL, nodularity is produced by dense collagenous bands that divide the cellular portion of the node into sections (Fig. 93.1). In this type of HL, RS cell variants, rather than classic RS cells, are commonly found in the cellular areas. These lacunar RS cells have faintly stained cytoplasm and appear separated from adjacent cells by empty space, an artifact of formalin fixation (Figs. 93.2 and 86.20). Nodular sclerosis HL is the most distinctive form of HL. Although the other subtypes of HL may be regarded as a histologic continuum and transformation among other subtypes is commonly seen, when patients with the nodular sclerosis subtype undergo repeat biopsies, the nodular sclerosis form of HL is confirmed in more than 90% of cases.⁶⁰ This form of HL classically presents as stage I or II disease with cervical and mediastinal involvement in young adults, although more advanced stages of disease are not uncommon (Table 93.2).

P.1986

TABLE 93.1 RELATIVE INCIDENCE OF HISTOPATHOLOGIC SUBTYPES OF HODGKIN LYMPHOMA

Author (Reference)	Lymphocyte Predominant (%)	Nodular Sclerosis (%)	Mixed Cellularity (%)	Lymphocyte Depleted (%)
Dorfman ⁵⁸	7	74	17	2
Jones et al. ³¹	2	65	26	6
Bernhards et al. ⁵⁹	3	74	22	1
Medeiros et al. ⁵⁷	7	63	26	4

Note: Percentages refer to “classified” cases, as some studies contain cases of unclassified Hodgkin disease.

A “syncytial variant” of nodular sclerosis HL has been recognized in which numerous RS cell variants have been observed in sheets and clusters. This variant of HL may be confused with NHL, thymoma, or metastatic cancer.⁶¹

HL of the mixed cellularity pattern is a diffuse lymphoma composed of a mixture of cells including RS cells (Figs. 93.3 and 86.18). Distinguishing mixed cellularity HL from diffuse mixed forms of NHL may be difficult on the basis of histology alone, but should be resolved with modern immunohistochemical stains. This subtype of HL has a greater tendency than nodular sclerosis HL to be advanced at the time of presentation and to be associated with symptomatic disease. Mixed cellularity and nodular sclerosis HL make up the majority of HL cases.

Lymphocyte-depleted HL is composed predominantly of histiocytes and lymphocytes with varying numbers of eosinophils and RS cells (Figs. 93.4 and 86.21). The host reaction is often scant relative to the number of malignant giant cells, and a varying amount of fibrosis is generally present. The disease is the least common type of HL and tends to be advanced at diagnosis (i.e., stage III or IV). Most patients have B symptoms,⁶² retroperitoneal nodal involvement is common, and approximately one half of patients have bone marrow involvement.^{63, 64, 65} Many older case series contain cases that

would now be classified as peripheral T-cell lymphomas⁶⁶ or anaplastic large cell lymphomas.^{67, 68} Therefore the older literature regarding this entirety must be treated cautiously.

FIGURE 93.1. A: Nodular sclerosing Hodgkin lymphoma. Gross appearance of the cut surface of a resected node shows a thickened capsule, white fibrous bands, and yellow parenchymal nodules. B: Nodular sclerosing Hodgkin lymphoma. Low magnification shows a fibrous capsule and bands of sclerosis circumscribing abnormal lymphoid nodules.

LRCHL⁵¹ is characterized by rare RS cells or variants dispersed in a background of predominantly small lymphocytes. The tumor cells have the appearance of classic RS cells as well as the immunophenotype of classic RS cells (CD30⁺, CD15⁺, but CD20 negative) (Figs. 93.5 and 86.19).

LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA

Nodular lymphocyte-predominant HL (NLPHL) is an uncommon subtype of HL, representing about 5% of cases,⁶⁹ with unique pathologic features distinguishing it from classical HL.⁷⁰ The neoplastic cell is a large cell, the LP cell, otherwise known as a popcorn cell due to its single, large, folded or multilobulated nucleus that typically has a smaller nucleus than observed in RS cells (Figs. 93.6 and 86.22). However, unlike the RS cell, these cells are typically CD30 and CD15 negative, with CD19, CD20, CD45, and CD79a positivity (Fig. 86.23). These cells are also PAX-5 and Oct-2 positive. The surrounding background lymphocytes are predominantly small CD20 B-cells, with rare eosinophils, neutrophils, or plasma cells. Surrounding the LP cells, CD4⁺ t-cell rosettes are found and CD21-positive follicular dendritic cells are present, consistent with the germinal center derivation of this malignancy.⁷⁰

Due to the rare occurrence of this malignancy, presentation, treatment, and patient outcomes are not well described in this disease. In a retrospective analysis of 8,298 patients enrolled on clinical trials for HL through the German Hodgkin Study Group,

P.1987

394 patients had NLPHL.⁶⁹ In this series, the median age at diagnosis was 37, 75% patients were male, and 79% of patients had early stage disease. Clinically, there appear to be two age peaks, one in children and another in patients aged 30 to 50. The presence of B-symptoms or bulky disease is unusual, observed in <10% of patients.⁷⁰ Unlike classical HL, patients with NLPHL typically have peripheral adenopathy (axillary or inguinal) at diagnosis rather than central or mediastinal involvement and nodal spread does not track from LN basin to LN basin as typical for classical HL. In NLPHL, nodal involvement is not contiguous and extranodal involvement is uncommon.

FIGURE 93.2. Nodular sclerosing Hodgkin lymphoma. High magnification shows Reed-Sternberg cells and lacunar variants in B5 fixed material.

An association exists with this subtype of lymphoma and a benign condition, progressive transformation of germinal centers, as well as with NHL, particularly T-cell-rich B-cell lymphoma and diffuse large B-cell lymphoma. Progressive transformation of germinal centers is described as lymph nodes with large, well-defined nodules with an excess of B-cells, or germinal centers overrun by lymphocytes.⁷⁰ This entity may be observed prior to, simultaneous with, or following a diagnosis of NLPHL. This entity is thought to be a benign condition, but as it occurs concurrently or following a diagnosis of NLPHL, biopsy of recurrent adenopathy is always required in this disease to confirm relapse. Likewise, T-cell-rich B-cell lymphoma and NLPHL can occur simultaneously or in succession, and frequently T-cell-rich B-cell lymphoma can be pathologically confused for NLPHL. With T-cell-rich B-cell lymphoma, large atypical B-cells that are CD20 positive are surrounded by an abundant background of T-cells and histiocytes. As about 5% of NLPHL eventually develop NHL including T-cell-rich B-cell NHL or diffuse large cell lymphoma, biopsy of recurrent lymph nodes is necessary to determine therapy at relapse. In a series of 22 patients treated with rituximab for NLPHL, 9 patients relapsed, including 5 who underwent biopsy at recurrence and of these 2 had diffuse large cell NHL within 13 months of follow-up.⁷¹

TABLE 93.2 RELATIVE INCIDENCE OF EACH STAGE FOR EACH HISTOPATHOLOGIC SUBTYPE OF HODGKIN LYMPHOMA

Stage	Histologic Subtype			
	Lymphocyte Predominant (%)	Nodular Sclerosis (%)	Mixed Cellularity (%)	Lymphocyte Depleted (%)

CLINICAL EVALUATION

Physical Examination: Sites of Disease

Staging, the basis for treatment planning in HL, begins with the physical examination. HL almost always presents with lymphadenopathy, and the involved nodes are usually freely movable with a rubbery consistency. Cases in which the microscopic appearance reveals fibrosis or sclerosis can be associated with hard firm nodes. Although any lymph node group can be involved (Table 93.3), cervical and supraclavicular adenopathy are the most common physical findings, and axillary presentations are not rare.^{72, 73}

FIGURE 93.4. Lymphocyte-depleted type Hodgkin lymphoma, diffuse fibrosis subtype. Reed-Sternberg cells are easily found, and the background is depleted of cellularity and composed of amorphous eosinophilic connective tissue.

P.1988

FIGURE 93.5. Lymphocyte-rich “classic” Hodgkin lymphoma. The background is primarily lymphocytes, and the Reed-Sternberg cells are usually CD15⁺ and CD30⁺ and negative for the B-cell marker CD20.

Mediastinal disease is often present, but it is rarely the only site of disease because it usually occurs in conjunction with cervical or supraclavicular disease. HL can present with iliac, inguinal, or femoral adenopathy, and in approximately 3% of cases, only subdiaphragmatic disease is present.^{74, 75} However, in a large series of cases in which the original diagnosis of HL was not confirmed on review, two features that predicted errors in diagnosis were primary extranodal disease and primary subdiaphragmatic disease.⁷⁶ Thus, the pathologic diagnosis of HL should be questioned in cases with subdiaphragmatic presentation. A complete physical examination of the patient with HL should include an evaluation of Waldeyer's ring and epitrochlear nodes even though these sites are only rarely involved.

Splenomegaly is noted at presentation in approximately 10% of cases of HL. However, splenomegaly may be a nonspecific manifestation of the HL, and in only one half of patients with splenomegaly was splenic involvement confirmed at laparotomy⁷³ in a study from the era of staging laparotomies. Additionally, splenic involvement may occur in 20% to 30% of patients in the absence of splenomegaly⁷³ even when abdominal computed tomography (CT) scans are used to assess splenomegaly by three-dimensional measurements.⁷⁷ This latter fact should not be surprising, because splenic involvement may be limited to a few microscopic nodules.

TABLE 93.3 FREQUENCY OF INVOLVEMENT OF NODAL SITES IN HODGKIN LYMPHOMA

Site	Frequency of Involvement (%)	Frequency of Involvement as Only Site of Disease (%)
Left cervical and/or supraclavicular nodes	70	7
Right cervical and/or supraclavicular nodes	62	4
Mediastinum	60	1

Spleen ^a	36	0
Para-aortic nodes ^a	34	<1
Left axillary nodes	25	1
Right axillary nodes	25	1
Hilar nodes	21	0
Iliac, inguinal, femoral nodes	16	1

^aData based on surgically staged patients.

Staging laparotomy and splenectomy in Hodgkin's disease: analysis of indications and patterns of involvement in 285 consecutive, unselected patients. *Natl Cancer Inst Monogr* 1973;36:291—301.

FIGURE 93.6. Lymphocyte-predominant Hodgkin lymphoma. High magnification shows variant lymphocytic and histiocytic cells (L and H cells), which have "popcorn" nuclei. A background of small lymphocytes and histiocytes is present.

Extranodal disease can occur at any site. However, the central nervous system and the testis, which are not uncommon sites for NHL, are exceptionally rare sites for HL. At presentation, lung, liver, bone, and bone marrow are the most common extranodal sites of disease, with each of these sites seen in approximately 5% to 10% of cases.^{78, 79} Disease at other individual sites occurs in <5% of cases. Primary extranodal HL should always lead the clinician to consider the possibility of an incorrect pathologic diagnosis.

Pattern of Spread

HL tends to spread in a contiguous fashion.^{72, 80} In fact, when one considers that the left supraclavicular area and the upper abdomen are contiguous (via the thoracic duct), a contiguous pattern of disease can be established at presentation in more than 90% of cases.⁷² For patients with only right supraclavicular involvement at presentation, abdominal disease is found in only 8% of cases; for patients with left supraclavicular involvement at presentation, the incidence of abdominal involvement is 40%. Hilar involvement with HL does not occur unless mediastinal disease is present. Pulmonary involvement by HL does not occur in the absence of mediastinal and hilar involvement.⁸¹

The spleen is the most commonly involved abdominal site of disease, possibly representing hematogenous spread. Liver involvement is uncommon at presentation in patients with HL, and it is exceptionally rare in the absence of splenic involvement.^{72, 82} Within the abdomen, the pattern of disease detected at staging laparotomy suggests spread from the spleen in a contiguous fashion. In a series in which staging laparotomies were performed with rigorous attention to biopsy of all nodal groups, the spleen and contiguous nodes were involved in 71% of cases, the spleen and noncontiguous nodes were involved in 16% of cases, and lymph nodes were involved in the absence of splenomegaly in only 13% of cases.⁸³ It is unknown whether the cases of apparent discontinuous spread represent cases in which early hematogenous dissemination has occurred or cases in which HL has spread through a node without involving the node.

P.1989

Initial Evaluation of the Hodgkin Lymphoma Patient

Clinical History

An accurate clinical history facilitates the management of HL patients in a number of ways. The presence of certain symptoms is associated with a less favorable prognosis and may be a clue to more advanced disease than otherwise suspected. Other symptoms may point out the need for additional studies (such as a bone scan or neck CT) for accurate staging. The discovery of additional sites of disease because of symptoms may lead to a modification of therapy and establish the need for additional follow-up studies on completion of treatment. A history of heart disease or lung disease may prompt closer assessment of those organs before chemotherapy or during its course. A history of HIV infection may affect choice of chemotherapy or infection prophylaxis. A history of smoking or autoimmune disease or a family history of breast cancer may influence the decision to incorporate radiation therapy into the treatment plan and may influence the follow-up plan.

The constitutional symptoms that are known to have prognostic value are unexplained fever to $>101^{\circ}\text{F}$, drenching night sweats, and weight loss equal to 10% of the patient's weight. These are the only symptoms that are accounted for in the Cotswold staging system (and whose presence is denoted by B appended on the numerical stage). Fever in HL can have any pattern, including continuous low-grade fever or occasional fever spikes. The pattern of recurrent episodes of daily high fevers separated by days without fever, Pel-Ebstein fever, was first associated with HL in 1885.^{84, 85} However, in the modern era it is a rare manifestation of HL and, although limited to patients with very advanced disease, it is uncommon even in those patients. Rarely, fever may be the only clinical manifestation of HL, for instance, in the case of patients with the lymphocyte-depleted HL who present with fever and disease limited to retroperitoneal nodes or the bone marrow, or both.⁸⁶

Before designating a patient as having the symptom of night sweats, the clinician should verify that the patient's sweating is abnormal. The night sweats of HL are drenching and not simply associated with increased ambient temperature. Perimenopausal women should be asked if they have vasomotor symptoms before the sweating, as flushing is not generally a symptom of the sweats of HL.

Pain at the site of HL in association with the ingestion of alcohol is well described and can be the first hint of a recurrence. The mechanism of this phenomenon is unknown and it does not have prognostic significance. The occurrence of alcohol-induced pain has become less common in recent decades, perhaps in association with earlier diagnosis and more effective therapy. Generalized pruritus may be a nonspecific manifestation of HL, and it may be an early manifestation of the disease in up to 10% to 15% patients. It also has no known prognostic implication. Similarly, fatigue and weakness may occur in patients with HL but do not cause a patient to be classified as symptomatic.

Although the staging classification divides patients into categories A and B for asymptomatic and symptomatic, respectively, clinicians are well aware that this binary classification is an oversimplification and that the presence of symptoms varies along a continuum^{87, 88} with respect to their clinical significance. When patients with stage IB and stage IIB HL were reviewed, it was found that the presence of fevers was associated with a relative risk of relapse after treatment of 4.3. For weight loss alone, the relative risk of relapse after treatment was 2.4; for night sweats, the relative risk of relapse was 0.8 (i.e., not increased).⁸⁷ Nevertheless, the presence of symptoms may suggest advanced disease. Symptoms are found in $<10\%$ of patients with stage I disease and in approximately two thirds of patients with stage IV disease.⁸⁹ The presence of B symptoms in a patient with apparent stage I disease is, therefore, suggestive that further evaluation will lead to the discovery of a more advanced-stage disease.

The Cotswold Staging System

The stage of the patient is the main determinant of therapy and prognosis in HL. The current classification system is the Cotswold classification system^{90, 91} (Table 93.4). Although the modalities used to stage patients have changed since the Cotswold conference in 1990 (e.g., PET and improved CTs have replaced staging laparotomy and gallium scans), and treatment algorithms have changed, the current staging system remains the backbone for clinical decision making and for clinical trial design.

Stage I disease is the involvement of a single lymph node region (or a single lymphoid structure). Stage II disease is the involvement of multiple lymph node regions (e.g., cervical nodes, supraclavicular nodes) but on only one side of the diaphragm. Stage III disease is the involvement of lymph node regions on both sides of the diaphragm and is further subdivided as to anatomic substage. Disease limited to the upper abdomen (i.e., spleen, splenic hilar nodes, celiac nodes, or porta hepatis nodes) in a patient with stage III disease is defined as substage III1. Patients with stage III disease in whom abdominal nodal involvement includes para-aortic, iliac, or inguinal nodes are classified as substage III2. The distinction between stages III1 and III2 is largely obsolete as all patients with stage III are now treated similarly with chemotherapy. Stage IV disease is visceral involvement (e.g., lung, liver, or bone marrow) that is not due to direct extension from a nodal site. The subscript E represents extension from a nodal site, such as extension of a mediastinal mass directly into the lung, for example, IIE.⁷⁸ The designations A and B are used to represent the absence and presence of symptoms (e.g., unexplained fever, drenching night sweats, and weight loss of 10% of body weight), respectively. The presence of "bulky" disease, defined as a mediastinal mass with a diameter greater than one-third the diameter of the chest as measured at the T5-T6 interspace on a postero-anterior chest radiograph, or any nodal

P.1990

mass with a greatest diameter of more than 10 cm, is represented by the designation X.^{92, 93, 94} The relative incidence of each stage of HL is shown in Table 93.5.

TABLE 93.4 COTSWOLD STAGING CLASSIFICATION FOR HODGKIN LYMPHOMA

Stage I

Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer ring)

Stage II

Involvement of two or more lymph node regions on the same side of the diaphragm (the mediastinum is a single site; hilar lymph nodes are lateralized); number of anatomic sites should be indicated by a suffix (e.g., II₃)

Stage III

Involvement of lymph node regions of structures on both sides of the diaphragm

III₁ With or without splenic hilar, celiac, or portal nodes

III₂ With para-aortic, iliac, or mesenteric nodes

Stage IV

Involvement of extranodal site(s) beyond that designated *E*

A No symptoms

B Fever, drenching sweats, weight loss

X Bulky disease, greater than one-third widening of the mediastinum, >10 cm maximum dimension of nodal mass

E Involvement of a single extranodal site, contiguous or proximal to a known nodal site

CS Clinical stage

PS Pathologic stage

TABLE 93.5 DISTRIBUTION OF HODGKIN LYMPHOMA CASES WITH RESPECT TO STAGE AND SYMPTOMATIC STATUS

Stage	A (%)	B (%)	A and B (%)
I	11.4	0.8	12.2
II	34.1	12.4	46.5
III	17.5	13.1	30.6
IV	3.3	7.4	10.7
Total	66.3	33.7	100.0

Required and Suggested Studies for Initial Evaluation

As treatment recommendations for HL depend heavily on stage, accurate staging is crucial. Staging also establishes a baseline so that the completeness of remission can be assessed on completion of therapy. The evaluation begins with a clinical history (see above) and a physical examination. The physical exam should focus on accessible lymphoid tissues, including Waldeyer's ring, all palpable lymph node areas, including the epitrochlear and popliteal nodes, as well as the spleen.

The role of radiographic imaging in HL patients is to determine the stage accurately, as stage determines treatment. A second role is to establish a baseline for comparison to mid-treatment or post-treatment scans. There is now a general agreement that positron emission tomography with integrated CT scanning (PET/CT) can supplant other imaging studies in the initial assessment of most patients with HL. PET/CT is reported to have very high sensitivity and specificity in HL. CT alone relies on size criteria to distinguish normal nodes from involved nodes and thus may understage patients with small but involved nodes. It is also poor at identifying a diffusely involved organ such as the spleen or liver, unless those organs are enlarged. It is reported that PET/CT (as compared to CT alone) changes the stage in up to 20% to 40% of cases and changes the treatment in 5% to 15%.^{95, 96, 97} The majority of these cases are upstaging. Some argue for omitting PET/CT in favor of CT alone for certain "clearly limited-stage" patients,⁹⁸ however, most clinicians and most guidelines (e.g., the National Comprehensive Cancer Network) favor initial PET/CT as a routine study for initial evaluation of HL. If a PET/CT is unavailable, or otherwise unused, patients should have CT scans of the chest, abdomen, and pelvis. A neck CT should be included if there is any clinical suspicion of involvement of neck nodes. A chest radiograph is performed in a patient with a mediastinal mass to assess whether the patient's disease meets the criteria for bulky mediastinal disease. Certain situations and patients may warrant other radiographic studies, for example, the patient with bone pain may be evaluated with bone scan or MRI.

A marrow biopsy is usually performed on any patient with B symptoms or abnormal blood counts, and on any patient with stage III or IV disease. Although the chance that an early stage asymptomatic patient with normal blood counts will have marrow involvement is low,^{79, 99} some clinicians perform a marrow biopsy on all patients with HL. Recent data suggest that PET/CT accurately identifies or rules out marrow involvement,¹⁰⁰ and clinicians may be able to decrease their use of marrow biopsy accordingly in the future.

Blood tests should include a complete blood count with differential and platelets, erythrocyte sedimentation rate, liver function tests including alkaline phosphatase, lactate dehydrogenase, albumin and bilirubin (abnormal liver function tests are not diagnostic of liver involvement, but are sometimes nonspecifically elevated and may complicate the use of certain chemotherapy agents); BUN and creatinine, and thyroid function tests as a baseline (if neck radiotherapy is contemplated). Serology for human immunodeficiency virus is appropriate in selected cases. A pregnancy test should be performed for women of childbearing potential.

Patients should be counseled about fertility preservation. An assessment of ejection fraction by echocardiogram or radionuclide study is appropriate if anthracycline chemotherapy will be used. Pulmonary function tests with diffusing capacity should be ordered if bleomycin-containing chemotherapy will be used.

A summary list of suggested initial procedures and tests is presented in Table 93.6.

Prognostic Indicators

As noted above, stage is the major prognostic factor in HL and the major basis on which therapy is determined. However, patients can be stratified for risk on the basis of prognostic factors in addition to stage. In a study of 5,141 patients with "advanced" HL, primarily stage III and IV disease, Hasenclever and Diehl¹⁰¹ performed a multivariate analysis of risk factors (Fig. 93.7). Seven independent factors that predicted freedom from progression (FFP) were identified: albumin <4.0 g/dl;

hemoglobin <10.5 g/dl; male sex; 45 years of age or more; stage IV disease; leukocytosis at or above 15,000/mm³; and lymphocytopenia (lymphocytes ≤600/mm³ and/or lymphocytes <8% of total white count). For patients with no risk factors (7% of all patients), FFP was 84%. For

P.1991

patients with one risk factor (22% of all patients), FFP was 77%. For patients with two risk factors (29% of all patients), FFP was 67%. For patients with three risk factors (23% of all patients), FFP was 60%. For patients with four risk factors (12% of all patients), FFP was 51%. For patients with five or more risk factors (7% of all patients), FFP was 42%. Of note, B symptoms did not have independent prognostic value in this model. At present this model is validated only for advanced-stage patients.

TABLE 93.6 RECOMMENDED INITIAL EVALUATION FOR PATIENTS WITH HODGKIN LYMPHOMA

History and Physical Examination, Including

Past medical history: including B symptoms (fever, night sweats, weight loss of >10% in past 6 mo), alcohol intolerance, itching, HIV risks, cardiac, renal, liver impairment

Family history: including lung cancer, coronary disease, breast cancer

Personal history: smoking

Examination of all peripheral lymph node regions (including epitrochlear, popliteal, Waldeyer's ring), liver, and spleen

Radiologic Studies

Chest radiograph

PET/CT

Assessment of EF (optional in younger patients)

Pulmonary function tests (optional in younger patients)

Laboratory Studies

Hematocrit, white blood cell count, differential, platelet count

Erythrocyte sedimentation rate, lactic dehydrogenase

Liver function tests including albumin, alkaline phosphatase transaminases, bilirubin

Bilirubin, alkaline phosphatase, liver function tests

Thyroid function tests if radiation to neck is contemplated

Bone scan (selected patients)

HIV serology

Bone Marrow Aspiration and Biopsy (Optional Unless Stage III)

CT, computed tomography; HIV, human immunodeficiency virus; PET, positron emission tomography.

FIGURE 93.7. Progression-free survival (A) and survival (B) as related to number of risk factors. (From Hasenclever D, Diehl V. A prognostic score for advanced Hodgkin's disease. *N Engl J Med* 1998;339:1506-1514, with permission.)

A number of prognostic classifications have been used for early-stage HL and have been used to tailor therapy further in clinical trials. These commonly employ some combination of age, erythrocyte sedimentation rate, mediastinal bulk, and number of involved nodal sites. See Table 93.7, "Unfavorable Prognostic Factors for Stage I—II HL, by Three Cooperative Groups."

OVERVIEW AND HISTORICAL PERSPECTIVE OF RADIATION THERAPY

Six years after the discovery of x-rays by Roentgen in 1895, Pusey reported that x-rays could shrink enlarged nodes in patients with HL.¹⁰² However, given the orthovoltage techniques of the day, therapy was only palliative. The modern radiotherapy era began with the Swiss radiotherapist Gilbert in 1925.¹⁰³ Based on observed patterns of spread in patients with HL, Gilbert advocated treatment of both involved areas and adjacent, apparently uninvolved, areas. This approach was also adopted by Peters, who, in 1950, was the first to report that radiation therapy of HL could produce cures.¹⁰⁴ Over

the next two decades, the curability of HL was confirmed by Peters,¹⁰⁵,¹⁰⁶ Easson and Russell,¹⁰⁷ and Kaplan,¹⁰⁸,¹⁰⁹ the latter investigator establishing the critical relationship between radiation dose and the risk of recurrence in the treatment field (Fig. 93.8).

TABLE 93.7 UNFAVORABLE CHARACTERISTICS FOR STAGE I AND II HL, PER THREE COOPERATIVE GROUPS

Risk Factor	GSHG	EORTC	NCIC
Age		≥50	≥40
Histology			NC or LD
ESR and B symptoms	>50 if A; >30 if B	>50 if A; >30 if B	50 or any B
Mediastinal mass	MMR > .33	MTR > 35	MMR >.33 or >10 cm
# Nodal sites	>2 ^a	>3	>3
E lesions	any		

GSHG, German Hodgkin Study Group (^auses alternate definition of nodal sites); EORTC, European Organization for the Research and Treatment of Cancer; NCIC, National Cancer institute of Canada; MMR, mediastinal mass ratio: maximal width of mass/maximal intrathoracic width; MTR, mass to thoracic width at T5-T6 interspace on standing PA chest radiograph.

As originally suggested by Gilbert, the principle of treating involved and adjacent apparently uninvolved areas (i.e., extended field therapy) became a standard radiotherapeutic approach to HL. With the advent of staging laparotomy and evidence that the retroperitoneum could represent a potentially involved adjacent area of disease, the concept of extended field therapy came to include the standard mantle, para-aortic/splenic, and pelvic radiation ports shown in Figure 93.9.¹¹⁰

Although the radiotherapy pioneers were the first to cure HL, and they did so by conducting elegant and groundbreaking clinical trials, the era of radiation as single modality for the initial treatment of HL has passed. However, HL is a very radiation-sensitive disease, and radiation remains a useful component of the treatment of certain patients. Currently the most well documented role for radiation is in the early stage setting, discussed below.

Complications of radiation therapy depend on technique, dose, and the volume of irradiated tissue. Common complications include hair loss within the treatment fields, radiation pneumonitis, radiation pericarditis, mediastinal fibrosis, and pulmonary fibrosis. Symptoms of radiation pneumonitis generally occur within 1 to 3 months of completing therapy and are nonspecific because they include dyspnea, cough, and fever. Such

P.1992

complications are rarely seen at lung doses <15 Gy and occurred in <5% of patients receiving routine mantle irradiation. The presence of a large mediastinal mass or the concomitant use of chemotherapy essentially doubles the risk of radiation pneumonitis.¹¹¹,¹¹² Although infection and recurrent HL must be considered in the differential diagnosis of radiation pneumonitis, radiation injury is likely to be confined to the area of the lung that was irradiated. Infiltrates with sharp borders, representing the edge of the radiation field, strongly suggest the presence of radiation pneumonitis. Because HL and its therapy are both associated with immunosuppression, whenever radiation injury is considered in the differential diagnosis of a patient with HL, one must also consider the diagnosis of Pneumocystis jiroveci pneumonia.

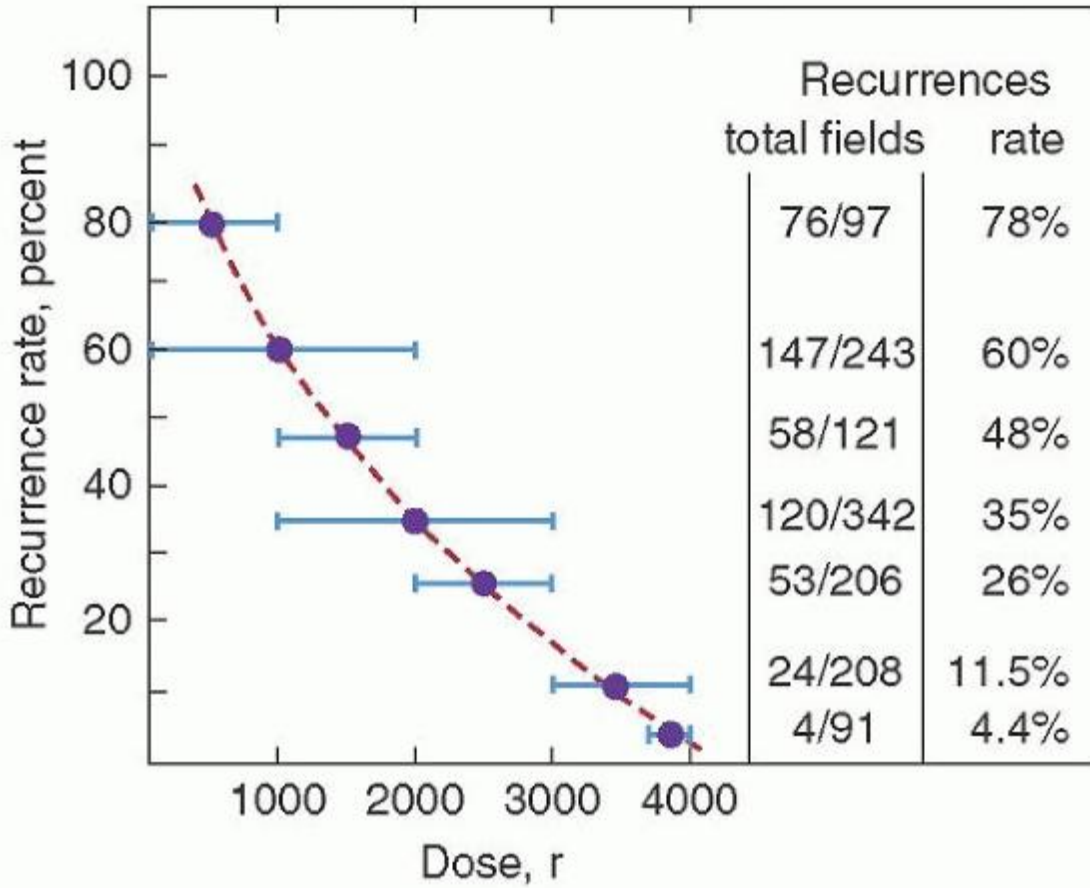

FIGURE 93.8. Rate of recurrence in a given treatment field as a function of radiation dose delivered to that field. (From Kaplan HS. Evidence for a tumoricidal dose level in the radiotherapy of Hodgkin disease. *Cancer Res* 1966;26:1221-1224, with permission.)

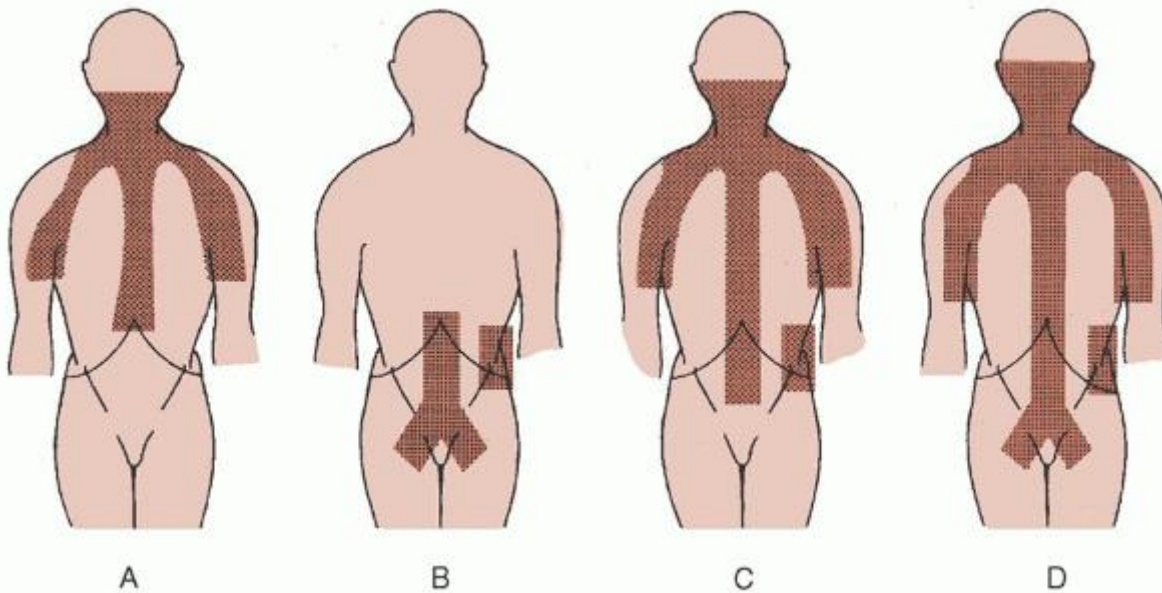

FIGURE 93.9. Treatment fields used as extended field irradiation of Hodgkin disease. A: Mantle field. B: Inverted Y field. C: Mantle and para-aortic field (extended mantle field). D: Total nodal field. The spleen is irradiated in conjunction with the

fields in B, C, and D, unless it has been surgically removed.

Cardiac toxicity of radiation therapy can include myocarditis, arrhythmias, pericarditis (rarely including constrictive pericarditis and tamponade), valvular heart disease, and coronary artery disease.^{113, 114, 115, 116, 117, 118} Although an increased risk of myocardial infarction appears to exist after radiation therapy,¹¹⁷ this risk is greater for patients who received radiation therapy before 1966, suggesting that modern treatment techniques have minimized this risk.

Spinal cord injury should not occur with modern radiation therapy techniques but may occur if radiation fields overlap. Splicing of fields over the spinal cord should be done with great care. The one neurologic problem that may occur despite the use of appropriate technique is the Lhermitte sign,⁸⁹ which includes numbness and tingling in the arms, legs, or both and electrical sensations up and down the spine made worse by flexion of the head. This complication is usually transient and of no clinical consequence.

Hypothyroidism is a common complication of radiation therapy,¹¹⁹ with actuarial analysis indicating that 52% of patients develop hypothyroidism 20 years after radiation.¹¹⁹ Thyroid cancer is an uncommon complication, but, based on the hypothesis that chronic elevations of thyroid-stimulating hormone in patients after thyroid irradiation may lead to thyroid tumors, the administration of thyroid replacement has been advocated in patients with an elevated thyroid-stimulating hormone even if they are clinically euthyroid.¹¹⁹

In addition to thyroid cancer, an increased risk of second malignancies, including lung cancer,^{120, 121} stomach cancer,¹²⁰ melanoma,^{120, 122} and breast cancer,^{123, 124, 125} has been noted in patients receiving radiation therapy for HL. These malignancies generally occur 10 to 20 years after radiation therapy, with the risk of second malignancies being increased in patients who have also received chemotherapy. The relative risk of breast cancer secondary to radiation is age related. The relative risk of developing breast cancer is 38 for patients radiated before age 20; the relative risk is 17 for patients radiated between the ages of 20 and 29; the relative risk is 4 for patients radiated after the age of 30, a relative risk that is not significantly different from 1.¹²³ Fortunately, the baseline risk of breast cancer in patients younger than age 30 is low, muting the quantitative impact of this increase in relative risk. Nevertheless, it has been recommended that women who receive radiation therapy for HL should receive mammography starting 8 years after completion of therapy because 95% of such tumors occur more than 10 years after radiation.¹²⁴

It should be recognized that radiation therapy developed as a primary treatment approach to HL when no other modalities were available. In the 1960s, 1970s, and 1980s, when chemotherapy and radiotherapy were both rational treatment options, radiotherapy was often seen as the simpler approach with minimal side effects. Over the last 10 to 15 years, however, there has been increased recognition of the fact that radiation therapy is associated with an increased incidence of late deaths and that for limited-stage patients those deaths eventually exceed the number of deaths from HL. At the same time, chemotherapy has become more tolerable. The result is an overall trend to use radiation therapy less often and to use chemotherapy more often.¹²⁶ This is discussed in detail in the sections on treatment.

OVERVIEW AND HISTORICAL PERSPECTIVE OF CHEMOTHERAPY

The development of cancer chemotherapy arose from the observation of lymph node necrosis in soldiers exposed to nitrogen mustard gas during World War I. Therefore, it is not surprising that HL and NHL were among the first disorders treated with nitrogen mustard when the drug was developed for therapeutic use.^{127, 128, 188, 189} Since then, several chemotherapeutic agents in several classes of drugs have been shown to be effective in HL. Single agents generally produced partial rather than complete remissions, and unmaintained remissions rarely lasted more than 3 months, with maintained remissions lasting 8 to 10 months (Table 93.8).^{129, 130, 131, 132} During the 1960s, efforts were made to combine effective agents,¹³³ culminating in the landmark demonstration by DeVita et al. that MOPP (Mustargen [mechlorethamine], Oncovin [vincristine], procarbazine, and prednisone) combination chemotherapy could cure advanced HL.¹³⁴ In the initial publication reporting results achieved with the MOPP regimen,¹³⁵ 81% of patients with advanced HL achieved a complete remission, and by actuarial analysis, 47% were projected to be long-term disease-free survivors. Follow-up studies^{136, 137} confirmed that these long-term disease-free survivals (DFSs) were equivalent to cure and projected cure rates of 56%.¹³⁷

P.1993

TABLE 93.8 RESULTS OF SINGLE-AGENT THERAPY IN HODGKIN LYMPHOMA

Response Rate (%)

Agent	Representative Dose and Route	CR	CR and PR
Nitrogen mustard	0.2-0.4 mg/kg IV, q4-6wk	13	65
Vincristine	0.2 mg/kg/wk IV	36	58
Procarbazine	50-150 mg/kg/d PO	38	69
Prednisone	40-60 mg/d PO	0	61
Cyclophosphamide	2 mg/kg/d PO	12	54
Chlorambucil	0.2 mg/kg/d PO	16	60
Vinblastine	0.2 mg/kg/wk IV	30	68
Bischloroethyl nitrosourea	100-200 mg/m ² IV, q6wk	4	47

Bleomycin	5 mg/m ² IV, varying schedules	6	37
DTIC	200 mg/m ² IV, daily ∞5, variable	6	56
Etoposide	50-120 mg/m ² IV, daily ∞5, variable	7	25
Cisplatin	75 mg/m ² IV, q3-4wk	8	35

CR, complete response; PR, partial response.

Modified from Kaplan HS. Hodgkin's disease, 2nd ed. Cambridge: Harvard University Press, 1980:199-201.

This study of MOPP in advanced HL¹³⁵ established combination chemotherapy as the treatment of choice for advanced HL (Table 93.9).^{135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145} Additionally, by demonstrating the cumulative and synergistic efficacy of combining drugs with different mechanisms of action and—to a degree—separate toxicities, it established the rationale for the use of combination chemotherapy in other malignancies. Subsequent investigations, as detailed below in the section on front-line therapy of advanced disease, have established alternative regimens as superior to MOPP with respect to efficacy and toxicity.

The primary toxicity of combination chemotherapy is hematologic, with neutropenia being more common than thrombocytopenia. Drug toxicity tends to be cumulative, with neutropenia having an increased degree and duration with each cycle of chemotherapy. Because there is evidence that optimal dose intensity (dose/time) is essential to achieving the best therapeutic results,^{137, 140, 146, 147} many clinicians have used a granulocyte colony-stimulating factor to avoid delays in therapy. However, a recent report showed increased lung toxicity in HL patients treated with filgrastim along with ABVD (26% vs. 9% without G-CSF)¹⁴⁸ and has led to some concerns about this approach although patients with testis cancer treated with bleomycin and using filgrastim support had no increase in lung toxicity as compared to a no-filgrastim group. Evens and colleagues reported their experience with proceeding with ABVD every 14 days without regard to neutrophil count and without administering colony-stimulating factors. They retrospectively compared the 61 patients treated in this manner to 23 patients treated with routine empiric filgrastim. Only 0.44% of the treatments given without filgrastim or dose reductions were complicated by neutropenic fever, and over 99% of the planned dose intensity was maintained.¹⁴⁹ Whether or not there is an increase in lung toxicity in HL patients treated with bleomycin and filgrastim, it seems reasonable to treat younger healthier patients without dose reductions or delays and without the routine use of colony-stimulating factors.

A major long-term complication of the MOPP regimen was myelodysplasia and leukemia, occurring in 2.6% at 5 years¹⁵⁰ and in more patients with longer follow-up. The addition of radiation may increase the risk to as much as 7% to 10% during the first 10 years.^{151, 152, 153, 154, 155, 156, 157, 158} ABVD does not seem to cause myelodysplasia.

Vincristine, and to a lesser extent vinblastine, cause a dose-dependent sensory neuropathy. This should not lead to dose modifications unless the sensory neuropathy involves the entire fingers or limits function. Motor neuropathy and obstipation are indications for dose reduction, but to limit the need for this dose modification, patients receiving vincristine should receive prophylactic laxatives.

Bleomycin may produce pulmonary fibrosis, and doxorubicin may produce cardiac toxicity. However, these toxicities are related to total dose administered. Bleomycin lung toxicity is seen in approximately 10% of patients receiving more than 250 mg/m² of bleomycin.¹⁵⁹ Clinical evidence of cardiac toxicity is observed in a similar percentage of patients receiving more than 450 mg/m² of doxorubicin.^{160, 161, 162} Thus, these toxicities are uncommon even when ABVD (Adriamycin [doxorubicin], bleomycin, vinblastine, and dacarbazine) is used. For patients receiving eight cycles of ABVD, the total cumulative doses would be 160 mg/m² of bleomycin and 400 mg/m² of doxorubicin, which approaches the toxic threshold. The threshold for drug toxicity is not absolute, and evidence of drug toxicity may be observed at lower doses, especially in older patients or in patients who have received radiation therapy to ports that include the lung or heart.

If the history or physical examination during ABVD therapy raises the suspicion of bleomycin pulmonary toxicity, a chest radiograph should be obtained, and tests such as a chest CT scan and pulmonary function tests with diffusing capacity of lung for carbon monoxide should be considered. Absolute criteria for the discontinuation of bleomycin have not been established, but we strongly caution against the continuation of bleomycin in the face of a corrected diffusing capacity of lung for carbon monoxide of ≤50%. In making a decision about further use of bleomycin, the clinician must consider the risks of further therapy as well as the risk of early discontinuation of an effective agent.

Sterility is another toxicity of HL treatment that must be considered in planning therapy because this complication may have a significant impact on a patient's quality of life. Although the formerly standard MOPP chemotherapy produced long-term azoospermia in 90% to 100% of patients,^{163, 164, 165, 166} limited data suggest that ABVD is associated with only transient azoospermia.¹⁶⁷ For men, permanent sterility is related primarily to the use and dose of alkylating agents; with ABVD, sterility is rare. In women, age, alkylating agent, and dose are important.¹⁶⁸ Many women become amenorrheic during chemotherapy, with hormonal findings consistent with ovarian failure.^{169, 170} In younger women, recovery of menses and recovery of fertility are generally seen. In women older than age 35, menses may resume, but menopause may occur prematurely. In women who are perimenopausal at the time of chemotherapy, menses may cease permanently. Although cryopreservation of semen before chemotherapy and artificial insemination have been successful in achieving pregnancy,¹⁷¹ the presence of decreased sperm counts and abnormal sperm motility before therapy in patients with HL limit this approach.¹⁷² In vitro fertilization for embryo cryopreservation is an option for some patients, but requires a delay in treatment. The cryopreservation of oocytes and of ovarian tissue is under investigation. Oral contraceptives or gonadotropin-releasing hormone-analogues have not been protective of fertility.¹⁷³ Offering information about fertility preservation should be considered even for those in whom limited ABVD is planned, as a minority of patients will progress and will go on to more intensive therapy.

P.1994

TABLE 93.9 CHEMOTHERAPY REGIMENS UTILIZED IN ADVANCED-STAGE HODGKIN LYMPHOMA

ABVD	Adriamycin 25 mg/m ²	IV	Days 1 and 15	Q28d
	Bleomycin 10 units/m ²	IV	Days 1 and 15	
	Vinblastine 6 mg/m ²	IV	Days 1 and 15	
	Dacarbazine 375 mg/m ²	IV	Days 1 and 15	
BEACOPP (baseline)	Bleomycin 10 mg/m ²	IV	Day 8	Q21d
	Etoposide 100 mg/m ²	IV	Days 1-3	
	Adriamycin 25 mg/m ²	IV	Days 1	
	Cyclophosphamide 650 mg/m ²	IV	Day 1	
	Vincristine 1.4 mg/m ² (capped at 2.0 mg)	IV	Day 8	
	Procarbazine 100 mg/m ²	IV	Day 1-7	
	Prednisone 40 mg/m ²	IV	Day 1-14	
BEACOPP	Bleomycin 10 mg/m ²	IV	Day 8	Q21d

(escalated)	Etoposide 200 mg/m ²	IV	Days 1-3
	Adriamycin 35 mg/m ²	IV	Days 1
	Cyclophosphamide 1,200 mg/m ²	IV	Day 1
	Vincristine 1.4 mg/m ² (capped at 2.0 mg)	IV	Day 8
	Procarbazine 100 mg/m ²	IV	Day 1-7
	Prednisone 40 mg/m ²	IV	Day 1-14
	Stanford V	Adriamycin 25 mg/m ²	IV
Vinblastine 6 mg/m ²		IV	Weeks 1, 3, 5, 7, 9, 11
Vincristine 1.4 mg/m ² (capped at 2.0 mg)		IV	Weeks 2, 4, 6, 8, 10, 12
		IV	Weeks 2, 4, 6, 8, 10, 12
Bleomycin 5 units/m ²		IV	Weeks 1, 5, 9
Mustard 6 mg/m ²		IV	Weeks 3, 7, 11
Etoposide 60 mg/m ²		PO	Weeks 1-9, taper by 10 mg
Prednisone 40 mg/m ²		QOD	QOD weeks 10 and 11

Although the detrimental effects of combination chemotherapy on fertility are well documented, neither the occurrence of infertility nor its persistence can be predicted with certainty. Because of the risk of birth defects, adequate contraception during chemotherapy is essential. Both during and following chemotherapy, patients desiring to avoid pregnancy should be advised not to rely on chemotherapy as their only form of contraception. In addition to decreased fertility, hormonal effects of chemotherapy have been associated with decreased libido in both men and women receiving chemotherapy for HL.^{169, 174, 175}

Limited-Stage Disease

Limited- or early-stage HL is further stratified into two groups for the purpose of clinical trials and for treatment planning. Favorable early-stage HL is defined as stage I or II HL without unfavorable features or risk factors, and unfavorable early-stage HL is defined as the stage I or II with one or more risk factors. The risk factors have been variously defined by different groups, (see Table 93.7) but generally include (1) a greater number or nodal sites, (2) elevated erythrocyte sedimentation rate, (3) B symptoms, (4) a large mediastinal mass or other bulky disease, and (5) age over 40 or 50 years. Unfavorable early-stage HL may also be thought of as comprising two further groups: those unfavorable on the basis of bulky disease, and those unfavorable on the basis of another risk factor.

Treatment of Favorable Early-stage Hodgkin Lymphoma

Favorable early-stage HL has traditionally been treated with extended field radiotherapy, with cure rates as high as 80%. Long-term follow-up of patients treated and cured with radiotherapy has now made clear that such patients suffer from high rates of life-threatening and/or debilitating late effects, such as early atherosclerosis and myocardial infarction, valvular heart disease, and secondary malignancies. Over the last 2 decades this recognition has led to a general move toward using chemotherapy for early-stage patients and simultaneously reducing the fields and doses of radiotherapy, and even eliminating radiotherapy entirely for certain highly susceptible patients (e.g., young women with mediastinal disease who would have a high risk of breast cancer with mediastinal irradiation). Reducing the fields and doses of radiotherapy has been shown to reduce the risk of at least some of the late side effects of radiation exposure.^{176, 177, 178, 179, 180}

In the last 15 years, a number of publications have shown the excellent results and tolerability of a treatment paradigm for favorable early-stage HL consisting of a limited number of courses of chemotherapy (generally ABVD) and limited radiotherapy at reduced total dose.^{181, 182, 183, 184} Although there is a paucity of randomized data comparing a modern combined modality regimen (i.e., a limited number of cycles of ABVD followed by involved field radiotherapy with relatively low total dose) to radiotherapy alone or to ABVD alone, the single-arm PFS rates of over 90% and short-term

tolerability, and the expected low rate of long-term side effects have made combined modality therapy a de facto standard for favorable early-stage HL. Extended field radiotherapy is no longer a standard of care, and chemotherapy alone is used primarily when there is particular concern about long-term side effects of radiation. A number of randomized trials have evaluated combined modality treatment, although most have used noncurrent radiotherapy, noncurrent chemotherapy, or both. As is the case in many trials of initial treatment of HL, a difference in OS is difficult to prove, presumably because of the efficacy of salvage therapy and the long survival times of patients. However, at least one randomized trial, the EORTC's H8F trial, which compared three cycles of MOPP/ABV (mechlorethamine, vincristine, procarbazine, prednisone, doxorubicin, bleomycin, and vinblastine) hybrid and involved field radiotherapy to subtotal nodal irradiation, shows an OS for the combined modality treatment advantage at 10 years follow-up (97% vs. 92%, $P = 0.001$).¹⁸³ Likewise a meta-analysis of trials comparing chemotherapy alone to combined modality therapy demonstrated an advantage in both tumor control and OS for the combined modality approach.¹⁸⁵

P.1995

Most recent investigations of combined modality therapy of favorable early-stage HL have used ABVD, based on its superiority to earlier regimens, although some studies incorporate the BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) or Stanford V regimens (see section "Advanced Therapy Treatment"). A currently accruing trial of the German Hodgkin Study group, HD13, randomizes favorable early-stage patients to ABVD versus ABV versus ABD versus AV.

Within the paradigm of combined modality therapy for favorable early-stage HL, several key questions remain, including the following. (1) What is the optimal number of cycles of chemotherapy? (2) What is optimal dose of RT? (3) Can radiotherapy be eliminated entirely?

Four cycles of ABVD followed by involved field radiotherapy has been used as a comparator arm in a number of studies and has emerged as a standard treatment for favorable early HL. For example Bonadonna and colleagues reported a study comparing radiotherapy fields in stages I and II HL (29% were unfavorable). The ABVD \times 4 and involved field radiotherapy arm had a 12-year FFP of 94% and an OS of 94%.¹⁸⁴ The HD 10 study of the German Hodgkin Study Group randomized favorable early-stage patients to either four or two cycles of ABVD, and later to one of two doses of radiation. A total of 1,190 patients from 329 institutions were analyzed for the comparison of ABVD \times 4 versus ABVD \times 2. At 5-year follow-up, there was no difference in OS (97.1% vs. 96.1%, NS) or PFS (93.1% vs. 91.2%, NS).¹⁸⁶ It is important to note that the inclusion criteria for this trial selected patients likely to be especially favorable, as compared to the study population in other favorable early-stage HL trials. In particular, the patients had two or fewer nodal groups involved (as opposed to three or fewer), and the definitions of the nodal groups are unique to the GHSG and not precisely concordant with the Cotswold definition. Details are available in the appendix to the paper online at http://www.nejm.org/doi/suppl/10.1056/NEJMoa1000067/suppl_file/nejmoa1000067_appendix.pdf. Thus the HD10 trial may be read as identifying a "very favorable" subgroup for whom ABVD \times 2 is adequate before involved field radiation therapy.

The appropriate dose of involved field radiation therapy in the combined modality approach to favorable early-stage HL has also been a topic of investigation. The Italian trial above¹⁸⁴ used a dose of 36 Gy with excellent 12-year results, and a Stanford trial of abbreviated chemotherapy (Stanford V \times 8 weeks), followed by involved field radiotherapy used a dose of 30 Gy with 10-year OS and PFS of 94%. The EORTC H9F trial (reported in abstract only) used the alternative chemotherapy EBVP (epirubicin, bleomycin, vinblastine, and prednisone) \times 6 followed by involved radiotherapy 30 Gy versus 20 Gy versus no radiotherapy. There was no significant difference between the 30 Gy and 20 Gy groups by 4-year freedom from treatment failure (FFTF, 87% vs. 84%).¹⁸⁷ The HD10 study of the German Hodgkin Study Group randomized patients (selected for two or fewer involved nodal groups, as above) to either 30 Gy or 20 Gy involved field radiation. There was no difference between the two doses of radiotherapy at 5 years (PFS 93.7% vs. 93.2% and OS 97.7% vs. 97.5%).¹⁸⁶

A number of groups have reported using chemotherapy alone for favorable early-stage patients. In a prospective single-arm study from Spain, investigators reported on stage I and II patients treated with ABVD \times 6 for early-stage HL. Among 49 patients who were favorable by EORTC criteria, the PFS and OS were 88% and 100% at 78-months follow-up.¹⁸⁸ Canellos et al reported a retrospective series of 75 patients with nonbulky early-stage HL who were treated with ABVD alone (the majority with 6 cycles). All patients attained a complete response (CR), and the PFS at 60 months was 92%.¹⁸⁹ It is important to note that this is a retrospective study: presumably those not achieving a CR would have been considered for RT and if they received radiation would not have been included in the study. Strauss et al. randomized 152 nonbulky stage

I, II, and IIIA patients to ABVD × 6 versus ABVD × 6 and 36 Gy of extended or involved field radiation therapy. At 60 months, FFS was 81% versus 86% (NS) and OS was 90% versus 97% (NS).¹⁹⁰ The inclusion of stage III patients and the use of “full-course” chemotherapy complicates the interpretation of this trial. The authors point out the trial is not powered to detect difference smaller than 20%. The HD6 trial of the National Cancer Institute of Canada randomized nonbulky early-stage patients to either ABVD alone (4 to 6 cycles) or a strategy in which favorable (<40 years, ESR <50, no MC or lymphocyte-depleted histology, <4 sites of disease) patients received extended field radiation alone and unfavorable patients received ABVD × 2 followed by radiation. Comparing the chemotherapy-only patients to the patients treated with a strategy including radiation, there is an advantage in PFS for the latter (93% radiation vs. 87% ABVD, $P = 0.006$) but no difference in event-free survival (EFS) and OS. Five-year PFS for the favorable patients receiving ABVD only (59 patients) is 87%. In this study, the only patients who were randomized to chemotherapy-only or combined modality therapy were unfavorable (though nonbulky), and thus the utility of these data for evaluating combined modality therapy versus chemotherapy alone are limited.¹⁹¹

In summary, the standard treatment of favorable early-stage HL is combined modality treatment, with two to four cycles of ABVD followed by 20 to 30 Gy of involved field radiation therapy. The lower limits of the above guideline are validated for the somewhat selected group identified in the HD10 study with two or fewer involved sites. Chemotherapy alone has a 5-year PFS rate of 81% to 92%. Although the PFS is likely somewhat lower than with combined modality therapy, chemotherapy alone might be preferred when radiation is deemed more dangerous or otherwise unsuitable. The most common of these situations is the case of a young woman who would be placed at higher risk of breast cancer if she underwent chest irradiation. Other scenarios include smokers in whom chest irradiation would further increase the risk of lung cancer or fibrosis, and anatomic situations where a vital structure such as the heart would be irradiated. A reasonable question for the clinician to ask himself is whether the additional margin of PFS after an initial combined modality approach is worth any extra toxicity over a chemotherapy-alone approach, especially if there is a reasonable chance of salvage for the small number of patients who relapse as a result of not receiving radiation therapy. In the future, an early response by PET may identify patients who do not have an additional benefit from post-CR radiation; this is a focus of a current intergroup trial, C50604.

Treatment of Unfavorable Early-stage Hodgkin Lymphoma

Many patients who are classified as having unfavorable early-stage HL (also known as intermediate stage HL) have a bulky mediastinal mass, although others will qualify as unfavorable on the basis of a high erythrocyte sedimentation rate or multiple nodal sites.

Combined modality therapy has long been the recommended therapy for this group of patients. The EORTC/GELA (Groupe d'Etude des Lymphoma de l'Adulte) H8U¹⁸³ study randomized patients to one of three treatment strategies, two of which were MOPP/ABV × 6 followed by involved field radiation and MOPP/ABV × 4 followed by involved field radiation. There was no statistical difference in 5-year FFS (84% vs. 88%) or the 10-year OS (88% vs. 85%). The same group's H9U study¹⁸⁷ randomized patients to ABVD × 6, ABVD × 4, or baseline BEACOPP, each followed by involved field radiation. The ABVD arms were

P.1996

equivalent, with 4-year FFS of 94% and 89%, respectively, and 4-year OS of 96% and 95%. BEACOPP was not more effective (4-year FFS 91%) and was more toxic. These studies established ABVD × 4 followed by 30 Gy involved field radiation as a standard for unfavorable early-stage HL.

The HD11 study of the German Hodgkin Study Group randomized 1,395 patients to either ABVD or baseline BEACOPP and further randomized them to involved field radiotherapy of 20 Gy or 30 Gy. Of these, 19.5% had a bulky mediastinal mass and 9.9% had an extranodal lesion. ABVD × 4 and 30 Gy was as effective (5-year PFS 87.2%) as BEACOPP and 30 Gy (87.9%) or BEACOPP and 20 Gy (87.0%), but ABVD × 4 and 20 Gy was inferior (82.1%). BEACOPP arms were more toxic. The authors concluded that ABVD × 4 and 30 Gy should be the standard in unfavorable early-stage HL because of superior tumor control and lower toxicity.¹⁹²

In an attempt to improve on the HD11 results, the German Hodgkin Study Group's HD 14 trial compared ABVD × 4 to escalated BEACOPP × 2 followed by ABVD × 3 (“2 + 2”), each followed by 30 Gy involved field radiation; 1,528 patients entered the study. The 2 + 2 arm was superior in PFS at 5 years (95.4% vs. 89.1%, $p < 0.001$) and OS was not significantly different. Toxicity was higher in the 2 + 2 arm as compared to the ABVD arm (at least one grade 3 or 4 toxicity 87.1% vs. 50.7%) and 4 patients (0.52%) died from toxicity in the 2 = 2 arm.¹⁹³ Despite the higher efficacy of the 2 + 2 arm, many would question the utility of the small increase in PFS without an increase in OS in this relatively short follow-up.

The current intergroup trial C50604 includes nonbulky unfavorable patients. Those who have a negative PET after two cycles will omit radiotherapy.

Therapy for lymphocyte predominant Hodgkin lymphoma is addressed after the section on Pregnancy.

FRONT-LINE THERAPY FOR ADVANCED-STAGE HODGKIN LYMPHOMA

Adriamycin (Doxorubicin), Bleomycin, Vinblastine, and Dacarbazine

Since the early 1990s, the treatment of patients with advanced-stage HL has relied on combination chemotherapy with ABVD (see Table 93.9). ABVD was first introduced by Bonadonna and colleagues in the late 1970s as an effective, non-cross-resistant chemotherapy option for patient with relapsed HL.¹⁴¹ Unlike MOPP (mechlorethamine, vincristine, procarbazine, and prednisone), the first successful combination chemotherapy regimen used in the treatment of HL, ABVD was not associated with sterility or secondary myelodysplasia or leukemia.^{154, 167} The success of ABVD in the second line setting eventually led to efforts to combine MOPP and ABVD in 12 alternating treatment cycles (MOPP/ABVD alternating regimen). As front-line therapy in patients with stage IV HL, MOPP/ABVD proved superior to MOPP alone with a FFP at 8 years of 64.6% versus 35.9% ($P < 0.005$) and 8-year OS rates of 83.9% versus 63.9% ($P < 0.06$).¹⁴³ In 1982, the Cancer and Leukemia Group B (CALGB) in the United States initiated a randomized multicenter trial in 361 patients with stage III-IV previously untreated HL, comparing MOPP for 6 to 8 cycles ($n = 123$), ABVD for 6 to 8 cycles ($n = 115$), and alternating MOPP/ABVD for 12 cycles ($n = 123$).²⁰⁰ In this trial, CR rate (67% MOPP, 82% ABVD, and 83% MOPP/ABVD, $P = 0.006$) and 5-year failure-free survival (FFS) (50% MOPP, 61% ABVD, and 65% MOPP/ABVD, $P = 0.02$) were superior in the ABVD and MOPP/ABVD arms, with less neutropenia, thrombocytopenia, and infectious toxicity in the ABVD arm (18%, 2%, and 2% ABVD, 47%, 36%, and 11% MOPP, and 53%, 28%, and 12% MOPP/ABVD, respectively).²⁰⁰ A subsequent randomized phase III US Intergroup trial compared ABVD and MOPP/ABV hybrid (combined MOPP and ABV drugs in each cycle rather than alternating cycles of MOPP and ABVD) for 8 to 10 cycles in 856 patients with stage III-IV HL. CR rates (76% vs. 80%, $P = 0.16$) and 5-year FFS rates (63% vs. 66%, $P = 0.42$) were similar in patients receiving ABVD or MOPP/ABV, respectively.¹⁵⁰ In this study, the 5-year FFS for patients with 0, 1, 2, 3, 4, and ≥ 5 risk factors by the International Prognostic Score (IPS),¹⁰¹ were 76%, 72%, 81%, 69%, 64%, and 67%, respectively; the 5-year OS was 82% using ABVD; and ABVD resulted in fewer pulmonary and hematologic toxicities, treatment-related deaths, and second malignancies including acute leukemia than observed with MOPP/ABV.¹⁵⁰ In a UK study comparing ABVD to other combination hybrid regimens (ChIVPP/PABIOE and ChIVPP/EVA), the 3-year EFS and OS with ABVD were 75% and 90%, respectively, once again similar to multidrug regimens, with less infectious and neurologic toxicity than observed with the hybrid regimens.²⁰¹ As a result of these trials, ABVD became the standard of care for initial therapy of advanced-stage HL; however, recently, two other combination chemotherapy regimens, Stanford V and BEACOPP (see Table 93.9), have challenged the role of ABVD as the standard front-line regimen in this patient population.

Stanford V

Stanford V, a multiagent combined modality regimen consisting of doxorubicin, vinblastine, mechlorethamine, vincristine, bleomycin, etoposide, and prednisone administered weekly over 12 weeks followed by 36 Gy consolidative radiotherapy to bulky mediastinal disease, tumor masses or lymphadenopathy ≥ 5 cm, and macroscopic splenic nodules, was designed to reduce the total doses of bleomycin and adriamycin. In initial phase II trials, respectively, the 5-year FFP utilizing this regimen was 85% to 89% in patients with bulky stage I-II and advanced-stage HL.^{202, 203} In a randomized Italian trial in 355 patients with stage IIB, III, and IV HL comparing six cycles of ABVD ($n = 122$), 12 weeks of Stanford V ($n = 107$), and six cycles of MOPPEBVCAD (mechlorethamine, vincristine, procarbazine, prednisone, epidoxorubicin, bleomycin, vinblastine, lomustine, doxorubicin, and vindesine), 5-year FFS were 78%, 54%, and 81%, respectively ($P < 0.01$).²⁰⁴ However, in this trial, radiation was only given to sites of initial bulky disease or sites of residual disease post-chemotherapy, and only 66% of patients receiving Stanford V also received radiation in the Italian study, compared to 91% in the prior single institution trial.^{202, 204} At 10 years of follow-up, 10-year FFS were 75%, 74%, and 49% ($P < 0.001$) and 10-year OS were 87%, 80%, and 78% ($P = 0.4$) for the ABVD, MOPPEBVCAD, and Stanford V arms, respectively; however, in looking at Stanford V patients treated with and without radiotherapy, 10-year DFS was statistically in favor of those patients receiving radiation (76% vs. 33%, $P = 0.004$).²⁰⁵ In a subsequent multicenter UK study in 520 patients with stage IIB, III, IV, or bulky stage I-II HL, there were no differences in 5-year FFS and OS in patients receiving six to eight cycles of ABVD (53% patients received radiation to sites of residual disease) or 12 weeks of Stanford V (73% patients received radiation to disease sites >5 cm or splenic nodules).²⁰⁶ More pulmonary toxicity was observed in the ABVD arm in this trial, although myelosuppression and neuropathy were slightly worse with Stanford V. A randomized phase III US Intergroup trial, conducted from 1999-2006, demonstrated no significant difference in 5-year FFS (73% vs. 71%, $P = 0.29$) or 5-year OS (88% vs. 87%, $P = 0.87$) in 812 patients with bulky stage I-II, III, or IV HL receiving six to eight cycles of ABVD with radiation to bulky mediastinal disease or 12 weeks of Stanford V chemotherapy with radiotherapy to disease >5 cm or splenic nodules, respectively.²⁰⁷ With

median follow-up of 5.25 years, 26 second malignancies were observed (14 ABVD and 12 Stanford V). Therefore, as a result of these trials, six cycles of ABVD has remained the standard treatment for patients with advanced-stage HL; however, Stanford V may be acceptable in patients

P.1997

where a shortened treatment duration or reduction in cumulative doses of bleomycin or adriamycin is desirable. Long-term follow-up is needed from the UK and US intergroup trials to determine the risks of second malignancies, particularly with Stanford V, as additional radiotherapy is required per the treatment protocol in the majority of patients.

Bleomycin, Etoposide, Doxorubicin, Cyclophosphamide, Vincristine, Procarbazine, and Prednisone

Intensification of initial therapy is one approach to improving outcomes in patients with advanced-stage HL. However, this approach may lead to increased short-term and long-term toxicity that may ultimately have a negative impact on OS, particularly in lower-risk patients. The German Hodgkin study group HD9 trial randomized patients ages 15 to 65 with stage IIB, III, and IV HL to either eight cycles of COPP/ABVD (cyclophosphamide, vincristine, procarbazine, and prednisone alternating with ABVD), BEACOPP-baseline, or BEACOPP-escalated (esc).²⁰⁸ With 10 years of follow-up, FTF was 64%, 70%, and 82% with OS of 75%, 80%, and 86% in the COPP/ABVD, BEACOPP-baseline, and BEACOPP-esc arms, respectively.²⁰⁹ By IPS, FTF at 5 years was 92%, 87%, and 82% with BEACOPP-esc for patients with 0 to 1, 2 to 3, and 4 to 7 risk factors, respectively.²⁰⁸ However, it is important to note that only 13% of patients receiving BEACOPP-esc had 4 to 7 risk factors on this trial, and although differences in FTF were significantly in favor of BEACOPP-esc among all three risk groups, statistically significant improvements in OS were only observed in patients with IPS scores of 2 to 3 ($P = 0.27$ for IPS 0-1, $P < 0.0027$ for IPS 2-3, and $P = 0.16$ for IPS 4-7).²⁰⁹ When analyzed by age, there was not a significant improvement in FTF and OS for patients ages 60 to 65 and increased toxicity occurred with BEACOPP-esc. Therefore, BEACOPP-esc is not recommended in patients over the age of 60.²⁰⁸ In an attempt to reduce toxicity, the HD12 trial examined eight cycles of BEACOPP-esc versus four cycles of BEACOPP-esc plus four cycles of BEACOPP-baseline.²¹⁰ Five-year FTF and OS were 86.4% and 92%, respectively with eight BEACOPP-esc compared to 84.8% and 90.3% with 4 + 4 arm, and toxicities were not significantly reduced with the 4 + 4 approach.²¹⁰

In a randomized Italian study comparing six cycles of ABVD with four cycles of BEACOPP-esc plus two cycles BEACOPP-baseline,²¹¹ 5-year PFS was superior for BEACOPP (81%) compared to ABVD (68%), although there were no differences in OS perhaps due to the smaller numbers of patients¹⁵⁰ on this trial compared to the 1,201 patients on the previous German HD9 trial. In a second Italian cooperative group study, the 7-year rate of freedom from first progression was 85% in patients receiving four cycles of BEACOPP-esc plus four cycles BEACOPP-baseline compared to 73% in patients receiving six to eight cycles of ABVD ($P = 0.004$).²¹² In this same trial, the 7-year rate of freedom from second progression was 88% in the BEACOPP group compared to 82% in the ABVD group ($P = 0.12$), suggesting that long-term outcomes may not differ between the two regimens when one factors in the efficacy of salvage chemotherapy and autologous stem cell transplant following ABVD.²¹²

Despite the success of the BEACOPP-esc regimen compared to hybrid regimens and ABVD in patients ≤ 60 years of age, this regimen is associated with infertility and a 6.0% second malignancy rate, including a 3.2% incidence of secondary AML/MDS.^{209, 213} In addition, BEACOPP-esc is associated with more acute toxicities including hematologic and infectious complications than observed with ABVD.²¹¹ Therefore, although several studies demonstrate the superiority of BEACOPP-esc with respect to PFS in patients with advanced-stage HL, it remains unclear if the risks of second malignancies, infertility, and acute infections associated with BEACOPP-esc are justified to improve patient outcomes in all patients with advanced-stage HL, especially if relapsing patients after ABVD can be effectively salvaged with high-dose therapy and stem cell transplantation. Current studies are examining the role of reduction of total cycles of BEACOPP-esc and PET-directed approaches that may maintain the advantage of improved disease control observed with BEACOPP-esc while reducing acute and late toxicities or at least limiting exposure to those patients at highest risk. However, these approaches utilizing interim PET/CT to reduce total number of cycles of BEACOPP-esc in patients who have negative interim PET/CT or to limit exposure to BEACOPP-esc to only the most unfavorable patients with interim positive PET/CT remain under investigation and long-term follow-up will be needed to assess for late toxicities that affect OS. Currently ABVD, Stanford V, and BEACOPP-esc are all accepted front-line therapy in patients with advanced-stage HL.

Radiation Therapy as Consolidation in Stage III-IV Hodgkin Lymphoma

Several studies have examined the role of consolidative radiotherapy in patients with advanced-stage HL, and to date, no study has demonstrated a clear OS advantage with combined modality therapy in patients achieving a CR or PR with chemotherapy alone. The H89 GELA study randomized 533 patients with stage III-IV HL to six cycles of MOPP/ABV hybrid

or six cycles of ABVPP followed by either two more cycles of chemotherapy or subtotal nodal radiation for patients achieving a CR or PR after six cycles.²¹⁴ In the chemotherapy alone arms 10-year OS was superior (90% for ABVPP × 8, 78% for MOPP/ABV × 8, 82% for MOPP/ABV × 6 with radiation, and 77% for ABVPP × 6 with radiation, $P = 0.03$). Using an ABVD backbone, Laskar and colleagues demonstrated an improvement in 8-year EFS and OS with chemotherapy and involved field radiotherapy in patients achieving a CR; however, this trial was small with only 179 patients randomized to observation versus radiotherapy and included all stages ($n = 80$ with stage III-IV disease).²¹⁵ A larger, although nonrandomized, UK study restricted to advanced-stage HL patients analyzed outcomes in 807 patients treated with six cycles of ABVD, CHLVPP/PABIOE, or CHLVPP/EVA, and involved field radiotherapy to sites of residual masses or bulky disease. A total of 300 patients (43%) received involved field radiotherapy, and although non-RT patients tended to be more often in CR, 5-year EFS was 86% with RT and 71% without RT ($P < 0.001$) and 5-year OS was 93% with RT and 87% without RT ($P < 0.001$).²¹⁶ In contrast, a randomized study of 739 patients with advanced-stage HL assigned patients with a CR after six to eight cycles of MOPP/ABV hybrid to observation or involved field RT, and demonstrated no difference in 5-year OS ($P = 0.07$) or EFS ($P = 0.35$) in the radiotherapy ($n = 172$, OS of 85% and EFS of 79%) group compared to the observation group ($n = 161$, OS of 91% and EFS of 84%).²¹⁷ The HD12 trial randomized responding patients after BEACOPP with stage IIB, III, and IV HL and with bulk or residual tumor on CT imaging to either additional consolidative RT or no RT.²¹⁰ In this trial, 1,085 patients received initial BEACOPP therapy, 207 required no RT due to lack of bulky disease or CR; 148 received RT due to less than a PR to chemotherapy (less than 50% tumor reduction); and 730 patients were randomized to RT or no RT. At 5 years, FTF was 87% in those patients who did not receive RT, compared to 90.4% in the RT arm ($P = 0.08$).²¹⁰ Therefore, based on these studies, it appears that consolidation with IFXRT does not improve outcomes in patients achieving a CR after combination chemotherapy, although additional studies need to be done in patients with a PR, particularly utilizing a PET-based response determination. In one such trial, the HD15 trial, patients with stage IIB, III, and IV HL received involved field radiotherapy after six to eight cycles of BEACOPP if they had residual disease more than 2.5 cm and were PET positive. In this study, 311 of 1,788 enrolled had residual disease

P.1998

>2.5 cm on CT and PET was positive in 66 of these patients.²¹⁸ With 1 year of follow-up, PFS for the PET-negative patients who were not radiated was 96% and for the PET-positive patients was 85% ($P = 0.011$), and therefore PET-directed radiotherapy may be feasible in this population.²¹⁸ In addition, as demonstrated by the GELA study,²¹⁴ prolonged follow-up beyond 10 years is needed from these trials to determine if OS is adversely affected with the incorporation of involved field radiotherapy at the end of therapy in patients with advanced-stage HL due to the potential late complications of second malignancies and cardiovascular disease related to the radiotherapy.

Autologous Transplant as Consolidation in Stage III-IV Hodgkin Lymphoma

Several trials have examined the role of autologous transplant to improve outcomes in patients with high-risk, advanced-stage HL, and to date none have demonstrated a role for this following standard ABVD chemotherapy. A European intergroup trial randomized 163 patients with stage III-IV HL and two risk factors (elevated LDH, bulky disease, stage IV with two or more extranodal sites, anemia, or inguinal involvement) achieving a CR or PR after four cycles of ABVD or doxorubicin containing induction (MOPP/ABVD, MOPP/ABV, CVPP/ABV) to either four additional cycles of the same induction chemotherapy or autologous stem cell transplantation after BEAM (carmustine, etoposide, cytarabine, and melphalan) or CBV (cyclophosphamide, carmustine, and etoposide) conditioning regimens.²¹⁹ The 5-year FFS with continued chemotherapy was 82% compared to 75% ($P = 0.4$) with consolidative autologous transplantation, and the 5-year OS were 88% and 88% ($P = 0.99$), demonstrating no clear benefit from early high-dose consolidation in high-risk advanced-stage HL. Two other studies using hybrid induction chemotherapy regimens versus chemotherapy followed by myeloablative transplant in 126 to 158 high-risk patients also similarly demonstrated no difference in OS with front-line transplantation.^{220, 221}

Future Directions/Upcoming Studies in Frontline Therapy for Stage III-IV Hodgkin Lymphoma

In the future, therapy for advanced-stage HL may be tailored based on a patient's pre-treatment risk factors (clinical or selected biologic markers) or on results of interim PET/CT. In previous studies, 2-year PFS for patients with a positive PET/CT after two cycles of ABVD were 12.8% compared to 95% for interim PET/CT negative patients ($P < 0.0001$), and interim PET/CT results were more predictive of outcome than IPS score in multivariate analysis.²²² Although the prognostic potential of PET/CT may be dependent on initial treatment, timing of scans, and definitions of PET negativity, PET/CT does represent an important tool that may in the future direct therapy. To date, altering therapy based on interim PET/CT results remains investigational; however, a number of trials are ongoing examining this question in patients with advanced-stage HL. Risk-adapted therapy was first described by Dann et al., who prospectively assigned 108 patients with

unfavorable HL (stages I-II with risk factors, B-symptoms, or bulky disease and stages III-IV) to either two cycles of BEACOPP-esc if IPS score ≥ 3 or BEACOPP-baseline if IPS < 3 followed by interim PET/CT or gallium scan.²²³ Patients with a positive interim scan received four more cycles of BEACOPP-esc and those with a negative interim scan received four cycles of BEACOPP-baseline. Using this IPS and imaging directed therapeutic approach resulted in 5-year EFS and OS of 85% and 90%, respectively.²²³ Currently, UK and US intergroup studies are exploring intensification of therapy in patients who are interim PET/CT positive after two cycles of initial ABVD therapy, and the German Hodgkin Study Group HD18 trial is reducing therapy after two cycles of initial BEACOPP-esc in patients who are interim PET/CT negative. Central review of interim PET/CT is critical in these studies using PET/CT to alter treatment approaches. In addition to efforts to risk-stratify therapy based on initial high-risk features or interim PET/CT, efforts are also being made to incorporate promising new therapies into traditional ABVD backbones to improve outcomes in advanced-stage HL further. Brentuximab vedotin, a CD-30 antibody-drug conjugate, which is FDA-approved for the treatment of relapsed and refractory HL and is further described below, has recently been added to the ABVD regimen.²²⁴ In this phase I trial, patients with stage III-IV HL received ABVD with escalating doses of brentuximab vedotin ranging from 0.6 to 1.2 mg/kg on days 1 and 15 of each 28-day cycle. Initial toxicities included significant pulmonary toxicity, leading to removal of bleomycin from the regimen and treatment of an expanded cohort of patients with AVD plus brentuximab.²²⁴ Randomized studies in patients with bulky stage II, III, and IV HL comparing the AVD plus brentuximab regimen to traditional ABVD are planned, but this may offer an alternative strategy for improving therapy in high-risk patients using a novel targeted agent and may ultimately become an attractive option in young, high-risk patients with less risk of secondary malignancies or infertility than intensification with BEACOPP-esc. However, long term follow-up will be needed from randomized studies comparing AVD plus brentuximab with ABVD and BEACOPP-esc to determine the efficacy and risks with AVD plus brentuximab before this approach to therapy is accepted in advanced-stage patients.

THERAPY FOR RELAPSED OR REFRACTORY HODGKIN LYMPHOMA

Salvage Therapy and Autologous Hematopoietic Cell Transplant

Salvage chemotherapy followed by autologous stem cell transplant is the standard of care for patients with relapsed or refractory HL (Chapter 104). With respect to salvage regimens prior to autologous transplant, patients typically receive two to three cycles and then proceed to transplant. However, there are no randomized data on optimal salvage regimens and numerous options exist. Regimens include ICE (ifosfamide, carboplatin, etoposide), GVD (gemcitabine, vinorelbine, liposomal doxorubicin), DHAP (dexamethasone, cytarabine, cisplatin), ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin), GDP (gemcitabine, dexamethasone, and cisplatin), IGEV (ifosfamide, gemcitabine, vinorelbine, prednisolone), mini-BEAM (carmustine, etoposide, cytarabine, melphalan), and Dexa-BEAM (dexamethasone, carmustine, etoposide, cytarabine, melphalan; see Table 93.10) with responses ranging from 70% to 90%.^{225, 226, 227, 228, 229, 230, 231, 232, 233} Ideally, the salvage regimen chosen should result in a high overall response rate with acceptable toxicity and not impair stem cell mobilization if transplantation is planned.

In 1997, physicians at Stanford University compared outcomes for 60 patients with relapsed or refractory HL treated with a non-cross-resistant combination therapy until maximal response followed by autologous transplant with 103 matched historical patients receiving chemotherapy alone.²³⁴ The 4-year OS, EFS, and FFP were 54% versus 47% ($P = 0.25$), 53% versus 27% ($P < 0.01$), and 62% versus 32% ($P < 0.01$), respectively, favoring transplant compared to conventional salvage therapy. The British National Lymphoma Group randomized 40 patients with relapsed HL to either BEAM (carmustine, etoposide, cytarabine, and melphalan) followed by autologous transplant or mini-BEAM alone, demonstrating a significant PFS benefit ($P = 0.005$) with transplantation.²³⁵ A larger trial of 161 chemosensitive patients randomized to two cycles of Dexa-BEAM and autologous transplant

P.1999

or two further cycles of Dexa-BEAM demonstrated a 3-year FFTF of 55% with transplantation compared to 34% without transplant ($P = 0.019$).²²⁹ However, neither trial demonstrated an OS benefit perhaps due to limited follow-up or small patient numbers.

TABLE 93.10 SALVAGE COMBINATION CHEMOTHERAPY REGIMENS UTILIZED FOR RELAPSED OR REFRACTORY HODGKIN LYMPHOMA

GVD (not previously transplanted) ²²⁷	Gemcitabine 1,000 mg/m ²	IV	Days 1 and 8	Q21d
	Vinorelbine 20 mg/m ²	IV	Days 1 and 8	

GVD (previously transplanted) ²²⁷	Liposomal doxorubicin 15 mg/m ²	IV	Days 1 and 8	Q21d
	Gemcitabine 800 mg/m ²	IV	Days 1 and 8	
	Vinorelbine 15 mg/m ²	IV	Days 1 and 8	
ICE ²²⁶	Liposomal doxorubicin 10 mg/m ²	IV	Days 1 and 8	Q14d
	Ifosfamide 5,000 mg/m ²	IV over 24 h	Day 2	
	Mesna 5,000 mg/m ²		Day 2	
	Etoposide 100 mg/m ²	IV over 24 h	Days 1-3	
DHAP ²³¹	Carboplatin AUC = 5 (maximum dose of 800 mg)	IV	Day 2	Q21d
		IV		
	Dexamethasone 40 mg	IV/PO	Days 1-4	
	Cisplatin 100 mg/m ²	IV over 24 h	Day 1	
ESHAP	Cytarabine 2,000 mg/m ²	IV every 12 h	Day 2	Q21d
	Etoposide 40 mg/m ²	IV	Days 1-4	
	Methylprednisolone 500 mg	IV	Days 1-5	
	Cytarabine 2,000 mg/m ²	IV	Day 5	
Mini-BEAM ²³²	Cisplatin 25 mg/m ²	CIV	Days 1-4	Q21-28d
	BCNU (carmustine) 60 mg/m ²	IV	Day 1	
	Etoposide 75 mg/m ²	IV	Days 2-5	
	Cytarabine 100 mg/m ²	IV every 12 h	Days 2-5	
Dexa-BEAM ²³³	Melphalan 30 mg/m ² (maximum of 50 mg)	IV	Day 5	Q28d
	Dexamethasone 24 mg	PO	Days 1-10	
	BCNU (carmustine) 60 mg/m ²	IV	Day 2	
	Melphalan 20 mg/m ²	IV	Day 3	
	Etoposide 200 mg/m ²	IV every 12 h	Days 4-7	
	Cytarabine 100 mg/m ²	IV every 12 h	Days 4-7	
IGE ²²⁵	GCSF 300-480 μg	IV every 12 h	Day 9 until WBC >2,500/μl	Q21d
		SQ		
	Ifosfamide 2,000 mg/m ²	IV	Days 1-4	
	Gemcitabine 800 mg/m ²	IV	Days 1 and 4	
GDP ²³²	Vinorelbine 20 mg/m ²	IV	Day 1	Q21d
	Prednisolone 100 mg	PO	Days 1-4	
	Gemcitabine 1,000 mg/m ²	IV	Days 1 and 8	
	Cisplatin 75 mg/m ²	IV	Days 1 and 8	

ChlVPP ²⁴⁸	Dexamethasone 40 mg	PO	Days 1-4	
	Chlorambucil 6 mg/m ²	PO	Days 1-14	Q28d
	Vinblastine 6 mg/m ²	IV	Days 1 and 8	
	Procarbazine 100 mg/m ²	PO	Days 1-14	
	Prednisone 40 mg	PO	Days 1-14	
Brentuximab Vedotin ¹⁹⁴	1.8 mg/kg (capped at maximum of 100 kg)	IV	Day 1	Q21d

For patients who are refractory to front-line or salvage therapy, PFS of 25% to 38% with high-dose therapy and hematopoietic cell transplantation (HCT) have been reported,^{236, 237, 238} suggesting that these patients also benefit from transplantation, although not unexpectedly with inferior outcomes compared to patients with chemosensitive disease. These studies are limited by differing definitions of refractory disease, the fact that many of the patients received MOPP containing inductions which is inferior to standard ABVD, and that few patients who did not respond to salvage therapy were transplanted. For example, in 86 patients of whom 91% failed to achieve a CR with front-line hybrid regimens and 9% had disease progression within 3 months of completing front-line therapy, 62% responded to salvage therapy and 24% progressed.²³⁸ All patients did undergo HCT and 5-year EFS and OS were 25% and 35%, respectively, with response to salvage therapy significantly associated with survival in multivariate analysis.²³⁸ In a retrospective review of 122 patients who failed to achieve a CR after at least one induction combination chemotherapy regimen and underwent autologous transplant between 1989-1995 at centers participating in the Autologous Bone and Marrow Transplant Registry, 56% had a CR or PR with pretransplant salvage and 44% had less than a PR.²³⁷ Similar to the previous trial, 3-year PFS and OS were 38% and 50%, respectively.²³⁷ A retrospective study from Vancouver also demonstrated 15-year OS of 39% in patients with refractory disease to initial induction therapy, compared to 67% in chemosensitive patients.²³⁹ In a retrospective analysis of 175 patients with SD or PD to initial induction and who also failed to respond according to CT findings to salvage therapy, 5-year OS and PFS were 36% and 32%.²³⁶ In multivariate analysis, > 18 months interval between diagnosis and HCT was favorably associated with OS. Therefore, in patients with primary refractory disease defined either as failure to achieve a CR on CT (not PET/CT) with front-line chemotherapy or a short remission duration who respond to salvage therapy, high-dose therapy with HCT may lead to prolonged durable remissions. Fewer data are available in those patients who fail to respond to salvage therapy.

Although the study by Sweetenham suggests that some patients who are refractory to salvage therapy may benefit from HCT,²³⁶ PET/CT may be helpful in guiding treatment approaches for these patients. A number of studies have recently demonstrated the prognostic value of FDG PET/CT pre-transplant, with EFS/PFS of

P.2000

10% to 31% in patients who are PET positive compared to 68% to 93% for patients with a negative PET/CT prior to HCT.^{240, 241, 242} Using PET/CT to determine eligibility for HCT remains investigational, however, it is reasonable to recommend two to three cycles of salvage chemotherapy, confirmation of response by PET/CT, and then autologous stem cell transplantation in responding patients. For those patients with clearly progressive disease on PET/CT, alternative salvage regimens should be offered and if patients respond, autologous transplant could be considered. For those patients with improving disease on CT scan, but persistent PET positivity prior to autologous transplant, HCT is still recommended based on previous retrospective data and possibility of false-positive PET/CT^{237, 238}; however, further prospective study is needed in this patient population that incorporates centrally reviewed PET/CT into the response assessment and transplant determination.

Tandem transplantation or sequential high-dose therapy has also been evaluated with poor risk or refractory disease and remains investigational. In the largest multicenter trial of 247 patients, 105 patients with primary refractory (defined as less than a PR or progression within the first 90 days from induction doxorubicin containing chemotherapy) or at least two risk factors (time to relapse <12 months, stage III-IV at relapse, or relapse within irradiated sites) underwent tandem ASCT and 95 patients with intermediate risk disease (only 1 risk factor) received a single transplant. In this study, 5-year FFP and OS were 73% and 85%, respectively, in the intermediate risk group; and 46% and 57%, respectively, for the high-risk group who underwent tandem transplant which compares favorably to historically observed 3- to 5-year PFS of 25% to 39% in primary refractory patients.²⁴³ However, in a second trial, use of sequential high-dose conditioning regimens (i.e., high-dose cyclophosphamide, methotrexate, and etoposide followed by BEAM and then HCT) did not improve FTF or OS over

standard BEAM and HCT.²⁴⁴ Therefore, single versus tandem transplant and use of sequential high-dose conditioning regimens remains investigational in patients with relapsed HL.

Therapeutic Options for Patients Relapsing after Autologous Hematopoietic Cell Transplantation

Although many of the previously discussed combination salvage regimens including ICE, GVD, DHAP, ESHAP, GDP, and IGEV have significant activity in patients with HL that has progressed after autologous HCT, often the goals in this patient population are palliation, with minimization of symptoms as well as treatment-related toxicity. Furthermore, prolonged therapy over several months rather than two to three cycles may be necessary to control disease. Therefore, single-agent regimens are often preferred and combination regimens reserved for patients with organ involvement or significant disease-related symptoms. A number of single-agent regimens can be utilized in this setting and include vinblastine, etoposide, gemcitabine, and vinorelbine. With vinblastine, 4 to 6 mg/m² weekly or every 2 weeks until disease progression or toxicity, response rates as high as 59% and median EFS of 14 months have been reported.²⁴⁵ Gemcitabine and vinorelbine both have single-agent activity in 39% to 50% of patients.^{246, 247} Combination therapy with ChIVPP (chlorambucil, vinblastine, procarbazine, and prednisone) also has activity in this patient population.²⁴⁸ Selected patients with nonbulky lymphadenopathy and no organ involvement who are otherwise asymptomatic could also be observed in this setting.

Radiotherapy should also be considered in the setting of relapsed HL. In a retrospective analysis of salvage radiotherapy used in 100 patients at first treatment failure, typically after COPP/ABVD initial therapy, 5-year FFTF and OS were 28% and 51% with radiotherapy alone.²⁴⁹ Advanced stage at relapse and B-symptoms adversely affected OS in multivariate analysis.²⁴⁹ Therefore, in highly selected patients with limited-stage disease at relapse who may not be eligible for autologous HCT due to age and co-morbid conditions, involved field radiotherapy may lead to prolonged remissions. For younger patients with relapsed HL, due to potential risks of second malignancies within the radiation field and improved survival with autologous stem cell transplantation, radiotherapy alone is not recommended at first relapse. However, involved field radiotherapy should be considered in these patients as consolidation post-autologous transplant to bulky, nonirradiated sites or to sites of relapsed limited-stage disease in previously nonirradiated fields. For those patients with limited-stage relapse post-transplantation, radiotherapy may lead to prolonged remissions and delay the need for palliative chemotherapy.

Brentuximab Vedotin (SGN-35)

Recently, the Food and Drug Administration approved brentuximab vedotin, a novel anti-CD30 drug-antibody conjugate for the treatment of patients with relapsed or refractory HL after previous stem cell transplant. Brentuximab vedotin is comprised of a CD30 antibody conjugated by a plasma-stable linker to the antimicrotubule agent, monomethyl auristatin E. In phase I testing, the maximum tolerated dose was 1.8 mg/kg every 3 weeks with an overall response rate of 38% in 45 patients, including 11 CRs.²⁵⁰ In a pivotal phase II study with 102 patients with relapsed (29%) or refractory (71%) HL who had previously received a median of 3.5 prior therapies (range 1 to 13), the ORR was 75% with a 34% CR rate.¹⁹⁴ The median duration of response was 20.5 months in this trial and grade 3 to 4 toxicity consisted of sensory neuropathy (5%), fatigue (2%), neutropenia (14%), and thrombocytopenia (3%).¹⁹⁴ Therefore, with its significant single-agent activity and tolerability, brentuximab vedotin should be considered as initial therapy for patients with relapsed HL post-autologous transplantation. Brentuximab vedotin may be administered for up to 16 cycles, with dose reductions or delays if needed for myelosuppression or neuropathy.

On the basis of this striking efficacy and tolerability in a heavily pre-treated relapsed and refractory patient population, brentuximab vedotin has recently been added to ABVD chemotherapy in a phase I trial in patients with stage IIB, III, and IV previously untreated HL.²²⁴ Due to increased risks of bleomycin toxicity (40% incidence in 25 patients treated with ABVD + brentuximab vedotin), the study has dropped bleomycin from the combination and is currently examining AVD in combination with brentuximab vedotin utilizing brentuximab vedotin at 1.2 mg/kg days 1 and 15 of each cycle.^{224a} There are 26 patients who have received AVD + brentuximab vedotin without bleomycin and no pulmonary toxicity has been observed now that the bleomycin has been dropped from the treatment regimen. An international study sponsored by Seattle Genetics/Millennium randomizing patients with stage III and IV HL to ABVD × 6 cycles versus AVD + brentuximab vedotin × 6 cycles is in development as are multicenter phase 2 studies using this agent alone and in combination with ICE as pre-transplant salvage therapy, and in the future it is hoped we will determine if it is safe to incorporate this agent into front-line therapy, the effect of this agent on stem cell mobilization, and if PFS and OS are improved with the addition of brentuximab to front-line or pre-transplant therapy.

Allogeneic Transplant

Allogeneic HCT has been used for patients with relapsed HL after prior autologous transplant, although the presence of a graft-versus-Hodgkin lymphoma effect remains controversial.²⁵¹ Most trials of allogeneic transplant in HL demonstrate 2-year PFS rates of 30% and OS of 35% to 60%. A European Blood and Marrow Transplantation trial compared reduced intensity

P.2001

(n = 89) to myeloablative (n = 79) allogeneic HCT.²⁵² In this trial, with reduced intensity conditioning, 1-year treatment-related mortality (TRM) was 23% and 5-year OS was 28%, compared to 46% 1-year TRM and 5-year OS of 22% with myeloablative conditioning. In the reduced intensity group 5-year PFS was 18%. Other prospective and retrospective studies have reported 2- to 3-year PFS of 25% to 32% and OS of 43% to 64% with reduced intensity conditioning allogeneic stem cell transplantation in patients with relapsed HL.^{253, 254} Overall, these studies and others demonstrate that in selected patients with available donors, reduced intensity allogeneic stem cell transplantation is an option for patients with relapsed or refractory HL after prior autologous transplantation and may lead to prolonged DFSs in 18% to 30% of patients.

HODGKIN LYMPHOMA IN THE ELDERLY

Older patients with HL have generally been underrepresented in clinical trials. Outcomes in this population are inferior to those in younger patients, most likely because of more frequent co-morbid conditions in older patients. This may lead to dose attenuation and loss of dose density and thus inferior outcomes.

Fit older patients without limiting co-morbidities may be candidates for treatment with standard ABVD-based protocols, as long as there is normal cardiac and pulmonary function. Data regarding the outcome and toxicity of this approach is limited, however. The GHSG reported that grade 3 to 4 toxicity occurred in 67% and 69% of patients with a median age of 65 and 64 years receiving ABVD × 4 on the HD 10 and HD 11 studies;^{255, 256} they included a prospective stratification of elderly (age 66 to 75 years) patients randomized to COPP/ABVD or BEACOPP (standard dose). The complete remission rate and OS rate were similar; however, the rate of toxic death during the treatment was 21% (9 of 42 patients) in the BEACOPP group as opposed to 8% in the COPP/ABVD group. Thus most would consider BEACOPP inappropriate for even the fit elderly.

Recently the GHSG published their experience with PVAG (prednisone 40 mg/m² days 1-5, vinblastine 6 mg/m² day 1, doxorubicin 50 mg/m² day 1, and gemcitabine 1,000 mg/m² day 1, repeated every 21 days) in patients 60 to 75 years old with early unfavorable or advanced HL. Patients received six to eight cycles of PVAG and radiotherapy was added for patients not in complete remission after chemotherapy.²⁵⁷ PFS and OS were 58% and 66% of 59 patients. Grade 3 or 4 toxicity was reported in 73%, but there was only one toxic death.

HODGKIN LYMPHOMA AND HUMAN IMMUNODEFICIENCY VIRUS

Although HL is not considered an AIDS-defining illness, the incidence of HL is increased perhaps tenfold among patients with HIV infection.^{27, 28, 258, 259} In contrast to patients without HIV infection, HL in patients with HIV infection is most commonly of the mixed cellularity subtype and is associated with B symptoms and with advanced stage, commonly due to bone marrow involvement.²⁶⁰ Despite the excellent results seen in patients with advanced-stage HL in the absence of HIV infection, early in the AIDS epidemic, median survival in HIV-positive patients with HL was poor, generally <2 years.²⁶⁰ With the advent of immune reconstitution with highly active antiretroviral therapy, outcomes approach those in the HIV-negative population using standard chemotherapy.^{261, 262, 263} As in the general population, an interim PET scan is highly predictive of good outcome.²⁶⁴

HODGKIN LYMPHOMA AND PREGNANCY

Because HL is commonly seen in women of childbearing years, it is not surprising that HL may occur in women who are pregnant. This problem has been extensively reviewed;¹⁶⁸ although agreement regarding optimal management of these patients does not exist, several key observations have been made, and guidelines for therapy have been advocated. Pregnancy does not affect the course of HL as compared to age-adjusted controls with Hodgkin disease who are not pregnant.²⁶⁵

Staging of the pregnant patient with HL must be modified to decrease the risks associated with radiation exposure of the fetus. Such an evaluation must be performed in the context of treatment planning. If the overall plan is to delay treatment until after delivery, unless bulky disease is found, then a modified approach to staging is reasonable. A chest radiograph, complete blood counts, liver and renal function tests, serum lactic dehydrogenase, and bone marrow biopsy are indicated.

Abdominal ultrasound is probably adequate to establish or rule out the presence of extensive abdominal disease, but more accurate staging must be deferred until after pregnancy as pregnancy precludes the use of CT or PET scans.

The risk of fetal malformations is approximately 15% when chemotherapy is given in the first trimester, but there is no evidence of an increase in fetal malformations when chemotherapy is given in the second and third trimester.²⁶⁶ The risk of late sequelae of chemotherapy to the fetus is unknown. Therefore, unless disease is clearly bulky and symptomatic, one can consider following patients to term if disease is diagnosed in the late second or third trimester.

If a decision is made to delay therapy until after delivery, the patient should be monitored closely, and the clinical plan should be re-evaluated if progressive disease is noted. If chemotherapy is given during pregnancy, it is probably best to avoid chemotherapy during the 3 weeks before delivery to avoid having the baby be neutropenic at birth.

THERAPY FOR LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA

With respect to treatment for NLPHL, no standard front-line or relapsed therapy exists, although a number of options are available. In the large German Hodgkin Study Group series, outcomes for these patients appears to be excellent, with ORR of 85% to 91% in patients with early-stage NLPHL compared to ORR of 83% to 86% in patients with early-stage classical HL treated with the same regimens.⁶⁹ For advanced-stage patients, outcomes are similarly good with ORR of 78% in patients with NLPHL compared to 78% in patients with stage III-IV classical HL. FTF at 50 months was 88% in patients with NLPHL and 82% for patients with classical HL. Interestingly, late relapses >1 year after therapy are observed more commonly in patients with LPHL (7.4%) compared to classical HL (4.7%). Adverse prognostic factors in LPHL include advanced stage, hemoglobin < 10.5 g/dl, age ≥ 45 years, and lymphopenia (< 8% of total white cell count).⁶⁹

For early-stage NLPHL, typically involved field radiotherapy alone or in combination with rituximab or chemotherapy is recommended. However, given the excellent long-term survivals of these patients, the risks of late secondary malignancies and cardiovascular disease must be considered. In a single institution study of 113 patients with stage I-II NLPHL, 93 patients were treated with radiation alone, 13 patients received combined-modality therapy, and 7 received

P.2002

chemotherapy alone.^{194a} Of 106 patients receiving radiotherapy, 20 relapsed (19%), compared to 6 of 7 patients treated with chemotherapy alone; 10-year PFS for stage I and II patients treated with radiotherapy were 89% and 72%, respectively. No differences were observed in patients treated with extended field, regional, or limited field radiotherapy and the use of combined modality therapy did not improve PFS or OS over radiotherapy alone. However, 12 patients receiving radiotherapy did develop second cancers, 5 of which were fatal. The GHSG evaluated 131 patients with stage IA LPHL treated with extended field (n = 45), involved field (n = 45), and combined modality treatment (n = 41), and found a FTF rate of 95% and OS of 99% at 43 months, with no differences with respect to FTF or OS among the three treatment arms.^{69a} In this series, only one secondary cancer was observed, gastric carcinoma in the extended field group. In a retrospective evaluation from the Australasian Radiation Oncology Group of 202 patients with stage I-II NLPHL treated with radiotherapy alone, the 15-year FTF and OS were 83% and 82%, respectively.¹⁹⁵ Second malignancies included NHL (n = 9), acute leukemia (n = 1), and 18 carcinomas including breast, lung, GI, melanoma, and unknown primary carcinomas. Deaths due to cardiac and respiratory complications after radiotherapy occurred in 9 patients. In contrast to these three trials demonstrating excellent PFS and OS with RT alone in early-stage NLPHL, a retrospective comparison of 32 patients treated with RT alone versus 56 patients receiving combined modality therapy with ABVD × 2 cycles and RT demonstrated improved PFS survival (65% vs. 91%, P = 0.0024) with combined modality therapy as compared to radiation alone.¹⁹⁶ Therefore, although most series support very favorable outcomes with radiotherapy alone in early-stage NLPHL with the exception of late second malignancies and cardiovascular disease, at least one series advocates treating these patients similarly to current classical HL treatment approaches with combined modality therapy and both approaches are standardly utilized. Due to the risks of second malignancies and the excellent long-term outcomes observed in patients with LPHL, in selected patients where the disease is completely resected, observation may also be a suitable alternative to involved field radiotherapy.¹⁹⁷

Chemotherapy is typically reserved for those patients with advanced-stage disease or where the risks of late complications of radiotherapy are increased due to field or dose of radiotherapy required. In early-stage patients, where the risks of secondary malignancies with radiotherapy are of concern, chemotherapy alone is occasionally utilized. For example, a study conducted in the United Kingdom and France prospectively examined the results of three cycles of cyclophosphamide, vinblastine, and prednisolone (CVP) in children and adolescents with stage I-II NLPHL. In this trial, the ORR was 100% and the 40-month FTF and OS were 75% and 100%, respectively.¹⁹⁸ In a study of single-agent rituximab as front-line therapy in 28 patients with stage IA NLPHL, the ORR was 100% and at 36 months the PFS was 81%.¹⁹⁹ Therefore,

although the FTF may be slightly lower with chemotherapy alone compared to radiotherapy or combined modality therapy, these early-stage patients who relapse can be effectively salvaged with additional chemotherapy and radiotherapy and such an approach may reduce the rates of second malignancies.

In the advanced-stage setting, chemotherapy options include six cycles of ABVD, alkylator regimens (CVP or CHOP), or rituximab. Due to the CD20 expression on LP cells, rituximab is increasingly utilized in the front-line treatment of advanced-stage NLPHL. In one of the initial series examining the activity of this agent, Ekstand and colleagues reported an ORR of 96% in 22 patients, 12 with previously untreated NLPHL; however, response duration is limited, with a median freedom of progression of 9.2 months.⁷¹ With the notable activity of single-agent rituximab in relapsed and previously untreated HL, it is frequently combined with ABVD or alkylator-based (CHOP or CVP) therapy as part of initial treatment with those for stage III-IV disease. Limited data exist comparing ABVD to alkylator therapy either alone or in combination with rituximab, and therefore, these regimens are all frequently utilized as front-line and salvage therapy for relapsed stage III-IV NLPHL.

FOLLOW-UP OF PATIENTS WITH HODGKIN LYMPHOMA

Follow-up of patients with HL must address both the risk of relapse as well as potential late complications of therapy (Fig. 93.10). In a study of 1,261 patients treated for HL before the age of 41 from 1965-1987, 534 patients died, including 54% due to HL and 22% from second malignancies.²⁶⁷ The likelihood of HL recurrence declined after 5 years, whereas the incidence of second malignancies and cardiovascular disease continually increased beginning 10 to 15 years from the start of treatment.²⁶⁷ Within the first 5 years from diagnosis, patients are typically monitored for HL recurrence with history- and symptom-directed evaluation, physical examinations, and laboratory testing (CBC, platelets, chemistries, and ESR if elevated at initial diagnosis) every 2 to 3 months for the first 2 years and every 3 to 6 months during years 3 to 5. However, limited data exist regarding the utility of routine blood work in detecting relapsed disease, and in one series, relapse was detected in 55% of patients by history, 23% by CXR, and 1% by laboratory findings.²⁶⁸ In a second study of 107 patients, 22 patients relapsed and 64% were detected clinically, 9% detected by laboratory testing, and 9% by CT imaging.²⁶⁹

With respect to imaging studies, although the convention has been to recommend CT of initially involved sites every 6 to 12 months during the first 5 years from diagnosis, several previous studies have demonstrated no survival benefit with routine CT surveillance and it does not appear to be cost effective.^{269, 270, 271} A more recent examination of follow-up PET/CT demonstrated a high false-positive rate, with an overall positive predictive value of only 28%, limiting its utility as a follow-up tool for HL.²⁷² In this study, 161 patients had 299 routine or clinically indicated follow-up PET/CTs (defined as PET/CT performed based on clinical suspicion) and in this setting the true positive rates were only 5% and 13%, respectively.²⁷² Therefore, with the low risk for relapse in most patients with HL, and no demonstrated survival benefit with routine surveillance CT or PET/CT, follow-up should consist

P.2003

of history and physical exam with only symptom-directed imaging during the first 5 years after HL diagnosis.²⁷¹ The risks of routine laboratory and imaging studies including false-positive findings should be discussed with the patients and the use of routine imaging limited without clinical suspicion. Routine surveillance PET/CT finding is currently not recommended²⁷¹ based on low positive predictive value and associated costs of this testing and work-up of false-positive results.

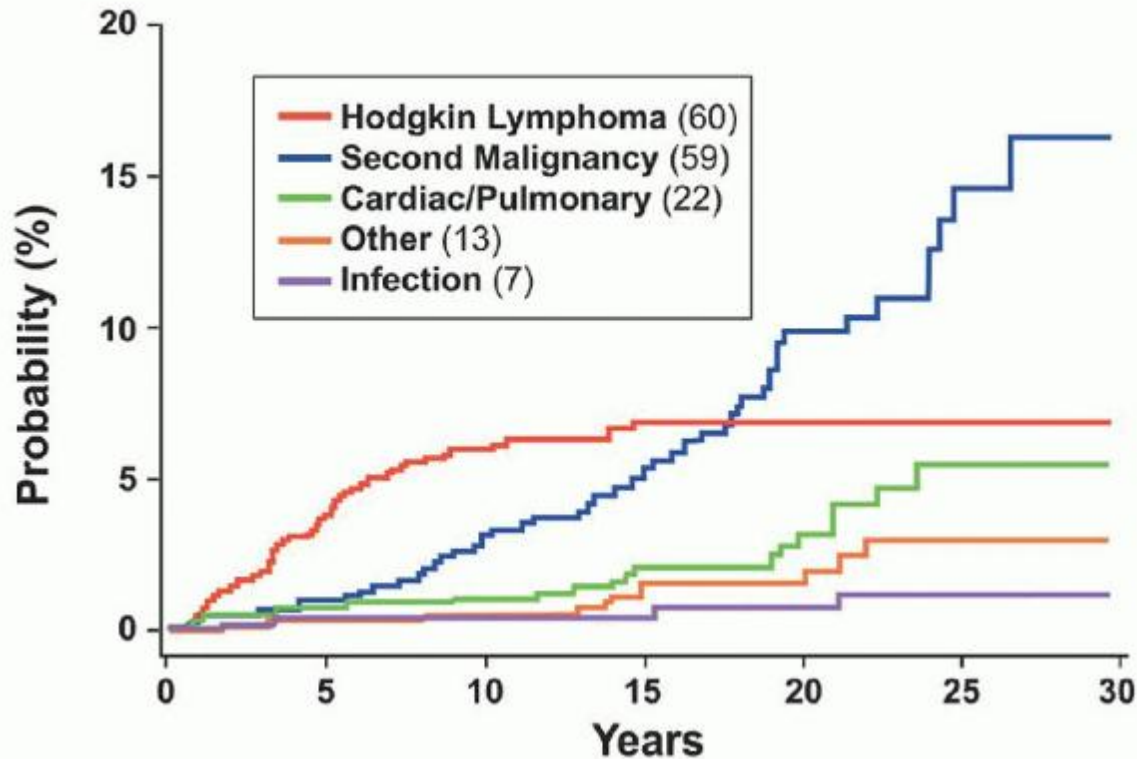

FIGURE 93.10. Causes of death in limited-stage Hodgkin lymphoma. At approximately 15 years Hodgkin lymphoma is not the major cause of death. (From Ng A, Bernardo M, Weller E. Long-term survival and competing causes of death in patients with early-stage Hodgkin's disease treated at age 50 or younger. *J Clin Oncol* 2002;20:2101-2108, with permission.)

Secondary late therapy-related effects in HL survivors include hypothyroidism, fertility issues, secondary cancers, and cardiovascular disease. The risks of second malignancies and cardiovascular disease continue even beyond 30 years from diagnosis,^{267, 273} and therefore, monitoring of late complications is a lifelong endeavor for HL survivors. In a meta-analysis, second cancers were more commonly encountered in patients receiving chemoradiation or radiation alone compared to chemotherapy alone, and no significant differences in the second malignancy rate were observed with involved field versus extended field radiotherapy.²⁷⁴ Therefore, any patient receiving previous radiotherapy should be monitored for second malignancy and cardiovascular disease. Specifically, annual breast screening (typically mammography) is recommended 8 to 10 years after completion of treatment or at the age of 40, whichever comes first, in women who received chest or axillary radiation.^{271, 273} The risk of secondary breast cancers is associated with young age at the time of radiation, particularly women under the age of 30.^{267, 271, 275} Lung cancer risk is also increased in patients receiving mediastinal radiation, particularly patients with a smoking history, and chest imaging annually should be considered for these patients at greatest risk.²⁷¹ Cardiovascular disease including increased risk of coronary artery disease, pericardial disease, cardiomyopathy, and valvular disease is also observed in HL survivors, particularly after mediastinal radiation or anthracycline-based chemotherapy, starting about 5 years after treatment and is also associated with age at treatment.²⁶⁷ Although optimal screening strategies are unclear, monitoring and aggressive management of cardiovascular risk factors including smoking, hypertension, diabetes, and hyperlipidemia is recommended along with consideration of a baseline stress test or echocardiogram.

Other late toxicities associated with radiotherapy include hypothyroidism which can occur in up to 50% of patients and radiation pneumonitis or lung fibrosis, which is fairly uncommon occurring in 3% to 10% of patients.²⁷¹ Annual thyroid function tests are recommended for patients with radiation to the neck or upper mediastinum and evaluation for pulmonary fibrosis should be considered in symptomatic patients.

Secondary leukemia is rarely associated with ABVD chemotherapy, but can be observed in up to 3.2% of patients treated with eight cycles of BEACOPP-esc.²⁰⁹ It remains to be seen with prolonged follow-up if efforts to reduce the total cycles of BEACOPP using PET-directed approaches or to alternate escalated and baseline BEACOPP will reduce this secondary leukemia rate. However, patients treated with BEACOPP or who have received MOPP should have a CBC monitored

annually for this risk. Lastly, with respect to fertility, several studies have demonstrated no impact of ABVD on gonadal function and most patients are able to maintain their fertility; however, patients treated with MOPP or BEACOPP typically become infertile²¹³ and should be counseled about this risk and referred for sperm banking or reproductive endocrinology evaluation if interested prior to treatment.

Finally, in addition to the risks discussed above, patients who undergo autologous HCT for relapsed disease should also be monitored for risks of secondary leukemia, other secondary malignancies, hypogonadism and its complications including declines in bone mineral density, and also considered for re-vaccination. In a retrospective study of 153 patients treated with autologous HCT for relapsed HL, the relative risk of second malignancies was 6.5 compared to the general population and 2.4 compared to nontransplanted patients with HL.²⁷⁶ Second malignancies occurred in 15 patients, at a median of 9 years post-transplantation and consisted of AML/MDS (n = 6), NHL (n = 3), non-small cell lung cancer (n = 2), colon cancer (n = 2), gastric cancer (n = 1), and adenocarcinoma of unknown primary (n = 1). All patients with AML/MDS had MOPP as part of their initial treatment regimen. In 100 patients treated with autologous HCT in Vancouver, second malignancies occurred in 7 patients at median time of 4.2 years from transplantation and consisted of AML/MDS, glioblastoma, renal cell carcinoma, colon carcinoma, NHL, and breast cancer.²³⁹ In this series, 5 patients developed cardiovascular disease including myocardial infarctions 4 to 11 years post-transplant, arrhythmia, and aortic stenosis. In the largest retrospective series of outcomes post-autologous transplantation, 16 of 494 patients who underwent autologous HCT for relapsed or refractory disease developed second malignancies and second malignancy was associated with use of total body irradiation as part of conditioning, age \geq 40, or use of radiation prior to transplantation.²⁷⁷ Therefore, all survivors of HL who are transplanted should be monitored lifelong for second malignancies, with close attention to those treated with radiation either pre- or post-transplant or with TBI during transplant conditioning.

In addition, patients typically experience hypogonadism post-transplantation and monitoring for consequences of hormonal deficiency is recommended including monitoring for bone mineral density reduction using DEXA scanning. Lastly, immunity typically wanes post-autologous transplantation, and it is recommended that patients receive pneumococcal, tetanus, Haemophilus influenza type B, hepatitis B, and annual influenza vaccinations. Measles, mumps, and rubella and varicella vaccinations can be considered in immunocompetent patients no sooner than 24 months post-transplantation.

SUMMARY

HL is a success story of modern medical and radiation oncology. A disease once universally fatal is now cured in 80% of patients. The study of this disease has led to major advances in our understanding of the use of noncross-reactive chemotherapy to cure patients with advanced malignancies and of the long-term effects of radiotherapy and chemotherapy.

Despite this success, some patients are not cured, and others may be overtreated by the current treatment paradigms. A major remaining question is how to tailor our treatment not only to subgroups of patients but to individuals. Two current US intergroup studies nearing completion, SWOG 0816 and CALGB 50604, address this question through the investigation of responseadapted therapy. Patients with an FDG-PET positivity after two cycles of ABVD go on to more intensive therapy.

In the future the two objectives of increasing efficacy of treatment and of lessening late effects will be increasingly the focus of trials. New agents and individualized therapy may be the key to simultaneously achieving these goals.

Chapter 94

Hodgkin Lymphoma in Children

Debra L. Friedman

INTRODUCTION

The first description of Hodgkin lymphoma (HL) was in 1832 when Thomas Hodgkin described seven patients with enlarged lymph glands and spleen. This was followed with histologic descriptions of multinucleated giant cells, by Sternberg in 1898¹ and Reed in 1902.² In the 1960s, the clonality of the Reed-Sternberg cell was established.³ More recently, work has focused on the molecular biology of the disease, including the role of immunoglobulin genes, transcription factors, apoptotic pathways, and Epstein-Barr virus (EBV) incorporation.^{4, 5, 6, 7}

Therapeutic advances in HL began in 1902 when Pusey reported⁸ on the use of radiotherapy,⁸ followed by the use of single-agent chemotherapy, mechlorethamine (nitrogen mustard) in 1946,⁹ then combination chemotherapy with MOPP in

1964,¹⁰ and ABVD in the 1970s.¹¹ Donaldson and colleagues at Stanford introduced the concept of combined modality therapy for pediatric patients using the MOPP backbone and low-dose radiation therapy (RT)¹² (see Table 94.1 for acronyms of treatment protocols). Multimodality, risk-adapted therapies are now the standard of care for pediatric and adolescent HL. The goals of contemporary clinical trials are to balance short- and long-term toxicity with efficacy, in order to maximize cure and minimize adverse sequelae of treatment simultaneously.

EPIDEMIOLOGY

Incidence

Supported by data from United States Surveillance, Epidemiology End Results [SEER],¹³ HL makes up 8.8% of all childhood cancer under the age of 20 years, but 17.7% of cancer in children between ages 15 and 17 years. The overall annual incidence rate in the United States is 12.1 per million for children under 20 years and increases to 32 per million when limiting the analysis to adolescents between 15 and 19 years. Overall there is a slight female predominance when considering all children less than 20 years (M:F = 0.9). The Caucasian:African American ratio is 1.3:1.¹³

TABLE 94.1 COMMON CHEMOTHERAPY PROTOCOLS AND ACRONYMS

Acronym	Chemotherapy Agents
ABV	Doxorubicin, bleomycin, vinblastine
ABVD	Doxorubicin, bleomycin, vinblastine, dacarbazine (DTIC)
BEACOPP	Bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone
CHOP	Cyclophosphamide, doxorubicin, vincristine, prednisone
COP (P)	Cyclophosphamide, vincristine, procarbazine (prednisone)
COPDAC	Cyclophosphamide, vincristine, prednisone, dacarbazine
D(A)BVE (PC)	Doxorubicin, bleomycin, vincristine, etoposide (prednisone, cyclophosphamide)
MOPP	Mechlorethamine (nitrogen mustard), vincristine, procarbazine, prednisone
VAMP	Vincristine, doxorubicin, methotrexate, prednisone
VEPA	Vinblastine, etoposide, prednisone, doxorubicin
OEPA	Vincristine, etoposide, prednisone, doxorubicin
OPPA	Vincristine, procarbazine, prednisone, doxorubicin
ICE	Ifosfamide, carboplatin, etoposide
IV	Ifosfamide, vinorelbine
BEAM	Carmustine, etoposide, cytarabine, melphalan

Adolescent and young adults are most likely to have disease of the nodular sclerosing subtype. Although among children <20 years of age, the nodular sclerosing subtype accounts for 70% of cases, this subtype accounts for 74% of cases in those 15 to 19 years of age. Under the age of 20 years, the mixed cellularity subtype accounts for 16% of cases, but under the age of 10 years, 32% of cases and across the pediatric age group, it is more common in males.¹³

Risk Factors

There are several factors that are known to increase the risk of HL, which include family history of HL, Epstein-Barr virus (EBV) infections, socioeconomic status, and social contacts. For young adult disease (ages 16 to 44 years), there is a 99-fold increased risk among monozygotic twins and a seven-fold increased risk among other siblings.^{14, 15, 16} There is a fascinating interaction between EBV and HL epidemiology and biology. EBV-associated HL, with incorporation of the EBV in the genome, is most commonly reported with the mixed cellularity histologic subtype in children from underdeveloped and developing nations and in young adult males. Conversely, in young adult HL, incorporation of EBV in the tumor genome is unusual but a history of infectious mononucleosis and high-titer antibodies to EBV are associated.^{7, 17, 18, 19, 20} Interestingly, the association between HL and socioeconomic status also differs by age. In children under 10 years, the

disease is associated with lower socioeconomic status and large sibship.^{21, 22} In contrast, risk in young adult patients increases with socioeconomic status and with the related characteristics of a small nuclear family, single-family housing, and fewer siblings or childhood playmates. These findings may be related to an association with infections, where increased infections in early childhood may reduce risk of young adult HL.^{23, 24} There are inconsistent data regarding clustering of young adult cases.^{25, 26}

Biology

The hallmark of classical HL is Reed-Sternberg (RS) cell which most commonly derives from a neoplastic clone originating from B-lymphocytes in lymph node germinal centers, but is then embedded within a reactive infiltrate of lymphocytes, macrophages, granulocytes, and eosinophils.²⁷ The RS cell is a binucleated or multinucleated giant cell that is often characterized with a bilobed nucleus, with two large nucleoli, described commonly as an owl's eye appearance.²⁸ Sequence analyses of RS cell clones reveal rearrangements of immunoglobulin variable-region genes resulting in deficient immunoglobulin production. RS cells then evade the apoptotic pathway, leading to the genesis of HL, and perhaps the paraneoplastic immune-mediated phenomena that sometimes accompany the disease.^{4, 5} The B lymphoid cells from which RS arise have high levels of constitutive nuclear NF- κ B, a transcription factor known to mediate gene expression related to inflammatory and immune responses, and deregulation of NF- κ B has been postulated as a mechanism by which RS cells evade apoptosis.^{6, 29} NF- κ B dimers are held in an inactive cytoplasmic complex with inhibitory proteins, the I κ Bs.²⁹ B-cell stimulation by

P.2006

diverse signals results in rapid activation of the I κ B kinase (IKK). The IKK complex phosphorylates two critical serine residues of I κ Bs,^{30, 31, 32} thereby targeting them for rapid ubiquitin-mediated proteasomal degradation. Active NF- κ B dimers are then released and translocated to the nucleus, where they activate gene transcription. Activation of NF- κ B appears to be a final common effect of co-stimulatory interactions, genetic aberrations, or viral proteins that operate in HL.³³

RS cell survival is dependent on several downstream pathways. RS cells express CD40 and CD40 ligand (CD40L) is expressed on inflammatory T and dendritic cells that surround them. CD40/CD40L interactions normally provide a second signal from activated helper T-cells to normal B-cells, resulting in activation of NF- κ B. NF- κ B in turn causes proliferation and induces expression of BCL-xL, which protects B-cells from apoptosis.³⁴ Tumor necrosis factor receptor-associated factor 1 (TRAF 1) is overexpressed in EBV-transformed lymphoid cells and RS cells³⁵ and is associated with activation of NF- κ B and protection of lymphoid cells from antigen-induced apoptosis. Activation of NF- κ B, in turn, leads to expression of TRAF1, thereby establishing a positive feedback loop that maximizes NF- κ B-dependent gene expression.³⁶ EBV latent membrane protein 1 (LMP1) interacts with TRAF1, and tumors with TRAF1-LMP1 aggregates exhibit high NF- κ B activity.^{37, 38} LMP1 activates NF- κ B by promoting I κ Ba turnover.³⁹ RS cells express CD30 and CD30 ligation promotes proliferation of HL-derived cells with constitutive activation of NF- κ B.⁴⁰

EBV genome fragments can be found in approximately 30% to 50% of HL specimens, and may play a role in the rescue and repair of RS cells, further aiding in their evasion of apoptosis and enhanced survival.^{7, 41, 42, 43} Three latent viral antigens are expressed in EBV-positive HL in RS cells: Epstein-Barr nuclear antigen-1 (EBNA1), required for viral episome maintenance, LMP1 with transforming properties, and LMP2, which is nontransforming.^{44, 45}

Histology

HL can broadly be divided into two pathologic classes: classical Hodgkin lymphoma (CHL) and nodular lymphocyte predominant Hodgkin lymphoma (NLPHL).^{46, 47} In turn, CHL can be further divided into four subtypes: lymphocyte rich (LRCHL), nodular sclerosis (NSHL), mixed cellularity (MCHL), and lymphocyte depleted (LDHL). See Chapter 86 for descriptions of the subtypes. As noted above, different cell types are more common in younger or older children and adults with HL.

In CHL, the RS cells do not express B-cell antigens such as CD45, CD19, and CD 79A, but virtually all express CD30 and approximately 70% express CD15, with only 20% to 30% expressing CD20.⁴⁸ In comparison, in NLPHL, the tumor cells do express B-cell antigens such as CD19, CD20, CD22, and CD79A, may or may not express CD30 and do not express CD15.⁴⁹ In addition, the OCT.2 and BOB.1 oncogenes are down-regulated in CHL but not in NLPHL, correlating with immunoglobulin transcription.⁵⁰

CLINICAL CONSIDERATIONS

Presentation and Staging

The most common presentation of HL, occurring in 80% of patients, is painless adenopathy. Mediastinal involvement is present in approximately 76% of adolescents but only in 33% of children 10 years of age and younger. A large mediastinal mass with a maximum diameter that is greater than one third of the chest diameter and/or a node or nodal aggregate greater than 10 cm occurs in about 20% of patients.^{51, 52} B symptoms, defined as (1) unexplained loss of >10% of body weight in the 6 months preceding the diagnosis; (2) unexplained fever with temperatures >38°Celsius for more than 3 days; or (3) drenching night sweats, are seen in 20% of patients at the time of initial disease presentation.^{52, 53, 54} Staging is performed clinically, based on the Ann Arbor staging system⁵⁵ as revised in 1989.⁵³ Approximately 80% to 85% of children and adolescents with HL have involvement limited to or with direct extension from the lymph nodes and/or the spleen (Stages I to III), whereas 15% to 20% of patients are Stage IV with involvement of the lung, bone marrow, bone, or liver.⁵⁵ Although staging definitions by nodal region, B symptoms, and definition of extranodal involvement are well defined, bulk disease and substaging have not been consistent across studies (Table 94.2).

Diagnostic Evaluation

A detailed history is required to elucidate B symptoms, which becomes important in risk stratification. A thorough physical evaluation should be performed, documenting the location and size of adenopathy, presence of splenomegaly and any evidence of organ dysfunction. This should be complemented by computed tomography (CT) scans of the neck, thorax, abdomen, and pelvis. FDG-PET imaging is the standard of care in HL and response to disease is now judged by FDG-PET alone or in combination with CT. With the advent of combined CT-PET scans, areas of disease can be evaluated simultaneously with both modalities in an overlapping fashion.^{56, 57, 58, 59} Technetium-99 bone scintigraphy can be considered in patients with bone pain or elevated alkaline phosphatase, although PET may obviate the need for this. In addition, an upright chest radiograph (CXR) with posteroanterior (PA) and lateral views has traditionally been required for documentation of a large mediastinal mass (bulk mediastinal disease) for clinical trials, defined as tumor diameter >1/3 the thoracic diameter (measured transversely at the level of the dome of the diaphragm on a 6-foot upright PA CXR),⁶⁰ although the ongoing value of this remains unclear.

Bone marrow biopsy is recommended for all Stage III and IV patients or patients with B symptoms. There are less consistent recommendations for lower-stage patients without B symptoms.^{61, 62} Laboratory studies include a complete blood count, blood chemistries to evaluate hepatic and renal function and may include acute phase reactants such as ferritin, erythrocyte sedimentation rate, and serum copper, which may be seen as nonspecific markers of tumor activity, but may correlate with prognosis or response.

Prognostic Factors

Adverse prognostic markers established from clinical trials often form the basis for risk stratification and subsequent modification of therapeutic algorithms. In sequential trials, as treatment is then risk-based, these adverse factors are abrogated by the changes in therapy. Pre-treatment factors that have been shown to be associated with adverse outcome include advanced stage, B symptoms, bulk disease, extranodal extension, male sex, and elevated erythrocyte sedimentation rate; and in some studies, hemoglobin <110 g/L or white blood cell count >11.5 × 10⁹/L, age 5 to 10 years, and increased numbers of sites of disease.^{63, 64, 65, 66, 67, 68, 69} Patients with NLPHL appear to have an overall better prognosis than those with CHL, and among those with CHL, histologic subtype is not consistently associated with prognosis.^{67, 70} Serum markers that may confer adverse prognostic risk include soluble vascular adhesion molecule-1, tumor necrosis factor, soluble CD-30, beta-2 microglobulin, transferrin, serum IL-10, and serum CD 8 antigen.^{71, 72, 73, 74, 75, 76} High RS cell levels of caspase 3 may be associated with a more favorable outcome.⁷⁷ Early response to treatment, which may be a correlate for biology, may also be an important prognostic factor, allowing titration of therapy to the individual.^{68, 78, 79, 80}

P.2007

TABLE 94.2 CLINICAL AND STAGING CRITERIA FOR HODGKIN LYMPHOMA

A. Stage Grouping

Stage I: Involvement of single lymph node region (I) or localized involvement of a single extralymphatic organ or site (IE).

Stage II: Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized contiguous involvement of a single extralymphatic organ or site and its regional

lymph node(s) with involvement of one or more lymph node regions on the same side of the diaphragm (IIE).

Stage III: Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by localized contiguous involvement of an extralymphatic organ or site (IIIE), by involvement of the spleen (IIIS), or both (IIIE+S).

Stage IV: Disseminated (multifocal) involvement of one or more extralymphatic organs or tissues, with or without associated lymph node involvement, or isolated extralymphatic organ involvement with distant (nonregional) nodal involvement.

B. Symptoms and Presentations

“A” Symptoms: Lack of “B” symptoms.

“B” Symptoms: At least one of the following:

Unexplained weight loss >10% in the preceding 6 mo

Unexplained recurrent fever >38°C

Drenching night sweats.

X Bulk disease (see C below)

E Involvement of a single extranodal site that is contiguous or proximal to the known nodal site.

C. Bulk disease

One or both of the following presentations are considered “bulk” disease:

- *Large mediastinal mass:* tumor diameter >1/3 the thoracic diameter (measured transversely at the level of the dome of the diaphragm on a 6-foot upright PA CXR) In the presence of hilar nodal disease the maximal mediastinal tumor measurement may be taken at the level of the hilus. This should be measured as the maximum mediastinal width (at a level containing the tumor and any normal mediastinal structures at the level) over the maximum thoracic ratio.

- *Large extramediastinal nodal aggregate:* A continuous aggregate of nodal tissue that measures >6 cm^a in the longest transverse diameter in any nodal area.

^a Some studies use 10 cm for definition of extramediastinal bulk disease.

INITIAL TREATMENT FOR PEDIATRIC HODGKIN LYMPHOMA

To our knowledge, the biology and natural history of HL does not differ between children and adults. As a result, early therapeutic approaches for pediatric HL were similar to or modeled after those developed for adults with HL. This seemed particularly logical and HL is most commonly a disease of adolescents as opposed to adults. However, with high cure rates, contemporary standard approaches to adolescent and young adult HL include multiagent chemotherapy with or without low-dose involved field radiotherapy. The overriding principles of these treatment regimens are to balance efficacy with both acute and, perhaps, more important, long-term toxicities.^{81, 82, 83} A summary of common protocols for upfront therapy is found in Table 94.3. Figure 94.1 shows the timeline of evolution of therapy for pediatric HL.

Challenges inherent in comparing data across pediatric HL trials are differing patient populations, with differing definitions of stratification. However, overall, results are quite good with 3- to 10-year EFS rates ranging from 67% to 94% for combined modality therapy and 60% to 91% for chemotherapy alone, as reviewed by Olson and Donaldson.⁸⁴

Chemotherapy regimens have largely built upon the MOPP and ABVD backbones and have been quite successful overall.

To decrease alkylator therapy and potential cardiotoxicity and to provide dose-intensive treatment, the Pediatric Oncology Group (POG) developed a series of studies built upon the ABVD backbone, substituting dacarbazine with etoposide. The use of vincristine instead of vinblastine allowed for escalation of doxorubicin and etoposide. POG 9226 piloted therapy with 4 cycles of DBVE followed by low-dose IFRT in patients with Stages I, IIA and IIIA. The 5-year EFS was 89%.⁸⁵ This pilot was followed by a Phase III study using the same therapy (POG 9426) in a non-randomized response-based manner. Those with a rapid response

P.2008

(60% tumor reduction, gallium negative) after 2 cycles proceeded to consolidative IFRT without further chemotherapy; slow responders continued to receive 4 cycles plus IFRT. The overall EFS was 88.3%.⁸⁶ In POG 9425 (for patients with advanced stage disease) prednisone and cyclophosphamide were added to the ABVE backbone, with more rapid delivery of therapy to intensify the weekly therapeutic intensity. Response was assessed after three cycles (9 weeks). Those with rapid response did not receive the additional two cycles of chemotherapy. All patients received consolidative regional low-dose (20 Gy) RT. Overall 3-year EFS was 87%.⁷⁹ Both studies evaluated the efficacy of dexrazoxane in reducing cardiac and pulmonary toxicity. Although it is still too early to know whether there was a significant benefit, dexrazoxane was associated with an increased risk of acute (hematologic/infectious) toxicities and development of second malignancies, mostly treatment-related leukemia.⁸⁷

TABLE 94.3 SOME COMMON STANDARD THERAPY PROTOCOLS FOR PEDIATRIC CLASSICAL HODGKIN LYMPHOMA

Stage and Presentation	Commonly Accepted Chemotherapy Regimens
IA, IIA < 4 nodal regions without B symptoms, bulk disease, or extranodal extension	VAMP × 4 COPP/ABV hybrid × 4 ABVE × 4 OEPA or OPPA × 2 CHOP × 3-4 ± Rituximab ABVD × 2-4
IA, IIA with bulk disease, ≥3 nodal regions, or extranodal extension	COPP/ABV × 6 ABVE-PC × 3-5
IIB*, IIIA, IVA	OPPA/OEPA × 2 + COPP × 2 OEPA-COPAC ABVD × 4-6
IIB*, IIIB, IVB	ABVE-PC × 3-5 BEACOPP × 8 (or BEACOPP × 4 + ABVD × 2 or + COPP/ABV × 4) OPPA/OEPA × 2 + COPP × 4 OEPA-COPAC Stanford V ABVD × 6-8

All regimens should consider LD-IFRT (low-dose involved field radiotherapy; 15 to 25 Gy), but there are variations in recommendations based on risk and early and complete response to chemotherapy.

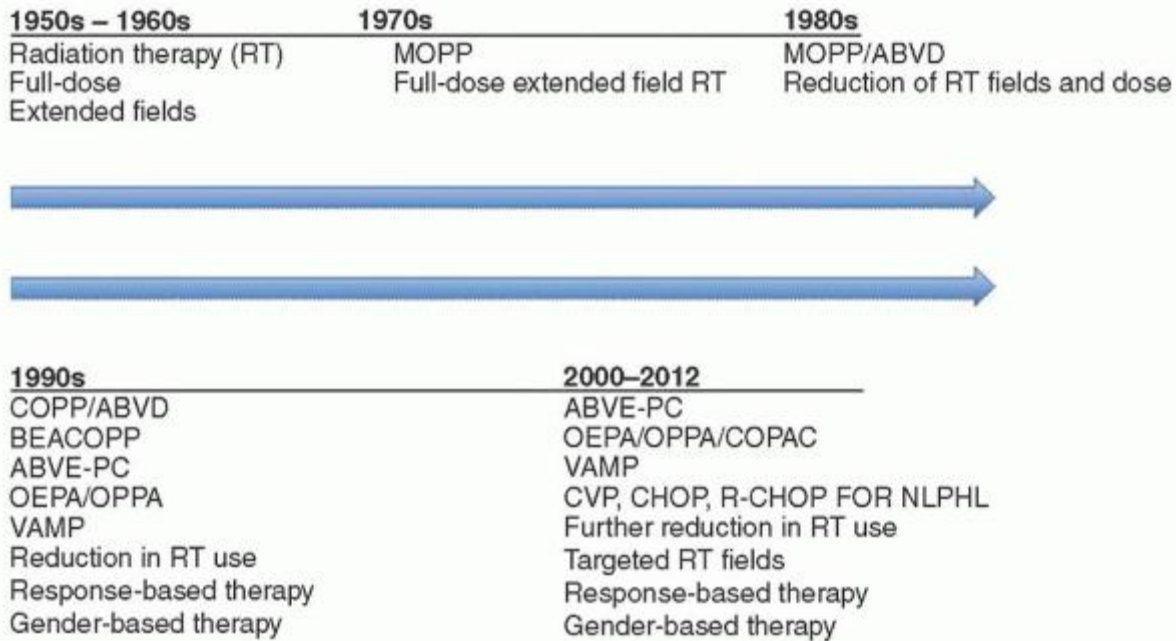

FIGURE 94.1. Timeline of Hodgkin lymphoma upfront therapy.

With the goal of balancing efficacy with toxicity, and specifically to decrease long-term risk for organ dysfunction and second malignancies, there have been a number of studies conducted to evaluate the avoidance of RT in the POG and Children's Cancer Group (CCG), and more recently in the Children's Oncology Group (COG), representing the merger of those groups. In the Children's Cancer Group (CCG) 521 study, patients were randomized between 12 cycles of alternating MOPP/AVBD versus 6 cycles of AVBD + low-dose regional chemotherapy. Event-free survival was 77% for Stage III and IV patients and there was excess pulmonary toxicity with the ABVD arm.⁸⁸ POG 8725 compared eight cycles of MOPP/ABVD with and without IFRT in Stage IIB, III, and IV patients. There was no significant benefit for RT, but patients were exposed to significant doses of alkylating agents and anthracyclines, which are associated with significant long-term risk for gonadal toxicity, cardiac toxicity, and secondary leukemia.⁸⁹ Response post three cycles was a strong prognostic factor, with a 94% EFS in the rapid early responders as opposed to a 78% EFS in those who did not respond quickly.⁸⁹ In a randomized Phase III trial, CCG 5942 evaluated the avoidance of radiotherapy in patients who had a complete response following chemotherapy. Patients were treated with four cycles of COPP/ABV, six cycles of COPP/ABV, or two cycles each of COPP/ABV, cytarabine/etoposide, and CHOP, depending on the stage of disease and presence of bulk disease. Of the 829 eligible patients, complete response was achieved in 83% and 501 were randomized to receive IFRT or no further therapy. Event-free survival at 3 and 10 years was 87% and 83%, respectively. In all groups, the difference in EFS post randomization was highly significant and overall EFS was 91% at 3 and 10 years for the group who received IFRT and 86% at 3 years and 83% at 10 years for those who did not receive IFRT. Despite the differences in EFS, early evaluation of overall survival is not affected by the inclusion of IFRT.^{63, 90} A pilot study of 99 patients in CCG 59704 utilized the German Hodgkin Disease Group's BEACOPP backbone for patients with B symptoms or advanced stage disease. Overall the 5-year EFS was 94% with patients receiving six to eight cycles of chemotherapy with or without radiotherapy on the basis of a gender-stratified, response-based therapeutic algorithm.⁹¹

A series of studies in the COG have just completed accrual and have evaluated the principles of response-based risk-adapted therapy, where therapy is decreased for those at lowest risk and with favorable early responses to chemotherapy and augmented for those with more advanced disease or a slow response to initial chemotherapy. These studies have utilized the ABVE-PC backbone of the POG 9425 and 9,426 studies.

The Dana Farber-Stanford-St. Jude pediatric Hodgkin lymphoma consortium studies have focused efforts on reduction in alkylating agent, anthracycline, and radiotherapy doses. Low-risk patients have been treated with four cycles of an alkylator-free chemotherapy protocol, VAMP, with radiotherapy doses of 15 Gy or 25.5 Gy based upon response to the first two cycles of chemotherapy. This approach resulted in a 5-year EFS of 93% and 10-year EFS of 89%.⁹² For patients with higher risk disease, two protocols have been evaluated, VAMP/COP and VEPA, both with IFRT. Results have been less acceptable with 5-year EFS of 74% and 68%, respectively.^{93, 94} The group is now evaluating the Stanford V regimen⁹⁵ that has been successfully employed in adult patients.

In the same era, the German cooperative groups have built upon COPP chemotherapy in both pediatric and adult HL. To decrease gonadotoxicity, which is more prevalent in males exposed to alkylating agents, some of these therapies have been gender-based. The DAL-HL-90 study used OEPA/COPP for males and OPPA/COPP for females, both followed by IFRT. EFS for Stages II, III, and IV was 92%, 86%, and 90%, respectively.⁹⁶ The GPOH-95 study was designed to assess elimination of radiotherapy for those with a complete response. It built on the OPPA/OEPA backbones by adding cycles of COPP for patients with more advanced disease. Radiotherapy dose was determined by the post-chemotherapy disease reduction. Complete response was defined as complete resolution of all disease (as opposed to a 70% reduction in CCG 5942 and 59704). Only 22% achieved a complete response. A total of 50% achieved between 75% and 95% disease reduction and were treated with 20 Gy radiotherapy, and 4% had less than a 75% reduction and were treated with 30 Gy. In addition, 20% of patients had residual masses treated with boost doses to 35 Gy. Overall the EFS was 92% for those receiving radiotherapy, compared with 88% in those treated with chemotherapy alone, but for patients with IA, IB, and IIA disease, EFS was not

P.2009

different among those with a CR to chemotherapy and no other therapy (97%) and those with a partial response, subsequently treated with radiotherapy (94%). However, for all other patients the EFS was 79% for those treated with chemotherapy alone compared with 91% for those treated with combined modality therapy.⁹⁷ This was followed by the GPOH-HD-2002 study, where OEPA-COPDAC chemotherapy was tested in males compared with OPPA-COPP in females for intermediate and advanced HL. The 5-year EFS was 89.0% without significant difference between males and females.⁹⁸

For low-risk patients with NPLHL, some patients may be treated with surgery alone. There are multiple small reports in both adult and pediatric HL of patients of successful treatment of completely resected Stage I disease. For those who did relapse, salvage rates were encouraging and death from disease very low.^{99, 100, 101, 102} This has prompted a study in the COG to formally evaluate surgery only in patients with involvement of a single completely resected lymph node with NPLHL. Although adults with NPLHL may be treated with radiotherapy alone, the dose required without adjuvant chemotherapy exceeds that optimal in children and adolescents, and thus this strategy is not used in pediatric NPLHL. The optimal treatment of patients with advanced stage NPLHL remains undetermined. These patients are traditionally treated with regimens that are used for patients with advanced stage classical HL with outcomes equivalent to or better than those with CHL. However, the biology of NPLHL may be more similar to indolent CD20+ B-cell non-Hodgkin lymphoma (NHL) than classical HL and thus the question remains of whether regimens for NHL would be more effective with potentially less toxicity in these patients. A retrospective analysis at MD Anderson Cancer Center from 1995 to 2010 found that patients with NPLHL treated with R-CHOP had better 5-year progression-free and overall survival compared to those treated on the HL regimen.¹⁰³ From 2005 to 2010, a study was conducted in France and the United Kingdom, testing CVP in 55 patients with early-stage NPLHL. The 40-month freedom from treatment failure was 75.4%, but with an overall survival of 100%, respectively.¹⁰⁴

However, prospective multicenter randomized studies have not been conducted to answer such questions and it is unlikely, given the exceptional overall survival, that such studies will be successfully conducted.

Radiotherapy for Hodgkin Lymphoma

It has been recognized since the 1950s that HL is an extremely radiosensitive disease. Currently, for children and adolescents with HL, radiotherapy is exclusively delivered in the context of multimodality therapy. Doses of 15 to 25 Gy are commonly used, and as noted above, clinical trials have been and continue to be conducted to identify groups of patients for whom the exclusion of radiotherapy is possible, without affecting disease-free survival.

Below are some basic principles for radiotherapy in pediatric and adolescent HL. However, delivery of radiotherapy, particularly in children and adolescents, requires careful considerations of the age, tumor burden and location, response to chemotherapy, and an assessment of both short- and long-term potential toxicity.

Megavoltage energies are now the treatment of choice for pediatric and adolescent HL. Although there are differences in treatment techniques among radiation oncologists and specific institutions, the general technical principles remain constant.¹⁰⁵ Proton beam radiotherapy is currently under investigation at several centers across the United States, but there is insufficient data to know whether this modality will provide the best option for long-term cure, while decreasing adverse long-term effects of treatment.^{106, 107}

Radiotherapy fields must be designed with the goal to deliver the optimum volume of radiotherapy for disease control, while avoiding normal tissue damage. Customized shielding blocks should be utilized as appropriate to protect normal tissue. Blocking the genitalia is of specific importance when pelvic fields are included. In females, oophoropexy results in

doses of 8% to 10% and 4% to 5%, respectively, of the pelvic dose,¹⁰⁸ which will be compatible with the preservation of fertility. For males, a frog leg position and an individually fitted shield will provide the greatest shielding to the testes, reducing scatter to approximately 0.75% of the pelvic lymph node dose.¹⁰⁹

TREATMENT FOR RELAPSED HODGKIN LYMPHOMA

HL may be cured even if it has recurred after initial treatment. Potentially curative options include conventionally dosed combined modality protocols: radiotherapy alone for those relapsing in a limited nodal pattern, re-induction chemotherapy followed by autologous hematopoietic stem cell transplantation (HSCT), full and reduced intensity allogeneic transplants, and evolving targeted antibodies.^{110, 111} Some common retrieval regimens are shown in Table 94.4 and the choice of regimen is dependent on previous treatment and patterns of relapse. Two ifosfamide-based regimens have been used with good response rates, ICE and IV with EFS exceeding 75%.^{112, 113} Gemcitabine has also been used in combination with vinorelbine with excellent overall response rates in recurrent HL with similar EFS.^{114, 115, 116, 117}

Autologous HSCT is most commonly used for recurrent or refractory HL, particularly when used following dose-intensive regimens or for high-risk disease.^{115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128} However, an allogeneic effect has been observed, and full and reduced intensity allogeneic approaches as well as immune modulation and induction of autologous graft versus host disease have been explored to enhance the allogeneic effect.^{129, 130, 131, 132, 133, 134, 135, 136}

The most promising new agent in the treatment for HL is brentuximab vedotin (SGN35), which is also being utilized in the earlier relapse period with several recently reported as well as ongoing trials, although pediatric experience is quite limited.¹³⁷ In a recent Phase 2 study, the efficacy and safety of brentuximab vedotin was evaluated in 102 patients with relapsed or refractory HL after ASCT. Reductions in tumor size were observed in 94% of patients. The overall response rate was 75%, with complete remission achieved by 34% of patients and partial response in 40%.¹³⁸ A retrospective analysis by the German Hodgkin Study Group with brentuximab vedotin as single agent was reported in 45 patients with refractory or relapsed CD30 (+) HL, with an objective response rate of 60%, including 22% complete remissions.¹³⁹ A case series of 20 transplant-naïve patients who either refused or were ineligible for transplant, enrolled in two Phase I multicenter studies, reported six responses.¹⁴⁰ In a study of

P.2010

25 patients with recurrent HL post-allogeneic transplant, who had received a median of 9 (5-19) prior regimens, overall and complete response rates were 50% and 38%, respectively, among 24 eligible patients, with a median progression-free survival time of 7.8 months.¹⁴¹ These data led to accelerated approval of brentuximab vedotin for the treatment of patients with HL after failure of autologous stem cell transplantation (ASCT) or after failure of at least two prior multiagent chemotherapy regimens in patients who are not ASCT candidates.¹⁴² Studies are now ongoing evaluating brentuximab vedotin as part of multiagent protocols in the upfront and recurrent setting.

TABLE 94.4 COMMON TREATMENT OPTIONS FOR RECURRENT HODGKIN LYMPHOMA

ICE (Ifosfamide, carboplatin, and etoposide)

DECA (Dexamethasone, etoposide, cisplatin, cytarabine)

IV (Ifosfamide and vinorelbine)

GV (Gemcitabine and vinorelbine)

IEP-ABVD-COPP (Ifosfamide, etoposide, prednisone-doxorubicin, bleomycin, vinblastine, dacarbazine-cyclophosphamide, vincristine, procarbazine, prednisone)

APE (Cytosine arabinoside, cisplatin, etoposide)

SGN-35 (brentuximab vedotin)—antibody-drug conjugate targeting CD30

These therapies can be used as stand-alone therapy or as re-induction prior to planned stem cell transplant. Radiotherapy can be considered together with this therapy.

ADVERSE LONG-TERM OUTCOMES OF THERAPY

In pediatrics, a significant consideration when deciding therapy is the risk of adverse long-term risks of therapy, which include organ dysfunction and second malignancies.¹⁴³ The common potential long-term effects of radiotherapy and chemotherapy for HL are summarized together with general monitoring recommendations in Table 94.5. In a review from

the Childhood Cancer Survivor Study (CCSS), among 2,633 HL 5-year survivors, initially treated between 1970 and 1986, there were 500 deaths with the following causes: HL, 35%; second malignancies, 23%; cardiovascular disease, 14%; pulmonary disease, 4%; external cause, 7%; other and unknown cause, 17%. Adjusting for demographics and medical conditions, treatment with radiotherapy or alkylating agents were independent risk factors for overall mortality and those same exposures as well as anthracycline treatment for second malignancies. In this cohort, the 30-year cumulative incidence for second malignancy was 18.7%. Based on self-report, the 30-year cumulative incidence of grade 3 to 5 chronic health conditions in the cohort were as follows: cardiovascular, 11%; pulmonary, 5%; and thyroid, 51%.¹⁴⁴ Other studies of subsequent malignancy cite female gender, radiotherapy field and dose, and follow-up time since diagnosis as risk factors. The most significant risk is for secondary breast cancer in female survivors treated with thoracic radiotherapy, where even lower doses of radiotherapy, with ongoing follow-up now are associated with increased risk.^{145, 146, 147, 148, 149} Thyroid dysfunction and thyroid cancer are also of concern in this population. In the CCSS, self-report thyroid status was assessed in 1,791 HL survivors treated from 1970 to 1986. Of the entire cohort, 34% have been diagnosed with at least one thyroid abnormality. Hypothyroidism was the most common disturbance, with a relative risk of 17.1 compared to sibling controls. Hyperthyroidism was reported by 5% of survivors, which was 8-fold greater than the incidence reported by the controls. The risk of thyroid nodules was 27 times that in sibling controls. Female gender and higher radiation dose increased risk for thyroid abnormalities.¹⁵⁰ In a pooled cohort of childhood cancer survivors including 16,757 patients, with 187 developing primary thyroid cancer, radiation-dose-related relative risks increased approximately linearly for <10 Gy, leveled off at 10 to 15-fold for 10 to 30 Gy and then declined, but remained elevated

P.2011

for doses >50 Gy. Dose-related excess relative risks increased with decreasing age at exposure but did not vary with attained age or time-since-exposure, remaining elevated 25+ years after exposure. Gender and number of treatments did not modify radiation effects. In another pooled analysis, three models of assessing absolute risk for secondary thyroid cancer were developed and validated. Model M1 included self-reported risk factors, model M2 added basic radiation and chemotherapy treatment information abstracted from medical records, and model M3 refined M2 by incorporating reconstructed radiation absorbed dose to the thyroid. All models were associated with elevated relative risks (M1 = 10.8; M2 = 6.8; M3 = 8.2) and had good discriminatory ability. Past thyroid nodule was consistently the strongest risk factor in the models.^{151, 152} Cardiac toxicity following anthracycline therapy and mediastinal radiotherapy is well recognized among survivors.^{144, 153} Among 1,132 survivors of HL treated between 1978 and 1995, treated with a relatively low doxorubicin dose (160 mg/m²), at a median of 19.5 years, cardiac diseases had been diagnosed in 50 patients. Valvular defects were diagnosed most frequently, followed by coronary artery diseases, cardiomyopathies, conduction disorders, and pericardial abnormalities. Multivariate analysis showed the mediastinal radiotherapy dose to be the only significant variable associated with cardiac disease.¹⁵⁴ In a cohort of 1,362 5-year survivors diagnosed between 1966 and 1996, with 50 cardiac events reported, cumulative incidence of anthracycline (dose), cardiac irradiation (dose), combination of these treatments, and congenital heart disease were significantly associated with developing a cardiac event.¹⁵⁵ Reproductive outcomes have been examined for all survivors in the CCSS, but risk factors for impairment are generally those seen with HL therapy. Sklar and colleagues evaluated premature menopause and a multiple Poisson model showing risk factors to include attained age, exposure to radiation to the ovaries in a dose-dependent manner, number and cumulative dose of alkylating agents, and a diagnosis of HL.¹⁵⁶ Green and colleagues found that male survivors were less likely to sire a pregnancy than siblings. Among survivors, the hazard ratio of siring a pregnancy was decreased by RT to the testes, higher cumulative alkylating agent dose, and treatment with cyclophosphamide or procarbazine.¹⁵⁷

TABLE 94.5 GENERAL GUIDELINES FOR RISK AND SURVEILLANCE FOR ADVERSE LONG-TERM OUTCOMES

System	Therapeutic Exposure	Potential Effects	Monitoring Recommendations^a
Cardiac	Thoracic RT	Cardiomyopathy	Electrocardiogram and echocardiogram
	Doxorubicin	Pericarditis	
		Coronary artery disease	
		Valvular disease	
Pulmonary	Thoracic RT	Pulmonary fibrosis	Pulmonary function tests (PFTs) (including DLCO and spirometry)
	Bleomycin	Restrictive lung disease	

Thyroid	Neck RT	Overt or compensated hypothyroidism Thyroid nodules or cancer Hyperthyroidism	Free T4; TSH			
Gonadal (female)	Pelvic RT	Delayed/arrested puberty	FSH, LH, estradiol			
	Alkylating agents	Early menopause Ovarian failure				
Gonadal (male)	Pelvic RT	Germ cell failure	FSH, LH, testosterone Semen analysis			
	Alkylating agents	Infertility/Azoospermia Leydig cell dysfunction Hypogonadism Delayed/arrested puberty				
		Bone		Corticosteroids	Decreased bone mineral density	Bone density evaluation (DEXA or quantitative CT)
		Second Malignancies		Radiotherapy	Sarcomas CNS tumors Breast cancer Melanoma Nonmelanoma skin cancer Thyroid cancer Other solid tumors	Routine cancer screening per general population guidelines Mammography to screen for female breast cancer at age 25 y or 10 y post RT exposure, whichever is later
	Doxorubicin Etoposide Mechlorethamine Cyclophosphamide	Therapy-related myelodysplasia and acute leukemia	Annual cbc with differential for 10-y post exposure			

^a Monitoring recommendations all include a risk-adapted health history and physical examination. The frequency with which diagnostic studies should be performed is dependent on many factors including radiotherapy dose, chemotherapy exposures, age at exposure, and other clinical parameters. See Children's Oncology Group guidelines for more details (www.survivorshipguidelines.org).

DEXA, Dual-energy X-ray absorptiometry; DLCO, Diffusing capacity; FSH, follicle stimulating hormone; LH, luteinizing hormone; RT, radiation therapy; TSH, thyroid stimulating hormone.

Studies of HL survivors treated in the more contemporary age of chemoradiotherapy are underway to see if reduction in anthracyclines, alkylating agents, and radiotherapy have resulted in fewer long-term adverse chronic health conditions.

Various pediatric cooperative groups have developed long-term follow-up guidelines, which provide a foundation for the type of follow-up care that should be delivered. However, the recommendations are not completely consistent with one another and recommendations are consensus-based, and thus, the optimal follow-up strategy is yet to be fully elucidated. Efforts are underway for international harmonization among large childhood cancer groups.^{158, 159, 160, 161, 162, 163, 164, 165, 166, 167}

CONCLUSIONS

Cure rates for HL are one of the highest in pediatric oncology, but the very therapies that have afforded such cure rates share the etiologic limelight for adverse long-term health outcomes. Ongoing clinical trials thus seek to balance efficacy

with both short- and long-term toxicity. For a meaningful minority of patients with higher risk initial disease, refractory, and recurrent disease, the challenge remains increasing the cure rate and incorporating novel agents that may better target the underlying biology and pathophysiology. And last, additional study is required to understand the complex biology and epidemiology of HL better to understand better how they interface with one another, affect disease presentation, response to therapy, and long-term outcomes.

Key Summary Points

For initial diagnosis:

Work-up: History and exam; CT neck, chest, abdomen, pelvis, FDG-PET scan, Bone marrow; CBC/differential, metabolic panel, erythrocyte sedimentation rate, ferritin, bone marrow; excisional lymph node biopsy.

Initial treatment: Risk-based (Table 94.3); Enroll on open clinical trial when available.

For refractory or recurrent disease:

Work-up: As per initial diagnosis.

Treatment: Risk based (Table 94.4). If relapse is not low stage after low-density low-risk chemotherapy protocol without radiotherapy, consider stem cell transplant once response is evident (FDG-PET non-avid).

For follow-up:

Follow clinically with imaging studies for first year to 18 months, then clinically follow for long-term toxicity using COG guidelines (www.survivorshipguidelines.org).

Chapter 95

Practical Approach to Evaluation of Monoclonal Gammopathies

Francis K. Buadi

Joseph R. Mikhael

William G. Morice II

The real incidence of monoclonal gammopathy is unknown; however, it increases with age, with most cases being identified in the 7th or 8th decade of life.^{1, 2, 3} The presence of a monoclonal protein is indicative of an underlying clonal plasma cell or B cell disorder. These disorders encompass a spectrum of disease entities ranging from clinically benign monoclonal gammopathy of undetermined significance (MGUS) to clinically significant diseases such as multiple myeloma, and also including Waldenström macroglobulinemia, chronic lymphocytic leukemia, and various neurologic and cutaneous diseases.^{4, 5, 6, 7, 8, 9, 10, 11, 12} Among 43,000 monoclonal gammopathies evaluated at Mayo Clinic from 1960 to 2010 most had MGUS (57.5%), multiple myeloma (18%), or primary (AL) amyloidosis (9%) (Fig. 95.1). However, 4% of these cases were associated with other conditions, such as POEMS syndrome, cryoglobulinemia, Castleman's disease, and light chain deposition disease, which do require therapy and should not be missed during evaluation. A systematic approach to the patient with a monoclonal immunoglobulin (monoclonal protein) disorder is required, on the one hand to prevent unnecessary testing in the majority who will not need treatment for the underlying condition, and on the other hand to ensure that those with a clinically significant condition will be adequately diagnosed.

This chapter addresses the initial approach to an individual with a monoclonal protein or suspected immunoglobulin disorder. We review the various conditions to consider in a patient with a monoclonal protein, so as to help guide the evaluation. The basic principles on the use of the various tests used, their interpretation, and limitations are also reviewed. Subsequent chapters in this book will deal with the detailed evaluation of specific diseases associated with monoclonal gammopathy.

Monoclonal Gammopathies

Mayo Clinic

1960-2010

FIGURE 95.1. Distribution of monoclonal gammopathies seen at Mayo Clinic between 1960 and 2010. MGUS, monoclonal gammopathy of undetermined significance; SMM, smoldering multiple myeloma.

CLASSIFICATION OF MONOCLONAL IMMUNOGLOBULIN DISORDERS

A prior understanding of the various conditions associated with the production of monoclonal immunoglobulins (monoclonal protein) is essential in the evaluation of an individual with a monoclonal gammopathy. The clinical presentation may be due to the magnitude of the underlying tumor burden or the direct toxic effect of the monoclonal protein. However, a simple way of approaching the evaluation of these cases is to start with the type of monoclonal protein (Table 95.1). Although the various diseases can be broadly classified based on the type of monoclonal protein, there is overlap in the underlying conditions. For example, an IgM monoclonal protein is usually associated with lymphoproliferative diseases such as Waldenström macroglobulinemia and some lymphomas, but may also be associated with cases of IgM-associated multiple myeloma.¹³

Initial Evaluation

The usual test that will detect a monoclonal protein is not part of the typical healthy adult physical evaluation.¹⁴ It is therefore usually detected during the evaluation of a clinical symptom or during further evaluation of an abnormal routine blood test. Abnormalities in routine clinical tests that suggest the possibility of a monoclonal protein disorder include rouleau formation in a peripheral blood smear, elevated total serum protein, proteinuria, anemia, renal dysfunction, or hypercalcemia. Clinical situations that may require evaluation for

P.2015

a monoclonal protein include back pain, osteoporosis disproportionate to age, pathologic fracture, osteolytic or sclerotic bone lesions, recurrent sinopulmonary infections, progressive peripheral neuropathy, infiltrative or restrictive cardiomyopathy, and Raynaud's phenomenon. It must, however, be noted that in these conditions a monoclonal protein

may not always be detected by standard testing, and further evaluation may be needed to confirm or exclude an underlying plasma cell or lymphoproliferative disorder, particularly if the index of suspicion is high. Most patients with monoclonal protein are asymptomatic, especially those in whom a routine blood abnormality leads to further testing, resulting in the identification of a monoclonal protein. A simple algorithm taking into consideration the various tests available and clinical presentation is shown in Figure 95.2. Although there may be some overlap, following this algorithm should lead to the correct diagnosis in most cases.

TABLE 95.1 CLASSIFICATION OF MONOCLONAL PROTEINS

Clinical implication	Laboratory finding	
	Non-IgM monoclonal proteins	IgM monoclonal proteins
Premalignant or undetermined	IgG, IgA, light chain, and other MGUS	IgM MGUS other lymphoproliferations
Intermediate	SMM	Smoldering macroglobulinemia
Malignant	Active MM Plasma cell leukemia	Waldenström macroglobulinemia or other lymphoproliferative disorders

MGUS, monoclonal gammopathy of undetermined significance; MM, multiple myeloma; SMM, smoldering multiple myeloma.

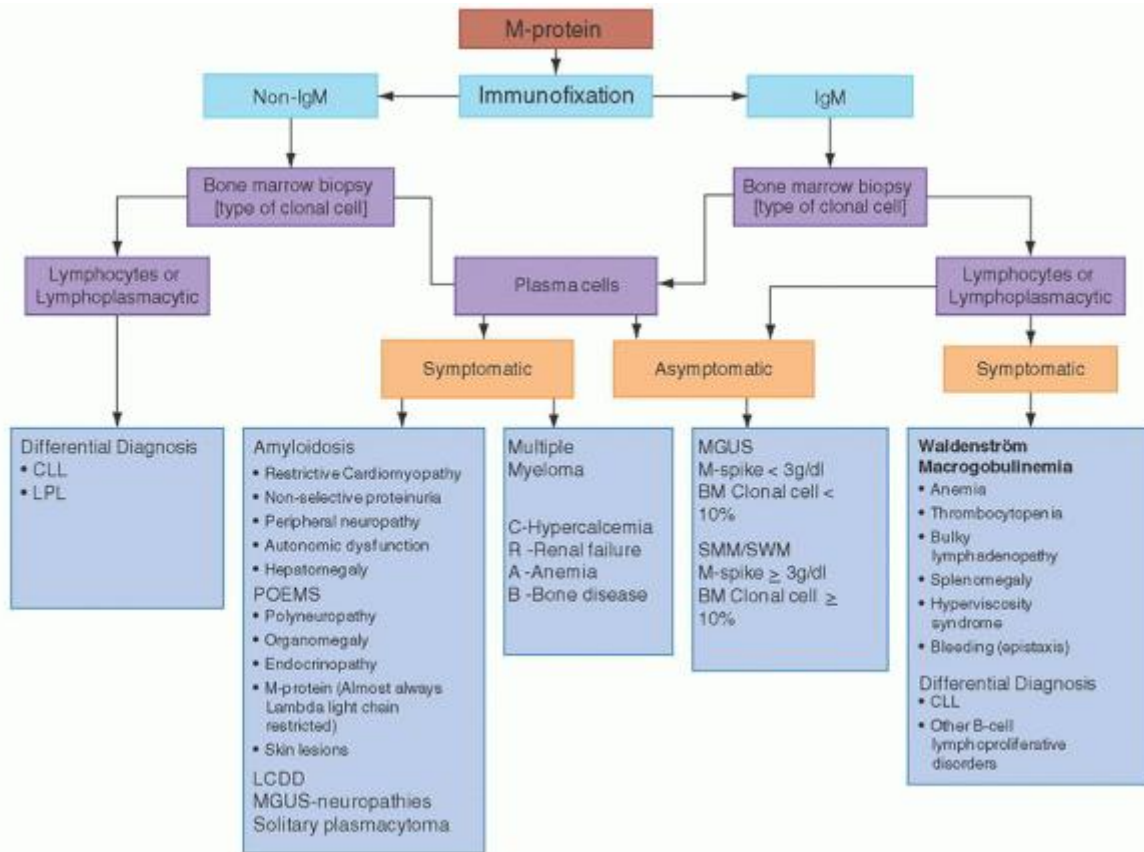

FIGURE 95.2. Simple diagnostic algorithm for patients with a monoclonal gammopathy. CLL, chronic lymphocytic leukemia; MGUS, monoclonal gammopathy of undetermined significance; SMM, smoldering multiple myeloma; SWM, Smoldering Waldenström macroglobulinemia; LCDD, light chain deposition disease; LDL, Lymphoplasmacytic lymphoma.

Laboratory Evaluation

The following are important tests that will help in the evaluation of a patient with or suspected to have a monoclonal protein.

PROTEIN ELECTROPHORESIS

Serum and urine should both be evaluated for the presence of a monoclonal protein. High-resolution agarose gel electrophoresis or capillary zone electrophoresis is the preferred method for screening for a monoclonal protein.^{15, 16, 17, 18, 19} These tests will separate serum or urine proteins into their various components in an electric field based primarily on their physical properties such as size and charge; the proteins are detected either by staining a solid matrix or by their electrical impedance as they exit the column. There are usually five components seen, albumin, α -1, and α -2, β -, and γ -globulin (Fig. 95.3).

Monoclonal proteins will usually migrate into the gamma regions; however, occasionally they may be seen in the β or α -2 region. Samples with a monoclonal protein usually will result in a spike in the gamma region (Fig. 95.4). This is referred to as the M-protein or M-spike with the "M" referring to monoclonal, not IgM. Further testing is then required to determine the type and quantity. All spikes should be evaluated, since in certain cases there may be two (biclinal gammopathy), or more, different monoclonal proteins in a single M-spike that should not be missed.^{20, 21, 22, 23} It must also be stressed that the gamma region contains all immunoglobulin isotypes (IgM, IgA, IgD, and IgE) and not only IgG. This same test can be used to determine the amount of monoclonal protein present using the densitometer tracing or peak size by capillary zone electrophoresis (Fig. 95.4). The measured M-protein by densitometry tracing is usually lower than the total involved immunoglobulin measured by nephelometry.¹⁶ Protein electrophoresis occasionally

P.2016

may fail to identify the presence of a monoclonal protein, especially in cases where there is only minimal production of the monoclonal protein, or minimal amounts of immunoglobulin free light chains.²⁴ Currently in such cases performing immunofixation despite a negative protein electrophoresis or using the serum free light chain analysis may be the only way to confirm the presence of an underlying clonal disorder, although tandem mass spectroscopy methods are currently being explored.^{21, 25, 26} A monoclonal protein spike should not be confused with a polyclonal increase in immunoglobulin, which usually will be seen as a broad-based band in the gamma region and is not associated with a clonal cell disorder²⁷ (Fig. 95.5).

FIGURE 95.3. Images of a normal serum electrophoresis, showing the five protein components.

FIGURE 95.4. Images of a serum protein electrophoresis and immunofixation depicting a monoclonal protein.

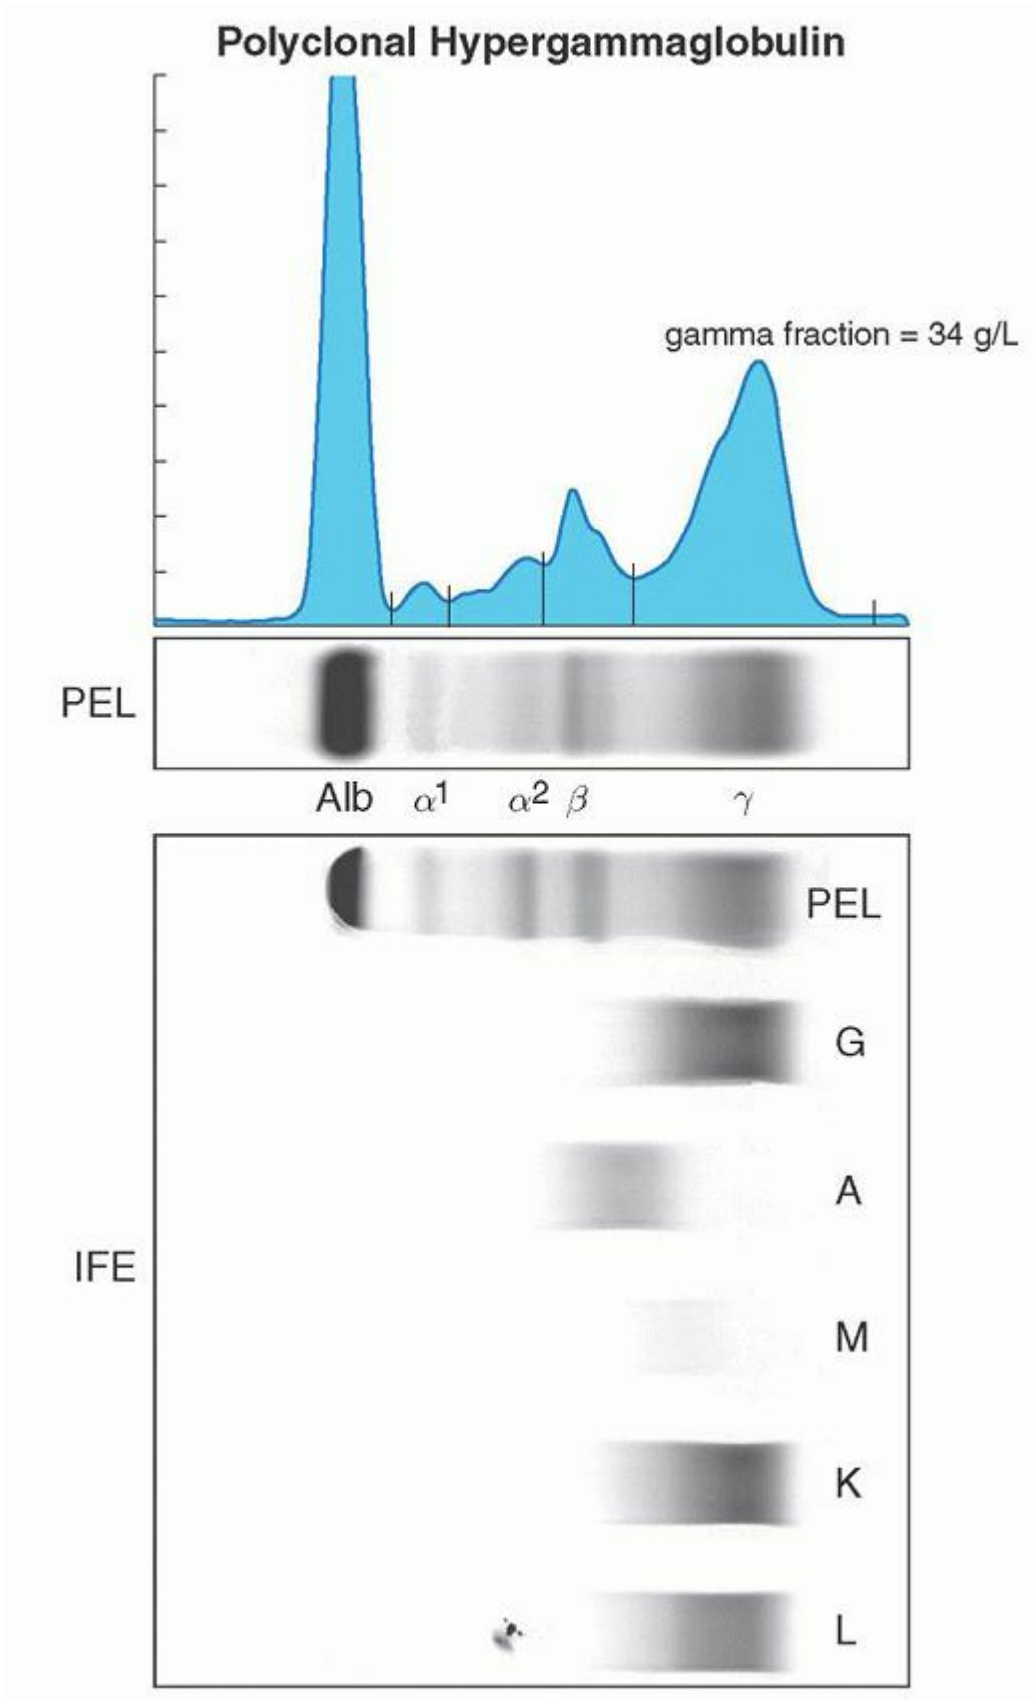

FIGURE 95.5. Images of a serum protein electrophoresis depicting a polyclonal gammopathy. IDENTIFICATION OF THE TYPE AND QUANTITATION OF THE MONOCLONAL PROTEIN

The heavy and light chain isotypes of a monoclonal protein is usually determined by immunoelectrophoresis or immunofixation.^{15, 16, 21} Immunoelectrophoresis, although less expensive, is infrequently used, as it is relatively insensitive. Immunofixation involves the application of anti-heavy and antilight chain antibodies to the electrophoretic gel and has higher detection sensitivity. Immunofixation will identify both the heavy chain isotype (IgG, IgM, IgA, IgD, or IgE) and the light chain type (κ or λ) and should always be performed on all cases of protein electrophoresis with an M-spike. A case with an IgG heavy chain isotype and a κ -light chain will be reported as an IgG- κ monoclonal protein (Fig. 95.6). Most laboratories will initially only perform immunofixation for IgG, IgA, and IgM. Immunofixation for IgD and IgE must be performed if an M-spike is present and either initial immunofixation studies are negative or detect only a monoclonal light chain (Fig. 95.7). The isotype and quantity of the monoclonal protein is important for classification and prognosis. For example in MGUS, the risk of progression is lower in patients with IgG isotype and an M-spike less than 0.5 g/dl. The type of protein and quantity is also important for monitoring patients during therapy. Immunofixation should still be performed in cases where there is a strong suspicion of the presence of a clonal plasma cell or

P.2017

lymphoproliferative disorder, even if the protein electrophoresis is negative for an M-spike. Capillary zone electrophoresis with immunosubtraction is an automated system that is slightly more sensitive than high-resolution agarose gel electrophoresis and can be used in the identification, subtyping, and measurement of the M-protein.^{17, 19} This method is laborious and time consuming, however, making it less frequently used for typing of the monoclonal protein.

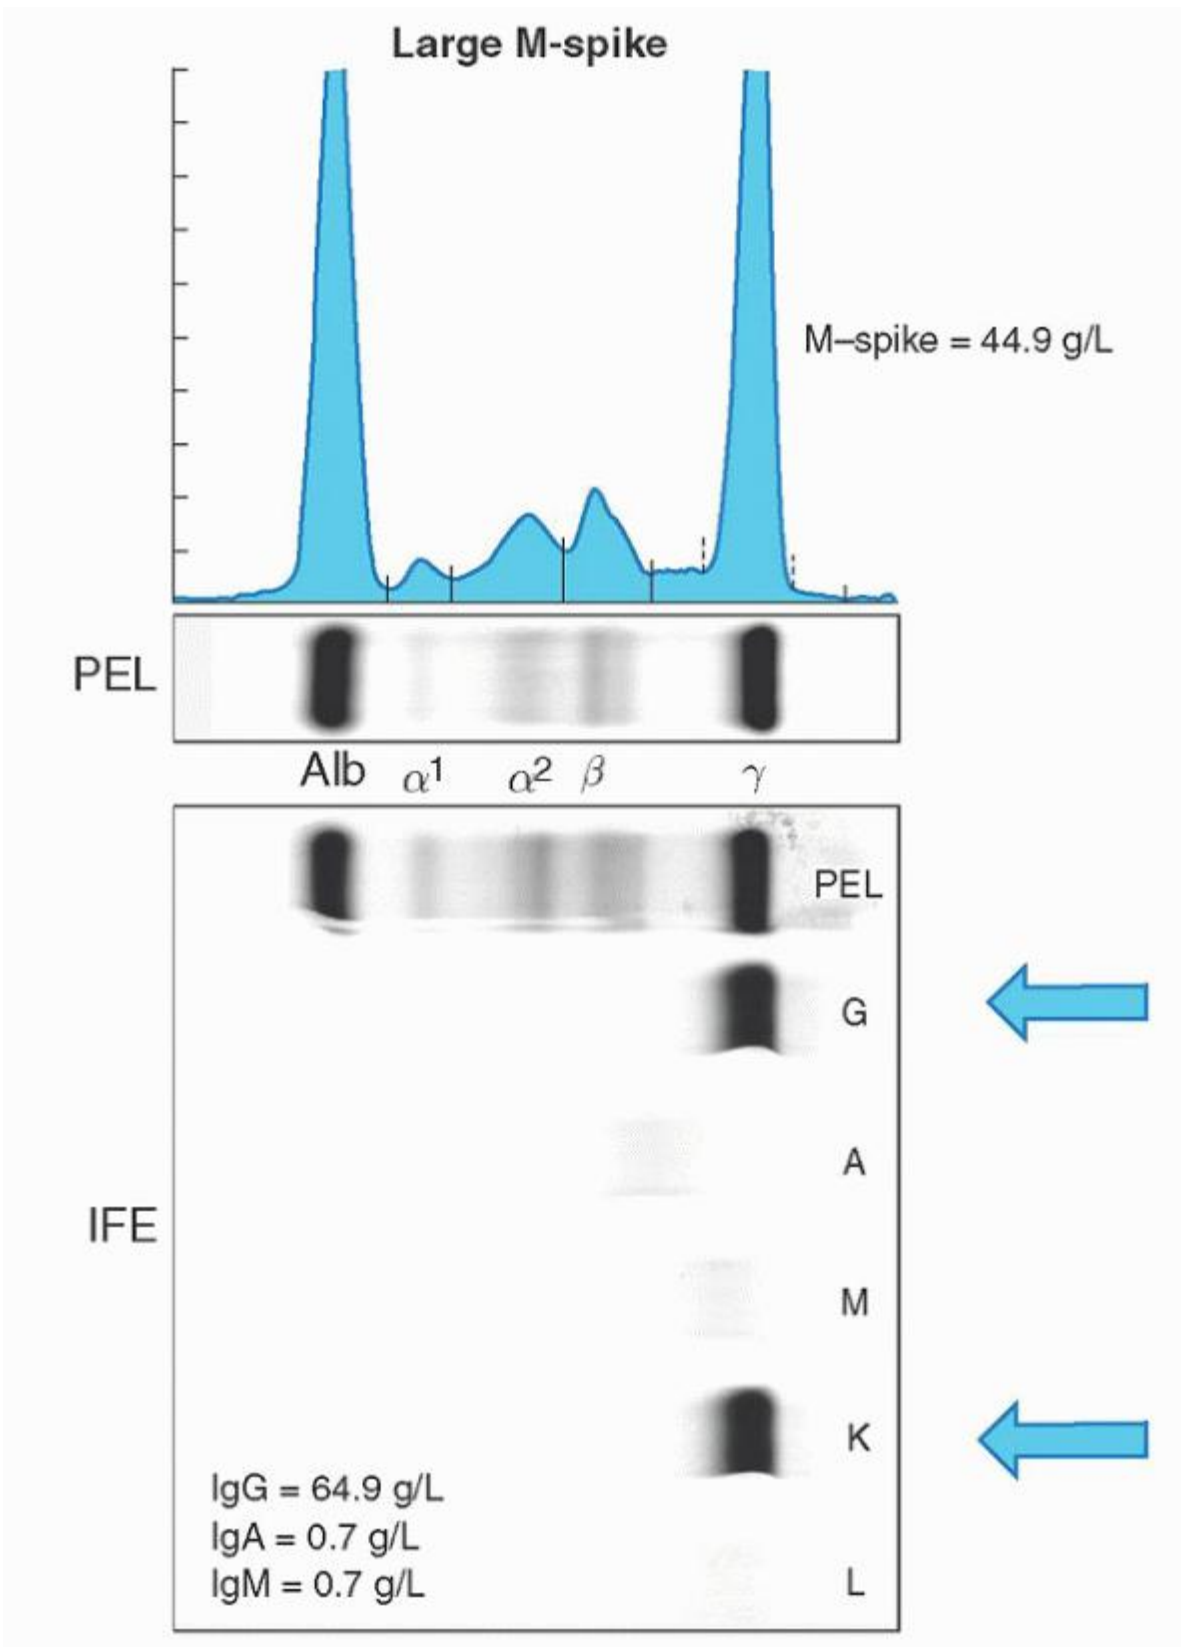

FIGURE 95.6. Protein electrophoresis and immunofixation studies characterize a monoclonal IgG- κ protein. The arrows indicate the lanes that show reactivity with the specific antibodies. The reactivity is consistent with the same migration shown in the extreme left column that shows the electrophoresis. Thus, in this assay the nature of the monoclonal protein seen in the electrophoresis is elucidated: isotype G and light chain- κ .

QUANTITATION OF IMMUNOGLOBULINS

Immunoglobulin (IgG, IgA, IgM) levels should always be measured at diagnosis and monitored regularly during therapy, especially the involved immunoglobulin. If immunofixation showed an IgD or IgE M-protein, then their levels should also be determined. In most clonal plasma cell disorders the levels of the uninvolved immunoglobulins are suppressed or reduced. Rate nephelometry is a reliable and rapid method for immunoglobulin quantification, although this method does not differentiate between monoclonal and polyclonal immunoglobulin.^{28, 29} Rate nephelometry also does not provide information on how much of the measure immunoglobulin is abnormal; therefore, in patients with normal total immunoglobulin it is not clinically helpful. This test does have value in clinical care however, as knowing the level in severely hypogammaglobulinemic states will help determine who should receive immunoglobulin replacement, especially those with recurrent sinopulmonary infections.

FIGURE 95.7. Images of a positive protein electrophoresis but initial negative immunofixation for IgG, IgA, or IgM isotype with further testing for IgD and IgE showing an IgD isotype with λ -light chain.

P.2018

FREE LIGHT CHAIN ASSAY

A significant population of patients with clonal plasma disorders produces excess amounts of light chain but not a full immunoglobulin molecule: Bence Jones proteinemia.³⁰ Most of these patients will have a negative protein electrophoresis and immunofixation. In these patients the free light chain assay test may be the only way to detect the presence of a clonal plasma cell disorder.^{24, 25, 26} Immunoglobulin free kappa (κ) and lambda (λ) light chains concentration in the serum is usually dependent on the rate of production from plasma cells and renal clearance. This results in a defined serum concentration and ratio. In clonal plasma cell disorders there is an excess production of only one of the light chain types, resulting in higher levels, with suppression of the uninvolved light chain, leading to an abnormal κ/λ ratio. The levels and ratio, however, may be affected by renal failure, since the light chains are cleared by the kidneys. This test has become very important in the evaluation and monitoring of patients with amyloidosis, since this is the major protein involved in AL-type amyloid deposits.³¹

URINE EVALUATION

In all patients with a serum M-protein or suspected to have a clonal plasma cell or lymphoplasmacytic disorder, a 24-hour urine collection should be examined for the presence of a monoclonal protein and 24-hour urine protein and monoclonal protein excretion. The excretion of immunoglobulin free light chain in the urine is referred to as Bence Jones proteinuria.³⁰ The pattern of protein excretion, whether the urine protein is solely albumin or Bence Jones protein, is of diagnostic importance. For example, nonselective proteinuria (albumin predominance) is associated with glomerular diseases such as AL amyloidosis caused by the presence of a monoclonal protein.^{12, 31}

FIGURE 95.8. Identification of abnormal and normal plasma cells (PCs) by flow cytometry. All plasma cells are CD38 and CD138 positive. The abnormal plasma cells are CD19 and CD45 negative and λ -immunoglobulin light chain restricted.

Bone Marrow and Tissue Evaluation

Bone marrow aspiration and biopsy should be performed in all patients except in a selected group of completely asymptomatic patients with a very small monoclonal protein if a diagnosis of MGUS is favored.^{32, 33, 34} Even in the latter

setting, however, most hematologists will recommend this test, since apart from giving information on the type of clonal cell disorder, it also provides information on the extent of disease. For example, the presence of less than 10% marrow plasma cells distinguishes MGUS from smoldering multiple myeloma (SMM).¹⁰

Basic evaluation of the bone marrow sample should include extent of infiltration by the cells of interest, reported as a percentage of the total marrow nucleated cells and/or cellularity. Flow cytometric or immunophenotyping can confirm both the cell type (lymphoid vs. plasma cell) and clonality^{35, 36} (Fig. 95.8). Flow cytometry is particularly useful when following patients on therapy, as it is more sensitive in assessing the depth of response. Plasma cell DNA content can also be measured by flow cytometry, allowing measurement of ploidy status and proliferation rate, which, along with the proportion of normal plasma cells provides important prognostic information.³⁷ Plasma cell proliferation can also be measured by the labeling index (PCLI) which uses a BrdU pulse label and immunofluorescent detection.³⁸ However, it is not generally accessible and is not necessary in the majority of patients.

Metaphase cytogenetics and fluorescent in situ hybridization for specific gene targets should be obtained in a subset of cases, since these provide prognostic information in certain clonal cell disorders. For example, in multiple myeloma, cytogenetic abnormalities provide important prognostic information, and therefore this must be obtained in all suspected cases at the time of initial evaluation.^{39, 40, 41, 42} Gene expression profile analysis of the malignant plasma cells in multiple myeloma is of prognostic value and should be obtained if available.^{43, 44, 45}

P.2019

CONGO RED STAIN

In certain cases, a Congo red stain of subcutaneous fat aspirate or a bone marrow biopsy will have to be performed, looking for amyloid deposition.^{12, 46, 47} In about 70% of cases of AL amyloidosis Congo red staining of bone marrow or subcutaneous fat aspirate will be sufficient to make the diagnosis. The remaining cases will require biopsy of the involved organ. All patients with peripheral neuropathy, significant albuminuria, or infiltrative cardiomyopathy in the setting of a monoclonal protein should have this test done. It should also be considered in patients in whom there is a high clinical suspicion of amyloidosis. If this is positive, then liquid chromatography tandem mass spectrometry of peptide extracts from the congophilic material should then be done for subtyping of the amyloid deposits.⁴⁸

Imaging

The imaging required for the evaluation of a patient with monoclonal protein depends on the clinical syndrome and type of monoclonal protein. A metastatic skeletal survey should be performed in all patients with non-IgM monoclonal protein. In multiple myeloma this may show lytic bone lesions (Fig. 95.9). One should also look for vertebrae compression fractures, and osteoporosis or osteopenia. These radiologic studies should also be performed in IgM monoclonal gammopathies if there is a strong clinical suspicion of IgM myeloma. For all cases of suspect multiple myeloma, a skeletal survey is still considered the standard test for bone evaluation.^{49, 50, 51} More sensitive modalities such as magnetic resonance imaging or PET-CT may provide further information.^{52, 53, 54, 55} Magnetic resonance imaging is particularly useful for the assessment of the extent and nature of soft tissue disease arising from bone lesions, especially those in the spine which may cause neurologic compromise. PET-CT is usually helpful in the evaluation of plasmacytomas and cases of nonsecretory multiple myeloma^{56, 57, 58} (Fig. 95.10). In our experience, this modality has been helpful in the evaluation of patients with POEMS syndrome, by helping identify hypermetabolic osteosclerotic bone lesions. Computer tomography (CT) scanning of the chest, abdomen, and pelvis should be performed in cases of IgM gammopathy, since they are usually associated with lymphoproliferative disorders which may involve the lymph nodes, spleen, and mucosa-associated lymphoid tissues.

FIGURE 95.9. Skeletal bone survey showing lytic lesions typically seen in multiple myeloma.

History and Physical Evaluation

A detailed history and physical examination should be obtained any time a monoclonal protein is identified. Certain signs and symptoms may help guide the evaluation and ultimately indicate the appropriate diagnosis. For instance, patients presenting with bone pain, pathologic fractures, weight loss, and symptoms of hypercalcemia or acute renal failure are more likely to have multiple myeloma.⁹ Alternatively, those with night sweats, epistaxis,

P.2020

and lymphadenopathy are more likely to have lymphoproliferative disorders such as Waldenström macroglobulinemia, marginal zone lymphoma, or chronic lymphocytic leukemia/small lymphocytic lymphoma.^{8, 35, 59, 60, 61}

FIGURE 95.10. PET-CT scan showing multiple soft tissue plasmacytomas in a patient with negative marrow biopsy.

Other less common conditions may also be revealed by patient assessment. A diagnosis of amyloidosis may be indicated by the presence of edema, shortness of breath, hepatomegaly, peripheral neuropathy (e.g., carpal tunnel syndrome), autonomic dysfunction, periorbital purpura, and macroglossia.^{12, 31, 47} Skin rash, neuropathy, and Raynaud's phenomenon should prompt evaluation for cryoglobulinemia.^{5, 62} Those presenting with polyneuropathy, multiple endocrinopathy, skin lesions like glomeruloid hemangiomas, and organomegaly may have POEMS syndrome.¹¹ Importantly, one should never overlook the initial reason that led to the identification of the monoclonal protein. Most patients in whom a monoclonal protein is identified are asymptomatic. For these patients, the key to a correct diagnosis may be the reason for the initial testing for the monoclonal protein. In a case where a mildly elevated serum creatinine was the key factor, a nephrology evaluation with possible kidney biopsy may be the only way to diagnose immunoglobulin deposition disease of the kidney.^{6, 63, 64}

Monoclonal gammopathies are common in the elderly, who are also at risk for other pathologic conditions and are usually on multiple medications with their side effects. Therefore it is necessary to always confirm that the identified abnormality is due to the clonal cell disorder or monoclonal protein rather than to another unrelated pathologic condition. For example, mild hypercalcemia in association with a monoclonal protein may be due to parathyroid disease or medication in a patient with benign MGUS rather than myeloma. Renal failure or proteinuria in a hypertensive or diabetic patient with monoclonal protein should be investigated thoroughly before attributing it to the monoclonal protein. Such cases may require a kidney biopsy.

Diagnostic Algorithm (Fig. 95.2)

In a patient suspected of having an underlying gammopathy, one should first define the isotype and then quantity of the monoclonal protein. This will certainly help in identifying and defining the underlying clonal cell disorder. In the majority of cases, appropriate tissue biopsy and histopathologic evaluation should aid in providing a definitive diagnosis. Bone marrow biopsy is usually requisite. In certain situations, directed biopsy of a single bone lesion, lymph node, or soft tissue mass may also be needed. Tissue diagnosis can also be helpful in deciding therapeutic intervention; for example, the use of rituximab for the treatment of an IgM MGUS associated neuropathy can be indicated by finding an underlying CD20-positive lymphoproliferative disorder. Once the type of monoclonal protein and underlying clonal cell disorder has been established, the physician then needs to look into the patients' history, physical examination, and laboratory data to determine whether this clonal disorder is having any systematic effect. The typical issues are usually with the hematopoietic (anemia, thrombocytopenia, bulky lymphadenopathy), skeletal (lytic lesion, pathologic fracture, and sclerotic lesions), renal (cast nephropathy, immunoglobulin deposition disease, and nephrotic range proteinuria), nervous

system (peripheral neuropathy, autonomic dysfunction), cardiovascular (restrictive cardiomyopathy), and/or the endocrine systems. There may be overlap of symptoms, but understanding the various syndromes is important in helping to arrive at the correct diagnosis.

Differential Diagnosis of Monoclonal Gammopathy (Table 95.2)

The majority of non-IgM monoclonal gammopathies are initially classified as MGUS.¹⁰ In most MGUS patients the M-protein is a complete immunoglobulin molecule; however, some may have only light chain and therefore are classified as light chain MGUS.² MGUS patients do not have any symptoms or laboratory abnormalities attributable to the underlying clonal plasma cell disorder; specifically, they do not have anemia, hypercalcemia, renal insufficiency, or disease-associated bone disease. They should have less than 3 g/dl of monoclonal protein and less than 10% bone marrow plasma cell. Patients with similarly minimal clinical sequelae and an M-protein ≥ 3 gm/dl or $\geq 10\%$ clonal bone marrow plasma

P.2021

cell are classified as having SMM.⁶⁵ Distinguishing between MGUS and SMM has prognostic significance and will determine frequency of follow-up. As bone marrow examination may be the only factor that will upgrade an MGUS to SMM, this must be strongly considered in the evaluation of all monoclonal gammopathies. Neither MGUS nor SMM require therapeutic intervention; patients with MGUS have a lower risk of progression to MM at about 1% per year, compared to 10% to 20% in patients with SMM. Closer follow-up is needed for SMM compared to MGUS.¹⁰

TABLE 95.2 DIFFERENTIAL DIGNOSIS OF MONOCLONAL GAMMOPATHIES

IgM type
IgM MGUS (may also be biclonal)
Smoldering Waldenström macroglobulinemia
Waldenström macroglobulinemia
Other (including lymphoma and IgM MM)
Non-IgM type
Non-IgM MGUS (may also be biclonal)
SMM
MM
Plasma cell leukemia
Solitary plasmacytoma
Amyloidosis complicating a B cell neoplasm (AL)
Miscellaneous monoclonal gammopathy-associated conditions
Osteosclerotic MM with peripheral neuropathy
POEMS syndrome
Cryoglobulinemia
Peripheral neuropathy associated with MGUS
SLONM
Fanconi's syndrome
Light or heavy chain deposition disease
Castleman's disease
Scleromyxedema
Necrobiotic xanthogranuloma

Systemic capillary leak syndrome

Angioimmunoblastic lymphadenopathy with monoclonal protein

Other

MGUS, monoclonal gammopathy of undetermined significance; MM, multiple myeloma; SLONM, sporadic late onset nemaline myopathy SMM, smoldering multiple myeloma.

Patients with myeloma should meet the CRAB criteria, defined as hypercalcemia, renal insufficiency, anemia, or bone disease.⁶⁶ It is necessary to confirm that these complications are due to the underlying clonal plasma cell disorder. These patients do require therapy and should be under the care of a specialist with detailed knowledge of the management of multiple myeloma and associated complications. Solitary plasmacytomas should also be recognized, since these require only limited therapy.⁵⁶ These patients have a single bone or soft tissue mass, a negative bone marrow biopsy, and do not meet the CRAB criteria. Local therapy such as radiation, cryotherapy, or surgical excision is usually all that is required.⁶⁷ They do have a better prognosis.

A significant number of patients with monoclonal gammopathy develop complications as a result of the toxic effect of the monoclonal protein. In amyloidosis, misfolding of the monoclonal protein, usually the light chain component, results in the formation of insoluble amyloid deposits in major organs of the body.^{12, 31, 47} This deposition results in structural and physiologic dysfunction of the affected organ. An amyloid diagnosis is easy to make when presenting with macroglossia in association with periorbital purpura.⁶⁸ Most, however, will present with symptoms secondary to the organ involvement, such as chest pain and shortness of breath due to restrictive cardiomyopathy in cardiac cases, and peripheral neuropathy and autonomic dysfunction in nervous system disease. Nonselective proteinuria with hypoalbuminemia is seen in kidney involvement. Hepatomegaly with elevated alkaline phosphates will be seen in those with liver disease, and those with gastrointestinal involvement will have constipation or diarrhea. Patients may present with multiple organ involvement, causing a protean constellation of findings; in such cases a strong suspicion of amyloidosis is required in order not to miss the diagnosis.

Nonamyloidotic immunoglobulin deposition diseases such as light chain deposition diseases are a group of conditions that should be considered during the evaluation of monoclonal gammopathy.⁶⁹ This involves the deposition of light chains in the kidney or heart. Renal involvement presenting with renal failure with some proteinuria is the most common.⁶⁴ Heart involvement, although not common, does occur, presenting with restrictive cardiomyopathy, and should be differentiated from amyloidosis.⁷⁰

IgM monoclonal gammopathy is usually associated with an underlying B cell lymphoproliferative disorder, and true IgM myeloma is exceedingly rare.¹³ A large percentage of these IgM monoclonal gammopathy patients will have an IgM MGUS or Waldenström macroglobulinemia.^{59, 71} The remainder often has a variety of other B cell lymphoproliferative diseases such as chronic lymphocytic leukemia, marginal zone lymphoma, and large cell lymphoma.⁸ Those with Waldenström macroglobulinemia may present with cytopenias, hyperviscosity syndrome, epistaxis, lymphadenopathy, and splenomegaly.^{35, 61, 72}

There are other rare monoclonal gammopathy associated conditions that should be considered during the evaluation of a monoclonal protein. The evaluation in these cases is usually dictated by the clinical presentation; for example, those with neuromuscular complications should be evaluated for conditions such as POEMS syndrome, the antimyelin associated glycoprotein-associated neuropathy, or sporadic late onset nemaline myopathy.^{11, 73, 74} POEMS patients, in addition to the neuropathy, do have organomegaly (lymphadenopathy, splenomegaly, cardiomegaly, and hepatomegaly), multiple endocrine dysfunction, and skin changes (glomeruloid hemangiomas, hyperpigmentation). Almost all POEMS patients do have a λ -light chain restricted monoclonal protein, and it may be a non-IgM or IgM monoclonal protein. If a patient has a κ -light chain monoclonal protein, they most probably do not have POEMS syndrome.

Skin conditions such as scleromyxedema, necrobiotic xanthogranuloma, and cryoglobulinemia should be considered in the differential diagnosis when patients present with cutaneous lesions.^{7, 62, 75, 76, 77, 78}

Summary and Recommendations

The diagnostic approach to monoclonal gammopathy should be thorough and involve a detailed history, physical examination, appropriate laboratory testing, and imaging. This should distinguish benign from clinically relevant conditions that need immediate intervention. A good understanding of conditions associated with monoclonal gammopathy is essential. Testing and evaluation should include the following considerations.

- Serum and urine protein electrophoresis, followed by immunofixation will confirm the presence of the monoclonal protein, identify and classify the isotype, and provide an estimation of the amount. Immunoglobulin free light assay will help identify cases with only free light chain production, but negative protein electrophoresis.
- Immunoglobulin isotype quantification is helpful for monitoring.
- A bone marrow evaluation will determine the nature of the underlying B-lineage disorder (plasma cell or lymphoproliferative) and also the extent of marrow infiltration.
- Complete blood count analysis will identify cytopenias which may be due to bone marrow replacement or immune mediated causes.
- Comprehensive metabolic panel, looking at serum calcium, creatinine, bilirubin, lactate dehydrogenase, and liver transaminases is essential.
- Bone and soft tissue imaging, looking for bony lesion and soft tissue masses such as lymphadenopathy or plasmacytoma is also needed.
- A detailed history and physical evaluation should help direct further testing.

INTRODUCTION

Multiple myeloma (MM) is an age-dependent monoclonal tumor of bone marrow (BM) plasma cells (PCs), often with significant end organ damage that can include lytic bone lesions, anemia, loss of kidney function, immunodeficiency, and amyloid deposits in various tissues.¹ It has an estimated incidence of 21,700 in 2012, with 10,710 deaths in the United States.² Despite recent therapeutic advances, MM continues to be a mostly incurable disease but with a 5-year survival rate reported in the SEER database that has increased from 28% (1987 to 1989) to 43% (2002 to 2008).³ In fact, a subset of

younger patients initially treated in 1999 can be identified with a 10-year survival rate of 75%,⁴ with presumably even better results possible for patients starting treatment today. The incidence is higher in blacks than whites, and in men than women (Fig. 96.1),³ and it is evident from the SEER registry data that although the incidence of MM continues to rise with an annual percentage change of close to 1%, since 1995 the mortality rate has been decreasing at an even faster rate. MM cells are similar to postgerminal center (GC) long-lived PCs, characterized by strong BM dependence, extensive somatic hypermutation (SHM) of immunoglobulin (Ig) genes, and absence of IgM expression in all but 1% of tumors.⁵ However, MM cells differ from healthy PCs because they retain the potential for a low rate of proliferation (1% to 3% of cycling cells). MM has served as a useful model for understanding the pathogenesis of lymphoid tumors because it is characterized by the presence of a premalignant precursor tumor and defined stages, with researchers able to isolate purified tumor cell populations at all stages.

FIGURE 96.1. Differences in US incidence and mortality rates over time, by race and gender. Source is the SEER 9 areas and US mortality files. The most recent annual percentage change for each rate is indicated adjacent to the respective regression line.

MULTIPLE MYELOMA IS A PLASMA CELL TUMOR OF POSTGERMINAL CENTER B CELLS

Pre-GC B cells can generate short-lived PC that mostly remain in the primary lymphoid tissue (Fig. 96.2). Post-GC B cells can generate plasmablasts (PB) that have successfully completed multiple rounds of SHM and antigen selection, followed by IgH switch recombination, with both B cell-specific DNA modification processes having oncogenic potential.⁶ These PB typically migrate to the BM, where stromal cells facilitate terminal differentiation into long-lived PC.⁷ The surface immunophenotype of normal BM PCs is CD38⁺CD138⁺ CD19⁺CD45⁺CD56⁻. Although monoclonal gammopathy of undetermined significance (MGUS), SMM, and MM tumor cells also are CD38⁺CD138⁺, 90% are CD19⁺, 99% are CD45⁻ or dim, and 70% are CD56⁺.^{8, 9} The reason for this immunophenotypic difference is not known. Possibly there is a normal PC with an MM phenotype, but it is rare, and/or transient, and it has yet to be identified. Alternatively, the change in the phenotype may be a consequence of the transformation process.

FIGURE 96.2. Normal and malignant plasma cell development. Pre-germinal center (GC) B cells expressing surface immunoglobulin can enter germinal centers where the immunoglobulin genes undergo repeated rounds of somatic hypermutation followed by IgH isotype switch recombination. In multiple myeloma (MM), IgH translocations occur as a result of errors in these two physiologic DNA modification processes (10% and 90%, respectively). Post-GC B cells can generate plasmablast that homes to the bone marrow where stromal cells facilitate differentiation into long-lived PC. Normal plasma cell (PC) express surface CD138, CD19, and CD45; whereas MM cells express CD138, only 10% express CD19, 99% are CD45⁻ or dim, and 70% express CD56. Ig, immunoglobulin; PB, plasmablasts.

P.2023

MULTIPLE MYELOMA IS ALMOST ALWAYS PRECEDED BY AN ASYMPTOMATIC MONOCLONAL GAMMOPATHY

An age-dependent premalignant tumor called monoclonal gammopathy of undetermined significance (MGUS)^{10, 11} is present in about 4% of individuals over the age of 50^{12, 13} and precedes almost every case of MM. A PC tumor must contain at least a billion cells to produce enough monoclonal Ig (M-Ig) or M-IgL (in the 15% of tumors that produce only IgL) to be detected by serum or urine electrophoresis or a serum-free IgL assay. It can be subclassified as lymphoid (15%) or PC (85%) MGUS, which can progress sporadically at average rates of 1% per year to chronic lymphocytic leukemia/lymphoma/lymphoplasmacytoma/Waldenström's macroglobulinemia and MM, respectively.¹⁴ Lymphoid MGUS and PC MGUS can be distinguished by morphology, although clinically the distinction is primarily based on the type of M-Ig detected in serum or urine: mostly IgM for lymphoid MGUS and mostly non-IgM (including Ig light chain only) for PC MGUS. MGUS is distinguished from MM by having a M-Ig of <30 g/L, with no more than 10% of BM mononuclear cells being tumor cells, and no end organ damage or other symptoms. In primary amyloidosis (AL) there is a monoclonal gammopathy which is symptomatic because of pathologic deposits of intact or portions of M-Ig in various tissues.¹⁵ Unfortunately, the pathologic deposits can lead to organ failure, so that the median survival of patients with AL is only 3 years, even with a very small number of premalignant tumor cells.¹⁶ Progression of MGUS to smoldering MM and symptomatic MM is associated with an expanding BM tumor mass and increasingly severe organ impairment or symptoms.¹ Despite BM dependence, sometimes the tumor extends to extramedullary locations, such as spleen, liver, and extracellular spaces. Extramedullary MM (EMM) typically is a more aggressive tumor that sometimes is associated with secondary or primary plasma cell leukemia (PCL), depending on whether or not preceding intramedullary MM was recognized.

Human MM cell lines (HMCLs), which provide a renewable repository of most oncogenic events involved in initiation and progression of the corresponding MM tumor, can sometimes be generated, but usually only from EMM tumors.^{17, 18}

A SELECTION FOR GENETIC MUTATIONS THAT ALLOW INDEPENDENCE FROM THE BONE MARROW MICROENVIRONMENT

In considering the diverse array of mutations in MM, it is helpful to place their pathways in the context of the biology of normal BM-localized PCs. MGUS and MM cells, similar to long-lived PC, are dependent on the BM microenvironment, which includes the extracellular matrix and many kinds of cells, e.g., stromal cells, osteoclasts, osteoblasts, immune cells (T lymphocytes, dendritic cells), other hematopoietic cells, and their precursors, vascular endothelial cells.^{5, 19, 20} These cells mediate reciprocal positive and negative interactions by a variety of adhesion molecules, cytokines, and receptors. Additional stimuli such as hypoxia result in activation of HIF1- α and secretion of VEGF.²¹ For MM, there are several

biologic phenomena that are affected by these tumor-host interactions, including differentiation, and proliferation of tumor cells (most notably IL-6, IGF-1, APRIL); homing to BM; spread to secondary BM sites by the blood stream; generation of many paracrine factors that are involved in survival; angiogenesis; osteoclastogenesis; inhibition of osteogenesis; enhanced resistance to chemotherapeutic agents; humoral and cellular immunodeficiency; and anemia. Many of these tumor-host interactions (e.g., homing, differentiation, and survival) appear to be qualitatively similar for PC and MM tumor cells, whereas the altered composition of the BM microenvironment represents a pathologic response to the MGUS and MM tumor cells. Several therapies (IMiDs, proteasome inhibitors) might target not only the tumor cell but also its interaction with the BM microenvironment. Several of the secondary genetic events associated with the progression of MM discussed below constitutively activate the pathways implicated downstream of the interaction of the MM cell with the BM microenvironment.^{22, 23}

Seven Primary IgH Translocations Are an Early Oncogenic Event in Monoclonal Gammopathy of Undetermined Significance and Multiple Myeloma

Like other B cell tumors, translocations involving the IgH locus (14q32) or one of the IgL loci (κ , 2p12, or λ , 22q11) are common in MM. It seems likely that these events are mediated by errors in IgH switch recombination, or SHM, since the breakpoints are usually located near or within IgH switch regions, but sometimes near VDJ sequences.²⁴ Since there is no evidence that IgH switch recombination or SHM mechanisms are active in normal PC or PC tumors, it is presumed that these translocations usually represent primary—perhaps initiating—oncogenic events as normal B cells pass through GCs. The translocations result in dysregulated or increased expression of an oncogene that is positioned near one or more of the strong Ig enhancers. However, translocations involving an IgH switch region uniquely dissociate the intronic from one or both 3' IgH enhancers, so that an oncogene might be juxtaposed to an IgH enhancer on either or both of the derivative chromosomes, as first demonstrated for FGFR3 on der(14) and

P.2024

MMSET on der(4) in MM. Rarely, tumors can have translocations involving two of the primary translocation groups, suggesting that there can be some complementation.¹⁸

These IgH translocations are efficiently detected by fluorescent in situ hybridization analyses. Large studies from several groups show that the prevalence of IgH translocations increases with disease stage: about 50% in MGUS or SMM, 55% to 70% for intramedullary MM, 85% in PCL, and >90% in HMCL.^{25, 26} Limited studies indicate that IgL translocations are present in about 10% of MGUS/SMM tumors, and about 15% to 20% of intramedullary MM tumors and HMCL.¹⁸ Translocations involving an IgK locus are rare, occurring in only 1% to 2% of MM tumors and HMCL.¹⁸

There are three recurrent primary IgH translocation groups, with the chromosomal sites, target oncogenes, and approximate prevalence in MM (~40% prevalence for all three groups) as follows: CYCLIN D (11q13-CYCLIN D1-15%; 12p13-CYCLIN D2- < 1%; 6p25-CYCLIN D3-2%) MAF (16q23-MAF-5%; 20q12-MAFB-2%; 8q24.3-MAFA-< 1%; MMSET/(FGFR3)-4p16-(MMSET in all but also FGFR3 in 80% of these tumors)-15%.

Chromosome Content Is Associated with at Least Two Different Oncogenic Pathways

There is a consensus that chromosome content reflects at least two pathways of pathogenesis. Nearly half of MGUS and MM tumors are hyperdiploid (HRD), with 48 to 75 (mostly 49 to 56) chromosomes, usually with extra copies of three or more specific chromosomes (3,5,7,9,11,15,19,21). Nonhyperdiploid (NHRD) tumors have <48 and/or >75 chromosomes. Strikingly, HRD tumors rarely (~10%) have a primary IgH translocation, whereas NHRD tumors usually (~70%) have an IgH translocation.²⁷ Tumors with a t(11;14) may represent a distinct category of NHRD tumors as they often are diploid or pseudodiploid. Curiously, EMM tumors and HMCLs nearly always have a NHRD genotype, suggesting that HRD tumors are more stromal cell dependent than NHRD tumors. Although it has been proposed that NHRD and HRD tumors represent different pathways of pathogenesis, the timing, mechanism, and molecular consequences of hyperdiploidy is unknown. Interestingly, in patients with t(4;14) or t(14;16) or t(14;20) or del17p, the presence of one or more trisomies is associated with a substantially better prognosis than with the absence of trisomies. This suggests that the phenotype associated with trisomies may be dominant.²⁸

Universal Cyclin D Dysregulation

Almost all cases of PC neoplasms starting from the MGUS stage express 1 or more of the CYCLIN D genes in an aberrant fashion, despite a low proliferation index.²⁹ Therefore, it has been proposed that dysregulation of a CYCLIN D gene provides a unifying, early oncogenic event in MGUS and MM. MGUS and MM appear closer to normal, nonproliferating PCs than to normal proliferating PB, for which 30% or more of the cells can be in S phase; yet the expression level of

CYCLIN D1, CYCLIN D2, or CYCLIN D3 mRNA in MM and MGUS is distinctly higher than in normal PCs. This can be due to direct dysregulation in MM tumors with a CYCLIN D gene translocation or indirectly in tumors with a translocation of MAF, encoding a transcription factor that markedly upregulates CYCLIN D2. Although MMSET/FGFR3 tumors express moderately high levels of CYCLIN D2, the cause of increased CYCLIN D2 expression remains unknown. While normal BM PC express little or no detectable CYCLIN D1, the majority of HRD tumors express CYCLIN D1 biallelically, whereas most other tumors express increased levels of CYCLIN D2 compared to normal BM PC, both by unknown mechanisms. Only a few percent of MM tumors do not express increased levels of a CYCLIN D gene compared to normal PC, but many of these tumors appear to represent samples that are substantially contaminated by normal cells and another large fraction of these tumors often have inactivated RB1, the inhibitor downstream of CYCLIN D, eliminating the necessity of overexpressing a CYCLIN D gene.

Primary IgH Translocations

It is thought that CYCLIN D translocations only dysregulate expression of a CYCLIN D gene. By contrast, MAF translocations dysregulate expression of a MAF transcription factor that causes increased expression of many genes, including CYCLIN D2 and adhesion molecules that are thought to enhance the ability of the tumor cell to interact with the BM microenvironment.^{29, 30} The contributions of the two genes dysregulated by t(4;14) remain controversial. MMSET is a chromatin-remodeling factor that is overexpressed in all tumors with a t(4;14), whereas about 20% of tumors lack der(14) and FGFR3 expression. The rare acquisition of FGFR3 activating mutations during progression confirms a role for FGFR3 in MM pathogenesis. Although an activated mutant FGFR3 can be oncogenic, it recently was shown that wild-type FGFR3 (as is found in most t[4;14]) can contribute to B cell oncogenesis.³¹ It remains to be determined if FGFR3 is critical early in pathogenesis but becomes dispensable during progression of t(4;14) MM. Preclinical studies suggest that tyrosine kinase inhibitors are active only against t(4;14) HMCL with activating mutations of FGFR3, whereas anti-FGFR3 monoclonal antibodies that inhibit FGFR3 signaling but also elicit antibody-dependent cell-mediated cytotoxicity are active against HMCLs expressing wild-type FGFR3.^{32, 33} Despite an apparently indispensable role in t(4;14) MM, it remains to be determined how MMSET, which sometimes has amino-terminal truncations caused by the translocation, contributes to MM pathogenesis. There are some clues. It is a histone methyltransferase for H3K36me2, and when overexpressed it results in a global increase in H3K36 methylation, and a decrease in H3K27 methylation, which might explain some of the many changes in gene expression associated with t(4;14) tumors.^{29, 34, 35, 36} In addition, it recently has been determined that MMSET has a role in DNA repair (Fig. 96.3). Following DNA damage MMSET is phosphorylated on Ser102 by ATM and is recruited to sites of double strand breaks (DSBs), where it results in methylation of H4K20, which is required for recruitment of p53 binding protein (53BP1). 53BP1 is required for p53 accumulation, G2/M checkpoint arrest, and the intra-S-phase checkpoint in response to ionizing radiation. Approximately half of the translocation breakpoints in t(4;14) MM result in a truncated MMSET that lacks Ser102 and cannot be recruited to DSBs, resulting in a failure to recruit 53BP1 and a loss of the normal DNA damage response pathway. It is not known whether this biologic difference results in a different clinical outcome for t(4;14) MM patients with a truncated versus full-length MMSET.³⁷ Importantly, loss of MMSET expression alters adhesion, suppresses growth, and results in apoptosis of HMCLs, suggesting that it is an attractive therapeutic target.³⁵

Molecular Classification of Multiple Myeloma

The patterns of spiked expression of genes deregulated by primary IGH@ translocations and the universal overexpression of CCNDs genes either by these translocations or other mechanisms led to the translocations and cyclin D (TC) classification that includes eight groups: those with primary translocations (designated 4p16, 11q13, 6p21, MAF), those that overexpressed CCND1 and CCND2 either alone or in combination (D1, D1 & D2, D2), and the rare cases that do not overexpress any CCND genes ("none") (Table 96.1).²⁹ Greater than 95% of the D1 group are HRD.

In addition, most of the patients with HRD MM and trisomy 11 fall within the D1 and D1 & D2 groups, while those without trisomy 11 fall within the D2 group, although a majority of the D2 group are NHRD. This classification system therefore focuses on the different kinds of mechanisms that dysregulate a CCND gene as an early and unifying event in pathogenesis.

FIGURE 96.3. MMSET is involved in DNA repair. An ideogram of MMSET highlights the important functional domains of the protein, with arrows indicating the initiation of translation of the truncated forms, lacking Ser102, that result from translocation breakpoints in between the coding exons. Following DNA damage MMSET is phosphorylated on Ser102 by ATM and is recruited to sites of double strand breaks by MDC1, where it methylates H4K20. Dimethylation of H4K20 recruits p53-binding protein (53BP1), a key transducer of the DNA damage checkpoint signal.

P.2025

An MM classification based on an unsupervised analysis of microarray gene expression profiling from the UAMS identified seven tumor groups characterized by the coexpression of unique gene clusters.³⁸ This classification was partially replicated in an independent unsupervised analysis of a combined HOVON-GMMG dataset that identified 10 tumor groups with considerable overlap with the UAMS groups.³⁹ Interestingly, these clusters also identify subgroups corresponding to the different primary translocations and hyperdiploidy. Importantly, however, they also highlight other important secondary events that can occur in each subtype of MM: proliferation (PR), expression of NFκB target genes (NFκB), cancer-testis antigens, and the phosphatase PTP4A3/PRL3 (PRL3). The CD-1 and CD-2 groups represent subgroups of patients with t(11;14) and t(6;14), with the former characterized by arginosuccinate synthetase 1 expression, and the latter by expression of B cell antigens (CD20, VPREB, CD79A). Interestingly, they identify patients with markedly different clinical outcomes. Of all the molecular subgroups, CD-1 has the quickest onset and highest frequency of CR (90%), whereas CD-2 has the slowest onset and lowest frequency of CR (45%), when treated with Total Therapy 3. However, after the MF, the CD-1 has the shortest CR duration (77% at 2 years), whereas the CD-2 has the longest (100% at 2 years).⁴⁰

TABLE 96.1 COMPARISON OF DIFFERENT MOLECULAR CLASSIFICATIONS IN MULTIPLE MYELOMA

Group	TC	Gene	%	CYCLIN D	UAMS	HOVON-GMMG
Cyclin D translocation	11q13	CCND1	15	CYCLIN D1	CD-1 CD-2	CD-1 CD-2
	12p13	CCND2	<1	CYCLIN D2		
	6p25	CCND3	2	CYCLIN D3		
MAF translocation	16q23	MAF	5	CYCLIN D2	MF	MF
	20q12	MAFB	2	CYCLIN D2		
8q24	MAFA	<1	CYCLIN D2			
MMSET translocation	4p16	MMSET/FGFR3	15	CYCLIN D2	MS	MS

Hyperdiploid with trisomy 11	D1		33	CYCLIN D1 HY	HY CD-1 NFκB CTA PRL3
	D1 + D2		7	CYCLIN D1 PR & D2	PR CTA
Hyperdiploid without trisomy 11 and others	D2		18	CYCLIN D2 LB	LB CTA PRL3
Other	None	RB1 biallelic deletion	2	No CYCLIN PR D	PR CTA

Additional Oncogenic Events in Monoclonal Gammopathy of Undetermined Significance and Multiple Myeloma

MYC Dysregulation

There is increased expression of c-MYC in most newly diagnosed MM tumors compared to MGUS tumors.⁴¹ Recently, it was shown that sporadic activation of a MYC transgene in GC B cells in an MGUS-prone mouse strain led to the universal development of MM tumors.^{42, 43} Hence, increased MYC expression seems to be responsible for progression from MGUS to MM. Complex translocations involving MYC (c-MYC>>N-MYC>L-MYC) appear to be secondary progression events that often do not involve Ig loci.⁴⁴ They are rare or absent in MGUS, but occur in 15% of newly diagnosed tumors, 50% of advanced tumors, and 90% of HMCLs.^{18, 45} A recent report suggests that a small molecule inhibitor of BRD4 can inhibit MYC RNA expression in MM, with therapeutic effect.⁴⁶

P.2026

Chromosome 13 Deletion

A recent study concludes that chromosome 13 deletion can be an early event in MGUS (e.g., in MAF, MMSET tumors) or a progression event (e.g., in t(11;14) tumors).⁴⁷ The pathogenic effect of this chromosome deletion is unknown, though it is possible that haploinsufficiency of RB1 promotes tumorigenesis.²⁵ A recent genome-wide sequencing study identified mutations of DIS3, a gene of unknown function on 13q, in about 10% of MM. Although only very few mutations have been reported to date, it has been suggested that DIS3 mutations occur in parallel with deletions of RB1,⁴⁸ suggesting a possible dependence between these two events.

Activating Mutations of RAS and BRAF

The prevalence of activating NRAS or KRAS mutations is about 15% to 18% each in newly diagnosed and relapsed MM tumors,^{25, 49} but substantially higher in tumors that express CCND1 compared to tumors that express CCND2. For MGUS tumors, the prevalence of NRAS mutations is 7%, but KRAS mutations have not been described.¹⁴ This is consistent with increasing evidence that NRAS and KRAS mutations have overlapping but nonidentical effects,⁵⁰ and also with the hypothesis that KRAS mutations provide a molecular mark of the transition of MGUS to MM.^{51, 52} MM tumors depend on the continued expression of activated but not wild-type RAS.⁵³ Recently, BRAF mutations were described in 4% of MM tumors, suggesting a possible role for BRAF inhibitors in these cases.⁵⁴

Mutations that Activate the NFκB Pathway

Extrinsic ligands (APRIL and BAFF) produced by BM stromal cells provide critical survival signals to long-lived PCs by stimulating TACI, BCMA, and BAFF receptors to activate the NFκB pathways.⁵⁵ Most MGUS and MM tumors highly express NFκB target genes, suggesting a continued role of extrinsic signaling in PC tumors.^{56, 57} Activating mutations in positive regulators and inactivating mutations in negative regulators of the NFκB pathway have been identified in at least 20% of untreated MM tumors and ~50% of HMCLs, rendering the cells less dependent on ligand-mediated NFκB activation (Fig. 96.4).⁵⁴ Small molecules that inhibit extrinsic signaling (including TACI.Fc, IKKβ, and NIK [MAP3K14]) are being developed as potential therapeutic agents.^{58, 59} There also is some evidence suggesting that cells addicted to constitutive NFκB activation may be particularly sensitive to proteasome inhibition.⁵⁷

FIGURE 96.4. Role of NFκB pathway in normal plasma cell (PC), monoclonal gammopathy of undetermined significance (MGUS), and multiple myeloma (MM). A: Molecular components and processing events for the classical and alternative NFκB pathways are depicted, both of which result in the translocation of an active NFκB transcription factor into the nucleus. Both pathways can be activated by a variety of stimuli, including the interaction of external factors with PC receptors. Positive regulatory proteins (red) and negative regulatory proteins (green) are targets for mutations that constitutively activate NFκB during the progression of some MM tumors. Bortezomib (BTZMB) may act partially by inhibiting NFκB activity. B: Normal PC, as well as most MGUS and MM tumor cells, have a high NFκBi as a result of bone marrow (BM) stromal cell ligands that stimulate their receptors. Tumors with NFκB mutations generate human MM cell line (HMCL) with a high NFκBi, whereas HMCL from tumors with other kinds of mutations has a low NFκBi. Potential therapeutic agents to block NFκB activation include BCMA-Fc, TACI-Fc, IKKβ inhibitors, and Bortezomib.

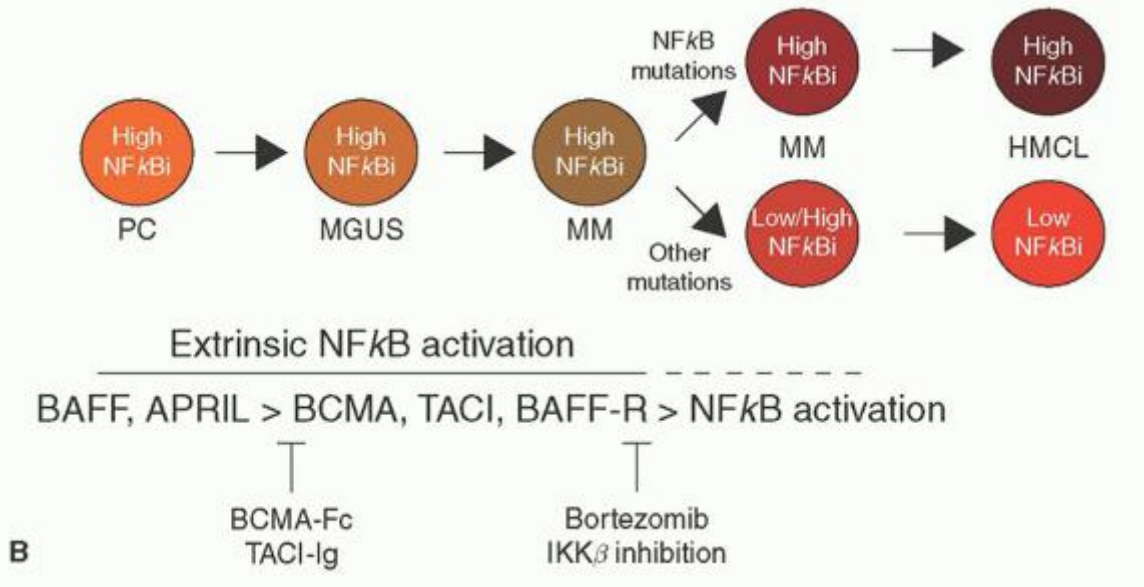

FIGURE 96.4. (continued)

Chromosome 17p Loss and Abnormalities of TP53

Deletions that include the TP53 locus occur in ~10% of untreated MM tumors, and the prevalence increases with disease stage.^{25, 60} TP53 mutations were present in 37% of untreated MM tumors with del17p, but not in patients without del17p.⁶¹ It remains to be determined if the poor prognosis associated with monoallelic del17p but no TP53 mutation is due to haploinsufficiency or to predisposition to complete inactivation of TP53 that is selected for with tumor progression. Recently, decreased expression of microRNAs miR-199, -192, and -215 in MM was reported to increase MDM2, an inhibitor of TP53.⁶²

Gain of Chromosome 1q and Loss of Chromosome 1p

These genomic events frequently occur together in MM, and each is associated with a poor prognosis.^{25, 63} The relevant genes on 1q are unclear at this time. By contrast, there are potential targets on two regions of 1p that are associated with a poor prognosis: CDKN2C (p18INK4c) at 1p32.3, and FAM46C at 1p12.^{64, 65} Homozygous deletion of CDKN2C, which is present in about 30% of HMCL and about 5% of untreated MM tumors, is associated

P.2027

with increased proliferation and a poor prognosis, whereas monoallelic deletion is not. Mutations of FAM46C—often with hemizygous deletion—were identified in 3.4% and 13% of MM tumors in two studies, and in 25% of 16 HMCL.^{54, 64}

Other Pathogenic Events

Secondary Ig translocations, including most IgK and IgL translocations and IgH translocations not involving one of the seven primary partners, can occur at all stages of disease, and with a similar frequency in HRD and NHRD tumors, but apart from MYC, few partner loci have been identified.¹⁸ Other genomic rearrangements are frequent, but only a few specific target genes have been identified.^{63, 66, 67} Changes in DNA methylation are frequent, with one study suggesting that a marked increase in hypomethylation is associated with the MGUS to MM transition,⁶⁸ whereas a second study suggests only a small increase in hypomethylation for MM compared to MGUS.⁶⁹ Mutations in seven genes regulating RNA metabolism, protein translation, and homeostasis were identified in 16 of 38 patients.⁵⁴ In addition to previous studies implicating roles for MMSET and KDM6A (UTX), genomic sequencing studies found that other histone-modifying enzymes are frequent targets of mutation, although the epigenetic consequences are unknown.⁵⁴ Similarly, changes in microRNA expression at different stages have been identified, but more extensive studies are needed.^{62, 70}

Intraclonal Tumor Heterogeneity Associated with High-risk Multiple Myeloma

Although the evidence is still emerging, it appears that many of the genetic events in MM are secondary and often present only in subclones of the tumor population.^{48, 67, 71} Recently, a high level of intraclonal tumor heterogeneity has been described in some patients with high-risk MM^{48, 67, 71} associated in one case with alternating clonal dominance under therapeutic selective pressure, observations with important clinical implications. The findings suggest a competition between subclones for limited resources and raise the possibility that early, suboptimal treatment may eradicate the “good” drug-sensitive clone, making room for the “bad” drug-resistant clone to expand. They support the use of aggressive multidrug combination approaches for high-risk disease with unstable genomes and clonal heterogeneity, and sequential one- or two-drug approaches for low-risk disease with stable genomes and lacking clonal heterogeneity.

CONCLUSION

Significant progress has been made in understanding the molecular pathogenesis and biology of MM (Fig. 96.5). Oncogenic pathways can be activated through cell intrinsic or extrinsic mechanisms. Similar to other cancers, MM is characterized by multistage accumulation of genetic abnormalities deregulating different pathways. Much of this knowledge is already being utilized for diagnosis, prognosis, and risk-stratification of patients. Importantly, from a clinical standpoint, this knowledge has led to development of novel therapeutic strategies, some of which are already in clinical use, and many others showing promise in preclinical and early clinical studies.

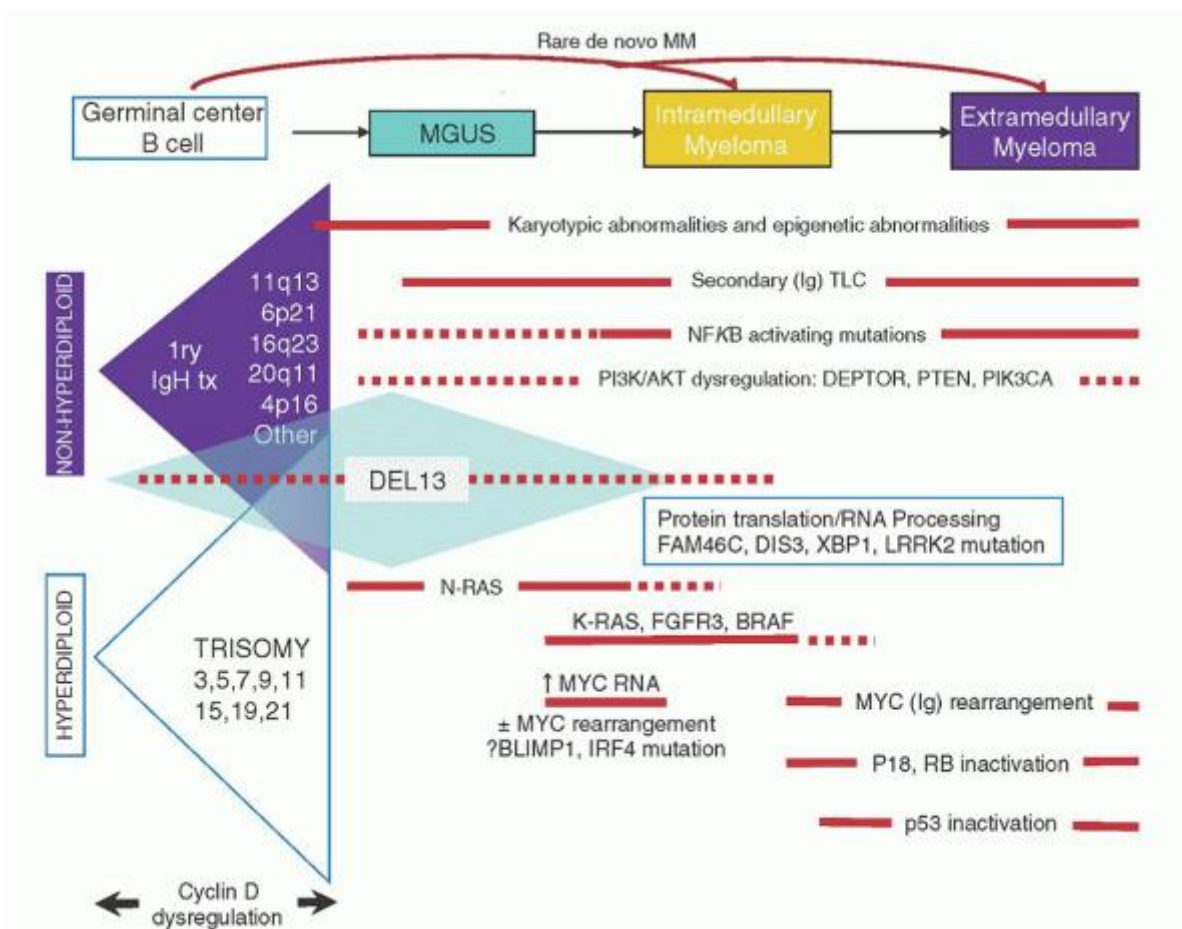

FIGURE 96.5. A model for the multistep molecular pathogenesis of multiple myeloma. Two largely nonoverlapping pathways (immunoglobulin [Ig] translocations versus multiple trisomies) are primary events associated with dysregulated cyclin D expression. The most common secondary genetic events associated with tumor progression are shown, including early and late dysregulation of MYC, and late inactivating mutations of p53.

Monoclonal Gammopathies of Undetermined Significance and Smoldering Multiple Myeloma

S. Vincent Rajkumar

Robert A. Kyle

John A. Lust

INTRODUCTION

Nomenclature

Monoclonal gammopathy of undetermined significance (MGUS) is an asymptomatic, pre-malignant clonal plasma cell proliferative disorder.^{1, 2, 3, 4} It was initially referred to as essential hyperglobulinemia by Jan Waldenström, as well as several other terms such as benign, idiopathic, asymptomatic, nonmyelomatous, discrete, cryptogenic, and rudimentary monoclonal gammopathy; dysimmunoglobulinemia; lanthanic monoclonal gammopathy; idiopathic paraproteinemia; and asymptomatic paraimmunoglobulinemia.^{5, 6} However, because there is an indefinite risk of progression to multiple myeloma (MM) or related disorder such as Waldenström macroglobulinemia (WM) or amyloidosis (AL), the term MGUS is now the accepted nomenclature.^{1, 2, 7, 8} Smoldering multiple myeloma (SMM) is a clinically defined pre-malignant stage between MGUS and MM.^{9, 10} MGUS and SMM must be differentiated from MM, and from a number of related plasma cell disorders using the criteria listed on Table 97.1.^{8, 11}

Detection of Monoclonal Proteins

Immunoglobulins consist of two heavy polypeptide chains of the same class and subclass and two light polypeptide chains of the same type. The various types of immunoglobulins are designated by capital letters that correspond to the isotype of their heavy chains, which are designated by Greek letters: gamma (γ) constitutes immunoglobulin G (IgG), alpha (α) is found in IgA, mu (μ) is present in IgM, delta (δ) occurs in IgD, and IgE is characterized by epsilon (ϵ). IgG1, IgG2, IgG3, and IgG4 are the subclasses of IgG; the subclasses of IgA are IgA1 and IgA2. Kappa (κ) and lambda (λ) are the two types of light chains. An intact immunoglobulin consists of two heavy chains of the same class and two light chains of the same type. A monoclonal increase in immunoglobulins results from a clonal process such as MGUS or MM, and a polyclonal increase in immunoglobulins is caused by a reactive or inflammatory process. The monoclonal immunoglobulin secreted by clonal plasma cells in MGUS, SMM, MM, and related monoclonal gammopathies is referred to as a monoclonal protein or M protein.

Electrophoresis and Immunofixation

Monoclonal proteins are detected using agarose gel or capillary electrophoresis of the serum and urine.¹² An M-protein is usually visible as a localized band on protein electrophoresis, and as a tall narrow spike or peak in the β or γ region or, rarely, in the α 2-globulin area of the densitometer tracing (Fig. 97.1A). A polyclonal increase in immunoglobulins produces a broad band or broad-based peak that migrates in the γ region. A suspected M protein on electrophoresis must be confirmed on immunofixation, which also determines the immunoglobulin heavy-chain class and its light chain type.¹³ In addition, immunofixation is also done when MM, WM, AL (light chain) amyloidosis, or a related disorder is suspected, because small M proteins may not be detected with electrophoresis alone. Immunofixation is performed using commercial kits or systems such as Sebia, or Pentafix (Fig. 97.1B).

Quantitative Immunoglobulins

In patients with detectable M proteins, another assay that aids in monitoring is quantitation of immunoglobulins performed with a rate nephelometer. It can accurately measure 7S IgM, polymers of IgA, and aggregates of IgG. However, levels of IgM obtained by nephelometry may be 1,000 to 2,000 mg/dl higher than those expected on the basis of the serum protein electrophoretic tracing. The quantitative IgG and IgA levels may be increased similarly.¹⁴

Serum Free Light Chain Assay

The serum free light chain (FLC) assay (Freelite™, The Binding Site Limited, Birmingham, UK) is an automated nephelometric assay that measures free kappa (κ) and lambda (λ) light chains that are not bound to intact immunoglobulin.^{15, 16} The normal serum free- κ level is 3.3 to 19.4 mg/L and the normal free- λ level is 5.7 to 26.3 mg/L.¹⁷ The normal ratio for FLC- κ/λ is 0.26 to 1.65. The normal reference range in the FLC assay reflects a higher serum level of free λ light chains than would be expected given the usual κ/λ ratio of 2 for intact immunoglobulins. This occurs because the renal excretion of free κ (which exists usually in a monomeric state) is faster than free λ (which is usually in a dimeric state).^{15, 16} Patients with a κ/λ FLC ratio <0.26 are considered to have a monoclonal λ free light chain and those with ratios >1.65 are defined as having a monoclonal κ free light chain. If the FLC ratio is >1.65 , κ is referred to as the “involved” FLC and λ the “uninvolved” FLC, and vice versa if the ratio is less than 0.26.

The serum FLC assay can be used in place of urine protein electrophoresis and immunofixation in the initial screening algorithm for M proteins. In a study of 428 patients, Katzmann et al. found that urine studies can be eliminated by using the serum FLC assay in combination with the SPEP and immunofixation.¹⁸ However, if a monoclonal plasma cell disorder is

identified on screening, a 24-hour urine collection followed by electrophoresis and immunofixation should always be done to aid in the assessment of disease progression and response to therapy over time. In addition to its role as a substitute for urine studies in the screening of plasma cell disorders, the FLC assay is used to predict prognosis in MGUS, SMM, AL, and solitary plasmacytoma.^{19, 20, 21}

In addition, it is also used to monitor oligo-secretory MM, nonsecretory MM, light chain only form of MM, and AL amyloidosis.^{16, 22, 23, 24} In order to use the FLC assay to monitor disease progression, the baseline FLC ratio must be abnormal and the involved FLC level ≥ 100 mg/L.^{24, 25}

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Definition

MGUS is defined by the presence of a serum M protein < 3 g/dl, bone marrow plasma cells $< 10\%$, and absence of anemia, hypercalcemia, lytic bone lesions, or renal failure that can be attributed to the plasma cell proliferative disorder (Table 97.1).^{26, 27} In the case of IgM MGUS, there should be no evidence of

P.2030

lymphadenopathy or organomegaly attributable to the clonal lymphoid/plasma cell proliferative disorder. A new subtype of MGUS termed light chain MGUS is defined by the presence of an abnormal FLC ratio (< 0.26 or > 1.65), elevated level of involved FLC, no immunoglobulin heavy chain (IGH) expression on immunofixation, bone marrow plasma cells $< 10\%$, and absence of anemia, hypercalcemia, lytic bone lesions, or renal failure that can be attributed to the plasma cell proliferative disorder (Table 97.1).⁴ A diagnosis of MGUS requires exclusion of plasma cell malignancies (MM, solitary plasmacytoma, and WM), monoclonal immunoglobulin deposition disorders (AL, light chain deposition disease), as well as SMM. In addition to these closely related disorders which are unique progression events, MGUS can be associated with a variety of malignant and nonmalignant disorders where the association between the monoclonal process and the associated disorder can vary from a coincidental finding to a direct paraprotein related syndrome.

P.2031

TABLE 97.1 DIAGNOSTIC CRITERIA FOR PLASMA CELL DISORDERS

Disorder	Disease Definition	References
Monoclonal gammopathy of undetermined significance (MGUS)	All three criteria must be met: <ul style="list-style-type: none"> • Serum monoclonal protein < 3 g/dl • Clonal bone marrow plasma cells $< 10\%$, and • Absence of end organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) that can be attributed to the plasma cell proliferative disorder; or in the case of IgM MGUS no evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder. 	(275)
Light chain MGUS	All criteria must be met: <ul style="list-style-type: none"> • Abnormal FLC ratio (< 0.26 or > 1.65) • Increased level of the appropriate involved light chain (increased κ FLC in patients with ratio > 1.65 and increased λ FLC in patients with ratio < 0.26) • No immunoglobulin heavy chain expression on immunofixation 	(4)

	<ul style="list-style-type: none"> • Clonal bone marrow plasma cells <10%, and • Absence of end organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) that can be attributed to the plasma cell proliferative disorder; or in the case of IgM MGUS no evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder. 	
Smoldering multiple myeloma (also referred to as asymptomatic multiple myeloma)	<p>Both criteria must be met:</p> <ul style="list-style-type: none"> • Serum monoclonal protein (IgG or IgA) ≥ 3 g/dl and/or clonal bone marrow plasma cells 10-60%, and • Absence of end organ damage such as lytic bone lesions, anemia, hypercalcemia, or renal failure that can be attributed to a plasma cell proliferative disorder 	(275)
Multiple myeloma	<p>All three criteria must be met except as noted:</p> <ul style="list-style-type: none"> • Clonal bone marrow plasma cells $\geq 10\%$ • Presence of serum and/or urinary monoclonal protein (except in patients with true nonsecretory multiple myeloma), and • Either $\geq 60\%$ clonal plasma cells in the marrow or evidence of end organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically <ul style="list-style-type: none"> ○ Hypercalcemia: Serum calcium ≥ 11.5 mg/dl or ○ Renal insufficiency: Serum creatinine >1.73 mmol/L (or >2 mg/dl) or estimated creatinine clearance less than 40 ml/min ○ Anemia: Normochromic, normocytic with a hemoglobin value of >2 g/dl below the lower limit of normal or a hemoglobin value <10 g/dl ○ Bone lesions: Lytic lesions, severe osteopenia or pathologic fractures 	(276, 277)
IgM monoclonal gammopathy of undetermined significance (IgM MGUS)	<p>All three criteria must be met:</p> <ul style="list-style-type: none"> • Serum IgM monoclonal protein <3 g/dl • Bone marrow lymphoplasmacytic infiltration $<10\%$, and • No evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder. 	(75, 277, 278, 279, 280)
Smoldering Waldenström macroglobulinemia (also referred to as indolent or	<p>Both criteria must be met:</p> <ul style="list-style-type: none"> • Serum IgM monoclonal protein ≥ 3 g/dl and/or bone marrow lymphoplasmacytic infiltration $\geq 10\%$, and • No evidence of anemia, constitutional symptoms, 	(75, 277, 278, 279, 280, 281)

asymptomatic Waldenström macroglobulinemia)	hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder.	
Waldenström macroglobulinemia	<p>All criteria must be met:</p> <ul style="list-style-type: none"> • IgM monoclonal gammopathy (regardless of the size of the M protein), and • $\geq 10\%$ bone marrow lymphoplasmacytic infiltration (usually intertrabecular) by small lymphocytes that exhibit plasmacytoid or plasma cell differentiation and a typical immunophenotype (e.g., surface IgM⁺, CD5^{+/-}, CD10⁻, CD19⁺, CD20⁺, CD23⁻) that satisfactorily excludes other lymphoproliferative disorders including chronic lymphocytic leukemia and mantle cell lymphoma. • Evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder. 	(75, 277, 278, 279, 280)
Solitary plasmacytoma	<p>All four criteria must be met</p> <ul style="list-style-type: none"> • Biopsy proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells • Normal bone marrow with no evidence of clonal plasma cells • Normal skeletal survey and MRI of spine and pelvis (except for the primary solitary lesion) • Absence of end organ damage such as hypercalcemia, renal insufficiency, anemia, or bone lesions (CRAB) that can be attributed to a lympho-plasma cell proliferative disorder 	(81, 282)
Systemic AL amyloidosis	<p>All four criteria must be met:</p> <ul style="list-style-type: none"> • Presence of an amyloid-related systemic syndrome (such as renal, liver, heart, gastrointestinal tract, or peripheral nerve involvement) • Positive amyloid staining by Congo red in any tissue (e.g., fat aspirate, bone marrow, or organ biopsy) • Evidence that amyloid is light chain related established by direct examination of the amyloid (possibly using mass spectrometry (MS)-based proteomic analysis, or immunoelectron microscopy; note that immunohistochemistry results to type amyloid may be unreliable), and • Evidence of a monoclonal plasma cell proliferative disorder (serum or urine M protein, abnormal free light chain ratio, or clonal plasma cells in the bone marrow). <p>Note: Approximately 2-3% of patients with AL amyloidosis will</p>	(283)

not meet the requirement for evidence of a monoclonal plasma cell disorder listed above; the diagnosis of AL amyloidosis must be made with caution in these patients.

POEMS syndrome	All four criteria must be met	(137, 284)
----------------	-------------------------------	------------

- Polyneuropathy
- Monoclonal plasma cell proliferative disorder (almost always λ)
- Any one of the following three other major criteria:
 1. Sclerotic bone lesions
 2. Castleman's disease
 3. Elevated levels of vascular endothelial growth factor (VEGF)^a
- Any one of the following six minor criteria
 1. Organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy)
 2. Extravascular volume overload (edema, pleural effusion, or ascites)
 3. Endocrinopathy (adrenal, thyroid, pituitary, gonadal, parathyroid, pancreatic)^b
 4. Skin changes (hyperpigmentation, hypertrichosis, glomeruloid hemangiomas, plethora, acrocyanosis, flushing, white nails)
 5. Papilledema
 6. Thrombocytosis/polycythemia

FLC, free light chain.

Note: Not every patient meeting the above criteria will have POEMS syndrome; the features should have a temporal relationship to each other and no other attributable cause. Anemia and/or thrombocytopenia are distinctively unusual in this syndrome unless Castleman disease is present.

^a The source data do not define an optimal cut-off value for considering elevated VEGF level as a major criterion. We suggest that VEGF measured in the serum or plasma should be at least three- to fourfold higher than the normal reference range for the laboratory that is doing the testing to be considered a major criterion

^b In order to consider endocrinopathy as a minor criterion, an endocrine disorder other than diabetes or hypothyroidism is required inasmuch as these two disorders are common in the general population

Modified from Kyle RA, Rajkumar SV. Criteria for diagnosis, staging, risk stratification and response assessment of multiple myeloma. *Leukemia* 2009;23:3-9.

Epidemiology

Prevalence

MGUS is the most common plasma cell proliferative disorder (Fig. 97.2). The prevalence of MGUS has been estimated in a large population-based study that included 21,463 of the 28,038 enumerated residents (77%) of Olmsted County, Minnesota, who were 50 years or older.³ MGUS was identified in 694 (3.2%) of these subjects. Age-adjusted rates were greater in men than in women, 4.0% versus 2.7% ($P < 0.001$; Fig. 97.3). The prevalence of MGUS was 5.3% among persons 70 years or older and 7.5% among those 85 years or older. Several other studies have reported similar prevalence estimates (Table 97.2).²⁸ In addition, approximately 1% of the general population over the age of 50 have light chain MGUS.⁴

The incidence of M proteins is higher in blacks than in whites. In the study by Cohen et al., the prevalence of an M protein was 8.4% in 916 blacks and 3.6% in whites.²⁹ Landgren et al., in a study of 4 million African American and white males admitted to Veterans Affairs Hospitals, found that the prevalence of MGUS was 0.98% in African Americans and 0.4% in whites.³⁰ The age-adjusted prevalence ratio of MGUS in African Americans compared with whites was 3.0 (95% confidence interval, 2.7 to 3.3). The increase of MGUS in blacks may be related to genetic or environmental factors. A population-based study found that the increased risk of MGUS seen in African Americans was also seen in blacks in Ghana, suggesting that the racial disparity may be due more to genetic factors.³¹

Furthermore, a study of women in the southern part of the United States found that the racial disparity between blacks and whites persisted even after adjusting for socioeconomic status, again suggesting that the differences were more likely genetic rather than environmental.³²

P.2032

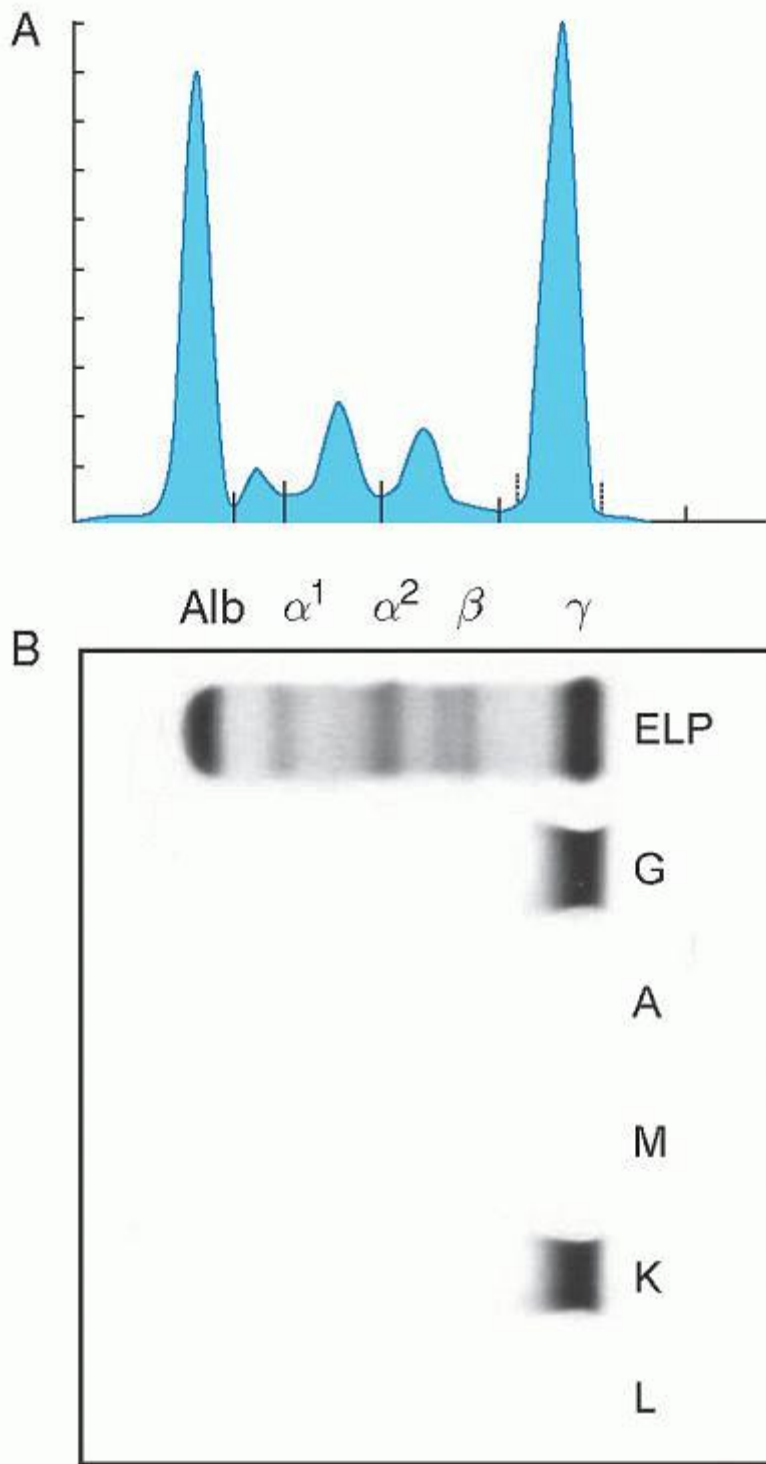

FIGURE 97.1. Monoclonal (M) protein on serum protein electrophoresis. Note tall, narrow-based peak of fast γ mobility (A). Immunofixation of serum with antisera to immunoglobulin G (IgG), IgA, IgM, κ , and λ shows a localized band with IgG and κ , indicating an IgG κ monoclonal protein (B).

One study found that only 2.7% of elderly Japanese patients had a monoclonal gammopathy.³³ A subsequent population-based study in Japan found that the risk of MGUS was lower compared with the white population of Olmsted County.³⁴

Incidence

The annual incidence of MGUS in males is estimated to be 120/100,000 at age 50, and rises to 530/100,000 at age 90 years.³⁵ The rates for women are 60/100,000 at age 50, and 370/100,000 at age 90. The fact that the increased prevalence of MGUS with rising age is not just related to accumulation of new cases but due to an actual increase in incidence suggests that an age-related cumulative damage model is at play in the pathogenesis of MGUS.

Risk Factors

The incidence and prevalence of MGUS rises with age.^{3, 35} MGUS is also more common in males. Blacks have a higher risk of MGUS than whites as discussed above.^{29, 30, 31, 32, 36} In addition to age, race, and gender, there are other risk factors that have been identified, both genetic and environmental. First-degree relatives of patients with MGUS and MM have a two- to threefold higher risk of MGUS compared to those with no known affected relatives.^{37, 38, 39} Obesity and immunosuppression are also known risk factors for MGUS.^{32, 40, 41}

FIGURE 97.2. Distribution of 1,733 cases of monoclonal gammopathy seen at the Mayo Clinic in 2011. MGUS, monoclonal gammopathy of undetermined significance.

Pathophysiology

MM is almost always preceded by the asymptomatic pre-malignant MGUS stage.^{42, 43} For the screening arm of the nationwide population-based prospective prostate, lung, colon, ovarian (PLCO) cancer screening trial, annual blood samples were collected on 77,469 healthy adults. From this cohort, a joint study by the National Cancer Institute and the Mayo Clinic identified 71 individuals who developed MM during the course of the study. Serial serum samples (up to 6) obtained 2.0 to 9.8 years prior to MM diagnosis were then studied. The study found that an asymptomatic MGUS phase always preceded MM and was found in 100% of cases 6 years prior to MM.⁴²

The events responsible for malignant transformation of MGUS to MM or a related plasma cell proliferative disorder are unknown. Genetic changes, bone marrow angiogenesis, various cytokines related to MM bone disease, and infectious agents may play a role in the progression of MGUS to MM or a related disorder.^{44, 45} However, the specific role of these alterations is not well understood.

Initiation of the Clone

The precise sequence of events that leads to the initiation of the MGUS clone are not known. However, antigenic stimulation and/or immunosuppression are thought to be predisposing factors. Toll-like receptors (TLRs) are normally expressed by B lymphocytes, and are essential for these cells to recognize infectious agents and pathogen-associated molecular patterns (PAMP) which then initiate the host-defense response.^{46, 47, 48} The aberrant expression of TLRs by plasma cells may be an initiating event that causes these cells to respond abnormally to TLR-specific ligands resulting in increased MM cell proliferation, survival, and resistance to apoptosis, mediated in part by autocrine interleukin-6 (IL-6) production.^{46, 47}

Immunosuppression may also contribute to the initiation of monoclonal gammopathies inhibiting tumor surveillance.

Monoclonal proteins are known to arise in the context of immunosuppressive states such as bone marrow or stem cell transplantation (SCT), organ transplantation, and human immunodeficiency virus (HIV) infection.^{40, 41, 49, 50, 51} Moreover, patients undergoing renal transplantation develop monoclonal proteins dependent on the level of immunosuppression to which they are subjected.⁴¹

P.2033

FIGURE 97.3. Prevalence of monoclonal gammopathy of undetermined significance, according to age. Of 21,463 residents 50 years of age or older, 694 had a monoclonal protein. The I bars represent 95% confidence interval. Years of age older than 90 have been condensed to 90 years of age (χ -axis). (From Kyle RA, Therneau TM, Rajkumar SV, et al. Prevalence of monoclonal gammopathy of undetermined significance. *N Engl J Med* 2006;354:1362-1369. Used with permission.)

Cytogenetic Changes

Cytogenetic changes are common in MM and in MGUS. On the basis of fluorescence in situ hybridization studies, almost all patients with MM have either IGH translocations involving chromosome 14q32 or trisomies. These cytogenetic changes referred to as “primary cytogenetic abnormalities” are also present in MGUS.⁵² Thus, approximately 50% of patients with MGUS have primary translocations on chromosome 14q32 (IgH translocated MGUS/SMM).^{52, 53} The most common partner chromosome loci are 11q13, 4p16.3, 6p21, 16q23, and 20q11.^{54, 55, 56} These translocations lead to the dysregulation of oncogenes such as CCND1 (cyclin D1) (11q13), FGFR3/WHSC1 (fibroblastic growth factor receptor 3/Wolf-Hirschhorn syndrome candidate; 4p16.3), CCND3 (cyclin D3; 6p21), MAF (16q23), and MAFB (20q11). The dysregulation of these oncogenes is thought to be critical for the initiation of the MGUS clone rather than progression of MGUS to MM. Approximately 40% of patients (40%) with MGUS have trisomies of odd-numbered chromosomes leading to hyperdiploidy (IgH nontranslocated MGUS). In a small subset, there are likely both IgH translocations and trisomies, and in some neither abnormality can be detected.

From Wadhera RK, Rajkumar SV. Prevalence of monoclonal gammopathy of undetermined significance: a systematic review. *Mayo Clin Proc* 2010;85:933-942.

Deletions of chromosome 13 have been found to have an adverse prognostic value in MM. However, this cytogenetic abnormality occurs early in the disease pathogenesis and present in the MGUS stage.^{57, 58} Although deletions of chromosome 13 confer an adverse effect on MM, there are no data that the rate of progression from MGUS to MM is accelerated because of this abnormality. K- and N-RAS mutations and deletion of 17p are uncommon in MGUS in contrast to MM.⁵⁹

P.2034

Angiogenesis

Bone marrow angiogenesis is increased in MM and has prognostic value.⁶⁰ In a study of 400 patients with a spectrum of plasma cell disorders, the median microvessel density (in vessels per high-power field) was 1.3 in the 42 normal controls, 1.7 in AL, 3 in MGUS, 4 in SMM, 11 in MM, and 20 in relapsed MM.⁶¹

Thus bone marrow angiogenesis increases progressively from the pre-malignant MGUS stage to advanced MM. Using a chick embryo chorioallantoic membrane angiogenesis assay, Vacca et al. reported that 76% of MM bone marrow samples had increased angiogenic potential compared with 20% of MGUS samples.⁶² Their findings suggest that increased angiogenesis may play a role in progression of MGUS to MM.

Cytokines

There is overexpression of CD126 (IL-6 receptor α -chain) in MGUS compared to normal plasma cells.^{63, 64} IL-6 is a major growth factor for plasma cells and may therefore play a role in the clonal proliferation of plasma cells in MGUS. Another cytokine that is of importance is IL-1 β . IL-1 β is produced by plasma cells in all patients with MM, but is undetectable in

most patients with MGUS.⁶⁵ IL-1 β has strong osteoclast-activating factor activity, increases the expression of adhesion molecules, and induces paracrine IL-6 production. This activity parallels the development of osteolytic bone lesions, homing of MM cells to bone marrow, and IL-6-induced cell growth.^{66, 67}

As the MGUS clone evolves with additional cytogenetic abnormalities and changes in the microenvironment, there is overexpression of receptor activator of nuclear factor- κ B ligand (RANKL) by osteoblasts (and possible plasma cells) and macrophage inflammatory protein 1- α (MIP 1- α) by plasma cells.^{68, 69} Furthermore, there is a reduction in osteoprotegerin, the decoy receptor for RANKL. This leads to osteoclast activation and bone resorption. In addition, increased dickkopf 1 (DKK-1) expression by MM cells is felt to play a major role in simultaneous suppression of osteoblasts and new bone formation.⁷⁰ This combination of factors is thought to be critical for development of lytic bone lesions in MM.

Clinical Features

MGUS is an asymptomatic condition. It is typically detected as an incidental finding when electrophoresis and immunofixation of the serum and/or urine or the serum FLC assay are performed during the work-up of suspected MM or WM. Thus, MGUS is usually detected during the work-up of unexplained weakness or fatigue, increased erythrocyte sedimentation rate, anemia, unexplained back pain, osteoporosis, osteolytic lesions or fractures, hypercalcemia, proteinuria, renal insufficiency, or recurrent infections. MGUS is also detected during work-up of patients with symptoms suggestive of AL amyloidosis such as unexplained sensorimotor peripheral neuropathy, carpal tunnel syndrome, refractory congestive heart failure, nephrotic syndrome, orthostatic hypotension, malabsorption, weight loss, change in the tongue or voice, paresthesias, numbness, increased bruising, bleeding, and steatorrhea.

Most cases of MGUS remain undiagnosed due to the asymptomatic nature of the condition. At age 60, the proportion of prevalent cases that are clinically recognized is only 13%.³⁵ This rate rises to 33% at age 80. When MGUS is first diagnosed, it is estimated that the condition has already been present in an undiagnosed form for a median duration of over 10 years.³⁵

For example, it is estimated that 56% of women age 70 diagnosed with MGUS have had the condition for over 10 years, including 28% for over 20 years. Corresponding values for men are 55% and 31%, respectively.

TABLE 97.3 CLASSIFICATION OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Type	Risk of Progression
Non-IgM MGUS ^a	1% per year risk of progression to multiple myeloma, AL amyloidosis, or related disorder
IgM MGUS ^b	1.5% per year risk of progression to Waldenström macroglobulinemia; rare patients can progress to IgM multiple myeloma
Light chain MGUS ^c	Risk of progression to light chain myeloma and AL amyloidosis. Rate of progression not defined.

IgM, immunoglobulin M; MGUS, monoclonal gammopathy of undetermined significance

^a Almost all patients are IgG or IgA type. Occasional patients may have IgD or IgE monoclonal proteins.

^b Note that conventionally IgM MGUS is considered a subtype of MGUS. Thus, when the term MGUS is used, in general, it includes IgM MGUS.

^c Because light chain MGUS was only defined in 2010, studies pertaining to MGUS prior to that time do not include patients with this entity; unless otherwise specified studies since then may also not include patients with light chain MGUS.

From Rajkumar SV. Preventive strategies in monoclonal gammopathy of undetermined significance and smoldering multiple myeloma. *Am J Hematol* 2012;87:453-454.

There are three distinct categories of MGUS each with a different mode of progression: IgM MGUS, non-IgM MGUS, and light chain MGUS, each with a different mode and risk of progression (Table 97.3).^{4, 7, 71}

Prognosis

Mayo Clinic Referral Population

The prognosis of MGUS was first established in a study of 241 patients seen at the Mayo Clinic from 1956 through 1970.¹ The actuarial rate of progression to MM or related disorder at 10 years was 17%; at 20 years, 34%; and at 25 years, 39% (Fig. 97.4).⁷² Of the 64 patients with progression, 44 (69%) had MM.

P.2035

Southeastern Minnesota Study

The risk of progression has also been estimated in a larger population-based study of 1,384 persons with MGUS who resided in the 11 counties of southeastern Minnesota, the risk of progression of MGUS to MM or related disorder was found to be 1% per year.² The median age at diagnosis of MGUS was 72 years. The M-protein level at diagnosis ranged from unmeasurable to 3.0 g/dl. On the basis of the heavy-chain type of immunoglobulins, 70% of the M proteins were IgG, 12% IgA, and 15% IgM. A biclonal gammopathy was found in 45 patients (3%). The light chain type was κ in 61% and λ in 39%. A reduction of uninvolved (normal or background) immunoglobulins was found in 38% of 840 patients in whom quantitation of immunoglobulins was determined. The 1,384 patients in this study were followed up for a total of 11,009 person-years (median, 15.4 years; range, 0 to 35 years). During follow-up, MM, primary AL, lymphoma with an IgM serum M protein, WM, plasmacytoma, or chronic lymphocytic leukemia developed in 115 patients (8%). The cumulative probability of progression to one of these disorders was 10% at 10 years, 21% at 20 years, and 26% at 25 years (Fig. 97.5). Patients were at risk for progression even after 25 years or more of stable MGUS. Although the risk of progression is 1%

per year, it must be emphasized that this does not take into account other competing causes of death in elderly patients. After adjusting for competing causes of death, the true lifetime probability of progression of MGUS for the average patient is only approximately 10% (Fig. 97.6).

The number of patients with progression to a plasma cell disorder (115 patients) was 7.3 times the number expected on the basis of the incidence rates for those conditions in the general population (Table 97.4). The risk of MM developing was increased 25-fold; WM, 46-fold; and AL amyloidosis, 8.4-fold. The risk of development of lymphoma was only modestly increased at 2.4, but this risk was underestimated because only lymphomas associated with an IgM protein counted in the observed number, whereas the incidence rates for lymphomas associated with IgG, IgA, and IgM proteins were used to calculate the expected number. The risk of development of chronic lymphocytic leukemia was only slightly increased.

FIGURE 97.5. Probability of disease progression among 1,384 residents of southeastern Minnesota in whom monoclonal gammopathy of undetermined significance (MGUS) was diagnosed from 1960 through 1994. The top curve shows the probability of progression to a plasma cell cancer (115 patients) or of an increase in the monoclonal protein concentration to more than 3 g/dl or in the proportion of plasma cells in the bone marrow to more than 10% (32 patients). The bottom curve shows only the probability of progression of MGUS to multiple myeloma, IgM lymphoma, primary amyloidosis, macroglobulinemia, chronic lymphocytic leukemia, or plasmacytoma (115 patients). The error bars indicate 95% confidence intervals. (From Kyle RA, Therneau TM, Rajkumar SV, et al. A long-term study of prognosis of monoclonal gammopathy of undetermined significance. *N Engl J Med* 2002;346:564-569. Used with permission.)

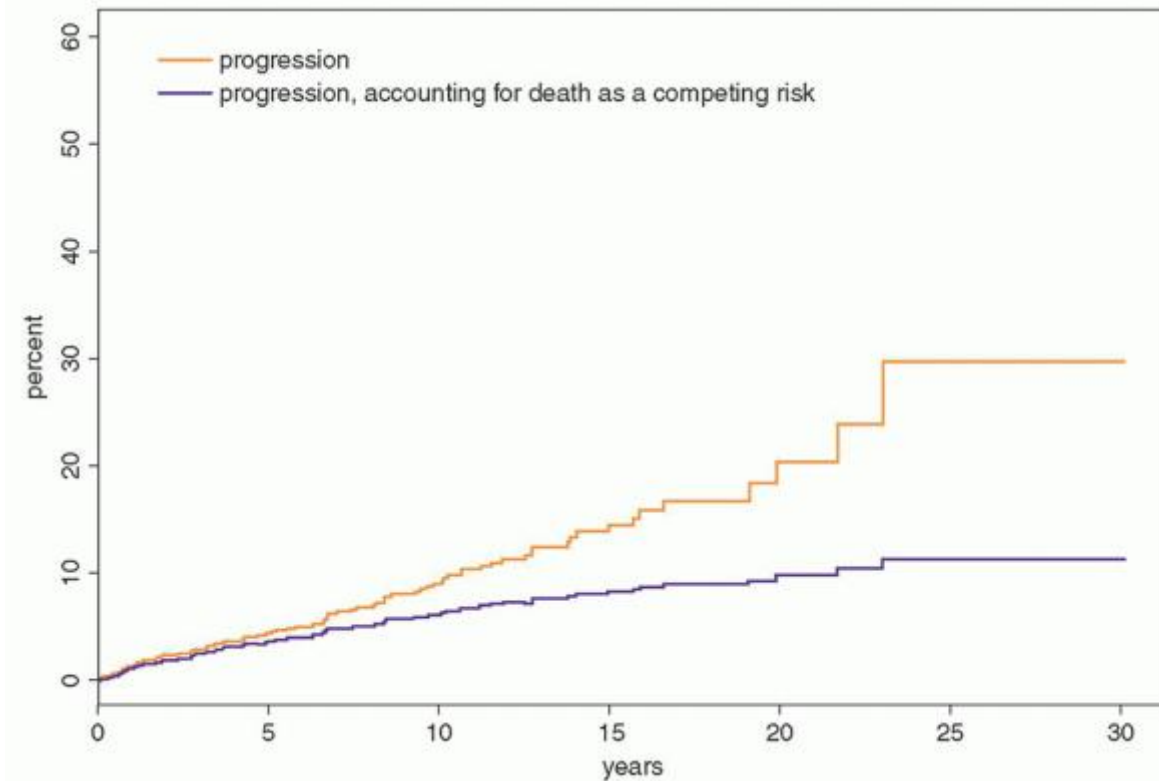

FIGURE 97.6. The risk of progression to myeloma or related disorder in 1,148 patients with monoclonal gammopathy of undetermined significance. The upper curve illustrates risk of progression of all patients without taking into account competing causes of death. The lower curve illustrates risk of progression after accounting for other competing causes of death. (From Rajkumar SV, Kyle RA, Therneau TM, et al. Serum free light chain ratio is an independent risk factor for progression in monoclonal gammopathy of undetermined significance (MGUS) *Blood* 2005;106:812–817. © the American Society of Hematology.)

The 75 patients in whom MM developed accounted for 65% of the 115 patients who had progression to a plasma cell disorder. The mode of development of MM among the patients with MGUS was variable. The M-protein level increased within 2 years of the recognition of MGUS in 11 patients, whereas the serum M-protein level was stable for more than 2 years and then increased within 2 years in 19 patients; in 9 others, the M-protein level increased gradually after having been stable for at least 2 years. In 9 patients, the M-protein level increased gradually during

P.2036

follow-up until the diagnosis of symptomatic MM was made.

In 10 patients, the serum M-protein level remained essentially stable; the diagnosis of MM was unequivocal in these 10 patients because of an increase in bone marrow plasma cells, development of lytic lesions, or occurrence of anemia, renal insufficiency, or an increased level of urine M protein. Seventeen patients had an insufficient number of serum M-protein measurements to determine the pattern of increase. In patients with WM, the M-protein level showed a gradual increase in 3, stable levels were followed by a sudden increase in 2, and data were insufficient in 2.

TABLE 97.4 RISK OF PROGRESSION AMONG 1,384 RESIDENTS OF SOUTHEASTERN MINNESOTA IN WHOM MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE WAS DIAGNOSED, 1960-1994

Type of progression	No. of Patients		Relative Risk	
	Observed	Expected ^a	(95% CI)	
Multiple myeloma	75	3.0	25.0 (20-32)	
Lymphoma ^b	19	7.8	2.4 (2-4)	

Primary amyloidosis	10	1.2	8.4 (4-16)
Macroglobulinemia	7	0.2	46.0 (19-95)
Chronic lymphocytic leukemia ^c	3	3.5	0.9 (0.2-3)
Plasmacytoma	1	0.1	8.5 (0.2-47)
Total	115	15.8	7.3 (6-9)

CI, confidence interval.

^a Expected numbers of cases were derived from the age- and sex-matched white population of the Surveillance, Epidemiology, and End Results program in Iowa except for primary amyloidosis.

^b All 19 patients had serum IgM monoclonal protein. If the 30 patients with IgM, IgA, or IgG monoclonal protein and lymphoma were included, the relative risk would be 3.9 (95% CI, 2.6-5.5).

^c All 3 patients had serum IgM monoclonal protein. If all 6 patients with IgM, IgA, or IgG monoclonal protein and chronic lymphocytic leukemia were included, the relative risk would be 1.7 (95% CI, 0.6-3.7).

From Kyle RA, Therneau TM, Rajkumar SV, et al. A long-term study of prognosis of monoclonal gammopathy of undetermined significance. *N Engl J Med* 2002;346:564-569. (Used with permission.)

Spontaneous disappearance of M protein after the diagnosis of MGUS was rare.² The M protein disappeared without an apparent cause in 27 patients (2%), and only 6 of these 27 patients (0.4% of all patients) had a discrete spike on the densitometer tracing of the initial electrophoresis (median, 1.2 g/dl); the rest had small M proteins detected on immunofixation only.

Follow-up in Other Series

The risk of progression of MGUS has been estimated in several other studies, and the results mirror those seen in the Southeastern Minnesota study. For example, Baldini et al. noted that 6.8% of 335 patients with MGUS had progression during a median follow-up of 70 months.⁷³ In the Danish Cancer Registry, 64 new cases of malignancy (5 expected; relative risk, 12.9) were found among 1,229 patients with MGUS.⁷⁴

Prognostic Factors

No findings at diagnosis of MGUS can reliably distinguish patients whose condition will remain stable indefinitely from those in whom MM or related malignancy develops. However, there are several known prognostic factors that assist in estimation of the risk of progression for appropriate counseling and management.

Size of M Protein

The size of the M protein at recognition of MGUS is one of the most important predictors for the risk of progression. In the study of 1,384 patients from Southeastern Minnesota, the risk of progression to MM or a related disorder 10 years after diagnosis of MGUS was 6% for patients with an initial M-protein level of 0.5 g/dl or less, 7% for 1 g/dl, 11% for 1.5 g/dl, 20% for 2 g/dl, 24% for 2.5 g/dl, and 34% for 3.0 g/dl.²

Corresponding rates for progression at 20 years were 14%, 16%, 25%, 41%, 49%, and 64%, respectively. The risk of progression in a patient with an M-protein level of 1.5 g/dl was almost twofold greater than that in a patient with an M-protein level of 0.5 g/dl, and the risk of progression in a patient with an M-protein level of 2.5 g/dl was 4.6 times that of a patient with a 0.5-g/dl spike.

Type of M Protein

Patients with an IgM or IgA M protein have a higher risk of progression compared with those with an IgG M protein.² IgM MGUS is a unique subtype of MGUS in which patients are at risk of progression to WM rather than MM.⁷⁵ Due to a confusion in terminology, some patients with WM are referred to as having non-Hodgkin lymphoma or lymphoplasmacytic lymphoma (a term commonly used by pathologists to describe the bone marrow findings of patients with WM). Rarely do patients with IgM MGUS evolve into IgM MM.⁷¹ Among 213 patients in the Southeastern Minnesota MGUS study, 23 developed "non-Hodgkin lymphoma" or WM, 3 developed chronic lymphocytic leukemia, and 3 developed AL

amyloidosis.⁷⁵ The risk of progression was 1.5% per year. The risk of progression of light chain MGUS relative to IgA, IgG, or IgM MGUS is not known.

Bone Marrow Plasma Cells

Cesana et al. have found that patients with MGUS who have 5% to 9% bone marrow plasma cells have a higher risk of progression compared with those with <5% bone marrow plasma cells.⁷⁶ Of 1,104 patients with MGUS in this study, at a median follow-up of 65 months, 64 MGUS cases (5.8%) evolved to MM or related plasma cell disorder. Patients with greater than 5% marrow plasmacytosis had a significantly higher risk of progression compared to those with 5% or fewer plasma cells, 1.35 versus 0.64 per 100 person years, respectively, $P = 0.004$.

Abnormal Serum-Free Light Chain Ratio

An abnormal FLC ratio is an independent risk factor for progression of MGUS. In a study of 1,148 patients with MGUS, 379 (33%) had an abnormal FLC ratio.¹⁹ The risk of progression in patients with an abnormal FLC ratio was significantly higher than that in patients with a normal ratio (hazard ratio 3.5; $P < 0.001$) and was independent of the size and type of serum M protein (Fig. 97.7). The production of excess monoclonal FLC in MGUS may be a biomarker for plasma cells bearing a higher degree of cytogenetic abnormalities thereby serving as a biomarker for a higher risk of progression.

Risk Stratification

A risk-stratification model can be used to predict risk of progression in MGUS, and is useful for management.¹⁹ The model is based on the size and type of the M protein and the FLC ratio (Table 97.5). Patients with all three risk factors consisting of an abnormal serum FLC ratio, IgA or IgM MGUS, and an increased serum M-protein value (≥ 1.5 g/dl) have a risk of progression at 20 years of 58%, whereas the risk is 37% with any two risk factors present, 21% with one risk factor present, and 5% when none of the risk factors are present. When competing causes of death were

P.2037

taken into account, the risk of progression in the low risk group is only 2% at 20 years.

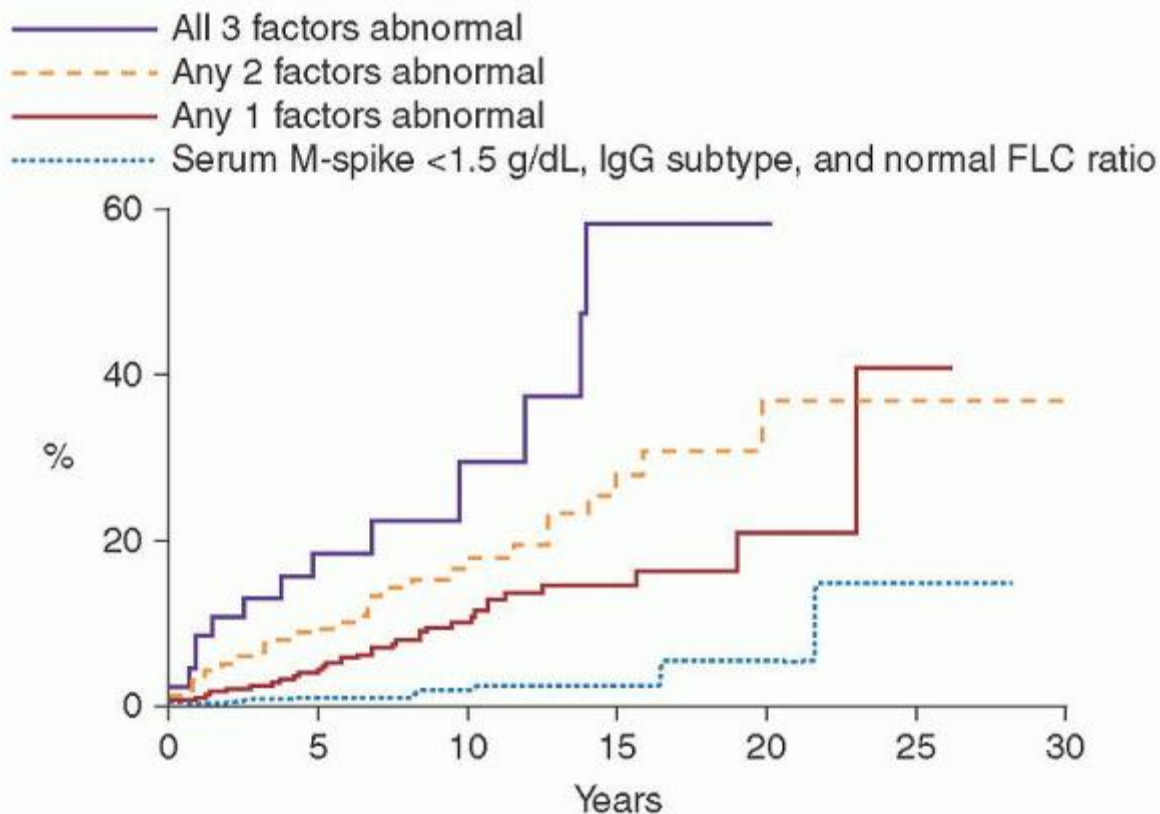

FIGURE 97.7. Risk of progression of monoclonal gammopathy of undetermined significance (MGUS) to myeloma or related disorder. The top curve illustrates the risk of progression with time in patients with three risk factors: abnormal serum $\kappa:\lambda$ free light chain (FLC) ratio (<0.26 or >1.65), a high serum monoclonal (M)-protein level (≥ 1.5 g/dl), and non-IgG MGUS. The

second curve is the risk of progression in patients with any two of these risk factors. The third curve illustrates the risk of progression with one of these risk factors. The bottom curve is the risk of progression for patients with none of the risk factors. (From Rajkumar SV, Kyle RA, Therneau TM, et al. Serum free light chain ratio is an independent risk factor for progression in monoclonal gammopathy of undetermined significance (MGUS) *Blood* 2005;106;812–817. © the American Society of Hematology.)

Life Expectancy and Cause of Death

In the Mayo Clinic study of 241 patients with MGUS, survival was shorter compared with an age- and sex-adjusted 1980 U.S. population (13.7 vs. 15.7 years).⁷⁷ Similarly, in the population-based study of 1,384 patients with MGUS in Southeastern Minnesota, median survival was 8.1 years compared with the expected median of 11.8 years for Minnesota residents of matched age and sex ($P < 0.001$).² In the study by van de Poel et al.⁷⁸, the long-term survival of 334 patients with MGUS was slightly shorter than the expected survival of an age- and sex-adjusted population. However, it is not clear from these studies if there is an excess risk of death from MGUS once the deaths due to malignant progression are accounted for.

TABLE 97.5 RISK-STRATIFICATION MODEL TO PREDICT PROGRESSION OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE TO MYELOMA OR RELATED DISORDERS

Risk Group	No. of Patients	Relative Risk	Absolute Risk of Progression at 20 Years (%)	Absolute Risk of Progression at 20 Years Accounting for Death as a Competing Risk (%)
Low risk (Serum M protein <1.5 g/dl, IgG subtype, normal FLC ratio (0.26-1.65))	449	1	5	2
Low-intermediate risk (Any 1 factor abnormal)	420	5.4	21	10
High-intermediate risk (Any 2 factors abnormal)	226	10.1	37	18
High risk (All 3 factors abnormal)	53	20.8	58	27

From Rajkumar SV, Kyle RA, Therneau TM, et al., Serum free light chain ratio is an independent risk factor for progression in monoclonal gammopathy of undetermined significance (MGUS) *Blood* 2005; 106;812-817. © The American Society of Hematology.

Management

The differentiation between MGUS and MM and other related disorders is based on the criteria listed on Table 97.1.⁸ At the time of initial diagnosis all patients need a complete blood count (CBC), serum calcium, and serum creatinine, and a radiographic survey of the skeleton. A bone marrow aspiration and biopsy is also recommended for most patients, and cytogenetic studies should be done at baseline on the bone marrow sample. Although a bone marrow biopsy is required for the definition of MGUS, not all patients need to have such an examination if the clinical picture is otherwise consistent with MGUS, and the patient is low-risk by the risk-stratification model shown on Table 97.5.¹⁹ If available, peripheral blood flow cytometry for circulating plasma cells should be done.

Once the diagnosis is made, the CBC, serum calcium, creatinine, and serum protein electrophoresis (and serum FLC if light chain MGUS) must be repeated in 6 months.⁷⁹ If stable, then in patients with low-risk MGUS, an assessment of the M protein level is needed only if symptoms worrisome for progression develop. This recommendation is based on the fact that the progression risk is very low in these patients, and that there are no data that monitoring can prevent complications in a timely manner.⁸⁰ In all other patients with MGUS, annual follow-up of the M protein is recommended lifelong.

No single factor can differentiate a patient with a benign monoclonal gammopathy from one in whom a malignant plasma cell disorder develops subsequently. However, the presence of a high plasma cell proliferative rate, circulating plasma

cells or other concerning clinical or laboratory features in a patient with MGUS needs to be followed up frequently for other evidence of progression.

P.2038

SMOLDERING MULTIPLE MYELOMA

Definition

SMM is defined by the presence of a serum M protein ≥ 3 g/dl and/or bone marrow plasma cells 10% to 60%, and absence of anemia, hypercalcemia, lytic bone lesions, or renal failure that can be attributed to the plasma cell proliferative disorder (Table 97.1).^{26, 27}

Epidemiology

SMM accounts for approximately 15% of all cases of newly diagnosed MM.⁸¹ In a study conducted at the M.D. Anderson Cancer Center, 95 (15%) of 638 patients with MM were considered to have asymptomatic MM.⁸² Other investigators have found a higher proportion of patients with SMM, but the sample size in these studies is small.^{83, 84} The prevalence estimates for SMM are distorted because many reports include asymptomatic patients with lytic bone lesions on skeletal survey. Some exclude patients with bone lesions on skeletal survey but include patients who have lytic lesions on magnetic resonance imaging. Calculation of the true prevalence of SMM on the basis of strict criteria is not available.

Pathophysiology

SMM is not a unique biologic entity.^{44, 45} It is a heterogeneous entity created primarily for clinical purposes to identify a group of patients with asymptomatic plasma cell dyscrasia that have a much higher risk of progression than MGUS (10% per year) so that these patients can be monitored more closely.^{10, 44, 85} From a biologic standpoint, SMM includes patients with pre-malignancy (biologic MGUS) and patients with early asymptomatic malignancy (MM).^{45, 86} Unfortunately, at present, histopathologic and other laboratory methods cannot distinguish SMM patients with pre-malignant MGUS from those who have early MM because there is no clear marker of malignancy that can distinguish a clonal pre-malignant plasma cell from a clonal malignant MM cell.

Clinical Features

As with MGUS, SMM is asymptomatic and is diagnosed during the routine work-up for a variety of symptoms and signs.^{79, 85} SMM should be differentiated from related plasma cell disorders using the criteria listed on Table 97.1.⁸

Prognosis

The risk of progression of SMM is much higher compared with MGUS, 10% per year compared with 1% per year. In a study of 276 patients with SMM, the risk of progression was 10% per year for the first 5 years, 5% per year for the next 3 years, and then 1% to 2% per year thereafter.¹⁰ This pattern of progression in which there is a plateau after 10 years is consistent with the heterogeneous nature of SMM; in the first 10 years, the subset of patients with early MM declare themselves with symptomatic disease, and after 10 years, the remaining cohort of patients is identical to MGUS in biology and clinical behavior. A subset of patients can remain free of progression for several years.⁹ Another study has reported a lower rate of progression of only 20% at 6 years.⁷⁶ However, the definition of SMM used in this study was different; it considered patients to have SMM only if they had no disease progression after 1 year of follow-up.

Prognostic Factors

The assessment of prognostic factors for SMM is hampered by varying diagnostic criteria used to define the cohort. Several studies also include patients with lytic lesions. Future studies of SMM need to use more uniformly accepted criteria so that results can be compared.

Extent of Bone Marrow Involvement

The natural history of SMM in the literature is based almost exclusively on data from patients with bone marrow plasma cells of less than 60%. In studies describing the diagnosis, natural history, and progression of SMM, no upper limit of bone marrow involvement was defined.¹⁰ In a study of 276 patients with SMM only 6 of 276 patients (2%) had a bone marrow plasma cell percentage of $\geq 60\%$.⁸⁷ Four of these 6 patients progressed to symptomatic MM between 3 to 9 months following diagnosis of SMM. The median progression free survival was 7.7 months. In a separate cohort of 655 patients with SMM seen from 1996 to 2010 at the Mayo Clinic, only 21 patients (3.2%) had a bone marrow plasma cell percentage

of $\geq 60\%$. Ninety-five percent of patients with $\geq 60\%$ bone marrow plasma cells progressed to MM within 2 years of diagnosis, with a median time to progression (TTP) of 7 months. Patients with SMM who have bone marrow involvement of 60% or greater almost invariably progress to MM within 2 years, and we now recommend that such patients be considered as MM regardless of the presence or absence of end organ damage and be initiated on therapy.^{86, 87} The prognostic value of levels of bone marrow involvement from 10% to 60% needs further study.

Circulating Plasma Cells

The ability of plasma cells to escape from the bone marrow microenvironment and circulate in the peripheral blood ("marrow emancipation") is a likely hallmark of aggressive disease as well as malignant transformation. Except for the small subset of solitary plasmacytoma, most MM patients present with lytic bone lesions in multiple bones, suggesting hematogenous dissemination once a malignant transformation has occurred. Patients with abnormal peripheral blood monoclonal plasma cell studies, defined as an increase in the number or proliferative rate of circulating plasma cells by immunofluorescent assays, are at higher risk for earlier progression to MM. In a study of 57 patients, Witzig et al. found that the median TTP was 9 months for those with abnormal circulating plasma cell values on a slide-based immunofluorescent assay versus 30 months for those with normal results ($P < 0.01$).⁸⁸ In a more recent study of 91 patients diagnosed with SMM at the Mayo Clinic, Bianchi et al. found that the level of circulating plasma cells could be used to identify patients with a high risk of progression to MM within the first 2 years.⁸⁹ Patients with a high level of circulating plasma cells on an immunofluorescent assay (absolute peripheral blood plasma cells $>5,000 \times 10^6/L$ and/or $>5\%$ cytoplasmic immunoglobulin positive plasma cells per 100 peripheral blood mononuclear cells) were significantly more likely to progress to active disease within 2 years compared with patients without high circulating plasma cells, 71 versus 25%, respectively, $P = 0.001$. Corresponding rates for progression within 3 years were 86 versus 35%, respectively, $P < 0.001$. The slide-based immunofluorescent method is not widely available, and these results can be more practically applied by detecting and quantifying circulating plasma cells using a six-color flow cytometric assay. In the flow assay, circulating plasma cells can be detected with high sensitivity by counting 150,000 mononuclear cell events, and can be used to calculate the absolute number of blood plasma cells per μL in SMM patients.

Abnormalities on Magnetic Resonance Imaging

Patients who undergo magnetic resonance imaging often have abnormalities detected even when the skeletal survey shows no

P.2039

lytic lesions.^{81, 90} Abnormal focal lesions on magnetic resonance imaging are associated with a shortened TTP in SMM.^{91, 92}

Serum Free Light Chain Assay

The serum FLC ratio can predict risk of progression in MGUS.¹⁹ Similarly, among 116 patients with solitary plasmacytoma, an abnormal FLC ratio was associated with higher risk of progression to MM ($P = 0.039$).²¹ In a study of 273 patients with SMM, an FLC ratio of ≤ 0.125 or ≥ 8 was an independent risk factor for progression (HR, 2.3; 95% CI, 1.6 to 3.2). Patients identified as high risk based on this assay had a 25% per year risk of progression in the first 2 years.²⁰

Absence of Normal Plasma Cells on Multiparametric Flow Cytometry

Certain immunophenotypic markers distinguish MM cells from normal PCs with a high degree of accuracy.⁹³ A Spanish study defines abnormal (MM-type) plasma cell immunophenotype as lack of expression of CD19 and/or CD45, expression of CD56, or weak expression of CD38. In SMM, if $>95\%$ plasma cells in the bone marrow have an abnormal immunophenotype, there is a 17-fold increased risk of progression.⁹⁴ In other words, the presence of $<5\%$ normal bone marrow plasma cells in a patient with SMM is associated with a significantly higher risk of progression.

Cytogenetic Abnormalities

The prognostic value of cytogenetic abnormalities in SMM have not been fully evaluated. In general, the presence of MYC abnormalities, 17p deletion, and RAS mutations, particularly K-RAS, are markers of malignant transformation and are likely associated with higher risk of progression in SMM.⁵⁹

Plasma Cell Proliferative Rate

A cardinal feature distinguishing MGUS from MM is the proliferative rate of the clonal plasma cell population. Indeed, using a slide-based immunofluorescent assay, there are preliminary data that high plasma cell labeling index (PCLI) values (≥ 1) identify patients with SMM who progress within 2 years with high specificity.⁹⁵ However, the PCLI method is subjective, and not widely available. A six-color flow cytometric assay, currently in clinical practice, offers greater

sensitivity and reproducibility. Further studies are needed to investigate the flow cytometry-based proliferative rate as a biomarker that can distinguish SMM patients with malignant transformation from those who have MGUS.

Management

The current standard of care in SMM is close follow-up once every 3 to 6 months without chemotherapy.^{79, 85} Two trials done prior to the arrival of thalidomide, lenalidomide, and bortezomib found no significant improvement in OS in patients who received immediate treatment with melphalan plus prednisone compared with those who received treatment at progression for stage I or asymptomatic MM. Hjorth et al. randomly assigned 50 patients with asymptomatic stage I MM to observation versus chemotherapy with melphalan and prednisone.⁹⁶ No differences were observed in OS between the two groups. Grignani et al. reported similar survival time with immediate or deferred therapy in a series of 44 patients with asymptomatic MM.⁹⁷ However, these trials were underpowered, and more data are needed.⁸⁶ The recommendation to observe closely without treatment until progression is also based on the possible short-term and long-term side effects of therapy, and the fact that in some patients SMM may not progress for months to years.

More recently, clinical trials have found that thalidomide may delay TTP, but there are long-term side effects associated with this treatment that make it unsuitable for intervention in an asymptomatic population.^{98, 99} In a randomized trial, Witzig et al. compared thalidomide plus zoledronic acid versus zoledronic acid alone in patients with SMM.¹⁰⁰ The TTP was superior for patients treated with thalidomide plus zoledronic acid ($n = 35$) compared with zoledronic acid alone ($n = 33$); median TTP 2.4 years (95% CI:1.4 to 3.6) versus 1.2 years (95% CI:0.7 to 2.5), respectively, $P = 0.02$. Lenalidomide plus dexamethasone has also shown promising activity in high-risk SMM. A recent randomized trial of lenalidomide plus dexamethasone in high-risk SMM is an excellent example of this strategy, in which the investigators demonstrated a significant prolongation of TTP, and preliminary evidence of a survival benefit.¹⁰¹ An ECOG trial is comparing lenalidomide versus observation in this patient population. Other trials are exploring agents such as bisphosphonates, IL-1 β inhibitors, clarithromycin, and dehydroepiandrosterone in an attempt to delay progression of SMM to symptomatic MM.¹⁰²

In addition to clinical trials, efforts are also under way to identify biomarkers that can predict patients who will inevitably progress to symptomatic MM within 2 years with high (80% or greater) accuracy.^{45, 86} Many groups are actively working toward this goal, and several promising biomarkers have already been identified as candidates for further study (Table 97.6).^{20, 94} If such biomarkers are validated, patients with SMM who are considered as high risk (>80% progression risk within 2 years) may be candidates for initiation of therapy similar to MM.

VARIANTS OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Secondary Monoclonal Gammopathy of Undetermined Significance

During the course of MM, new M proteins of an isotype distinct from the original clone can arise, and are referred to as secondary MGUS. In a study of 1,942 patients with MM, 128 (6.6%) developed a secondary MGUS, at a median time of 12 months from the diagnosis of MM.¹⁰³ The median duration of secondary MGUS was 6 months. In 34 (27%) of the 128 patients with secondary MGUS, there were multiple secondary MGUSs of varying isotypes. Secondary MGUS was more common in patients who had undergone SCT compared to those who had not undergone such a procedure: 23% versus 2%, respectively, $P < 0.001$. Most secondary

P.2040

MGUS M proteins were small, detectable by immunofixation only in 84 patients (66%). OS was significantly superior among patients who developed secondary MGUS compared with those who did not develop a secondary MGUS: 73 months versus 38 months, respectively, $P < 0.001$. Other studies on secondary MGUS have also found a survival benefit with secondary MGUS that appears in MM patients following SCT.^{20, 104, 105} Among patients with secondary MGUS, there is a trend to better OS in those in whom the MGUS resolved compared to those with persistent MGUS.

Biclonal and Triclonal Gammopathy

Biclonal gammopathies are characterized by the presence of two different M proteins and occur in 3% to 6% of patients with monoclonal gammopathies. The two M proteins may be caused by the proliferation of two different clones of plasma cells, each producing an unrelated M protein, or by production of two M proteins by a single clone of plasma cells. In one study, biclonal gammopathy of undetermined significance was found in 37 of 57 patients with a biclonal gammopathy.¹⁰⁶ Riddell et al. reported that 2.5% of 1,135 patients with monoclonal gammopathy had biclonal gammopathy.¹⁰⁷ They postulated that in some patients complete class switching in a single plasma cell clone resulted in the production of two M proteins, but in others the M proteins arose from two separate plasma cell clones.

Triclonal gammopathy is rare. Most reported cases have been associated with immunodeficiency syndromes or lymphoproliferative disorders.^{108, 109, 110}

Idiopathic Bence Jones Proteinuria (Benign Monoclonal Light Chain Proteinuria)

Idiopathic Bence Jones proteinuria represents a more advanced stage of light chain MGUS, in which there is excretion of monoclonal light chains in the urine without any evidence of end organ damage to suggest MM or related disorder.^{111, 112} It is best considered as representing light chain SMM.⁷ In one study, two patients with stable serum M-protein levels excreted 0.8 g/d or more of Bence Jones protein for more than 17 years without disease progression.¹¹¹ In a separate study, seven patients with Bence Jones proteinuria (>1 g/24 hour) were described in whom there was no evidence of heavy chain expression in the serum or urine, and no evidence of MM or a related disorder.¹¹³ During long-term follow-up, three of the seven patients developed MM, two others had an increase of their Bence Jones protein (BJP), and two remained stable during follow-up. One of the two patients who remained stable died of lung cancer after 10 years follow-up without change in the BJP, whereas the other patient died of a cardiac arrhythmia 36 years after diagnosis. An autopsy showed no evidence of MM or AL amyloidosis. The precise cut-off of urine M protein excretion that will distinguish LC-MGUS from idiopathic Bence Jones proteinuria remains unclear and is the subject of ongoing studies. Although idiopathic Bence Jones proteinuria may remain stable for years, as with MGUS or SMM, there is a continued risk of progression to MM or related disorder, and therefore patients must be followed up indefinitely.

IgD Monoclonal Gammopathy of Undetermined Significance

In most studies of MGUS, there are few if any patients with IgD MGUS making it hard to ascertain the natural history of this entity. In general, because IgD is not usually secreted, the presence of a serum IgD M protein almost always indicates MM, AL amyloidosis, or plasma cell leukemia. However, IgD MGUS has been reported occasionally. O'Connor et al. described a patient with an IgD λ protein level of 0.5 g/dl who was followed up for more than 6 years without evidence of progressive disease.¹¹⁴ Similarly, an IgD λ MGUS patient has been reported from the Mayo Clinic who remained stable for more than 8 years without development of MM or related disorder.¹¹⁵ The IgD λ protein in this patient has remained stable after 24 years follow-up.

ASSOCIATION OF MONOCLONAL GAMMOPATHY WITH OTHER DISEASES

Serum protein electrophoresis is commonly done in patients presenting with a wide variety of clinical symptoms. This results in the incidental diagnosis of MGUS in a wide variety of clinical settings. Inasmuch as MGUS is common in the general population, and because the prevalence increases with age, "associations" with various diseases can occur just coincidentally. Thus over the years, over a hundred different medical conditions have been reported to be associated with MGUS, and most such reported associations are not likely causally related. The only method to ascertain definitively true disease associations with MGUS that are etiologically related is to screen all persons in a geographic population for the presence or absence of MGUS, and then determine the diseases that are significantly associated in patients with and without MGUS. Only one such systematic study has been conducted so far. Bida and colleagues studied the association of MGUS with all diseases in a population-based cohort of 17,398 patients, all uniformly tested for the presence or absence of MGUS.¹¹⁶ Among 17,398 persons, 605 MGUS cases and 16,793 negative controls were identified. The computerized Mayo Medical Index was used to obtain information on all diagnoses entered between January 1, 1975 and May 31, 2006

totaling 422,663 person-years of observations. The study encompassed all prior reported associations in detail, and also looked for new associations not hitherto described. Data were analyzed using stratified Poisson regression, adjusting for age, gender, and total person-years of observation. The study confirmed a significant association in 14 (18.7%) of 75 previously reported disease associations with MGUS, including vertebral and hip fractures and osteoporosis (Table 97.7). Several of these associations were known progression events of MGUS such as MM and Waldenström macroglobulinemia. A systematic analysis of all 16,062 diagnostic disease-codes found additional previously unreported associations, including hyperlipidemia, mycobacterium infection, and superficial thrombophlebitis.

Some commonly reported disease associations are briefly discussed below. In some of these cases, the association with MGUS is undoubtedly causal and has great clinical relevance such as MGUS-associated neuropathy, membranoproliferative glomerulonephritis (MPGN), and several dermatologic disorders. In others, the association is real, but carries limited clinical consequences such as M proteins that arise with immunosuppression. In others, such as the association with leukemia and other hematologic disorders, connective tissue disorders, neurologic disorders, and rheumatologic disorders it is impossible to determine whether the reported associations are coincidental, and they have limited clinical or etiologic significance. Most such associations are reported from studies in which not all patients were screened for the presence or absence of MGUS. Thus, the reported associations merely reflect the type of diseases and clinical settings in which a serum protein electrophoresis is ordered rather than a true association with the result of the test.

Monoclonal Gammopathy of Undetermined Significance Associated Neuropathy

MGUS-associated neuropathy is a well-described entity.^{117, 118} In a Mayo Clinic study of 279 patients with a sensorimotor peripheral

P.2041

neuropathy of unknown cause, MGUS was found in 6%.¹¹⁹ Other series have found similar rates.^{120, 121, 122} In one study, neuropathy was found on testing in 2 of 34 patients with IgG (6%) MGUS, 2 of 14 with IgA MGUS (14%), and 8 of 26 with IgM MGUS (31%).¹²²

However, the neuropathy was not clinically apparent in approximately 50% of these patients.

CI, confidence interval; CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; MGUS, monoclonal gammopathy of undetermined significance

^a Rates age and sex adjusted

^b Unadjusted P values.

From Bida JP, Kyle RA, Therneau TM, et al. Disease associations with monoclonal gammopathy of undetermined significance: a population-based study of 17,398 patients. *Mayo Clin Proc* 2009;84:685-693.

In most cases, MGUS-related neuropathy is predominantly a demyelinating process with some features of axonal degeneration.¹²³ When patients classified as having chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) are studied, patients with an associated MGUS have a more indolent course, less severe motor symptoms and weakness, but more frequent sensory loss.¹²⁴ Occasionally a MGUS neuropathy can present with a predominant axonal pattern. This subtype is associated with mild, symmetric, slowly progressive, predominantly sensory neuropathy involving the lower extremities.¹²⁵ In a Mayo Clinic series, the size of the M spike was not associated with the severity of the neuropathy.¹²⁶

The most common type of M protein in MGUS neuropathy is IgM. The clinical and electrodiagnostic manifestations resemble those of chronic inflammatory demyelinating polyneuropathy.^{122, 127} Motor involvement is less prominent than sensory involvement. Cranial nerve and autonomic functions are intact.¹²⁸ The course of the neuropathy is progressive in more than two-thirds of patients.¹²⁶ In approximately half of patients with an IgM monoclonal gammopathy and peripheral neuropathy, the M protein binds to myelin-associated glycoprotein (MAG).^{129, 130} The MAG-reactive polyneuropathies are characterized by a slowly progressive, mainly sensory neuropathy beginning in the distal extremities and extending proximally. In a Mayo Clinic study, the type and severity of neuropathy with anti-MAG were not greatly different from those without anti-MAG.¹²⁶ Discriminative and proprioceptive modalities are more severely involved than touch, pain, and temperature. The IgM protein may also bind to various other peripheral nerve components such as anti-GM-1 IgM antibodies, but the pathogenetic relationship needs further study.^{131, 132, 133}

The relationship of IgG and IgA M proteins to peripheral neuropathy is less well documented.^{118, 134} IgG and IgA neuropathy may have more motor impairment and may have more features of axonal degeneration than IgM neuropathy.¹²²

Differential Diagnosis

Inasmuch as 3% to 4% of the general population has an MGUS, in most patients the association of MGUS and neuropathy is likely coincidental. Therefore, the first step in a diagnostic evaluation should be to consider and exclude other causes of neuropathy. MGUS neuropathy is a diagnosis of exclusion, and there are no specific clinical or laboratory tests that are specific for the diagnosis. Intervention often involves administering anticancer therapy in patients without malignancy, therefore a diagnosis of MGUS neuropathy should not be made lightly. In the absence of other causes of neuropathy, the younger the patient, and the more severe the neuropathy, one should be more serious in considering MGUS as the cause of neuropathy and one that warrants intervention. The differential diagnosis of MGUS neuropathy should also consider other plasma cell disorders that are

P.2042

associated with neuropathy, namely AL amyloidosis and POEMS syndrome.^{135, 136, 137} In neuropathy related to AL amyloidosis both upper and lower extremities tend to be affected, whereas in MGUS neuropathy peripheral regions of the lower extremities are primarily affected. AL amyloidosis also has a greater tendency to be associated with autonomic features (postural hypotension, sphincter dysfunction, anhidrosis). In most cases, MGUS neuropathy tends to be primarily demyelinating, whereas neuropathy in AL amyloidosis is characterized by axonal degeneration. A diagnosis of AL amyloidosis is often suggested by the presence of other organ involvement, and requires demonstration of Congo red positive amyloid material on fat aspirate, or an affected organ. POEMS syndrome is associated with a predominantly motor chronic inflammatory demyelinating polyneuropathy, sclerotic bone lesions, and a varying number of associated abnormalities such as hepatomegaly, hyperpigmentation, hypertrichosis, gynecomastia, testicular atrophy, clubbing, polycythemia, thrombocytosis, and Castleman's disease. In POEMS syndrome, the neuropathy is often progressive and disabling. Although MGUS neuropathy is also demyelinating in most instances, it is typically more of a sensory neuropathy. MM and WM can also be associated with neuropathy, either directly due to the plasma cell disorder, or as a result of therapy. When related to the plasma cell disorder, the neuropathy in MM and macroglobulinemia is similar in pathogenesis to MGUS neuropathy; in contrast the pathogenesis of neuropathy in AL amyloidosis and POEMS syndrome is probably different mechanistically from MGUS neuropathy.

Treatment

The results of treatment of peripheral neuropathy and monoclonal gammopathy have been disappointing. A variety of interventions has been tried, but there are few good trials.¹³⁸ Most treatment recommendations are based on anecdotal experience. Intravenous immunoglobulin has been used, but the results have been disappointing.¹³⁹ However, intravenous immune globulin may be of benefit in patients with IgG MGUS related neuropathy, with 40% of patients showing improvement in one study.¹⁴⁰ Plasmapheresis has been of benefit in some patients.¹⁴¹ In a double-blind controlled trial conducted at the Mayo Clinic, 39 patients with peripheral neuropathy and MGUS of the IgG, IgA, or IgM type were randomly assigned to undergo plasmapheresis or sham plasmapheresis.¹⁴² Plasma exchange prevented worsening of or ameliorated the neuropathy. Patients with IgG or IgA gammopathy had a better response to plasma exchange than those with IgM gammopathy. In another study, 8 of 13 patients with a monoclonal gammopathy and peripheral neuropathy obtained benefit from plasma exchange.¹⁴³ Patients who do not respond to this program may be given rituximab when the M protein is of the IgM type or standard treatments used for MM such as lenalidomide and dexamethasone, or melphalan plus prednisone for IgG and IgA gammopathies.¹⁴⁴ In one study, 21 patients with IgM MGUS neuropathy treated with rituximab were compared with 13 untreated controls.¹⁴⁵ Rituximab treatment was associated with decreased IgM levels and improvement in strength. Two randomized trials have investigated the role of rituximab in IgM MGUS neuropathy.¹⁴⁶ In one trial, the authors randomized 26 patients with anti-MAG positive IgM MGUS to rituximab versus placebo.¹⁴⁷ An improvement in neuropathy was noted in approximately 25% of patients. In another randomized trial, 54 patients were studied, and a similar benefit was observed.¹⁴⁸ Additional studies, with placebo controls and blinded outcome measures, are warranted to further test the efficacy of rituximab treatment of IgM-associated polyneuropathies. In patients with IgM MGUS neuropathy refractory to rituximab, fludarabine or other treatments used for WM can be tried.^{149, 150, 151}

Membranoproliferative Glomerulonephritis

A substantial proportion of cases with "idiopathic" immune-complex mediated MPGN are now felt to be related to MGUS.^{152, 153} In a study of 126 patients with MPGN conducted at the Mayo Clinic, 22% were associated with a monoclonal gammopathy.¹⁵² Excluding other known causes such as hepatitis B and hepatitis C, approximately 40% of cases of idiopathic MPGN could be attributed to MGUS. MGUS-associated MPGN is characterized by subendothelial and mesangial deposition of immune complexes that show light chain restriction on immunofluorescent studies. The optimal treatment has not been well defined, but depending on the clinical symptoms, therapy targeted against the M protein is reasonable.¹⁵³ In a small subset of patients light chain restricted MPGN is seen on renal biopsy with no M protein in the serum or urine, and no clonal plasma cells in the bone marrow. The natural history of this subset is unclear.

Inasmuch as the kidney is often involved in plasma cell disorders such as light chain cast nephropathy, light chain deposition disease, and AL amyloidosis, renal involvement in patients with M proteins requires a careful evaluation and differential diagnosis. Besides MPGN and these known entities, other reported associations include rapidly progressive glomerulonephritis,¹⁵⁴ dense deposit disease,¹⁵⁵ and "idiopathic" focal and segmental glomerulosclerosis.¹⁵⁶

Dermatologic Diseases

A variety of dermatologic diseases has been associated with MGUS.¹⁵⁷ Lichen myxedematosus (papular mucinosis, scleromyxedema) is a rare dermatologic condition frequently associated with an IgG λ monoclonal protein.¹⁵⁸ Scleredema (Buschke's disease) has been noted with an M protein, but the role of the M protein is unknown.¹⁵⁹ Other known associations include pyoderma gangrenosum,¹⁶⁰ diffuse plane xanthomatosis,^{161, 162, 163} and subcorneal pustular dermatosis.^{164, 165} Necrobiotic xanthogranuloma, is frequently found with an IgG M protein,^{166, 167} and Schnitzler's syndrome is a rare disorder characterized by the presence of chronic urticaria and an IgM monoclonal gammopathy.^{168, 169, 170, 171}

Immunosuppression

M proteins arise in patients with immunosuppression. M proteins have been reported in patients with the acquired human immunodeficiency syndrome, but do not appear to have any prognostic significance.^{172, 173} M proteins have been detected in approximately 5% to 10% of patients following renal transplantation.^{174, 175, 176} Others have reported rates as high as 30%.^{177, 178} In fact, in one study, the incidence was 10 times greater than that in a control group with chronic renal insufficiency who were receiving dialysis.¹⁷⁷ The presence of cytomegalovirus infection after renal transplantation in pediatric patients has been associated with an increased incidence of M proteins.¹⁷⁹ M proteins have also been reported in patients receiving other forms of organ transplantation. Approximately 25% of patients following heart transplantation,^{180, 181} and approximately 30% of patients following liver transplantation have been reported to develop M proteins.^{182, 183}

The effect of organ transplantation on patients with MGUS is unclear. In a report of five patients with MGUS undergoing transplantation, SMM developed in two and one had an increase in the serum M protein.¹⁸⁴ Amyloidosis developed 10 years after an IgG κ M protein was recognized after renal transplantation in another patient. In a more recent study, 3,518 patients who underwent renal transplantation at the Mayo Clinic were studied.¹⁸⁵ MGUS was identified in 42 patients: 23 prior to transplantation, and 19 after transplantation. Of the patients who had MGUS prior to

P.2043

renal transplantation, 2 developed progression of the plasma cell disorder, both to SMM. None of the 19 patients who developed an MGUS after transplant progressed to MM or related disorder. Thus, progression of MGUS following renal transplantation is rare. A few patients in this study developed post-transplant lymphoproliferative disorder and the relationship of this entity with MGUS needs further study.

Leukemia and Other Hematologic Disorders

Mailankody and colleagues studied the risk of acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS) in patients with MM and MGUS using population-based data from Sweden.¹⁸⁶ They identified 8,740 patients with MM and 5,652 patients with MGUS diagnosed between 1986 and 2005. They found a 11.5-fold increased risk of AML or MDS in patients with MM. But more strikingly, MGUS patients also had an 8-fold (95% CI 5.4 to 11.4) increased risk of AML/MDS compared with controls. The risk was confined to IgG/IgA MGUS, and the highest risk was seen in patients with an M protein of >1.5 g/dl. A subsequent study from the Mayo Clinic has also found an increased risk of acute leukemia and MDS in MGUS.¹⁸⁷ This study utilized data from the population-based cohort established in Olmsted County to estimate the prevalence of MGUS in the general population and therefore was not subject to detection or ascertainment bias.³ MGUS patients had a significantly higher risk of developing acute leukemia (AML or acute lymphoblastic leukemia) or MDS compared with controls, risk ratio 2.20 (95% CI 1.23, 3.92), $P = 0.008$.¹⁸⁷ These findings suggest that there may be an inherent increased risk of acute leukemia and MDS in patients with plasma cell disorders that is independent of MM therapy.

An association between MGUS and chronic lymphocytic leukemia has been reported. In one study, 100 patients with chronic lymphocytic leukemia and an M protein in the serum or urine were described.¹⁸⁸ The M protein type was IgM in 38%, and IgG in 51%. No major differences were apparent in patients with chronic lymphocytic leukemia, whether they had an IgG or an IgM M protein. Monoclonal gammopathy also has been reported in hairy cell leukemia,¹⁸⁹ adult T-cell leukemia,¹⁹⁰ mycosis fungoides,¹⁹¹ Sézary syndrome,¹⁹² non-Hodgkin lymphoma,¹⁹³ Kaposi sarcoma,¹⁹⁴ and chronic myeloid leukemia,¹⁹⁵ but the significance of these associations is not known.

MGUS has been reported in patients with MDS,¹⁹⁶ and myeloproliferative disorders including chronic myeloid leukemia, myelofibrosis and polycythemia vera.^{197, 198, 199, 200, 201} Duhrsen et al. found that the frequency of M proteins was 8.5% (16 of 188) among patients with idiopathic myelofibrosis, which suggests a possible true association.²⁰¹

MGUS has also been linked to a variety of coagulation disorders. Cases of acquired von Willebrand's disease resulting from monoclonal gammopathy have also been described.^{201, 202, 203, 204} In several patients, a specific interaction between the M component and the antigenic portion of the factor VIII molecule was demonstrated.^{205, 206, 207, 208, 209} In these patients, intravenous gamma globulin had a longer-lasting effect than did infusion of von Willebrand's factor concentrate.²¹⁰ In addition to acquired von Willebrand disease, a bleeding diathesis may also occur in MGUS from binding of an M protein to thrombin.²¹¹ Thromboembolic disease has also been noted to be more frequent in patients with MGUS.²¹² The mechanisms are unknown, but in rare instances the paraprotein in MGUS may have lupus anticoagulant activity.²¹³ An increased incidence of antiphospholipid antibodies has also been reported in patients with MGUS.²¹⁴

Other rare associations that have been reported include Gaucher disease²¹⁵ and pernicious anemia,²¹⁶ as well as pure red cell aplasia caused by a block in the maturation of the erythroid burst forming unit (114).^{217, 218}

Connective Tissue Disorders

Rheumatoid arthritis,²¹⁹ seronegative erosive arthritis,²²⁰ systemic lupus erythematosus, and other connective tissue disorders have been reported with MGUS.^{221, 222, 223} Polymyalgia rheumatica and polymyositis have also been reported with monoclonal gammopathy.^{224, 225, 226}

Neurologic Disorders

Several instances of monoclonal gammopathy and amyotrophic lateral sclerosis have been reported, including one series of 120 patients with amyotrophic lateral sclerosis in whom 11 (9%) had an associated M protein.^{227, 228, 229} However, a causal relationship has not been established. Other neurologic disorders that been reported in association with MGUS include myasthenia gravis,^{230, 231} ataxia-telangiectasia,^{232, 233} and nemaline myopathy.²³⁴

Miscellaneous Conditions

Systemic Capillary Leak Syndrome

Numerous other associations have been reported with MGUS. One important association is with angioneurotic edema and acquired deficiency of C1 esterase inhibitor.²³⁵ In some instances, the M protein functions as an antibody that modifies the interaction between C1 inhibitor and its target protein.²³⁶ The most important consequence is systemic capillary leak syndrome which can be life-threatening.²³⁷ In a review of the literature, all 21 patients with a systemic capillary leak syndrome had a serum M protein (IgG κ in 12; IgG λ in 7; IgA in 1; IgG with an unspecified light chain in 1).²³⁸ In another series of 25 patients with systemic capillary leak syndrome seen at the Mayo Clinic, the median age at diagnosis was 44 years.²³⁹ The median time to diagnosis from symptom onset was approximately 1 year, but in 25% the time to diagnosis was longer than 4 years (interquartile range, 0.5 to 4.1 years). A monoclonal gammopathy, mostly IgG- κ type, was found in 19 patients (76%). The degree of albumin decrease during an attack was correlated with the development of rhabdomyolysis. Acute attacks are usually managed with fluids and supportive care. Long-term prophylactic therapy usually consists of theophylline (or aminophylline) along with terbutaline. A leukotriene inhibitor can be tried in patients refractory to theophylline or terbutaline.

Hepatitis C

Most cases of type II cryoglobulinemia are related to hepatitis C, and are associated with an IgM monoclonal protein.^{240, 241} The incidence of hepatitis C virus infection was 69% in 94 patients with mixed cryoglobulinemia and 14% in 107 patients without cryoglobulinemia²⁴². In another series of 102 cases of MM, WM, or MGUS, hepatitis C virus infection was found in 16% of patients but in only 5% of controls.²⁴³ An M protein was found in 11% of 239 hepatitis C virus-positive patients but in only 1% of 98 hepatitis C virus-negative patients. Thus, the prevalence of M proteins in patients with hepatitis C virus-related chronic liver diseases is high.²⁴⁴

Other Disorders

M proteins have been noted in numerous other disorders such as chronic active hepatitis, primary biliary cirrhosis, Henoch-Schönlein purpura, bacterial endocarditis, Hashimoto thyroiditis, idiopathic pulmonary fibrosis, pulmonary alveolar proteinosis, idiopathic pulmonary hemosiderosis, sarcoidosis, thymoma,

P.2044

hereditary spherocytosis, Doyme macular heredodystrophy, and eosinophilic fibrohistiocytic lesions of the bone marrow, but these associations are likely coincidental.¹¹⁶ M proteins have also been associated with corneal crystalline deposits and hyperlipoproteinemia, and the relationship of monoclonal gammopathy to these diseases is not clear.

M Proteins with Antibody Activity

M proteins may have autoantibody activity, and there have been numerous reported associations.^{245, 246} Of 612 patients in whom M proteins were studied for their antibody activity against actin, tubulin, thyroglobulin, myosin, myoglobin, fetuin, albumin, transferrin, and double-stranded DNA, 36 (5.9%) had antibody activity.²⁴⁷ In some patients with MGUS, MM, or Waldenström macroglobulinemia, the M protein has exhibited unusual specificities to dextran,²⁴⁸ antistreptolysin O,²⁴⁹ antinuclear activity,²⁵⁰ smooth muscle,²⁵¹ riboflavin,^{252, 253} thyroglobulin,²⁵⁴ insulin,²⁵⁵ double-stranded DNA,²⁵⁶ apolipoprotein,²⁵⁷ thyroxine,²⁵⁸ cephalin,²⁵⁹ lactate dehydrogenase,²⁶⁰ anti-HIV,²⁶¹ and antibiotics.²⁶²

In one patient, xanthoderma-xanthotrichia (yellow discoloration of the skin and hair) was caused by an IgG λ protein with antiriboflavin antibody activity. Xanthoderma disappeared when the IgG level decreased to less than 2 g/dl after chemotherapy.²⁵² Another patient with similar clinical and laboratory features has been reported.²⁵³

DiMinno et al. described a patient with MM and a bleeding diathesis in whom an IgG1 κ protein reacted with platelet glycoprotein IIIa.²⁶³ This produced a thrombasthenia-like state. An IgM κ M protein that agglutinated platelets and produced a pseudothrombocytopenia has been reported.²⁶⁴

The binding of calcium by M protein may produce hypercalcemia without symptomatic or pathologic consequences.^{265, 266} This situation must be recognized so that patients are not treated for hypercalcemia.²⁶⁷ Copper-binding M protein has been found in two patients with MM.^{268, 269} Binding of an M protein with transferrin, producing a high serum iron level, has been reported.^{270, 271} Hilgard et al. described a patient with multiple thrombi from intravascular precipitation of an IgG λ monoclonal cryoglobulin with transferrin and fibrinogen.²⁷² Pettersson et al. described a patient with an IgG κ protein that bound phosphate, producing a spurious elevation of the serum phosphorus level.²⁷³ Transient M proteins with antibody activity have also been recognized after infection in children. One report described a newborn with congenital toxoplasmosis who had an IgG λ protein.²⁷⁴

Chapter 98

Multiple Myeloma

Angela Dispenzieri

Martha Q. Lacy

Shaji Kumar

Multiple myeloma (MM) is a neoplastic plasma cell dyscrasia (PCD) characterized by a clinical pentad: (1) anemia, (2) a monoclonal protein in the serum or urine or both, (3) bone lesions and/or bone pain, (4) hypercalcemia, and (5) renal insufficiency. With the exception of monoclonal gammopathy of undetermined significance (MGUS), it is the most common PCD, with an incidence of about 4.5 per 100,000 per year in the United States. Solitary plasmacytoma and plasma cell leukemia (PCL) are recognized as separate entities and are much less prevalent. The underlying pathogenesis of the plasma cell malignancies is not well understood but is an area of active investigation. At present, according to the WHO (World Health Organization) classification system, there is only one category for MM.¹ Results of clinical trials are confounded by this underclassification. Emerging information about the genetic underpinning of the disease, however, will likely change this deficiency.

The interactions among the plasma cells, their antibody product, the local bone and bone marrow environment, and other organs are complex. There is no cure for MM, but there are many effective treatments that prolong and improve the quality of life in patients with the disease.

HISTORY

The Earliest Diagnoses and Diagnostic Methods

Samuel Solley reported the first well-documented case of MM (mollities ossium) in Sarah Newbury in 1844.^{2, 3} Several years later, William MacIntyre described and recorded the properties of the disease we now call MM in Thomas Alexander McBean.⁴ Both Drs. MacIntyre and Bence Jones noted and described some of the peculiar urine properties of this same patient. On heating, the urine was found to be “abound in animal matter,” which dissolved on the addition of nitric acid but reappeared after cooling. These urinary proteins became known as Bence Jones proteins.⁵ MacIntyre and Dalrymple described the post-mortem examination of Mr. McBean's bones.⁴ The former described the affected bones as softened and fragile, with their interiors replaced with a soft “gelatiniform” blood-red substance. Dalrymple suggested that the disease began in the cancellous bone and extended through the periosteum. The nucleated cells, which formed the bulk of the gelatinous material, were heterogeneous in size and shape, but the majority were round to oval. Many of the larger and more irregular cells frequently contained two or three nuclei.³ The term “multiple myeloma” was coined in 1873 by von Rustizky,⁶ who independently described a similar patient to emphasize the multiple bone tumors that were present.

In 1889, Professor Otto Kahler⁷ described a case involving a 46-year-old physician with MM and published a major review of the disease. He described the skeletal pain, albuminuria, pallor, anemia, a precipitable urinary protein, and the findings on necropsy and linked these findings as part of a clinical syndrome that bears his name (MM has also been referred to as Kahler disease).

In 1898 Weber predicted the usefulness of Roentgen x-rays in establishing the diagnosis^{3, 8} and later postulated the Bence Jones protein was produced in the bone marrow.⁹ Wright¹⁰ emphasized that MM arose specifically from plasma cells of the marrow, Jacobson¹¹ recognized Bence Jones proteins in the bloodstream, and Walters¹² concluded that the Bence Jones protein was probably derived from blood proteins through the action of the abnormal cells in the bone marrow. The technique of bone marrow aspiration¹³ facilitated the diagnosis of MM.

Serum electrophoresis, described by Tiselius in 1937,¹⁴ made it possible to separate serum proteins. Longsworth et al.¹⁵ applied electrophoresis to the study of MM and described the tall narrowbased “church spire” peak. The use of filter paper as a support for protein electrophoresis permitted the separation of protein into distinct zones that could be stained with various dyes.¹⁶ Paper electrophoresis was supplanted by filter paper in 1957 and most recently by high-resolution electrophoresis on agarose gel. Immunoelectrophoresis¹⁷ and immunofixation or direct immunoelectrophoresis¹⁸ made it possible to detect small monoclonal light chains not recognizable by electrophoresis. The immunoglobulin free light chain assay has been added to the diagnostic armamentarium to detect circulating free light chains in the majority of patients previously designated nonsecretory.¹⁹

Kunkel²⁰ hypothesized that monoclonal proteins were the product of malignant plasma cells and were the equivalent of normal antibodies produced by normal plasma cells. Before 1960, the term “gamma globulin” was used for any protein that migrated in the gamma mobility region of the electrophoretic pattern; however, in 1959, Heremans²¹ proposed the concept of a family of proteins with antibody activity. In 1961 in a Harvey Lecture,²² Waldenström distinguished between monoclonal and polyclonal hypergammaglobulinemia.

In 1928, Geschickter and Copeland²³ reported on the largest case series of MM—13 cases—and reviewed the 412 cases reported in the literature since 1848. They documented a higher incidence in men than women and an overall survival (OS) of about 2 years. They emphasized six features: (1) involvement of the skeletal trunk, (2) pathologic rib fractures, (3) Bence Jones proteinuria in 65% of cases, (4) backache with early paraplegia, (5) anemia in 77% of cases, and (6) chronic renal disease. They did not note abnormalities of blood protein or an increased erythrocyte sedimentation rate.³ In 1931, Magnus-Levy²⁴ described amyloidosis as a complication of MM. Salmon, Durie, and Smith developed methods to quantitate the total body burden of tumor cells²⁵ and to stage patients²⁶ in 1970 and 1975, respectively.

Prior to the discovery in 1950²⁷ of salutary effects of adrenocorticotrophic hormones on MM (Fig. 98.1), medications used to that point included stibidine and urethane, neither of which had activity upon critical testing.³ During that decade, it was recognized that the adrenocorticotrophic hormones cortisone and prednisone were useful agents in patients with MM. Corticosteroids decreased bone pain, improved hypercalcemia, increased hemoglobin values, and decreased abnormal serum and urine globulin concentrations.²⁸ However, it was not until 1967 that high-dose corticosteroids were recognized as effective antineoplastic agents against MM.²⁹

Blokhin et al.³⁰ reported benefits in 3 of 6 patients with MM who were treated with sarcolysin (a racemic mixture of the d- and l-isomers of phenylalanine mustard). Subsequently, the d- and l-isomers were tested separately, and the anti-MM activity was found to reside in the l-isomer, melphalan. Bergsagel et al.³¹ reported significant improvement in 14 of 24 patients with MM with the use of melphalan; this activity was quickly substantiated by others.³² Similar effectiveness was noted with cyclophosphamide.³³ Subsequently, interferon- α (IFN), doxorubicin, carmustine, thalidomide, bortezomib, lenalidomide, bendamustine, and carfilzomib^{34, 35, 36, 37, 38, 39} have each been reported to have activity as a single agent in MM.

P.2047

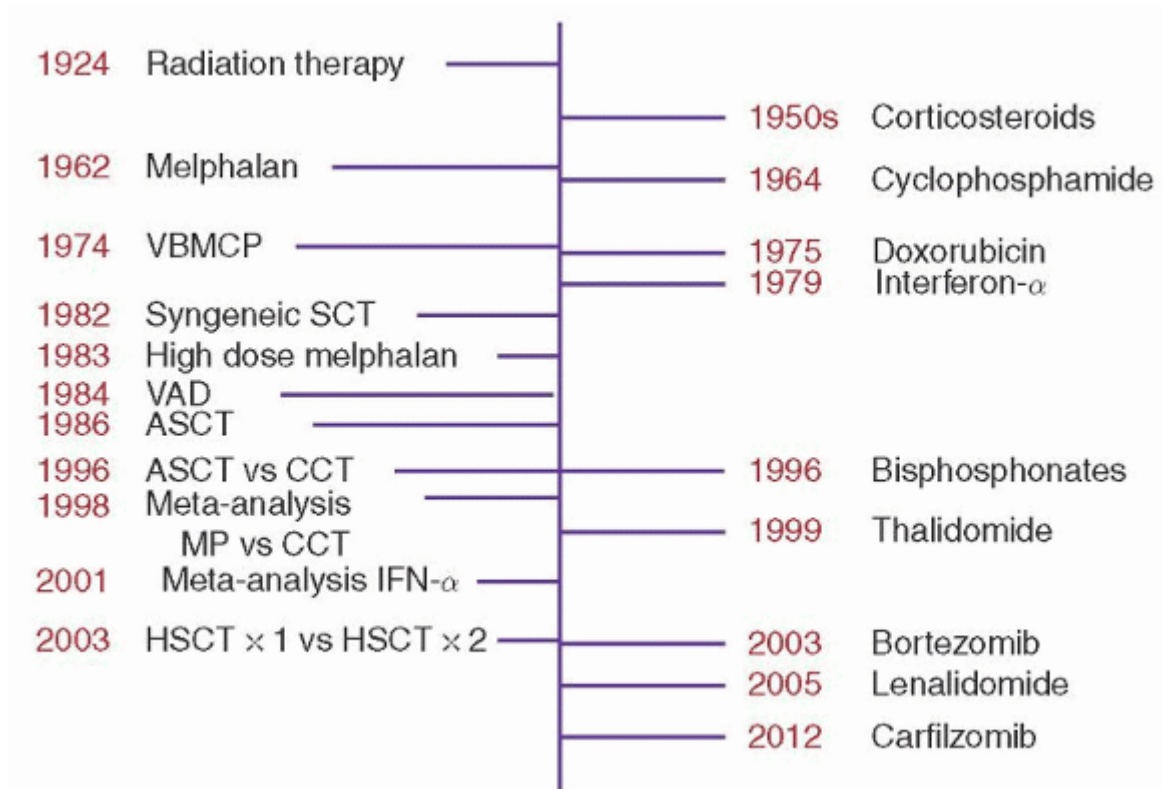

FIGURE 98.1. Landmark therapeutic innovations. ASCT, autologous stem cell transplant; BCNU, melphalan, cyclophosphamide, and prednisone (M-2 regimen); CCT, conventional chemotherapy; VAD, vincristine, doxorubicin, dexamethasone; VBMCP, vincristine.

INCIDENCE AND EPIDEMIOLOGY

As described in Chapter 97, recent evidence supports the theory that all MM arises from a preceding MGUS.⁴⁰ Increasingly it is becoming apparent that there is an increased risk of developing MM or MGUS among first-degree relatives of both MGUS and MM patients.^{41, 42} Whether this family linkage is due to either genetic susceptibility factors or shared environmental risk factors (or both) is yet to be determined.

Epidemiology of Myeloma

The 2012 annual estimate in the United States for new cases of MM is 21,700 and for deaths is 10,710.⁴³ SEER (Surveillance, Epidemiology, and End Results) data incidence age-adjusted rates from 1992 through 1998 show an overall incidence of 4.5 per 100,000 per year, with the incidence among whites being 4.2 per 100,000 per year and among blacks, 9.3 per 100,000 per year.⁴⁴ Male-to-female ratio is 1.3 to 1.⁴³ The median age at diagnosis of MM is 71 years. Since the turn of the century, 5-year survival rates in blacks and whites have equalized.⁴³ MM accounts for 1% of all malignancies and 10% of all hematologic malignancies in whites and 20% in African Americans.⁴⁴ International mortality data reveal that the highest rates of MM occur in Northern Europe, North America, Australia, and New Zealand and the lowest rates are in Japan, Yugoslavia, and Greece.⁴⁵ Geographic clusters⁴⁶ and familial clusters^{47, 48, 49, 50, 51, 52} of MM among first-degree

relatives have been documented. Modest increases in MM rates were observed when incidence data from 1973 to 1992 were calculated in nine population-based cancer registries.⁵³ These increases are likely due to a heightened awareness of the disease.

Etiologic Factors

Radiation Exposure

Reports of increased MM incidence and mortality among Japanese atomic bomb survivors have suggested an association between ionizing radiation and MM. Initial evaluations of cancer incidence⁵⁴ and mortality⁵⁵ among Japanese atomic bomb survivors suggested an increased risk of MM with increasing radiation dose, an observation that was no longer seen with additional years of follow-up.⁵⁶ Subsequent data would suggest that the prevalence of MGUS is higher among those younger patients exposed to higher doses of radiation.⁵⁷

An excess of MM deaths among American radiologists was reported in the 1960s.⁵⁸ MM risk was considered to be two times higher among radiologists exposed to low doses of radiation than among physicians not exposed to radiation.⁵⁹ However, among 27,000 Chinese diagnostic radiography workers, no excess incidence of MM was observed in a 30-year period.⁶⁰ An analysis of 115,000 workers from the combined roster of four different nuclear plants showed a positive association between MM and radiation exposure in older age groups.⁶¹ No increases in MM incidence and mortality have been observed among British⁶² or New Zealand⁶³ military men who participated in atmospheric nuclear weapons testing.

Diagnostic x-ray exposure has not been linked with the development of MM in most epidemiologic studies.^{64, 65, 66, 67, 68, 69} A large multicenter population-based case-control study showed no evidence of excess risk of MM among individuals who reported exposure for 10 or more diagnostic radiographs.⁷⁰ One study reported that the overall risk for MM was not high (RR, 1.14), but that there was evidence of increasing risk with exposure to increasing numbers of radiographic procedures.⁷¹ Of historic interest is the finding of an association between MM and the use of Thorotrast.⁶⁵ Studies of the effects of therapeutic irradiation on MM risk have shown conflicting results, but a study of 180,000 women treated for cervical cancer demonstrated no overall excess risk of developing MM.⁷² Similarly, a study of 14,000 patients suffering from ankylosing spondylitis and treated with radiation revealed no significant increase in the risk of developing MM.⁷³

Workplace Exposures

Several epidemiologic studies have evaluated the risk of MM among agricultural workers, with positive associations reported by many^{74, 75, 76, 77, 78, 79} but not all of the studies.^{80, 81, 82} Khuder and Mutgi⁸³ found a relative risk of 1.23 in a meta-analysis of several studies. Workers in various metal occupations and industries have been reported to have an increased MM risk.^{84, 85, 86}

Benzene has been suggested as a possible etiologic agent for MM.^{87, 88, 89} A comprehensive review of the published literature found no evidence of a link between benzene exposure and MM.⁹⁰ Subsequently, Sonoda and colleagues⁹¹ conducted a meta-analysis of case-control studies and showed no excess risk for the development of MM. A meta-analysis by Wong and Raabe⁹² of more than 350,000 petroleum workers similarly showed no increased risk.

Cigarette Smoking, Alcohol Consumption, and Diet

Multiple studies to date have found no etiologic role for cigarette smoking or alcohol consumption in the development of MM.^{93, 94, 95, 96} In contrast, Tavani et al.⁹⁷ suggested a dietary link for MM and found a higher risk among people consuming large quantities of liver (odds ratio [OR], 2.0) and butter (OR, 2.8), and a lower risk among people consuming large amounts of vegetables (OR, 0.4) No association of MM and consumption of coffee or red meat has been found.⁹⁷ Brown and colleagues⁹⁸ looked at diet and nutrition as risk factors for MM among blacks and whites in the United States. Only obesity was associated with increased risk, and obesity was more frequent in black than in white controls. Frequent consumption of cruciferous vegetables, fish, and vitamin C supplements was associated with decreased risk of MM. The authors concluded that the greater use of vitamin C supplements by whites and the higher frequency of obesity among blacks may explain part of the higher incidence of MM among blacks compared with whites in the United States.

Personal use of hair dyes was evaluated as a risk factor for MM,⁹⁹ including two prospective studies.^{100, 101} Thun et al.¹⁰⁰ found that women using permanent hair dyes are not generally at increased risk of fatal cancer. However, women with prolonged use of dark, particularly black, hair dyes may have increased risk

P.2048

of fatal non-Hodgkin lymphoma and MM, but these women are a small fraction of hair dye users. A subsequent meta-analysis by Correa et al.¹⁰² showed no increased risk.

Socioeconomic Status

Some investigators have reported that there is an inverse relationship between the risk of MM and socioeconomic status,¹⁰³ and that this inverse correlation may account for a substantial amount of the black and white differential of MM incidence.¹⁰⁴ Earlier studies did not show a link between socioeconomic status and MM.¹⁰⁵

Chronic Antigenic Stimulation

Repeated or chronic antigenic stimulation of the immune system may lead to MM. Several case-controlled studies have suggested that MM risk is associated with past history of infections, inflammatory conditions, connective tissue disorders, autoimmune illnesses, and allergy-related disorders.^{94, 106, 107} Patients with the human immunodeficiency virus may have an increased likelihood of developing MM.^{108, 109} In addition, MM and hepatitis C may be associated.^{110, 111, 112} The finding of human herpes virus 8 has been suggested as a possible etiologic agent,¹¹³ but this has not been confirmed.^{114, 115, 116, 117} Increased risk for MM has been observed in patients with rheumatoid arthritis.^{51, 118, 119} Other studies of individuals with these conditions have shown no increased risk of MM.^{120, 121, 122, 123}

CLINICAL MANIFESTATIONS

The symptoms of MM may be nonspecific and include fatigue, bone pain, easy bruisability and bleeding, recurrent infections, manifestations of anemia, hypercalcemia, lytic bone lesions, hyperviscosity, thrombocytopenia, and hypogammaglobulinemia (Fig. 98.2). Weakness, infection, bleeding, and weight loss are reported in as many as 82%, 13%, 13%, and 24% of patients, respectively.^{124, 125, 126, 127} Hypercalcemia is present in 18% to 30% of patients.^{124, 125, 126} One to two thirds of patients present with spontaneous bone pain.^{124, 125, 126} "Tumor fever" is present in less than 1% of presenting patients.

Anemia

The most common clinical feature of MM is anemia. A hemoglobin concentration of less than 120 g/L occurs in 40% to 73% of patients at presentation^{124, 125, 126} and contributes to the weakness and fatigue observed in as many as 82% of patients.^{124, 125, 126} The anemia is normochromic, normocytic in most patients, but macrocytosis may be observed as well. When there are high concentrations of serum immunoglobulin, rouleau formation may be observed (Fig. 98.3A). The combination of anemia and hyperproteinemia leads to a marked increase of the erythrocyte sedimentation rate in more than 90% of cases.¹²⁸

FIGURE 98.2. Signs and symptoms of 1,027 newly diagnosed myeloma patients seen at the Mayo Clinic from 1985 through 1998.

The anemia is related partially to direct infiltration and replacement of the bone marrow. Hemoglobin concentration is also correlated directly with the percentage of MM cells in S phase,¹²⁹ suggesting that the bone marrow cytokine milieu,

permissive for MM cell proliferation, is not conducive to efficient erythropoiesis. Cytokines, like tumor necrosis factor- α and IL-1, may inhibit erythropoiesis.¹³⁰ Fas ligand-mediated erythroid apoptosis is also increased in patients with MM.¹³¹ Finally, relative erythropoietin deficiency from MM-induced renal insufficiency also contributes to the observed anemia.

Monoclonal Proteins

The M protein (M component, myeloma protein, or M spike) is a hallmark of the disease; 97% of MM patients have either an intact immunoglobulin or a free light chain that can be detected by protein electrophoresis, immunoelectrophoresis, or immunofixation studies of the serum or urine (Fig. 98.3B,C).^{124, 126} Those cases without a detectable monoclonal protein have been referred to as nonsecretory MM, which had accounted for approximately 1% to 3% of MM cases. With the immunoglobulin free light chain assay, small free light chain monoclonal proteins heretofore not seen by aforementioned methods are seen in approximately two thirds of the cases that had been referred to as nonsecretory.¹⁹

Historically, monoclonal proteins have had a valuable role in the fields of immunology and molecular biology, for distinguishing MGUS from MM and for calculating MM tumor burden and kinetics.^{25, 132, 133} Practically, both serum and urine M protein concentrations are used to stage MM patients and to document their response to treatment.

In a series of 1,027 newly diagnosed cases of MM, the immunoglobulin type was IgG, IgA, IgD, and free light chain only (Bence Jones MM) in 52%, 20%, 2%, and 16% of cases, respectively.¹²⁶ Fewer than 1% of MM cases are IgM; most IgM monoclonal proteins are associated with diagnoses of MGUS, lymphoma, Waldenström macroglobulinemia, or primary systemic amyloidosis.¹³⁴ A total of 93% of patients have a monoclonal protein detected in their serum. About 90% of MM patients have reduction in at least one of their uninvolved immunoglobulins.¹³⁴ About 70% have a monoclonal protein—or fragment thereof—detected in the urine.

Histopathology

The bone marrow microenvironment is hospitable to malignant plasma cells that circulate through the blood. There is a complex interaction among the malignant clone, its surrounding stromal cells, and the remaining immune cells. The morphologic and immunologic phenotypes of MM cells can vary, and they often resemble normal plasma cells. Plasma cells are at least two to three times the size of peripheral lymphocytes and are round to oval, with one or more eccentrically placed nuclei (Fig. 98.3D). The nucleus, which contains either diffuse or clumped chromatin, is displaced from the center by an abundance of rough-surfaced endoplasmic reticulum, the site of specialized immunoglobulin synthesis. Intranuclear and cytoplasmic inclusions are not uncommon.¹³⁵ There is a perinuclear clear zone that is the site of the Golgi apparatus, the machinery used for immunoglobulin packaging and glycosylation for secretion. Derangements of immunoglobulin secretion are responsible for an assortment of cytologic aberrations, including flaming cells, Mott cells, Russell bodies, and Gaucher-like cells. Flaming cells are plasma cells that have intensely eosinophilic cytoplasm with a magenta or

P.2049

carmine coloring of their margins, which is due to plugging of peripheral secretory channels by precipitated immunoglobulin or immunoglobulin fragments. These cells are most commonly seen in IgA MM. Thesaurocytes are large flaming cells with a pyknotic nucleus that is pushed to the side. Mott cells (grape cells or morula forms) are plasma cells filled with dense spherical immunoglobulin inclusions; these inclusions are colorless, pink, or blue. Other inclusions are Russell bodies and their intranuclear counterparts (intranuclear dense bodies); these appear cherry red and can be as large as several microns in diameter. Gaucher-like cells are not uncommon in MM infiltrates; these cells are macrophages laden with sphingolipids released by the dying plasma cells.¹³⁶ None of these interesting inclusions is specific for malignancy nor do they have prognostic value.

FIGURE 98.3. Laboratory findings in patients with multiple myeloma. A: Rouleaux. B: Serum protein electrophoresis, illustrating a 3-g/dl monoclonal protein spike. C: Immunofixation electrophoresis, illustrating a monoclonal IgG lambda monoclonal protein. D: Bone marrow: myeloma cells on aspirate specimen.

In MM, there is often discordance between the nucleus and cytoplasm, the former appearing immature and the latter highly differentiated. About 20% of MM cases have plasmablastic morphology: a diffuse chromatin pattern, nucleus greater than 10 microns or nucleolus greater than 2 microns, relatively less abundant cytoplasm, and a concentrically placed nucleus with little or no hof.^{137, 138} Both diffuse and nodular infiltration patterns can be observed, although the former is more common. A minority of patients have plasma cells that have a lymphoplasmacytic appearance. MM cells are commonly present in cords around bone marrow microvessels. There is a high correlation between the extent of bone marrow angiogenesis, evaluated as microvessel area, and the proliferating fraction of marrow plasma cells in patients with MM.^{139, 140} Mild marrow fibrosis may be observed in as many as 27% of cases; extensive fibrosis is rare.^{141, 142} Less than 1% of cases have an extensive idiopathic granulomatous reaction.¹³⁵

The immunophenotype of MM cells is complex. In general, MM cells are CD45 negative and CD38 and CD138 positive.^{143, 144} However, there is increasing evidence that a subset of MM cells is CD45 positive,^{144, 145} with an increasing proportion of CD45 positive MM cells in less advanced disease.^{146, 147} CD19 and CD20 are earlier B-cell antigens that are variably expressed on MM cells; surface immunoglobulin is seen in up to one third of patients. CD56 is strongly positive in about 55% to 78% of MM cases.^{144, 148, 149} CD56-negative MM cells tend to be present in more aggressive disease, such as end-stage MM or plasma cell leukemia.^{149, 150} Other surface antigens such as CD10 (CALLA), CD28, CD117 (c-KIT), CD13, CD33,

and CD20 are present on a minority of patients' MM cells.^{143, 144, 145, 151, 152} Co-stimulatory molecules involved in the activation of B- and T-lymphocytes (CD28 and CD40) are seen in 40% and 70% of patients, respectively.^{153, 154}

No individual bone marrow finding, however, is pathognomonic for a malignant plasma cell process; the bone marrow diagnosis of MM relies on percentage of clonal bone marrow plasma cells, with 10% accepted as a cutoff. The clinical diagnosis, of course, is made from a synthesis of bone marrow findings and other clinical features.

Bone Disease

Approximately one third to two thirds of patients present with bone pain.^{124, 125, 126, 127} There is an uncoupling of the balance between osteoclastic and osteoblastic activity. Even before the development of bone lesions, enhanced osteoblastic recruitment with an increased generation of new osteoclasts is observed in early MM.¹⁵⁵ Regardless of the initiating signal, whether IL-1 β ,

P.2050

IL-6 and sIL-6R, tumor necrosis factor- α , MIP-1 α , receptor activator of NF-kappa β (RANK) ligand, or parathyroid hormone-related protein (PTHrP),¹⁵⁶ the eventual outcome is bone destruction.¹⁵⁷

MM bone disease is a major source of morbidity and may present as an area of persistent pain or as a vague migratory bone pain, often in the lower back and pelvis. The type, location, and duration of the pain have no characteristic features. At times, pain and tenderness may be sudden in onset, especially when associated with a pathologic fracture, and are most commonly precipitated by movement. Persistent localized pain also may be associated with a pathologic fracture.

A myelomatous lesion may extend through the cortex of a vertebral body and cause either nerve root or spinal cord compression in less than 2% of patients.¹²⁵ Alternatively, the MM can disturb the mechanical integrity of a vertebral body, resulting in compression fracture with retropulsion of either plasmacytoma or bony fragments into the spinal canal, again causing neurologic deficit. Approximately 75% of patients have punched-out lytic lesions, osteoporosis, or fractures on conventional radiography (Fig. 98.4A,B). The vertebrae, skull, ribs, sternum, proximal humeri, and femora are involved most frequently.^{124, 126, 127} A small subset of patients has de novo osteosclerotic lesions,¹⁵⁸ and in a few patients osteosclerosis is seen after therapy and may serve as a marker of healing.

Because myelomatous bone lesions are characteristically lytic, conventional radiography is superior to technetium-99m bone scanning.^{159, 160} About twice as many myelomatous bone lesions are detected by radiograph as by bone scan; an exception to this general finding is at the lumbar spine and the rib cage, where the two methods are equally reliable.¹⁶⁰ There have been reports supporting the use of technetium-99m sestamibi scans. These scans are almost as sensitive as plain radiographs for bone disease in untreated patients (i.e., patients with active disease).¹⁶¹ They may be able to distinguish active myelomatous bone lesions from inactive lesions¹⁶¹ and are quite sensitive for bone marrow involvement.^{162, 163, 164} There is a high concordance between scintigraphic findings and clinical status in patients undergoing chemotherapy or autologous stem cell transplantation (ASCT).^{165, 166} 18-Fluorodeoxyglucose positron emission tomography (FDG-PET) also shows promise in the staging of MM, with sensitivity and specificity rates of 84% to 92% and 83% to 100%, respectively¹⁶⁷ (Fig. 98.4D,E).

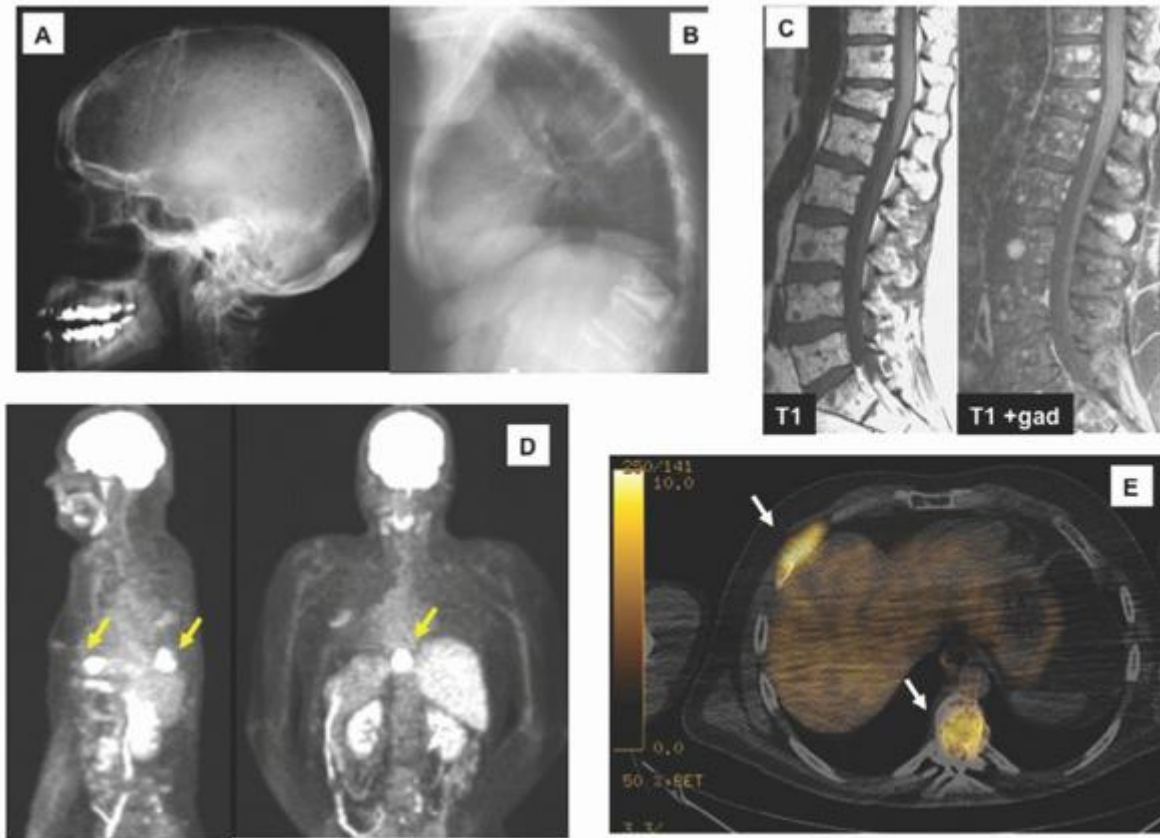

FIGURE 98.4. Myeloma bone disease. A: Plain radiograph of a skull with punched-out myeloma lesions. B: Plain radiograph of a compression fracture thoracic spine. C: Myelomatous marrow involvement of the lumbar spine by magnetic resonance imaging (MRI) with and without gadolinium. D: 18-Fluorodeoxyglucose positron emission tomography (FDG-PET), spine and rib involvement. E: Fusion image of CT/FDG-PET scan demonstrating lesion at rib and thoracic vertebra.

Computed tomography and magnetic resonance imaging (MRI) are more sensitive than conventional radiography (Fig. 98.4C). Both reveal specific lesions in 40% of stage I MM patients.¹⁶⁸ The presence of lacunae larger than 5 mm with trabecular disruption on computed tomography appears to be sensitive and specific for MM. This information may be useful in distinguishing between senile and myelomatous osteoporosis and compression fractures.¹⁶⁹ Among asymptomatic MM patients with normal radiographs, 50% have tumor-related abnormalities on MRI of the lower spine.¹⁷⁰ In patients with Durie-Salmon stage I MM, MRI can distinguish patients at higher and lower risks of progression.¹⁷¹ One third of patients with an apparently solitary plasmacytoma of bone have evidence of other plasma cell tumors on MRI.¹⁷²

MRI is superior to radiographs for the detection of lesions in the pelvis and the spine, but overall it is inferior to radiographs for detecting bone involvement in MM (79% versus 87%, respectively).¹⁷³ On MRI, vertebral fractures due to spinal infiltration or osteoporosis are seen in 48% of patients with symptomatic MM, and spinal canal narrowing with impingement occurs in 20%.¹⁷⁰ Nanni et al.¹⁷⁴ compared MRI to FDG-PET/CT in 28 newly diagnosed myeloma patients. In 25% of patients FDG-PET/CT

P.2051

detected more lytic bone lesions, all of which were out of the field of view of MRI, and in 25% of patients MRI detected an infiltrative pattern in the spine that was not discerned on FDG-PET/CT. In subsequent studies, whole body MRI has been reported to have a higher sensitivity and specificity than FDG-PET/CT¹⁷⁵ and than multidetector-row computed tomography.¹⁷⁶ A major limitation, however, to MRI and PET/CT is that there are no uniformly accepted standard acquisition or interpretation protocols, limiting their generalizability. Detection of marrow infiltration on MRI does not translate into a deficit of cortical bone integrity. Also, given the expense of MRI, it cannot be recommended for routine clinical use in all patients.

Hypercalcemia

Hypercalcemia occurs in 18% to 30% of patients. About 13% have concentrations greater than 11 mg/dl. Rates of hypercalcemia at presentation have been decreasing in the last few decades, perhaps because of the earlier diagnosis of patients.^{124, 125, 126, 127} Hypercalcemic patients may complain of fatigue, constipation, nausea, or confusion. Calcium can precipitate in the kidneys and aggravate renal insufficiency. Inorganic phosphate is rarely decreased, except in cases of acquired Fanconi syndrome.¹⁷⁷

Renal Insufficiency

Approximately 25% of MM patients have a serum creatinine value greater than 2 mg/dl at diagnosis. Another 25% have mildly elevated creatinine values.^{124, 125, 126, 127, 178, 179, 180, 181} Patients with Bence Jones or IgD MM have the highest rates of renal insufficiency.^{179, 181} Free light chain proteinuria is a risk factor for renal failure.¹⁸² Contributing factors to the renal insufficiency associated with MM kidneys include hypercalcemia, dehydration, hyperuricemia, and the use of nephrotoxic drugs.¹⁸³ If the renal insufficiency reverses with therapy, as it does in more than half of cases,^{183, 184} survival is fourfold to sevenfold higher than in those in whom it does not.^{178, 185} Factors predicting for renal function recovery include a serum creatinine less than 4 mg/dl, serum calcium value greater than 11.5 mg/dl, proteinuria less than 1 g/24 h, and adequate rehydration.¹⁷⁸

The pathologic lesion of MM kidney consists of monoclonal light chains in the tubules in the form of dense, often laminated, tubular casts. These casts contain albumin and Tamm-Horsfall protein. Light chains are normally filtered by the glomeruli and reabsorbed and catabolized in the nephron's proximal tubules. It is postulated that these systems become overwhelmed, and casts result. When other causes contributing to renal insufficiency are excluded, there is a good correlation between the extent of MM cast formation and the severity of renal insufficiency.^{186, 187} Tubular atrophy and degeneration correlate well with renal dysfunction.¹⁸⁸ The most common findings on autopsy include tubular atrophy and fibrosis (77%), tubular hyaline casts (62%), tubular epithelial giant cell reaction (48%), and nephrocalcinosis (42%). Evidence of acute and chronic pyelonephritis were observed in 20% and 23% of cases, respectively. Plasma cell infiltrates and amyloid may be observed in 10% and 5% of cases, respectively.¹²⁷ Rarely, MM may be associated with acquired Fanconi syndrome.^{177, 189}

An important feature of myeloma kidney is that it is primarily a tubular, rather than a glomerular, disease.¹⁸⁸ Glomerular function is preserved initially, and there is a predominance of immunoglobulin light chain protein in the urine instead of the nonspecific protein loss observed in glomerular disease. This feature helps predict the renal lesion: nonspecific protein loss (i.e., mostly albumin) is more compatible with primary systemic amyloidosis, light chain deposition disease of the kidney, or proteinuria unrelated to the PCD;¹⁸⁶ a free light chain predominance is consistent with myeloma kidney.

Infection

Patients with MM are at high risk for bacterial infections and for dying of overwhelming bacteremia. Overall, the incidence of infection is from 0.8 to 1.4 per patient-year.^{190, 191, 192} During the first 2 months after initiating chemotherapy the infection incidence is as high as 4.68 infections per patient-year¹⁹² but decreases to 0.44 to 0.49 per patient-year in those reaching a plateau phase.^{191, 192} Risk factors for infection are serum creatinine values greater than or equal to 2 mg/dl^{190, 192} and decreased levels of polyclonal serum immunoglobulins.^{191, 192} Since the 1960s, Gram-negative bacilli have become more common pathogens than *Streptococcus pneumoniae* in patients with MM.¹⁹³ At disease onset, infections with encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae* are most common.¹⁹³ After diagnosis, the proportion of infections due to Gram-negative bacilli and *Staphylococcus aureus* increases markedly, and are responsible for more than 90% of deaths from infection.¹⁹³

Hemostasis in Multiple Myeloma

MM can be associated with hemostatic abnormalities, more often bleeding than thrombosis. Bleeding as a complication of MM may be present in as many as one third of patients¹⁹⁴ and is related to thrombocytopenia, uremia, hyperviscosity, and interference with the function of coagulation factors. Rarely, MM proteins may also interact with coagulation proteins.^{192, 193}

The association with thrombosis is less clear because of co-existing factors such as old age and immobility that confound the interpretation of available data, however, the risk of thrombosis may be increased in MM patients.^{194, 195} Individual cases of aberrance have been reported. Monoclonal proteins have been shown to be responsible for lupus anticoagulants,^{196, 197} acquired protein S deficiency,^{198, 199} acquired activated protein C resistance,²⁰⁰ and inhibition of tissue plasminogen activator.²⁰¹

Fewer than 7% of MM patients have a viscosity greater than 4.^{124, 126} Symptoms of hyperviscosity include bleeding (particularly of the oronasal areas), purpura, decrease in visual acuity, retinopathy, neurologic symptoms, dyspnea,

expanded plasma volume, and congestive heart failure. Most patients become symptomatic when the serum viscosity is 6 or 7 centipoise (normal is less than or equal to 1.8 centipoise).

“Acute Terminal Phase of Plasma Cell Myeloma” and Cause of Death

Bergsagel and Pruzanski²⁰² described the “acute terminal phase” of patients with MM, which they observed in about one third of their preterminal patients. They defined the syndrome as rapidly progressive disease with an unexplained fever and pancytopenia and a hypercellular marrow. Extramedullary plasmacytomas are also not uncommon preterminally.²⁰³ As the disease progresses, and at autopsy, cutaneous, visceral, and even meningeal involvement is possible.²⁰³ Besides “progressive disease,” the most frequent causes of death are infection in 24% to 52% and renal failure in about 20%.^{127, 183, 202, 203} Acute leukemia, myelodysplastic syndromes, and hemorrhage are the causes of death in a minority of patients.^{127, 202, 203} In one autopsy series, 85% of patients had evidence of either bacterial or fungal infection, and myelomatous involvement was found in the spleen, liver, lymph nodes, and kidneys in 45%, 28%, 27%, and 10% of patients, respectively. Other less frequent areas of myelomatous involvement were the lung, pleura, adrenal glands, pancreas, and testis.¹²⁷

DIAGNOSIS

The diagnosis of MM has not been subject to static norms. In 1973, the Chronic Leukemia-Myeloma Task Force²⁰⁴ set forth guidelines for the diagnosis of MM (Table 98.1). These criteria,

P.2052

which by today's standards are not stringent enough, have been replaced by a more modern definition.²⁰⁵ In the last 3 decades, the terms and definitions of MGUS, smoldering MM, indolent MM, and symptomatic MM^{124, 206, 207, 208} have evolved and are now to be replaced by the following designations: MGUS, inactive (smoldering) MM, and active (or symptomatic) MM.²⁰⁵

TABLE 98.1 CRITERIA FOR DIAGNOSIS OF MGUS, SMM, AND MM

	Chronic Leukemia-Myeloma Task Force Definition of Multiple Myeloma (1973)^a	Criteria for Diagnosis of MGUS, SMM, and MM, International Working Group (2003)^b
Monoclonal Gammopathy of Undetermined Significance	Not described	- Serum monoclonal protein (<30 g/L) - Bone marrow <10% plasma cells - No evidence of other B-cell proliferative disorders - No related organ or tissue impairment ^{c, d}
Smoldering Myeloma (asymptomatic)	Not described	- No related organ or tissue impairment ^c - Serum monoclonal protein (≥30 g/L) <i>and/or</i> - Bone marrow clonal plasma cells ≥10%
Multiple Myeloma	If M protein present in serum or urine, one or more of the following must be present: MM - Marrow plasmacytosis >5% in absence of underlying reactive process - Tissue biopsy demonstrating replacement and distortion of normal	ACTIVE OR SYMPTOMATIC MM - Monoclonal protein present in serum and/or urine - Clonal bone marrow plasma cells

- | | |
|---|---|
| tissue by plasma cells | or plasmacytoma |
| - >500 plasma cells/mm ³ in peripheral blood | - Related organ or tissue impairment ^a |
| - Osteolytic lesion unexplained by other causes | |
| If no M protein in serum and urine, radiologic evidence of osteolytic lesions or palpable tumors and one or more of the following required: | |
| - Marrow plasmacytosis of >20% from two sites in absence of reactive process | |
| - Tissue biopsy demonstrating replacement and distortion of normal tissue by plasma cells | |

MM, multiple myeloma; MGUS, monoclonal gammopathy of undetermined significance; SMM, smoldering MM.

^a From Chronic Leukemia-Myeloma Task Force, National Cancer Institute, 204 shown for historical purposes.

^b From Chronic Leukemia-Myeloma Task Force, current definitions. 205

^c The absence of CRAB (calcium elevation [> 1 mg/dl above upper limit of normal], renal dysfunction [creatinine >2 g/dl], anemia [hemoglobin 2 g/dl below lower limit of normal], bone lesions [lytic lesions or osteoporosis with compression fracture] attributable to the plasma cell disorder).

^d The existence of immunoglobulin light chain amyloidosis or another paraneoplastic disorder attributable to the monoclonal gammopathy, like a peripheral neuropathy would be termed “monoclonal gammopathy associated with...”

Because MM includes a spectrum of biologic features, physicians should not feel compelled to start treatment as a result of a single threshold value. The diagnosis of active MM is not a straightforward pathologic one; rather, it is a clinical diagnosis that requires thoughtful synthesis of multiple variables. Patients with Durie-Salmon stage I disease, who also meet the criteria for smoldering or asymptomatic MM, should be managed expectantly. Median progression-free survival in asymptomatic stage I patients, observed without any therapy, is 12 to more than 48 months;^{209, 210, 211, 212} for similar stage II patients, progression-free survival is 12 months.²⁰⁹ Until recently,²¹³ no survival advantage had been demonstrated by treating asymptomatic MM patients.^{208, 210, 211, 214}

SYSTEMIC THERAPY FOR MULTIPLE MYELOMA

Before starting therapy for MM, a distinction must be made between smoldering (asymptomatic) MM and active MM (Table 98.1). Approximately 20% of patients with MM are recognized by chance without significant symptoms; such patients can be carefully monitored without instituting therapy (see Chapter 97). Once the decision has been made to treat for symptomatic disease, a long-term plan for managing the disease should be formulated before instituting therapy. Because high-dose therapy with autologous hematopoietic stem cell transplantation (ASCT) has been accepted as an important treatment modality for patients younger than age 70, only a limited amount of alkylator-based therapy should be used prior to the collection of hematopoietic stem cells in patients considered candidates for high-dose therapy.

Historically, the bifunctional alkylating agents, including melphalan and cyclophosphamide, had been the foundation of therapy for MM. MM cells tend to proliferate slowly, and alkylators, whose effectiveness does not rely heavily on cell division and DNA replication, are useful therapeutic agents. Prior to 1999, the bifunctional alkylators, nitrosoureas, doxorubicin, and glucocorticoids were the primary agents shown to have single-agent activity against MM *in vivo*.²¹⁵ These

drugs along with vincristine, either singly or in combination, had been the mainstay of chemotherapy for MM from the early 1960s to the present (Fig. 98.1). Until recently, the higher response rates seen with regimens that combine multiple active agents as part of initial therapy, had not resulted in improved OS rates.²¹⁶ IFN- α had been incorporated into induction and maintenance protocols with minimal benefit.^{34, 217, 218, 219} Both autologous and allogeneic stem cell transplantation (AlloSCT) have become important therapeutic options since McElwain and Powles' description in 1983²²⁰ of the benefit of dose intensification of melphalan in patients with MM. With the recognition of thalidomide's activity against MM in 1999³⁷ and the subsequent development of bortezomib,³⁸ lenalidomide,³⁹ and carfilzomib²²¹ there is hope that the next 4 decades of MM treatment will be even more promising than the last.

Before discussing induction, transplantation, maintenance, and salvage therapies, two general concepts are reviewed: interpretation of study response data and the efficacy of single

P.2053

chemotherapeutic agents commonly used to treat MM. Figure 98.5 is one potential algorithm for treating patients with newly diagnosed MM.

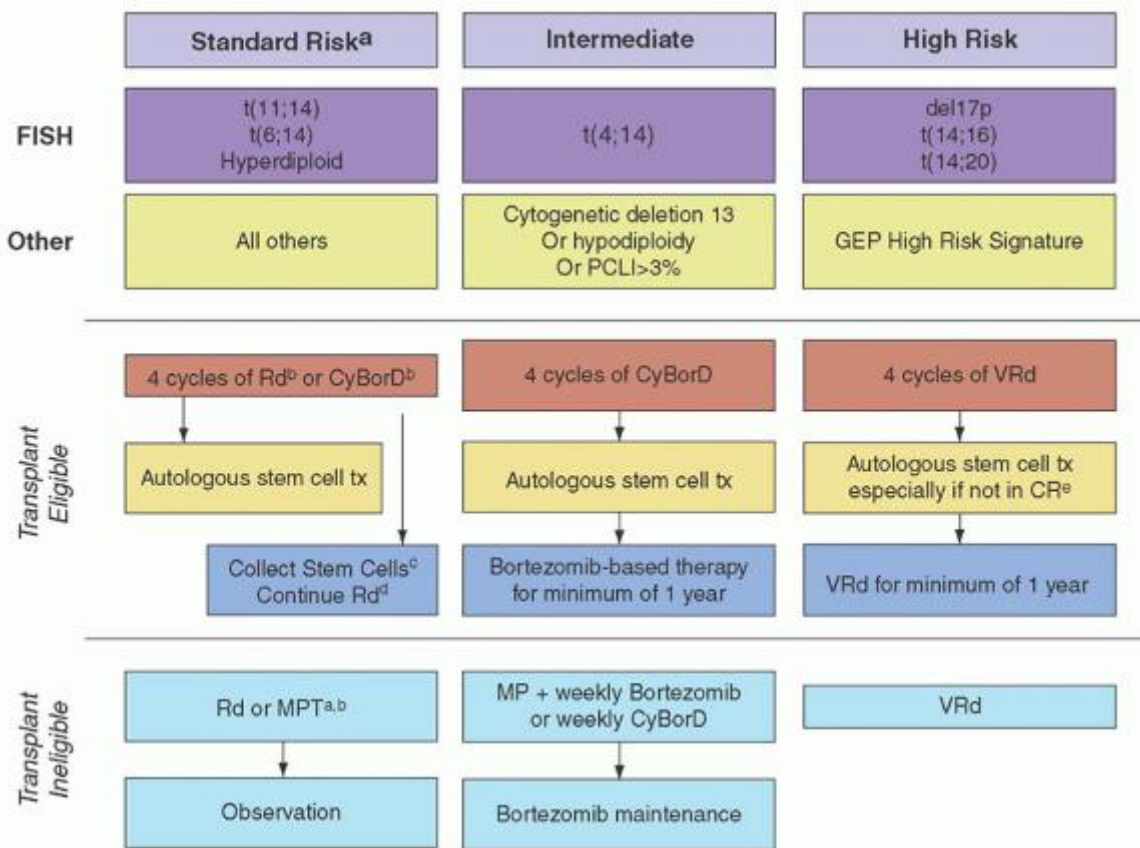

FIGURE 98.5. Mayo stratification for myeloma and risk-adapted therapy (mSMART).^{357, 358} Possible treatment algorithm for patients with newly diagnosed myeloma for patients not being treated on a clinical trial. CR, complete response; CyBorD, cyclophosphamide, bortezomib, and dexamethasone; MPT, melphalan, prednisone, and thalidomide; Tx, transplantation; VRd, bortezomib, lenalidomide, and dexamethasone, VGPR, very good partial response. ^aNote that a subset of patients with these factors will be classified as high-risk by GEP. ^bBortezomib containing regimens preferred in renal failure or if rapid response needed. ^cIf age >65 or > 4 cycles of Rd Consider G-CSF plus cytoxin or plerixafor. ^dContinuing Rd is option for patients responding to Rd and with low toxicities; Dex is usually discontinued after first year. ^eConsider allogeneic stem cell transplantation in suitable patients.

Interpreting Study Response and Survival Data

Four points are emphasized regarding the interpretation and comparisons of the MM treatment literature. First, historically definitions of response have varied (Table 98.2). Second, definitions of evaluable patients may be different. Third, concurrent corticosteroid therapy, either as part of the regimen or for other indications, may confound

interpretation of efficacy. Finally, patient population risk and prognosis may differ substantially. Lead-time bias and treatment of MGUS or smoldering MM can significantly distort survival figures, as can effective salvage regimens.

The measurement of MM disease burden is complex, and investigators have used different methods to define response (Table 98.2). The four most common response criteria that had been used until acceptance of the Uniform Response Criteria (URC) in 2006²²² were the Chronic Leukemia-Myeloma Task Force (CLMTF),²⁰⁴ Southwest Oncology Group (SWOG),^{223, 224} Eastern Cooperative Oncology Group (ECOG),²²⁵ and Autologous Blood and Marrow Transplant Registry and the International Bone Marrow Transplant Registry (IBMTR/ABMTR).²²⁶ Although all address calcium, bone changes, and bone marrow plasmacytosis, the main distinction among them is their consideration of the serum and urine M components. With the exception of the old SWOG criteria,^{223, 224} a partial response (PR) has been considered to be a 50% reduction in serum M component and a greater than 50% to 90% reduction in urine M component. Until about 1990, a SWOG objective response was defined as a 75% reduction in the tumor mass index (NOT serum M protein) and improvement was defined as a 50% to 74% reduction in the tumor mass index.²²⁴ A subsequent iteration of the SWOG response criteria used the M component (rather than the tumor mass index) as the primary measurement of the plasma cell burden.

In the earliest literature, response included such factors as increasing hemoglobin concentration or performance status, or decreasing blood urea nitrogen levels. Neither the CLMTF or SWOG originally had a complete response (CR) category, because it was unusual for the M protein to disappear completely. It was not until the advent of high-dose melphalan that investigators^{227, 228} began to define a complete remission category. Earliest definitions of CR only included disappearance of M protein as determined by electrophoresis, which is less sensitive than immunoelectrophoresis or immunofixation. Subsequent definitions have required immunofixation negativity to qualify as complete remission.²²⁶ The first iteration of an international consensus definition of MM response was the IBMTR/ABMTR response criteria.²²⁶ After nearly 8 years of use, several deficiencies were noted, and the International Myeloma Working Group issued a new consensus definition called the International Uniform Response Criteria (URC) which includes the Intergroupe Français du Myélome (IFM) very good partial response category,²²⁹ the ability to measure response using the serum immunoglobulin free light chain, and a new category of "stringent complete response," which requires documentation of the absence of clonality in the bone marrow and by including a normal serum immunoglobulin free light chain ratio in the definition.²²²

P.2054

TABLE 98.2 RESPONSE CRITERIA

Response	Study	% BMPC	M protein		Duration, wk
			Serum	Urine	
Stringent CR (sCR)	IRC ²²²	<5 ^a	IF — ^b	IF —	0
Complete response	IRC ^c	≤5	IF —	IF —	6
	IBMTR ^{c, 226}	<5	IF —	IF —	6
	SWOG ²²⁴	<1 ^a	IF —	IF —	8
	ECOG ²²⁵	≤3	IF —	IF —	6
	CLMTF ²⁰⁴	Not defined			—
Very good partial response	IRC		≥90% reduction	< 100 mg/24 hr	
Objective response	SWOG	—	↓ ≥ 75% ^c	↓ ≥ 90%	8
Partial Response	IRC ^d	—	↓ ≥ 50%	↓ ≥ 90%	6
	ECOG/IBMTR	—	↓ ≥ 50%	↓ ≥ 90% ^e	6
	SWOG ("Improvement")	—	↓ ≥ 50% ^c	↓ ≥ 75%	8

	CLMTF ^f	—	↓ ≥ 50%	↓ ≥ 50%	—
Minimal response	IBMTR	—	↓ ≥ 25%	↓ ≥ 50%	
Progression	IRC/IBMTR/SWOG	—	> 25% ^g	> 25% ^h	—
	ECOG	—	≥ 50% ⁱ	≥ 50% ^h	—

BMPC, bone marrow plasma cells; CLMTF, Chronic Leukemia-Myeloma Task Force; CR, complete response; ECOG, Eastern Cooperative Oncology Group; IBMTR, International Blood and Bone Marrow Transplant Registry; IF, immunofixation; IRC, International Response Consensus; IF, immunofixation; MR, minimum response; PR, partial response; SWOG, Southwest Oncology Group.

^a Clonal plasma cells as measured by flow cytometry, immunohistochemistry, or immunofluorescence.

^b Also requires normalization of serum immunoglobulin free light chain ratio.

^c Change in synthetic index and not monoclonal protein concentration.

^d Allows for immunoglobulin free light chain responses in patients whose serum and urine are not measurable.

^e Or <200 mg/24 hours.

^f Response also takes into account reduction in size of plasmacytomas, >2 g/dl Hb rise, weight gain, correction of calcium, renal function, albumin.

^g Absolute increase must be at least 5 g/L.

^h Absolute increase must be greater than 200 mg/24 hours.

ⁱ For ECOG, Absolute increase must be at least 20 g/L.

Efficacy of Single Chemotherapeutic Agents

Single agents are not commonly used as upfront therapy, but they are used in the relapsed setting, and understanding each drug's activity provides insight into how much they may be contributing to combination therapy.

Melphalan

Bergsagel et al.³¹ demonstrated the benefit of melphalan in 14 of 24 patients with MM. Others (Table 98.3) have substantiated that melphalan as a single agent results in response rates of 20% to 34% and median OS duration of 15 to 27 months.^{32, 230, 231, 232, 233} Since early reports by Blokhin et al.³⁰ and Bergsagel et al.,³¹ various schedules of melphalan have been tried, including continuous daily dose, 6 to 10 mg/day for 2 to 3 weeks, followed by maintenance therapy of 0.01 to 0.03 mg/kg per day; intermittent total doses of 0.25 mg/day given for 4 days every 4 to 8 weeks; or 0.15 mg/kg per day for 7 days every 6 weeks.^{232, 234} Several studies suggest that the intermittent schedule is superior to continuous daily dosing.^{232, 234}

Cyclophosphamide

Korst et al. were the first to report on the activity of oral cyclophosphamide.³³ A partial response (50% M-protein reduction) was achieved by 24% of MM patients, and 48% had objective improvement. Median survival was 24.5 months in all 207 patients and 32 months in the group that received at least 2 months of cyclophosphamide therapy. The single-agent activity of cyclophosphamide (Table 98.3) has been demonstrated in a placebo-controlled trial,²³¹ in multiple studies of previously untreated patients,^{235, 236} and in those who relapsed or had refractory disease.²³⁷

Despite documented equivalency for low-dose oral regimens of cyclophosphamide and melphalan,²³⁵ induction therapies of MP have historically been preferred over those of cyclophosphamide and prednisone. Cyclophosphamide has most commonly been used in multidrug combinations for induction, for therapy in relapse, and for stem cell mobilization rather

than as a single agent for induction, as has melphalan. In newly diagnosed MM, oral daily dosing of cyclophosphamide (150 mg/d)^{235, 238, 239} or intravenous doses of 600 mg/m² every 3 weeks²³⁶ with or without prednisone resulted in a response rate of approximately 25% and median survival of 24 months.

Glucocorticoids

In 1950, Thorn et al.²⁷ reported the first observations on the beneficial effects of adrenocorticotrophic hormone in MM. Adams and Skoog²⁸ observed a marked decrease in the MM serum protein in 18 of 26 patients treated with corticosteroids. Surprisingly, Mass²⁴⁰ failed to show a difference between the survival of 55 patients randomly assigned to prednisone therapy or placebo despite clinical improvement in the former group. Subsequently, high-dose corticosteroids have been shown to produce response rates of 40% to 50% in previously untreated patients, and 25%

P.2055

in refractory or relapsed patients;^{29, 241, 242, 243, 244, 245, 246, 247} median survival of responding patients is 16 to 22 months.^{243, 244, 245} In reviewing their experience with single-agent dexamethasone and VAD, Alexanian et al.²⁴⁴ noted that in patients with refractory disease, response rates with single-agent dexamethasone were comparable to those with VAD (27% vs. 32%). In contrast, in relapsed disease, response rates achieved with single-agent dexamethasone were inferior to those with VAD. These data were not randomized but rather serial observations. On occasion, patients who do not respond to high-dose dexamethasone can be salvaged with intermittent high-dose methylprednisolone.²⁴⁵

TABLE 98.3 EARLY (1969 TO 1982), ALKYLATOR-BASED RANDOMIZED TRIALS FOR NEWLY DIAGNOSED MYELOMA

Study Year	Agent	Schedule	N	RR (%)	OS, mo

^a Difference is significant.

^b Survival estimated from survival curves.

^c Patients stratified for good and poor risk; median survival given as all patients (good risk, poor risk). Authors note that much quicker response observed with prednisone but worse survival with prednisone in poor-risk patients.

Despite their contribution to quicker and more abundant responses, there are conflicting data as to whether corticosteroids prolong survival.^{230, 232, 248} As initial therapy for elderly patients, single-agent dexamethasone is responsible for both higher treatment-related morbidity and mortality as compared to melphalan-containing regimens.²⁴⁹ The mechanism of action of this drug class is complex. Corticosteroids suppress the production of cytokines important in MM growth, such as IL-6 and IL-1 β , and reduce nuclear factor κ B activity, resulting in enhanced apoptosis.^{250, 251, 252, 253}

Vincristine

Although never evaluated as a single agent in newly diagnosed MM, vincristine has little activity as a single agent in refractory disease. There were 21 patients treated with a 0.5 mg bolus of vincristine followed by 0.25 to 0.5 mg/m² per day as a continuous infusion over 5 days on a 3-week schedule. Two patients had transient responses (1.2 and 2.2 months).²⁵⁴ Finally, the activity credited to vincristine as a maintenance therapy is also ambiguous. Although a superior survival (35 vs. 27 months, P = 0.003) was reported in patients treated with single-agent melphalan and maintained on bimonthly vincristine (1 mg/m²) and prednisone (0.6 mg/kg for 7 days), the benefit could easily be attributed to prednisone alone.²⁵⁵

Alexanian et al.^{256, 257} suggested that regimens which included vincristine resulted in better patient outcome than protocols not including this agent. The theory behind its posited utility was that after an initial kill of MM cells by alkylating agents, the subsequent increase in the mitotic index made MM cells more sensitive to vincristine.²⁵⁸ Reports by Lee, Salmon, and Case have been cited as confirmatory evidence for activity of vincristine in MM.^{259, 260, 261} However, several randomized controlled trials do not support this premise.^{262, 263, 264, 265} The most compelling of these is the MRC IV Trial in Myelomatosis, which randomized 530 newly diagnosed MM patients to monthly MP, with or without monthly vincristine. Median survival in both arms was 26 months.²⁶⁴ Even though vincristine has not been shown to have significant single-agent *in vivo* activity or to improve OS,^{254, 264, 265, 266} it has been included in multiple therapeutic regimens.

P.2056

Anthracyclines

Doxorubicin is the most commonly used anthracycline in the treatment of MM, but it has not been studied as a single agent in newly diagnosed MM patients. Its activity as a single agent in relapsed or refractory disease is modest, with response rates of about 10%.^{35, 267} The pegylated form has been used in a number of MM regimens since the 1990s.^{268, 269} A phase II trial of mitoxantrone as a single agent (12 mg/m² every 3 weeks) yielded a partial response rate of 3% (1 of 35). An additional 4 patients showed clinical improvement lasting 4 to 7 months.²⁷⁰ Idarubicin is another anthracycline that has been studied in MM. Response rates of 0% to 27% have been observed in relapsed and refractory patients with single-agent oral regimens (30 mg/week in three divided doses given 3 of 5 weeks or 40 mg/m² every 3 weeks).^{271, 272}

Etoposide

In relapsed and refractory disease, single-agent etoposide (200 to 250 mg/m² over 5 days) has minimal activity; in 85 patients the response rate was < 5%.²⁷³ Barlogie et al.²⁷⁴ treated 14 patients with 200 mg/m² by continuous infusion, and 2 responded. In addition, there are two anecdotal reports of activity of low-dose (25 to 50 mg/day) oral etoposide.^{275, 276}

Nitrosoureas

The nitrosoureas have single-agent activity in MM. In a randomized trial of 361 previously untreated patients, objective response frequency with carmustine (BCNU; 40%) and lomustine (CCNU; 42%) was lower than that of melphalan (59%), although the survivals for all groups were not significantly different.²⁶²

Interferon

Despite the encouraging reports that daily human leukocyte IFN (3 to 9 MU/day) could induce responses in as many as 60% of MM patients^{34, 217} subsequent studies with recombinant IFN yielded rates of 10% to 20%.^{219, 277, 278, 279, 280} Toxicity was not inconsequential.²⁸⁰ In vitro activity had good predictive value for in vivo clinical response in 26 patients studied.²⁷⁸ However, IFN has a stimulatory effect in about one third of MM samples tested in vitro.²⁷⁸ This drug has been used most commonly in the maintenance setting as discussed below.

Bendamustine

Bendamustine is a multifunctional alkylating agent with a purinelike ring system and a novel mechanism of action. Bendamustine appears to be more efficient in inducing DNA double-strand breaks compared with other more commonly used alkylating agents such as cyclophosphamide or phenylalanine mustard.

In a phase I study of bendamustine, Knoop et al. enrolled 31 patients with MM that had progressed after high-dose chemotherapy. Bendamustine 100 mg/m² on days 1 and 2 per cycle was found to be the maximal tolerated dose. The overall response rate was 55% with a median progression-free survival of 26 (0 to 61) weeks. Toxicity was mild and mainly hematologic.^{281, 282} In this retrospective analysis of a single institution experience, 39 patients with relapsed or refractory MM received bendamustine as salvage therapy.²⁸³ Bendamustine used at 80 to 150 mg on day 1 + 2 of a monthly cycle with or without steroids resulted in 3% VGPR, 33% PR, 18% MR, 26% SD, and 20% PD. The median EFS and OS were 7 and 17 months, respectively.

Thalidomide

Thalidomide is the first in the class of drugs called immune modulatory drugs (IMiDs). Recognition of the role of increased angiogenesis in the pathogenesis and progression of MM,¹³⁹ and evidence of thalidomide's antiangiogenic properties,^{284, 285} led to clinical trials in MM.^{37, 286} The observed responses in patients without high-grade angiogenesis suggest that thalidomide may act via other mechanisms as well.²⁸⁷ In vitro data suggest that the drug and its metabolites may inhibit angiogenesis, but in addition may modulate adhesion molecules of MM cells and their surrounding stroma, modulate cytokines, and affect natural killer cells. There is evidence that thalidomide and its analogues induce apoptosis and G1 growth arrest in MM cells.²⁸⁷

The first report of the utility of thalidomide in patients with relapsed MM³⁷ who were treated with escalating doses of thalidomide was published in 1999. Patients were started on 200 mg each evening; the dose was escalated every 2 weeks, if tolerated, to a final maximal dose of 800 mg daily. A total of 25% of patients had at least a 50% reduction in their serum paraprotein. Preliminary evidence of response was apparent within 2 months in more than three quarters of the patients who did respond. Other investigators have confirmed a partial response rate of 25% to 58%, with an additional 6% to 26% achieving a minimal response, median response duration of 9 to 12 months, 2-year progression-free survival of 10% to 20%, and 2-year OS of 48%.^{286, 288, 289, 290, 291, 292, 293, 294, 295, 296} As a single agent in previously untreated patients, response rates of 25% may be achieved.^{297, 298, 299} The role of dose intensity in thalidomide effectiveness is unclear.^{293, 300} In the original reports, the highest dose tolerated was administered.³⁷ In high-risk patients there was a suggestion that response rates were higher and survival longer in patients receiving high doses of thalidomide (greater than or equal to 600 mg/day).³⁰¹ However, in some patients, responses may be seen with doses as low as 50 to 100 mg/day.³⁰⁰

Toxicities associated with thalidomide include fetal malformations, constipation, weakness or fatigue, somnolence, skin problems, and sensory neuropathy in more than one third of patients. There is also an increased risk of thrombosis in patients treated with thalidomide, which appears to be exacerbated by the use of concurrent combination chemotherapy, with rates as high as 28%.^{302, 303, 304} Other life-threatening complications have included Stevens-Johnson syndrome and hepatitis.^{305, 306}

Thalidomide received US Food and Drug Administration approval for use in conjunction with dexamethasone for newly diagnosed MM in 2006.

Lenalidomide (CC-5013; Revlimid™)

This drug is a small molecule derivative of thalidomide and a member of the immunomodulatory (IMiD) class. Lenalidomide is more potent than thalidomide in mediating direct cytokine-related and immunomodulatory effects against human MM cell lines and patient-derived cells in vitro. It induces apoptosis of MM cells; overcomes cytokine and bone marrow stromal cell-mediated drug resistance; has antiangiogenic effects; and stimulates host anti-MM T and natural killer cell immunity.^{39, 307} In the original phase I study, 30% of patients responded to the single-agent drug, with a median duration of response of 6 months.³⁹ At 50 mg per day the dose limiting toxicity was myelosuppression. In the randomized phase II trial, two schedules were evaluated: 25 mg daily and 15 mg twice daily. In both arms, drug was given only 21 out of 28 days. Overall approximately 17% of relapsed or refractory patients achieved a partial response, including a 4% complete response rate, with a median progression-free survival (PFS) of 4.6 months for the patients receiving once-daily dosing.^{39, 307} Aside from myelosuppression, other grade 3 to 4 toxicities included neuropathy and fatigue in 3% and 7% of patients. In the open label phase II trial, including 222 patients, there was 25% partial response rate, with a time to progression of 5.1 months.³⁰⁸ newly diagnosed MM, single agent lenalidomide induces responses in fewer than one-third of patients.³⁰⁹ The FDA approved the drug in combination with dexamethasone as second line therapy for patients with MM in 2006.

P.2057

Pomalidomide (CC-4047; Actimid™)

Pomalidomide is another IMiD with activity³¹⁰ that is currently undergoing clinical trials in relapsed MM.^{311, 312} Preclinical studies have shown changes that suggest a significant immunomodulatory effect of the drug, with decrease in CD8+/CD45RA+ cells and CD4+/CD45RA+ initially following therapy, which was also accompanied by a corresponding increase in CD8+/CD45RO+ cells and CD4+/CD45RO+, suggesting a switch from naïve cells to activated effector T-cells.³¹⁰ It also has an effect on the inflammatory pathways via transcriptional inhibition of cyclooxygenase-2 (COX-2) production, which is associated with increased prostaglandins in human lipopolysaccharide (LPS)-stimulated monocytes.³¹³ In addition to the direct anti-MM activity and the immunomodulatory functions, pomalidomide also alters the tumor microenvironment. In vitro studies also have shown potent inhibitory effect on osteoclast differentiation as well as bone marrow angiogenesis.^{314, 315} A total of 54% of previously treated patients respond to the single-agent drug. Median PFS was 9 months. Additional studies have been done as are described in the section of relapsed/refractory disease. As of this writing, the drug is not available except in clinical trials.

Bortezomib (Velcade™, PS-341)

Bortezomib is the first drug in its class of proteasome inhibitors. It is a boronic acid dipeptide that reversibly and selectively inhibits the proteasome, an intracellular complex that degrades primarily ubiquitinated proteins. The proteasome has a key role in protein degradation, cell-cycle regulation, and gene expression. Tumor cells, including MM, are heavily dependent on proteasomeregulated proteins for their growth and interaction with stromal cells. Inhibition of the proteasome has emerged as an important antitumor target, and bortezomib has been shown in vitro and in vivo to cause growth arrest, to induce apoptosis, and to inhibit angiogenesis.

Of newly diagnosed MM patients, 38% to 48% will respond to single-agent bortezomib.^{316, 317, 318} The addition of dexamethasone results in an overall response rate of 67% to 88%.^{317, 319} Single-agent response rates in relapsed/refractory MM range from 28% to 38% with a median duration of response of 8 months.^{308, 320, 321, 322} The most common adverse events associated with bortezomib are: gastrointestinal disturbances, fatigue, peripheral neuropathy, and myelosuppression. There were 75% of patients who had serious (grade 3 to 4) adverse events, the most common of which were thrombocytopenia, neutropenia, anemia, gastrointestinal disturbances, fatigue, and peripheral neuropathy (sensory, motor, and pain).^{321, 323} In a review of 256 patients treated on two phase II studies, over 80% of patients had baseline peripheral neuropathy. Treatment-emergent neuropathy was reported in 35% of patients. Grade 1-2, 3, and 4 neuropathy occurred in 22%, 13%, and 0.4% of patients, respectively. Grade 3 neuropathy was more likely to occur in patients with a baseline neuropathy. A total of 71% of patients with neuropathy greater than or equal to grade 3 and/or requiring discontinuation who had resolution to baseline or improvement. Subcutaneous administration and/or weekly administration of bortezomib reduces the incidence of severe peripheral neuropathy by nearly 40%.³²⁴

The FDA approved bortezomib for patients with refractory MM in 2003, patients who failed one prior regimen in 2005, and as initial therapy in 2008. Because of toxicity, two important modifications to bortezomib administration have been made over the past decade. The first was introduction of weekly bortezomib rather than twice weekly followed by a 10-

day rest; the second was the subcutaneous administration rather than the intravenous route of administration. This latter change was approved by the FDA in 2012 based on a randomized control trial that demonstrated comparable efficacy but significantly lower toxicity.³²⁴ Overall response rate for both arms was 42% to 43%, but grade 3 or higher peripheral neuropathy was 6% versus 16% and any neuropathy was 38% versus 53%, favoring the subcutaneous administration.

Carfilzomib (PX-171, Kyprolis™)

Carfilzomib is a selective proteasome inhibitor that binds irreversibly to its target. It differs from bortezomib in that it does not contain a boronic acid residue, and irreversibly binds to the proteasome subunit. It was FDA approved for the indication of relapsed or refractory MM among patients who have had prior exposure to an IMiD and bortezomib. Two schedules had been tested in hematologic malignancies,^{325, 326} and best tolerance was seen with an IV infusion on days 1, 2, 8, 9, 15, and 16 every 28 days. In bortezomib-naïve patients,²²¹ response rates were seen in 25% of patients treated at the 20 mg/m² level and in 52% of patients treated with first cycle 20 mg/m², but subsequent cycles at 27 mg/m². An additional 17% and 12% of patients had a minimal response (i.e., a 25% reduction in their serum M-protein) in the 20 mg/m² cohort and the 20/27 mg/m² cohorts, respectively. Median duration of response is 13 months among patients achieving a PR or better. The most common side effects of drug are fatigue, nausea, anemia, dyspnea, cough, and pyrexia occurring in 34% to 62% of patients. The most common grade 3 or higher AEs were hematologic (13% to 16%) and pneumonia (12%). Treatment-emergent peripheral neuropathy was rare with only 1 patient in 129 developing a grade 3 PN. Because fever, chills, shortness of breath, and/or rigors may occur during cycle 1 and sometimes cycle 2, dexamethasone 4 mg daily can be given before each dose in cycle 1 and before the first dose of the cycle 2 if dose escalation is planned.

Other Agents

Barlogie et al.²⁷⁴ explored the utility of cisplatin therapy for patients with MM. A total of 14 patients were treated with 10 mg/m² for 7 days by continuous infusion, and 2 responded. The drug has been incorporated into other regimens for relapsed disease^{274, 327, 328} and induction therapy.³²⁹

Cytosine arabinoside,³³⁰ tenoposide,³³¹ topotecan,³³² deoxycoformycin,^{333, 334} arsenic trioxide,^{335, 336} and paclitaxel^{337, 338} have been reported to produce response rates of 7%, 28%, 16%, 0% to 15%, 7.1%, and 15% to 29%, respectively. Topotecan induces significant toxicity including greater than or equal to grade 3 granulocytopenia and thrombocytopenia in 93% and 53% of patients, respectively.³³² Patients treated with paclitaxel were premedicated with 40 mg of dexamethasone every 21 days,^{337, 338} bringing into question whether the observed responses were attributable to dexamethasone or paclitaxel.

Agents that do not appear to have any activity in MM include drugs that are interesting from an historical perspective and drugs that have known activity in other diseases. Agents in the former category include diamidines, such as stilbamidine; 1-aminocyclopentanecarboxylic acid; amsacrine,^{339, 340} aclarubin,³⁴¹ chlorozotocin,³⁴² hexamethylmelamine³⁴³ and azaserine.³² Other agents without activity against MM include: methotrexate, 6-mercaptopurine, 6-thioguanine, 5-fluorouracil, fluorodeoxyuridine, hydroxyurea, mitomycin C,³² vinblastine, vindesine,²⁴³ carboplatin,³⁴⁴ bleomycin,²⁶⁷ ATRA (all trans-retinoic acid), fludarabine,³⁴⁵ 2-chlorodeoxyadenosine,³⁴⁶ flavopiridol,³⁴⁷ and imatinib.³⁴⁸ Although Durie et al.³⁴⁹ reported a 57% response rate with clarithromycin, subsequent reports did not corroborate this response rate, and the activity observed in the original report was attributed to concurrent corticosteroid therapy.^{350, 351, 352}

Combination Chemotherapy for Induction

Combining multiple active agents in an effort to achieve synergy is a logical corollary. The last 3 decades of the 20th century were spent combining alkylators, anthracyclines, corticosteroids, and IFN. Thirty years of study indicate that the higher response rates

P.2058

afforded by these combinations as initial therapy did not translate into longer OS rates than standard MP therapy²¹⁶ (Fig. 98.6), and the data are conflicting as to whether patients with more advanced disease benefited from combination alkylator chemotherapy.^{210, 216, 233, 258, 353, 354, 355} Once IMiDs and proteasome inhibitors were shown to have activity, clinical investigators began using these drugs in combination. Table 98.4 serves as a reference for commonly cited regimens. For expediency, the section on induction regimens is separated into three larger categories: those commonly used in all types of MM patients, those specifically for transplant-ineligible patients, and those for transplant-eligible patients.

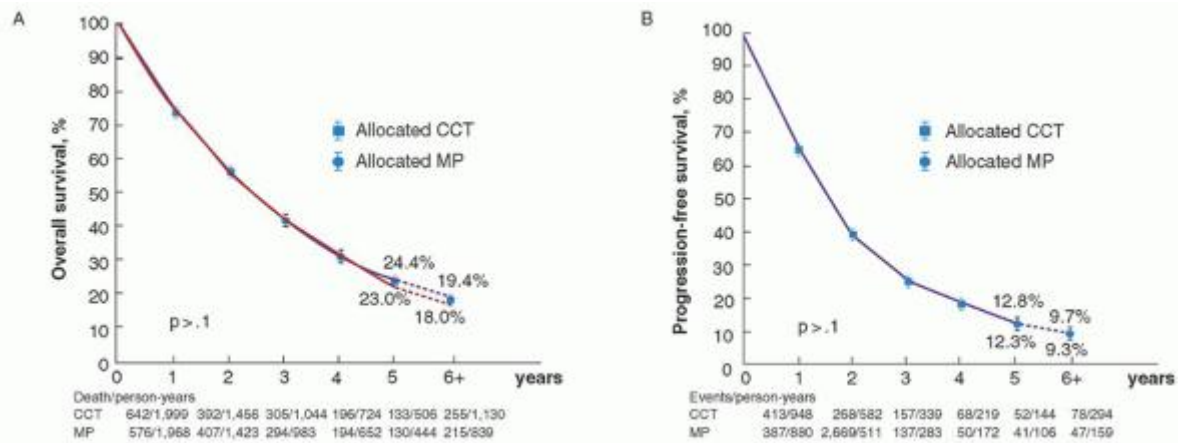

FIGURE 98.6. Melphalan and prednisone (MP) versus combined chemotherapy (CCT) as induction. Results from 6,633 patients from 27 randomized trials. A: Overall survival. B: Response duration. (From the Myeloma Trialists' Collaborative Group.²¹⁶ By permission of the American Society of Clinical Oncology.)

Clinical research in MM began to move at breakneck speed starting in the first decade of the 21st century. Because of the abundance of induction data and the absence of definitive “best options,” the Mayo Clinic group has published a treatment algorithm for patients with newly diagnosed MM called mSMART.^{357, 358} This is an online algorithm that is updated as new data emerge (Fig. 98.5; <http://www.msmaart.org/index.html>). As a general rule, patients who are being considered for stem cell collection and transplantation receive nonalkylator-containing induction regimens, or if alkylator-containing regimens are used, the number of cycles is restricted to four prior to stem cell mobilization.

Commonly Used Regimens for Any Newly Diagnosed Multiple Myeloma Patient

Three of the most commonly used induction regimens in the United States—lenalidomide/dexamethasone (Rd), bortezomib/lenalidomide/dexamethasone (VRD), and cyclophosphamide/bortezomib/dexamethasone (CyBorD)—are regimens that can be used for patients regardless of their transplant eligibility. Surprisingly, these three regimens have the least published phase III data to support their use. The mSMART method of prioritizing their use is shown in Figure 98.5.^{357, 358} Table 98.5 also lists these regimens, as well as other phase II regimens of interest that are discussed later in this chapter.

Lenalidomide/Dexamethasone (Rd)

In previously untreated patients with active MM, the combination of lenalidomide and dexamethasone with or without clarithromycin yields overall response rates of 91% to 95%, with complete response/very good response rates of 32% to 38%.^{359, 360} Rajkumar et al.³⁵⁹ treated 34 patients with lenalidomide 25 mg orally days 1 to 21 and dexamethasone 40 mg days 1 to 4, 9 to 12, and 17 to 20, both repeated every 28 days. Aspirin was given as DVT prophylaxis. The overall response rate was 91%, with 6% achieving complete response and 32% very good partial response. Grade 3 to 4 neutropenia occurred in 12% of patients. A total of 47% of patients experienced grade 3 or higher nonhematologic toxicity, most commonly fatigue (15%). The 2-year progression-free survival rates for patients proceeding to SCT and patients remaining on Rev-Dex were 83% and 59%, respectively; the OS rates were 92% and 90% at 2 years and 92% and 85% at 3 years, respectively. The 3-year OS rate for the whole cohort was 88%.³⁶¹

Niesvizky et al.³⁶⁰ treated 72 patients with clarithromycin, lenalidomide, and dexamethasone (BiRD). The rationale for the clarithromycin use is that it alters the hepatic metabolism of both drugs, resulting in higher effective doses. The lenalidomide schedule was as above, but dexamethasone was administered only once weekly. Clarithromycin was given 500 mg twice daily. Aspirin was given as DVT prophylaxis. The overall response rate was 90%, including 39% CR and 35% VGPR. Twenty patients went on to receive ASCT. Two-year EFS for the nontransplant group was 75%. The most common grade 3 or higher nonhematologic AEs were myopathy (11%) and thromboembolic events (12.5%). Grade 3 or higher hematologic toxicities were neutropenia in 19.4%, anemia in 13.8%, and thrombocytopenia in 22.2%.

A randomized controlled trial comparing lenalidomide with standard dexamethasone (12 days/month schedule)—RD—to lenalidomide with reduced intensity dexamethasone (weekly dexamethasone)—Rd.³⁶² After 4 months of therapy, 79% of the RD patients and 68% of the Rd patients had achieved a partial response or better; however, at 1 year, OS was superior in the Rd arm as compared to the RD arm (92% vs. 87%, $P = 0.0002$). Among those aged less than 65, the 1-year OS was 91% with RD and 98% with Rd; among those older than 65, the 1-year OS was 83% with RD and 94% with Rd. The trial was

stopped due to this safety concern, and patients receiving high-intensity dexamethasone (RD) were crossed over to the low-intensity arm (Rd). Grade 3 to 4 AEs and early deaths were higher in the RD group (52% vs. 35%, $P = 0.0001$ and 5.4% vs. 0.5%, $P = 0.003$), respectively. The most common grade 3 or higher toxicities were DVT (26% vs. 12%, $P = 0.0003$), infections (16% vs. 9%, $P = 0.04$), and fatigue (15% vs. 9%, $P = 0.08$).

Because of the ease of administration and low early death rate, many consider Rd an excellent first-line therapeutic option. Others express concern that a 68% response rate and a VGPR or better rate of 40% is insufficient, and therefore favor the use of triplets, especially in younger patients. To date, there are no

P.2059

completed randomized trials demonstrating survival advantage of any of the triplets over the Rd. Several clinical trials are ongoing that compare a triplet (MPT, VRD) to Rd. In the absence of prospective data, a retrospective comparison of three consecutive clinical trials [RD (lenalidomide-dexamethasone, $n = 34$), CLD (cyclophosphamide-lenalidomide-dexamethasone, $n = 53$), and CyBorD (cyclophosphamide/bortezomib/dexamethasone, $n = 63$)], has been reported.³⁶³ Overall response rates were comparable at 94%, 85%, and 90%, but complete response/near complete response rates were highest in the CyBorD arm, 35%, 15%, and 41%, $P = 0.006$. Despite this difference, however, PFS and OS were no different among the groups. Respective median PFS rates were: 3.2, 2.3, and 2.7 years, $P = 0.11$, and respective 3-year OS rates were 88%, 79%, and 88%. Poor cytogenetic risk was not overcome by any of these regimens. A notable finding of this study was that 80% of patients were alive at 4 years.

B, bortezomib; BCNU, carmustine; C, cyclophosphamide; Car, carfilzomib; CDDP, cisplatin; CI, continuous infusion; CP, cyclophosphamide and prednisone; CTX, cyclophosphamide; C-VAMP, cyclophosphamide, vincristine, doxorubicin, and methylprednisolone; d, day; D, dexamethasone; Dex, dexamethasone; Dox, doxorubicin; IMiD, immune modulatory drug; IV, intravenous; L, lenalidomide; M, melphalan; MP, melphalan and prednisone; MPT, MP and thalidomide; po, by mouth; P, prednisone; q, every; qod, every other day; T, thalidomide; VAD, vincristine, doxorubicin, and dexamethasone; VAMP, vincristine, doxorubicin, and methylprednisolone; M-2, VBMCP; VCR, vincristine; VMCP, vincristine, melphalan, cyclophosphamide, and prednisone; VDT-PACE, bortezomib, dex, thalidomide, cisplatin, doxorubicin, cyclophosphamide, etoposide; gluco, corticosteroid; VMP, MP and bortezomib; wk, week.

^a Repeated at 4-week intervals.

^b Repeated at 6-week intervals.

^c Repeated at 3-week intervals.

^d Initial treatment strategy for VISTA trial was bortezomib 1.3 mg/m² on days 1, 4, 8, 11, 22, 25, 29, and 32, repeated every 6 weeks for four cycles, and then repeated every 5 weeks, with bortezomib schedule changing to weekly administration for 4 weeks followed by 1 week rest. Due to high rates of neuropathy, recommended modification is to start with weekly administration and 5-week cycles.³⁹⁷

^e Repeated every 5 weeks.

^fDexamethasone 40 mg days 1-4, 9-12, 17-20 for cycle 1; then days 1, 8, 15, and 22.

Despite the concern of an increased rate of secondary malignancies when using lenalidomide as maintenance after ASCT and in conjunction with MP, the use of Rd appears to impart a lower rate of acute myeloid leukemia and myelodysplastic syndrome than MPT with respective rates of 0.15 per 100 person-years (95% CI 0.05 to 0.47) versus 1.04 per 100 person-years (95% CI 0.56 to 1.94),

P.2060

respectively. Rates of other secondary primary malignancies were comparable in both arms and within the expected range for an elderly population.³⁶⁴

BiRD, biaxin, lenalidomide, and dexamethasone; borteZ, bortezomib; CarRd, carfilzomib, lenalidomide, and dexamethasone; CLD, cyclophosphamide, lenalidomide, and dexamethasone; CR, complete response; CyBorD, cyclophosphamide, bortezomib, and dexamethasone; dex, dexamethasone; EFS, event-free survival; LD-PAD, low-dose PAD; N, number of patients; NA, not available; OR, overall response rate; OS, overall survival; PFS, progression-free survival; PR, partial response; ThaDD, thalidomide, pegylated doxorubicin, and dexamethasone; mo, months; thal, thalidomide; mCyBorD, modified CyBoD; MDT, MD and thalidomide; MPR, melphalan, prednisone and lenalidomide; mVCD, modified VCD; PAD, bortezomib, doxorubicin, and dexamethasone; RVDD, lenalidomide, bortezomib, doxorubicin, and dexathasone; ThaDD, thalidomide, pegylated doxorubicin, and dexamethasone; T-DVd, thalidomide, pegylated doxorubicin, vincristine, and dexamethasone; ThaDD, thalidomide, doxorubicin, and dexamethasone; VCD, bortezomib, cyclophosphamide, and dexamethasone; VDD, bortezomib, doxorubicin, and dexamethasone; VDRC, bortezomib, dexamethasone, lenalidomide, and cyclophosphamide; VDT, bortezomib, pegylated liposomal doxorubicin, and thalidomide; VGPR, very good partial response; VMP, MP and bortezomib; y, year; VRD, bortezomib, lenalidomide, and dexamethasone; VT, bortezomib and thalidomide.

^a Includes nCR as well as CR.

Cyclophosphamide, Bortezomib, and Dexamethasone (CyBorD or VCD)

The combination of cyclophosphamide, bortezomib, and dexamethasone (CyBorD or VCD) has been explored both in the relapsed setting and in patients with newly diagnosed MM. The first resport was that of a four 28-day cycles of bortezomib 1.3 mg/m² intravenously on days 1, 4, 8, and 11, cyclophosphamide 300 mg/m² orally on days 1, 8, 15, and 22, and dexamethasone 40 mg orally on days 1 to 4, 9 to 12, and 17 to 20 on a 28-day cycle for four cycles.³⁶⁵ Among the 33 pateints enrolled, responses were rapid. The overall response rate was 88%, with 39% achieving complete/near complete response. Peripheral neuropathy rate was 66%, with 7% grade 3. A modified extension of that trial included another 30 patients to maximize dose delivery and reduce toxicity.³⁶⁶ Patients received the same weekly cyclophosphamide schedule, but bortezomib was increased to 1.5 mg/m² IV on days 1, 8, 15, and 22 and dexamethasone was modified to 40 mg once weekly after cycle 2. Response rates were comparable and toxicity was less; grade 3/4 AEs dropped from 60% to 40% of patients, and no patient had grade 3 PN.

Bensinger reported results from a phase II study of two sequential three-drug combinations: three 21-day cycles of bortezomib, cyclophosphamide, and dexamethasone (VCD) followed by three 21-day cycles of bortezomib, thalidomide, and dexamethasone (VTD).³⁶⁷ Among the 42 evaluable patients, overall response rate was 95%, including 19% stringent complete response (sCR). Adverse cytogenetics did not appear to affect response. With a median follow-up of 21 months, 1-year EFS and are OS were 81% and 91%, respectively. The most common nonhematological grade 3/4 AE was periphaeral neuropathy, which occurred in 11% of patients. Four patients had cardiovascular events all during the VTD cycles.

A randomized phase II study comparing bortezomib, dexamethasone, cyclophosphamide, and lenalidomide (VDCR); bortezomib, dexamethasone, and lenalidomide (VRD); and two formulations of VCD in 140 previously untreated patients has

P.2061

been reported.³⁶⁸ A maximum of eight 21-day cycles followed by maintenance bortezomib (1.3 mg/m² every other week for 24 weeks) was administered. The bortezomib was administered as 1.3 mg/m² days 1, 4, 8, and 11 and the dexamethasone was administered as 40 mg days 1, 8, and 15 for all patients. The VRD patients received lenalidomide 25 mg days 1 to 14, whereas the VDCR patients received lenalidomide 15 mg days 1 to 14 and cyclophosphamide 500 mg/m² days 1 and 8. The VCD paitents received cyclophophamamide 500 mg/m² days 1 and 8, whereas, the VCD-mod patients received cyclophophamamide 500 mg/m² days 1, 8, and 15. Nearly all patients responded and the VGPR or better (CR) rates were 58% (25%), 51% (24%), 41% (22%), and 53% (47%) for patients on VDCR, VDR, VCD, and VCD-mod, respectively. The corresponding 1-year progression-free survival was 86%, 83%, 93%, and 100%. Grade 3 or higher AEs were seen in 76% to 88% of patients, with the highest rate of AE resulting in discontinuation in the VDCR arm. The highest rate of grade

3/4 hematologic AEs was in the VDCR and VCD arms. Grade 3/4 peripheral neuropathy rates ranged from 9% to 18%. The two regimens recommended by the authors were VCD-mod and VRD.

Kropff et al. reported phase I results of a variant of CyBORd. Thirty patients were treated with three 21-day cycles of bortezomib 1.3 mg/m² on days 1, 4, 8, 11 plus dexamethasone 40 mg on the day of bortezomib injection and the day after plus cyclophosphamide at 900, 1,200, or 1,500 mg/m² on day 1.³⁶⁹ The maximum tolerated dose of cyclophosphamide was defined as 900 mg/m². Overall response rate across all levels was 77%, with a 10% CR rate.

Bortezomib, Lenalidomide, Dexamethasone (VRD)

Richardson and colleagues reported on 66 patients treated on a phase I/II study using the combination of bortezomib, lenalidomide, and dexamethasone for previously untreated MM patients.³⁷⁰ Patients received eight 3-week cycles and either proceeded to transplantation or maintenance. All patients responded, and 67% achieved a VGPR or better. A total of 42% proceeded to ASCT. With median follow-up of 21 months, estimated 18-month PFS and OS for the combination treatment with/without transplantation were 75% and 97%, respectively. Sensory neuropathy occurred in 80% of patients and 32% reported neuropathic pain (grade 2/3 in 14%). Grade 3 to 4 neutropenia and thrombocytopenia occurred in 9% and 6% of patients respectively.

Summary statement: Based on complete response rates, the triplets are superior. Based on toxicity, lenalidomide and dexamethasone are superior. There are no compelling OS data to support one option over another.

Transplant Ineligible Patients

Transplant Ineligible Patients: Phase III Trials of Induction Regimens Including IMiDs and/or Proteasome Inhibitors (Table 98.6)

The combination of melphalan and prednisone (MP) was the standard for all patients with MM for nearly 40 years. The combination of MP has been studied extensively.^{223, 230} Response rates are 40% to 60% and anticipated median survivals are 18 to 42 months.^{210, 216, 223, 230, 232, 236, 257, 263, 264, 354, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386} Because of the variable gastrointestinal tract absorption of melphalan, intravenous regimens of 15 to 25 mg/m² every 4 weeks along with oral prednisone or dexamethasone have been tried and resulted in response rates of 50% to 82%.^{386, 387} An important phase III trial (IFM 95-01) directed at the elderly (age 65 to 75 years) was a fourarm study comparing MP to melphalan-dexamethasone (MD), dexamethasone, or dexamethasone-IFN.²⁴⁹ A total of 488 patients was randomized, and follow-up was 83 months. Response rates were significantly higher among patients receiving MD, and PFS was significantly better among patients receiving melphalan (22 vs. 13 months), but there was no difference in OS among the four treatment groups. The median survival for the whole series was 35 months. The morbidity associated with dexamethasone-based regimens was significantly higher than with MP.

With the advent of ASCT, MP was relegated to those not eligible for ASCT. As drugs outside the alkylator, anthracycline, and corticosteroid classes began to show activity around 2000, combining these drugs with alkylator and prednisone became the obvious path for study.^{388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400} Such regimens have become part of the standard for treating elderly patients with MM (Table 98.6) in addition to a few combinations that have not been directly compared to MP, but have shown promise in either phase II or III trials.^{362, 365, 366, 370} A major limitation of several of the trials that compare a doublet to a triplet is that it is often unclear what percentage of the doublet patients got access to the third drug at the time of relapse or progression.

There have been seven randomized controlled trials comparing MP to MP and a novel agent.^{388, 389, 390, 391, 392, 393, 394, 395, 396} In terms of the six MPT studies, all have favored MPT with regard to higher CR rates. Four of six have been positive with regard to PFS, again in favor of three drugs over two drugs, but only three of six have been positive with regard to OS. An individual patient meta-analysis has recently been reported.⁴⁰¹ In aggregate, MPT was superior to MP in terms of overall response rate (59% vs 37%), median PFS (20 versus 15 months), and median OS (39 vs. 33 months). Although this meta-analysis is an extraordinarily important study, there was no effort to examine what percentage of the relapsing MP patients received thalidomide as salvage. In a side meta-analysis examining serious adverse events of individual patient data of these same six trials,⁴⁰² a higher cumulative incidence of grade 3 to 4 nonhematologic (39% vs. 17%, HR 2.78, 95%CI 2.21 to 3.50) and hematologic (28% vs. 22%, HR 1.32, 95%CI 1.05 to 1.66) toxicities was documented with MPT. Nonhematologic toxicities were more likely to occur in patients with a baseline poorer performance status (HR 1.18, 95%CI 1.06 to 1.32). The specific serious adverse events that were more common in patients receiving MPT were peripheral neuropathy, neurologic other than peripheral neuropathy, thrombosis, and dermatologic toxicity. The experience of a nonhematologic grade 3 to 4 AE had a negative impact on both PFS (HR 1.24, 95%CI 1.07 to 1.45, P = 0.006) and OS (HR 1.23, 95%CI 1.03 to 1.47, P = 0.006).

The first positive MP versus MPT trial (Table 98.6) is the IFM 99-06 study,³⁸⁸ in which 447 patients were randomized to twelve 6-week cycles of either of MP (melphalan 0.25 mg/kg per day and prednisone 2 mg/kg/day days 1 to 4 every 6 weeks) or MPT (MP plus 200 to 400 mg of thalidomide daily) or to two sequential miniautologous peripheral blood stem cell transplants (MEL100). The thalidomide was not continued past the twelfth cycle of therapy. Higher response rates and longer PFS were seen with the MPT as compared to either the MP or MEL100 groups, with respective PFS times of 28, 18, and 19.0 months. With a median follow-up of 51 months, there was a significant survival advantage for the patients on the MPT arm, with respective OS times not reached at 52 months, 33 months, and 38 months.³⁸⁸

The IFM01-01³⁹¹ included 129 patients over the age of 75. They were randomized to twelve 6-week cycles of either of MP (melphalan 0.2 mg/kg per day and prednisone 2 mg/kg/day days 1 to 4 every 6 weeks) or MPT (MP plus 50 to 100 mg of thalidomide daily). With a median follow-up of 47.5 months, in the MPT arm both median OS (44 vs. 29 months, P = 0.03) and PFS (24 vs. 19 months, P = 0.001) were longer. Grade 2 to 4 peripheral neuropathy (20% vs. 5%, P = 0.001) and neutropenia (23% vs. 9%, P = 0.003) were more frequent in the MPT arm.

In the GIMEMA MP versus MPT trial, patients were randomized to either standard dose oral MP for 6 months or to MP for 6 months with concurrent thalidomide, which was continued indefinitely.^{389, 390} Overall response rates were significantly higher with the MPT than the MP as were the complete response rates and the median PFS rates (22 vs. 14 months, P = 0.004). In the initial

P.2062

report, there was a trend toward an improved 3-year OS in favor of MPT, but a second report with 38 months follow-up showed no difference in OS. This trial addressed a maintenance question as much as an induction question.

CR, complete response; MP, melphalan and prednisone; MPT, melphalan, prednisone, thalidomide; NA, not available; OS, overall survival; PFS/EFS, event-free survival or progression-free survival; VMP, bortezomib, melphalan and prednisone; VMPT, bortezomib, melphalan, prednisone and thalidomide.

^a Third arm of this study which treated patients with two sequential miniautologous ASCTs is not included in this table.

^b Thalidomide was continued as maintenance in MPT arm.

^c Received thalidomide or bortezomib; number of patients in control arm receiving thalidomide as salvage not specified.

^d Complete response + very good partial response.

^e Secondary randomization to either VT or VP.

In the Dutch-Belgium Hemato-Oncology Cooperative Group (HOVON) 49 trial, patients were randomized to either eight cycles of MP (melphalan 0.25 mg/kg per day and prednisone 2 mg/kg/day days 1 to 5 every 4 weeks) or MPT (MP plus 200 mg/day thalidomide). The median EFS was 9 months with MP and 13 months with MPT, and 2-year PFS was 33% versus 21%, $P < 0.05$. OS of those treated with MPT was also superior (40 vs. 31 months, $P < 0.05$). In a partner health-related quality-of-life study,⁴⁰³ the higher frequency of adverse events associated with the MPT arm did not translate into a negative effect on the health-related quality of life. Only the score for paresthesia worsened in the MPT arm, but subscales rating emotional function and future perspectives favored the MPT arm.

In the Nordic study,³⁹² 357 patients were randomized to MP (4 days of melphalan 0.25 mg/kg per day and prednisone 100 mg/day every 6 weeks) or MPT (MP plus 200 to 400 mg/day thalidomide). Treatment was continued to plateau and the thalidomide was continued until relapse. Although there were superior CR and PR rates in the MPT arm, there was no difference in PFS or OS between the two groups. In fact, there was a higher mortality rate in the first 6 months among the MPT patients over age 75. In a partner health-related quality-of-life study, patients in the

P.2063

MPT arm had higher rates of constipation and lower rates of diarrhea, physical function, and social function.

The final MP versus MPT study was conducted in Turkey where 114 patients were randomized to 12 months of MP (melphalan 9 mg/m²/day and prednisone 60 mg/m²/day for 4 days every 6 weeks) or MPT (MP plus thalidomide 100 mg/day continuously). Although response rates were higher in the MPT patients than the MP patients, PFS and OS did not differ.

CTDa (cyclophosphamide, thalidomide, and dexamethasone) is a variation on the theme of MPT. The MRC IX trial³⁹⁹ randomized elderly patients to either MP or CTDa (Table 98.4) to maximum response, with a minimum of six cycles to a maximum of nine cycles (Table 98.6). There was a secondary randomization to thalidomide or no thalidomide

maintenance.⁴⁰⁴ Median follow-up is 44 months, and PFS was marginally better in the CTDA arm, but OS was not different between the two arms. Patients in the CTDA group had higher rates of sensory and motor neuropathy, thromboembolic events, constipation, infection, rash, and elevated alkaline phosphatase levels than did those in the MP group, but lower incidence of cytopenias.

The combination of thalidomide and dexamethasone (TD) has also been compared to MP.⁴⁰⁵ In these 282 elderly patients although there were higher response rates using TD (68% vs. 52%, $P = 0.002$), there was also higher rates AEs: neuropathy (72% vs. 33%), psychological toxicity (36% vs. 18%, $P < 0.001$), constipation (33% vs. 13%, $P < 0.001$), and a trend toward more DVTs (10% vs. 4%). The only toxicity more commonly seen in the MP arm was myelosuppression. With a median follow-up of 28 months, there was no difference in PFS, but there was a trend toward shorter OS among TD-treated patients which was more notable in patients older than 75 years. MP has also been compared to the combination of melphalan, prednisone, and lenalidomide in a three-arm phase III trial³⁹⁸: MP versus MP with lenalidomide (MPR) versus MPR with lenalidomide maintenance (MPR-R). A total of 459 patients was randomized to either MP (nine 4-week cycles of melphalan 0.18 mg/kg/day and prednisone 2 mg/mg/kg/day days 1 to 4), MPR (nine 4-week cycles of MP plus lenalidomide 10 mg days 1 to 21), or nine cycles of MPR with indefinite lenalidomide maintenance (10 mg days 1 to 21 every 4 weeks). Overall response rates were lowest in the MP (50%) arm with progressively better rates for MPR (68%) and MPR-R (77%). With a median follow-up period of 30 months, however, neither PFS nor OS was better among patients treated with MPR as compared to MP. MPR-R patients had better PFS (31 months vs. 14 and 13 months) but not 3-year OS (70%) as compared to the other two groups (62% vs. 66%). Toxicity was substantially higher in the lenalidomide arms.

The VISTA trial³⁹⁵ is the one large trial comparing MP to bortezomib and MP (VMP). Patients received nine 6-week cycles of either melphalan (at a dose of 9 mg/m²) and prednisone (60 mg/m²) on days 1 to 4, alone or in combination with bortezomib (1.3 mg/m²) on days 1, 4, 8, 11, 22, 25, 29, and 32 during cycles 1 to 4 and on days 1, 8, 22, and 29 during cycles 5 to 9. All response and survival outcomes were superior with the VMP, most notably CR rates of 30% versus 4%. Median PFS was 24 months as compared to 17 months, and 3-year OS was 68% as compared to 54%.³⁹⁶ Time to response was also quicker with VMP 1.4 months versus 4.2 months. Grade 3 to 4 adverse events, however, were more frequent in patients receiving VMP (46% vs. 36%). A total of 33% of patients discontinued bortezomib due to toxicity. Peripheral sensory neuropathy occurred in 44% of patients with grade 3 to 4 in 13%. Neuralgia was also reported in 36% of patients.

There are three phase III trials for the elderly that compare VMP to other regimens.^{400, 406} A major finding of two of these trials was the feasibility and efficacy of changing the bortezomib scheduled from days 1, 4, 8, 11 every 21 days to a once-weekly schedule. This alteration dramatically reduced rates of peripheral neuropathy.

With median follow-up of 32 months, the VMP vs. VTP trial was negative.⁴⁰⁰ Response rates, PFS, and OS were comparable but grade 3 to 4 AEs were significantly higher in the VTP arm. More patients in the VTP arm discontinued therapy prematurely, and they had higher rates of cardiac events (8% vs. 0%) but lower rates of infection (1% vs. 7%). An analysis based on cytogenetic risk was done, comparing outcomes based on hyperdiploidy versus nonhyperdiploidy. The 3-year OS in the VMP-treated patients was no different based on cytogenetic risk category implying that this regimen may abrogate the risk of nonhyperdiploid cytogenetics; this difference was not observed in the VTP-treated patients. There was a secondary randomization in this trial to maintenance with either bortezomib and thalidomide (VT) or bortezomib with prednisone (VP).

Palumbo and colleagues randomized patients to receive either nine 5-week cycles of VMP (Table 98.6) or nine 5-week cycles of VMPT, which also added thalidomide 50 mg continuously, and continued with maintenance thalidomide along with alternate week bortezomib. Median follow-up at the time of the publication was 23 months. Response rates and PFS were higher in the four-drug combination with maintenance as compared to the three-drug with no maintenance, but OS was not different. Toxicity was significantly higher using the four-drug regimen: grade 3 to 4 neutropenia (38% vs. 28%; $P < 0.02$), cardiologic events (10% vs. 5%; $P < 0.04$), and thromboembolic events (5% vs. 2%, $P < 0.08$). The most important observation of this trial was that the bortezomib schedule could be changed from days 1, 4, 8, 11, 22, 25, 29, and 32 to days 1, 8, 15, and 22 without reducing efficacy (or actual dose of drug delivered) but significantly reducing adverse events. Severe sensory peripheral neuropathy was reduced from 16% to 3%.

The multicenter, phase IIIb UPFRONT study compares the efficacy and safety in newly diagnosed MM patients ineligible for HDT-SCT of three bortezomib-based induction regimens followed by weekly bortezomib maintenance: VcD (bortezomib-dexamethasone); VTD; and VMP.⁴⁰⁶ Although this has only been presented in abstract and oral presentation, the findings are important. Despite the highest rates of VGPR or better in the VTD arm (51% vs. 37% and 40%), with a median follow-up of 26 months, there was no difference in PFS or OS among the groups, but the mean global health status score (QOL) worsened for all groups during induction. During maintenance, QOL trended back toward baseline for the VcD and the VMP arms, but remained much lower than baseline for the VTD cohort.

Two trials address the combination of thalidomide-dexamethasone (TD) versus dexamethasone alone.^{407, 408} The smaller trial is discussed in a later section and is reviewed in Table 98.7 inasmuch as the majority of patients proceeded to ASCT.⁴⁰⁷ The larger trial is summarized in Table 98.6 and includes patients not destined for ASCT. In the TD arm, time to progression was significantly better (17.4 months, 95% CI: 8.1 months not reached versus 6.4 months, 95% CI: 5.6 to 7.4 months), but grade 3 to 4 adverse events were also higher: DVT/PE 15.4 versus 4.3%; cerebral ischemia 3.4% versus 1.3%; myocardial infarction 4.7% versus 1.3%, and peripheral neuropathy 3.8% versus 0.4%.⁴⁰⁷

In E4A03, the subset of patients aged 70 or older who were treated with lenalidomide with high-intensity dexamethasone (RD) or low-intensity dexamethasone (Rd) are considered.^{362, 409} Although in this trial there is no comparator to MP, it is still relevant because many judge it to be an effective and well-tolerated option for elderly patients. The major findings are shown in Table 98.6. Patients treated on the high-intensity dexamethasone arm had slightly higher response rates, comparable PFS, and inferior OS as compared the low-intensity dexamethasone arm. Rates of nonhematologic toxicity in the RD and Rd arms were 68% and 61%, respectively, with treatment-related deaths in 13% versus 4% of patients. The 2-year OS survival rate of 90% for patients treated with Rd in this randomized trial prompted a large trial

P.2064

comparing Rd to MPT, which has completed accrual (MM-020), but has not yet been reported.

^a Regimens listed as “induction” + “consolidation/maintenance.”

^b The basis of TT2 is a complex 6 or 7 drug induction followed by 2 autologous stem cell transplants,

followed by 2 cycles of 5 drug consolidation, indefinite interferon maintenance, and 1 year of dexamethasone.

^c Statistically significant difference between arms.

^d Maintenance not included in response, although patients were randomized to thalidomide or prednisone.

^e ASCT was not a predetermined part of these trials, so data include both patients who did and did not undergo ASCT.

Transplant-Ineligible Patients: Induction Chemotherapy for Patients Ineligible for ASCT Prior to the 21st Century

The 1970s and 1980s were a testing ground for various combinations of alkylators, corticosteroids, and doxorubicin. Melphalan-cyclophosphamide-prednisone,²⁵⁶ carmustine-cyclophosphamide-prednisone,^{371, 372} melphalancyclophosphamide-carmustine-prednisone (MCBP),^{256, 353} and vincristine-melphalan-cyclophosphamide-prednisone (VMCP)²⁵⁶ resulted in response rates of 47%, 37% to 50%, 49% to 68%, and 62%, respectively. Median survivals with these regimens were 25 to 36 months.^{256, 353, 371, 372} Lee and Case²⁶⁰ introduced the five-drug regimen of vincristine-carmustine-melphalan-cyclophosphamideprednisone (VBMCP or the M-2 regimen), which included the same four drugs as MCBP plus vincristine; dose intensities, however, were different in these two regimens. The response rate for VBMCP was about 85% in previously untreated patients with a median survival of 38 months.^{260, 410} The success of the VBMCP regimen supported the value of vincristine. However, the MRC IV trial, which randomized 530 previously untreated patients with MM to MP versus melphalan-vincristine-prednisone, revealed no difference in either response rate or OS between the two arms.²⁶⁴ VMCP has not produced any response or survival advantage over MP.^{383, 411}

Although subsequent randomized trials have substantiated the superior response rates of VBMCP over standard MP, P.2065

they have not demonstrated superior survival.^{263, 376, 385, 412} In fact, the meta-analysis performed by the Myeloma Trialists' Collaborative Group²¹⁶ involving 6,633 patients in 27 randomized trials, revealed a superior response rate (60.2% vs. 53.2%, $P < 0.000001$, two-tailed) but no survival benefit for combination chemotherapy over standard MP (Fig. 98.6). A prior meta-analysis of 18 published trials (3,814 patients) also demonstrated no benefit for combination chemotherapy in terms of survival. There was a suggestion of a survival advantage in the subgroup of patients with more aggressive disease,³⁵⁵ but this was not substantiated in the larger meta-analysis.²¹⁶

The use of alkylator-doxorubicin-based combination chemotherapy was stimulated by a report on the benefits of a combination of doxorubicin and BCNU in patients who had become resistant to melphalan.⁴¹³ Regimens such as MAP (melphalan-doxorubicin-prednisone), CAP (cyclophosphamidodoxorubicin-prednisone), VCAP (vincristine and CAP), and VBAP (vincristine-BCNU-doxorubicin-prednisone) were tried; by SWOG response criteria, objective response rates were 41%, 46%, 64%, and 61%, respectively.^{256, 414} Median survival ranged from 30 to 32 months; subsequent analysis demonstrated a superior median survival for the VBAP arm of 37 months.⁴¹⁵ Enthusiasm for alternating VMCP and VBAP (or VCAP) was generated by the SWOG study of 237 patients randomized to MP or the above regimens.^{380, 381} Response rates and OS were superior in the alternating combination chemotherapy arms compared to the MP arm,^{414, 415} but the survival benefits of this initial study were not reproducible by others.^{257, 377, 378, 382, 384, 416, 417} The V MRC myelomatosis trial randomized patients to ABCM (VBAP-VMCP without the vincristine or prednisone) or melphalan as a single agent on the basis of findings emanating from the IV MRC trial, which demonstrated a lack of benefit attributable to the addition of vincristine. Median survival in the ABCM group was superior to that of the melphalan-only arm (32 vs. 24 months, $P = 0.0003$).^{233, 266}

Combination Chemotherapy with Interferon- α for Induction

IFN and dexamethasone have been combined as an induction regimen in patients with newly diagnosed myeloma and a low tumor mass. A retrospective comparison showed that the response rate of this regimen (57%) was similar to the response rate (48%) previously observed with dexamethasone alone.⁴¹⁸ A randomized trial comparing MP, melphalan-dexamethasone, dexamethasone, and dexamethasone-IFN did not demonstrate any added benefit by incorporating IFN into the treatment regimen.²⁴⁹ Ahre et al.⁴¹⁹ randomized 55 patients to MP or IFN (3 to 6 MU daily); response rates in the MP arm were significantly higher than in the IFN arm (44% vs. 14%, $P < 0.001$). These results spawned a multitude of trials

adding IFN to MP^{420, 421, 422, 423, 424, 425, 426, 427, 428} and numerous alkylator-corticosteroid combinations with or without anthracycline^{422, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438} as part of an induction regimen. Results have been mixed. Two meta-analyses have been performed in an attempt to reconcile these conflicting results.^{439, 440} The first, reported in 2000,⁴³⁹ used published data and included 17 induction trials^{420, 421, 422, 423, 424, 425, 426, 427, 428, 430, 431, 432, 433, 434, 435, 437, 438} with 2,333 evaluable patients,⁴³⁹ the second, reported by The Myeloma Trialists' Collaborative Group in 2001,⁴⁴⁰ used primary data from 12 induction trials^{420, 421, 422, 423, 424, 425, 426, 427, 428, 430, 432, 433, 434, 436, 437, 438, 441} involving 2,469 patients.⁴⁴⁰ Overall, the results were similar. In the first meta-analysis, the benefits attributable to the addition of IFN to the induction regimen included a 6.6% higher response rate ($P < 0.002$) and a 4.8-month and 3.1-month prolongation of relapse-free ($P < 0.01$) and OS ($P < 0.01$).⁴³⁹ In the second meta-analysis, patients receiving IFN had a slightly better response rate (57.5% vs. 53.1%, $P = 0.01$) and PFS (30% vs. 25% at 3 years, $P < 0.0003$), with a superior median time to progression of about 6 months. The survival advantage of 2 months, however, was not significant ($P = 0.1$).⁴⁴⁰ These meta-analyses suggest that incorporation of IFN into induction provides a modest prolongation of response and possibly of survival. Wisloff et al.⁴⁴² evaluated the quality of life of 583 patients randomized to either MP or MP plus IFN as induction. During the first year of treatment with IFN, the patients reported significantly more fever, chills, dry skin, fatigue, pain, nausea, vomiting, and appetite loss than the control patients. After the first year, however, the only symptom reported more often was dizziness. Although patients receiving IFN had a 5- to 6-month prolongation of the response and plateau phase, there was no late quality-of-life benefit observed to compensate for the early impairment. The authors questioned the clinical value of the plateau phase prolongation and reported that only 60% of patients continued to receive IFN after 24 months, suggesting that their data might underestimate the potential toxicity of the drug.

Transplant Eligible Patients

VAD-like regimens—incorporating different corticosteroids,^{243, 246, 443} and C-VAMP (cyclophosphamide-vincristinedoxorubicin-methylprednisolone)²⁴⁵ had commonly been used as induction therapy before stem cell collection and transplantation, but have been largely replaced by regimens incorporating IMiDs and/or proteasome inhibitors. These VAD-like regimens had initially been piloted with salutary effect in relapsed disease, and were subsequently applied in previously untreated patients with response rates of 50% to 84%.^{444, 445, 446, 447, 448, 449, 450, 451, 452, 453} Median survival for patients treated initially with VAD and no transplant was about 36 months.⁴⁵⁴ The complete response rate of C-VAMP was higher than that of VAMP alone, but survival was not different.⁴⁴⁷ Response rates of 80% have also been achieved using the CAD (cyclophosphamide-doxorubicin-dexamethasone) regimen.⁴⁵⁵ The addition of etoposide to C-VAD appears to contribute only toxicity.⁴⁵⁶

By the late 1990s and early 2000s, single-agent high-dose dexamethasone was used by some experts in lieu of VAD for induction in those patients destined for stem cell collection based on a nearly comparable response rate of single-agent high-dose dexamethasone of 43%²⁴² and the advantage of an oral noninfusional therapy. This strategy was used successfully, resulting in adequate collections of peripheral blood stem cells without any apparent adverse effects on complete remission rates or progression-free survival in several single-arm studies.^{457, 458} With the advent of additional therapies, single-agent dexamethasone is no longer a standard induction option.

There is controversy about which induction is best for patients before stem cell collection and ASCT. In the absence of mature data, there are two philosophical camps. There are the proponents of “deepest response,” who argue that using those multidrug regimens yielding highest CR rates is essential. These investigators point to the circular reasoning that those patients with the deepest response do best.⁴⁵⁹ The counterargument posed by others is that until randomized controlled trials demonstrate a survival advantage or at least a PFS advantage with improved quality of life for one regimen over another, selection of a regimen that may give a higher CR rate but more toxicity and cost may not prove to be the most prudent course of action. Unfortunately, for the majority of regimens there are no completed prospective randomized trials to answer this question. Many of the trials discussed here suffer from a paucity of information about future access to the novel agent in the control arm, making it impossible to discern whether an advantage seen using a multiagent induction regimen lies in synergy of a particular combination or merely in access to yet another drug with activity against MM.

Transplant-Eligible Patients: Phase III Trials of Induction Regimens Including Immune Modulatory Drugs and/or Proteasome Inhibitors (Table 98.7)

Table 98.7 includes published phase III induction regimens that are part of an ASCT transplant treatment plan. Five of them include a mix of patients who are and are not destined for transplant,^{362, 407, 460, 461, 462} five include planned maintenance,^{463, 464, 465, 466, 467, 468} and three do not specify post-transplant

maintenance.^{469, 470, 471} Further limitations of many of these trials are short follow-up and different maintenance arms, making it difficult to tease out benefit due to induction versus maintenance. There is also a paucity of information about quality of life associated with these protocols. Patterns arise in terms of response and PFS: that is, addition of thalidomide is better than no addition, but addition of bortezomib is better yet. Despite these advantages in response rate and PFS, to date only one study has shown a better OS, the HOVON-65 trial. As more drugs are added, there is more toxicity, especially peripheral neuropathy.

The IFM 2005-1 randomized 482 patients to either four cycles of VAD or bortezomib dexamethasone (BD)⁴⁷⁰ followed by DCEP (dexamethasone-cyclophosphamide-etoposide-cisplatin) for two cycles versus no DCEP. Patients were to have a single ASCT, and those without a VGPR or better were to receive a second ASCT. An undefined number of patients received maintenance lenalidomide as part of a different trial of lenalidomide versus placebo (IFM 2005-2 trial). Pretransplant CR, VGPR, and PR were superior with BD. By protocol, fewer patients who received BD were deemed candidates for second ASCT than patients who had VAD induction, but only 21% and 27%, respectively, actually received a second ASCT. The improvement in response in the BD arm persisted after transplant, but with a median follow-up of 32 months, there was no difference in PFS or OS. The incidence of grade 3 to 4 adverse events appeared similar between groups, but hematologic toxicity and deaths related to toxicity (0 vs. 7) were more frequent with VAD. In contrast, rates of grade 2 (20.5% vs. 10.5%) and grades 3 to 4 (9.2% vs. 2.5%) peripheral neuropathy during induction through first transplantation were significantly higher with BD.

Based on the promising phase II results using VTD in previously untreated myeloma,⁴⁷² the GIMEMA group randomly allocated 480 patients to either three 21-day cycles of thalidomide (100 mg daily for the first 14 days and 200 mg daily thereafter) plus dexamethasone (40 mg daily on 8 of the first 12 days), either alone or with bortezomib (1.3 mg/m²) on days 1, 4, 8, and 11).⁴⁶⁶ After double autologous stem-cell transplantation, patients received two 35-day cycles of their assigned drug regimen, VTD or TD, as consolidation therapy. All patients were subsequently maintained on dexamethasone 40 mg days 1 to 4 every 28 days. After induction therapy, higher rates of complete or near complete response were observed in the VTD arm as compared to TD (31% vs. 11%, $P < 0.0001$). These improved response rates persisted after first and second ASCT and after two cycles of consolidation. 3-year PFS was better in the VTD group (68% vs. 56%, $P = 0.006$), but with a median follow-up of 36 months, the estimated 3-year OS rates were no different. Grade 3 or 4 adverse events post induction were recorded in a significantly higher number of patients on VTD than in those on TD (56% vs. 33%, $P < 0.0001$), with a higher occurrence of grade 3 to 4 peripheral neuropathy in patients on VTD (10% vs. 2%, $P = 0.0004$).

The HOVON 50/GMMG-HD3-trial is a phase III study of 536 randomized patients up to 65 years⁴⁶⁴ to either three cycles of TAD (thalidomide, 200 mg for HOVON and 400 mg for GMMG; adriamycin 9 mg/m², days 1 to 4; and dexamethasone 40 mg, days 1 to 4, 9 to 12, 17 to 21) or VAD. TAD resulted in more grade 2 to 4 AEs as compared with the VAD arm (31% vs. 21%, $P = 0.008$). The TAD had superior overall response rates pre- and post-ASCT, but with a median follow-up of 52 months, there was no significant difference in median OS (73 vs. 60 months, $P = 0.77$). Patients who had been randomized to the thalidomide arm had a markedly shorter survival post-relapse.

In the MRC IX trial (transplant pathway), 1,111 patients were randomized to either oral cyclophosphamide-thalidomidedexamethasone (CTD) or to infusional cyclophosphamide, vincristine, doxorubicin, and dexamethasone (C-VAD).⁴⁶⁵ As many as six cycles were given prior to ASCT. The post-induction overall response rate was significantly higher with CTD than C-VAD (82.5% vs. 71.2%, $P < 0.0001$, including superior complete response rates (13.0% vs. 8.1%, $P = 0.008$). This response advantage persisted post-autologous stem-cell transplantation (complete response, 50.0% vs. 37.2%, respectively; $P = 0.00052$). Patients had a secondary randomization to either maintenance thalidomide or prednisone. With a median follow-up of 47 months, there was no difference in either PFS or OS. FISH risk had no impact on outcome.

To date, the HOVON-65 trial is the only randomized trial incorporating novel therapies into induction that has shown an improvement in OS.⁴⁶⁷ These results are confounded by the fact that these same patients had different maintenance regimens as well, making it difficult to know if the induction, the maintenance, or merely access to bortezomib was the value-added step, in terms of the OS benefit. This trial randomized 827 patients to 3 weeks of initial therapy with either VAD or bortezomib, doxorubicin, and dexamethasone (PAD), followed by one or two ASCT. Post-ASCT maintenance for the VAD group was thalidomide 50 mg daily and for the PAD group bortezomib 1.3 mg/m² once every 2 weeks. Maintenance was continued for 2 years. After completing induction therapy with PAD, 31% of patients had achieved a CR in contrast to 15% of VAD patients. This improved CR rate persisted even after one or two ASCT. PFS was superior in the PAD-bortezomib maintenance arm as compared to the VAD-thalidomide arm, 35 months versus 28 months. After a median follow-up of 66 months, OS was also better in the PAD arm, 5-year OS of 61% versus 55%, $P = 0.05$ when adjusted for risk

factors (age, performance status, ISS, double ASCT, and FISH abnormalities) in the multivariate analysis. Of note, the hazard ratio for double ASCT was similar to that of being on the PAD-bortezomib arm. Peripheral neuropathy grades 2 to 4 were reported in 18% of VAD patients versus 40% of PAD patients, $P < 0.001$. The discontinuation rate of thalidomide maintenance was higher than that of bortezomib maintenance (30% vs. 11%, $P < 0.001$). An important observation made in this trial is that the use of bortezomib both before and after ASCT appeared to attenuate the poor prognostic impact of deletion 17p.⁴⁷³

The Spanish Myeloma Group conducted a trial to compare VTD versus TD versus vincristine-BCNU-melphalan-cyclophosphamide-prednisone alternating with vincristine-BCNU-doxorubicin-dexamethasone plus bortezomib (VBMCP/VBAD/B) in patients aged 65 years or younger with MM destined for ASCT.⁴⁶⁸ A total of patients was allocated. The CR rate was significantly higher with VTD than with TD (35% vs. 14%, $P = 0.001$) or with VBMCP/VBAD/B (35% vs. 21%, $P = 0.01$). The median PFS was significantly longer with VTD (56.2 vs. 28.2 vs. 35.5 months, $P = 0.01$). With a median follow-up of 35 months, the 4-year OS was 74% for VTD, 65% for TD, and 70% for VBMCP/VBAD/B, $P = NS$.

The IFM 2007-2 trial⁴⁷¹ was a randomized trial to compare bortezomib-dexamethasone (VD) as induction ASCT to a combination consisting of reduced doses of bortezomib and thalidomide plus dexamethasone (vtD), the latter of which was comprised of four 3-week cycles of IV bortezomib 1 mg/m²/m² day 1, 4, 8, and 11 along with thalidomide 100 mg/day orally, and dexamethasone 40 mg days 1 to 4 (all cycles) and days 9 to 12 (cycles 1 and 2). In the case of less than PR after cycle 2, the dose of bortezomib was increased to 1.3 mg/m² and the dose of thalidomide to 200 mg/day. The VD patients received two drugs on the same schedule as vtD, but the dose of bortezomib was 1.3 mg. Patients receiving the three-drug regimen had similar overall response rates and CR rates, but VGPR or better occurred significantly more often in the vtD group. This same pattern was observed after a single ASCT. Of note, the number of stem cells collected was less in patients receiving the three-drug regimen. Subsequent post-ASCT consolidation and/or maintenance was at treating physician's discretion; more patients receiving VD received maintenance therapy. Despite these differences, there was no significant difference in PFS or OS with a median follow-up of 32 months. There were significantly

P.2067

higher rates of peripheral neuropathy among patients on the VD arm: overall 70% versus 53%, $P = 0.01$ and grade 3 in 11% versus 3%, $P = 0.03$. The authors concluded that vtD, including reduced doses of bortezomib and thalidomide, yields higher VGPR rates compared with VD and can be considered a new effective triplet combination before HDT/ASCT.

E1A00,⁴⁰⁷ E4A03,³⁶² and S0232⁴⁶⁰ (Table 98.7) were conducted with response endpoints rather than PFS or OS. The two trials comparing variants of VAD using pegylated doxorubicin had response and toxicity as major endpoints.^{461, 462} E1A00 compared single-agent dexamethasone to thalidomide-dexamethasone (TD). Its premise was to validate whether the addition of thalidomide to dexamethasone increased response rates as reported in phase II studies. The overall response rate of TD was significantly higher than dexamethasone alone (63% vs. 41%); however, toxicity was greater using the combination with grade 4 to 5 toxicity being 45% vs. 21%, $P < 0.001$.⁴⁰⁷ For nearly a decade TD was used as induction in the months before stem cell collection because of its high response rates and its ease of administration, but with the introduction of lenalidomide and bortezomib, the TD doublet is not commonly used in the United States as induction. The results of the two lenalidomide trials (E4A03³⁶² and S0232⁴⁶⁰) have been discussed.

In an attempt to avoid the continuous infusion required to administer VAD, the use of the pegylated liposomal doxorubicin has been explored in two randomized trials. Doxil-vincristine-dexamethasone (DVD)—using either standard high dose dexamethasone⁴⁶² or attenuated doses of dexamethasone⁴⁶¹—was compared to VAD. Results were comparable between arms with regards to response rates, 42% in the attenuated dexamethasone trial⁴⁶¹ and 61% with the standard dose dexamethasone trial.⁴⁶² PFS and OS were comparable, but there was more alopecia, grade 3/4 neutropenia in the nonliposomal doxorubicin arms and more palmar-plantar erythrodysesthesia in liposomal doxorubicin arms.

Total Therapy Approach

Barlogie and colleagues have championed the “total therapy” (TT) approach since 1990.^{329, 463, 474, 475} The concept is to use all therapies with activity against malignant plasma cells as early as possible with prolonged treatment courses. Advances have come from this approach, especially the concept of tandem transplantation, but the major limitation of the total therapy studies is that they have not been compared to less aggressive strategies in a randomized fashion. With successive trials—total therapy 1 (TT1), total therapy 2 (TT2), and total therapy 3 (TT3)—there have been improvements in outcomes including complete response, PFS, and OS (Table 98.8).³²⁹ Complete response rates have increased from 38% to 62% of patients and 5-year OS rates have increased from 57% to 73%. Although other investigators have not reported duration of complete response rates that approach those of TT3, since the beginning of the 21st century 5-year OS rates

of 50% to 80% among transplant-eligible patients are increasingly common using less intensive treatment strategies.^{363, 476} Moreover, toxicity of the total therapy strategies is not inconsequential. For example in TT2 grade 3/4 adverse events include PN in 27%, thrombosis or embolism in 30%, bowel obstruction in 14%, and syncope in 12%.⁴⁶³

TABLE 98.8 TOTAL THERAPY APPROACH^{329, 463, 474, 475}

	TT1 (n = 231)	TT2 + thal (n = 345); TT2 - thal (n = 323)	TT3A (n = 303); TT3B (n = 177)
Induction	VAD × 3	VAD followed by DCEP +/- thal	VTD-PACE × 2
Mobilization	High dose CTX	DCEP +/- thalidomide	Using above
Transplant × 2	Yes	Yes	Yes
Consolidation	DCEP	DPACE quarterly × 1 year +/- thal	A: VTD-PACE × 2; B: VRD-PACE × 2
Maintenance	IFN	Dex × 1 year, IFN continuously +/- thal indefinitely	A: VTD × 1 year followed by TD × 2 years, or B: VRD for 3 years
Duration of therapy ^a	1 year	TT2 + thal: > 3 years; TT2 - thal: 3 years	>4.2 years
Number of drugs	6	TT2 + thal: 8; TT2 - thal: 7	TT3A: 8; TT3B 9
Accrual years	8/1990-8/1995	10/1998-2/2004	2/2004-7/2006
Age < 65, %	91	TT2 + thal: 79; TT2 - thal: 80	72
Median follow-up	17.1 years	8.7 years	5.5 years
CR, %	38	60 with thal; 43 no thal	A: 62
CR duration	35 ^{25, 45}	59 ^{52, 66} with thal; 52 ^{43, 60} no thal	A: 79 ^{73, 85}
PFS	27 ^{21, 32}	56 ^{50, 61} with thal; 42 ^{37, 47} no thal	A: 67 ^{62, 73}
5-year OS, %	57 ^{50, 63}	68 ^{63, 73} with thal; 65 ^{60, 70} no thal	A: 73 ^{68, 78}

DCEP, dexamethasone, cyclophosphamide, etoposide, cisplatinin; DPACE, dexamethasone, cisplatinin, doxorubicin, cyclophosphamide, etoposide; IFN, interferon; VAD, vincristine, doxorubicin, dexamethasone; Thal, thalidomide; TT, total therapy; VTD-PACE, bortezomib, thalidomide, dexamethasone, cisplatinin, doxorubicin, cyclophosphamide, etoposide.

^aExcluding interferon maintenance duration.

Other Induction Regimens of Interest

Table 98.5 includes a number of regimens that have reported in the up-front setting,^{316, 317, 318, 319, 360, 365, 366, 367, 368, 472, 477, 478, 479, 480, 481, 482, 483, 484, 485} but no recommendation can be made regarding their use given the absence of randomized trials that may better define their role in patients with myeloma. Several have been discussed in previous sections.^{365, 366, 367, 368, 472, 480, 481, 486} All of the other regimens are novel triplets or quadruplets. Response rates are listed in Table 98.5, therefore much of the emphasis of this section focuses on toxicity.

Four phase II studies use either single-agent bortezomib or bortezomib in combination with dexamethasone. One study is notable because all patients on that study (E2A02) were high-risk as defined by B2M and/or cytogenetic abnormalities, and none of the pateints had early transplantation. Median PFS was 8 months and 2-year OS was 76%.³¹⁶

Two regimens exclude corticosteroids, VT (bortezomib, and thalidomide),⁴⁷⁸ and VDT (bortezomib, pegylated liposomal doxorubicin, and thalidomide).⁴⁸² The VT study treated 27 patients with bortezomib 1.3 mg/m² on days 1, 4, 8, and 11 every 21 days and thalidomide 150 mg/d for a maximum of eight cycles.⁴⁷⁸

The overall response rate was 81.5% with 25.8% near complete response or greater. The most common grade 3 toxicities were peripheral neuropathy (22%), pneumonia (15%), fatigue (7%), and anemia (7%). No venous thromboembolic events were observed even in the absence of prophylactic anticoagulation. Forty-three newly diagnosed MM patients were enrolled onto the VDT study.⁴⁸² The overall response rate and complete response (CR) + near complete response (nCR) rate were 78% and 35%, respectively. Median time to progression was 29.5 months. Fatigue, rash, neuropathy, constipation, and infections were the most common side effects.⁴⁸²

Kumar et al. built on the Rd experience by adding cyclophosphamide.⁴⁸⁷ A total of 85% of patients responded, and the toxicities were manageable with over 80% of planned doses delivered; 6 patients went off study for toxicity. The median PFS for the entire group was 28 months (95% CI: 22.7 to 32.6) and the OS at 2 years was 87% (95% CI: 78 to 96). Note that 14 patients with high-risk MM had similar PFS and OS as the standard-risk patients (n = 39).

Carfilzomib, lenalidomide, and dexamethasone⁴⁷⁹ have been used in the up-front setting with excellent response rates.⁴⁷⁹ The long-term utility of this regimen is not known, but in a phase I/II study in 53 patients with newly diagnosed MM the maximum tolerated dose was 28-day cycles of: carfilzomib 20/ 36 mg/m², days 1, 2, 8, 9, 15, 16, and 1, 2, 15, 16 after cycle 8; lenalidomide 25 mg/d, days 1 to 21; and weekly dexamethasone 40/20 mg cycles 1 to 4/5+. Most patients did not require dose modifications. Thirty-five patients underwent stem cell collection after cycle 4, and 7 proceeded to early transplant. After a median of 12 cycles (range, 1 to 25), 62% achieved at least near-complete response (CR) and 42% stringent CR. With median follow-up of 13 months, 24-month progression-free survival estimate was 92%. Grade 3/4 toxicities included hypophosphatemia (25%), hyperglycemia (23%), anemia (21%), thrombocytopenia (17%), and neutropenia (17%); peripheral neuropathy was limited to grade 1/2 (23%).

Lenalidomide, bortezomib, pegylated doxorubicin, and dexamethasone (RVDD) were tested in a phase I/II trial including 72 patients.⁴⁸⁵ The MTD was 3-week cycles of lenalidomide 25 days 1 to 14, bortezomib 1.3 mg/m² on days 1, 4, 8, and 11, and pegylated doxorubicin 30 mg/m² in day 4, and dexamethasone 20 mg days 1, 2, 4, 5, 8, 9, 11, and 12 (cycles 1 to 4, but 10 mg for cycles 5 to 8). The maximum number of treatment cycles was 8, and patients who did not go to ASCT were to receive maintenance that included lenalidomide, bortezomib, and dexamethasone indefinitely. The median treatment duration was 4.5 cycles and 15% of patients achieved stringent CR. Grade 3/4 AEs included neutropenia (19.4%), infections (14%), thrombocytopenia (11%), sensory peripheral neuropathy (6%), and thromboembolism in 3%. All grade fatigue, constipation, sensory neuropathy, and infection occurred in 83%, 69%, 65%, and 57%, respectively. The 18-month PFS for patients proceeding and not proceeding to ASCT was 93% and 64%, respectively. Although the decision of proceeding to ASCT was nonrandomized, there was a significant difference in PFS between the groups. With a median follow-up of 15 months, the 2-year OS for all patients was approximately 75%.

TABLE 98.9 CONVENTIONAL CHEMOTHERAPY VERSUS SINGLE AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION, RANDOMIZED TRIALS

	N	CR/VGPR (%)		ORR (%)		PFS, mo		OS, mo		SCT (%)

HOVON-24 ^{c 503}	303	13	28 ^a	86	90	23	24 ^a	50	55	—	—

CR/VGPR, complete response or very good partial response; ORR, any response greater than or equal to a partial response; OS, overall-survival; PFS, progression-free survival; SCT, patients known to receive an autologous hematopoietic stem cell transplant.

^a Significant.

^b Transplant arm is 2 low dose (melphalan 100 mg/m²) autologous stem cell transplants.

^c Often included in “double transplant” tables because both arms received melphalan 70 mg/m² × 2 without stem cell support as induction therapy.

There are three phase II reports of adding thalidomide to pegylated doxorubicin, and dexamethasone with^{488, 489} or without vincristine.⁴⁹⁰ Response rates were comparable. In the ThaDD trial which did not include vincristine, grade 3 to 4 infections and thromboembolic accidents were observed in 22% and 14% of patients, respectively.⁴⁹⁰ In the DVd-T and T-DVD trials grade 3 to 4 toxicities included: neutropenia (14% to 15%), thrombosis (10% to 25%), pneumonia (12%), constipation (10%), rash (5% to 8%), and peripheral neuropathy (5% to 22%). It is notable that although the ThaDD cohort⁴⁹⁰ was older and received lower doses of the thalidomide and no vincristine, similar response rates and less toxicity were seen.

Hematopoietic Stem Cell Transplantation

Autologous Transplant

To overcome resistance of the myeloma cells to conventional dose chemotherapy, McElwain and Powles²²⁰ pioneered the use of high-dose melphalan to treat MM and plasma cell leukemia. The treatment was complicated by prolonged myelosuppression. Barlogie et al.⁴⁹¹ subsequently used a regimen combining high-dose melphalan with total body irradiation supported by autologous bone marrow transplantation in MM patients refractory to VAD. Ten years hence, Attal et al. published the first prospective randomized controlled trial demonstrating an improved OS for patients undergoing high-dose therapy with autologous stem cell support compared to conventional chemotherapy.²²⁹

Although high-dose therapy followed by ASCT is not curative, it improves event-free and OS in three^{229, 492, 493} of the seven published randomized controlled trials addressing this issue,^{494, 495, 496, 497} Table 98.9. Three of the four “negative” studies are

P.2069

largely “early” versus “delayed” transplant trials, and the fourth “negative” study excludes from their randomization those patients who did not respond to induction therapy.⁴⁹⁷ Response rates with ASCT are 75% to 90%, and complete response rates are 20% to 40%.^{229, 492, 493, 494, 495, 496, 497}

In contrast to the experience with malignant lymphoma, stem cell transplantation appears to be useful for patients with primary resistant disease.^{498, 499, 500} Patients with MM, in whom first-line therapy such as VAD fails, can be sensitive to high-dose chemotherapy with stem cell reconstitution. Alexanian et al.⁴⁹⁸ reported a decrease of 75% in tumor burden in 56% of patients and a marked improvement in survival compared with matched historical controls. Kumar et al.⁵⁰⁰ also looked at stem cell transplantation in primary refractory disease and found that although there was a lower complete response rate (20% vs. 35%) in the primary refractory patients, the 1-year PFS was similar to that of patients with chemosensitive disease. The benefit of high-dose therapy is less clear among patients who fail induction with immunomodulatory agents. A more recent retrospective study from the Mayo Clinic⁵⁰¹ analyzed PFS and OS in patients who did not have a partial response (never responded or progressed during continuous therapy) after induction therapy with a regimen that included thalidomide or lenalidomide. Patients who did not achieve partial remission had a significantly shorter OS from ASCT (73.5 vs. 30.4 months) and a shorter PFS (22.1 vs. 13.1 months; P < 0.001).

As shown in Table 98.9, the Intergroupe Français du Myélome²²⁹ published the first randomized trial comparing high-dose chemotherapy followed by autologous bone marrow transplantation with conventional chemotherapy (Fig. 98.7). A total of 200 patients with previously untreated MM were randomized to receive ASCT or combination chemotherapy (CCT). The 5-year EFS (28% vs. 10%) and OS rates (52% vs. 12%) were higher in the transplantation group. An updated analysis with a median follow-up of 7 years confirmed that high-dose chemotherapy improves EFS (median, 28 months vs. 18 months), as well as OS (median, 57 months vs. 44 months).⁵⁰²

The Medical Research Council VII trial was the second published study addressing the question of CCT versus ASCT.⁴⁹² This trial included 401 randomized patients. They found that the complete response rates (8% vs. 44%), the median EFS (19 vs. 31 months), and the OS (42 vs. 54 months) all significantly favored the ASCT arm, even though only 75% of the patients assigned transplant actually received it and 15% of patients in CCT arm received salvage ASCT.

FIGURE 98.7. Conventional chemotherapy versus autologous hematopoietic stem cell transplantation, IFM 90 Trial. (With permission, Attal M, Harousseau JL, Stoppa AM, et al. A prospective, randomized trial of autologous bone marrow transplantation and chemotherapy in multiple myeloma. Intergroupe Francais du Myelome. *N Engl J Med* 1996;335:91-97. Copyright © 1996 Massachusetts Medical Society. All rights reserved.)

Three trials address the “early” versus “delayed” transplant strategy.^{494, 495, 496} The first is the MAG90 trial in which Ferman et al. demonstrate that among the 185 patients randomized to either early or late ASCT, the OS in both groups was 64 months and the percentage of the respective groups actually receiving a ASCT was 98% and 78%, respectively.⁴⁹⁵ This trial was important because it gave patients and physicians license to time their transplant either up-front or delayed. Most chose to transplant early because the time without systemic therapy (TWiST) was longer in the early than the delayed ASCT group, potentially providing better quality of life for the early transplant group. The MAG91 trial⁴⁹⁴ randomized 190 patients under the age of 56 to CCT or HSCT, but this trial ended up being another early versus late transplant trial. Only patients 55 to 65 years of age were included. EFS (19 vs. 25 months), but not OS (47.6 vs. 47.8 months) was better in the ASCT arm. Despite the 120-month follow-up, the OS statistics are confounded by the fact that only 75% of the “ASCT” arm received ASCT, and that 22% of the “CCT” received an HSCT. The intergroup trial (S9321) randomized 510 patients 70 or younger to CCT or ASCT.⁴⁹⁶ With a 76-month follow-up, 7-year OS was no different between the arms, but again only 82% of the “ASCT” group received an ASCT and 34% of the “CCT” group received an ASCT. What is quite striking in this study is the fact that at 7 years after a myeloma diagnosis, 38% of patients were still alive.

Of note, there are no prospective randomized clinical trials addressing the “early versus late” question in the context of up-front IMiDs and proteasome inhibitors. One retrospective study tried to address this question and found that in ASCT-eligible patients who received IMiDs as initial therapy followed by early stem cell mobilization, delayed ASCT results in

similar OS compared with early ASCT. It was noteworthy that an excellent 4-year survival rate of >80% was observed among ASCT-eligible patients who received initial therapy with lenalidomide and dexamethasone regardless of the timing of ASCT.⁴⁷⁶

The Spanish Cooperative Group prospective trial is dissimilar from the other randomized trials in that only those patients responding to therapy were randomized. At enrollment, 216 patients were treated initially with four cycles of VBMCP and VBAD (vincristine, carmustine, doxorubicin, and dexamethasone),⁴⁹⁷ and only 164 were randomized to receive eight additional courses of chemotherapy versus ASCT. There was no difference between the groups with respect to complete response rate, overall response rate, PFS, or OS. These data are discordant from the other ASCT trials, but can be interpreted in two possible ways: one, patients who achieve response with alkylator-based induction do not require consolidation with ASCT; or two, with longer follow-up and more events (i.e., deaths), an OS difference will be seen.

The MMSG97 trial was unique in that it randomized patients aged 50 to 70 years of age to either MP or two half-dose melphalan transplants.⁴⁹³ Patients receiving MP had significantly worse outcomes. A significant difference between two low-dose ASCT and MP was not seen in the IFM 999-06 trial.²⁴⁹

The Hovon-24 trial is commonly grouped in the “single versus double” transplant category, although it is actually an “intensified chemotherapy without transplant” versus “intensified chemotherapy followed by high dose chemotherapy and a single ASCT.”⁵⁰³ There was a significantly higher complete response rate and EFS in the more intensive treatment arm. The differences in EFS, PFS, and TTP were not seen until 4-year follow-up had been reached. The authors reported that the lack of difference in OS was likely due to a “high proportion” of patients from the control arm receiving ASCT at first relapse.

P.2070

It should be noted that all randomized studies of ASCT were designed and implemented before the availability of thalidomide, lenalidomide, and bortezomib. Therefore the role of transplant may evolve in the future. Studies are ongoing to evaluate whether prolonged treatment with bortezomib, lenalidomide, and dexamethasone (VRD) followed by lenalidomide maintenance is superior to induction chemotherapy followed by ASCT.

Single versus Double Transplantation

As the evidence was mounting that one course of dose-intensified chemotherapy with ASCT was superior to conventional chemotherapy, investigators began experimenting with applying two consecutive ASCT. The concept of double or tandem transplant was promulgated by Dr. Barlogie and colleagues at the University of Arkansas.^{329, 504, 505, 506} These investigators reported high complete response rates and survival.^{329, 504, 505, 506} In the first report of “Total Therapy 1” which included 231 patients with newly diagnosed myeloma, the OS with this approach was 68 months.³²⁹

The largest and most mature randomized trial comparing single transplant to double ASCT was the IFM 94 study (Table 98.10). They found no difference in EFS or OS between double and single ASCTs after 2 years of follow-up⁴⁸⁴; however, by 4 years and beyond, an OS benefit was detected.⁴⁸¹ Although the response rate was not significantly different between the two groups (complete response and very good partial response, 42% in the single-transplant arm vs. 50% in the double-transplant group, $P = .15$), both EFS (25 vs. 30 months) and OS (48 vs. 58 months) were improved in the double-ASCT arm. The respective 7-year OS (21% vs. 42%) and EFS rates (10% vs. 20%) also significantly favored the double-ASCT group (Fig. 98.8 REALLY 98.8).⁵⁰⁷ In this trial, four factors were associated with a longer survival: low β_2 -microglobulin levels at diagnosis ($P < 0.01$), young age ($P < 0.05$), low lactate dehydrogenase (LDH) at diagnosis ($P < 0.01$), and the treatment arm to which the patient was assigned ($P < 0.05$). When the authors did an unplanned subgroup analysis, they found that patients who benefited most from the tandem ASCT were those who did not achieve a very good partial response or better after their first ASCT. Cavo et al.⁴⁸² have made similar observations based on preliminary data, including the benefit of a second ASCT being limited to those patients who do not achieve a very good partial response or better after their first ASCT. Most patients under the age of 65 years should have enough stem cells collected for at least two transplants.

A meta-analysis was done comparing single ASCT to tandem ASCT for patients with MM.⁵⁰⁸ Included were 1,803 patients enrolled in six randomized controlled trials. Patients treated with tandem ASCT did not have a better OS or EFS than patients treated with a single ASCT. Some of this difference may be in part related to patients receiving a second ASCT at relapse. Table 98.11 illustrates post-second ASCT performed in the salvage setting; patients can enjoy median OS rates

ranging from 19 to 53 months.^{509, 510, 511, 512, 513, 514, 515, 523, 524} Factors affecting OS included time to progression after first ASCT, number of prior lines of therapy, and chemosensitivity at time of second ASCT.

Hematopoietic Stem Cell Collection

Autologous peripheral blood stem cell transplantation has replaced autologous bone marrow transplantation because engraftment is more rapid and there is less contamination with myeloma cells.^{525, 526, 527} Hematopoietic stem cells should be collected before the patient is exposed to alkylating agents^{528, 529} because prolonged melphalan exposure leads to an impaired harvest of peripheral blood stem cells when stem cells are mobilized with chemotherapy plus growth factors⁵³⁰ or growth factors alone.⁵³¹ Data also suggest lenalidomide exposure may have adverse effects on the ability to collect stem cells.⁵³² This appears to be related to the duration of lenalidomide therapy as well as the age of the patient. For this reason, early mobilization of stem cells, preferably within the first four cycles of initial therapy, is now recommended.⁵³³ Stem cell mobilization for myeloma patients is primarily performed using filgrastim granulocyte-colony stimulating factor alone or after cyclophosphamide chemotherapy. The target CD34⁺ cell dose to be collected as well as the number of apheresis performed varies by center, but a minimum of 2 million CD34⁺ cells/kg has been traditionally used for the support of one cycle of high-dose therapy.⁵³⁴ In the setting of ASCT, CD34⁺ cell doses of >3 million/kg have been associated with better outcomes, primarily due to faster hematologic recovery and lower incidence of infectious and bleeding complications.^{535, 536} The use of plerixafor in conjunction with filgrastim has enhanced the ability to mobilize successfully the majority of patients undergoing ASCT. Plerixafor is a novel stem cell mobilizing agent. It is a bicyclam molecule that inhibits the SDF-1 alpha/CXCR4 binding that occurs between CD34⁺ stem cells and the marrow stroma. The inhibition of this interaction results in the release of CD34⁺ stem cells into the bloodstream facilitating their collection through apheresis methods.⁵³⁷

Historically, all peripheral blood cell products have been shown to be contaminated with malignant cells.^{538, 539} Purging marrow with cyclophosphamide derivatives⁵⁴⁰ or with monoclonal antibodies^{541, 542, 543} is feasible although associated with prolonged myelosuppression after transplantation. CD34⁺ selection of peripheral blood progenitor cells provided effective hematopoietic support in a group of 55 patients with advanced MM after myeloablative chemotherapy.⁵⁴⁴ However, two phase III randomized trials have shown no clinical benefit to using CD34⁺ selected autologous peripheral blood stem cells.^{545, 546} Moreover, the risk of infection was higher in the CD34⁺ selected group.⁵⁴⁶

Autologous Hematopoietic Stem Cell Transplantation in Special Populations

The mortality rate from ASCT is currently less than 5%. Age older than 65 years alone is not a contraindication for transplantation, although there are no randomized data proving or disproving its utility in this age group. Such patients are candidates for transplantation if they have good functional status and limited comorbidities.^{547, 548} Patients with renal failure, including dialysis patients can successfully undergo ASCT with melphalan 140 mg/m², with similar response rates and PFS, and a proportion will even have reversal of their renal failure. Treatment-related morbidity is higher,⁵⁴⁹ and their OS is inferior to their dialysis-independent counterparts.^{550, 551}

Conditioning Therapy and Stem Cell Transplantation

In an effort to improve ASCT, various preparative regimens have been used. There has been only one prospective randomized controlled trial comparing conditioning regimens in patients with myeloma.⁵⁵⁴ Moreau et al.⁵⁵⁴ randomized 282 patients to receive either melphalan (140 mg/m²) plus total body irradiation or melphalan alone (200 mg/m²). There was no difference in response rates or EFS. Survival at 45 months favored the melphalan alone arm (65.8% vs. 45.5%, P = 0.05). Toxicity with melphalan alone was significantly less. Most investigators have now discontinued the use of total body irradiation and give only melphalan (200 mg/m²) as the preparative regimen.

^b Number of lines of therapy affected OS.

^c VGPR or CR after salvage affected OS.

^d Included allogeneic transplant patients.

Other regimens including various combinations of melphalan, busulfan, cyclophosphamide, idarubicin, etoposide, and/or thiotepa have been used,^{555, 556, 557, 558, 559, 560} without any evidence of superiority of these regimens over melphalan 200 mg/m² and several with significantly more toxicity^{556, 560} and morbidity.⁵⁵⁵ Innovative trials supplementing melphalan with skeletal targeted radiation (samarium 153-ethylenediaminetetramethylene phosphonate⁵⁶¹ and holmium 166 to 1,4,7,10-tetraazocyclodecane-1,4,7,10-tetramethylenephosphonic acid⁵⁶²) have been reported. Others have been studying bortezomib as a chemosensitizer for the melphalan.^{563, 564, 565}

P.2072

Desikan et al. retrospectively compared the impact of different conditioning regimens used for the second ASCT.⁵⁶⁶ Outcomes of patients treated with melphalan 200 mg/m² were better than those conditioned with melphalan 200 mg/m² plus cyclophosphamide 120 mg/m², and melphalan 140 mg/m² plus total body irradiation (1,125 cGy).

Allogeneic Stem Cell Transplantation

AlloSCT includes both myeloablative and nonmyeloablative or “reduced intensity conditioning” (RIC) transplants. AlloSCT is appealing in theory because it avoids infusion of stem cells contaminated with myeloma cells and because there can be a beneficial graft versus myeloma effect.⁵⁴⁷ Complete response rates of 22% to 67%, including molecular remissions in about one third,^{495, 548, 549} can be achieved. Prolonged PFS is observed in approximately one quarter to one third of patients^{471, 495, 550} (Table 98.12). The high treatment-related mortality (10% to 63%) and significant toxicity from graft-versus-host disease have limited the role of this procedure in the treatment of myeloma.^{495, 551, 554}

Myeloablative Allogeneic Stem Cell Transplantation

There are no prospective randomized controlled trials that examine the role of myeloablative AlloSCT in myeloma. The US intergroup trial S9321⁴⁹⁶ attempted to answer this question. Newly diagnosed patients with MM were treated with four cycles of VAD. Patients were randomly assigned to either high-dose therapy with melphalan (MEL) plus total body irradiation (TBI) or to standard dose therapy with VBMCP. Patients who were ≤55 years of age with an HLA-compatible sibling donor were offered the option of allogeneic transplantation with MEL 140 mg/m² plus TBI. However, this arm was closed when an excessive first-year treatment-related mortality rate of 53% was observed after enrollment of 36 eligible patients. With 7 years of follow-up the OS of the conventional chemotherapy, autologous and allogeneic transplant groups were identical at 39%. It was intriguing that that AlloSCT group showed a survival plateau whereas the other two groups did not, suggesting long-term benefit.

There have been seven case-control or cohort-control studies comparing autologous to AlloSCTs (Table 98.12).^{558, 559, 560, 561, 562, 563, 564} The largest of these was by Bjorkstrand et al.⁵⁵⁸ In their retrospective analysis of data compiled by the European Blood and Marrow Transplantation Group, there was inferior OS for myeloma patients treated with AlloSCTs compared to case-matched controls treated with ASCT (18 vs. 36 months).⁵⁵⁸ The six smaller studies, which had relatively short follow-up, showed mixed results with regard to PFS and OS; transplant-related mortality, however, was consistently higher in the allogeneic groups (19% to 25%). Only one report favored allogeneic transplantation.⁵⁶⁴ However, patients in the AlloSCT group were better-prognosis patients; they were significantly younger and less likely to have IgA myeloma. Although not reaching statistical significance, there were more ASCT patients having their transplant as salvage (37% vs. 23%). In addition, cyclophosphamide and TBI were used to condition both the ASCT and AlloSCT patients. With follow-up times for the two groups of 24 and 43 months, respectively, the 1-year OS was 86 and 64%, and the 4-year OS was 50% and 64%.

Reduced Intensity Conditioning Allogeneic Stem Cell Transplantation (Table 98.13)

Another strategy is to use ASCT to cytoreduce the myeloma followed by a reduced intensity conditioning alloSCT (allo-RIC). After two large series reported encouraging results,^{567, 568} four prospective trials have looked at this approach (Table 98.13). Only one of the five trials noted improved OS in patients undergoing tandem auto/allo transplants. Graft-versus-myeloma effect appears to be tightly linked to graft-versus-host disease (Fig. 98.9),⁵⁶⁹ which has the potential to significantly affect quality of life.

Bruno and colleagues^{570, 571} enrolled 162 consecutive patients with newly diagnosed myeloma who were ≤65 years of age. All patients were initially treated with VAD, followed by high-dose melphalan and ASCT. Patients without an HLA-identical sibling received a second ASCT. Patients with an HLA-identical sibling then received nonmyeloablative TBI and stem cells from the sibling. The median OS was longer in the 80 patients with HLA-identical siblings than in the 82 patients without HLA-identical siblings (80 months vs. 54 months, P = 0.01).

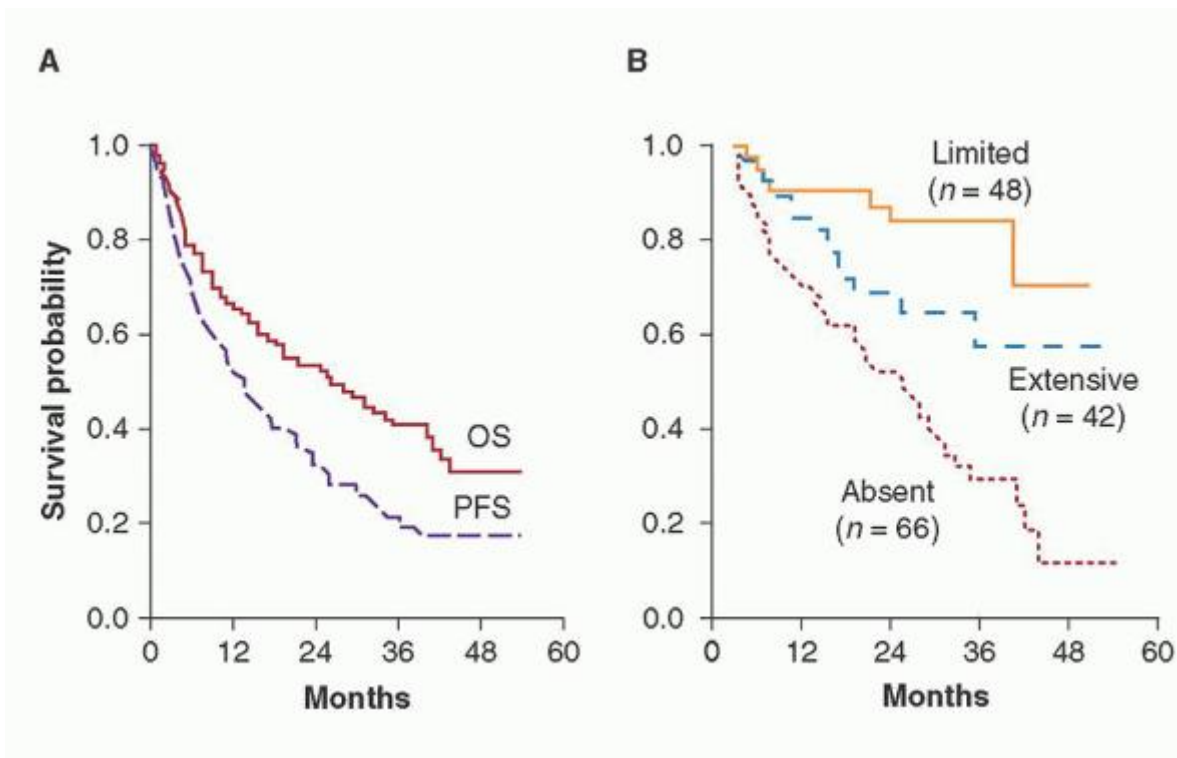

FIGURE 98.9. European blood and marrow transplantation registry data on the role of reduced intensity conditioning allogeneic transplantation regimens. A: Overall and progression free survival. B: Overall survival relative to presence or absence of graft versus host disease. (From Crawley C, Lalancette M, Szydlo R, et al. Outcomes for reduced-intensity allogeneic transplantation for multiple myeloma: an analysis of prognostic factors from the Chronic Leukaemia Working Party of the EBMT. *Blood* 2005;105:4532-4539. Copyright © the American Society of Hematology.)

The IFM enrolled 503 patients with high-risk MM (beta2-microglobulin level greater than 3 mg/L and chromosome 13 deletion at diagnosis) in two clinical trials.⁵⁷² In both protocols, the induction regimen consisted of VAD followed by first ASCT prepared by melphalan 200 mg/m². Patients with an HLA-identical sibling donor were subsequently treated with allo-RIC (IFM99-03 trial), and patients without an HLA-identical sibling donor were randomly assigned to undergo second ASCT prepared by melphalan 220 mg/m² and 160 mg dexamethasone with or without anti-IL-6 monoclonal antibody (IFM99-04 protocol). There were 284 patients enrolled in the IFM99-03 trial and 219 in the IFM99-04 trial. There were no differences in OS or EFS.

The PETHEMA group enrolled 110 patients with MM who had failed to achieve at least near-complete remission (nCR) after a first ASCT.⁵⁷³ They received a second ASCT (85 patients) or a allo-RIC (25 patients), depending on the availability of an HLA-identical sibling donor. Those who received the allo-RIC had higher rates of complete remission (40% vs. 11%, $P = 0.001$) but no difference in EFS and OS. They noted a 66% incidence of chronic GVHD. The European Bone Marrow Transplant (EBMT), MM subcommittee

P.2074

enrolled 357 patients up to age 69. Patients with an HLA-identical sibling were allocated to the ASCT- allo-RIC arm and the remaining to a tandem ASCT arm. Complete response rates were higher in the ASCT- allo-RIC group as was PFS, but there was no difference in OS with a median follow-up of 61 months. Only 41% of patients in the tandem ASCT arm actually got a second ASCT whereas 85% of patients in the ASCT-allo-RIC group received their second transplant.

The Blood Marrow Transplant Clinical Trials Network (BMT CTN) enrolled 710 patients⁵⁷⁴ and biologically randomized them to tandem ASCT or ASCT- allo-RIC. They, too, noted no difference in OS or PFS.

Given the toxicity of this approach—rates of chronic graft-versus-host disease of 50%—and the lack of suitable donors, allogeneic transplant, whether myeloablative or RIC, should be considered experimental in patients with myeloma.

Donor Lymphocyte Infusions

A graft-versus-myeloma effect has been noted after the administration of donor peripheral blood mononuclear cells for relapse after allogeneic transplantation.^{575, 576} DLI has been used in two ways in myeloma patients. Initially, it was used to treat relapsed or residual disease after full myeloablative AlloSCT.^{575, 576} Subsequently, it was used to re-introduce T-cells into a patient who had received an allogeneic T-cell depleted graft.^{577, 578} Most recently, it has been implemented in the context of allo-RIC programs to treat mixed chimerism, as well as for the older inductions.^{579, 580, 581} In the largest DLI series for relapsed MM (n = 54), 52% of patients responded (35% with a partial response and 17% with a complete response). The majority of patients received some chemotherapy before DLI. PFS and OS were 19 and 23 months, respectively. Rates of overall acute GVHD and of grade III-IV acute GVHD were 57% and 20%, respectively. Rates of overall chronic GVHD and of extensive GVHD were 47% and 30%, respectively. Acute and chronic graft-versus-host disease following DLI were the strongest predictors for response.⁵⁸²

Maintenance Therapy

Strategies for maintenance therapy can be divided into two broad categories: continued induction therapy ad infinitum, and addition of a novel therapy after induction therapy. The former strategy was prevalent until recognition of the risk of developing alkylator-induced myelodysplastic syndromes and leukemia.^{583, 584, 585, 586, 587, 588} The latter strategy has predominantly applied immune modulators, including prednisone, IFN, cellular therapies, thalidomide, lenalidomide, and, most recently, bortezomib. To date, the benefit with these aforementioned strategies has been marginal at best, but for several of the agents, more study is required. The role of maintenance thalidomide, lenalidomide, and bortezomib are currently areas of both study and controversy as discussed below. No benefit has been observed with maintenance levamisole,^{257, 381} azathioprine,⁵⁸⁹ or bacillus Calmette-Guérin (BCG).⁴¹⁴

Maintenance Thalidomide

In terms of randomized controlled trials evaluating the role of thalidomide maintenance as compared to placebo or prednisone, there have been seven performed in the post-ASCT setting^{404, 463, 464, 574, 590, 591, 592} and another three in the setting of low-dose alkylator-based therapy^{390, 392, 393, 404} (Table 98.14). In toto in all of the post-ASCT trials there was a PFS benefit among patients receiving maintenance thalidomide, but there was an OS benefit in only two of these trials.^{590, 591} Quality of life was significantly worse among patients receiving thalidomide in the NCIC CTG-MY.10 trial.⁵⁹²

Among the four nontransplant trials,^{390, 392, 393, 404} there was improvement in PFS in three of the trials, but an OS benefit in only one.³⁹³ Three of these four nontransplant trials not only tested the value of maintenance thalidomide, but also used it as part of an induction triplet of MPT.^{390, 392, 393} Due to this design limitation, it is impossible to state whether the induction component or the maintenance component contributed to any differences in outcomes. The MRC IX trial,⁴⁰⁴ which compared attenuated CTD to MP, had a double randomization, so the effect of induction versus maintenance could be more easily separated. Although there was a modest improvement in PFS in this study (11 vs. 9 months), there was no difference in OS between the maintained and the nonmaintained groups.

Maintenance Lenalidomide (Table 98.14)

There are three randomized controlled trials evaluating lenalidomide maintenance (Table 98.14). The most experience, however, with lenalidomide maintenance is the continuous use of lenalidomide plus dexamethasone as the primary induction therapy without early transplant. All published studies evaluating this up-front combination have continued drug until ASCT or progression, and there are currently no studies that challenge this practice. The MM-020 trial, which has completed accrual, will in part address this question.

The use of the drug as maintenance after alkylator-based therapy has been addressed in three randomized controlled trials.^{398, 593, 594} The first of these is the MM-015, which randomized patients among three arms: MP, MPR, and MPR with lenalidomide maintenance.³⁹⁸ PFS was superior in the maintenance arm, but so far there is no difference in OS. The authors note that the greatest benefit was observed in those patients aged 65 to 75 years. Slightly more than twice as many secondary malignancies were seen in the lenalidomide maintenance arm.

The next two randomized controlled trials addressing lenalidomide maintenance are after ASCT. Both show improved PFS and a higher rate of secondary malignancies with maintenance lenalidomide,^{593, 594} but only the CALGB 100404 trial had a better OS (3-year OS 88 vs. 80 months, P = 0.03).⁵⁹⁴ However, this OS advantage did not persist when the arms were stratified for beta-2 microglobulin and prior thalidomide use. A limitation to the CALGB 100404 trial is that in December 2009 (enrollment was April 2005 to July 2009), the study-drug assignments were unblinded when a planned interim analysis revealed a superior PFS in the lenalidomide arm. Patients who had been on placebo were encouraged to cross over to the lenalidomide. In contrast, in the IFM 2005-02 study,⁵⁹³ the 4-year OS was 73% for the maintenance group and 75% for the placebo group. The duration of maintenance in this study was limited to 2 years once their data safety monitoring board noted a higher cumulative incidence of secondary malignancies in the lenalidomide arm. At last follow-

up the incidence of second primary cancers was 3.1 per 100 patient-years for the lenalidomide arm as compared to the 1.2 per 100 patient-years for the placebo arm, P = 0.002. Another difference between the IFM 2005-02 study and the CALGB 100404 study is that all patients received two cycles of lenalidomide upon post-ASCT registration prior to getting either placebo or lenalidomide.⁵⁹³ At this time no definitive recommendation regarding lenalidomide maintenance can be made.

Maintenance Strategies Incorporating Bortezomib

There are four randomized clinical trials that incorporate bortezomib into a maintenance strategy.^{397, 400, 467, 468} Due to the complexity of these trials, however, it is difficult to isolate the actual clinical benefit of the bortezomib maintenance. The first of the two ASCT trials was the HOVON-65/GMMG-HD4 trial,⁴⁶⁷ which randomized patients to either PAD induction followed by one or two ASCT followed by maintenance bortezomib every other week for 2 years versus VAD induction followed by one or two ASCT followed by thalidomide maintenance for 2 years. Although OS was superior (5-year OS 61% vs. 55%) in the bortezomib containing arm, it is impossible to isolate the

P.2075

effect of induction versus maintenance. Moreover, there was no information regarding the availability of salvage bortezomib in the VAD plus thalidomide arm. The other post-ASCT trial is the PETHEMA/GEM05MENOS65 trial,⁴⁶⁸ which is a complicated study of 387 patients who were randomized to one of three induction regimens followed by an ASCT followed by a secondary randomization to bortezomib (1.3 mg/m² days 1, 4, 8, and 11 every 3 months) plus thalidomide (100 mg/day), to single-agent thalidomide, or to thrice weekly IFN. PFS was superior with the VT as compared to the T or the IFN, but with 24 months follow-up there was no difference in OS.

TABLE 98.14 RANDOMIZED CLINICAL TRIALS INCORPORATING IMIDS OR BORTEZOMIB FOR MAINTENANCE

	Trial Design ^a	N	Initial Intended Dose, mg	Months of Maintenance	FU, mo	EFS PFS	OS, %	% Getting Maintenance Drug as Salvage

ASCT, autologous stem cell transplantation; f/u, follow up; mo, months; MP, melphalan and

prednisone; MPT, MP and thalidomide; MS, median survival; NA, not available; OS, overall survival; Thal, thalidomide.

^a Induction regimens for trial design not specified if same in both arms. If no comparator maintenance drug listed, the comparator is either nothing or placebo.

^b Statistically significant difference between arms.

^c Risk of death 1.8 × higher in patients with adverse cytogenetics if thal.

^d Other details of this study included in Table 97.8.

^e Received thalidomide or bortezomib; number of patients in control arm receiving thalidomide as salvage not specified.

The other two bortezomib maintenance trials were among elderly patients, who did not undergo ASCT. The first is the PETHEMA/GEM trial,⁴⁰⁰ which randomized newly diagnosed elderly patients to either VMP or VTP with a secondary randomization to either VT or VP. After a median follow-up of 22 months from second randomization, PFS from this timepoint was 32 months for patients receiving VT and 24 months for those receiving VP (HR 1.4, 95% CI 0.8 to 2.1; P = 0.1). No difference in OS was observed. In the Italian study comparing VMP with no maintenance to VMPT plus VT maintenance,³⁹⁷ PFS was superior with the four-drug combination with two-drug maintenance compared to the three-drug regimen without maintenance (32 months vs. 24 months), but there was no difference in OS. Based on these data, no recommendation regarding the utility of bortezomib maintenance can be provided.

Maintenance with Alkylators, Steroids, or Interferon

Through the 1970s and 1980s, several randomized studies established that alkylator-based maintenance therapy does not produce a survival benefit.^{210, 236, 264, 266, 376, 411, 589, 595, 596} In general, patients not receiving maintenance had similar to slightly shorter remission duration than those receiving maintenance^{210, 376, 411, 589, 596, 597} but had higher rates of second remission.^{596, 597} Induction was commonly discontinued after plateau was reached (no change in M protein of more than 25% for 4 to 6 months).^{210, 264, 598} With alkylator-based therapy, the ability to achieve a plateau is as important, if not more important, than the degree of response achieved.^{210, 598, 599, 600, 601, 604} No benefit has been documented for treatment beyond 12 months,³⁷⁶ although it has been suggested—but not validated—that prolonged primary

P.2076

chemotherapy may be beneficial in patients achieving less than a partial response, that is, a minimal response or stable disease.⁶⁰⁵ Patients who relapse off alkylator-based chemotherapy have response rates of 25% to 80% with resumption of the original regimen.^{210, 414, 596, 597} In a study of 115 newly diagnosed patients treated with VBMCP for about 1 year, an initial response rate of 82% was achieved, with a median duration of response of 22 months. After a first relapse, 26 of 38 patients (68%) responded again and had a median duration of response of 11 months. After a second relapse, 7 of 16 patients (44%) responded, with a duration of response of 3.5 months.⁶⁰⁶

There are four studies that address the utility of corticosteroids as maintenance therapy. None justify a recommendation of prednisone as a standard maintenance regimen for all patients.

SWOG 9210 compared prednisone 10 mg every other day to prednisone 50 mg every other day in patients who had responded to 6 to 12 months of a VAD-based program, that is, a corticosteroid-intensive program. Median PFS for the higher-dose prednisone arm was 14 months compared to 5 months for the lower dose (P = 0.003). OS also was marginally better at 37 and 26 months (P = 0.05).⁶⁰⁷ An earlier randomized study, which compared dexamethasone maintenance (20 mg/m² orally daily for 4 days repeated monthly) to IFN maintenance after induction with melphalan and dexamethasone, demonstrated equivalence to inferiority of dexamethasone compared with IFN.⁶⁰⁸ The CALGB 7,461 study addressed this issue less directly. Patients were treated initially with alkylator therapy and were randomized to observation or vincristine and prednisone as maintenance. OS and response rates were significantly longer and higher in the vincristine-prednisone maintenance group who had received up-front melphalan (median, 35.3 months vs. 27.0 months; P = 0.003) but not in patients who had received up-front BCNU or CCNU.²⁵⁵ Finally, SWOG 8624, which evaluated the influence of corticosteroid dose intensity on response and survival, indirectly provided data on corticosteroid maintenance. Higher objective

response and median OS (40 months vs. 31 months, $P = 0.02$) were observed in patients who received prolonged administration of glucocorticoids (prednisone 50 mg every other day) between chemotherapy courses.⁴⁵⁴

IFN has been studied both after conventional chemotherapy and after ASCT. The initial positive findings by Mandelli et al.⁶⁰⁹ in 1990 demonstrated a superior disease-free and OS in chemotherapy-responsive patients randomized to maintenance IFN, but it took meta-analyses to clarify divergent results observed in over 1,500 patients in 13 maintenance trials.^{439, 440} With IFN there was a 4.4-month prolongation of relapse-free survival ($P < 0.01$) and a 7.0 month increase in OS ($P < 0.01$).⁴³⁹ There are fewer data available examining the utility of IFN after ASCT.^{610, 611} The use of IFN in this setting cannot be recommended outside of clinical trials.

Management of Relapsed or Refractory Disease

The advances in the initial therapy of MM during the past decade has led to more effective control of the disease early in its course and has significantly improved the OS of these patients. However, the disease remains incurable with the current approaches and eventually relapses after the initial therapy. The combination of improved OS and the inability to eliminate the disease has led to an increased number of patients living with the disease, making the management of relapsed disease an important component of the care of the myeloma patient.

At the same time, the increasing number of initial treatment approaches employed for myeloma has led to a significant heterogeneity among patients with relapsed MM. This combined with the underlying biologic heterogeneity intrinsic to the disease has precluded development of uniform approaches to management of relapsed disease. Recent studies using advanced genomic analyses have clearly shown that significant clonal evolution as well as clonal selection occurs as the disease suffers multiple relapses over time.

Definitions

Attempts have been made to standardize the definitions for relapsed and refractory disease. In general, relapses can be classified as biochemical relapses where the increase in the monoclonal protein component, bone marrow plasmacytosis, or size of plasmacytoma(s) meet the definitions of relapse as per the International Myeloma Working Group Uniform Response Criteria.²²² However, a significant proportion of patients who meet these criteria do not require therapy right away, a concept similar to how we manage early-stage asymptomatic myeloma. However, patients can have clinical evidence of progression, that may or may not satisfy the biochemical criteria, but clearly require therapeutic intervention. These typically include development of one or more components of the CRAB criteria that is used at the time of diagnosis. Several additional qualifying criteria need to be included in defining the patient with relapsed disease. This is not only important from a clinical trial perspective, allowing us to better compare results across different trials, but also helps us in deciding the future course of therapy. The most important aspect is the differentiation between relapses occurring on therapy and off therapy, with the former often having a poorer prognosis. An accepted definition for refractory disease, currently used in most of the clinical trials, is relapse occurring while on a particular therapy or relapse within 60 days of stopping the therapy. A subset of these patients may have never responded to the initial therapy or may have progressed within 60 days of stopping the initial therapy, a group referred to as having primary refractory disease.⁶¹² These definitions should be further qualified by the class of agents or the treatment modality to which the patient is refractory.

Prognostic Factors in Relapsed Disease
