Chapter 12

B Lymphocytes

Frixos Paraskevas

ONTOGENY

Pluripotential stem cells give rise to all hematopoietic lineages, undergoing asymmetric division, i.e., one daughter cell follows a pathway of differentiation, whereas the other remains as a self-renewing stem cell. Depending on their interaction with the appropriate stromal cells, as well as growth and differentiation factors, stem cells differentiate into various lineages including B and T lymphocytes. Their differentiation is guided by the type of stromal elements to which they are exposed; i.e., in the thymic microenvironment they develop as T cells, whereas in contact with bone marrow-derived stromal cells they develop as B lymphocytes or myeloid cells. Multiple checkpoints ensure proper differentiation of precursor to mature B lymphocytes, and several have been found disrupted in patients with primary immunodeficiency. The differentiation of the B cell involves critical processes divided into two periods; the first from stem cell to immature Ig-M⁺ B cell is antigen-independent, while the second period from immature B cell to plasma cell is antigen-dependent. The first period is subdivided into two stages: from stem cell to progenitor B (pro-B) cell and from pro-B cell to immature Ig⁺ B cell. Differentiation has been studied in animals and humans with cells obtained from different stages of development (embryonic as well as adult) and with cells from patients with lymphoproliferative disorders, which are considered “frozen windows” of normal differentiation. This approach, however, is not accepted universally because evidence from acute leukemias suggests the existence of some degree of asynchronous maturation with phenotypes not found normally.¹

STEM CELL TO PROGENITOR B CELL

See Figure 12.1

Transcriptional Regulation

Hematopoiesis is coordinated by several genes that orchestrate multiple cell interactions which release growth and differentiation factors.² More than eight specific cell lineages have been identified which differentiate from pluripotent stem cells, guided through a well-defined hierarchical sequence to mature functional cells.³

During fetal life lymphopoiesis takes place in the yolk sac and liver and after birth in the bone marrow.⁴ “Master” genes regulate differentiation of lineages through transcription factors which activate target genes, progressively narrowing their differentiation potential to specific lineages,³ and which coordinate the various stages of lymphocytic development.^{5,6,7,8} A common progenitor gives rise to separate myeloid and lymphoid progenitors, and the latter to lymphocytic lineages B, T, natural killer (NK), and dendritic cells (DC).

Normal development of lymphopoiesis depends on the Ikaros family of transcription factors, which regulate lymphocytic development. The Ikaros gene (IKZF1) encodes a zinc finger protein (ZFP), which is a transcription factor expressed by B and T cells at different stages of differentiation (except plasma cells).⁹

A long-standing goal of molecular biology has been the construction of DNA-binding proteins for the control of gene expression by using the classical Cys2-His2 design of a ZFP, ideally suited for such purposes; and it was adopted for discriminating genes with closely related DNA sequences.¹⁰ The classical ZFs are one of the most common protein domains in higher eukaryotes widely used in zinc finger nucleases (ZFN) and are currently used in human clinical trials with an aim of therapeutic gene editing. ZFPs are nucleases designed to cut at specific DNA sequences and are becoming powerful tools in gene targeting to replace a gene within a genome by homologous recombination (HR), or to permanently modify plant and mammalian genomes, including the human genome. They were developed and used in *Drosophila*, rats, and zebra fish to generate modified organisms with genotargeted mutations and/or deletions.

This brief review emphasizes the point that Ikaros is a master regulator of gene expression and chromatin remodeling, and its biologic roles include regulation of the development and function of the immune system and overall even the hematopoietic differentiation.

The Ikaros^{-/-} mice have a complete block of B-cell differentiation, with lack of pro-B and precursor B (pre-B) cells in fetal liver and bone marrow. The Ikaros gene generates eight protein isoforms by alternative splicing and some of them bind, through the N-terminal ZFP motif, to DNA sequences which contain GGGGA core motifs. This family of DNA-binding proteins, restricted to lymphocytes, are highly conserved in humans and mice and regulate the expression of other genes. They are localized in the nucleus of most primitive hematopoietic stem cell subsets, particularly at two stages: (a) long-term self-renewing stem cells and (b) multipotent progenitors, which are not self-renewing, but able to differentiate into lymphoid-committed progenitors.¹¹ The isoforms detected in hematopoietic stem cells differ from those detected in lymphoid progenitors, but all of them share two C-terminal zinc fingers that mediate their self-association, forming multiple heteromeric complexes. Other members of the Ikaros family (i.e., Aiolos and Helios) encode transcription factors that form multimeric complexes with Ikaros.¹²

The Ikaros gene is required not only for the early stages of lymphocytic differentiation but also for late stages, especially in T-cell maturation. It exerts multiple regulatory functions by recruiting repressor complexes, or what are known as

chromatin remodeling machines, an unconventional function of transcription factors. IKAROS is also needed for the maintenance of B cells by regulating BCR signaling, and importantly overall it acts as a master regulator of hematopoietic differentiation and as a tumor suppressor in acute lymphoblastic leukemia (ALL), especially forms of the disease associated with poor prognosis.¹³

The transcription factor PU.1 acts at the pluripotent level of myeloid-lymphoid progenitors, and its expression maintains the hematopoietic progenitor pool by supporting the generation of the earliest lymphoid and myeloid progenitors.¹⁴

It regulates early B-cell development by activating the IL7R α gene, rendering B-cell progenitors responsive to appropriate differentiation signals, and thus promoting differentiation to the pro-B-cell stage. Among the three main B-cell populations, B-1, B-2 (follicular), and marginal zone B cells, PU.1 directs differentiation toward the B-2 subpopulation¹⁵ and enhances the activity of other transcription factors, i.e., the interferon (IFN)-regulatory factor. The B-1 and B-2 B cells which are involved in innate and adaptive immune responses, respectively, arise from distinct progenitors.¹⁶

The TCF3 (previously E2A) gene is important for lymphocytic differentiation encoding two proteins, E12 and E47 of the basic helix-loop-helix family by differential splicing. The proteins encoded by TCF3 bind uniquely to the DNA of B cells as homodimers¹⁷ and are essential for the coordination of Ig gene

P.253

rearrangements;¹⁸ therefore in their absence B-cell differentiation is blocked before entrance into the pro-B-cell stage. The basic region mediates DNA binding, whereas the HLH domain is required for protein dimerization. The E12 targets the genes of the early B-cell factor (EBF)¹⁹ and the Pax5,²⁰ directing differentiation along B lineage while it blocks myeloid differentiation.

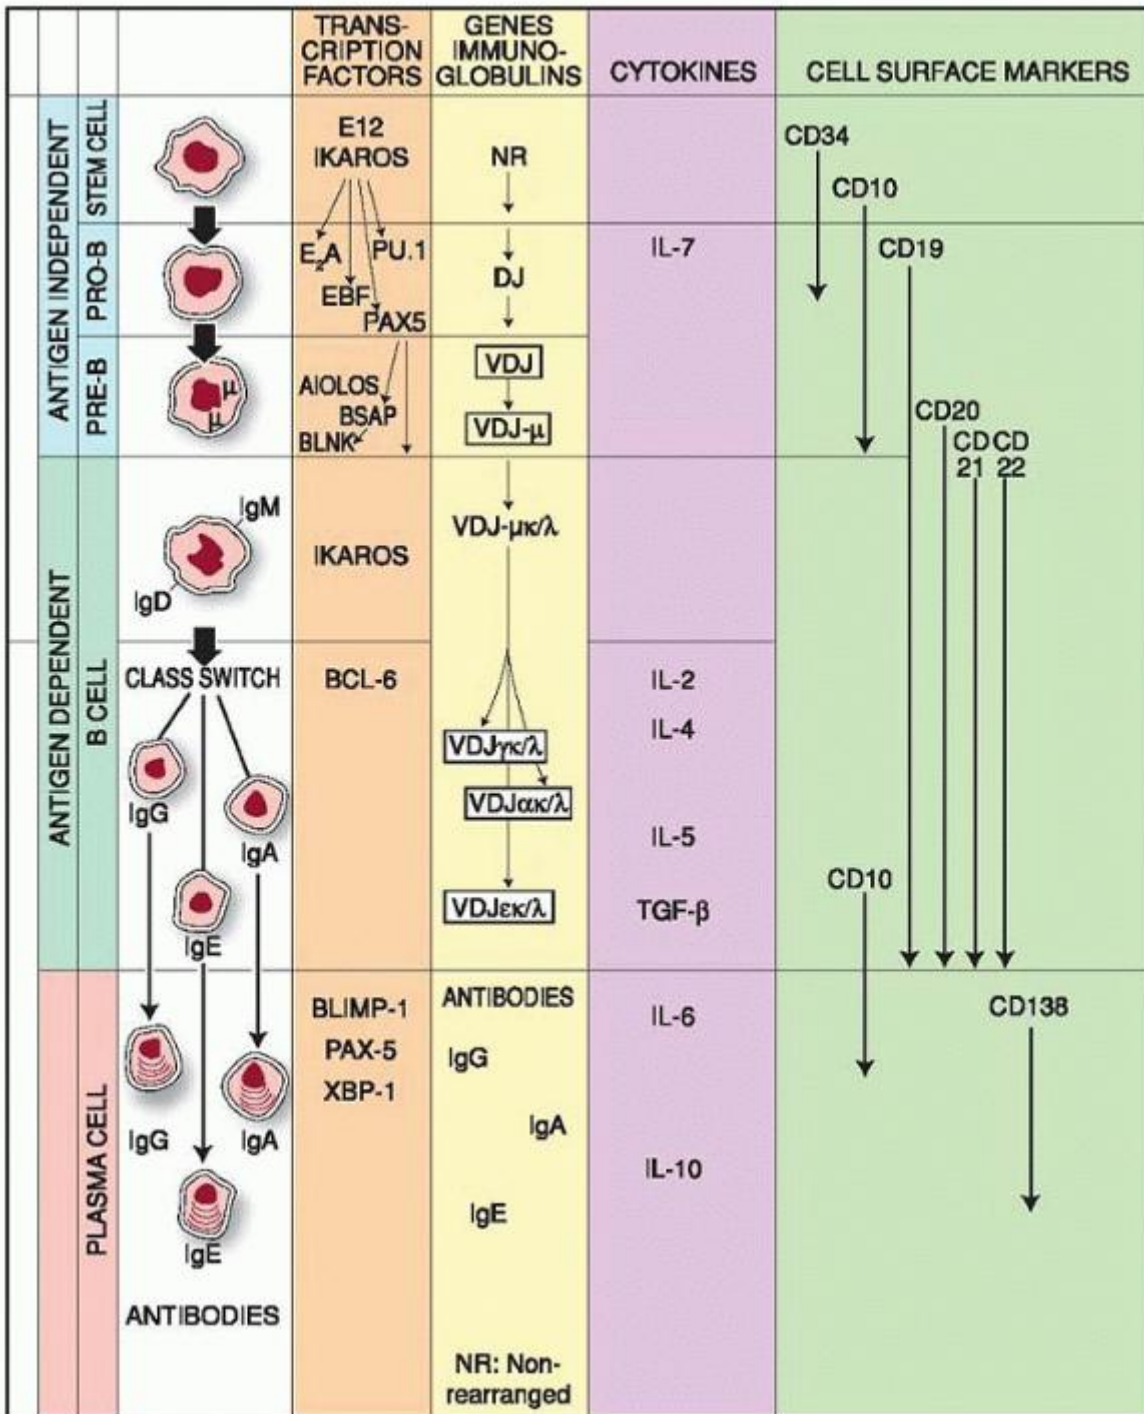

FIGURE 12.1. B-cell differentiation. The first stage of B-cell development takes place in the bone marrow. Normal development of lymphopoiesis depends on the Ikaros family of transcription factors, which form multimeric complexes with other members, i.e., Aiolos and Helios. These complexes are known as chromatin remodeling machines, and their targets induce a second wave of transcription factors, i.e., PU.1, E2A, EBF, PAX5, etc. Their targets are a third set of genes, forming BSAP that acts on the adaptor protein BLNK (SLP-65). Targets of BSAP are the genes for CD-19, V-preB, and λ5, i.e., markers distinctly of the B-cell lineage. BLNK regulates the transition from pro-B to pre-B, whereas PAX5 is needed for V(D) J recombination. This stage of development is independent of exposure to antigen and is followed by an antigen-dependent stage that unravels in the peripheral lymphoid organs. Antigen receptors, i.e., Igs, expressed on their surface interact with antigen and helper T cells, and trigger B-cell differentiation (plasma cells) and antibody secretion. Class switching generates distinct classes of antibodies suitable to dispose antigens in the various microenvironments, i.e.,

inside the body as well as on body surfaces.

The Pax5 is exclusively expressed in the stage between pro-B cell and mature B cell.²⁰ The B-cell-specific activator protein, BSAP/ PAX5, is a paired domain DNA-binding protein expressed in the developing nervous system, testis, and in all B-lineage cells, except terminally differentiated plasma cells. BSAP regulates transcription of several genes expressed in B cells and also the activity of the 3'-IgH enhancer and targets the genes of CD19, VPRED1, the gene transcribing for the lambda light chain, and several intronic sites of the C4B gene. The Pax5 gene regulates the V(D)J Ig heavy-chain gene rearrangements after the first DJ-H rearrangement,²¹ which generates the pro-B-cell population. Mice deficient for Pax5 have a pre-B-1 cell population which do not express CD19 or Ig- α and to a lesser extent Ig- β , V-preB, and lambda-5. These cells proliferate normally in vitro on stromal cells in the presence of interleukin IL7 and carry out D-J rearrangements of both IgH chain alleles. Removal of IL7 from the cultures inhibits differentiation to surface Igm expressing B cells. Transplantation of Pax5-deficient pre-B I clones into Rag-deficient hosts leads to full reconstitution of the thymus with D(H)J(H) rearrangements and normal positive and negative selection of CD4⁻CD8⁻ and CD4⁺CD8⁺ thymocytes and the development of normal, mature CD4⁺ and CD8⁺ T-cell compartments in the peripheral lymphoid tissues.

The target for BSAP is the adaptor protein B-cell linker protein (BLNK) which is linked with surface IgM by CMTM7, a tetra-spanning membrane protein, co-localized with clathrin and sIgM on the plasma membrane. The linking of sIgM with BLNK, a pivotal adaptor protein in the signal transduction, results in its recruitment to the vicinity of the tyrosine kinase Syk and initiation of signal transduction. This culminates in MAP kinase activation as well as other downstream signaling proteins, i.e., PLC- γ_2 , Bruton tyrosine kinase (Btk), etc.²² The BSAP regulation of BLNK gene expression controls also the pro-B to pre-B transition and mediates the constitutive signaling of the pre-B cell receptor (pre-BCR) in cell proliferation, growth factor responsiveness, and V(D)J recombination. BSAP diverts differentiation of a common myeloid/lymphoid progenitor to lymphocytic differentiation as a result of its ability to suppress the response of the progenitor cell to myeloid growth factors,²³ and represses genes inappropriately expressed at the pro-B-cell stage.²⁴

Essential for early B-lymphocyte development is the EBF which regulates the expression of Ig- α (mb-1) and Ig- β (B-29) coreceptors. Isolated human EBF factor binds to Ig- α and Ig- β promoters, and EBF-deficient mice lack Ig- α and Ig- β transcripts in pro-B cells.^{25,26} EBF activates transcription of B-cell-specific genes and initiates necessary events such as gene activation of other transcriptional regulators (i.e., Pax5) that direct the early stages of B-cell lymphopoiesis.²⁷ Mutations of E2A or EBF arrest B-cell development at a stage earlier than that of PAX5, because recombinase expression is blocked and expression of pre-BCR, λ_5 , and V-preB genes is inhibited.²⁷ The three transcription factors PAX5, TCF3 (E2A), and EBF form a cross-regulatory network with the TCF3 gene being the most potent B-cell regulator, essential for expression of PAX5 and EBF, which in turn is needed for expression of E47. Collectively, the targets of IKZF1 are the genes of the transcription factors TCF3 (E2A), PU.1, EBF, and PAX5, all of which regulate stages of B-cell differentiation before the expression of Ig genes. It has been shown however, that the TCF3 gene plays a central role for some aspects in subsequent stages of B-cell lymphopoiesis.²⁸ TCF3 (E2A) proteins are required for the interleukin IL7-dependent expansion of pro-B cells and their progression to the pre-B-cell stage and even later, for the regulation of rearrangements of the IgK gene and heavy-chain isotype switching.^{29,30,31} TCF3 encodes proteins that enhance hypermutation by recruiting AID to the Ig loci²⁹ and is essential in promoting pre-B- and B-cell survival.³⁰

CELL INTERACTIONS IN EARLY B-CELL DEVELOPMENT

Study of B-cell differentiation has become feasible with the development of long-term bone marrow culture techniques. This approach has helped to define the cells that are essential for the development of B cells and the factors that support B-cell growth and differentiation. The bone marrow stroma makes a critical contribution to hematopoietic differentiation and the term stroma is used in a collective sense to include a variety of cells, such as adventitial reticular cells, adipocytes, fibroblasts, and endothelial cells of the sinuses.³² The stroma includes also the extracellular matrix, composed of various fibrous proteins, glycoproteins, and heparan sulfate, effective in binding cytokines.

Granulocyte-macrophage colony-stimulating factor can bind to marrow stromal glycosaminoglycans and be presented to hematopoietic stem cells. Stroma cells have been isolated from adult bone marrow³³ or fetal bone marrow after removal of adherent cells (i.e., macrophages, endothelial cells). Stroma cells have the morphology of an adventitial/reticular/fibroblast cell, which expresses several adhesion molecules. They support, in cultures, differentiation of fetal bone marrow cells (CD34⁺, CD19⁻)³⁴ toward B-cell lineage, i.e., with loss of CD34 and acquisition of CD19 and the V-pre-B protein.

Several adhesion molecules have been implicated in the mediation of interactions between B-cell progenitors and stroma cells. Critical among them are vascular cell adhesion molecule-1 (VCAM1) on stroma cells and very late antigen-4 (VLA-4) on B-cell progenitors.^{33,35} The CD34 is expressed not only on stem cells,³⁶ but also on stroma cell precursors³⁷ and

endothelial cells,³⁸ and thus mediates interactions with its counterreceptor, L-selectin expressed on progenitor cells. Among cytokines with a wide range of functions is IL7, which acts in an early stage of common lymphoid progenitors (CLP, B/T/NK), mediates growth and differentiation of lymphocytes in the bone marrow, and plays a critical role in B-cell development.³⁹ IL7 maintains B-cell differentiation programs open; and although in the absence of IL7 the differentiation of T/NK proceeds normally, B-cell differentiation is arrested since IL7 modulates EBF expression, which activates target genes that are specific for B-cell differentiation programs.⁴⁰

In mice lacking IL-7R the recombination process comes to a halt, because normally it is the IL-7R which targets V_H segments to the recombinase complex; and furthermore, aberration in the expression of Pax5, a gene with pivotal importance in B-cell development and regulation, is associated with B-cell malignancies.⁴¹ Even though the block from IL7 deficiency is after the pro-B cell stage, these cells have certain abnormalities, such as failure to upregulate terminal deoxynucleotidyl transferase (TdT) and the high-affinity IL-7R chain.⁴² The net result of IL7 deficiency is lack of expression of the μ -chain and the pre-BCR, events that normally promote the advancement from pro-B-cell to pre-B-cell stage. Stimulation of proliferation and expression of the μ -chain follows distinct signaling pathways, because the Y449F mutation in the cytoplasmic region of the $I7\alpha$ chain, which abrogates proliferation induced by IL7, does not block μ -chain expression.⁴³ In the absence of IL7, the thymic stroma lymphopoietin (TSLP) (see Chapter 11) assumes a host of functions, i.e., regulation of the development of IgM^+ B cells from IgM^- precursors, the promotion of B-cell and Th-2 differentiation of naive $CD4^+$ T cells, and the activation of NK T cells, basophils, and other innate immune cells at the initial stage of inflammation.

TSLP affects B cell maturation and activation and may also influence differentiation and development of T regulatory T (Treg) cells.⁴⁴ Human X-linked severe immunodeficiency results from mutations of the γ chain, a common subunit for several cytokine receptors (i.e., IL2, IL4, IL7, IL9, and IL15). The patients lack T and NK cells but have normal or even elevated B cells,⁴⁵ and normal numbers of B cells are detected in patients with mutations of the $IL7R\alpha$ chain.⁴⁶ The IL7 exerts changes in gene expression, which effect differentiation of pro-B cells to pre-B cells, especially in concert with other growth factors of stromal cells.⁴⁷ It synergizes with FMS-like tyrosine kinase 3 ligand (FLT3LG) and induces strong expansion of fetal B cells in vitro.⁴⁸ IL7R has been detected on human B-cell progenitors, with a pro-B-cell phenotype, which lack expression of CD19 and clonogenic capacity,⁴⁹ are $CD34^+$, have messenger RNAs (mRNAs) for CD79B, RAG1, PAX5, and are TdT⁺. The $IL7R-\alpha^-/CD19^-/CD34^+$ cells do not differentiate in short-term cultures into pro-B cells, therefore the expression of IL7R- α defines an entry into a stage characterized by upregulation of multiple B-lymphoid-associated markers. Single adult human $CD34^+ CD38^- CD7^-$ cells cultured over a murine fetal liver adherent cell line supplied with IL7, FLT3LG, and IL3 differentiate into B cells, NK cells, myeloid cells, and DC.⁵⁰

B-lineage development therefore is based on a complex, interconnected network of genetic programs which provide lineage commitment and specification.^{8,51}

The CXCR4 chemokine receptor is detected in $CD34^+$ hematopoietic progenitors⁵² committed to B-cell development,⁵³ and its ligand is the stromal cell-derived factor-1 (SDF1 or PBSF, now known as CXCL12).⁵⁴ The CXCL12 chemokine orchestrates rapid revascularization of injured, ischaemic, and regenerating tissues via the CXC chemokine receptors CXCR4 and CXCR7. The CXCL12 induces intracellular actin polymerization in lymphocytes, a process that is thought to be a prerequisite for cell motility. Expression of CXCR4 on $CD34^+$ BM cells is one of the phenotypic alterations for committed lymphoid progenitors and allows discrimination of lymphoid progenitors from myeloid progenitors. Since $CD34^+CXCR4^+$ cells are differentiated from $CD34^+CXCR4^-$ cells, multipotential progenitors located in the BM are likely to be negative for CXCR4 expression.

CXCR4 is also known as fusin and acts as a coreceptor for human immunodeficiency virus (HIV) which infects host cells, but CXCL12 blocks the entry of HIV to T cells.⁵³ The $CD34^+CXCR4^-$ bone marrow cells generate myeloid and lymphoid progenitors, while the $CD34^+CXCR4^+$ cells, although they give rise to B cells and T cells, lack the potential for myeloid, erythroid, megakaryocytic, and mixed colony-forming progenitors. CXCR4 therefore defines B-lineage committed progenitors more accurately than other commonly used markers and is expressed earlier than IL7R or TdT.

PRO-B CELL TO Ig^+ B CELL

The early development of B cell differentiation is divided into two stages, the pro-B and the pre-B cells. In pro-B cells the first rearrangement involves the D_H to J_H segments of the immunoglobulin heavy chain (IGH@). With the completion of this step, the V_H to D_H-J_H rearrangement begins and if it is productive, an H chain is formed which binds a surrogate light chain (SLC) forming the pre-BCR. Further signaling by the pre-BCR stimulates proliferation followed by light chain rearrangement. IGK@ light chain rearrangement begins before the rearrangement of the IGL@ light-chain genes. These

epigenetic changes regulate the transition to the B cell stage, characterized by rearrangements of the light-chain genes with the kappa light chain preceding the rearrangement of the lambda chain gene.

Molecular definition of the stages of early B-cell development identified cells with μ H chains in the cytoplasm without L chains and no mature IgM molecules on the cell surface,⁵⁵ followed by phenotypic markers or Ig gene rearrangement.⁵⁶ Single-cell polymerase chain reaction analysis and Ig gene rearrangements allowed a more precise identification of B-lineage commitment and definition of the stages which characterize the transition from stem cells to pro-B-cell stage and B-cell development (Fig. 12.1). The pro-B cell stage in B cell development is followed by the pre-B cell, which may be divided into pre-B-I and pre-B-II stages.

Clones of pre-B I cells carry characteristic D(H)J(H) rearrangements on both IGH@ chain alleles. However removal of IL7 from the tissue cultures does not induce B-cell differentiation in B cells expressing surface IgM.

When the Ig gene rearrangements reach their final stage, IgM is expressed on the cell surface and differentiation reaches the end of the immature B lymphocyte stage. Three sets of genes regulate the transition from the pro-B-cell to the pre-B-cell stage, with expression of the complete Ig molecule on the surface of the B cell. One set includes RAG1 and RAG2 genes, and a third gene encodes the SLC which is composed of the proteins from the VPRED1 and λ 5 genes.

The proteins from two other genes, CD79A (mb1, PSMB5; IGB) and CD79B (CD79B; IGB) CD79B; IGB, form the coreceptor. These

P.254

genes support the expression of IgM on the surface of the B cell, the BCR repertoire, and allelic exclusion (i.e., expression of only one of the two alleles). The rearrangements of the Ig genes start with the joining of a D to J_H segment in the pro-B cells, which proliferate in contact with stromal elements and express the SLC linked to a gp30 protein, sometimes referred to as the surrogate heavy chain of the pro-B-cell complex.^{57,58} and ⁵⁹ SLC expression is required to establish immunoglobulin heavy chain allelic exclusion during early B-cell development and is easily detected on mouse pro-B cells but difficult to detect on human pro-B cells.^{58,59} The SLC consists of two noncovalently associated proteins, VPRED1 and λ 5 (Fig. 12.2), encoded by genes located on chromosome 22, where the λ -chain genes are also located.^{60,61} The VPRED1 and λ 5 proteins have several unusual features that distinguish them from conventional light chains. The VPRED1 protein is composed of 102 amino acids with homology to a conventional V domain and both have atypical sequences which target them to the endoplasmic reticulum (ER).⁶²

However, whereas the conventional V domain has a total of nine beta strands, including a sequence encoded by a J segment, the VPRED1 has no sequence similar to the J segment and is shorter by one strand, the β 7 strand, and its C-terminal portion has no homology to any other known protein. The N-terminal end of the λ 5 protein is unique, with only marginal sequence homologies to conventional domains. The C-terminal end of the λ 5 protein has an Ig-like fold, homologous to the conventional λ -chain C domain. This is followed by a sequence with marginal homology to the Ig structures and an extra β -strand that is homologous to the J region of the conventional V λ domains. Unique regions and Ig-like domains of the VPRED1 and lambda-5 proteins control the folding and assembly of SLC,⁶² which associates with the μ -chain to form the pre-BCR. The C-1 domain of the μ -H chain in the pre-BCR is protected from improper folding by the hsp-70 protein BiP, which retains the μ -H chain in the ER.⁶³ The protection from improper folding of CH-1 is taken over by the C- λ 5 protein at a later stage as long as the CH-1 is associated with the VPRED1 as SLC.⁶⁴ SLC escorts the μ -H chain to the surface of the cell, although not all μ -H chains can pair with the SLC, since some V segments have structural features that prevent their association. At this point, the RAG1, RAG2, and DNTT (TDT)TdT genes are turned off, securing allelic exclusion and thus preventing further rearrangements at the other allele.⁶⁵ The λ -5 chain of the pre-BCR represents the C domain of the conventional L chain of BCR, and has 85% homology with the C- λ domain, while the VPRED1 is the equivalent to the VL domain.⁶⁶ The SLC is linked by a disulfide bond to the μ _H chain through the C μ -1, i.e., the first constant domain,⁶⁷ and its role in the formation of the pre-BCR is dual. The C domain of λ -5 protein interacts with C μ -1 and the VPRED1 (and part of λ 5) with the V_H domain of the μ _H chain.⁶⁸ This last interaction is likely to be the first step in the selection of the B-cell repertoire⁶⁷ as the pre-BCR induces asymmetric divisions of pre-B cells.⁶⁹ In contact with pre-BCR ligands on stromal cells, i.e., heparin sulfate⁷⁰ or galectin-1,⁷¹ the SLC mediates receptor aggregation, signaling, and internalization, as well as transition from pro-B cells to pre-B cells.⁷² Pre-B-cell signals induce proliferative activity of pre-B cells, allelic exclusion of the heavy-chain locus, and activation of the light-chain loci preparing for V(D)J recombination.⁷³

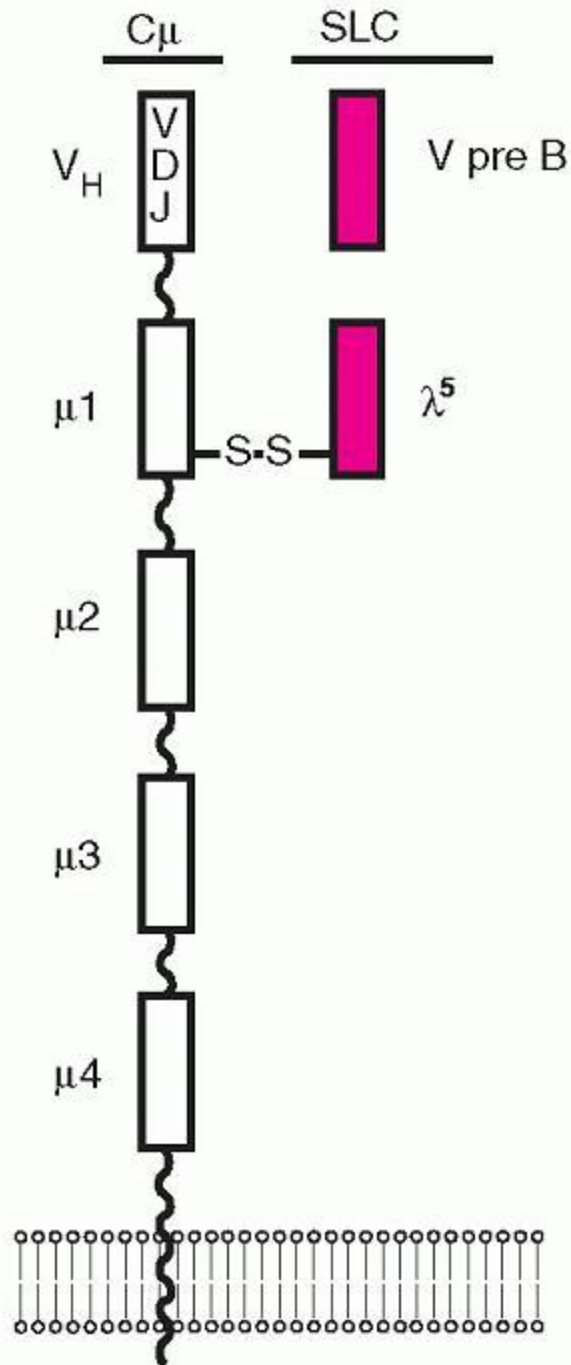

FIGURE 12.2. The structure of the pre-B-cell receptor. The pre-B-cell receptor is composed of the μ chain and a surrogate light chain that consists of two components, the λ^5 and the V-preB. The μ chain is linked by disulfide bond to the λ^5 component, whereas the V-preB is noncovalently attached. It is not yet clear whether the surrogate light chain can be expressed on the surface without the μ chain.

Productive rearrangement of the L chain completes induction of the IgM molecule expressed on the B cell surface, and marks the transition to the immature B-cell stage. The strong proliferative capacity of the pre-B cells was analyzed in Pax5^{-/-} mice, which showed that the pre-B cell has an extensive renewal capacity, multipotency, and the ability to reconstitute recipient animals with lymphoid and myeloid lineages.⁷⁴

Signaling is transmitted by the CD79A/CD79B partners of the pre-BCR, which is linked to several protein tyrosine kinases, i.e., Bruton's tyrosine kinase [BTK], SYK, ITK, BLNK, and phosphoinositide 3-kinase (PI-3K).⁷⁵ Ligand binding causes

aggregation of the pre-BCR, resulting in endocytosis of pre-BCR, loss of cell surface expression, and accumulation of pre-BCR within membrane lipid microdomains.

The pre-BCR signaling achieves two important outcomes for subsequent differentiation of the B cell: activation of MAP kinases, which block apoptosis usually triggered by the engagement of CD24;⁷⁶ and downregulation of RAG1/RAG2 expression to turn V(D)J recombination off, so that allelic exclusion is accomplished.⁷⁷ The RAG1/RAG2 proteins are still expressed on active proliferating cells of the pre-BI stage, but are silenced during the pre-BII stage. Because the cell has achieved its objectives (i.e., survival and allelic exclusion), it reactivates the V(D)J recombination machinery to allow rearrangements of the conventional κ/λ chains, to be able to form the complete IgM molecule and thus enter the immature B-cell stage.

Existing epigenetic mechanisms prioritize expression of single heavy and light chain alleles (allelic exclusion) in order to maintain monoallelic expression of both genes in a single B cell,⁷⁸ maintaining at the same time single specificity of the B cell receptor. At a later stage of B cell development, additional mechanisms contribute to prioritizing expression of single IGH@ and IGL@ alleles to help maintain the monoallelic expression of Ig.

The nontranscribed allele is in close association with heterochromatin, and the transcription factor IKZF1 initiates the silencing of transcription of the lambda-5 gene through a direct effect on the promoter.⁷⁹ Individual B lymphocytes normally express immunoglobulin (Ig) proteins derived from single Ig heavy chain (H) and light chain (L) alleles. At later stages of B cell development, additional mechanisms may contribute in prioritizing expression of single IGH@ and IGL@ alleles. The importance of pre-BCR signaling for progression from pro-B-cell to pre-B-cell stages and beyond is emphasized by the fact that deficiencies of any component of the pre-BCR or downstream signaling molecules blocks developmental progression of B cells at the pro-B or pre-B stage.⁸⁰ Targeting the genes for VPREB1,⁸¹ $\lambda 5$,⁸² or exons of the μ -chain blocks B-cell differentiation at the pro-B to pre-B-cell stage.⁸³ In mice with $\lambda 5$ -deficiency the expression of VPREB1 is normal, which excludes an essential role for pro-B and pre-B

P.255

cell receptors in VPREB1 regulation.⁸⁴ Similarly, in a patient with agammaglobulinemia, mutations in both $\lambda 5$ /IGLL1 genes were associated with agammaglobulinemia and reduced numbers of B cells.⁸⁵

The SLC is not detected on the surface or in the cytoplasm of a subpopulation of self-reactive cells found in germinal centers⁸⁶ and circulation.⁸⁷ B cells having a VPREB1 sequence in their BCR and RAG mRNA have also been described in normal human tonsils and the joints of patients with rheumatoid arthritis.^{88,89} The pre-B cell signaling that terminates pre-B cell expansion and induces Ig L-chain rearrangement is transmitted by Bruton's tyrosine kinase and the BLNK (Src homology-2 domain), which contains a leukocyte-specific phosphoprotein of 65 kD.⁹⁰ The V-region of a pre-B receptor and $\lambda 5$ proteins of the pre-BCR are invariant, but each contains unique evolutionarily conserved non-Ig sequences (unique regions or URs) attached to the Ig sequences.⁹¹ The URs interrupt the SLC complex and may be considered equivalent to the CDR3 of the Ig L chain which participates in antigen binding.⁹² The transcription factors that are most active and are specifically upregulated at this stage are TCF3, EBF1, PAX5, and IRF4.⁹³ The pre-BCR not only switches on the Ig genes, it appears to select preferentially those that provide μ H chains of a higher quality, i.e., with a higher potential to assemble with Ig L chains.⁹⁴

In conclusion, the pre-BCR plays a major role in the expansion of pre-B cells, allelic exclusion, repertoire selection, activation of V(D)J recombination, and developmental progression to IgM⁺ B cells.⁷³ Multiple checkpoints ensure proper differentiation of precursor and mature B lymphocytes. Many of these checkpoints have been found disrupted in patients with primary immunodeficiency; and it still remains unclear how B cells are affected, as 11 critical processes in B cell differentiation have been identified.

IMMUNOGLOBULIN GENES

Among the early successes of investigations in recombinant DNA, was the characterization of the Ig genes. There are three loci for the heavy chains and two for the light chains (κ , λ). The gene for the human heavy chain is located on chromosome-14,⁹⁵ the C(κ) gene on chromosome-2,⁹⁶ and the C- λ on chromosome-22.^{97,98} Separate genes encode the V and C domains of the Ig molecule. The human heavy-chain genes are not completely linked and the C μ gene is the closest to the Vdj segments.

At the 3' end of the H chain locus, there are two copies of a γ - γ - ϵ - α unit (Fig. 12.3). One of the duplicated ϵ -sequences is a pseudogene ($\psi\epsilon$) in which the CH1 and CH2 domains have been deleted. The genome contains a third closely homologous ϵ -related sequence, a "processed" pseudogene found on chromosome-9. These kinds of pseudogenes probably are

products of a reverse transcription from RNA and then are inserted at locations in the genome that are unrelated to the original locus. A γ -related pseudogene lacking the switch region is present between the two γ - ϵ - α duplications. The recombination events occur in a region on the 5' side of the C_H coding sequences.

This region contains repetitive DNA sequences and has been known as the switch region (S) sequence. Within the switch regions occur the recombination breakpoints during isotype switch (see Chapter 14). Usually the stimuli for switch recombination, like IL4 and CD40, promote transcription across the S regions to produce switch junctions, one retained in the chromosome while the other is found in a circular DNA (see Chapter 14).

FIGURE 12.3. Human immunoglobulin heavy-chain gene locus. The heavy-chain gene locus contains the μ and δ genes close to the J_H genes, whereas the remaining heavy-chain genes are farther downstream in two clusters from duplications. See text.

V_H -D- J_H GENES

The heavy chain of the IgM molecule is encoded by four sets of DNA: variable (V_H), diversity (D), joining (J_H), and the constant ($C-\mu$) genes.

A V_H gene encodes the first 95 or 96 amino acids of a V domain but the exact number of V_H genes is not known; it is estimated, however, to be 100 to 200. Of the available V_H genes only a portion are functional, and an even smaller portion is available for rearrangement.^{99,100} The V_H genes constitute seven families based on their homology at the DNA level and are known as V_{H1} to V_{H7} . Most V_H genes are polymorphic, but the degree of variation is usually small.¹⁰¹ The V_H segment encodes the hydrophobic leader sequence, the three framework regions, and the two complementarity-determining regions (CDR).

The name D gene, or segment, was proposed to indicate the diversity of an antibody at positions after amino acid 99 to the beginning of the J segment,¹⁰² which spans the third CDR. The D segments are located in chromosome band 14q32, with the major locus between V_H and J_H loci and several D segments interspersed within the V_H segments, sandwiched between signal sequences (see later). The CDR-3 is encoded by the 3' end of the V_H segment, the D gene segment, and the D- J_H junctional area. There are approximately 30 D segments grouped in seven families, and each one spans approximately 70 kb, with a promoter on its 5' end that allows initiation of transcription when Ig genes at the pre-B-cell stage start rearrangements. The first rearrangement produces a DJ_H complex, which together with the μ gene, encodes a protein known as $D\mu$ protein. There are six functional J_H genes and three pseudogenes, each J_H gene encoding the 3' end of CDR-3 and the fourth framework region.

V (D) J RECOMBINATION: FORMATION OF THE CODING AND SIGNAL JOINTS

Next to the V, D, and J genes are conserved sequences of seven nucleotides (heptamers), which are attached to the 3' side of the V segments, the 5' side of the J segments, and on both sides of the D segments (Fig. 12.4). The heptamer is followed by 12 or 23 nonconserved base pairs (bp) (spacers), followed by another sequence of 9 bp (nonamers), which may diverge from the consensus sequence. This noncoding sequence is known as the recombination signal sequence (RSS).

Recombination signal sequences for V(D)J joining consist of a conserved heptamer (CACAGTG) and a nonamer (ACAAAAACC) separated by a spacer of a constant length of 12 or 23 bp. The presence of three consecutive A residues in the nonamer is necessary for efficient recombination, and the nucleotides flanking the A-rich core should be other than A residues, so that the border of the A-stretch is precisely defined. This may be important when the recombinase measures the distance between the heptamer and the nonamer to satisfy the 12/23-bp spacer rule.¹⁰³

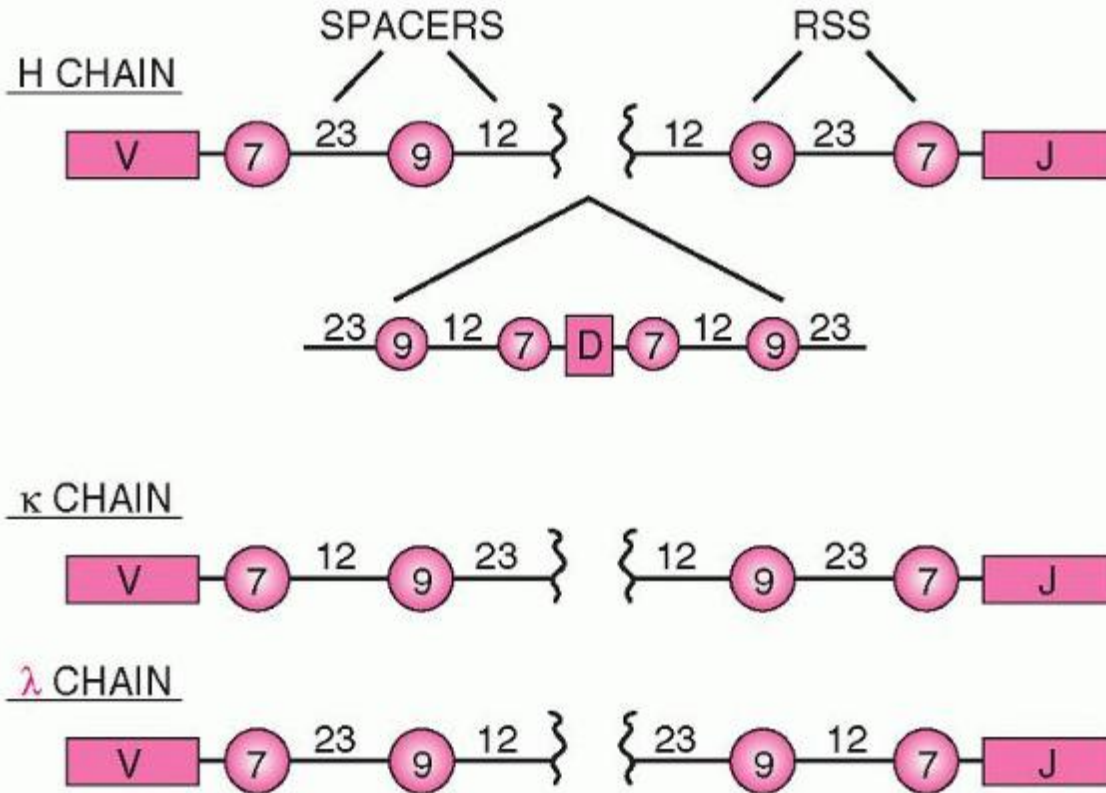

FIGURE 12.4. Recombination signal sequences (RSS) and heptamer/nonamer spacing sequences. The coding sequences of the immunoglobulin genes are flanked by a 7-nucleotide sequence (heptamer), which is followed by either 12 or 23 nucleotides, which in turn are followed by a 9-nucleotide sequence (nonamer) and again by a 23- or 12-nucleotide spacer. This order allows rearrangements only between a segment in which the 7/9 sequences are separated by a 12-mer spacer and another segment in which they are separated by a 23-mer spacer. This is known as the 12/23 rule.

The 12-bp spacer corresponds to one turn of the DNA α -helix, whereas the 23-bp spacer corresponds to two turns. This way, the recombining segments are juxtaposed on the same side of the DNA helix, so that they can be recognized by the enzymes of the recombination machinery.^{104,105} Joining of the various segments is limited between an RSS with a 12-bp spacer and one with 23 bp¹⁰⁶ (the 12/23 rule). Recombination follows strictly the 12/23 rule of spacers, which prevents inappropriate recombination, i.e., a V_H segment joining directly to a J_H segment, as both of them have a 23-bp spacer between their heptamers and nonamers.¹⁰⁶ The pattern of the RSS at each locus is uniform. For example, in the Ig locus, all V_k segments have next to their heptamers a 12-bp spacer, whereas all J_k segments have a 23-bp spacer. This prevents accidental joining of two V_k or J_k segments. The RSS sequences are the only ones that are required for recombination, whereas the coding sequences (V, D, or J) can be replaced by other DNA while the joining still occurs if the 12/23 rule is satisfied. During recombination, two new structures are formed: the joining of the coding sequences (coding joint), which is imprecise, and the joining of the RSS (signal joint), which is precise.

The V(D)J recombination (Fig. 12.5) is mediated by two enzymes known as RAG proteins,¹⁰⁷ the RAG1 and RAG2, which are not related to other proteins. Their expression normally is limited to immature B and T cells, even after the expression of surface antigen receptor, until the receptor is cross-linked. Deficiency of RAG proteins in mice^{108,109} or humans¹¹⁰ results in SCID. The RAG2 is divided into an N-terminal (core) domain and a C-terminal (non-core) domain. The core domain is necessary and sufficient for carrying out the V(D)J recombination. The C terminus of RAG2 contains a PHD finger motif, usually present in chromatin-associated proteins. The PHD (Plant Homeodomain) is encoded by many genes, including RAG2, and recognizes or "reads" the gene status of expression for histone H-3, lysine-4, and DNA damage, i.e., histone modifications, and as a result is known as a chromatin reader. The PHD finger of RAG2 modulates V(D)J recombination,¹¹¹ and mutations of RAG2 at this site result in immunodeficiencies. Tetramers of the RAG1/RAG2 proteins initiate the V(D)J recombination, which proceeds in three steps.^{112,113,114,115} The RAG1 binds to the nonamer, which acts as an anchoring platform, while the heptamer stabilizes the complex in the presence of RAG2. The recognition by RAG proteins of the RSS is assisted by sequence-nonspecific DNA-binding proteins, HMG1/2 (high-motility group), which enhance binding and

cleavage. In the RAG1/RAG2 complex, the RAG2 C terminus probably interacts directly with histones and stabilizes the RAG1/RAG2 complex.¹¹⁶ This interaction, which requires Mg^{2+} , may bring the recombinase to specific signal sequences which may be required for the postcleavage phase of the recombination. HMGB proteins bind to DNA through two DNA-binding domains known as HMG-box-A and -B.¹¹⁷ Each consists of 80 amino acids interacting with the minor groove of the DNA. Box-A bends distorted DNA structures, whereas box-B bends severely linear DNA sequences. Mutations in HMGB proteins block synaptic complex formation, or possibly recognize distorted DNA structures induced initially by RAG1/RAG2 binding. Their binding stabilizes the formation of the synaptic complex and thus promotes the DNA cleavage.¹¹⁸ The recognition by RAG proteins of the RSS is assisted by sequence-nonspecific DNA-binding proteins, HMG $\frac{1}{2}$, which enhance binding and cleavage. During the first step of V(D)J recombination, the RSSs are recognized by the recombinase and are brought in juxtaposition, forming the synaptic complex, which is composed of a dimer of RAG-2 and at least a trimer of RAG1.¹¹⁹ In the second step the recombinase nicks the phosphoester bond between the last nucleotide of the coding sequence and the first nucleotide of the RSS (Fig. 12.5, Panel 1). The precise mechanism of the hydrolysis of the phosphate ester bond is not known. The nicking reaction requires the physiologic divalent cation Mg^{2+} . The cleavage leaves blunt phosphorylated signal ends and hairpin sealed coding ends (Fig. 12.5, Panels 2 and 3), which are formed between the 3'-OH of the coding sequence (top strand) and the central phosphorus atom of the phosphate group between the coding sequence and the RSS of the opposite strand (the lower strand in Fig. 12.5). Formation of the hairpin requires significant bending of one or both DNA strands (Fig. 12.5, Panel 4). In the third step, the hairpin must be nicked open, so that the two coding ends form the coding joint. Opening of the hairpin may be done by a DNA repair complex¹²⁰ or by RAG proteins themselves.¹²¹ Because the nicking may not be exactly in the center of the hairpin, the opening creates an overhang in one strand formed by the nucleotides from the other strand (Fig. 12.5, Panels 5 and 6). These are known as P-nucleotides, which are coming from the opposite or complementary end of the hairpin or palindrome (from the Greek palindromicos, meaning successive movement forward and backward, like the piston of an engine). As a result, they have an inverse complementary relationship with the adjacent coding end. Most of the coding ends detected in normal lymphoid precursors have 3' overhangs.¹²² TdT adds nucleotides known as N-nucleotides (nongermline) to the strand with the missing nucleotides (Fig. 12.5, Panels 7 and 8). Disruption of TdT drastically lowers junctional insertions. In fetal and neonatal periods, the N insertions are low or absent as a result of the developmental regulation of TdT. The alterations in the coding joint as a result of P- and N-nucleotides are the basis for junctional diversity (Fig. 12.5, Panel 9).

The RAG proteins continue to be bound to the signal and coding ends in a four-end complex, known as a cleaved signal complex, at least while the coding ends are still processed. The RSSs are highly conserved among vertebrates, from sharks to humans. The three heptamer nucleotides closest to the recombination site are the most important, whereas mutations at other heptamer positions still allow recombination. Variations in the position of RSS may influence the use of gene segments IGK@ vs. IGL@.

The RSS joint is assumed to be lost by being converted to reactive, broken DNA, disposed of in the next cell division (deletional recombination). However, the existence of inverted segments of DNA in these loci indicates that sometimes signal joints are retained in the chromosome (inversional recombination), a mechanism that restores chromosomal integrity. The fate of the signal joint has taken an unexpected direction as a result of findings indicating that the RAG proteins perform genetic transposition

P.257

(i.e., act as transposases).^{123,124} The name given to the enzyme indicates its function, i.e., transposing or inserting pieces of DNA in a new location. The transposase MuA of the bacteriophage Mu is the best characterized in this class of enzymes, consisting of a tetramer in which two of the subunits nick the two ends of the Mu genome, while the other two catalyze the transfer of the ends into the target DNA. These reactions are important in the transmission of drug resistance among bacteria and the integration of retroviruses, such as HIV and others, into the genome. In fact the active site of MuA exhibits a striking similarity to the HIV integrase. It is interesting that the RAG1/2 act as tetramers in V(D)J recombination and resemble the HIV integrase responsible for inserting DNA copies of the viral genome into the cellular chromosomes. There are also similarities between the mechanisms of transposition and V(D)J recombination, suggesting that the RAG proteins may be members of the retroviral integrase superfamily.¹²⁵ Hairpins during V(D)J recombination are the targets of the RAG-mediated transposition. Notable differences, however, exist in the nick-cleavage mechanisms between the two.¹²⁶ Transposition of RSS in various positions, targeted to DNA, results in branched molecules.^{127,128} The high Mg^{2+} concentration prevailing in mammals, however, results in removal of transposed DNA by disintegration. No transposition in vivo has been reported as yet, probably because it is suppressed by GTP

P.258

and the C terminus of the RAG2 protein.^{129,130} Active transposition events are detrimental to the host because of the mutagenic potential of genomic rearrangements.

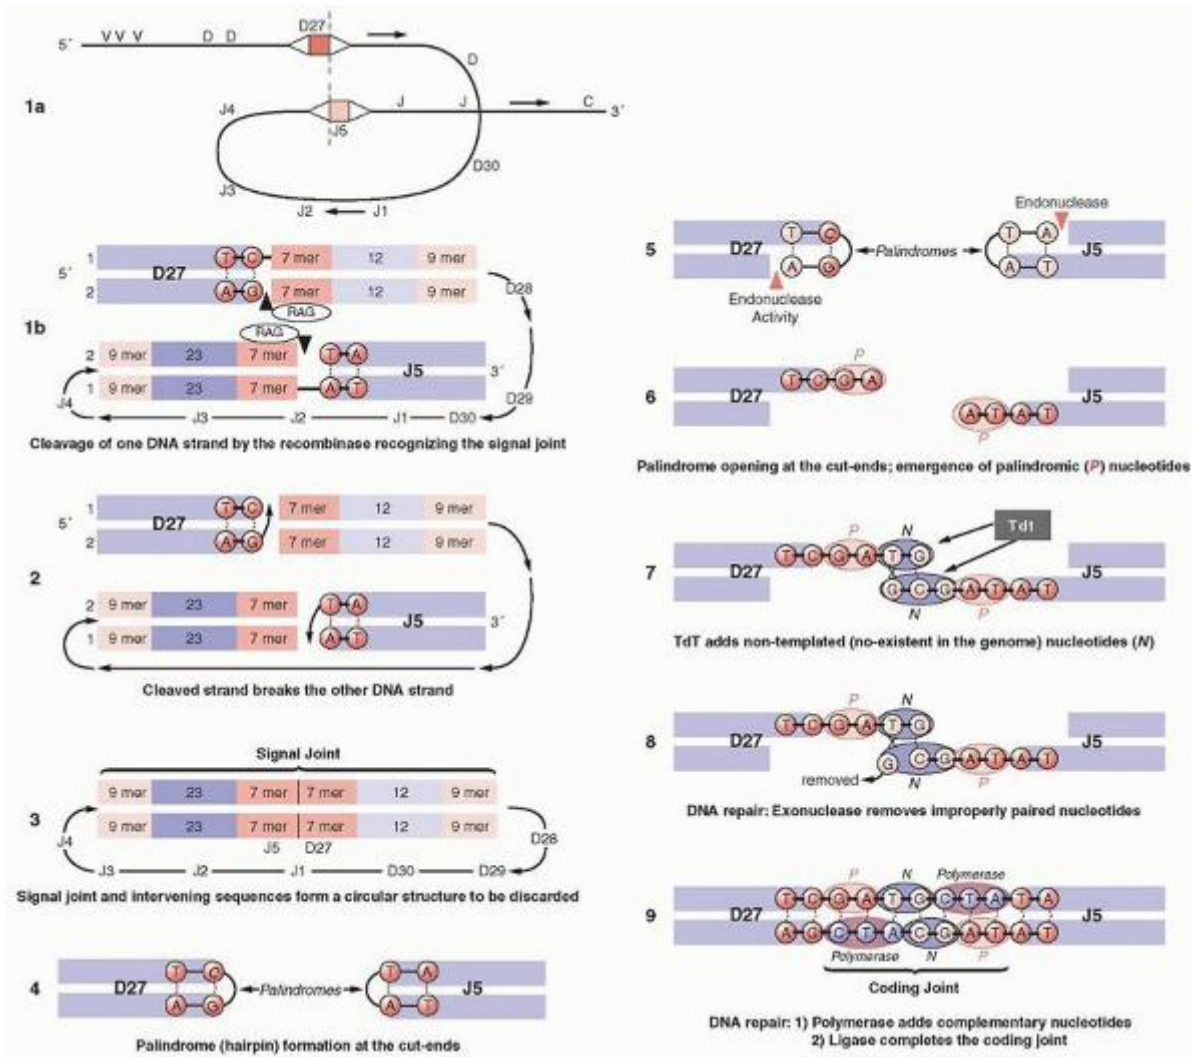

FIGURE 12.5. V(D)J recombination. Shown in this figure is the recombination of two hypothetical segments, D27 and J5. The recombination begins with recombination-activating gene-1 (RAG-1) and RAG-2 recognizing the heptamers and monomers (see text) (Panel 1). They cut out one strand at the junction between the heptamer and the coding sequence. The other strand is severed by a nucleophile attack from the cut end (Panel 2). The two blunt ends of the heptamers form the signal joint (Panel 3), while a hairpin seals the cut coding ends (Panel 4). The hairpin is nicked open either by the RAG proteins or by a ubiquitous DNA double-strand repair complex (Panels 5 and 6). The opening is usually asymmetric and creates overhangs, with the nucleotides at the end of the overhang being complementary because they derive from the complementary opposite strand. These are known as palindromic (P) nucleotides (Panels 5 and 6) (from the Greek palindromicos, meaning moving forward and backward in succession). The double DNA strand breaks of the coding joint receive nucleotides from the function of TdT (nongermline nucleotides) known as N-nucleotides (Panel 7). Improperly paired nucleotides are removed (Panel 8), and the coding joint is completed with the addition of missing nucleotides (Panel 9). The P- and N-nucleotides added to the coding joint constitute the junctional diversity.

As a result of these recent insights into the nature of V(D)J recombination and the function of RAG1/2, the question of the fate of the signal joint becomes very important. Signal joints have been found to be cleaved quite efficiently.¹²⁸ In vitro experiments showed that transposition is targeted not to a particular DNA sequence, but to structural features, such as hairpins, inverted repeats, supercoiling of DNA forming cruciform structures, and generally distorted DNA structures.^{131,132} In vitro experiments demonstrating transposition were performed with only the core part of RAG1/2; it is conceivable that other parts of the molecule exert an inhibitory effect on this potential function of RAG1/2. Although the in vitro

experimental evidence suggests that there is a bias toward transposition, there is no evidence that this occurs *in vivo*, as it severely compromises genomic stability in the lymphocytes. On the other hand, lymphoid malignancies are associated with chromosomal translocations, many of which involve the Ig or T-cell receptor (TCR) loci and potentially may be mediated by the V(D)J recombinase.¹³³

DNA REPAIR MECHANISMS

Cleavage of DNA is always potentially dangerous, and although the recombinase function is essential for the integrity and normal function of the immune system, it is, at the same time, perilous. The V(D)J recombination, as well as class switch recombination, are necessary processes, but they demand double-strand DNA breakage. As vital as these two processes are for survival, the DNA double-strand break (DSB) is a threat to survival and it does occur in viral infections and malignancies. If genetic integrity is to be maintained, the DNA breaks need to be repaired.¹³⁴ Although nature has developed a highly complex repair mechanism, it is, however, efficient. Double-strand breaks generate an alarm mechanism, based on the transduction of signals from the sensors to the transducers and eventually to the effectors for the DNA repair job. An important sensor is the MRN complex, consisting of a nuclease (Mre-11) and the chromosome protein (RAD50), which maintain chromosomal structure and protein NBN.^{135,136,137} RAD50 and NBN are recruited rapidly to DSB sites for processing broken ends. MRN transduces the early signals to a kinase, the main transducer, known as ATM (ataxia telangiectasia mutated), which rapidly phosphorylates various substrates needed in the repair pathway. ATM belongs to a family of proteins known as PI-3-K-like protein kinases (PIKK), with five members, while an additional protein is the catalytic subunit of the DNA-PK kinase. Four of the PIKKs are involved in the DNA damage response: DNA-PK, ATM, ATR, and SMG1. ATM is the first to be recruited to DSBs, where it is activated by MRN, probably as a result of changes in chromatin configuration; it then phosphorylates and activates several DNA repair and cell cycle checkpoint proteins, *i.e.*, the histone λ H2AX and NBN, required for recruiting other ATM targets.

ATM initiates a pathway that activates NF- κ B (associated with cellular survival), as well as phosphorylates BID, which plays an anti-apoptotic role.

The DNA-PK (DNA-dependent protein kinase) complex consists of a catalytic subunit (DNA-Pkcs) and a DNA-binding complex called Ku, which binds altered DNA structures such as double-strand breaks, nicks, or hairpin loops. Recombination of broken DNA strands occurs either between strands that have long stretches of homology (HR) or between DNA strand breaks, without relying on the presence of considerable homology between them. This recombination is known as nonhomologous end joining (NHEJ).¹³⁸ Mutations in this system result in the accumulation of V(D)J-specific double-strand breaks, indicating a defective repair mechanism, which causes SCID. A new gene has been added to those already known that regulate double-strand DNA break repairs. It was named ARTEMIS (now known as DCLRE1C),¹³⁹ after the Greek goddess who was the protector of small children and animals.¹⁴⁰ It belongs to the superfamily of metallo- β -lactamase enzymes and is now called DNA cross-link repair K (DCLRE1C).¹⁴¹ It is involved in the nonhomologous end joining pathway, a DNA repair process used by eukaryotic cells,^{142,143} as well as in the repair of broken DNA ends from the V(D)J recombinase activity.

The repair requires that the hairpin in the coding joint is opened by the DNA-PK-DCLRE1C protein complex.^{141,144} In such a complex, DCLRE1C acquires endonuclease activity, which it does not possess by itself.¹⁴⁴ DCLRE1C has been shown to be mutated in patients with SCID, expressing radiosensitivity.¹³⁸ Patients with hypomorphic mutations in DCLRE1C have not only immunodeficiency, but also a predisposition to lymphoma.¹⁴⁴

RAG1 AND RAG2 PROTEINS

The evolutionary origin of the RAG proteins has been controversial. Up to now it was accepted that the RAG genes originated from a horizontal gene transfer of a transposon, *i.e.*, a mobile DNA element, and therefore are related to transposases, as discussed earlier.

Recently, however, two genes in sea urchins (Echinodermata) were detected that bear structural similarities to the RAG proteins.¹⁴⁵ Echinodermata are an earlier evolutionary stage of chordates, to which vertebrates and humans belong. It is therefore possible that RAG proteins may have arisen very early in evolution and acquired their present-day function early in vertebrate evolution.

Both RAG proteins are required for V(D)J recombination, because lack of function of either one leads to SCID.^{146,147} A region that retains the recombinase activity is known as the core and has been used for studies *in vitro*. For RAG1, the core is located in the sequence 384-1,008 from a total of 1,040 amino acids, and for RAG2 in amino acids 1 to 383 of a total of 527. The core of RAG2 contains six repeats, each consisting of an antiparallel β -sheet, formed by four β -strands. The repeats are arranged in a circular formation like blades of a propeller,¹⁴⁷ a structure that is known to mediate protein-

protein interactions. The C-terminal quarter of RAG2 consists of a plant homeodomain fold, which is found in proteins with chromatin-binding properties.¹⁴⁸

Mutational analysis of the RAG proteins has provided some clues about structure-function relations. The catalytic properties of the proteins have similarities with members of the retroviral integrase superfamily¹³² and require divalent metal ions for their function—a requirement that is characteristic of some nucleases, the functions of which depend on acidic amino acids. Indeed, in RAG1, several acidic amino acids are critical for both nicking and hairpin formation, without affecting the DNA binding.¹⁴⁹ For RAG1, the N terminus is important for activity,¹⁴⁹ and the binding of RAG1 directly to DNA is supported by basic residues of RAG2.¹⁵¹ Deletion of the C-terminal region of RAG2 results in a reduction of the number of B and T cells.¹⁵² The plant homeodomain of RAG2 regulates differential access to sites of recombination, and although it is dispensable for D/J_H recombination, it is essential for the V_H/DJ_H step.¹⁵³

SOMATIC HYPERMUTATION

The primary importance of somatic hypermutation (SHM) is related to affinity maturation, i.e., the increase of the affinity of antibodies following repeated antigenic stimulations.¹⁵⁴ However, a wider scope of hypermutation is to provide a better defense

P.259

against hypermutating microorganisms. Many pathogens such as Trypanosoma, Neisseria, influenza virus, and HIV evade the immune system by variations of the antigens of their coat (antigenic variation). Accordingly, SHM is the adaptation of the B cell in response to hypermutating microorganisms.¹⁵⁵ SHM introduces mutations in the V gene at the rate of about 10³ mutations/base pair/cell division, i.e., 10⁶-fold higher than spontaneous mutations of somatic cells. At this rate genomic integrity can be maintained only if the SHM specifically targets the Ig genes. However, it has been suggested that SHM is not a mechanism specific for the Ig genes but it may occur in other genes. Perhaps the apparent preference for the Ig genes may be due to their higher density of certain hot spots,¹⁵⁶ and SHM appears to target preferentially certain hot spots, such as the short DNA motif DGYW.

HUMAN HEAVY- AND LIGHT-CHAIN GENE LOCI

The heavy and light chains of the Ig molecule are assembled from a large collection of preexisting gene segments by the lymphoid-specific RAG1 and RAG2 proteins. The RAG proteins cooperate to make double-strand breaks at specific recognition sequences (recombination signal sequences) or RSS.¹⁵⁷ The recombination takes place between one RSS with 12-bp spacer (12-signal) and one with a 23-bp spacer (23-signal) and this arrangement is called the 12/23 rule. In the presence of the metal ion Mn²⁺, a single signal sequence supports double-strand cleavage, whereas Mg-2⁺ requires two signal sequences.¹⁵⁷ The two light-chain isotypes, κ (kappa) and λ (lambda), comprise approximately 60% and 40% of all Igs, respectively, and consist of a V domain and a C domain of approximately 107 residues each in length. The V domain is encoded by the V and J segments, the former encoding the first 95 to 96 residues and the latter encoding the remaining 12 to 13. There is a single C-κ gene, and several C-λ genes. The κ locus contains approximately seventy-six V-κ segments grouped into six families, and five J-κ segments, but no d segments. The λ-locus contains 10 families of V-λ segments, a high number of pseudogenes, and several C-λ genes, each preceded by a single J-λ segment.

One of the consequences of the imprecision of the V(D)G recombination is a change in the reading frame at the junction between the two gene segments, causing the segments to join out of phase, so that the triplet reading frame for translation is not preserved. In this case the rearrangement results in V(D) J combinations with numerous stop codons which interrupt the translation. Recombination may be nonproductive or productive; when the junction lies within a codon, the resulting amino acid is encoded by nucleotides from both gene segments involved. It is estimated that only one in three recombination attempts are productive, but the imprecision in the joints between variable gene segments increases their diversity by at least 100-fold. Difference in mRNA stability allows pro-B cells to distinguish between productive and nonproductive Ig gene rearrangements.

The Ig gene rearrangements follow a certain sequence of the various loci and use only some of the available gene segments (allelic exclusion), which indicates that there are regulatory mechanisms underlying the process of rearrangement. For the IgG molecule the IGH@ gene is rearranged first and forms a complete V gene from three individual segment clusters, i.e., V, D, and J. One of the D segments joins a J_H segment forming the D-J_H complex and in the next step, which is regulated by the D_μ protein, the V segment joins the complex. A D-J_H rearrangement has also been found sometimes in T cells. The D_μ protein, which lacks a V_H segment, is encoded by the D-J_H complex and the constant gene of the μ-heavy chain and may be expressed on the membrane of the cell with an SLC. Expression of D_μ protein prevents further V_H-to-DJ_H rearrangement, or the rearrangements are diverted to another pathway such as κ-chain

rearrangements, which are accelerated. Completion of the μ -chain inhibits further rearrangements by the opposite allele (known as allelic exclusion).¹⁵⁸ Completion of the μ -chain rearrangement is followed by rearrangements of the IGH@ gene, and if both κ alleles fail to rearrange productively, the IGL@ gene is rearranged (Fig. 12.6). However, this hierarchical order of Ig gene rearrangements has been challenged, because examination of B cells at different stages of early development shows that the heavy and light-chain genes rearrange independently.¹⁵⁹ At the end of its early developmental stage, the B cell emerges with the expression on its surface of a unique antigen receptor consisting of IgM accompanied by two accessory molecules, CD79A and CD79B.¹⁶⁰

REGULATION OF V(D)J RECOMBINATION

Initiation of rearrangements by the recombinase requires that the gene must be accessible, i.e., the locus must be able to act as a template for the recombinase. In cells competent for rearrangement it was found that J_{κ} and V_H genes have already been transcribed, but these RNAs, named germline or sterile transcripts, are incapable of encoding the protein. Several possibilities may exist to explain this finding, and since inactive genes are not accessible to the recombinase, it is possible that the altered structure of the chromatin allows the recombinase to recognize the RSS. Alternately, the enhancers may establish altered chromatin regions where both the recombinase and the transcription machinery have access; this is known as the accessibility hypothesis.^{104,161} Enhancers and promoters function as accessibility control elements (ACEs), which regulate V(D)J recombination. Enhancers maintain an open chromatin state in multiple embryonic tissues independent of their activity level. Regions of nonprotein coding genomic DNA bind protein transcription factors (TFs) and thus direct the expression of target genes. The enhancer of the IgM heavy chain (E_{μ}) is located within the intron between the J_H segments and the C_{μ} gene and is associated with matrix attachment regions (MAR), which improve production of the protein by recombination.¹⁶² Transcriptional regulation by enhancers is fundamental to the evolutionary diversity of metazoans as well as their embryonic development. The regulation of a gene is an exceedingly complex process controlled by interacting proximal and distal DNA elements usually placed in a cis configuration, proximal to the basal promoter where the general transcription machinery assembles. A promoter is always located in close proximity to the 5'-end of a gene and is necessary, but not sufficient, for its transcription, while enhancers or silencers are distant elements.

Enhancers are thought to be composed of binding sites for transcription factors (TF), which upon recruitment to the enhancer loop over the promoter and activate the transcription of the target gene. There are three additional enhancers within the Ig heavy-chain locus, and one of them (DQ52) competes more efficiently in conferring accessibility to the JH region. Interaction between DQ52 and E_{μ} is likely responsible for ordered rearrangement, i.e., D to J_H followed by V_H -to- DJ_H complex.¹⁶³ The κ -light chain intronic enhancer is active only in mature B cells and plasmacytomas, and its stage restriction is dictated by a single motif that binds the transcription of nuclear factor- κ B (NF- κ B), which recognizes a 10-bp motif. The NF- κ B consists of two subunits and the DNA-binding function is mediated by the smaller one. The enhancers for the Ig transcription lie in the vicinity of the C- α gene and κ locus. The enhancer between the J_{κ} and C_{κ} genes becomes transcriptionally active in the transition from the pre-B to B-cell stage.¹⁶⁴ The matrix attachment regions are regions rich in AT

P.260

and demarcate regions of chromatin that undergo base unpairing and other regions that mediate binding of topoisomerase II. This regional division of chromatin may also be regulated from a distance by trans-acting factors, which bind to specific motifs within the enhancer or promoter. Despite the promiscuity and redundancy of regulatory sequences, transcription is still specific for tissue lineage and even stage of development. Several transcription factors and other signals lead to changes in expression levels, yet no clear model exists to explain the complexity of transcriptional regulation. The clear result is that disruption of the TCF3 and EBF1 transcription factors results in blocking of B-cell development at a stage before Ig heavy-chain gene rearrangements.

FIGURE 12.6. Heavy-chain immunoglobulin (Ig) M and kappa light-chain rearrangement. With the completion of the V(D)J recombination of the μ chain and the formation of a complete μ H chain, the LK chain rearranges, and, if successful, it forms the complete IgMK molecule. If both κ alleles rearrange unsuccessfully, the λ gene rearranges. If successful, an IgM λ molecule is formed. If both λ genes cannot rearrange successfully, the cell dies by apoptosis.

BCR V GENE REPERTOIRE

Certain aspects of the study of the Ig V gene repertoire and the Ig gene rearrangement have found wide applications in clinical medicine.¹⁶⁵ The total number of V genes defines the available repertoire. However, not all genes are equally functional, and as a result, the repertoire which is usually expressed is biased, because some of the V genes are expressed with a significantly higher frequency than would be expected if all had an equal chance for rearrangement. This biased expression affects all V, D, and J gene segments; thus the J_{H4} segment (one of the existing six), on the basis of equal opportunity among all five segments, should be detected in 17% of B cells, yet it is found in 32% of B clones from fetal liver and in 42% of pre-B-cell ALL. The bias of the expressed repertoire shows striking association with certain diseases. For example, the V_{H4-21} , a member of the V_{H4} family, is found in cold agglutinins.¹⁶⁶ Preferential expression of certain V_H segments is also detected in ALL clones. In ALL the frequency of N-nucleotide additions differs in children less than 3 years of age (12.5%) compared with children greater than 3 years old (89%).¹⁶⁷ Because in fetal B lymphocytes the frequency of N-nucleotide additions is low, it is suggested that the transforming event in the younger age group probably occurred during fetal life.

In chronic lymphocytic leukemia (CLL), the use of V genes is also restricted, and the same is true in non-Hodgkin lymphomas. It is interesting that in certain cases of follicular lymphoma, the V genes not only have undergone somatic mutations, but also continue to do so during the course of the disease, suggesting that the malignant clone is responsive to an antigen.^{168,169} Somatic mutations, as expected, have also been detected in multiple myeloma, because the malignancy derives from an advanced stage of differentiation of B cells.¹⁷⁰ This brief summary emphasizes the fact that defects in V(D)J recombination¹⁷¹ are associated with human diseases such as loss of RAG1/RAG2 function, which results in SCID. In certain autosomal recessive diseases, hypersensitivity to DNA-damaging agents results in chromosomal breaks and rearrangements, with an increased incidence for development of leukemia and other malignancies. They have been classified as DNA repair disorders and include AT, Fanconi anemia, xeroderma pigmentosum, and Bloom syndrome (see later). Genomic instability is most often linked to DNA repair deficiencies, which suggests that evaluation of deficiencies in repair mechanisms in pluripotent human stem cells should be a necessary step prior to their clinical and research use. The DNA repair pathways and repair capacities in pluripotent cells are more heterogeneous than those of differentiated cell lines. In mice the SCID mutation, an autosomal recessive mutation, results in the absence of B and T cells as a result of

impairment of the V(D)J recombination. Both lymphoid and nonlymphoid SCID cells are hypersensitive to killing by ionizing radiation because of a DNA double-strand base-repair

P.261

defect. It is rather important that a human gene on chromosome 8q11 has been identified that restores V(D)J recombination, double-strand base repairs, and normal resistance to irradiation in SCID cells.^{172,173} V(D)J recombination is necessary for immune diversity and survival, but this objective can be achieved only through DSBs which threaten genomic stability. The complexity of the recombinase function is matched by complex DNA repair machinery. Disorders related to V(D)J recombination may be considered in two categories: those related to the first step (cleavage) and those related to the second step (cleavage repair).¹⁷⁴

THE MUTATION IN SEVERE COMBINED IMMUNODEFICIENCY

Two fundamental processes operate in V(D)J recombination, i.e., double-strand breaks during the gene rearrangements, followed by DNA repair. The SCID mutation in mice¹⁷⁵ is associated with lack of mature lymphocytes and agammaglobulinemia. SCID T cells have long P-nucleotide sequences and accumulate hairpins at the TRD@ coding ends. In addition to the lack of rearrangements, there is an inability to repair damage from irradiation. In mice the SCID mutation is located on chromosome 16, and since human chromosome 8 can complement mouse SCID defects, it has been assumed that the SCID defect for humans should be in chromosome 8, although human chromosome 8 is not associated with any known immunodeficiency or DNA repair diseases. The gene, however, for the DNA polymerase- δ , is in chromosome 8p11-12. Mutated RAG genes have been detected in nine patients from seven families.¹⁷⁶ Recombination activity was undetectable with mutations in the RAG core domains, and in four patients there was a complete B-cell differentiation arrest between the pre-BI and pre-BII stages.

V(D)J RECOMBINATION: DNA CLEAVAGE

Two types of RAG1 and RAG2 gene inactivations have been identified in mice. The first type results in the inactivation of the recombinase so that V(D)J recombinations cannot be initiated,^{108,109} and as result the mice have no mature T and B lymphocytes, although there is an increase of immature lymphocytes in the lymphoid organs. The second type of mutation consists of a single conservative amino acid substitution in both proteins. It does not affect the initiation of V(D)J recombination, but severely impairs the coding and signal joint formation.^{177,178} The mutant enzymes are defective in hairpin opening in vitro and the formation of the coding joint in vivo. This evidence indicates that the RAG proteins, in addition to their cleavage function, are important for the formation of the joints; therefore, they must remain associated with the postcleavage complex to achieve opening of the hairpin.

In severe combined immune deficiency (SCID), approximately 20% of the patients lack both T and B lymphocytes, but have normal NK cell counts;¹⁷⁹ some of these patients have RAG1 or RAG2 gene mutations,¹¹⁰ while others have increased radiosensitivity of their bone marrow cells and fibroblasts (RS-SCID).¹⁸⁰ The RAG2 structure consists of two globular domains separated by a hinge of approximately 60 amino acids. The largest domain which is enzymatically active has 350 residues and includes the previously described core region of RAG2. This domain forms a β -propeller with six blades arranged in a circle from a center. The β -propellers are made of 4 to 10 β -sheet units (blades) circularly arranged around a central tunnel, and have probably evolved by duplication and fusion of a rudimentary repetitive unit. The beta-propeller fold is phylogenetically widespread and able to support a variety of functions such as catalysis, ligand binding and transport, regulation, and protein binding. Interestingly, it appears that the beta-propeller topology is also compatible with strikingly diverse sequences. Amongst this diversity there are three large groups of proteins with related sequences and very important cellular and intercellular regulatory functions. The WD-40 repeat proteins have a variety of functions, such as signal transduction, transcription regulation, cell cycle control, autophagy, and apoptosis. The YWTD proteins and the Kelch repeats interact directly with the actin-binding protein LASP1 in membrane ruffles at the tips of pseudopodia, where both proteins are necessary for pseudopodial elongation. A common characteristic among the proteins of these families is the internal repeats of 40 to 45 residues. The β -propellers are widely utilized in nature as recognition modules, and the well-conserved β -propeller fold exhibits a high degree of functional diversity, which is probably accomplished through variations in the surface properties of the proteins.¹⁸¹ The β -propeller fold shows a high degree of functional diversity, probably accomplished through variations in the surface properties of the proteins. It is present in some integrins and other proteins which are known to mediate protein-protein interactions. Six out of seven mutations so far described in RAG2 in humans are clustered on one side of the propeller. This side is involved in interactions between RAG1 and RAG2 which are critical for functional activity. Two of these mutants (C41W and M285R) reduce the interaction

between RAG1 and RAG2 in vitro but no DNA-binding activity of the complex was detected.¹⁸² This is consistent with the hypothesis that RAG2 stabilizes the RAG1/RAG2 complex.¹⁸³

OMENN SYNDROME

Omenn syndrome (OS) is an inherited disorder characterized by absence of circulating B cells, infiltration of the skin and intestine with activated oligoclonal T lymphocytes (HLA-D⁺), eosinophilia, and elevated serum IgE.¹⁸⁴

The immunologic hallmark of OS is the expansion and activation of an oligoclonal population of autoreactive T cells. These cells should be controlled rapidly by immunosuppressive agents.¹⁸⁵ The patient has diffuse erythroderma, lymphadenopathy, hepatosplenomegaly, protracted diarrhea, and failure to thrive. The T cells are activated, secrete Th-2 types of cytokines,¹⁸⁶ and express oligoclonal expansion of TRB@ chains with VDJ junction similarities, suggesting a common antigenic specificity with possible autoimmune proliferation and a critical defect in the development of lymphocytes.¹⁸⁷ The hallmarks of OS are expansion and activation of an oligoclonal population of autoreactive T cells, skin erythroderma, and elevated IgE in the absence of circulating B cells.¹⁸⁸ The syndrome expresses clinical symptoms and signs which define an inflammatory condition associated with various genetic defects.¹⁸⁸ The patients have activated oligoclonal T cells, and it appears that genes other than those directly involved in V(D)J recombination may play a role in the pathogenesis of OS. Omenn-like features are associated with mutations of genes involved in the maturation steps of lymphoid cells and not those directly regulating V(D)J recombination.¹⁸⁸

OS is characterized by a cellular infiltrate of the skin, gut, liver, and spleen and a resemblance to graft-versus-host-like disease. The V(D)J recombination process is impaired but not abolished and leads to the generation of a few T cells which expand in the periphery and infiltrate target organs such as skin and gut, resulting in severe erythroderma and colitis, supporting the evidence that Omenn is an inflammatory condition.

Inherited mutations in RAG1 and RAG2 genes have been reported^{189,190} in a series of 20 patients with OS, and were shown to result in partial V(D)J recombinase activity.¹⁹¹ Because similar mutations have been detected in patients with T/B SCID, it has been suggested that an additional factor exists in OS to account for the different clinical picture, such as an autoantigen or an external antigen that drives T-cell activation. In a 5-week-old girl with

P.262

Omenn-like SCID, the RAG1 gene had a mutation with deletion of nucleotide (631 del-T),¹⁹⁰ and as a result the N-terminal region of RAG1 protein was deleted by a premature stop codon. The patient had a high number of T cells with almost a polyclonal TCR gene rearrangement, but there were no B cells and hardly detectable Ig gene rearrangements. The truncated RAG1 protein apparently could still support TCR, but not Ig gene rearrangements. This suggests that the N terminus of RAG1 is specifically involved in Ig V(D)J rearrangements. Another case of OS was reported with a mutation in the DCLRE1C (ARTEMIS) gene,¹⁹² a mutated maternal allele, and as a result the DCLRE1C protein was not functional as endonuclease, lacking the hairpin opening activity in a V(D)J recombination assay. In a cohort of nine patients with OS, only two of the nine had RAG mutations,¹⁹³ but the cause of OS in seven other patients remains unknown.

All patients, however, expressed restricted TCR-V and B cell repertoire, which might have occurred in response to infections. Missense mutations in RAG1 (p.Arg474Cys and p.Leu506Phe) result in reduced RAG activity with idiopathic CD4⁺ T lymphocytopenia (ICL) and reduction of T and B cells, but no evidence of autoimmunity or infections. It is therefore likely that RAG mutations are associated with conditions such as severe immune defects or even an almost normal condition.

V(D)J RECOMBINATION: DNA REPAIR

A double-strand break (DSB) is one of the most significant of DNA lesions which threatens cell integrity, but the cells have developed an exquisite repair machinery to maintain genomic stability. Immune diversity, which is a function vital for the survival of an organism, has to cross the dangerous path of DSBs.¹⁹⁴ The body uses the nonhomologous machinery to repair the damage caused by the recombinase,¹⁹⁵ and the major mechanism for repair in mammalian cells is nonhomologous end joining. Five proteins operate in nonhomologous end joining; three of them form the DNA-PK complex (KU70/XRCC6, KU80/XRCC5, PRKDC), the XRCC4, and the DNA ligase IV.¹⁹⁶ The Ku protein is an autoantigen that induces autoantibodies in patients with scleroderma, polymyositis, or systemic lupus erythematosus. Two proteins, the XRCC6 (KU70) and XRCC5 (KU80), form a stable heterodimer, which binds DNA ends regardless of sequence composition. The heterodimer forms a complex with a third component, the DNA-PK complex, which phosphorylates many DNA-binding proteins, including transcription factors c-Jun and p53. However, the most efficiently phosphorylated substrates are those close to DSBs, including the Ku components of the DNA-PK complex, which appears to regulate the

nonhomologous end joining process which is the main function of the DNA-PK complex. Mice that are defective in Ku proteins have SCID,^{197,198} and in general the defects in the DSB repair machinery are associated with immune deficiencies.¹⁹⁹

ATAXIA TELANGIECTASIA

AT is an autosomal recessive disorder characterized by immunodeficiency, progressive cerebellar ataxia, oculocutaneous telangiectasias, clinical radiosensitivity, chromosomal instability, and elevated risk for development of lymphoid malignancies. AT is due to deficiency of a protein kinase that mediates repair to double-strand breaks generated during metabolic processes or from DNA-damaging agents.¹³⁷ One of the hallmarks of AT is the generation of aberrant rearrangements during V(D)J recombination, such as translocations, large chromosomal deletions, and inversions. A protein kinase known as ATM mediates repairs of DSB by phosphorylating and activating several repair proteins.^{135,137}

Immunodeficiency affects both T and B cells and there is a decrease of serum IgA. The AT cells display γ -irradiation sensitivity, a cell cycle checkpoint control (i.e., inability to arrest at the G₁-S and S-phase checkpoints), and a G₂-M arrest. AT cells have also a DNA repair defect,²⁰⁰ i.e., they can rejoin DNA at the DSB efficiently. The defect is localized on a protein member of the PI-3K family of kinases with serine-threonine protein kinase activity,²⁰¹ which phosphorylates a number of proteins involved in the mechanisms of damage repair (i.e., p53 and CHK).^{202,203}

NIJMEGEN BREAKAGE SYNDROME

Nijmegen breakage syndrome is a rare autosomal disorder with clinical features overlapping with those of AT. The patients have defective humoral and cellular immunity, radiosensitivity, chromosomal instability, and predisposition to cancer.²⁰³

The patients have recurrent bacterial sinopulmonary infections, hypogammaglobulinemia, and impaired antibody responses to antigens. The cells from the patients have defects at some checkpoints of the cell cycle.²⁰⁴ The defective protein is NBN (nibrin or NBS1), which shows homology with the protein Xrs-2, involved in DNA repair response in yeast.

BLOOM SYNDROME

Bloom syndrome (BS) is a rare autosomal recessive disorder with immunodeficiency, genomic instability, and predisposition to cancer. It presents with a variable clinical picture including respiratory infections, chronic lung disease, and low IgM levels. Affected individuals show sun sensitivity on the face and infertility.²⁰⁵ BS is caused by mutations in the BLM gene, located in chromosome 15 at 15q26.1, which encodes the BLM protein,²⁰⁶ a member of the helicase subfamily. It displays ATP- and Mg²⁺-dependent 3'-5'-DNA helicase activity. It is a member of the BASC (BRCA-1-associated genome surveillance complex) family, which includes ATM and NBN, which are defective in Nijmegen syndrome.

DEFECTS OF LIGASES

There are multiple DNA ligases in higher organisms and a point mutational change in DNA ligase-1, which does not abolish the activity of the enzyme. It was found in an individual who experienced recurrent sinopulmonary infections leading to bronchiectasis.²⁰⁷ The patients display pancytopenia and microcephaly and the V(D)J recombination shows mildly impaired fidelity, which may result in oncogenesis.¹⁷⁴ In bacterial and viral infections a severe form has been reported with a SCID presentation, evolving into an Epstein-Barr virus (EBV)-induced lymphoma.²⁰⁷

XERODERMA PIGMENTOSUM

Xeroderma pigmentosum is a rare disorder associated with sun sensitivity, high risk of cutaneous malignancy in sun-exposed areas, and immunodeficiency in some patients.²⁰⁸ Some aspects of immunosuppression associated with xeroderma pigmentosum are due to defects in the DNA repair machinery. The patients have impaired NK cell cytotoxicity.

GENETIC DEFECTS OF B-CELL DEVELOPMENT

Signaling during B-Cell Development

After the V_H-to-DJ_H rearrangement of the IGH@ gene, the cytoplasmic μ -chain pairs with the SLC and traffics to the cell surface in association with the signal-transducing chains CD79A and

P.263

CD79B to form the pre-B-cell complex. Signaling for the transition from pre-B cells to Ig⁺ B cells requires the immunoreceptor tyrosine-based activation motif (ITAM) of the cytoplasmic domains of the CD79A and CD79B chains, because inactivation of ITAMs by mutation blocks the transition to the Ig⁺ B-cell stage.²⁰⁹ Deficiency of CD79B chain by

gene targeting abolishes formation of the CD79A-CD79B dimer and blocks assembly of the SLC. As a result, the differentiation of B cells is arrested at the pro-B-cell stage.²¹⁰

Interactions of pro-B and pre-B cells with stromal elements are necessary for progression through the early stages of B-cell development, but a ligand for the pre-BCR has not yet been identified and it is conceivable that the receptor may be signaling constitutively. It is apparent that the presence of ITAM motifs and the concentration of signaling molecules around them are the critical factors in determining progression through the early stages of B-cell development. Pro-B cells are able to become pre-B cells in the absence of the μ -H chain as long as the CD79A/CD79B chains are aggregated and thus can recruit sufficient numbers of signaling molecules around their ITAMs.²¹¹ Furthermore, signaling by other molecules unrelated to pre-BCR, such as EBV latent protein-2A (LMP-2A), can drive pro-B- to pre-B-cell transition. LMP-2A protein with ITAM motifs in its cytoplasmic region, spanning the membrane twelve times, possesses constitutively its own signaling activity in nontransformed cells.²¹² Phosphorylation of these motifs recruits SYK and SRC kinases and thus bypasses the normal checkpoints of B-cell development. Of all the signaling molecules assembled around the cytoplasmic tail of the pre-BCR complex, the CD79A and CD79B chains' ITAMs act as docking sites for SYK kinase and trigger its activation, which is important for the transition from pro-B- to pre-B cell.²¹³ An important signaling function is provided by the adaptor protein BLNK, which acts as a scaffolding to link BTK (and other molecules) to downstream signaling molecules. In *Blnk*^{-/-} mice the transition from the pro-B- to the pre-B-cell stage is blocked,²¹⁴ and a similar defect has been detected in a patient with deficiency of BLNK, which blocks B-cell development.²¹⁵ SYK kinase deficiency is more effective than BLNK deficiency in arresting B-cell development.

Signaling Defects

Failure of B-cell development may result from defects in signaling through the pre-BCR. These experiments of nature have helped in delineating the molecular mechanisms of early B-cell development.⁸⁰ Immune deficiencies resulting from arrest of B-cell development are usually associated clinically with recurrent bacterial infections, laboratory findings of markedly reduced numbers of B cells, and hypogammaglobulinemia. Of all the patients, 85% have mutations in BTK, whereas the remaining 15% constitute a heterogeneous group with defects of various signaling molecules.

Defects of λ -5 Genes

The SLC is formed from two components: the BPREF1 and the lambda 5 (λ 5). In humans there is one VPREF1 gene and three immunoglobulin lambda-like (lambda 5) genes (IGLL1, IGLL3P and IGLL2P).²¹⁶ A boy with mutations in both alleles of the λ -5 genes expressed recurrent infections, hypogammaglobulinemia, and lack of B cells at an early age. The patient had three base-pair changes in a single allele and alterations within exon-3. Changes in codons 131 and 140 were silent, whereas that in codon 142 resulted in the replacement of proline, which in this place is highly conserved, by leucine (P142L).⁸⁵ The boy at 9 years of age had 0.1% CD19⁺ cells in the blood, but these cells were of the mature phenotype. In contrast to this patient, mice that are deficient in λ -5 have a leaky block at the pro-B-cell stage and still maintain 10 to 20% of the B cells.

Defects of CD79A

While screening several patients with defects of B-cell development, one 2-year-old girl was identified with an A-to-G substitution in the splice-acceptor site preceding exon 3 of Ig α ,²¹⁷ resulting in CD79A transcripts that were aberrant, because most of them had no exon 3. The patient showed failure to thrive, had diarrhea in the first month of life, and, later, had bronchitis and neutropenia. She had severe hypogammaglobulinemia and absent B cells. The block of B-cell development was at the pro-B-cell stage.

Defects of the μ Heavy Chain

Defects in μ H have been associated with agammaglobulinemia in individuals from two families. The defects consist of a large deletion of a 75- to 100-kb segment, including D, JH, and μ genes, or a base-pair substitution in the alternative splice site, with inhibition of the synthesis of the membrane form of Ig.²¹⁸ Mutations of the μ -H chain with agammaglobulinemia should be distinguished from X-linked agammaglobulinemia, because the disease from μ -H mutations can occur in females. Another report described a female patient with a cytosine insertion at the beginning of the CH-1 exon of the μ gene, which resulted in premature codon and absence of the μ -H chain.²¹⁹

Defects of B-cell Linker Protein

The gene for human BLNK is located on the long arm of chromosome 10 at 10q23.22. The BLNK is an adapter protein which, after phosphorylation by SYK, recruits several signaling molecules (i.e., PLCG2, VAV1, CBL, and BTK). A 20-year-old man with absent B cells and hypogammaglobulinemia was found to have two base-pair alterations: One of them did not change the amino acid (proline), but the second which was an A-to-T substitution, affected the position of the splice-

donor site for intron-1, approximately 20 bp downstream from the first alteration. The second defect resulted in a marked decrease of the BLNK transcripts and BLNK protein.²¹⁵ The patient had recurrent infections, undetectable serum Ig, and at the age of 20 years less than 0.01% of CD19⁺ cells in the blood. Mice with Blnk deficiency have only a leaky block of B-cell differentiation at the pro-B-cell stage; and in humans, mutations of λ -5 or BLNK cause a profound block of B-cell differentiation.

BRUTON AGAMMAGLOBULINEMIA

In 1952 Bruton described a male child with hypogammaglobulinemia and early onset of bacterial infections,²²⁰ later found to be inherited in an X-linked pattern that became known as X-linked agammaglobulinemia.²²¹ The constellation of findings consisted of very low serum Ig levels (i.e., for IgG approximately 10% of the normal control), no antibody production after immunization, markedly decreased B cells (0.3% of normal levels), and no germinal centers.²²² The genetic defect was located in the midportion of the long arm of the X chromosome (i.e., Xq22).²²³ There are several variants of the disease in relation to immunologic function and clinical heterogeneity.²²⁴ The product of this gene was identified as an SRC protein tyrosine kinase (PTK) that was called Bruton tyrosine kinase or BTK,^{225,226} and more than 400 mutations have been characterized to date.²²⁷ BTK is essential to BCR signaling and the BTK protein and the mRNA are significantly overexpressed in CLL compared with normal B cells. Although BTK is not always constitutively active in CLL cells, BCR or CD40 signaling is accompanied by effective activation of this pathway.

BTK is a member of the BTK-Tec family of PTKs, which includes BTK, TEC, ITK, TXK, and BMX.²²⁸ In the C-terminal end the BTK contains the catalytic SH-2 domain, and next to it lies the SH-3 domain, which associates with phosphorylated tyrosines

P.264

in other signaling molecules. The SH-2 is followed by one SH-3 domain, which binds proline-rich sequences in protein-protein interactions, and next is a T-ec homology (T-H) domain, which contains the Zn²⁺-binding BTK motif and a proline-rich stretch. At the N terminus is the pleckstrin homology (PH) domain, which binds with high-affinity phosphatidylinositol-3,4,5-triphosphate (PIP₃) and is responsible for the translocation of BTK to the membrane. BTK occupies a central position in BCR signaling and regulation of lineage development and is linked to multiple downstream signaling pathways through BLNK (also known as SH2 domain-containing leukocyte protein [SLP-65]). BLNK functions as a scaffolding protein and binds to the SH2 domain of BTK.²²⁹ It connects Syk to BTK and links BTK to downstream signaling molecules, like PLCG2, a linkage essential for Ca²⁺ signals.²³⁰ BTK also associates with Wiskott-Aldrich syndrome protein via the SH₃ domain; this is the reason that in XLA patients with defective BTK, the collagen-induced tyrosine phosphorylation of Wiskott-Aldrich syndrome protein in platelets is reduced.²³¹ Different regions of BTK are critical for its activation and signal transduction, that is, the PH domain binds to Ca²⁺-dependent (α , β -I, β -II) and Ca²⁺-independent isoforms of protein kinase C (PKC) (ϵ and ζ), to I-P₃,²³² and to heterotrimeric G proteins.²³³ Sequential phosphorylations of regulatory tyrosines by the BCR-associated Src kinases activate BTK, such as the phosphorylation of Tyr551 in the kinase domain or Tyr 223 in the SH-3 domain.^{234,235}

In SRC kinases, negative regulation is mediated by the Tyr-527 in their C-terminal region, but BTK has no equivalent residue, and it is likely that such a function is mediated by the recently identified inhibitor of BTK (I-BTK). I-BTK binds to the PH domain and downregulates Btk function, such as Ca²⁺ mobilization and NF- κ B activation.²³⁶

BTK is a bidirectional regulator with the capacity to deliver survival or apoptotic signals, depending on the expression of surface receptors and the stage of the cell differentiation.^{237,238} The molecular mechanism of BTK function in XLA is still not quite clear. Mutations of BTK gene, i.e., deletions, insertions, or substitutions,²³⁹ produce variable degrees of immunodeficiency, whether in the kinase domain²²⁶ or in other domains.

Evidence from the bone marrow of XLA patients shows that there is an expansion of pro-B cells, whereas the numbers of more mature B cells are negligible.²⁴⁰ Based on the expression of VPBEB1, the pre-BI cells are SLC-positive, and a number of them are large in size and cycling, whereas the pre-BII cells are SLC-negative. It appears that BTK blocks normal B-cell maturation at a point just before that stage (i.e., it interferes with the transition of pro-B cells to pre-BI stage).²⁴⁰ Some patients express an inactive form of BTK and have a more severe form of XLA than those expressing no BTK molecule.²⁴¹

EARLY STAGES OF B-CELL DEVELOPMENT

The study of phenotypes of B-cell precursors in normal adult bone marrow is hampered by the relative paucity of these cells. Therefore, some investigators have resorted to the study of leukemias, under the assumption that they accurately reflect normal B-cell development. Because aberrant phenotypes in acute leukemias have been identified, suggesting

asynchronous antigen expression, the validity of the results from such an approach has been challenged.^{1,242} Studies which used normal adult bone marrow²⁴³ or fetal bone marrow and fetal liver^{244,245} as a source of B-cell precursors in cultures or after injection in SCID mice have shown that B lymphocytes derive from cells expressing high levels of CD34.^{246,247}

The development of B cells can be separated into three stages according to phenotype: (a) pre-B cells (which includes pro-B cells and pre-B cells), (b) immature B cells, and (c) mature B cells (Fig. 12.1). Markers defining the first stage are CD19; occasionally some other promiscuous markers, such as CD2 or CD7, are detected, but probably the best marker is the SLC, a hallmark of a B cell, which may be detected by a monoclonal antibody. Entrance into the immature B-cell stage is defined by the expression on the surface of the cell of IgM, with antisera not only for μ chains but also for κ or λ light chains. This indicates that the μ chain is associated with a light chain and not with the SLC, and therefore the Ig gene rearrangements are complete. The immature B-cell stage is characterized by expression of only IgM without IgD. Functionally, this is important because the former phenotype defines a cell that is vulnerable to tolerogenic stimuli, indicative of its immaturity. At this stage the cell expresses other markers, such as CD10 at high density. The mature B-cell stage is simply identified by coexpression of IgD as well as other markers such as CD20, CD21, and CD22.

Another useful phenotypic marker for precursors of B cells is the nuclear enzyme TdT,²⁴⁸ which is a DNA polymerase catalyzing the elongation of polynucleotide chains without template,²⁴⁹ and which adds N-nucleotides at the DNA cleavage site during V(D)J recombination. CD24 is also expressed at a very early stage and at a higher density compared to mature slgM^+ B lymphocyte.²⁵⁰ The expression of the CD2 has been detected on biphenotypic ALL cells and also on their normal counterparts in human fetal hematopoietic tissues,^{251,252} but whether they represent common T- and B-lineage progenitors remains to be seen. Pre-B cells have been detected during fetal life, first in the liver (by 8 weeks) and later in the bone marrow (by 12 weeks).^{253,254} In the liver they are mixed among other myeloid cells next to liver parenchyma in extrasinusoidal areas.²⁵⁵ The small pre-B cell, the immediate precursor of the immature B cells, starts to express slgM by the end of the first trimester, and in adults the pre-B cells are present in the bone marrow, where they constitute 0% to 7% of the nucleated cells but rarely are noted in the peripheral lymphoid organs.

During the last phase of pre-B cell development, expression of CD34 and TdT disappears, CD10 is downregulated, and the cell expresses first CD22 and later CD20. Before its appearance on the cell surface, the CD22 is detected in the cytoplasm very early during development. It is identical to the surface CD22 and is B-lineage-restricted.²⁵⁶ The receptors for Fc are not present on pre-B cells, but receptors for C3b have been detected in some large pre-B cells and in approximately 40% of the small pre-B cells.²⁵⁷

MATURE B LYMPHOCYTES

The expression of slgM is the hallmark of B lymphocytes, which early in life are mostly CD5^+ and settle in the primary lymphoid follicles. By 13 weeks most of the B cells are IgM^+IgD^+ , but later IgG or IgA are added. This phenotype of fetal B cells persists until birth and is converted to the adult phenotype during the first few months of life. By 10 weeks of age practically all B cells in the spleen are IgM^+IgD^+ , whereas in the bone marrow only 30% to 40% coexpress the two isotypes. Maturation of B lymphocytes is associated with a change in the density of the two isotypes from $\text{IgM}^{\text{high}}\text{IgD}^+$ eventually to $\text{IgM}^{\text{low}}\text{IgD}^{\text{high}}$. New markers appear on B lymphocytes with the expression of IgM (Fig. 12.1), such as the CD21 which is present in more than 90% of the cells, as well as the C3d/EBV receptor. Activation triggers loss of CD21 and CD22, while CD23 is expressed and is upregulated by IL4.²⁵⁸ The EBV nuclear antigen-2 (EBNA-2)²⁵⁹ is downregulated by interferon- γ . Expression of CD24 decreases with B-cell maturation and in combination with the expression of CD45, it can be used to identify the mature stage of B cells, and it is useful in B-cell neoplasias.²⁶⁰ CD45 expression varies with B-cell maturation and is low in the most immature precursors in the bone marrow. It is upregulated as normal B-cell differentiation progresses and then declines at the terminal stages of differentiation as plasma cells become negative for CD45.²⁶¹

P.265

Probably the most important application of the B cell phenotype is in B-cell malignancies such as leukemias and lymphomas, which arise in distinct stages of differentiation. An attempt to incorporate the immunophenotype into the traditional morphologic features resulted in the revised classification of well-defined disease entities²⁶² by the World Health Organization.²⁶³

SURFACE IMMUNOGLOBULIN

Surface Ig on the surface of B lymphocytes serves as the receptor for antigen and is identified most commonly with the use of fluorochrome-conjugated anti-Ig antisera. The first Ig to appear on B lymphocytes is IgM, which is composed of only

one subunit, in contrast to the secreted pentameric form of membrane IgM (mIgM), containing two H and two L chains. The second isotype to appear is IgD, which is present either as a complete four-chain molecule or as a half-molecule. IgD is present in the serum in very low concentrations and it is not known to have a role in humoral responses, by tuning finely the BCR for its binding with the antigen.²⁶⁴ The ratio of secreted Ig to mIg increases with maturation from resting B cells to plasma cells. The transmembrane and secreted forms are encoded by the same gene. There are two polyadenylation sites for transcription termination; one is 3' to the last exon of the constant chain and the second is 3' to the second transmembrane exon (Fig. 12.7). Termination at the first site results in loss of the transmembrane exons and production of the secreted form, whereas polyadenylation at the second site produces the membrane form of Ig.

Each B lymphocyte contains on the average 50,000 to 100,000 molecules of Ig, although the density of sIg varies among individual B cells.²⁶⁵ The mIg is distributed on the surface in small clusters, including the microvilli^{266,267}; in human B lymphocytes the clusters are separated from each other by a few thousand angstroms of bare membrane, indicating restriction in the free distribution of mIg. In the mouse the clusters are interconnected by strands composed of a few molecules forming a lacy continuous network. When examined at 4°C in the fluorescent microscope with fluorescein-conjugated anti-Ig antibodies, the mIg appears distributed as a ring, and the increase in temperature to 37°C prompts the formation of clusters (patching) that move rapidly toward one pole of the cell, forming a cap²⁶⁸ (Figs. 12.8 and 12.9). Shortly after the formation of the cap, changes in cell shape occur accompanied by cell movement. The cell pushes out a projection located opposite to the cap, which corresponds to the membrane ruffles noted on scanning electron microscopic analysis²⁶⁹ (Fig. 12.10).

FIGURE 12.7. Expression of membrane versus secreted immunoglobulin (Ig) depends on alternative processing of the primary RNA transcript. There are two polyadenylation (poly A) sites, one for secreted (Se) and one for membrane (Me) forms. $C\mu 1$ - $C\mu 4$ are the exons of IgM. Cy, cytoplasmic region; mRNA, messenger RNA; TM, transmembrane region.

After the formation of the cap, a constriction under the cap encircles the cell and the cell takes the shape of a hand mirror, with the cap occupying the area of the uropod with numerous microvilli. A dense band of microfilaments is collected

under the constriction which separates the cell body from the uropod, and the area opposite the cap contains the cell organelles and the nucleus.²⁷⁰

The majority of human B lymphocytes cannot form a cap because the Ig clusters on the surface of the cell are widely separated from each other. Capping requires energy provided by the respiratory chain and glycolysis and is not affected by cell motility, which is complete in many B cells before any amoeboid movement is noticed.²⁷⁰

Colchicine, which disrupts microtubules, has no effect on capping and only a slight effect is noted with cytochalasin B, which disrupts the microfilaments; but the combination of these drugs inhibits mIg capping. Calcium, which plays an important role in contractile systems, is also involved in mIg capping.^{270,271} The fate of the complexes in the cap has been studied morphologically using autoradiography, electron microscopy, and measurements of radioactivity. The bulk of the complexes is internalized (endocytosed) in the presence of adequate antibody. Endocytosed material is catabolized within the lysosomes, and small fragments are released into the culture medium. With the completion of endocytosis, the B lymphocyte remains free of mIg until it is resynthesized to the original level in 24 hours.

BCR COMPLEX: STRUCTURE AND SIGNALING

The surface Ig (sIg) of the B lymphocyte, or BCR, forms a complex with several components assembled into two structurally and functionally distinct modules: an antigen-recognition module (sIg) and a signal-transducer module which is the heterodimer of the CD79A/CD79B polypeptide chains (Fig. 12.11).^{272,273,274}

The BCR is an antigen-specific receptor which transmits signals regulating activation, growth, and differentiation. Since the cytoplasmic tails of both heavy chains of mIgM consist of three amino acids, the mIgM is not suitable for signal transduction; as a result this function is undertaken by two other proteins, associated with the mIgM BCR: CD79A with a 61-residue cytoplasmic tail and the CD79B with a 48-residue tail. The cytoplasmic domain of the CD79A and CD79B proteins initiate their internalization by a signal from the first cytoplasmic tyrosine residue, Y-176 of the CD79A and Y-195 of CD79B. The genes encoding these proteins are also known as mb-1 and B-29, respectively. The transmembrane region of C μ is a highly conserved portion of the Ig molecule between species and isotypes and provides the site which binds the CD79A/CD79B heterodimer. The conserved amino acids are not all hydrophobic, but contain several hydrophilic residues; and its amphipathic nature indicates that mIg forms complexes with other proteins. These proteins carry in their cytoplasmic tails a sequence motif of six conserved and precisely distributed amino acids (tyrosines and negatively charged amino acids) over a sequence of 26 residues.

The motif named immunoreceptor tyrosine-based activation motif, or ITAM,²⁷⁵ is found in γ , δ , ϵ , ζ , and ϵ chains of CD3 and Fc receptors. The ITAMs are sequences in multiple receptor chains, and in TCR they mediate signal transduction following phosphorylation of the two tyrosines in the ITAM, which activates the SRC family kinase Lyn, but not SYK. In mice the B-lymphocyte accessory molecule Cd79a (I- α), which is encoded by the B cell-specific gene Cd79a (mb-1), Cd79b (Ig- β) and the

P.266

P.267

membrane-bound immunoglobulin (mIg) form the B-cell receptor (BCR). Cd79a and Cd79b form a heterodimer which, upon antigen binding and receptor clustering, initiates and controls BCR intracellular signaling, ultimately triggering an effector response. The signaling capacity of Cd79a is contained within its immunoreceptor tyrosine-based activation motif (ITAM), which is also a key component for intracellular signaling initiation in other immune cell-specific receptors and is required in Syk-dependent integrin signaling. Following the binding of the ligand by the BCR, the ITAMs transmit activation signals initiating proliferation and differentiation of the B cell. However, the ITAMs also transmit what have been called tonic signals, which have a role in B cell development and survival;²⁷⁶ but the molecular mechanism for their induction is not known. The CD79A and CD79B genes are active only in the B lineage and are expressed before the assembly of the V gene. In cells from multiple myeloma, however, only the CD79B is expressed and that prevents expression of Ig in plasma cells. The expression of surface Ig requires the complete assembly of the Ig with the CD79A/CD79B heterodimers, which explains the lack of detection of mIg on plasma cells;²⁷⁷ and indeed, the transfection of plasma cells with the CD79A gene results in expression of sIg.²⁷⁸ A patch of polar amino acids within the transmembrane region of C μ signals the retention of IgM within the ER until the CD79A/CD79B heterodimer associates with IgM for transportation to the cell surface.

FIGURE 12.8. Demonstration of surface immunoglobulin (Ig) by immunofluorescence on B lymphocytes. Viable normal B lymphocytes treated with anti-IgM antiserum at 4°C present a staining pattern of a uniform ring around the periphery of the cell (A) or discrete patches uniformly dispersed over the cell surface (B). (From Zucker-Franklin D, Greaves MF, Grossi CF. Atlas of blood cells, 2nd ed. Philadelphia, PA: Lea & Febiger, 1988, with permission.)

FIGURE 12.9. Redistribution of surface immunoglobulin (Ig). A: Mouse B lymphocytes treated with fluorescein-conjugated anti-mouse Ig antibody. a: Surface Ig is uniformly distributed around the cell (ring pattern). This pattern is seen only if the cell is kept at 0°C. b: Warming the cell to room temperature causes redistribution of the Ig so that it occupies only one pole (cap pattern). (From Taylor RB, Duffus WP, Raff MC, de Petris S. Redistribution and pinocytosis of lymphocyte surface immunoglobulin molecules induced by anti-immunoglobulin antibody. *Nature* 1971;233:225, with permission. Copyright (c)1971 Macmillan Magazines Limited.) B: Mouse B lymphocytes treated with rabbit anti-mouse Ig-conjugated with iodine-125 were examined by high-resolution radioautography. a: At the ultrastructural level, Ig is distributed around the entire surface of the cell, if it is maintained at 4°C. b: Surface Ig accumulates to one of the poles of the cell (uropod), forming a cap when it is warmed at 37°C. c and d: The cap is eventually endocytosed. (From Unanue ER, Perkins WD, Karnovsky MJ. Ligand-induced movement of lymphocyte membrane macromolecules. I. Analysis by immunofluorescence and ultrastructural radioautography. *J Exp Med* 1972;136:885-906. Reproduced by copyright permission of the Rockefeller University Press.)

FIGURE 12.10. Ultrastructure of a cap. A: Anti-immunoglobulin (Ig) labeled with hemocyanin in mouse spleen. B lymphocyte is heavily concentrated in the uropod around short microvilli. Some of the capped Ig has been endocytosed (E). The label in the cap is densely packed, whereas the adjacent areas are clear of label (arrows). (From Karnovsky MJ, Unanue ER, Leventhal M. Ligand-induced movement of lymphocyte membrane macromolecules. II. Mapping of surface moieties. *J Exp Med* 1972;136:907-930. Reproduced by copyright permission of the Rockefeller University Press.) B: A cell with a tightly packed cap with smooth surface in the remaining body. C: The cap is separated by a constriction from the rest of the body, which shows intense membrane ruffling. G, Golgi apparatus. (B and C from Karnovsky MJ, Unanue E. Cell surface changes in capping studied by correlated fluorescence and scanning electron microscopy. *Lab Invest* 1978;39:554-564, with permission.)

FIGURE 12.11. The B-cell receptor (BCR). The surface immunoglobulin (Ig) (two heavy and two light chains) constitutes the antigen-specific component of BCR, which is associated noncovalently with a heterodimer consisting of two chains, Ig α and Ig β . This heterodimer constitutes the signal transduction component. The Ig α chain associates with the H chains through ionic interactions. ITAM, immunoreceptor tyrosine-based activation motif; mIgM, membrane immunoglobulin M. The functional B-cell receptor is a complex consisting of IgM with one CD79A/CD79B heterodimer on each side.²⁷⁹ New P.268

evidence, however, indicates that each IgM molecule is associated with only one CD79A/CD79B heterodimer (Fig. 12.11).²⁸⁰ If this model is correct, the question remains whether both chains are linked to IgM, or whether only CD79A binds to both heavy chains and CD79A-BCR forms oligomers with additional molecules of the same isotype.

B-CELL RECEPTOR AND LIPID RAFTS

Ligand binding changes the orientation of the BCR molecules so that their ITAMs become more accessible to phosphorylation, which causes signal spreading restricted to BCRs of the same isotype.²⁸⁰ Lipid rafts are dynamic assemblies of proteins and lipids that float freely within the liquid-disordered bilayer of cellular membranes, but can also cluster to form larger, ordered platforms which regulate membrane function in eukaryotic cells.²⁸¹ These early events of BCR reorganization provide a mechanism for detecting low concentrations of antigens, thus increasing the threshold of activation. Cross-linking of BCR by multivalent antigen leads to a series of morphologic and molecular events that are interrelated, i.e., BCR aggregation and its loading to lipid rafts, signaling, and finally internalization and antigen presentation.

In the resting state the BCR floats on the cell membrane as monomer, but at the time of signal spreading it forms oligomers which are carried on specialized membrane microdomains referred to as lipid rafts. Lipid rafts are estimated to represent 30% to 40% of the cell surface in lymphocytes and have a role in B-cell activation as platforms for BCR signaling and might also act in antigen trafficking. Lipid rafts are an important component of B-cell signaling, since they facilitate the regulation of the BCR during B cell development by B-cell coreceptors.²⁸² Their size varies from submicroscopic dimensions which contain only a few hundred phospholipid molecules and four to ten protein molecules. Cross-linking of the BCR with antigen enhances its transfer to lipid rafts,^{281,282,283,284} while the pre-BCR which is constitutively located on lipid rafts generates a calcium signal.⁷⁵ Lipid rafts are also preferential sites of formation of prion proteins and β -amyloid associated with Alzheimer's disease.²⁸⁵

The mechanism of their action is not clear, but it is believed that they act as molecular sorting machines, coordinating signal transduction pathways. It is rather intriguing that they serve as portals of entry for various pathogens and toxins, such as HIV-1. In this case the raft microdomains mediate the mechanisms of the fusion of HIV-1 with the host cell. Lipid rafts are enriched in cholesterol and glycosphingolipids with saturated fatty acid side chains consisting of GM-1 gangliosides, and are resistant to solubilization in nonionic detergents at low temperatures. Most proteins are excluded from the lipid rafts, except proteins modified by saturated fatty acids such as acylated Src kinases and the α -subunits of trimeric G proteins. They facilitate BCR signaling by co-localizing signaling molecules, i.e., LYN, FYN, and BLK, members of the SCR family of kinases, but also by excluding molecules that inhibit BCR signaling such as CD22. Furthermore, in anergic or tolerized B cells, the BCR is unable to enter lipid rafts, indicating that inclusion of BCR within these microdomains is an absolute requirement for initiation of signaling.²⁸⁶ Similarly, localization of BCR within the rafts occurs only in mature, but not immature, B cells.²⁸⁷ The translocation of the BCR into lipid rafts is independent of any signaling initiated by the receptor and does not require actin cytoskeleton polymerization or the CD79A/CD79B complex.²⁸⁸ Lipid rafts facilitate not only activation but also apoptosis, because cross-linking of CD24, a glycosylphosphatidylinositol-anchored protein that is downregulated during B-cell differentiation, induces apoptosis via a lipid raft signaling system.²⁸⁹ CD24 cross-linking brings some BCR within the lipid rafts, activating LYN kinase. EZR (EZBIN) is a member of the ezrin-radixin-moesin (ERM) family, is dephosphorylated by BCR, and is detached from the actin as well as from lipid rafts, resulting in greater coalescence of lipid rafts and more effective B-cell activation.²⁹⁰ B cells are not only antibody-producing cells, but in addition are antigen-processing and -presenting cells. For this function they interact with antigen-specific T cells to receive T cell help.²⁹¹ Antigen captured by B cells induces BCR cross-linking, translocation into lipid rafts, where it is phosphorylated, promoting BCR internalization mediated by clathrin associated with the rafts. This is followed by BCR cross-linking, antigen internalization, which is diverted to the endocytic pathway for further processing and presentation to T cells.²⁸⁴

The B cell antigen receptor and the T cell receptor have no inherent kinase activity and, like other multichain immune recognition receptors (MIRRs), they are associated with members of the SRC family kinases to initiate signaling spatially organized by the lipid rafts and regulated by clathrin.

The CD21/CD19 complex coreceptor markedly enhances BCR activation, stabilizes the residence of BCR within the rafts, and thus prolongs B-cell activation.²⁹² In contrast, the FCGR2, which inhibits B-cell activation, destabilizes BCR-raft association.²⁹³ After translocation of BCR (or other immune receptors) onto lipid rafts, the rafts appear to form clusters, i.e., clustered rafts,²⁸¹ which increases the range of their diameters from hundreds of nanometers to micrometers. Clustering results from cross-linking of receptors located on separate rafts and eventually from the linking of rafts with linker proteins. In addition, cytosolic proteins that have been associated with the cytoplasmic domains of receptors residing on a raft may also contribute to the bridging of individual lipid rafts to form larger conglomerates. Cytoskeletal components are also linked to activated receptors and their reorganization bridges clustered rafts.

Continuation of raft clustering eventually leads to the formation of the synapse, a highly ordered membrane structure in which immune receptors, signaling molecules, and cell adhesion molecules are clustered.²⁹⁴ Synapse formation is a highly organized structure with a cluster of immune receptors in the center ringed by adhesion molecules and several signaling molecules and cytoskeletal components on the cytoplasmic side.

The formation of a synapse was first described in T cells, but it has now been detected on B cells,²⁹⁵ suggesting that this is a unique mechanism associated with foreign antigen capturing for processing and handling by the immune system to secure a cellular response. When DC capture the antigen, they trigger the formation of the synapse on B cells and during the close encounter between B cell and DC around the synapse, the B cell samples and gathers antigen for internalization and processing. Internalization of the antigen and signaling are two interrelated and inseparable events mediated by lipid rafts.^{282,296} B cells with deficiency of expression of the SRC kinases, which normally initiate B-cell signaling, fail to internalize the receptor, and as a result, targeting of antigen to MHC-II peptide-loading compartment is also disrupted.²⁹⁷ Internalization of BCR occurs when clathrin, which is associated with the rafts, is phosphorylated on its tyrosine after BCR

cross-linking.²⁹³ When lipid rafts are disrupted by the expression of LMP2A protein of the EBV or by reagents that sequester cholesterol, the internalization of the antigen does not occur.^{298,299}

Expression of LMP2A therefore not only inhibits BCR function, but generates a ligand-independent cellular activation signal, which provides a molecular switch for different EBV life cycle stages and thus contributes to EBV-associated lymphoproliferative disorders.

P.269

B-CELL RECEPTOR SIGNALING

The most important structural elements of signaling molecules for the initiation of B-cell activation and differentiation are the ITAM motifs of the CD79A/CD79B heterodimer and the PTKs associated with the complex (Fig. 12.12). The ITAM is characterized by a sequence of 26 amino acids, D/E-X₇-D/E-X₂-YXXL/I-X₆(7)-YXXL/I, with six of them being conserved (X = any amino acid). Critical for signaling are the two tyrosines (Y), and one or both of them are phosphorylated when the BCR is engaged by antigen. Some evidence suggests that activation of B cells may be triggered not only by the tyrosine-based activation motif (ITAM), but by a critical non-ITAM tyrosine 204 residue that is conserved in evolution.³⁰⁰

BCR signaling is a highly complex process,^{213, 301, 302} but for the sake of understanding, we divide the interactions somewhat arbitrarily into three major pathways: (a) initial interactions, (b) phosphoinositide pathways, and (c) the ras pathway.

INITIATION PATHWAY

BCR has no intrinsic protein tyrosine kinase (PTK) activity but uses several distinct families of cytoplasmic PTKs. Three distinct types of PTKs are activated on BCR engagement: (a) the SRC-PTKs (LYN, BLK, and FYN), (b) SYK, and (c) BTK.³⁰¹ Activation of LYN is one of the earliest events in BCR-induced signaling, which is constitutively acylated and, as a result, localizes in the cell membrane. It is responsible for the initial phosphorylation of the ITAMs of CD79A and CD79B. The kinase activity of LYN is regulated by phosphorylation of a carboxy-terminal regulatory tyrosine by the kinase CSK³⁰³ and dephosphorylation by the phosphatase CD45.³⁰⁴ LYN has one SH-3 domain on its N terminus, followed by one SH-2 domain and the kinase domain in the C terminus. SH-2 domains bind phosphorylated tyrosines, whereas the SH-3 domains bind proline-rich sequences. BCR engagement triggers dephosphorylation of Tyr-508 by the CD45 phosphatase, whereas Tyr394 within the catalytic domain is rapidly phosphorylated. SYK kinase is recruited to the phosphorylated ITAMs of CD79A and CD79B, and is phosphorylated by LYN or by an autophosphorylation mechanism.³⁰⁵

Activation of SYK is a critical event in BCR signaling and for recruitment of BLNK, or SLP-65, a linker protein with a major scaffolding function connecting several downstream signaling molecules.³⁰⁶ BLNK assembles macromolecular complexes that include PLCG2, VAV, BTK, and additional linker proteins GRB2 and NCK1.^{307,308}

Phosphorylation of five tyrosine residues of BLNK is required for coordination of the assembly of multimolecular complexes. BTK belongs to the TEC family of kinases and differs in several aspects from the SRC kinases (i.e., it is not myristoylated, does not contain a negative regulatory phosphorylation site in the C terminus, and has a pleckstrin homology domain [PH] in the N terminus). BTK function is regulated by phosphorylation of the Tyr551, which is essential for BTK participation in signal transduction.²³⁴ BTK also interacts with phosphatidylinositol-3,4,5-tri-phosphate (PIP3), an interaction required for recruitment of BTK to the cell membrane.³⁰⁹ Because PIP3 is generated from activated PI3 kinase, BTK is targeted to the membrane after PI3 kinase activation, where it could be phosphorylated by LYN or SYK.

GENERATION OF PHOSPHOINOSITIDES

Hydrolysis of inositol-containing phospholipids is mediated by the lipid metabolizing enzymes PLCG2 and PIK3CA. There are several pathways leading to activation of PLCG2 in B cells.³¹⁰ BLNK associated with PLCG2 (which is the main isoform in B cells) brings it to an appropriate position for activation by SYK kinase. On the other hand, BTK also contributes to PLCG2 activation because B cells from XLA patients show a profound reduction of IP3 production on BCR engagement.³¹¹ PIP₃, the product of PIK3CA activation, binds to the PH domain of PLCG2, thus providing another pathway for PLCG2 activation. PLCG2 activation leads to hydrolysis of phospholipids, generating IP₃ and DAG (diacylglycerol). IP₃ binds to appropriate receptors on the ER, leading to Ca²⁺ release from internal stores.

PIK3CA is activated by at least two pathways and a prominent substrate for tyrosine phosphorylation is the product of the oncogene CBL. BCR engagement phosphorylates p12-CBL, which is then associated with the 85-kDa component of PIK3CA.³¹² A second pathway is through the CD19/CD21 coreceptor complex.^{313,314} BCR stimulation phosphorylates the

two YXXM motifs of CD19, which then bind the SH-2 domain of the p85 regulatory subunit of PIK3CA. Enhanced phosphorylation occurs when the CD19/CD21 complex binds C3d fragments. Furthermore, the proline-rich region of the p85 subunit binds to SH-3 domains of LYN and FYN, further enhancing PIK3CA activation.

Ca²⁺ binds to calmodulin and promotes calmodulin-dependent protein kinase activation and calcineurin, a serine-threonine-specific protein phosphatase. Calcineurin directly dephosphorylates the NFAT family of transcription factors.^{315,316} DAG1, (diacylglycerol), one of the two second messengers produced by PLCG2 gene activation, activates cPKC. One target of PKC on B cells is MARCKS, (Myristoylated Alanine-Rich C- Kinase Substrate) that regulates actin reorganization. Elevation Ca²⁺ also activates a number of other transcription factors, such as NF-κB and ATF2. Phosphoinositides generated by PIK3CA bind to AKT1(PKB) kinase, an evolutionarily conserved kinase across species.³¹⁷ AKT1 is the product of an oncogene transduced by the acute transforming retrovirus (Akt8). The viral and cellular oncogenes encode a serine-threonine protein kinase consisting of a C-terminal kinase domain and an N-terminal PH domain. Mutations of the PH domain block AKT1 activation by growth factors or phosphoinositides. AKT1 activation is also mediated by the serine/threonine kinase PDK1 (Pyruvate Dehydrogenase Kinase 1), which is stimulated by PIP₃ and phosphorylates AKT1 on Thr308. AKT1 inhibits glycogen synthase kinase 3 (GSK3), which destabilizes MYC and cyclin D, both required for cell cycle progression. A combination of various AKT1 activation effects plays a role for its transforming and oncogenic potential. Some of its multiple effects include transcriptional regulation of gene expression, inhibition of apoptosis, cell cycle regulation, insulin-induced metabolic signals, endocytosis, etc.

THE RAS PATHWAY

BCR cross-linking leads to an increase of the guanosine triphosphate (GTP)-bound ras and its accumulation in the membrane under BCR. RAS is a guanine nucleotide-binding protein, which cycles between a guanosine diphosphate (GDP)-bound (inactive) and a GTP-bound (active) state. The proteins of the RAS family are proto-oncogenes, which, on mutation, accumulate in the GTP-bound state in human tumors. On activation of B lymphocytes, Ras is rapidly converted to the GTP-bound state. The cycle between GDP and GTP binding is controlled by guanine nucleotide exchange factors (GEFs) that promote the transition from a GDP- to a GTP-bound state. This is reversed by guanosine triphosphatase (GTPase)-activating proteins, which stimulate GTPase activity of Ras and result in hydrolysis of GTP to GDP. The balance between GEFs and GTPase-activating proteins regulates RAS activity.³¹⁸ The most likely pathway of ras activation is through the adapter protein SHC1, which is phosphorylated after

P.270

BCR engagement. SHC1 binds to a second adapter protein GRB2, which in turn binds to SOS, a nucleotide exchange factor.

FIGURE 12.12. B-cell activation. Signal transduction initiated by the engagement of the B-cell receptor (BCR) is a highly complex process. For better understanding, it is divided arbitrarily into three main signaling pathways: (a) initiation: with the assembly by adapter proteins such as BLNK (B-cell linker protein), Cbl, and others of signaling protein tyrosine kinase (PTK) complexes such as Src (Lyn, Fyn), Syk, and Btk; (b) inositol phosphatides generation by the activation of PI3K and PLC- γ ; (c) the ras/Erk pathway assembled by adapter proteins Grb, Shc, and Sos. These pathways carry the signals downstream to other signaling molecules Akt, calcineurin, and Erk/1,2, and to activation of transcription factors nuclear factor-AT (Nfat), NF- κ B, Creb, c-fos, etc.

This multimolecular complex is associated with the membrane.^{319,320} A guanine nucleotide exchanger protein, VAV, which is a GEF in the Rho family of GTPases, is recruited to the phosphorylated Tyr-341 and Tyr-345 of SYK through its SH-2 domain and is subsequently phosphorylated.³²¹ These RAS-like proteins are molecular switches that are active in the GTP-bound state and can promote site-specific actin polymerization to create alterations in plasma membrane structures such as filopodia and lamellipodia. VAV has a Dbl homology domain, which has the GEF activity, a PH domain (binds phosphoinositides), an SH-2 domain, and two SH-3 domains. The PH domain of VAV uses PIP₃ for recruitment to the cell membrane. VAV may also be recruited to the membrane by binding to Tyr-391 of CD19. A negative regulator of the RAS pathway is CBL, which competes for the binding to SOS. CBL (Casitas b-lineage lymphoma) is the cellular homolog of v-Cbl, part of the transforming gene of the Cas-NS1 retrovirus, a murine virus, capable of causing pre-B-cell lymphomas. It contains a proline-rich region (residues 481 to 688), a leucine zipper motif (residues 855 to the C terminus), and multiple potential SH-2-binding motifs. It binds to PTKs such as FYN, ZAP70, and BTK, to the adapter molecule GRB2, and to PI-3K.³²² In B-cell signaling, CBL binds to BLNK through its SH-2 domain and inhibits association of PLCG2 phosphorylation.³²³

Binding of SOS and CBL to GRB2 is mutually exclusive, because the proline-rich domains of these proteins compete for the same SH-3 domain of GRB2. A group of signal transduction pathways is characterized by successive phosphorylations of serine/threonine kinases. This group consists of a mitogen-activated protein kinase (MAPK), a MAPK kinase (MAPKK), and a MAPKK kinase (MAPKKK). RAS-GTP phosphorylates RAF1, which is the MAPKKK of this cascade. RAF1 phosphorylates and activates MAP2K1 (MEK1) and MAP2K2 (MEK2), which in turn phosphorylates MAPK3 (ERK1) and MAPK1 (ERK2). Phosphorylated ERKs form dimers and are translocated to the nucleus, where they phosphorylate transcription factors c-fos and JUN members of the ETS family.

ADAPTER MOLECULES: PLASTICITY AND DIVERSITY OF SIGNALING

Adapter proteins possess domains that mediate protein-protein or protein-lipid interactions, but they have no enzymatic activity. Two groups of adapter proteins can be identified: transmembrane adapter proteins and cytosolic adapter proteins (CAPs). In general, adapter proteins assemble multimolecular signaling complexes and direct their formation to specific cellular locations.^{324,325,326} and ³²⁷ At the initial stages of B-cell activation, LYN, SYK, and

P.271

BTK kinases are activated. A transmembrane adapter protein, PAG (phosphoprotein associated with glycosphingolipid-enriched microdomains), links Lyn to the kinase that phosphorylates the C-terminal tyrosine for LYN activation. The CAP adapter protein BLNK (or SLP-65, SH-2 containing Linker Protein of 65 kDa) connects BTK to SYK and brings PLCG2 on the lipid rafts. There are inhibitors for adapter proteins, such as I-BTK, which binds to the pleckstrin domain of BTK and negatively regulates its activation. BLNK, which connects several important molecules to BCR for the initial stage of signaling, is indispensable for LMP2A (latent membrane protein), a constitutively activated EBV protein in infected B cells. LMP2A signaling can substitute for the signaling of BCR and maintains survival of EBV-infected B cells, leading to infectious mononucleosis or Burkitt lymphoma. The CAP BLNK is clearly required for the translocation of PLCG2 from the cytosol to the plasma membrane and its subsequent activation. BLNK (SLP-65) is essential in pre-B-cell development and, with BTK, induces cell proliferation.

B-CELL SIGNALING BY ACCESSORY STRUCTURES

Many other cell surface molecules participate in B-cell signaling. The coreceptor complex CD19/CD21 activates the CD19-associated PTKs, which induce phosphorylation of tyrosine residues on CD19 motifs.³²⁸ These then become potential SH2-binding sites for PI3 kinase, which generates phosphoinositides. Recruitment of PI3K to CD19 requires phosphorylation of Tyr484 and Tyr515. Activation of PI3K generates PIP-3, which functions to localize BTK to the plasma membrane, where it is phosphorylated and activated by SRC and SYK kinases. BCR activation of BTK is dependent on CD19 expression, whereas activation of LYN and SYK is not.³²⁹ PLC activation generates DAG, which activates PKC and 1,4,5-triphosphate, which increases cellular Ca^{2+} . CD22 is associated with BCR, which on engagement phosphorylates some of the six tyrosines of CD22. This in turn leads to recruitment of PTPN6 (SHP-1) via its SH-2 domain to CD22.³³⁰ CD22 contains ITAMs and four immunoreceptor tyrosine-based inhibition motifs (ITIMs) in the cytoplasmic region. PI3K and PLCG1 associate with CD22 through the YXXM motif recognized by the N-terminal SH-2 domain of the p85 subunit of PI3K, whereas the protein tyrosine phosphatase PTPN6 (SHP-1) binds to ITIMs. As a result of multiple ITIMs, CD22 is probably a negative regulator of B cell activation. (For more details, see CD22 in Appendix A.)

INTERLEUKIN-4

Although several cytokines act on B cells, the action of IL4 was first demonstrated on B lymphocytes, and on these cells IL4 evokes the strongest reactions. IL4 binds to a transmembrane receptor and results in cross-linking with another protein termed common gamma chain (γ c), which is shared by other cytokines.^{331,332,333} Mutations in the γ c chain results in X-linked SCID, an inherited disease with profound suppression of cell-mediated and humoral immunity.^{334,335} IL4 binding induces phosphorylation of a substrate of 170 kDa designated as 4PS, which is unique because no other cytokine except IL13 binding phosphorylates a similar substrate. However, insulin and insulin growth factor-1 result also in 4PS phosphorylation. 4PS is structurally similar to insulin receptor substrate-1 (IRS-1). The gene for 4PS has been cloned and is called IRS2. IRS1/2 contains more than 20 potential tyrosine phosphorylation sites and 30 potential threonine/serine phosphorylation sites. The tyrosine phosphorylation sites bind with high affinity to cellular proteins possessing SH-2 domains and thus act as docking sites for several signal-transducing proteins such as PI3 kinase and growth factor receptor-bound protein-2 (GRB2). Mutational analysis has mapped a region of the IL4R between amino acids 437 and 557, which is important for IRS1 phosphorylation and therefore signal transduction.³³⁶ This region contains a single tyrosine, is shared by the IL4 receptor (IL4R) and the insulin receptor, and is known as the I4R motif.

Although the insulin receptor and IL4R have many similarities, they have an important difference. The insulin receptor is a receptor tyrosine kinase, whereas the IL4R and γ c are not, but are associated with nonreceptor PTKs. Association of IL4R and γ c activates kinases associated with IL4R, which then phosphorylates the tyrosine in the I4R motif. This allows 4PS to bind to the IL4R and to be phosphorylated by the kinases associated with the IL4R. The phosphorylated motif I4R interacts with the PTB domain of IRS1/2. PTB domains are found in adapter proteins, such as SHC, and bind phosphopeptides.

IRS1/2 becomes phosphorylated as a result of interaction with the IL4R α receptor and binds to the p85 subunit of PI3K, which as an adapter links IRS1/2 to the catalytic subunit p110. PI3K is activated as a result of conformational changes, acts on phosphatidylinositol of the cell membrane, and transfers phosphate groups from adenosine triphosphate to the D₃ position of inositol-generating PIP₃ and phosphatidylinositol 3,4-bisphosphate. The phosphoinositides act on downstream

kinases (i.e., PKC and AKT1) that make important contributions to cell survival. Activation of the IRS1/2 signaling proteins is associated with activation of the RAS/MAPK pathway (see "The RAS Pathway"). IL4R is also associated with the Janus kinases (or JAKs).^{337,338} The α chain binds to JAK1, whereas the γ chain binds to JAK3. The receptors bind to these kinases through their membrane-proximal domains, which are known as box 1 and box 2 motifs and have some similarity among cytokine receptors.

The sequence of residues 557 and 657 of the α -chain (known as the gene-regulation domain) is critical for expression of IL4-responsive genes. It contains three conserved Tyr residues (Y575, Y603, and Y631), which can potentially be phosphorylated and thus be able to associate with SH-2 domains. IL4 utilizes the STAT6 member of the transcription factor family known as STATs (signal transducers and activators of transcription). IL4-responsive genes include class II HLA, CD23, germline Ig ϵ and γ -1 chains, and IL4R α chains.

Engagement of IL4R results in the activation of JAK1 and JAK3, which phosphorylate tyrosines of the cytoplasmic region of the receptor. STAT6 binds through its SH-2 domains to the phosphorylated tyrosines and becomes itself phosphorylated at its C terminus by the activated JAK kinases. The phosphorylated STAT6 dimerizes and binds to promoters of the IL4-responsive genes.³³⁹ (For more on IL4 see Chapter 14.)

INTERLEUKIN-5

The α chain of IL5R is a type-I membrane protein of 415 amino acids, its extracellular region comprising three sets of fibronectin type III domains, whereas the intracellular domain does not contain sequences of tyrosine kinase but shows homology with a part of the actin-binding domain of β -spectrin.³⁴⁰ It also has a region rich in prolines conserved among receptors of other cytokines (e.g., IL3, granulocyte-macrophage colony-stimulating factor receptor or CD116; see Appendix A).

A second β -chain is important for signal transduction but it does not contribute to IL5 binding. A membrane-proximal region contains a conserved box-1/box-2 motif that is responsible for the interaction with JAK2, and the distal domain is responsible for the activation of the RAS-related pathways. IL5 signaling increases BTK activity.

P.272

INTERLEUKIN-6

IL6 is a pleiotropic cytokine that, among many other functions, is involved in terminal differentiation of B cells.^{341,342} The extracellular region of the IL6R consists of one constant region domain of the Ig superfamily and two fibronectin type III domains, which have four conserved cysteine residues and a motif containing two tryptophans and two serines. This motif is located in a groove between the two fibronectin domains. The intracellular domain is short and is not involved in signal transduction. Associated with the IL-6R is a protein known as gp130, which dimerizes when IL6 binds to the IL6R. The gp130 protein is shared by other cytokine receptors and initiates signal transduction. Homodimerization of gp130 induces activation of JAK kinases, which are associated with the membrane-proximal region of gp130, also known as box-1. This leads into phosphorylation of a tyrosine in the distal part of gp130 (box-3), resulting in binding through an SH-2 domain of the transcription factor STAT3, previously known as acute phase response factor or APRF. JAK kinases activate STAT3 by phosphorylation.

Another nuclear target for gp130 signaling is the transcription factor NF-IL6 with a leucine zipper motif. This factor is inducible in hepatocytes and monocytes by IL6 and other cytokines and mediates the expression of IL6-inducible genes. NF-IL6 has a consensus sequence for MAP kinase, suggesting that it is activated through this pathway, which is RAS-dependent. (For further details, see Chapter 14.)

CD 40

CD40 is a member of the tumor necrosis factor receptor family, which interacts with its ligand, CD154, expressed on T cells. (See "CD40 and CD40 Ligand [CD154]"; Appendix A.) Signal transduction by CD40 is mediated by certain proteins that bind to its cytoplasmic region and are known as TRAFs (tumor necrosis factor receptor activation factor) (see Appendix A: CDs). Engagement of CD40 by its ligand activates the SRC kinases LYN and FYN and BTK. Signaling follows the RAS pathway via the nucleotide exchanging factor SOS, leading to MAPK8 (JNK) and MAPK1 (ERK) activation. The functional outcome of CD40 depends on the state of activation of B cells and the intensity of stimulation. On naive B cells it induces proliferation and Ig production, but on memory cells it induces apoptosis. CD40 activation induces homotypic adhesion of B cells mediated by CD54 (intercellular adhesion molecule-1)-CD11/CD18 (ITGB2 or LFA-1), or CD23-CD21. The functional

outcomes depend on the type of TRAFs that are associated with CD40. For example, trimers of TRAF2 mediate apoptosis, whereas trimers of TRAF6 or TRAF5 mediate proliferation.³⁴³ Germinal-center formation and Ig class switch are hallmarks of T-cell-dependent responses, and TRAF6 plays a role in class switch (see Chapter 14).

POLYCLONAL ACTIVATION

Certain substances can activate B lymphocytes independently of their antigenic specificity. The response to these substances involves all B-cell clones, and for this reason these substances became known as polyclonal B-cell activators (PBAs).

PBAs are primarily microbial cell constituents such as lipopolysaccharide (LPS), purified protein derivative, staphylococcal protein A, streptolysin O, pneumococcal polysaccharide III, a water-soluble antigen from *Nocardia*, EBV, dextrans, etc.

PBAs can be categorized on the basis of their effect on B lymphocytes; some promote only B-cell proliferation, whereas others in addition stimulate Ig secretion.

LPS has been used experimentally as PBA for several years, but only recently was its receptor shown to be the CD14 molecule.³⁴⁴ LPS binding to CD14 is enhanced in the presence of a plasma protein, LPS-binding protein.³⁴⁵ CD14 is expressed primarily on monocytes and granulocytes. Its structure, function, and role in human disease have been reviewed.³⁴⁶

MORPHOLOGIC CHANGES ASSOCIATED WITH B-CELL DIFFERENTIATION

Plasma Cell

Elegant studies of morphologic differentiation in immunized animals at the ultrastructural level were performed by Harris et al., who isolated individual cells involved in antibody synthesis³⁴⁷ (Fig. 12.13). These authors showed that antibody production is detected while the cell still retains a lymphocytic morphology and contains no ER. These cells can be differentiated from inactive lymphocytes by the abundance of free polyribosomes and a large nucleolus. A spectrum of cells that actively secrete antibody can be ranked according to the size and development of the ER.^{348,349,350,351} and ³⁵²

During early differentiation, the ER is scarce and unorganized. Later, the lamellae increase in length and become parallel, until they fill the entire cytoplasm and give rise to its onion-skin appearance. The Golgi apparatus increases concomitantly. No dividing line exists that distinguishes the cells that make IgM from those that make IgG antibody, although a preponderance of IgM producers with lymphocytic morphology and of IgG producers with plasmacytic morphology is noted.³⁴⁸

The name plasma cell was first used by Waldeyer in 1875.³⁵³ His description, however, included several types of cells; and in 1881 Unna³⁵⁴ redefined the cells as he observed them in a case of lupus, emphasizing the characteristic basophilia of the cytoplasm (granuloplasm). In a subsequent report³⁵⁵ containing pictures of methyl green- and pyronin-stained cells, several cells are identified easily as characteristic plasma cells. In 1895, Marschalko took issue with Unna's description and emphasized that the appearance of the nucleus with its characteristic arrangement of angular chromatin blocks and its eccentric position within the cell are to be used as stringent criteria for the identification of plasma cells.³⁵⁶ The characteristic nuclear morphology was given the name radkern by Pappenheim. Early analytic reviews of plasma cells were provided by Downey³⁵⁷ and later by Michels.³⁵⁸ In those early years, whether the plasma cell was a normal constituent of tissues was the subject of considerable debate. Its origin was disputed, but several prominent investigators believed that it originated from lymphocytes.

The modern period of plasma cell study originated in 1937 with the clinical observations of Bing and Plum, who noted the close association of hyperglobulinemia and the presence of plasma cells.³⁵⁹ Subsequent studies in hyperimmunized rabbits were carried out by Bjornboe and Gormsen,³⁶⁰ who demonstrated that antibody production correlated with massive plasma cell proliferation in the spleen. In his doctoral thesis, Fagraeus³⁶¹ left little doubt about the importance of plasma cells in antibody formation. Differences among animals in their capacity to produce antibody could be related to differences in the number of plasma cells, particularly immature plasma cells. Fagraeus thought that mature plasma cells had "passed the stage of their greatest functional intensity."

Indisputable evidence in favor of antibody production by plasma cells was provided by Coons, who introduced the powerful technique of immunofluorescence to immunology.^{362,363} Plasma cells containing antibody were detected in the red pulp of the spleen, the medullary cords of the lymph nodes, and the focal granulomata of immunized animals.

FIGURE 12.13. Morphology of antibody production. Terminal B-cell differentiation (antigen-dependent) is characterized morphologically by the gradual increase of the amount of cytoplasm and, concomitantly, the appearance of strands and eventually well-organized endoplasmic reticulum. A: An antibody-producing lymphoid cell with sparse endoplasmic reticulum (ER). (From Harris TN, Hummeler K, Harris S. Electron microscopic observations on proteins such as BLNK (B-cell linker protein), Cbl, et al. of signaling protein tyrosine antibody-producing lymph node cells. *J Exp Med* 1966;123:161-172, with permission.) B: Endoplasmic reticulum (ERVS) is slightly distended, containing amorphous material. (From Hummeler K, Harris TN, Tomassini N, et al. Electron microscopic observations on antibody-producing cells in lymph and blood. *J Exp Med* 1966;124:255-262, with permission.) C: Mature plasma cell displaying well-organized ER and distinct Golgi apparatus (G). (From Gudat FG, Harris TN, Harris S, Hummeler K. Studies on antibody-producing cells. I. Ultrastructure of 19S and 7S antibody-producing cells. *J Exp Med* 1970;132:448-474, with permission.) M, mitochondrion; N, nucleus; NOS, nucleolus; NU, nucleus. (Figures A, B, and C reproduced from *J Exp Med*, as cited, by copyright permission of the Rockefeller University Press.)

Excellent detailed descriptions of the morphology and ultrastructure of plasma cells have been published.^{364,365} The plasma cell is round or oval, with an eccentrically located nucleus and chromatin arranged in pyramidal blocks against the nuclear membrane, giving the characteristic “cartwheel” appearance (Fig. 12.14). The cytoplasm is intensely basophilic because of the high content of ribonucleoprotein. Certain plasma cells stain red to violaceous rather than blue, and are known as flaming plasma cells, a name coined by Undritz. This coloration is attributed to the accumulation within the ER cisternae of Ig with a high carbohydrate content. Electron microscopic studies revealed that the nucleus is surrounded by a double membrane. The outer membrane is covered with ribonucleoprotein particles and is continuous with the cytoplasmic ER. The Golgi is well developed and consists of vesicles and tubules. The centrosome lies next to the nucleus, surrounded by the Golgi apparatus. Several microtubules radiate from the centriole. Many prominent mitochondria are scattered between the ER lamellae. A striking ultrastructural feature of the plasma cell is the rich and well-organized ER. It

consists of membranes studded on one side with ribosomal particles and arranged in parallel arrays. In the mature plasma cell, the ER fills the entire cytoplasm. The cisternae are sometimes distended with granular or homogeneous material, giving rise to cytoplasmic inclusions known as Russell bodies.³⁶⁶ The Russell bodies are composed of Ig,^{366,367} although sometimes Ig cannot be demonstrated,³⁶⁸ and it was suggested that these inclusions are

P.274

not made from Ig aggregates. Alternatively, the Ig is condensed to such a degree that it cannot be penetrated by the dyes. Russell bodies sometimes are detected within the nucleus (intranuclear inclusions). Under certain circumstances, the plasma cell contains large quantities of a homogeneous material that distends the cell and stains gray or sometimes red as in the flaming cells. These cells, called thesaurocytes,³⁶⁹ reveal, under electron microscopic analysis, dilation of the ER cisternae³⁷⁰ (Fig. 12.15). The flaming cell likely represents an early stage of the thesaurocyte in terms of storage of synthesized Ig.^{371,372} Two lines of evidence suggest that these forms are the result of disturbances in the secretion of Ig. In nonsecretory myelomas, the cells often are similar to thesaurocytes,³⁷³ or flaming plasma cells.³⁷⁴ Mott cells, which are considered plasma cells with multiple Russell bodies, may also result from a complete or partial block in the secretion of Ig, causing localized distention of ER cisternae.³⁷⁵

FIGURE 12.14. Plasma cells. A: Normal. B, C: Plasmacytes with vacuoles from the bone marrow of a patient with infection and arthritis.

The most immature plasma cell is the plasmablast, with a nucleus which has evenly dispersed chromatin and a large nucleolus. The ER is sparse and the cytoplasm is filled with clusters of polyribosomes. As the cell matures the chromatin forms clumps and the ER becomes more abundant and well organized. As the lymphocytes mature into plasma cells, they pass through intermediate stages, which are seen in the blood of patients with plasma cell dyscrasias or immunologic diseases characterized by hypergammaglobulinemia. Similar cells sometimes are encountered in the blood of patients with viral infections (Turk cells), including infectious mononucleosis. The intermediate forms have blue cytoplasm with abundant ER, but not as much as the mature plasma cells. Some intermediate forms resemble the less mature transformed lymphocytes with simple ER and many ribosomes and polyribosomes.

FIGURE 12.15. Unusual forms of plasma cells. Under certain circumstances related to immunoglobulin (Ig) secretion, the cisternae of endoplasmic reticulum are distended as a result of the accumulation of Ig. Plasma cells with accumulation of a homogeneous material that sometimes stains pink or red on Giemsa preparations (thesaurocytes). A, B: Giemsa stain of bone marrow from two patients with IgA myeloma. C, D: Ultrastructure of thesaurocytes with different degrees of distention of the cisternae of the endoplasmic reticulum. (From Bessis M, Breton-Gorius J, Binet JL. Étude comparée du plasmacytome et du syndrome de Waldenström. *Nouv Rev Fr Hematol* 1963;3:159, with permission.)

By the time the lymphocyte evolves into plasma cells, certain surface molecules such as the BCR, the major histocompatibility complex class II, CD19, and CD20 are downregulated; while other molecules such as syndecan-1 (CD138) and CD38 are expressed on the surface of plasma cells. The differentiation of lymphocyte to plasma cells requires the transcription factor PRDM1 (BLMP1), which is a transcriptional repressor.³⁷⁶ PRDM1 represses MYC transcription, which explains the cessation of the cell cycle in plasma cells, and also represses PAX5, which is required for lineage commitment of B-cell development and for isotype switching in germinal centers. Downregulation of PAX5 is necessary for the development of antibody-producing cells, because it represses XBP1, J-chain, and Ig heavy-chain gene transcription.³⁷⁷ PRDM1 promotes plasmacytic differentiation by extinguishing the expression of genes that are important for BCR signaling, germinal-center function, and proliferation, but allowing the expression of XBP1 (X-box binding protein). XBP1 is the only transcription factor required specifically for terminal differentiation of B lymphocytes to plasma cells.³⁷⁸ XBP1 is a basic region leucine zipper protein essential for the growth of hepatocytes and has been implicated in the proliferation of malignant plasma cells.³⁷⁹

P.275

A small subpopulation of germinal-center cells in the light zone express PRDM1, which functions upstream from XBP1.³⁸⁰

These cells have survived the selection and are probably destined to become plasma cells. PRDM1, a germinal-center-restricted transcriptional repressor, inhibits BCL6, required for germinal-center function. A negative feedback loop operates in the germinal centers between PRDM1 and BCL6, the expression of which blocks PRDM1 expression and plasma cell differentiation irreversibly (see also Chapter 14).

MOLECULAR AND ULTRASTRUCTURAL ASPECTS OF IMMUNOGLOBULIN BIOSYNTHESIS

Heavy and light chains are synthesized separately, the H chain on large 270S to 300S polyribosomes composed of 16 to 20 subunits, and the L chains on smaller 190S to 200S polyribosomes composed of 7 to 8 subunits. The size of these polysomes is such as to suggest synthesis of each chain as a single unit. Under normal conditions the L chains may be synthesized in slight excess. After completion of separate synthesis of H and L chains, intramolecular folding and assembly of the individual chains begins on nascent proteins and continues into the cisternae of the ER. Depending on the Ig class, the assembly begins with the formation of the H-L half-molecules, two of which then combine to form a complete Ig monomer. Alternatively, two H chains combine to form H₂, followed by H₂L, suggesting that the final H₂-L₂ structure may be reached by several pathways.³⁸¹ Assembly of H chains is restricted between chains of the same class, so that dimers between different H chain isotypes are not formed in cells expressing both. In most instances, polymeric Ig, such as IgM and IgA (9S, 11S, 13S), are assembled intracellularly from their constituent subunits.

The attachment of core oligosaccharides to the N-glycosylation acceptor site begins on the ribosome, but glycosylation is completed in the Golgi apparatus, where the polypeptides are transported from the ER.³⁸² The Golgi apparatus is also the site of final processing of the carbohydrate,³⁸³ and where the molecule is attached to membrane and then packaged into vesicles for secretion or incorporation into the plasma membrane.³⁸³ This mechanism of secretion is a form of reverse pinocytosis. Disruption of the traffic of the vesicles containing Ig inhibits Ig secretion.

The carbohydrate moiety may facilitate the secretion of Ig by the cell, although this effect depends on the Ig class and the amount of Ig synthesized. For some classes, such as IgM, Ig secretion is blocked when glycosylation is inhibited. H chains that have not bound to L chains form complexes with an H chain-binding protein (BiP).^{384,385} BiP prevents transportation of H chains to the Golgi complex until they become associated with the L chains that displace BiP. The presence of such complexes provides an explanation for the lack of secretion of μ chains in pre-B cells when L chains are not available. In contrast to the normal situation, free H chains are secreted in certain lymphomas (H chain disease).^{386,387} In these disorders, the H chains have a large deletion involving the CH-1 domain,³⁸⁸ which explains how these mutant chains can be secreted, i.e., complexes with BiP can be formed only through the CH-1 domain.^{389,390} Although the synthesis of L chains and H chains takes only 30 and 60 seconds, respectively, the addition of carbohydrates and the process of secretion take at least another 30 minutes. An adult synthesizes approximately 2.3 g of Ig daily,³⁹¹ and most Ig-synthesizing cells contain one type of H chain and one type of L chain,³⁹² but a few cells (usually <1%) contain more than one type of H chain, usually μ and γ .

Antibody first appears in the perinuclear cisternae³⁹³ and eventually is detected in the rest of the ER^{394,395} (Fig. 12.16). Activation of the ER cisternae is gradual, because not all of them within the same cell contain antibody at any one moment. Antibody is found in association with the ribosomes of ER and is not detected outside the ER cisternae. In most immature blasts with a sparse or nonexistent ER, antibody is present in the cytoplasm, synthesized on polyribosomal clusters. Not only the intracellular distribution but also the rate of synthesis increases with time; and Ig, in some cases, distends the cisternae, forming large spheric masses reminiscent of Russell bodies. Not all plasma cells contain antibody during the primary response. In the first 2 to 3 days after immunization, most of the plasma cells contain Ig that has no antibody activity.³⁹⁶ Antibody-containing plasma cells appear later in the response and throughout plasmacytic differentiation, the Golgi apparatus always contains antibody.

FIGURE 12.16. Ultrastructural localization of antibody. A: An immature plasma cell demonstrates antibody primarily in the perinuclear area. Antibody is also detected in the few strands of endoplasmic reticulum (ER, arrows) and the Golgi (GA)

apparatus. B: Plasma cell with well developed endoplasmic reticulum filled with antibody. Both cells were isolated from rabbits immunized with peroxidase. For the intracellular localization of the antiperoxidase antibody, the cells were treated with peroxidase before incubation with diaminobenzidine. (From Leduc EH, Avrameas S, Bouteille M. Ultrastructural localization of antibody in differentiating plasma cells. *J Exp Med* 1968;127:109-118. Reproduced by copyright permission of the Rockefeller University Press.)

B-CELL ACTIVATION AND DIFFERENTIATION

Malignancies arise from one cell; therefore they are monoclonal and inherit a unique Ig rearrangement.¹⁰⁶ The new technology of gene profiling enables identification of the genes that are activated

P.276

and very likely it is characteristic of each stage in the life of the B cell. This technology has already been applied on normal B cells to characterize their genetic profile in various functional states. Gene profiling inspects activation and gene transcription of hundreds or thousands of genes, providing a global genomic view.³⁹⁷ In contrast to gene sequencing (structural genomics), gene profiling is considered a new field of functional genomics.

Serial analysis of gene expression (SAGE) uses gene-specific 14-bp sequence tags for enumeration of genes expressed in a cell.³⁹⁸ In the new methods, DNA fragments from individual genes are placed on a solid support in an ordered array. Total cellular mRNA isolated from cells is used to generate, by reverse transcription, cDNA probes tagged by radioactivity or fluorescence. The cDNA probes are then applied to the arrays for hybridization with the DNA on the array. The hybridization results are quantitated by phosphor imagers for radioactive probes, or by scanning confocal microscopy for fluorescent probes. In one commonly used microarray system, oligonucleotides are produced by in situ synthesis in a technique called photolithography and are hybridized by fluorescent cDNA probes.^{399,400} In another technique, PCR products from cDNA clones are spotted onto coated glass slides.⁴⁰¹ In this technique, two cDNA probes from different samples, labeled with different fluorochromes (usually Cy3 or Cy5), are applied on the microarray simultaneously for hybridization. The expression for each gene is evaluated by the ratio of the fluorescence, and interpretation of the data uses algorithms. Various analytical tools are available, but no single tool is better than others. Their use may well depend on the experimental design and the questions asked.^{402,403}

One approach uses hierarchical clustering,⁴⁰⁴ and this algorithm begins by clustering pairs of genes with the most similar patterns of expression, eventually building larger and larger clusters. Clustering may be unsupervised (i.e., the arrangement of gene expression follows predefined parameters built into the algorithm). In supervised clustering, the investigator introduces other parameters such as clinical data. Several algorithms have been designed for data analysis, and more than one may be necessary for the analysis.

Three B-cell functional states were evaluated in an experimental model: naive B cells, B cells activated in vitro by a foreign antigen (hen egg lysozyme, HEL), and B cells tolerant against self. In this case B cells were obtained from transgenic mice (i.e., expressing HEL from birth); therefore, the B cells have developed tolerance against HEL as for any other natural self-antigen.^{405,406} The results show that the naive or resting state is maintained by several inhibitory genes, whereas activation is associated with loss of expression of some of the inhibitory genes rather than the induction of genes that regulate entry into the cell cycle. B cells tolerant to "self" are characterized by increasing expression of more inhibitory genes at the same time that they maintain the expression of the basal inhibitory gene profile.

Some other data reveal that the gene profile of in vitro activated B cells differs from that of germinal-center B cells, where they are activated by T cells.³⁹⁷ Germinal-center B cells differ from naive B cells in the expression of hundreds of genes.⁴⁰⁷ The function of signaling molecules has been studied by inactivation of the appropriate gene, but repercussions from changes in the expression of other genes cannot be heard. An attempt was made to provide an answer to this question from the effect of reduction of the function of PI3K or BTK to other genes. Reduced function of PI3K or BTK significantly affected 5% of BCR-dependent gene expression.⁴⁰⁸ The data also suggested that PI3K acts through BTK in regulating genes that are critical for determining entry into the cell cycle. By hierarchical clustering it has been possible to identify groups of genes that are characteristic of a lineage or a specific stage of differentiation or proliferation (i.e., germinal-center B cells), and each group of genes defines a signature of a cell type or of a function, etc.

Plasma cells, which represent the end stage of B-cell differentiation, were found to have 1,476 known genes, which were differently expressed compared to B cells.⁴⁰⁹ A number of factors characteristic of terminal differentiation (i.e., related to RNA polymerase I) were downregulated, while a number of transcription factors were maintained (e.g., AP-1, NFAT, and NF- κ B). Two genes specific for factors associated with neuronal cell positioning, reeling and neuropilin-1, were unexpectedly expressed and their role in plasma cell life remains to be determined.

B-CELL MALIGNANCIES

A large body of data has already been collected in the short period since this technology was developed for large-scale application, and the findings in B-cell malignancies hold a number of unexpected results.⁴¹⁰ Diffuse large B-cell lymphomas (DLBCLs) have been shown to have two different gene profiles.⁴¹⁰ In one group of patients, the cells had a germinal-center gene profile, whereas in the second group, the lymphoma cells showed a profile of mitogenically activated B cells, and these two groups differ in several genes. DLBCL with the germinal-center B-cell profile has retained the hypermutation machinery, but the second group resembling mitogenically activated B cells has not.⁴¹¹ The germinal-center B-like DLBCL also resembles closely follicular lymphoma.⁴¹² On the basis of sharing some gene expressions with a small population of germinal-center B cells, as well as with plasma cells, it has been suggested that the activated B-like DLBCL may arise from a cell in its transition to becoming a plasma cell.

Another important finding is the possibility that B-CLL, which phenotypically has been separated into two groups on the basis of CD38 expression, may actually be one genomic disease with two variants.⁴¹³ A small number of <30 genes may, however, be able to distinguish cases with IgV-mutated versus -unmutated profiles.⁴¹⁴ Furthermore, the gene profiles have indicated that in the majority of cases, the cells are related to memory B cells rather than naive B cells or B cells of any other category. This may not be unexpected, because the somatic hypermutation machinery is active in CLL and could play a role in intraclonal diversification development.⁴¹⁵ Microarray gene profiling has been used to identify B-CLL cases with cells resistant to apoptosis after DNA damage. Thirteen of 16 genes were found that were specific for resistant B-CLL cells.⁴¹⁶ A study of mantle cell lymphoma also detected resistance to apoptosis gene profiling. The FADD (Fas-Associated Death Domain) gene, a key gene associated with Fas-mediated apoptosis, was downregulated 10-fold in this lymphoma.⁴¹⁷

In multiple myeloma, the profiling suggests a classification into four subgroups.^{418,419} Group 1 patients (MM1) have a gene profile similar to MGUS (Monoclonal Gammopathy of Unknown Significance), whereas the patients in the MM4 group have poor prognosis, with a gene profile similar to myeloma cell lines. Numerous unexplained genes with unknown function have been detected, so that only 10% of all these genes have matched entries in the database Expressed Sequence Tags.⁴²⁰

The origin of Hodgkin and Reed-Sternberg (HRS) cells has remained elusive, and recently, strong evidence has been presented that in most cases with this disease, the cell is of B-lineage origin and only rarely originates from a T cell.⁴²¹ Identification of gene profiling demonstrated that the HRS cell expresses a distinct gene profile regardless of its B- or T-cell derivation. The gene profile is similar to that of EBV-transformed B cells or cell lines from large cell lymphomas, with features of in vitro-activated B cells.⁴²² Among the genes specifically identified in HRS are a cluster of genes for transcription factors (i.e., GATA3, MSC/ABF-1, NR2F1/EAR-3, and NFE2L3/NRF3). Downregulation of several genes that are active in B cells was identified. Several of these genes are positively regulated by the transcription factor

P.277

PAX5 (see "Stem Cell to Progenitor B [Pro-B] Cell"). However, the PAX5 gene is still expressed in HRS cells, and therefore the loss of B-cell-specific gene expression remains unknown.⁴²³

BTK mutations influence the expression of other genes in EBV-transformed cell lines and, in the absence of functional BTK, 11 genes were identified that were induced more than 1.9-fold.⁴²⁴ Microarray gene profiling has been applied to develop a molecular predictor of survival after chemotherapy for DLBCL. The study used 17 genes to construct a predictor of overall survival.⁴²⁵ Four gene groups were identified and clustered within individual signatures. The proliferation signature was the best predictor for adverse outcome. Signatures identifying good prognosis were the lymph node signature, encoding extracellular matrix, and the connective tissue growth factor, which promotes fibrosis and synthesis of extracellular matrix. Some of these genes are linked to histologic or other lymph node reactions, known already for their favorable prognosis. For example, the lymph node signature is associated with expression of genes that are also expressed in macrophages and NK cells, presumed to indicate a cellular antitumor response. The other favorable signature is the major histocompatibility complex class II gene expression.

B-CELL SUBPOPULATIONS

A subpopulation of B cells can be detected on the basis of expression of the CD5 antigen ordinarily present on T cells. The CD5 antigen (formerly T1 or Leu1) is a 67,000-dalton gp detected on all normal T cells,^{426,427} on a small subpopulation of normal B cells,⁴²⁸ and on all cells from patients with CLL.^{429,430} and⁴³¹ The CD5 B cells possess unique properties, i.e., they are phenotypically identical to CD5⁻ B cells,⁴³² but they are larger; in mice they have 10 times more mIgM with λ chains, which is expressed only rarely in mice. The CD5⁺ B cells are present in high numbers in fetal and neonatal life (50% of all IgM⁺ B cells), but they progressively diminish in number after birth and are present in small numbers in secondary

lymphoid organs in adult life.^{433,434} and ⁴³⁵ At birth most of the B cells in cord blood are CD5⁺,⁴³⁴ but they constitute less than 10% to 30% of B cells in adult spleen, lymph nodes, and peripheral blood. Their proliferative capacity is high and as a result, they give rise spontaneously to cell lines that demonstrate MYC amplification.⁴³⁶ Presently there are two views regarding the origin of the CD5⁺ subpopulation. According to one of them, the CD5⁺ cells (also known as B1a) belong to a lineage of B cells distinct from the conventional B lymphocytes (CD5⁻).^{437,438} and ⁴³⁹

The CD5⁺ (B-1) cells develop early in ontogeny and, in the adult, predominate in peritoneal and pleural cavities and are self-replenished; that is, they do not arise from undifferentiated progenitors. Progenitors of CD5⁺ cells are present in fetal liver and omentum but not adult bone marrow, whereas conventional B-cell progenitors are present in fetal liver and adult bone marrow. According to the second hypothesis, the B-1 cells derive from conventional B cells,^{440,441} based on in vitro evidence of stimulation of conventional B cells with anti-IgM antibodies and IL6, which generated the B-1 phenotype.⁴⁴²

B-1 cells may have different antibody repertoires (e.g., have few N-region insertions in their rearranged V genes), and the V_H repertoire is biased toward V gene families proximal to J_H, whereas in adult B cells it is more randomized.

Perhaps the most controversial aspect is the production of autoantibodies. In NZB mice (New Zealand Black), a strain well-known for autoimmune phenomena, the CD5⁺ B cells are increased in number and spontaneously secrete IgM autoantibodies.⁴⁴³ Increased numbers of CD5⁺ B cells are found in patients with rheumatoid arthritis,^{444,445} Sjögren syndrome,⁴⁴⁶ and progressive systemic sclerosis,⁴⁴⁷ but not in patients with systemic lupus erythematosus.⁴⁴⁷ Numbers of CD5⁺ B cells are also increased after bone marrow transplantation.⁴⁴⁸ In 95% of patients with B-cell CLL, the leukemic cells express the CD5 antigen,^{429,430,449} which is also detected on cells from other B-cell lymphomas, the CD5⁺ B cells from normal subjects,^{450,451} or from patients with CLL.⁴⁵² The CD5⁺ B-cell subpopulation may therefore play an important role in the development of B-cell repertoire related to natural immunity, which develops in the absence of an encounter with exogenous antigens. Certain V genes are selectively expressed in CD5⁺ B cells, and those are not changed by somatic hypermutations normally observed in CD5⁻ B cells responding to exogenous antigens. The marginal zone B lymphocytes share many phenotypic characteristics with B-1 cells and, like them, develop in response to T-independent type-2 antigens. The B-2 repertoire is selected by self-antigen and therefore tends to be autoreactive. Selection into the B-1a population is favored during fetal life because TdT is not expressed during this period; therefore, the repertoire is limited in its specificity range. This dangerous repertoire is kept under control by the CD5-mediated negative signaling, thus preventing inappropriate activation. On the other hand, this repertoire is useful because the B-1 cell specificities are directed against several pathogens and are important in mucosal immunity.⁴⁵³

Chapter 13

T Lymphocytes and Natural Killer Cells

Frixos Paraskevas

MORPHOLOGY

The T lymphocyte under routine staining procedures (Giemsa or Wright) is 5 to 8 μm in diameter, with a high nucleocytoplasmic ratio. The nucleus is purple with densely packed chromatin, and the cytoplasm forms a narrow light-blue rim.

By transmission electron microscopy, the nucleus shows shallow indentations with dense heterochromatin along the nuclear membrane and euchromatin occupying most of the remaining nuclear surface. One or two nucleoli are visible (Fig. 13.1). The cytoplasm shows a few organelles, such as mitochondria and a small Golgi apparatus. By scanning electron microscopy, the surface of the T lymphocytes is either smooth or shows short microvilli, depending on the method of preparation as well as the state of activation.^{1,2}

Some T lymphocytes present in normal subjects are characterized by a highly indented nucleus and are known as cerebriform mononuclear cells.³ These cells are not detected in T-lymphocyte-depleted fractions and constitute approximately 3% to 4% of the unfractionated T lymphocytes. They possess scanty cytoplasm, and the degree of their nuclear indentation is expressed as a nuclear contour index (nuclear perimeter/area).⁴ Their structural similarity to the cells present in cutaneous T-cell lymphomas suggests that they represent the normal equivalent of Sézary cells, which are derived from T lymphocytes.

FIGURE 13.1. Ultrastructure of T-cells. The normal T-cell has a small rim of cytoplasm with only a few organelles. Nucleus shows dense heterochromatin. (From Zucker-Franklin D, Greaves MF, Grossi CE. Atlas of blood cells, 2nd ed. Philadelphia: Lea & Febiger, 1988, with permission.)

ONTOGENY OF THYMIC MICROENVIRONMENT

The thymic anlage develops from epithelial structures of the third branchial complex (Fig. 13.2). Neural crest cells (Hoxa3-positive) invade the epithelial cluster to form the thymic rudiment. Several studies support the view that the cortical and medullary epithelia originate from a common precursor, and, in the early stages, the epithelium co-expresses markers that are later segregated to the cortical or medullary compartments. After completion of thymic organogenesis, the cortical epithelia are cytokeratin-8⁺, whereas medullary epithelia are cytokeratin-5⁺,⁵ except for a small subpopulation in the corticomedullary junction, which is cytokeratin 5⁺/8⁺.⁵ Furthermore, neoplastic human thymomas often express both cortical and medullary epithelial markers.⁶

The best evidence of the origin of thymic epithelia from a common progenitor is the identification by monoclonal antibodies of a cell that generates in vivo the thymic microenvironment.^{7,8} The monoclonal antibody MTS24 detects a glycoprotein with mucinlike characteristics and a peptide backbone.⁷ The antigen is detected during the early embryonic stages in the anterior

P.280

endodermal epithelium, the pharyngeal endoderm, and a portion of intermediate mesoderm, which develops the urogenital epithelium. The MTS24⁺ cells are positive for major histocompatibility complex (MHC) class II and express cytokeratin-5 and cytokeratin-8, which are markers of the medullary and cortical epithelium, respectively. Highly purified MTS24 cells, inserted under the kidney capsule, are able to develop into a complete thymus and, furthermore, provide the complete milieu necessary for T-cell development.

FIGURE 13.2. Morphogenesis of thymus. Elements from the third pharyngeal cleft form the epithelial rudiment, joined by mesenchymal cells from the neural crest. The common epithelial progenitor differentiates into cortical and medullary epithelium under the influence of the mesenchyme. The presence of endodermal cysts and tissue-specific “antigens” and “organoids” suggests some contribution from the endoderm. FGF, fibroblast growth factor; KGF, keratinocyte growth factor.

Because primordial epithelial cells normally need the cooperation of mesenchymal cells for thymus organogenesis,⁹ it is conceivable that, in the case of the ectopically placed MTS24 cells, this is provided by comparable cellular elements from

the kidney capsule. The MTS24 antibody completely blocks T-cell development in fetal thymic organ cultures, supporting the conclusion that the molecule recognized by the MTS24 antibody regulates normal epithelial function. During this early stage in the development of the thymus, the cell interactions are regulated by a number of transcription factors, such as HOXA3 and PAX1 which are part of cluster A on chromosome 7 and encode a DNA-binding transcription factor which may regulate gene expression, morphogenesis, and differentiation.^{10,11} An important step in our understanding of the genetic control of thymic development came from the study of the “nude” mouse and the cloning of the gene that confers the nude phenotype, designated Whn, for Winged h n,¹² more recently renamed Foxn1. The Foxn1 gene encodes a transcription factor with a DNA-binding domain of the forkhead/winged helix class. The defect responsible for the nude phenotype is a single base pair deletion in the third exon of the Foxn1 gene. It results in hair loss, the arrest of the thymic epithelial cell expansion, and inability to attract the hematopoietic precursors into the epithelial rudiment.^{13,14} Formation of the epithelial primordium is not affected by the loss of Whn function, but subsequent differentiation of the primitive epithelial precursors into subcapsular, cortical, and medullary epithelial cells is arrested¹⁵ and the epithelial rudiment becomes cystic.

In normal development, the epithelial rudiment is invaded by mesenchymal cells from the neural crest,¹⁶ which stimulate epithelial progenitor differentiation into cortical and medullary subpopulations.^{8,17,18,19} These mesenchymal-epithelial interactions are mediated by growth factors and their receptors, such as the fibroblast growth factor 10 (FGF10) and its specific receptor, FGFR2IIIb, on thymic epithelial cells. Deficiency of either the factor or the receptor results in severe thymic hypoplasia.^{20,21} When immature lymphoid cells begin to arrive in the thymic rudiment, another wave of cellular interactions takes place between the developing lymphoid cells and the stromal epithelial cells. This second stage of thymic development establishes thymic microenvironments conducive to thymocyte differentiation and repertoire selection. Further differentiation and maturation are under the regulation of interactions with thymocytes. Experiments in animals and experiments of nature in humans (disease processes) have clearly shown the symbiotic relationship between epithelial cells and lymphocytes. Prothymocytes regulate differentiation of cortical epithelial cells,²² whereas mature thymocytes organize the medullary microenvironment.^{23,24,25}

The epithelial cells in the cortex and medulla differ by ultrastructure, by immunophenotype, and by functional characteristics. Ultrastructurally, three subsets have been detected on the basis of cytoplasmic processes, secretory organelles, and desmosome connections.²⁶ Type I cells, located in the cortex, have stellate cytoplasmic processes and make contact with their neighbors, forming a syncytium. Type II cells are found in the medulla, are voluminous with many secretory intracellular vesicles, and have short cytoplasmic processes. Type III cells are rare, may contain vacuoles (pseudocysts), and are located in the medulla.

Six clusters of thymic epithelial staining (CTES) have been identified: type 1 epithelium (CTES II)²⁷ produces thymic hormones, type II (pale), type III (CTES III) of intermediate electron lucency, and type IV (dark with oval nuclei) are in the cortex proper. These cells extend fine cytoplasmic processes, establishing contacts with neighboring cells, and are connected by desmosomes forming a syncytium, the interstices of which are filled with thymocytes. Some tend to engulf up to 20 to 40 thymocytes in a lymphoepithelial cluster, known as nurse cells, detected in human thymus^{28,29} (Chapter 11, Fig. 11.9). The internalized thymocytes are located within caveolae lined by plasma membranes. The lack of penetration by certain dyes indicates that the nurse cells are not an artifact, are completely sealed from the rest of the thymus, and may play a role in T-cell selection. Their formation is not dependent on interactions of T-cell receptors (TCRs) with MHC because they are present in knockout mice deprived of TCR- $\alpha\beta$.³⁰

A better understanding of the thymocyte-epithelial cell interdependence for survival came from experiments with a variety of TCR-transgenic mice.³¹ The final organization of the cortical and medullary epithelium depends on interactions of the TCR on the thymocytes with ligands on stromal cells. Thymocytes expressing a transgenic TCR that triggers strong positive selection, resulting only in maturation of CD4⁺/CD8⁻ T-cells, lose the normal reticular pattern of cortical epithelial cells, and the epithelium in the medulla forms small scattered groups of cells surrounded by macrophages and dendritic cells.³²

Several other transgenic models demonstrated that maintenance of a balance among positive selection (PS), negative selection (NS), and nonselection is necessary to preserve normal compartmentalization and architectural integrity of the thymic epithelia.^{33,34} It is the diversity of signals emanating from these physiologic processes within the thymus during thymocyte maturation that are critical for the maintenance of epithelial organization. These signals are generated from the endogenously rearranged TCRs, which regulate positive and NS. In addition to thymocytes, the thymic vasculature is also an important epithelial organizer.³⁵ In Rag2^{-/-} mice, the medullary epithelium forms cuffs around intermediate-sized vessels, particularly the post-capillary venules. This anatomic arrangement may have important functional implications. The medullary epithelial cells have been linked to NS and tolerance induction^{36,37} and³⁸ and are therefore strategically

located around the post-capillary venules, where the concentration of autoantigens would be high. The possible functional importance of this peculiar anatomic arrangement of the medullary epithelium is also suggested from the detection of several molecules and structures considered to be tissue-specific within the medulla (i.e., parathyroid hormone, thyroglobulin, insulin, and even organized epithelial "organoids" with ultrastructural features of respiratory epithelium and thyroid follicles).³⁹ The ectopic location of these molecules and structures is supported by the detection of the expression of the appropriate genes.³⁹ It has also been postulated that, because these "ectopic" tissues within the medulla have their origin from primordial endoderm, the precursors of the epithelial cells in the medulla also may arise from pharyngeal endoderm. Further support of this view comes from the histologic appearance of medulla in athymic mice, in which further differentiation of these cells fails and the epithelium remains in the primordial condition of endodermal cysts.

Whereas epithelial development depends on FGF, its functional integrity is maintained by other growth factors contributed by the mesenchyme. The keratinocyte growth factor (KGF), a member of the FGF family, is a paracrine growth factor produced by mesenchymal cells. It acts on epithelial cells that express a splice variant of FGF (i.e., FGFR2IIIb). In fetal thymic organ cultures, exogenous KGF expands the medullary epithelium, and in Rag^{-/-} animals deprived of thymocytes, which normally produce KGF, the administration of KGF restores the normal medullary epithelial architecture.⁴⁰

The architectural integrity of the thymus is maintained throughout life, but eventually it atrophies with age.⁴¹ Changes
P.281

in signals between epithelial cells and thymocytes may determine thymic involution.⁴² Stat3 has been identified as an important signaling molecule between epithelial and mesenchymal cells in the thymic microenvironment.⁴³ Stat3 gene disruption in mice results in severe thymic atrophy and enhanced susceptibility of the thymus to environmental stress, such as glucocorticoids or γ -irradiation.

The extracellular matrix (ECM) is an important component of thymic stroma after the cells and certain interactions between differentiating thymocytes and thymic epithelial cells are mediated by ECM proteins that influence intrathymic migration events and thymocyte differentiation.⁴⁴ The ECM consists primarily of fibers of collagens, reticulin, glycosaminoglycans, and glycoproteins, including laminin and fibronectin.

Heterotrimeric laminin molecules consist of at least 15 naturally occurring isoforms, which are formed by five α , three β , and three γ subunits. In the human thymus, laminin with α_2 -chains (LN-2/4) or α_5 -chains (LN-10/11) are detected in the subcapsular epithelium and blood vessels.⁴⁵ The CD4⁻/CD8⁻ (double negative) thymocytes are located in the subcapsular area by strong attachment to LN-10/11 through their $\alpha_6\beta_1$ integrin. The CD4⁺/CD8⁺ (double positive) thymocytes, however, lose their capacity to adhere to LN-10/11 and move down to the cortex.

The interactions between thymocytes and stroma facilitate intrathymic migration and regulate positioning of the developing thymocytes to appropriate microenvironments during differentiation. The ECM proteins support the growth of thymocytes and epithelial cells and facilitate cell-cell interaction, especially migration of thymocytes in and out of nurse cells. Receptors for ECM proteins are highest in the double-negative precursors but gradually decrease with maturation.

T-CELL PROGENITORS

The T-cell progenitors in fetal life derive from the liver, whereas in adult life, they come from the bone marrow. The difference in stem cell origin has implications in subsequent lymphoid development, apparently as a result of precommitment or restriction of developmental options at the level of stem cell.⁴⁶ Human thymus becomes fully differentiated by approximately the 15th week of gestation (i.e., approximately 7 to 8 weeks after colonization of the thymic rudiment). These early migrants contribute to the development of the thymic microenvironment.

Cells with the CD34⁺/CD38^{weak}/CD90⁺ phenotype contain T-cell progenitors when they grow in fetal thymic organ cultures. In human adult bone marrow, CD34⁺/CD38⁺/HLA-DR⁺ stem cells have the potential to differentiate toward lymphoid and myeloid lineages.⁴⁷ These cells are CD45RA⁺, lack Thy1 (CD90) antigen, and may represent an intermediate oligopotent stem cell with T-cell-reconstituting ability.⁴⁸ By phenotype, there are three subpopulations in the bone marrow, which can differentiate to T-cells in the thymus: CD34⁺/CD2⁺, CD34⁺/CD7⁺, and CD34⁺/CD2⁺/CD7⁺ and all three are negative for CD3/CD4/CD8.⁴⁹ The thymus is populated by hematopoietic multipotent progenitors from the bone marrow.⁵⁰

Experiments with transgenic mice have shown that disruption of the zinc finger protein Zbtb1, resulted in a T(-)B⁺NK⁻ SCID phenotype.⁵¹ In knockout mice for Zbtb1 protein differentiation of common lymphoid progenitors is inhibited and it is associated with expanded populations of bone marrow hematopoietic stem cells and multipotent and early lymphoid

lineages⁵¹ corresponding to a common lymphoid progenitor subset.⁵² The most primitive thymocytes are Lin⁻, c-Kit^{high}, L-selectin⁺, TdT⁺, and RAG1⁺, a phenotype similar to progenitor population in the bone marrow which sustains the adult thymus.⁵³

Recruitment involves the chemokines CCL21 (or SLC, secondary lymphoid tissue chemokine) and CCL25 produced by the fetal thymus, which attract CD4⁻/CD8⁻/CD25⁻/CD44⁺ thymocytes.⁵⁴ At the site of entry P-selection of the thymic vascular endothelium binds arrests precursors expressing the P-selectin ligand (rolling). Chemokine CCL25 from endothelial cells activates precursors through the CCR9 receptor, and intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) of the endothelial cells bind the cells firmly through the integrins $\alpha_4\beta_2$ and $\alpha_4\beta_1$, respectively.⁵⁵ The multipotent T-cell progenitors entering the thymus trigger Notch activation, which is critical for T-cell development (see below) for later stages of TCR-dependent selection within the thymus as well as during peripheral T-cell differentiation.⁵⁵ There is some overlap of regulatory programs between those required for T-cell specification and those needed for stem cell maintenance or self-renewal, such as Notch pathway, GATA3, IKZF1 (IKAROS), and SPI1 (PU.1).⁵⁶ The genes that need to be turned on for a successful entrance in the early stage of T-cell development include RAG1 and RAG2 and CD3G and CD3E of the pre-TCR and TCR. Although certain options of differentiation are eliminated relatively early after T-cell lineage commitment, others such as differentiation into dendritic cells and natural killer (NK) cells remain through some stages of the T-cell development. The B-cell potential is lost early within the thymus probably as a result of Notch signaling. Additional factors, such as GATA3 (T-cell-specific among the hematopoietic cells), TCF3 (E2A), shared with B lineage and even non-T-cell-specific such as RUNX1 and IKZF1 are also used in T-cell development.

NOTCH AND T-CELL COMMITMENT

Signaling through the Notch receptor is a key factor for T-cell commitment.^{57,58,59} and ⁶⁰ Notch plays a pivotal role in determining T-/B-lineage choice, and signaling through Notch drives commitment of lymphoid precursors to T lineage.^{61,62} and ⁶³ Notch belongs to a family of conserved proteins that function as cell-surface receptors and direct regulators of gene transcription.⁶⁴ It was first isolated as a gene involved in chromosomal translocations with the TRB@ gene in a subset of cases of human T-cell acute lymphoblastic leukemia. The extracellular domain of Notch contains a variable number of tandem epidermal growth-factor-like repeats and three Lin/Notch repeats, which function for ligand binding and Notch activation.⁶⁵ The intracellular region contains six Cdc10/ankyrin repeats characteristic of protein-protein interactions and essential for signal transduction. The Notch protein initially is synthesized as a single-polypeptide chain, but, as a result of proteolytic processing, it is split into two parts. The extracellular region is separated and forms a noncovalent heterodimer with the remaining portion consisting of the transmembrane and the cytoplasmic regions.

Ligands for Notch are Delta, Serrate, and several other molecules corresponding to these two classes. In general, those homologous to Delta are referred to as Delta, and those homologous to Serrate are called Serrate or Jagged.⁶⁵ These ligands are transmembrane proteins with an extracellular domain with a variable number of epidermal growth-factor-like repeats and the unique domain for this family, the DSL (Delta/Serrate Lag-2) domain, which mediates binding to Notch and activation. Which of the two groups of ligands is important for lineage commitment remains controversial.⁶⁶ In cells of the immune system, there are two Notch receptors, NOTCH1 and NOTCH2, and four signals.⁶⁷ The pleiotropic signaling by Notch regulates differentiation, proliferation, and cell death, but it is not yet clear which function most precisely determines cell fate and ultimately directs T-cell commitment.⁶⁸ With Notch inactivation, the double-negative T-cells diminish in the thymus, whereas B-cell precursors increase, probably from a more efficient production of B-cells within the thymus.⁶⁹ On the other hand, transgenic expression of Notch in the bone marrow permits the accumulation of CD4⁺/CD8⁺ T-cells. The NOTCH1 functional role seems to

P.282

be in developmental specification, driving T-cell precursors at the expense of B-cell precursors and perhaps directing the choice of a common precursor between these two fates. Notch is also needed for later stages for TRB@ gene rearrangements, PS, and CD4/CD8 lineage choices.⁵⁶

PHENOTYPIC DIFFERENTIATION

The first migrants from the bone marrow to the thymus settle in the corticomedullary junction and are large dividing cells expressing CD34⁺/CD45RA⁺, CD2⁺, and CD7⁺, with the TCR genes in the germline configuration (Fig. 13.3). The new immigrants potentially are able to differentiate to other lineages, such as NK-cells, dendritic cells, and monocytes. The CD34⁺ cells then co-express other markers such as CD38 and CD71 (transferrin receptor) associated with proliferating cells, and a portion of them are CD10⁺. They are subdivided into three categories, double negative-1 (DN-1), DN-2, and DN-3, depending on the expression of CD44 and CD25.^{70,71} Recruitment involves interactions between P-selectin

expressed by thymic endothelium and P-selectin glycoprotein ligand-1 detected on the bone marrow progenitor cells.⁷² Upon arrival they migrate to the subcapsular cortex (DN-3 cells), where they acquire expression of CD1A and CD4 and CD8, and as a result become double positive (DP). In the cortex they are submitted to PS (vide infra) and those considered "useful" return back to the medulla, and they are separated into two distinct phenotypes, CD4⁺ and CD8⁺ single-positive (SP) cells. These migrations across the thymic parenchyma are mediated by several chemokine receptors, CXCR4, CCR7, and CCR9. Adherence of thymocytes to epithelial cells is also mediated by CD2 and the lymphocyte function molecule-3 (LFA3, CD58), ICAM, and LFA1. The SP thymocytes are submitted to another screening in the medulla. Those with high-affinity TCR against self-antigens are deleted (NS). After this checkpoint, the surviving thymocytes exit the thymus for the secondary lymphoid organs. Emigration of thymocytes requires the sphingosine-1-phosphate receptor 1 (S1P-1).

FIGURE 13.3. The first migrants from the bone marrow arrive and settle in the corticomedullary junction. They lack expression of CD4 and CD8 and are known as double negatives (DN). These new immigrants begin to move to the outer cortex and, depending on certain markers, are distinguished in three stages: DN1, DN2, and DN3. The migration is supported through interactions between P-selectin (thymic epithelium) and its ligand (progenitor cells). In the outer cortex they become double positive (DP) (i.e., CD4⁺/CD8⁺), and at the DN3 stage, undergo gene rearrangements with expression of the T-cell receptor (TCR)-β gene (β selection). Signals provided by the CCR-7 chemokine receptor guide the positively selected thymocytes that have already separated into the CD4 or CD8 lineages back to the medulla. A final

screening for the “affinity” of their TCR binding to autoantigens takes place in the medulla (NS). It is triggered by contacts of their TCR with tissue-restricted self-antigens (TRAs) on medullary thymic endothelial cells (mTECs). Promiscuous gene expression (pGE), for autoantigens, regulated by the AIRE gene (see text for details), controls central tolerance. The thymic medullary epithelium ultimately allows survival of the “useful,” and it ignores the “useless” and “destroys” the harmful¹²⁸. Exit of mature T-cells from the thymus is regulated by the G-protein-coupled receptor sphingosine-1-phosphate receptor 1 (S1P-1) as well as the very late antigen (VLA-) and lymphotoxin-β receptor.

In the process of differentiation, CD34 is progressively lost, whereas the intensity of CD7 decreases. Myeloid and NK-cells have been detected in various in vitro systems arising from thymocytes,^{73,74} and the thymic microenvironment is able to support myeloid differentiation.

Evidence of direct cellular communication between various thymic cells was provided by the demonstration of the existence of gap junctions formed by connexin 43 between two epithelial cells or between epithelial cells and thymocytes.⁷⁵

Of the cytokines that have been implicated in T-cell differentiation, interleukin-7 (IL7) is essential.⁷⁶ It is produced constitutively by epithelial cells, and it induces proliferation of DN thymocytes⁷⁷ or maintains their viability.⁷⁸ CD34⁺ thymocytes cultured with IL7 start to express CD8 and CD4 but remain CD3 and TCR negative, indicating that other stimuli from stromal cells are essential for generating CD3⁺/CD4⁺/CD8⁺ cells. IL7 also induces Tcrb gene rearrangements.⁷⁹ Mice genetically deficient in IL7 receptor have a profound reduction of T and B lymphocytes, and thymocyte development is blocked at a very early stage before the induction of CD25 and Tcrb gene rearrangements.⁸⁰ IL7 regulation is tightly coordinated during T-cell maturation within the thymus for thymocyte survival, as IL7 is essential for post-selection expansion of positively selected thymocytes.⁸¹

Other cytokines, such as IL1, IL2, and IL4, have also been shown to play some role in thymocyte differentiation.⁷⁶ The thymus is continuously colonized by hematopoietic progenitors that have the genes for the Tcr in germline configuration. Approximately 100 to 1,000 such progenitors enter the thymus daily, and it takes approximately 3 weeks to undergo complete differentiation to mature functional and self-tolerant T-cells.

The biologic processes within the thymus are highly complex, but for a better understanding, we divide them, somewhat arbitrarily, into three areas: (a) lineage determination i.e., TCR-αβ versus TCR-γδ, (b) separation of the two main T-cell subsets, i.e., CD4 versus CD8, and (c) selection for survival of those cells with a TCR able to recognize foreign antigens, i.e., PS and elimination of those possessing autoreactive configurations, i.e., NS. Understanding of these events will be facilitated by a prior description of the genes encoding the Tcrs.

T-CELL RECEPTOR GENES

Knowledge of the structure and patterns of expression of the various TCR genes is essential to our understanding of antigen recognition by T-cells. The TCR gene, “a needle in the haystack,” was isolated by the technique of subtractive hybridization.⁸² Four human and murine TCR genes have been identified: α (TRA@, Tcra),⁸³ β (TRB@, Tcrb),⁸⁴ γ (TRG@, Tcrg), and δ (TRD@, Tcrd)^{85,86} (Fig. 13.4).

The TRA@ gene is located on chromosome 14 (bands q11-12),⁸⁷ as is the immunoglobulin (Ig) gene (band q32). Rearrangement involving the region of the chromosome containing TRA@ has been detected in patients with T-cell malignancies.^{88,89} The TRD@ gene is located on chromosome 14 within the TRA@ gene.⁹⁰ The TRB@ and TRG@ genes are located on chromosome 7.^{91,92} Translocations and inversions of chromosomes 14 and 7 are

P.283

often seen in association with ataxia telangiectasia, probably involving fragile sites that normally are used during the TCR gene rearrangements.

FIGURE 13.4. Organization of the genes for human T-cell receptor chains (see text for details). (Adapted from Kronenberg M, Siu G, Hood LE, et al. The molecular genetics of the T-cell antigen receptor and T-cell antigen recognition. *Annu Rev Immunol* 1986;4:529-591; and Raulet DH. The structure, function, and molecular genetics of the γ/δ T-cell receptor. *Annu Rev Immunol* 1989;7:175-207.)

All TCR genes display an overall organization similar to that of the Ig genes. They are composed of variable (V) and constant (C) genes. The V gene is made of three segments (V, J, and D) in the TRB@ and TRD@ genes, but only two segments (V and J) in the TRA@ and TRG@ genes.⁸⁶ Each V gene family is divided into subfamilies like the Ig V genes, on the basis of sequence similarity (more than 75%). In humans, the TCR gene group consists of one C- α gene,⁹³ two C- β genes,⁹⁴ two C- γ genes, and one C- δ gene. With the exception of the C- γ gene, which is composed of three exons, all of the genes have four exons. The TRD@ locus is located between the C- α and J- α gene segments. Diversity of the TCR genes is generated through rearrangements, with each of the V and J segments and the D segment, in the case of TRB@ and TRD@ genes, forming the complete V gene. The TCR genes, however, contain a large number of J segments as compared to the Ig genes.

Associated with the C- α gene are approximately 50 V α and 61 J α segments that spread over 100 kb of DNA. The β -chain (TRB@) gene complex is located on chromosome six, spans 600 kb⁹⁵ and incorporates 57 V- β segments. Each of the two C- β genes possesses a set of J- β segments and one D- β segment. The V- β segments are all located upstream from the two clusters of C- β genes. During rearrangements, when a V- β segment forms a VDJ complex, the transcript is committed to using the same C- β segment genes. The TRG@ gene locus contains two C- γ genes, each associated with its own set of J- γ segments. There are approximately 14 V- γ segments, all located upstream separately from the two C γ -J γ clusters. The C- δ gene complex lies between the V and J segments of the TRA@ gene complex and contains eight V- δ , three D- δ , and three J- δ segments. The TCR gene segments, as are the Ig gene segments, are flanked by heptamer-spacer-nonamer sequences, which serve as recognition sites for the recombinase, the enzyme that initiates V(D)J recombination which is regulated by the RAG1 and RAG2 genes for both T- and B-cells. The RAG1/RAG2 proteins act in a lineage-specific manner; i.e., Ig genes are assembled only in B-cells and TCR genes only in T-cells. The recombinations are also developmentally regulated. For T-cells the β genes are recombined before TRA@ genes and for B-cells the IGH@ gene is recombined before IGL@. These differences are explained by differential accessibility of V genes during development. Accessibility for V(D)J recombination is usually accompanied by germline transcription at antigen receptor loci.⁹⁶ Two mutually exclusive T-cell lineages have been identified on the basis of TCR: $\alpha\beta$ and $\gamma\delta$.

Transcription increases the recombination of J (α) segments located within several kilobases of a promoter and prevents the activation of downstream promoters.⁹⁷ The mechanism of V(D)J recombination has been described in detail in Chapter 12.

The mechanisms generating diversity are combinatorial associations of different V, D, and J segments and combinatorial pairing of TCR protein. However in contrast to the Ig genes, fewer V segments are available to the TCR genes. The diversity of the TCR is mainly junctional, i.e., a result of additions of nucleotides at the DNA cleavage site. Additions that depend on the template are known as P nucleotides, whereas random additions are called N nucleotides, added by terminal deoxynucleotidyl transferase (TdT) (see Chapter 12). TdT is not expressed during fetal life and in TdT knockout mice, the T-cell repertoire is of fetal type (i.e., less diverse). TdT is expressed only in immature lymphocytes and is responsible for the transition from fetal to adult repertoire by contributing significantly to the lymphocyte antigen receptor repertoire. A

striking difference between Ig and TCR is the lack of somatic hypermutations, which is very important in generating high-affinity antibodies in the germinal centers (Chapter 11). Assembly of V segments of TRB@, TRG@, and TRD@ genes occurs during the DN stage. If the β -chain rearranges successfully, it forms a heterodimer with the pre-T α (PTA) chain and differentiates along the T- $\alpha\beta$ lineage entering the DP phenotype stage.

TCR gene rearrangements occur in two discrete stages of thymocyte development: first during the DN stage with the TRD@ gene rearranging first, followed by the TRG@ and TRB@ genes and the TRA@ gene rearranging during the DP stage. During the TRB@ gene rearrangement, a D- β segment joins a J- β segment and as with the IGH@ gene rearrangement, a V- β joins the D β -J β complex. If the rearrangement is not productive the cell may have one more chance at rearranging a second C- β cluster inasmuch as there are two C- β segments each with its own D and J segments.

PRE-T-CELL RECEPTOR AND T-CELL- $\alpha\beta$, T-CELL- $\gamma\delta$ LINEAGES

The decision in choosing a TCR- $\gamma\delta$ versus a TCR- $\alpha\beta$ lineage is made by any one of three proposed models. According to one mechanism each lineage starts from a separate precursor

P.284

(stochastic or independent pathway), and a second model proposes that there is a common precursor for both lineages (instructive pathway). The third model (competitive pathway) postulates that rearrangements for the genes of the lineages start concurrently and those finishing successfully first determine the fate of the cell. Some evidence appears to support a variant of the stochastic model.⁹⁶ It is agreed that the TRD@ gene rearrangement occurs in thymocytes that can adopt either one of the $\gamma\delta$ or $\alpha\beta$ fates, but activation of the TRA@ gene rearrangement during the DP stage seals the fate of the T-cell for the $\alpha\beta$ lineage.

Determination of lineage is regulated by transcription factors that act on promoters and enhancers and make appropriate genes accessible to the recombinase.^{97,98} Another regulatory mechanism involves the pre-TCR. At this stage of T-cell development, the TCR- β chain forms a heterodimer with the PTA chain and the complex is referred to as pre-TCR.⁹⁹ The PTA is a 33-kd type I transmembrane protein of the Ig superfamily, with a single Ig-like domain. Two cysteines form the intrachain disulfide bond, whereas a third cysteine just above the transmembrane region forms the disulfide bridge with the TCR- β chain.¹⁰⁰ The human PTA gene is located on the short arm of chromosome 6, in the vicinity of the HLA locus. The PTA chain is not essential for CD3 expression, but has a major role in TCR- $\alpha\beta$ versus TCR- $\gamma\delta$ commitment. It generates large numbers of CD4⁺/CD8⁺ T-cells with productive TCR- β rearrangements and directs these cells to the TCR- $\alpha\beta$ lineage.¹⁰¹ At the DN-3 stage, thymocytes undergo extensive DNA rearrangements at the TRB@, TRG@, and TRD@ gene loci and make a choice for selection, between the TCR- $\alpha\beta$ and TCR- γ receptors. Expression of the TCR- β chain in combination with the pre-TCR- α chain results in a process known as β selection, which leads to rearrangements of the TRA@ genes and formation of the complete TCR- $\alpha\beta$. If the TRD@ or TRG@ genes are rearranged, the cells follow the TCR- $\gamma\delta$ lineage ($\gamma\delta$ selection).^{102,103} and ¹⁰⁴

The selection for TCR- β is initiated at a stage phenotypically characterized by expression of CD4⁺/CD8 $\alpha^+\beta^-$.¹⁰⁵ The productive V- β gene rearrangement in one allele prevents rearrangements of the second allele, a process called allelic exclusion that is regulated by the pre-TCR. Signaling by the pre-TCR requires the CD-3 chains γ , ϵ , ζ , and η , and the LCK kinase,¹⁰⁶ which is associated with the CD3- ϵ and - γ chains and is indispensable for the pre-TCR function. Other functions mediated by pre-TCR signaling are cell survival and phenotypic changes. Pre-TCR promotes thymocyte survival, whereas signaling by TCR induces apoptosis.^{107,108} Because pre-TCR is expressed on DN T-cells, the antiapoptotic function of pre-TCR is crucial for their survival and differentiation of DN T-cells into the DP stage when the TCR is needed for positive or NS.

Both receptors follow initially similar signaling pathways, such as tyrosine phosphorylation and so forth, but in the apoptotic pathway, they diverge at the level of Fas ligand (FasL) induction, which requires induction of Nur-77 and transcription factors from the nuclear factor of activated T-cells (NFAT). These factors can be induced only by the TCR- $\alpha\beta$ but not by the pre-TCR. The PTA possesses a palmitoyl moiety that spontaneously targets the PTA chain to the cell membrane (lipid rafts).¹⁰⁹ This may offset the requirements for a ligand because the pre-TCR from such a location is able to signal constitutively. Signaling through pre-TCR results in expression of certain transcription factors required for the differentiation of precursors to $\alpha\beta$ T-cells, i.e., β selection (see above). Some of these factors are the E-proteins of the basic helix-loop-helix transcription activators required for expression of CD4, TCR- α and TCR- β chains and so forth.¹¹⁰

CD4/CD8 LINEAGE COMMITMENT

The DP thymocyte (CD4⁺/CD8⁺) differentiates into two phenotypically and functionally distinct lineages of αβ T-cells: CD4⁺ and CD8⁺. The TCR of the CD4⁺ cells interacts with peptides bound to class II MHC molecules, whereas the TCR of the CD8⁺ cells recognizes peptide-class I MHC complexes. The CD4 and CD8 proteins are not clonally distributed and are known as coreceptors because they recognize the same ligands as the TCR.¹¹¹ The mechanism by which the separation of the lineages from DP thymocytes is achieved remains unresolved.^{112,113}

According to one theory, known as instructive, thymocytes carrying an MHC class I restricted TCR differentiate to CD8⁺ lineage, whereas engagement of TCR with class II MHC induces commitment to CD4. An alternative model, known as stochastic (or selective), accepts that the DP thymocytes are already committed randomly to a lineage; they make a choice that is unrelated to the MHC specificity of their TCR. Data collected from a variety of approaches do not agree with any particular mechanism in lineage commitment. The instructive model proposes that the CD4 or CD8 transduces differentiation-specific signals, but no lineage-specific signals have ever been identified.

It is also possible that the cytoplasmic region of CD4 directs CD4 lineage commitment. A chimeric construct, for example, made of the cytoplasmic region of CD4 and the extracellular and transmembrane region of CD8a supported the development of cells with the CD4⁺/CD8a⁻ phenotype but with a class I restricted TCR.¹¹⁴ CD4 is preferentially associated with its cytoplasmic tail with the tyrosine kinase LCK. Therefore, CD4 is likely to deliver stronger signals than the coengagement of TCR and CD8.^{115,116}

The strength of signal model suggests that strong signals dictated by the frequency of the available ligand induce CD4 differentiation, whereas weak signals induce CD8. Another aspect of signaling that was evaluated was the duration of signals as an important parameter. When the interaction is limited to a few hours, the cells become CD8⁺, but exposure for longer periods of time results in CD4⁺ lineage commitment.¹¹⁷ Accordingly, TCR of a DP thymocyte initiates down-regulation of CD8 and produces a CD4⁺/CD8⁻ intermediate cell. At this stage, the duration of signaling determines the final outcome. That is, short signaling produces CD8⁺ T-cells, whereas persistence of signaling in the CD4⁺/CD8⁻ intermediate cell causes CD4⁺ differentiation.¹¹⁸ Variation of LCK function seems to be the single most important parameter in CD4/CD8 lineage decision. Constitutively active LCK promotes CD4 differentiation, even in the presence of class I MHC-restricted TCR. When, on the other hand, LCK is catalytically inactive, all thymocytes including those with class II MHC-restricted TCR, become CD8⁺.^{119,120} In the absence of LCK, cross-linking of CD3 induces CD8 differentiation.¹²¹ The LCK-dependent regulation of lineage commitment is not only phenotypic, but also functional, because the class II MHC-restricted CD8⁺ cells behave as killer cells, whereas the class I restricted CD4⁺ cells up-regulate CD40 ligand, a function characteristic of helper T-cells.¹¹⁹ Signaling initiating from LCK is channelled through the Ras-Erk pathway.¹²²

The various experimental approaches used in these studies make it clear that the signals required for CD4 differentiation are promiscuous, which is believed to indicate that CD-4 differentiation is a default pathway.¹²³ The multiplicity of the models entertained and the ambiguity of some of the results are also a testimony that the precise mechanism of T-cell lineage commitment remains still elusive and certainly complex.^{113,124}

More recently a new transcription factor Th-POK (T-helper-inducing POK factor) was found to be necessary and sufficient for CD4 lineage commitment and absence of Th-POK results in the development of CD8⁺ T-cells.¹²⁵ The existence of this factor was suspected as a result of studies of the spontaneous recessive mutant mouse with helper deficient cells (i.e., CD4⁺ T-cells).¹²⁶ Th-POK belongs to the POK family of transcription factors characterized by two motifs, a regulatory POZ/BTB domain (for interaction with other transcription factors) and a Zn finger DNA-binding domain.

In summary, LCK is a key regulator, but other signals originating from the TCR in the absence of a coreceptor or in the

absence of a significant recruitment of LCK provide sufficient SRC activity for a response. Such signals depend on the nature of the peptides involved in positive versus NS, which is linked to lineage selection.¹²¹ Although the prevailing opinion accepts that lineage commitment and the selection of thymocytes with useful TCRs are linked, some of the models proposed point to the opposite.¹²⁷ The latest view that CD4/CD8 lineage commitment is transcriptionally regulated will put an end to this question hotly debated for a long time.

POSITIVE AND NEGATIVE SELECTION

The random nature of rearrangements of TCR genes generates specificities directed not only against foreign antigens, but also against self-antigens. Self-reactive T-cells are harmful if they have the opportunity of exiting the thymus. Mechanisms have therefore been developed that allow the thymus to “select the useful, neglect the useless and destroy the harmful.”¹²⁸ The time for selection appears to begin at the DP stage when the TCR is expressed at low levels.^{129,130,131} and

¹³² The TCR of the thymocytes recognizes self-peptides presented by the MHC molecules. It has been widely accepted that the options for each DP thymocyte are determined by some fine qualities and properties of the TCR and MHC-peptide (pMHC) ligand interaction. If the affinity of interaction is “weak,” the cell is positively selected, whereas a T-cell with high affinity is negatively selected.¹³³

Cells with TCRs that cannot bind with sufficient avidity are neglected and die by apoptosis, whereas in the positively selected cell the expression of RAG, which encodes the proteins regulating V(D)J recombination and the PTCRA (pre-T-cell receptor) gene are turned off and expression of CD4 and CD8 are partially down-regulated. At this stage the cell moves from the cortex to the medulla, one of the coreceptors is re-expressed and the cell lineage is defined.^{122,134} Signaling by LCK regulates positive and NS and in its absence the selection mechanisms are compromised.¹³⁵ LCK interacts with the coreceptors CD4 and CD8 through two cysteines in the cytoplasmic region of each co-receptor and two cysteines in LCK.¹³⁶

The binding of TCR to the ligand induces phosphorylation of the three immunoreceptor tyrosine-based activation motifs (ITAMs) of the ζ -chain and the single ITAM in each of the CD3 ϵ -, δ -, and γ -chains. The ζ -chain is constitutively associated in thymocytes with the ZAP70 kinase, suggesting that a low level of activation takes place continuously.¹³⁷ The fate of the immature thymocyte depends on the type of APC that it encounters in the various histologic compartments of the thymus. The cortical thymic epithelial cells usually mediate PS,^{138,139} and the medullary hematopoietic cells mediate NS,¹⁴⁰ although under certain circumstances they may also contribute to PS.¹⁴¹ Interactions among thymocytes may also support PS if the selecting thymocyte carries MHC class II molecules.¹⁴² In this case the α -chain of the TCR, and particularly the highly diverse CDR3 loop of the α -chain, plays an important regulatory role.¹⁴³ Signals provided by the CCR7 chemokine receptor¹⁴⁴ guide the positively selected thymocyte to the medulla. The CCR7 signals provide guidance for the selected thymocyte through the corticomedullary maze, in preparation of the central tolerance in the medulla prior to their exit to the periphery.¹⁴⁴ An important selective force in these cellular interactions is the strength of the interaction, which determines the outcome. Strong interactions lead to deletion, whereas intermediate strength induces PS. This may explain the increase of PS following blocking of CD28/B7 interactions.¹⁴⁵ Removal of strong self-reactive cells is the sole purpose of the NS. Such clones potentially may initiate autoimmunity if they exit to the periphery. An estimated 2,000 to 3,000 tissue-specific antigens are expressed in human or murine medullary thymic endothelial cells (mTECs),^{146,147} i.e., 5% to 10% of the known mouse genes, in addition to their normal tissue expression. About 500 of these genes may be AIRE (autoimmune regulator) -dependent. Using hen egg lysozyme as reporter for the insulin promoter, it was shown that the expression of the antigen in the thymic stroma is necessary and sufficient for deletion.¹⁴⁸

Expression of tissue-restricted self-antigens (TRAs) by mTECs is the result of promiscuous gene expression (pGE) by the mTECs.¹⁴⁶ Some of the genes are expressed by both mTECs and cortical thymic endothelial cells (cTECs; pool 1), whereas others are expressed only by mTECs (pool 2), and finally others are expressed only in the more mature mTECs (i.e., strongly positive for MHC class II; pool 3). Depending on the stage of differentiation of mTECs, two models have been proposed for pGE: (a) in the developmental, or progressive restriction model, pGE is detected in immature and perhaps pluripotent progenitor cells and (b) in the terminal differentiation model, pGE is mutated in mTECs of a mature phenotype.¹⁴⁹ The pGE is regulated by AIRE, the gene mutated in the rare autoimmune disorder known as autoimmune polyglandular syndrome type 1 (APS-1).¹⁵⁰

AIRE has a nuclear localization signal and several potential DNA-binding and protein interaction domains. In cooperation with transcription factor CREB-binding protein it transactivates the transcription of other genes, although it is still a mystery how as a single molecule it controls the transcription of such an array of genes.

The pGE has been conserved across species barriers during evolution as a study recently with human pure populations of thymic cTECs and mTECs has shown.¹⁵¹ The AIRE gene showed the highest enrichment in mTECs and the promiscuously over-expressed genes are those remarkably well conserved among species. A set of 443 genes have been detected overexpressed in mTECs (comparable to 555 in mouse). This is an underestimate as most were detected by polymerase chain reaction. These genes show no preference for any chromosome. Another interesting aspect is the finding of clustering of nonhomologous genes. This clustering has been suggested to result from the juxtaposition during evolution of genes involved in the formation of a particular tissue. Because the promiscuously expressed genes do not all share such a function, the clustering is the result of epigenetic mechanisms of regulation. They become accessible to mTECs as a result of belonging to the same “gene neighborhood.” pGE not only is sufficient for self-tolerance, but also likely has been essential for survival of the species inasmuch as infertility as a result of gonad-specific autoimmunity is highly prevalent in APS-1¹⁵² and in Aire^{-/-} mice.¹⁵³ In addition to genetic control, self-tolerance may also be regulated by epigenetic mechanisms. The lymphotoxin β receptor (LT β R) directs the three-dimensional organization of mTECs,¹⁵⁴ and TRAF6, a cytoplasmic adaptor molecule, which does not bind to LT β R, was still shown to direct mTEC development.^{155,156}

Self-tolerance is mediated primarily by NS or clonal deletion,¹⁵⁷ but some of the self-reactive T-cells are submitted to nondeletional central tolerance and give rise to immunosuppressive CD4⁺ T-cells, also known as natural regulatory T-cells (T reg) cells.¹⁵⁸ T reg cells are T-cells with medium to high affinity for self-antigens. However, they escape NS and are positively selected by a subset of dendritic cells that have been educated by a thymic stromal lymphopoiectin produced by Hassall corpuscles.¹⁵⁹ Other evidence, on the other hand, indicates that CD4⁺ T reg cells are positively selected by thymic epithelial cells expressing self-antigens but not by bone-marrow-derived dendritic cells.¹⁶⁰ ZAP70 is indispensable for positive and NS because both processes are abrogated in ZAP70-deficient mice.¹⁶¹

The SRC-like adaptor protein (SLAP) down-regulates the TCR expression during the DP stage of development and rescues T-cell development in the absence of ZAP70. Overall, SLAP acts as a

P.286

negative regulator and probably “marks” activated receptors for retention and degradation.¹⁶² The main downstream signaling pathway for PS is the Ras/map kinase (MAPK) cascade.¹⁶³ TCR signaling alone is not sufficient to induce selection for survival or death.¹⁶⁴ CD2 expression exerts a strong influence on the TCR repertoire. In the absence of CD2, the thymocytes with high affinity for peptide MHC escape NS.¹⁶⁵ CD2 also influences pre-TCR function in the usage of V α genes, which is substantially altered in CD2-deficient mice.

The costimulatory interaction of CD40/CD40L is a master regulator of NS, usually acting in the regulation of the ligands of other costimulatory molecules, such as CD80 and CD86.¹⁶⁶ CD40 may also induce other co-stimuli required for thymocyte deletion, such as CD54 (ICAM-1), FASL, or tumor necrosis factor (TNF).^{167,168} and ¹⁶⁹ These molecules could regulate NS separately or in combination with CD5 and CD28. The CD28 costimulatory molecule engaged with TCR signals thymocytes to undergo apoptosis or maturation, depending on the intensity of costimulation.¹⁷⁰

Stimulation of maturation of DP thymocytes follows activation of the extracellular signal-regulated kinase ERK/MAPK pathway and up-regulation of the antiapoptotic protein BCL2. Apoptosis is triggered with the expression of the Nur77 family of transcription factors and occurs only if TCR engagement is accompanied by costimulation. Ca²⁺ fluxes in mature T lymphocytes regulate proliferation, differentiation, and survival. Some of the functions of Ca²⁺ are mediated by the Ca²⁺-dependent phosphatase calcineurin. The function of calcineurin is disrupted by cyclosporin A and FK506. Both of these substances form complexes with cellular proteins, termed immunophilins, that bind and sequester calcineurin. Cyclosporin A and FK-506 block the initial steps of PS.^{171,172} On the other hand, intracellular chelators reduce deletion,¹⁷³ which suggests that interference of Ca²⁺ fluxes and function exerts several effects on the selection process.

All signaling pathways end up targeting regulation of transcription factors, and various studies have examined the roles of NFAT and nuclear factor- κ B (NF- κ B), but only members of the Nur-77 family have been clearly shown to be involved in the process of selection, with a major role in apoptosis of massive numbers of thymocytes.¹⁷⁴ It has been estimated that 90% to 95% of thymocytes die inside the thymus, and the appearance of very large numbers of dead cells on histologic sections is the reason that histopathologists called the thymus the “graveyard” of T-cells. The timing of positive versus NS has been difficult to define. NS was believed to occur relatively late because the TCR affinity increases with time, and it is the high affinity of TCR that triggers NS.

THE CELLS AND MOLECULES IN THE SELECTION OF THYMOCYTES

Hematopoietic components of the thymic stroma are radiosensitive, whereas the epithelial components are radioresistant. These differences allowed the construction of chimeric thymuses (i.e., thymuses composed of epithelial and hematopoietic elements with a different MHC background). These experiments indicated that the thymic cortical epithelium is responsible for PS.¹⁷⁵ The hematopoietic stromal cells, on the other hand, are potent inducers of NS. The cortical epithelial cells have weak MHC expression and the developing DP thymocytes at that stage have low TCR expression; as a result, the interactions are only of low avidity, required by positive. Similarly, the hematopoietic cells in the corticomedullary junction express MHC molecules at higher density, and the T-cells have up-regulated their TCRs. As a result, the interactions in this anatomic location are appropriate for NS. The concentration of the peptide may also play a role in the selection process. thymocyte bearing a TCR specific for class-I-peptide complex is positively selected if the peptide it carries is in a low concentration and is killed if the peptide concentration is high.¹⁷⁶ However, the weak interactions required for PS and the strong interactions operating in NS can also be provided by the half-life of the pMHC complex (i.e., short half-life for positive and long half-life for NS).

The original question of affinity versus concentration was better answered with manipulation of the pMHC. PS is driven by peptides with varying affinities; however, by increasing the concentration of the peptide, even low-affinity ligands can positively select.¹⁷⁷ It has been argued that the recognition of self-peptides in PS must be relatively degenerate. In other

words, a single pMHC can trigger the PS of multiple thymocytes;¹⁷⁸ therefore, the peptide recognition during PS is cross-reactive.¹⁷⁹ This apparent degeneracy of the peptide binding to TCR is the result of a significant contribution to the binding by the MHC molecule.¹⁸⁰

Other parameters of a pMHC complex, such as the conformation¹⁸¹ and the concentration¹⁸² of the peptide, contribute to the repertoire selection. Despite the evidence that each pMHC complex selects more than one TCR, the large diversity of the fully developed T-cell repertoire depends on a large number of pMHCs¹⁸³ as well as on the quantity and quality of the stromal cells.¹⁸⁴ Peptide diversity during the selection seems to have a greater effect on negative than on PS. In thymus organ cultures, testing with a diverse array of peptides, the addition of 1% of dendritic cells reduced the number of CD4⁺ T-cells selected by 80% compared to that of the controls in the absence of dendritic cells. Thus, the quantity and quality of the selecting stromal cells have a significant impact on the selected repertoire by multiple peptides.¹⁸⁴ At the end of the selection process, mature T lymphocytes exit the thymus and home to the secondary lymphoid organs (see Chapter 11). There are two types of TCR- $\alpha\beta$ T-cells, the CD4⁺ (T helper cell) and the CD8⁺ (cytotoxic T-cell) and one TCR- $\gamma\delta$ cell.

THE α/β T-CELL RECEPTOR COMPLEX

The TCR complex is composed of two components: one is unique in each T-cell and is involved in antigen recognition (ligand binding) and the second component is the same in all T-cells and is involved in signal transduction leading to T-cell activation.^{185,186} and ¹⁸⁷

THE MAJOR HISTOCOMPATIBILITY COMPLEX-PEPTIDE COMPLEX

The $\alpha\beta$ receptor is formed by two chains, α and β (Fig. 13.5), each consisting of a constant domain, C- α and C- β , and a variable domain, V- α and V- β . The V- α domain is encoded by two gene segments, V- α and J- α , and is homologous to the V domain of the Ig heavy chain (IGH@). The V- β domain is formed by three polypeptides, V- β , D, and J- β . The constant domains correspond to the Ig C domains, but there are certain differences. The C- α -C- β interface is highly polar, whereas that of CL-CH1 is hydrophobic. C- β has a large loop, which extends out to the side of the domain. It has been proposed that it may interact with the coreceptors. The C- α domain has several structural deviations from the C-type Ig domain.

The V domains are very similar to the V domains of an antibody molecule. They contribute to the formation of the TCR-combining site, which is made up of hypervariable loops or complementarity-determining regions CDR 1, 2, and 3 from the α - and β -chains and another loop termed HV-4, which exhibits some hypervariability. The CDR1 and CDR2 are formed by the V segments, which are less polymorphic in the TCR than in IGH@ because fewer V segments are available for TCR, whereas the CDR3 is polymorphic as

P.287

a result of the larger number of J segments available for β -chain contributing to CDR3.

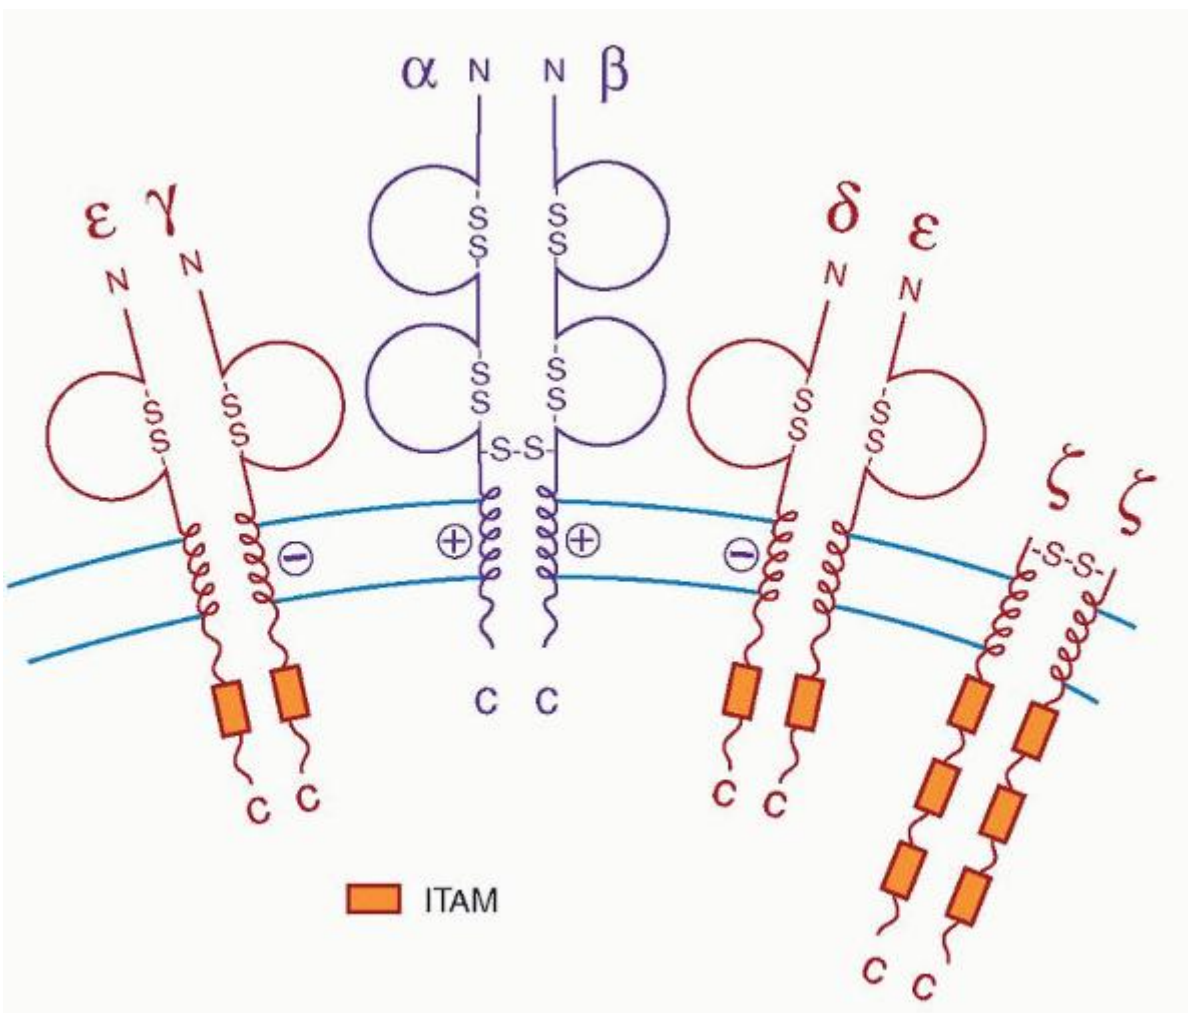

FIGURE 13.5. T-cell receptor complex. The T-cell receptor complex consists of two components: ligand binding (antigen recognition) and signal transduction. The antigen recognition component consists of two polypeptide chains, α and β . Because of their short intracytoplasmic tails, they cannot link themselves to the signal transduction cascade. The signal transduction component consists of the CD3 proteins γ , δ , and ϵ , members of the immunoglobulin superfamily, and two other proteins forming either a homodimer (two ζ proteins) or a heterodimer (ζ - ϵ). The γ -, δ -, and ϵ -chains have one immunoreceptor tyrosine-based activation motif each, and the ζ -chain has three. See text for details.

The loops of V- β that form the expected antigen-binding site of the TCR are similarly placed as in the IGH@ V region. The chains are linked by a disulfide bond, and the heterodimer is anchored to the cell membrane by the transmembrane region, ending in the cytoplasm by a short (three- to five-amino acid) cytoplasmic tail. Crystallization of the TCR shows that it resembles the Fab fragment of the Ig molecule.¹⁸⁷ However, the TCR- $\alpha\beta$ is extensively glycosylated with up to seven N-linked sites distributed between the α - and β -chains. The combining site is usually flat, similar to antiprotein antibodies and consistent with the TCR's function of binding to the generally flat, undulating surface of the pMHC.¹⁸⁸ The diversity of the CDR3 is much higher, implying that the function of CD-3 is in peptide discrimination, whereas CDR1 and 2 interact with more conserved structural elements of the MHC. The TCR contains many more J segments and thus are able to increase V- $J\alpha$ and V-D- $J\beta$ junctional diversity in the CDR3.¹⁸⁹ The residues of the TCR that contact the pMHC are always in the apices of the CDR (i.e., for CDR1 α , residues 27 to 30; for CDR2 α , residues 50 to 52; for CDR1 β residues 27 to 30; and for CDR2 β residues 52 and 53).

The TCR interacts with peptides bound to MHC molecules (Fig. 13.6). The aminoterminal domains, α_1 and α_2 of the MHC class I heavy chain, form the binding site for the peptide. The site consists of a floor of eight strands of antiparallel β -pleated sheets, which support two α helices, one contributed by the α_1 domain and the other by the α_2 domain aligned in an antiparallel orientation. The floor of the groove is supported by two Ig domains from below; one is the α_3 domain of the heavy chain and the other the β_2 -microglobulin. This arrangement forms a groove, on the floor of which lies the peptide from an antigen to be presented to the TCR. Some of the residues of the peptide are exposed above the groove

and interact directly with the TCR, whereas others point to the floor of the groove. Depressions in the floor of the groove, known as pockets A through F, interact with some side chains of the bound peptide.¹⁹⁰

FIGURE 13.6. T-cell receptor (TCR) interaction with HLA/peptide complex. Crystallographic studies of the HLA class I molecule have shown that the two variable domains (α_1 and α_2) form a groove that binds the peptide that is released as a result of antigen processing. The peptide groove is formed by the helices of the α_1 and α_2 domains (A). Binding of the peptide is mediated through anchor amino acids near both ends of the peptide (in A). The TCR binds to both the major histocompatibility complex molecule and the peptide. The complementarity-determining region (CDR) 3 of both the α - and β -chains interacts with amino acids of the peptide, whereas the CDR1 and CDR2 interact with the major histocompatibility complex molecule (B).

For HLA-B27, the side chain of the C-terminal of the bound peptide sits deep in the F pocket, whereas the N-terminal forms strong hydrogen bonds with the hydroxyl groups of conserved amino acids at the end of the groove.¹⁹¹ (For details of interaction with the pMHC, see Chapter 14.) For crystallization of TCR-pMHC, the peptide was attached covalently through a linker to the amino terminus of the β -chain of an MHC class II molecule¹⁹² or covalently connected to the amino terminus of the β -chain of the TCR¹⁹³ and thus tethered to the MHC groove. Such approaches provided stable complexes of HLA-DR1 and HLA-DR4 that permitted their crystallization. Several TCR-pMHCs have been analyzed to clarify the contributions of $V\alpha$ for the buried surface area (i.e., the interface between TCR and the pMHC). The contribution of $V\alpha$ is on the average 57% and that of the $V\beta$ 43%.¹⁹⁴ The orientation of the TCR over the pMHC is diagonal rather than

orthogonal.¹⁹⁵ It is more likely that the TCR turns around the MHC molecule by approximately 35° and varies also in its roll in a range of 19° (range 30°).¹⁹⁶ As shown by x-ray crystallography, with 2.5 angstrom resolution, of a complex of human $\alpha\beta$ -TCR bound to a complex of HLA-A2/HTLV-1 Tax peptide, (HTLV = human T-cell leukemia virus), the initiation of T-cell signaling is favored by a diagonal binding position of the TCR with the supramolecular assembly. This form of interaction of the TCR with its target is in striking contrast to antibody molecules, which use different binding positions even with the same antigen. The diagonal approach of the TCR, to the MHC/peptide complex, evolved to facilitate the initiation of T-cell signaling, inasmuch as the same MHC-bound antigen can be recognized by different TCRs. Unlike antibody molecules, which bind even to the same antigen by many different binding geometries, the TCRs interact with the MHC/peptide complex with a diagonal binding mode. The diagonal binding

P.288

geometry has implications for the mechanism of initiation of T-cell signaling, because it places the TCR in a orientation that facilitates the positioning of the CDR1 and CDR2 loops over the α_1/α_2 helices of MHC class I, and the α_1/β_1 helices for class II molecules. The V α domain is critical in setting up these orientations facilitating the read-out of the peptide sequence. Thus the CDR1 and CDR2 interactions of V α are conservative¹⁸⁶ and provide the basic affinity of the TCR. The CDR3 loop is primarily positioned for contact of the peptide in the peptide-binding groove whereas the V β interaction is more variable in the C-terminal half of the peptide. The contribution of the individual CDR loops to the interaction varies. CDR1 β and CDR2 β actually contribute little or nothing to the interaction whereas the CDR3 loops are centrally located and usually dominate the interactions.¹⁹⁴ The contribution of the peptide to the interactions with the TCR varies and usually, two to five side chains of the peptide make direct contact with the TCR. These contact points, known as hot spots, are peptide residues that bulge out of the groove which is more prominent and sometimes profound as in MHC class I.¹⁹⁷ In the interactions of MHC class II with the TCR, the contributions of the peptide side chains are more uniformly dispersed and the peptides are slightly deeper in the MHC binding groove.¹⁹⁷ No single contact dominates the TCR-pMHC interactions, as is often observed in the antigen-antibody interactions. A small number of amino acids dominate the energy landscape in antigen-antibody interaction, as shown by somatic mutations that result in higher-affinity binding.¹⁹⁸ Based on these considerations, it appears likely that the CDR1 and CDR2 loops interacting with the helices of the MHC are responsible for PS, and the CDR3 loops probably play a more important role in NS. As an extension of these considerations in delineating the roles of V-region loops of the TCR, the CDR1 and CDR2 loops provide the basic affinity in the interaction, whereas the CDR3 provides the specificity.¹⁹⁴ The residues of the peptide that protrude highest from the groove provide the basis for discrimination of peptide and for altering affinity or half-life of the TCR-pMHC interaction.

An important point that came out of these crystallographic studies is the role of the water that fills the TCR-pMHC interfaces. This water provides additional complementarity by filling the cavities in the interface, and some of these molecules mediate contact between TCR and pMHC.¹⁹⁹ Overall, the consistent feature of TCR-pMHC interaction is that the peptide contributes a smaller portion of the binding interface (21% to 34%) and a smaller proportion of contacts (26% to 47%) than the MHC. The central positions of the peptide play the critical role and those define the peptides as agonists, partial agonists, and antagonists.²⁰⁰ The binding of TCR to the pMHC results in T-cell activation and usually there is a broad correlation among affinity, half-life, and the functional outcomes.²⁰¹ Mutational analysis of the role of the centrally located residues indicates that in some systems, the biologic activity increases,²⁰² yet in others, the peptide is converted from an agonist to an antagonist;²⁰³ nevertheless the affinities of the pMHC for TCR change only marginally.

Contacts on certain hot spots are very sensitive in changing the functional read-out but are not based on changes in the affinity of binding or half-life differences in the TCR-pMHC complexes. It has been argued that affinities usually have been measured in isolated TCR-pMHC complexes, and true affinity measurements may require the presence of coreceptors and signaling components and need to be measured with cellular assays.²⁰³

Because changes in the TCR-pMHC complementarity interface are important for triggering biologic reactions, the conformational changes that have been observed in the TCR-complex crystal structures have been considered for initiation of signaling, but their role is not clear.²⁰⁴ Conformational changes contribute to an increase in the binding of a number of other peptides (i.e., an expansion of the repertoire).²⁰⁵

PEPTIDE-MAJOR HISTOCOMPATIBILITY COMPLEX INTERACTION: THE CORECEPTORS

The TCR is not alone in its interaction with the pMHC but is associated with coreceptors (i.e., CD4, CD8, and the CD3 chains). The monomorphic CD3 γ -, δ -, ϵ -, and ζ -chains, together with the $\alpha\beta$ heterodimer form the TCR complex. The CD4 or CD8 act as assistants to the TCRs in the helper or cytotoxic function of the cells, respectively. Therefore they have been known as coreceptors.¹¹¹ In the current model, the CD4 binds to the same MHC II as the TCR of the CD4⁺ T-cell and

similarly the CD8 binds to the same MHC I as the TCR of the CD8⁺ T-cell. The binding of the coreceptors occurs with another site of the MHC molecule than that involved in the TCR binding. The TCR binds to the pMHC surface at an angle of 45° to 80° relative to the axis of the two α -helices of MHC,²⁰⁶ which excludes the possibility for direct association of the coreceptors with the TCR that binds the same pMHC. One possibility is that the coreceptors could be linked with TCR in the cytoplasm through signaling molecules (i.e., ZAP70 and LCK).²⁰⁷ Another possibility is that the coreceptor associated with a TCR binds to a different pMHC to which a second TCR binds forming a pseudodimer.²⁰⁸

The CD8 acts as a dimer that includes either two α -chains or one α - and one β -chain, whereas CD4 is a monomer with four Ig-like domains. Both CD8 chains consist of an Ig-like V domain and a long mucinlike stalk. The Ig-like domain binds to the α 3 domain of MHC,²⁰⁹ forming also some hydrogen bonds with the α 2 domain and the β 2M-chain, away from the peptide interface. In CD4, only the fourth Ig-like domain binds directly to pMHC. The ternary complex (TCR-pMHC-CD4/CD8) within the T-cell-APC interface of the immunologic synapse (IS) has a V shape²¹⁰ (Fig. 13.7). Although the CD8 α stalk is longer than the CD8 β chain, even in its full extension, it reaches only 50 to 60 Å, which is not long enough to traverse the distance of approximately 100 Å to the TCR-pMHC complex. As a result, the TCR-pMHC has to tilt for the CD-8 to reach the MHC. The stalk of the CD8 chains is heavily glycosylated and changes in glycosylation (which occur after T-cell activation) result in a decrease of binding to MHC.²¹¹ The coreceptors enhance TCR signaling by strengthening the stability of the TCR-pMHC complex.²¹² The V-shaped ternary complex accepts that the coreceptors bind to the same pMHC as the TCR,²¹⁰ whereas the CD-3 components probably lie inside the "open angle" of the V-shaped structure (Fig. 13.7). Such an arrangement makes possible the association of signaling molecules, such as ZAP-70, LCK, and SRC kinases, with CD4 and CD8. With this topologic model, direct interaction of the coreceptors with TCR is not likely as was previously indicated.²¹³

The CD2 binds to CD58 (LFA-3) in humans based on electrostatic complementarity, with the CD2 surface heavily populated by basic residues, whereas the CD58 is acidic. The interactions span approximately 134 Å, very similar to that of TCR-pMHC. Therefore, the CD2/CD58 interaction in the contact zone between T-cell and the APC, would facilitate the scanning of pMHC by TCR and lower the threshold for TCR triggering in vitro and T-cell activation in vivo.²¹⁴

CD28 and CTLA4 (CD152) are type I membrane proteins consisting of one moderately to heavily glycosylated V Ig-like domain and are expressed as disulfide-linked homodimers. Their counterreceptors B7-1 (CD80) and B7-2 (CD86) consist of two Ig-like domains, a membrane-proximal C-2 type, and a membrane-distal V-type. B7-2 binds C-28 more effectively than CTLA4 and as a result, enhances costimulatory effects when CD28 and CTLA4 are co-expressed. In contrast, B7-1 binds preferentially CTLA4, and its inhibitory effect would not be affected in the presence of CD28. Delayed expression of B7-1 on APCs appears to be timed to enhance the inhibitory function of

P.289

CTLA4. The CTLA4 periodic arrays of crystal lattices enhance the avidity of interaction, whereas the CD28/B7-2 interaction does not have this potential. As a result, during an immune response the CD28/B7-2-activating complexes are 10,000-fold less stable than the inhibitory complexes formed later by CTLA4/B7-1.²¹⁵

FIGURE 13.7. T-cell receptor (TCR) major histocompatibility complex (MHC) coreceptor interaction. The CD4 and CD8 are coreceptors of the TCR (i.e., “assistants” in the interaction of TCR with peptide-MHC complex [pMHC]). In this function, the N-terminal domain of CD4 (D1) makes contact with the $\alpha 2$ and $\beta 2$ domains of MHC II. In the CD8, the CD8 α subunit of the CD8 $\alpha\beta$ heterodimer contributes the binding energy, interacting with both the $\alpha 2$ and $\alpha 3$ domains of pMHC I, and CD8 β binds only to $\alpha 3$. Therefore, both coreceptors recognize different sites of MHC from the TCR. The length of each receptor is not long enough to reach the MHC binding site, traversing alongside the TCR-MHC complex. It is proposed that TCR-MHC has to tilt for the coreceptor to reach the MHC, forming a V-shaped ternary complex. The CD3 components of the TCR (γ , δ , ϵ) probably are located inside the V-shaped structure. APC, T-cell-antigen presenting cell. (Courtesy of Dr. G. F. Gao.)

THE T-CELL RECEPTOR: SIGNAL TRANSDUCTION COMPONENT

The TCR- $\alpha\beta$ is accompanied by five other polypeptide chains, collectively known as CD3 proteins: γ , δ , ϵ , ζ , and η . They form disulfide-linked heterodimers, such as $\gamma\delta$, $\epsilon\delta$, $\zeta\epsilon$, or a homodimer $\zeta\zeta$ ²¹⁶ (Fig. 13.5). The γ , δ , and ϵ proteins show a significant degree of similarity to one another and consist of an Ig-like domain similar to a C domain, with an intrachain disulfide bond. The extracellular region of the ζ -chain is only nine amino acids long and contains the only cysteine of the molecule, which forms the disulfide bond with another ζ chain or with an ϵ -chain. In the transmembrane region, the γ , δ , and ϵ proteins have a negatively charged amino acid complementary to a positively charged amino acid of the transmembrane region of the TCR- $\alpha\beta$ chains. The cytoplasmic regions of γ -, δ -, and ϵ -chains are long, ranging from 40 to 80 amino acids, whereas that of the ζ -chain is longer with 113 amino acids. The ϵ -chain is a splice variant of the ζ -chain

and like a heterodimer with the ζ -chain, exists only in a small number of T-cells. The CD3 proteins have a dual mission in the function of the TCR: escort the receptor to the cell membrane and mediate the signals generated by the TCR-pMHC complex. The complex is assembled in the endoplasmic reticulum, transported to the Golgi apparatus, and then transferred to the plasma membrane. The numbers of the ζ -chain are the rate limiting of the synthesis of the other chains because, although it is synthesized at only 10% of the level of the other chains, it regulates the degradation of a vast majority of the newly synthesized α , β , or CD3 components within 4 hours of their synthesis. The remaining nondegraded chains are long lived and form the complete TCR-CD3 complexes with a limiting role by the ζ -chain. The TCR-CD3 complex lacking the ζ -chain, migrates through the endoplasmic reticulum and Golgi apparatus intact and it is then transported to the lysosomes, where it is degraded. A lysosome-targeting motif has been identified in the δ - and γ -chains and consists of a dileucine-based motif (DKQTLL) and tyrosine-based motif²¹⁷ in the carboxy terminal region. In the completed complex the TCR α -chain pairs with CD3 δ - and ϵ -chains, and the TCR β -chain pairs with CD3 γ and ϵ . The ζ -chain joins the TCR and the CD3 chains in the last stage of the assembly. The topology of the TCR-CD3 complex is shown in Figure 13.5. Two TCR $\alpha\beta$ heterodimers are associated with one each of $\gamma\epsilon$ and $\delta\epsilon$ heterodimers and one $\zeta\zeta$ homodimer. The signal transduction function of the CD3 proteins is based on the presence of one ITAM in each of the γ , δ , and ϵ proteins and three in the ζ -chain. An ITAM consists of two YXXY/L sequences separated by six to eight amino acids and in the one-letter code for amino acids: Y = tyrosine, X = any amino acid, and L = leucine).²¹⁸

Phosphorylation of the tyrosines turns the ITAM motifs into docking sites for protein tyrosine kinases, which bind to the ITAM through their SH2 domain (see below). An important protein tyrosine kinase in T-cell activation is the ZAP70, which is recruited to the ITAM motifs of the ζ -chain. The multiplicity of ITAM motifs in the cytoplasmic tails of the CD3 proteins results in signal amplification and increases the sensitivity of the TCR to ligand stimulation. Triplication of a single ITAM motif significantly enhances Ca^{2+} mobilization, association with ZAP70 and transcriptional activity in the NFAT complex involved in IL2 gene regulation.²¹⁹ Cross-linking of a single isolated ITAM results in approximately threefold induction in NFAT-regulated activity and cross-linking of a triplicated motif results in an approximately eightfold increase in NFAT-regulated activity (i.e., comparable to intact ζ -chain).

CORECEPTORS TO T-CELL RECEPTOR: CD4 AND C-8 CD4

CD4 is the characteristic marker of $\alpha\beta$ T-cells with helper activity and cytokine secretion. The molecule consists of four Ig-like domains, (D-1 to D-4), with domains D-1 and D-3 similar to a V domain and D-2 and D-4 similar to C domains (C-2 type), but with patches of sequences similar to the V domain. In D-1 and D-3 domains, the nine β strands form two β sheets, linked by a disulfide bond. The domains are linearly arranged, forming a rod with limited flexibility.²²⁰ The binding of CD4 to MHC II molecules and to HIVgp120-envelop protein was studied by mutational analysis. The binding is mediated by a sequence within the D1 domain of two β strands, C'C'', that form a ridge (residues 35 to 46).²²¹ Phe-43 within this sequence is critical for binding to gp120, as well as for CD4 coreceptor function²²² because it provides the major binding energy, whereas the surrounding charged amino acids facilitate specificity.²²³ Crystal structure of the D1/D2 domains from CD4 complexed with class II molecule shows that the CD4 N-terminal V domain is directed and reaching into the two membrane-proximal domains of the MHC II molecule.²²⁴ Both TCR and CD4 are tilted rather than vertically oriented, forming a V-shaped CD4-pMHCI-TCR ternary complex (Fig. 13.7).

In this complex, the antigen-binding groove of pMHC II is no longer parallel to the cell surface but makes an approximately 45° angle with the membrane. However, despite the V shape of the ternary complex, the membrane-proximal domains of each of the components are all roughly vertical, including domain 4 of CD4 and the α_2 and β_2 domains of pMHC II as well as the C- β domain of TCR. Only the C- α domain of TCR hangs almost parallel above the membrane with its lengthy stalk bridging the space.

The extracellular fragment of CD4 crystallizes as a dimer associated via the D-4 domains.²²⁵ The CD4 dimers are associated with superdimers or dimers of dimers of the MHC II molecules²²⁷ and each CD4 molecule of the CD4 dimer interacts with one dimer of MHC II. X-ray crystallography of several MHC class II molecules revealed a structure described as a dimer of heterodimers, or a superdimer. This discovery led to the hypothesis that the MHC class II molecule may interact with the TCR and CD4 as an α/β -2 superdimer, potentially providing more stable and stimulatory interactions than can be provided by the simple $\alpha\beta$ heterodimer alone and indeed oligomers of CD4 have been extracted from isolated lymphocytes.²²⁶

Amino acid substitutions in the faces of the MHC II molecules that participate in the formation of the superdimers block activation of CD4⁺ T-cells, implying that superdimer formation is a prerequisite for T-cell activation.²²⁷ Stable binding of the T-cell to MHC II requires oligomerization of CD4, facilitated by the D3/D4 domains. Existing evidence suggests that CD4,

once it binds to one MHC II molecule, forms tetramers or even larger oligomers and cross-linked lattices²²⁸ a process influenced not only by MHC II but also by the TCR.

When CD4 and TCR co-localize for interaction with the same pMHC II molecule, the CD4 brings p56^{lck}, associated with its short cytoplasmic tail to the site of immune recognition. This may constitute one of the main contributions of CD4 to TCR signaling.²²⁹

CD8

The CD8 consists of an Ig-like ectodomain, a membrane-proximal stalk (or hinge) region, a transmembrane region, and a cytoplasmic region. The Ig-like domain is involved in the binding to MHC, as shown by crystallographic evidence²³⁰ and mutational analysis.²³¹ The CDR loops of the A and B strands of the CD8 α molecule contact the α_2 , α_3 , and β_2 -M domains of MHC I.²³² The β -subunit of the CD8 interacts only with the α_3 domain, whereas the α -subunit interacts with the α_2 and α_3 domains.²³³ In these interactions, the α_3 domain is shifted for better accommodation of the CD8 binding.²⁰⁹ Multiple contacts between the coreceptor and MHC I promote the functional contributions of the coreceptor to T-cell activation.¹⁹⁵ CD8 enhances cytotoxic T lymphocyte (CTL) activation by promoting the stability of interaction between the APC and the T-cell.²³⁴

The α -chain of the CD8 is associated with the p56^{lck}, which is brought closer to the ZAP70 kinase associated with the TCR, a role that has also been assigned to the CD4 coreceptor. The contributions therefore of both coreceptors in ligand recognition and enhancement of TCR signaling are multiple and involve facilitation of TCR clustering, stabilization of the TCR-pMHC complex, and promotion of signaling by bringing together signaling molecules attached separately on the cytoplasmic tails of the TCR and coreceptors.²³⁵ The availability of pMHC tetramers has encouraged studies on the function of CD4 and CD8 coreceptors in TCR binding to pMHC. The CD4 is critical for signal transduction with pMHC tetramers,^{236,237} and²³⁸ but the CD8 coreceptor also contributes to the initial phase of interaction (binding), the duration of interaction (stability), and the delivery of signal transduction.^{239,240} The final result of CD8 function depends on an epitope of the CD8 involved in the interactions, which are more pronounced with low-affinity ligands. Blockade of CD8- β may affect TCR-C-8 rather than CD8-MHC interaction. The CD8 β is more efficient than CD8- α for association with the TCR.²⁴¹

An important function of the coreceptors in TCR-mediated activation is the demonstration that CD4 and CD8 associate with LAT (linker for activation of T-cells), a 36- to 38-kD membrane-associated adaptor protein, that plays a central role in TCR signaling.^{242,243} As a result of LAT association with surface coreceptors and coengagement of the TCR with the coreceptors, LAT is phosphorylated and recruits downstream signaling molecules.²⁴⁴ In conclusion, the contribution of the coreceptors in TCR signaling results from (a) the physical approximation of the LCK, which is associated with the coreceptors; (b) phosphorylation of the ITAMs of the CD3 chains of TCR; (c) recruitment of ZAP70; and (d) phosphorylation of LAT, also associated with the coreceptors. Individual TCR molecules are probably associated with either LCK or with LAT.²⁴⁴

T-CELL RECEPTOR AND T-CELL ACTIVATION

Topology of Immune Recognition

The $\alpha\beta$ -TCR recognizes short peptides (i.e., eight to ten residues long) for class I-restricted TCRs or 13 to 25 amino acids for class II restricted TCRs. However, approximately only nine amino acids contact the TCR. The peptide is held by the MHC molecule embedded in a groove formed by the α_1 - α_2 domains of MHC I or by the α_1 - β_1 domains of the MHC II (see Chapter 14). Interaction of TCRs initiates signal transduction leading to transcription of genes encoding cytokines in CD4⁺ T-cells or assembling and mobilizing the lytic machinery in CD8⁺ T-cells for killing cells infected by viruses, transformed to a malignant state, or being "strangers," such as in transplanted tissues. The crystal structure of $\alpha\beta$ -TCR has been solved and, for several of them in complex with their cognate pMHC ligand.^{193,195,196,245,246,247} The data support the docking model of the TCR ligand interaction, in which the TCR approaches the peptide held on an MHC platform. In this model, the V α domain of the TCR is closest to the N-terminal residues of the peptide, whereas the V β domain of the TCR is closest to the C-terminal end of the peptide. In this orientation, the TCR V β domain contacts the MHC I α_1 domain, whereas the TCR V α domain interacts with the α_2 of MHC I. The TCR orientation relative to the long axis of the MHC platform varies between 45° and 80° (i.e., the angle formed between a line passing through the centers of the V α and V β domains of the TCR and a second line defined by the peptide on the MHC platform).²⁴⁸ The peptides in all MHC I structures have their N- and C-termini anchored into two fixed pockets approximately 20 Å apart in the MHC I platform. Longer peptides usually bulge in the center. In MHC II, the peptides assume an extended conformation, and the middle portion is smooth and concaves away from the TCR. Residues 1 and 5 of the peptide (p-1, p-5) in MHC II point toward the TCR and are critical in TCR

recognition. The coreceptors bind to the same pMHC ligand as the TCR, but the binding of the coreceptor is independent of the TCR binding and is severalfold weaker.^{229,249}

The TCR, the pMHC, and the coreceptor form a ternary complex that assumes a V shape with the pMHC II at the apex and the TCR and CD4 as the two arms.

Overall, the data from crystallized complexes of TCR with pMHC suggest that TCR docking on the MHC platform involves residues that are conserved within the CDR1 and CDR2 of the TCR and provide a basal level of stabilizing energy in the formation of the complex.²⁵⁰ Variations within the CDR3 α and CDR3 β loops affect the way the TCRs footprint on the pMHC surface.

Lipid Rafts and the Immunologic Synapse

A model for T-cell activation proposes that a naive or resting T-cell needs to cross several stages to achieve full activation.²⁵¹ During the first stage, which lasts a few seconds, contacts need to be established by adhesion molecules that overcome charge repulsions between cells. In the next stage, active cytoskeletal

P.291

rearrangements bring together accessory molecules and the TCR and concomitantly exclude unligated molecules, such as CD45 (a protein tyrosine phosphatase) as well as CD43. CD43 is a highly glycosylated protein with strong repulsive forces forming a thick glycocalyx “cloud” approximately 45 nm thick around the cells. The distance spanned between the TCR and the MHC-Ag complex is a mere 15 nm; in order for the TCR to sample the complex, it is mandatory that the area of contact between TCR and MHC is clear from interfering tall molecules, such as CD43 and CD45. This process takes minutes. On the other hand, the fundamental signaling units consisting of several molecules, are “loaded” on a lipid raft that is sustained by the cytoskeleton, a process that takes hours. Lipid rafts in evolution are conserved structures that gather receptors involved in signaling in various cell types.^{252,253,254} and²⁵⁵ The lipid rafts are cholesterol-dependent microdomains, resistant to solubilization in nonionic detergents at low temperatures.²⁵⁶ The lipids contained within the cellular plasma membrane include glycerophospholipids, glycosphingolipids, and sterols. Rafts consist of sphingolipids and cholesterol, which can move through the more liquid-disordered phase of the membrane containing glycerophospholipids.²⁵⁷ Because of their consistency, lipid rafts have also been referred to as glycosphingo-lipid-enriched membrane microdomains or GEMs. Lipid rafts are anchored by filamentous actin and actin polymerization causes their coalescence.

Phosphatidylinositol-4,5 biphosphate (PIP2) activates proteins involved in actin-membrane interactions, such as binding of the ezrin-radixin-moesin family to CD44, a protein broadly expressed on detergent-resistant membranes. Detergent-resistant membranes are presumed to be isolated rafts. PIP2 activates actin nucleation and polymerization of raft domains. Raft size is poorly understood because they cannot be visualized by light microscopy without clustering.²⁵⁸ In resting T-cells, the TCR and GM1 are homogeneously distributed. Cross-linking, however, produces large enough aggregates to be visualized using epifluorescence microscopy. Fluorescence resonance energy transfer is sensitive to distances on the order of a few nanometers. Because fluorescence resonance energy transfer was detected between glycosylphosphatidylinositol (GPI)-anchored transferrin receptors interacting with natural ligands, it was concluded that rafts exist but that they are smaller than 70 nm in diameter.²⁵⁸ Others could not find microdomains enriched in GPI-anchored proteins or GM1. Some MHC II molecules loaded with a select set of peptides are detected on microdomains made up of tetraspan proteins, such as CD9, CD63, CD81, or CD82.²⁵⁶ These tetraspan microdomains are recognized by CDw78 antibody (mAb FN1), which originally was believed to recognize an epitope of HLA-class II molecules.

A central feature of lipid rafts is that they allow for the lateral segregation of proteins within the plasma membrane. This provides a mechanism for compartmentalization of signaling components within the membrane, concentrating certain components in lipid rafts and excluding others (Fig. 13.8). Proteins with GPI linkage, such as CD14, CD16, CD48, and CD58, are associated with the outer leaflet of lipid rafts. Cytoplasmic proteins, on the other hand, associate with the inner leaflet of lipid rafts through acylation. Most of the SRC signaling proteins are acylated and raft associated. The vast majority of transmembrane proteins are excluded from rafts constitutively and cannot be induced to partition into rafts on cross-linking.

Some proteins important in T-cell activation, such as LAT, CD4, and CD8, reside on rafts. Other proteins reside constitutively outside the rafts but, when activated, become translocated to rafts. The multichain immune recognition receptor family is an example.^{259,260} Translocation into rafts after ligand binding appears to be immediate, occurring within seconds of engagement of the receptors, and is selective. For example, CD45, α_4 integrin, and IL1 receptor are excluded

from rafts and do not translocate into rafts, even on cross-linking.^{261,262} The transmembrane domains of the receptors appear to have a significant influence on translocation, as exchange or mutation of the transmembrane regions

P.292

alters the translocation properties of the receptors. Translocation of the receptor into the lipid rafts does not need actin reorganization. However, stable residency into the rafts depends on interaction with actin cytoskeleton. The constitutive presence of receptors in rafts may be related to their role in cell survival. For example, the pre-TCR is constitutively associated with rafts and, with its signaling, instructs lineage commitment. TCR/CD28 is excluded from rafts in immature thymocytes and signaling leads to apoptosis.²⁵³

FIGURE 13.8. Rafts: elementary units of the immunologic synapse? In the resting state, the multichain immune recognition receptors (MIRR; i.e., T-cell receptor, B-cell receptor, etc.) "float" free on the lipid membrane, or transiently, some may

get on board on certain membrane “microdomains,” also known as “lipid rafts.” Interaction with a multivalent ligand aggregates several receptors that accumulate within the rafts, forming multimolecular clusters. On prolonged exposure to the ligand, the MIRR clusters result in raft coalescence with the formation of a large aggregate, the immunologic synapse. Cytoskeletal reorganization from multichain immune recognition receptor and chemokine signaling promotes immunologic synapse formation. (Adapted from a model proposed by Dykstra M, Cherukuri A, Sohn HW et al. Location is everything: lipid rafts and immune cell signaling. *Annu Rev Immunol* 2003;21:457-481.)

In addition to their role in signaling, lipid rafts serve as platforms for B-cell receptors (BCRs) to transport bound antigen for processing and presentation. The internalization of BCRs with captured antigen is initiated from rafts.

Retention of receptors in rafts is a mechanism for augmentation of cell activation. The CD19/CD21 complex is excluded from rafts, but its colligation with BCRs by antigen-antibody-complement complexes causes translocation of BCR and CD19/CD21 complex into rafts, where the complex prolongs the retention of BCR within the rafts.²⁶³

T-cell activation causes rearrangement of the actin cytoskeleton and polarization of the cell toward the site of activation, such as the APC. This polarization is reflected by re-orientation of the microtubule-organizing center (MTOC) toward the APC.^{264,265} The TCR is clustered together with associated molecules (CD4, CD8, CD2, CD28, etc.), a process known as capping. Capping depends on actin reorganization regulated by phosphoinositides, which activate Vav (a guanosine diphosphate-guanosine triphosphate [GTP] exchange factor) and the Wiskott-Aldrich syndrome protein (WASP). In patients with Wiskott-Aldrich syndrome, WASP is lacking or markedly reduced, and they have defects in actin polymerization, capping, and antigen-induced proliferative responses.²⁶⁶ WASP regulates the Arp2/3 complex, which mediates actin branching and polymerization.

PIP3 is a strong activator of Vav, which is targeted to detergent-resistant membranes after TCR activation. In Vav-deficient mice, the capping is severely disrupted, and T-cell proliferation is reduced. Raft aggregation is disrupted by the negative regulator of T-cell activation, Cblb (Casitas B-cell lymphoma-b), which is a molecular adaptor and part of the ubiquitin ligation machinery involved in the degradation of phosphorylated proteins. Cblb inhibits TCR clustering and sustained tyrosine phosphorylation. In Cblb-deficient mice, TCR/CD3 stimulation alone can activate receptor clustering without the need for CD28 costimulation.²⁶⁷

Immunologic Synapse

The TCR interactions with pMHC take place in an intercellular junction between the T-cell and the APC. In this junction, signal 1 (TCR) and signal 2 (costimulation) are processed. This interface reveals a dramatic reorganization of signaling components, forming what is called the IS, a term borrowed from Sherrington's turn-of-the-century definition of the interconnections of neurons as synapses (from the Greek *synapsis*, meaning joining, linking, connecting).²⁶⁸ The IS relays information across the cell junction in both directions²⁶⁹ organized into two major compartments. The central supramolecular activation cluster (cSMAC), enriched in TCRs and CD28 and the peripheral supramolecular activation cluster (pSMAC), which contains the LFA1 molecule and talin²⁷⁰ (Fig. 13.9). On the side of the APC, correspondingly, the cSMAC contains the pMHC and CD80 (ligand for CD28) and the pSMAC contains the ICAM-1 (counterreceptor for LFA1) and CD58, ligand for CD2. The IS develops over a period of minutes after interactions of the T-cell and the APC. Formation of the synapse depends on an intact cytoskeleton.²⁷¹ T-cell activation is accompanied by a dynamic reorganization of cortical actin with increase of filamentous actin. These cytoskeletal changes are accompanied by progressive morphologic changes of the T-cells, which first become round, followed by spreading of the cell.²⁷² In the absence of antigen, the T-cell maintains its motility, continues to crawl around the APC and may even leave for another partner. Some receptors on the APC may convey a “danger signal” for the T-cell to pay particular attention and explore the APC in search of antigen.²⁷³

In the first stage, the contact is antigen-independent and is mediated by CD28 on the T-cell and CD80/CD-86 on the APC, which are more abundant ($>10^4$) than the pMHC (approximately 100 to 200). The CD28 affinity for CD80 is at least two orders of magnitude above that determined for the TCR-pMHC interaction. These interactions of CD28 preceding the TCR encounters are actually contrary to the original definition of the costimulatory function of CD28, believed to parallel or even follow TCR signaling.

The second stage of IS formation is antigen-dependent and the T-cell extends large cytoplasmic, pulsatile protrusions toward the APC.^{274,275} Tyrosine phosphorylated Vav-1 and tyrosine phosphorylated LCP2 (SLP76) assemble with the p21-activated kinase (PAK1) via the adaptor protein NCK1.^{276,277} and ²⁷⁸

The T-cell-APC complex is stabilized in the third stage, which is regulated by increases of intracellular Ca^{2+} . By the end of the third phase, SMAC is in place with all the receptors and the signaling molecules, held together with clusters of GEMs (lipid rafts) on the surface and an elaborate cytoskeleton scaffolding underneath.

The kinetics of the IS from its early beginnings are coordinated and organized by the cytoskeleton.²⁷¹ The TCR-pMHC can only interact at a distance of 15 nm, which is significantly below the thick glycocalyxes of the two cells that separate their membranes by a 50-to 100-nm distance. Adhesion molecules, such as L-selectin, located on the tip of microvilli, may very well initiate the T-cell-APC interaction, until LFA1, lying on flat surfaces of the membrane, is released from its inhibitory state by activating signals delivered by chemokines. These signals also result in the formation of myosin II thick filaments, which disrupt and pull the thick network of polymerized actin away. In this clearing, new actin polymerization pushes forward new filopodia and lamellipodia (i.e., the cell becomes motile). Now that the T-cell is polarized, the long interfering molecules of the glycocalyx, such as CD43 and CD45, are pulled to the rear end, or uropod, of the cell.

In the meantime, activated high-affinity LFA1 released from inhibition stabilizes the contact area between the cells, moving laterally and forming strong bonds with ICAM-1 across the cell junction.²⁷⁹ In the membrane clearing created and stabilized by LFA1 adhesion, the TCRs sample MHC on the APC surface for complementary peptides. It has been noted that paradoxically, a large cluster of TCRs has been pulled to the rear of the cell, but through the mediation of myosin II is brought to the front, reinforcing the frontal cluster.²⁸⁰ Nascent IS is further stabilized by TCR links with the cytoskeleton. These links are mediated by some of the components of CD3 (i.e., ζ -chain), which, through its phosphorylated ITAMs, induces actin polymerization.

If pMHCs are present on the APC surface, the T-cell stops moving.^{275,281} The central area of T-cell closest to the APC includes the bulk of the TCRs, which are surrounded by integrins farther away.^{270,282}

The final arrangement defines the mature IS or the bull's eye²⁷⁰ (i.e., the cSMAC, a central area 1 to 3 μm in diameter that contains TCR, CD28, and C-2), surrounded by pSMAC, an adhesion ring that contains the LFA1 and talin. Formation of mature IS with APCs (instead of artificial lipid bilayers) shows that the TCR signaling precedes the completion of the mature IS.²⁸³ Bull's eye IS also has been observed with CD8⁺ T-cells during recognition and killing of target cells.²⁸⁴ Granule secretion occurs after the MTOC polarization in cSMAC, where membrane fusion occurs. Cellular functions between T-cells and the target cells have been demonstrated by transmission and scanning electron microscopy several years ago. These junctions are followed by disruption and blebbing of the target cell membrane.²⁸⁵

Synapses with dendritic cells are formed even in the absence of antigen or MHC.^{286,287} Encounters with dendritic cells are relatively short as compared to B-cells.²⁸⁸ This may be due to chemokine secretion by dendritic cells, which stimulate T-cell

P.293

P.294

migration. There also seem to be other differences between dendritic cells and B-cells, such as the length of time of the encounter, which is short for dendritic cells but longer for B-cells. The role of the dendritic cell in the formation of IS is active with full involvement of its cytoskeleton, whereas the B-cell remains passive and the T-cell makes the major contribution.²⁸⁹ The functional consequences of the formation of a mature IS are believed to be primarily related to polarized secretion^{290,291} and signaling.²⁹² IS may help to retain secreted substances close to the targeted cell. Although this is true for the synapses formed by killer lymphocytes such as the CD8⁺ cytotoxic T-cell or the NK-cell, it may not apply to the CD4⁺ T-cell, which uses the APC to pull the trigger for its activation. In this case, the IS concentrates crucial molecules, such as CD28, that provide costimulatory signals and enhance TCR-mediated signaling.^{293,294}

FIGURE 13.9. The structure of the immunologic synapse. The immunologic synapse is formed between T-cell and an antigen-presenting cell (APC; in the case of the CD4⁺ T-cell) or with a target cell (in the case of the CD81 T-cell). Immunologic synapse formation is a multistep process. A thick glycocalyx on both cells, made predominantly from the mucin molecule CD43, comes in conflict with the approaching T-cell and APC. This distance (50 to 100 nm) is too long for the T-cell receptor (TCR) peptide-major histocompatibility complex (MHC), which interacts at 15 nm. The integrin lymphocyte function molecule (LFA)-1 and its counterreceptor, intercellular adhesion molecule (ICAM), which interact at 40 nm, may bring the cells for an initial contact. More important, chemokine signaling that activates heterotrimeric G

proteins activates myosin II, and the cortical cytoskeleton collapses, disanchoring CD43 by the ERM (ezrin/radixin/moesin) adaptor proteins. With loss of the cell rigidity, a new F-actin network creates a pseudopod that propels the leading edge of the T-cell toward the APC. This approach at an intercellular distance of 15 nm prevents CD43 re-entry in the central area of T-cell-APC contact. Concomitantly, talin (a large cytoskeletal protein with attachment to integrins) maintains LFA-1 immobilized in a ring around the central part of the synapse. Although LFA-1/ICAM-1 interacts initially at a distance of 40 nm (extended LFA-1 form), after activation it assumes a bent form (high affinity) that brings the cell membranes closer ("ratchet"-like effect). Multiple other adhesion molecules of low affinity, such as between CD2 and CD58, contribute to the alignment of the two cell surfaces at a 15-nm distance, allowing the TCR to sample the small numbers of peptide-MHC ("proofreading"). The final mature immunologic synapse ("bull's eye") consists of a central supramolecular activation cluster and the peripheral integrin-rich zone. (From Dustin ML, Cooper JA. The immunological synapse and the actin cytoskeleton: molecular hardware for T cell signaling. *Nat Immunol* 2000;1:23-29; and Delon J, Stelon S, Germain RN, et al. Imaging of T-cell interactions with antigen-presenting cells in culture and in intact lymphoid tissue. *Immunol Rev* 2002;189:51-63.)

T-cell Receptor Signaling

Two models have been proposed for sustained T-cell signaling: (a) serial engagement (migration), when the T-cell migrates from one APC to the next and thus renews its signaling capacity;²⁸⁸ and (b) signaling based on formation of IS. Both models achieve similar results but require different molecular mechanisms. The mature IS forms a specialized mode of signaling and enables T-cells to remain responsive to antigen while still with the initial APC. For a better understanding of the complexities of signaling, we organize it into three phases: (a) initiation, (b) generation of phosphoinositides, and (c) the Ras pathway (Fig. 13.10, Table 13.1).

Initiation Phase of Signaling

Signaling is initiated by activation of LCK, which is regulated by two tyrosines: Tyr 394 in the activation loop and Tyr 505 in the C-terminus. LCK is kept inactive or "closed" by two intramolecular bonds: One is between Tyr 505, which is phosphorylated by the C-terminal SRC, Csk, and binds to the SH2 domain of LCK; a second bond is formed between the SH3 domain of LCK and a sequence connecting the SH2 and the kinase domains. For activation of LCK, the Tyr 505 needs to be dephosphorylated by CD45, a protein tyrosine phosphatase,²⁹⁵ whereas Tyr 394 is autophosphorylated and activates the kinase domain. The large-size CD45 isoforms are excluded from the IS,^{296,297} but some move back to cSMAC adjacent to the TCRs.²⁹⁸ LCK, recruited by CD4, is maintained in the activated state by CD28²⁹⁴ and phosphorylates the ITAMs of the ζ -chain of TCR in a sequential and ordered manner, establishing thresholds of T-cell activation.²⁹⁹ This mechanism determines whether a sufficient number of tyrosines are phosphorylated for full activation and supports the kinetic proofreading model of T-cell activation, which examines the relationship between kinetics of TCR-ligand interaction and intensities of T-cell activation.^{300,301,302} and ³⁰³

ZAP70 is recruited to the phosphorylated ITAMs of the ζ -chain and in turn activates the adaptor protein LAT, which then is localized in the rafts. LAT has a short extracellular and long intracellular region and possesses a central position in T-cell activation because it assembles other adaptor molecules and signaling proteins.

There are two groups of adaptor proteins: transmembrane adaptor proteins and cytosolic adaptor proteins.³⁰⁴ LAT (a transmembrane adaptor protein) is located in the rafts and is phosphorylated by ZAP70. As a result, it recruits PLCG1, phosphoinositide 3-kinase (PI3-K), IL-2-inducible T-cell kinase (ITK), adaptor proteins GRB2 and GADS (GRAP2), and, indirectly, Vav and LCP2 (SLP76).^{242,305,306} LCP2 is a cytosolic adaptor protein that has three protein-binding motifs and plays an essential role in signaling pathways required for IL2 secretion.³⁰⁷ It is expressed on thymocytes, T-cells, mast cells, NK-cells, and platelets. Through Gads, it binds indirectly to LAT after TCR ligation. So LAT and LCP2 function as mutually dependent intermolecular scaffolds, together recruiting crucial signaling regulators to sites of raft aggregation. In mice deficient in LCP2 (or LAT), thymocyte development is arrested at the stage at which the TCR β -chain is coupled to the pre-T α -chain. LCP2 recruits ITK to lipid rafts and allows for optimal phosphorylation of PLCG1, which also associates with ZAP70.

Phosphoinositide Metabolism

Phosphoinositides are produced by the action of PLCG1 and PI3-K. PLCG1 binds to LAT and is activated as a result of phosphorylation of multiple tyrosines by ZAP70. PLCG1 hydrolyzes inositol phospholipids generating diacylglycerol and inositol (1,4,5)-triphosphate (IP₃).

Diacylglycerol contributes to activation of protein kinase C (PKC), whereas IP₃ increases Ca²⁺ released from intracellular sources. There are multiple isoforms of PKC serine kinases, which are regulated by Ca²⁺, diacylglycerol, phospholipids, the classic PKC (α , β , γ), and the novel PKC (δ , ϵ , ζ , and θ).³⁰⁸ PKC- θ is recruited to the plasma membrane and is the only

isoform detected in cSMAC together with TCR.³⁰⁹ The PKC- θ targets are activation of the NF- κ B, production of IL2, regulation of integrin function, and control of the cytoskeleton through association with Vav. Both Ca²⁺ and PKC synergize in the increase in transcriptional activity of NFAT. Ca²⁺ acts through calcineurin, a calmodulin-dependent phosphatase that contributes to induction or function of NFAT.

The PI3-K produces phosphatidylinositol 3,4,5-triphosphate (PI-3,4,5-P₃), which acts as a second messenger. It binds to proteins that contain a pleckstrin homology domain and recruits them to the inner leaflet of the cell membrane.³¹⁰ PI3-K overall is involved in survival and cytoskeletal signaling processes and is essential for adhesion signals. Important targets for PI3-K products are the GTPases, Rac and Rho, stimulated by GEF (guanine nucleotide exchange) proteins promoting transition from the inactive guanosine-diphosphate-bound state to the active GTP-bound conformation. Rac and Rho regulate several functions in the life of the T-cell, and during T-cell activation, they regulate cytoskeletal rearrangements. The PI-3,4,5-P₂ product of PI3-K is converted to PI-3,4-P₂ by the phosphatidylinositol-5 phosphatase (SHIP). This product binds to the pleckstrin homology domain of the protein kinase B or AKT.

AKT moves to the nucleus, where it acts on several substrates regulating cell survival, NF- κ B activation, metabolism, and energy generation.³¹¹ It also regulates transcription factors (i.e., NFAT and the Forkhead family), promoting cell survival and progression through the cell cycle. All signals from PI3-K products are eventually terminated by the inositol phosphatase SHIP.

The Ras Pathway

The adaptor protein GRB2 is a bifunctional molecule having an SH2 domain with which it binds to phosphorylated tyrosines of LAT, whereas its SH3 domain binds other proteins that have proline-rich sequences. These proteins are cytosolic, but through association with LAT, they are translocated to the membrane.³⁰⁵ GRB2 functions in many cells and associates with a large number of proteins.³¹² In T-cells it is associated with the proline-rich domain of SOS, the mammalian homolog of the *Drosophila* "son of Sevenless" protein, which is a critical activator of the small G protein RAS.³¹³ The GRB2-SOS binding is also mediated by another small linker protein, SHC, and CBL binding to GRB2 inhibits activation.

The Ras pathway activates Erk kinase and MAPK. MAPK pathway may induce integrin activation, and, in reverse, the integrin may induce the MAPK pathway through PI3-K. There are other bidirectional signaling pathways that, in general, send signals to the nucleus and activate membrane molecules by a feedback pathway.

P.295

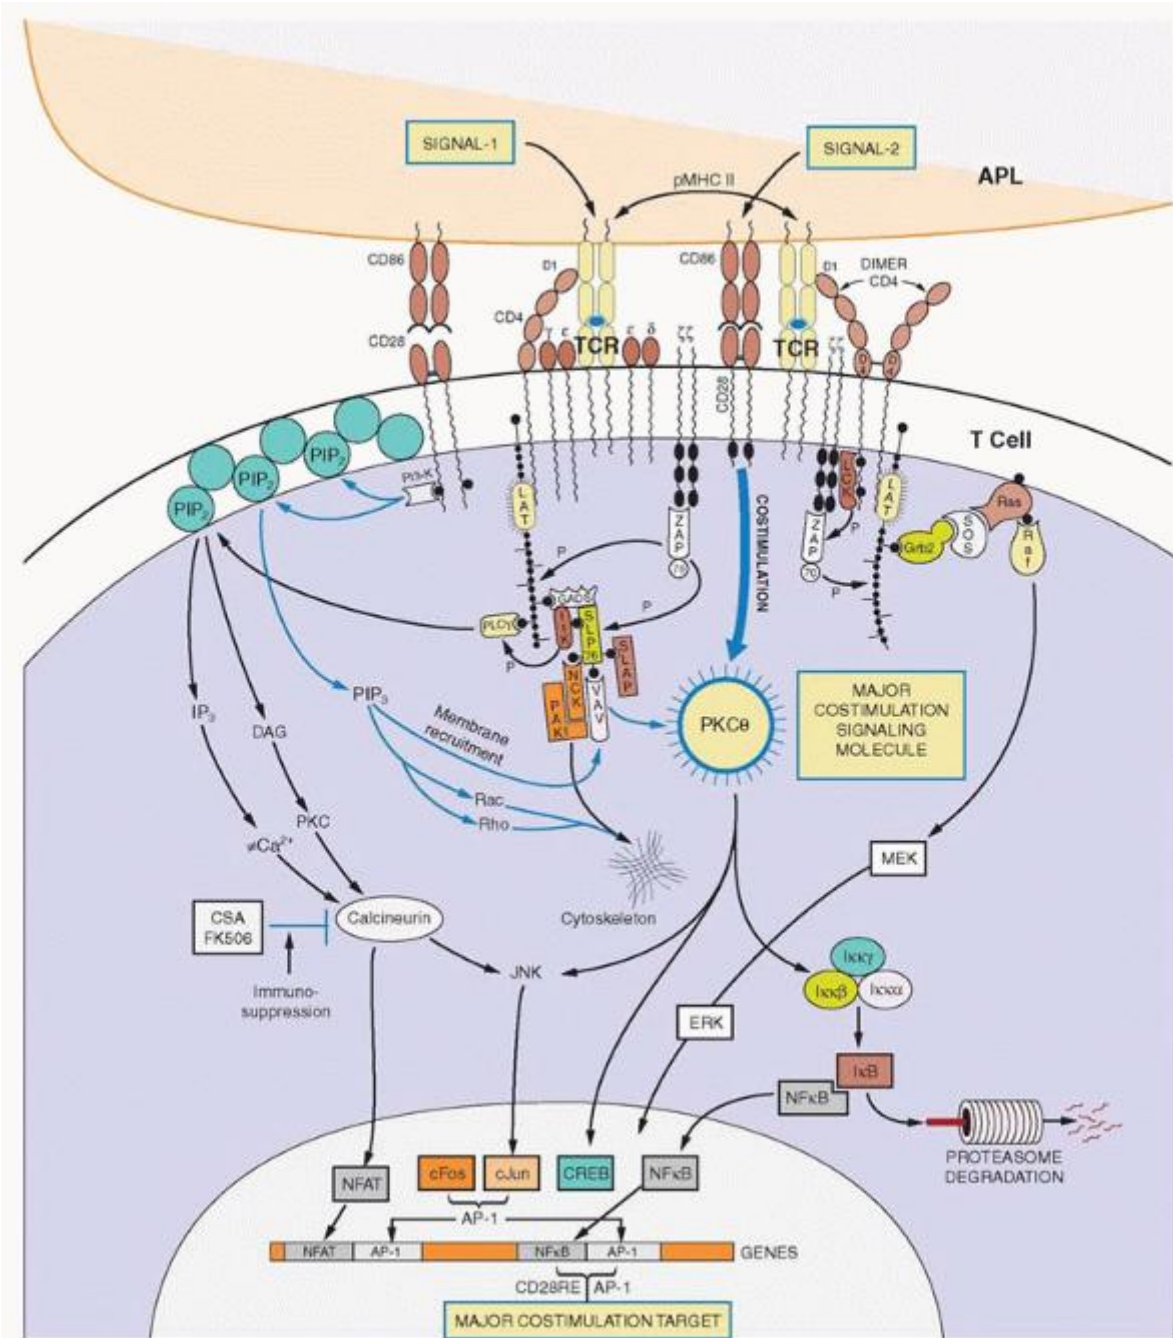

FIGURE 13.10. T-cell activation. T-cells are activated by two signals: signal 1 is delivered by the T-cell receptor (TCR) interacting with peptide-major histocompatibility complex (pMHC), and signal 2, or costimulatory signal, by CD28 interacting with CD80/CD86. A number of adaptor proteins (i.e., proteins acting as scaffolding) assemble a supramolecular signaling complex. Foremost among them are LAT (linker for activated T-cells) and SLP-76 (SH₂-domain-containing leukocyte-specific phosphoprotein of 76 kD). LAT expression is limited to T-cells, natural killer (NK) cells, platelets, and mast cells and is not expressed on B-cells or monocytes. LAT is a membrane adaptor protein as compared to SLP-76, which is cytoplasmic. Engagement of TCR activates Lck, which is associated with the coreceptor (CD4 or CD8). Lck phosphorylates ZAP-70 (ζ -chain-associated protein). ZAP-70 in turn phosphorylates LAT, which at this point makes the transition between proximal and downstream signaling events initiated by TCR. LAT is also associated with the coreceptor, competing in the binding with Lck. LAT and Lck are linked to individual coreceptors, rather than both of them being linked to the same molecule. LAT as an adaptor protein is a scaffolding that is associated with several downstream molecules: phospholipase (PLC)- γ generates phosphoinositides and increases Ca^{2+} , which activate protein kinase C (PKC) and calcineurin, respectively. Another cluster is formed with Gads (Grb-related protein), SLP-76, Vav, and so forth that regulates the

cytoskeleton together with the PIP₃ product of phosphoinositide-3-kinase (PI3-K). The other signaling pathway linked to LAT is through the Ras activation, linking to the activation of MAPK/ERK kinase (MEK) and extracellular signal-regulated kinase (ERK). A central position in T-cell signaling is occupied by the novel PKC isoform, PKC θ , which is selectively expressed in T lymphocytes and is recruited to the immunologic synapse. It induces essential activation signals for interleukin-2 synthesis in cooperation with calcineurin. It is a master inducer of NF κ B activation and its translocation to the nucleus. PI3-K associated with CD28 generates PIP₃ that recruits Vav and PKC θ to the membrane. APC, antigen-presenting cell; DAG, diacylglycerol; SLPP, serum lipophosphoprotein. T-cell Activation and the Cytoskeleton

The cytoskeleton plays an important role in IS formation and T-cell activation. T-cells polarize toward their target, focusing the signaling on the secretory apparatus at the APC or target cell. Cytochalasin, which disrupts the cytoskeleton assembly, blocks T-cell activation. Actin dynamics are controlled by a biphasic model at the IS. TCR engagement initiates actin solubilization through changes in the phosphorylation of ezrin, radixin, and moesin that allow certain molecules to move away from the points of contact with APC.³¹⁴ With the formation of new actin filaments, LFA-1 is anchored and stabilizes the adhesion between T-cell and APC.³¹⁵ Polarization of the MTOC requires TCR and involves members of the Rho family of GTPases CDC42, ATK1 (RAC), and RHO.

Disruption of the Rho family members disrupts the proliferation, differentiation, migration, and effector functions and even survival of T-cells.^{272,316} CDC42, as with all members of the Rho family of GTPases, functions as a binary switch regulated by nucleotide binding. When CDC42 binds GTP, it is converted from the inactive to the active form and binds effector molecules with high affinity. One of its important substrates is the WASP gene. Mutations are responsible for the clinical manifestations of Wiskott-Aldrich syndrome (i.e., thrombocytopenia, eczema, and recurrent infections). T-cells from Wiskott-Aldrich syndrome patients lack microvilli and have an abnormal cell shape. Mutants with inactive CDC42 prevent efficient conjugation of T-cells with APC. In contrast, T-cells with constitutively active CDC42 mutants form

extensive filopodia rich in F-actin, which interfere with the formation of IS because CDC42 accumulates in the T-cell-APC contact area. Activation of WASP is achieved by a complex formed by LCP2 (SLP76) adaptor protein, VAV, and NCK (phosphorylated by ZAP70). In this trimolecular complex, LCP2 binds VAV, which converts CDC42-guanosine diphosphate to the GTP form. CDC42-GTP binds to the GTPase binding domain of WASP. At the same time, the NCK binds by its SH3 domain to the polyproline sequence of WASP. These interactions release WASP from its autoinhibitory state and enable it to activate the Arp2/3 complex for actin-branching polymerization.^{317,318,319} and ³²⁰ Other studies suggest that WASP may not be the critical or even the sole regulator of actin polymerization, but other molecules, such as its homolog WASP, are involved. However, mice with a WASP deficient in the VCA domain have defects in T-cell development.³²¹

A significant contribution to the T-cell interaction with the APC is made by the ERM cytoskeletal proteins (i.e., ezrin-radixin-moesin).³²² These proteins act as linkers between cortical actin and plasma membrane, connecting the F-actin to cytoplasmic tails of several transmembrane proteins (i.e., ICAMs, CD43, FAS, etc.). In the resting T-cell, the plasma membrane is rigid because of the thick actin network kept by phosphorylated moesin. With TCR engagement, moesin is dephosphorylated, the actin network “thaws,” and the proteins linked to the cytoskeleton are freed to move. The tall ones, CD43, are “squeezed” out of the narrow junction between the T-cell and APC.³²³ At the same time, new F-actin networks create pseudopod extensions for contact with the APC. Moesin in the back of the cell is rephosphorylated and keeps the excluded molecules actively out of the IS. CD43 and other molecules that are excluded from the uropod form a cluster called the distal pole complex. This cluster may not be simply a negative contributor to T-cell activation by collecting tall molecules interfering in the formation of the IS, but it has its own signaling mechanism in some aspects of T-cell activation, such as cytokine secretion.³²⁴

Regulation of T-cell Activation: Costimulation and Inhibition

T-cell activation depends on signals delivered by the TCR engaged with pMHC. However, additional signaling is needed, and this function is known as costimulation. Costimulatory signals are delivered to the T-cell through the CD-28 molecule reacting with ligands (counterreceptors) on APCs (i.e., CD80 [B7-1] and CD86 [B7-2]). These receptors do not act independently but modify the responses mediated by TCR. The CD28 consists of one Ig-like domain of V-type, whereas the two ligands contain two Ig domains, one V-type and one C-type. CD28 is constitutively expressed on T-cells (all CD4⁺ and approximately 50% of CD8⁺).

Another receptor, the CTLA4 (CD152), shares approximately 30% identity with CD28; it is not detected in naive T-cells but is induced after T-cell activation.

Both CD28 and CTLA4 share the same ligands. In costimulation, the critical event is up-regulation of the B7 molecules on the surface of the APCs.³²⁵ The major role of CD28 function is to stimulate cell cycle progression and prevent apoptosis. It also enhances production of various cytokines, such as IL1, IL2, IL4, IL5, and interferon (IFN)- γ , and plays a fundamental role in Th1-Th2 differentiation. CD28/B7 interactions also play a critical role in B-cell stimulation. The importance of CD28/B7 interaction was established in transplantation. The importance of the CD28/B7 costimulation pathway was established with studies in transplantation in mice in which blockade of the pathway by CTLA4-Ig prolonged cardiac graft survival and prevented development of vascular lesions associated with chronic rejection.³²⁶ Another costimulatory receptor homologous to CD28 and CTLA4, termed ICOS (inducible costimulator), is a disulfide-linked homodimer.³²⁷ ICOS lacks the extracellular motif present in CD28, which is implicated in binding with the B7 molecules. It is an inducible molecule expressed in activated, but not resting, T-cells. ICOS augments T-cell proliferative responses and cytokine secretion, particularly IL10.³²⁸ The ligand for ICOS (ICOS-L or B7h) is a B7-like molecule expressed constitutively on B-cells and macrophages. Costimulation by ICOS promotes germinal center reaction and isotype switching. ICOS and CD28 regulate Th2 responses, but whereas CD28 is critical in the priming stage to induce Th-2 differentiation, ICOS plays a role in regulating Th2 effector functions.³²⁹ Activation of the ICOS pathway of costimulation initiates acute and chronic graft rejection, which indicates that the ICOS costimulatory pathway also regulates Th1 responses.³³⁰

P.297

CD4 T-CELL DIFFERENTIATION

Activated naive CD4⁺ helper T-cells (Th), in response to signals from TCR engagement with pMHC, proliferate and differentiate into cytokine-secreting effector cells, which have been distinguished into two major categories.³³¹ Th1 cells produce primarily IFN- γ , IL2, and TNF- β , whereas Th2 cells secrete IL4, IL5, IL6, IL10, and IL13. Both types of cells produce IL3, TNF- α , and granulocyte-macrophage colony-stimulating factor. Once the initial stimulus from TCR is received, the cells proliferate in response to the autocrine growth factor IL2. At this stage, they are called pT helper cells (pTh) because they

have not yet differentiated enough to secrete cytokines. Both Th1 and Th2 cells derive from a single precursor, and several factors regulate their differentiation.^{332,333} and ³³⁴ The Th1 cells induce predominantly inflammatory immune reactions and control intracellular bacterial infections (cellular immunity). They are also associated with some autoimmune diseases. The Th2 cells provide defense against extracellular pathogens, regulating the humoral antibody-mediated immune response. They are also the mediators of allergic reactions.

Th1 versus Th2 differentiation takes place in two stages. During the first stage, the activation signals delivered by TCR pre-condition the naive T-cell for one or the other pathway of differentiation. In the second stage, final development of effector cells is dependent on IL12 or IL4 (Fig. 13.11).

Transcriptional Regulation

In the early stages of Th cell differentiation, TCR stimulation activates a number of downstream signaling pathways. Differential signaling of MAPKs, PKC, and calcineurin pre-conditions Th cells toward one or the other pathway in the absence of cytokines from the environment.³³⁵ A number of parameters related to antigenic stimulation and costimulation influence the final outcome. Low doses of antigen or low affinity of binding favor Th2 development, whereas large doses of antigen or high affinity of binding support predominantly Th1 differentiation. Costimulatory signals modulate the outcome. CD28 ligation favors Th2 development, perhaps by enhancing IL4 production³³⁶ or by direct activation of signal transducer and activator of transcription 6 (STAT6).³³⁷

The CD40/CD40L interactions selectively induce Th1 cells, but this is the result of the production of IL12 from APCs.³³⁸ During the early stage of Th activation, key genetic and epigenetic events take place that lead to accessibility and activation of specific genes. Expression of certain transcription factors is critical in the early regulation of differentiation.^{339,340}

Th1 Regulation

The most prominent factor for Th1 differentiation is IL12. In naive T-cells, the IL12 receptor is not functional but is induced by IFN- α/β . Binding of IL12 to its receptor induces phosphorylation of Janus kinases JAK2 and TYK2, which phosphorylate STAT4. STAT4 translocates to the nucleus and activates target genes. The GTPase RAC2, which is selectively expressed on Th1 cells, activates the IFN- γ promoter via NF- κ B and MAPK.³⁴¹ During the early Th1 polarizing signaling, the key transcription factor for Th1 development is T-bet (for box expressed in T-cells) induced in naive T-cells.^{342,343} T-bet transactivates IFN- γ promoter, induces chromatin remodeling of the gene that encodes INF- γ ,³⁴⁴ and induces expression of the β_2 subunit of the IL12 receptor.³⁴³ The importance of T-bet in Th1 differentiation is underscored by the susceptibility of T-bet knockout mice to challenge with *Leishmania major*³⁴⁵ and their predisposition to allergic disease.

Th2 Regulation

The key transcription factor for Th2 differentiation is GATA3,³³⁹ induced in the early stages of Th2 signaling. GATA refers to a family of transcription factors, important regulators of T-cell development. STAT6 activation enhances expression of GATA3. GATA3 induces expression of another Th2-specific factor, MAF. MAF is a basic region/leucine-zipper transcription factor that binds to and transactivates the IL4 promoter.^{346,347}

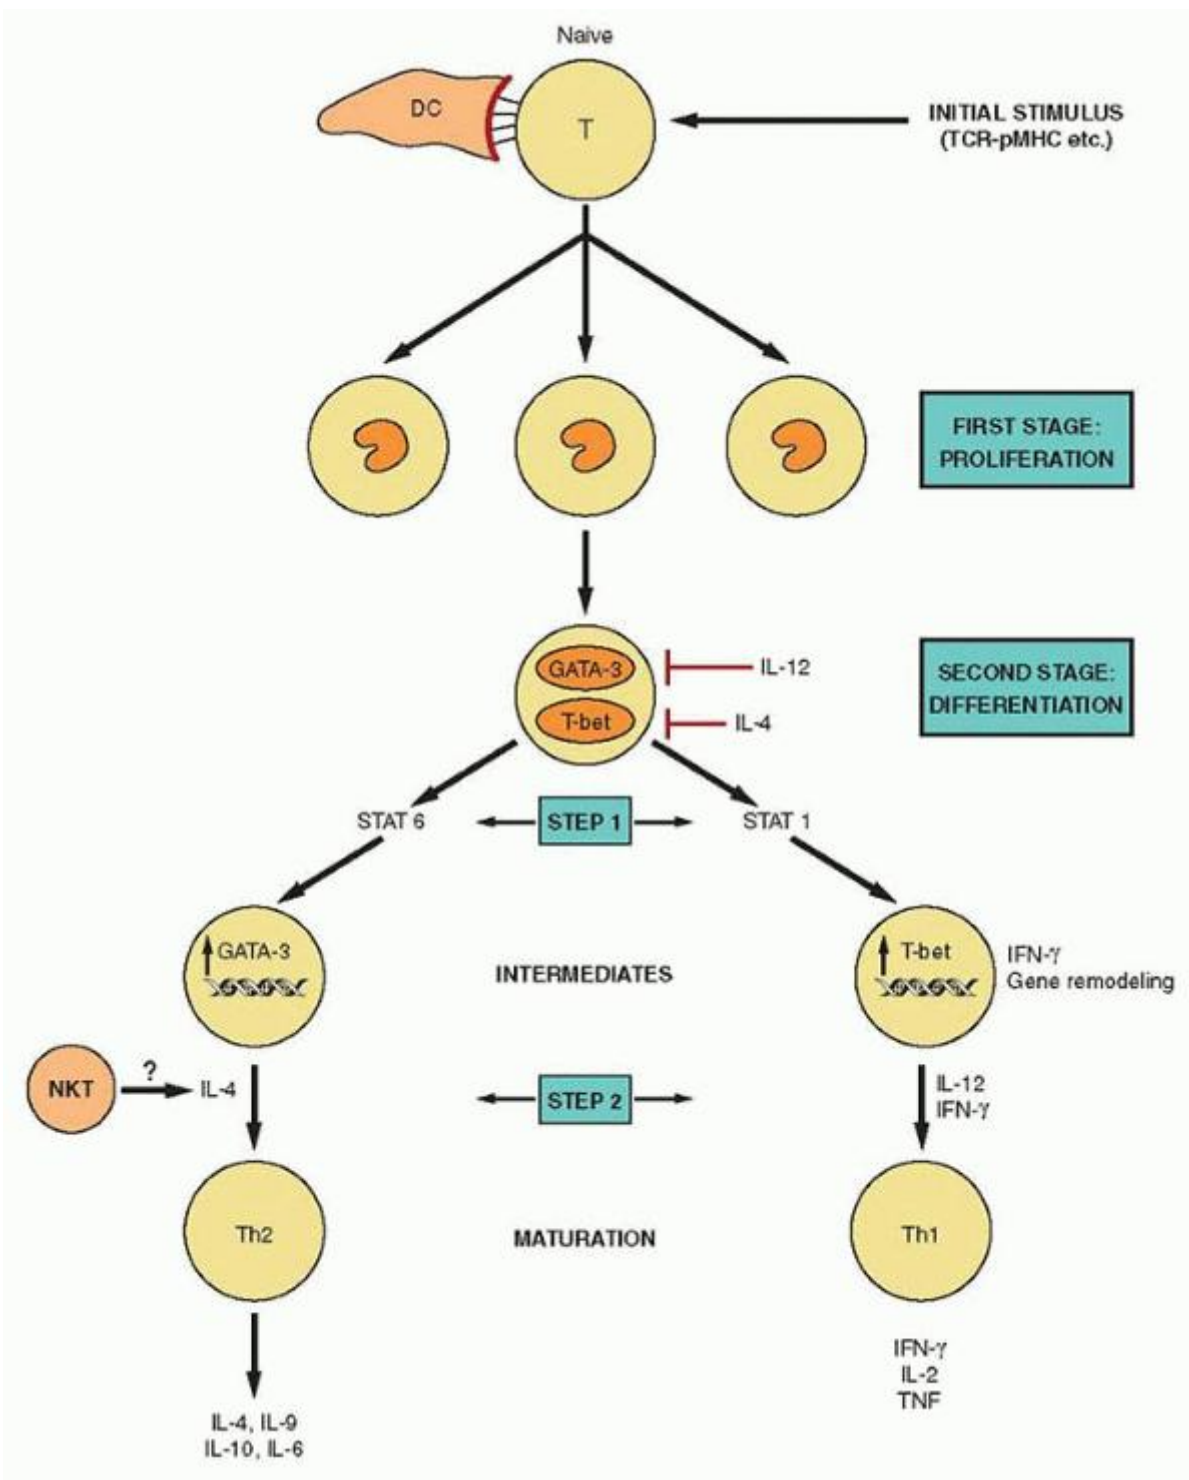

FIGURE 13.11. CD4⁺ T-cell differentiation. After their differentiation in the thymus into the two main lineages, CD4⁺ and CD8⁺, the CD4⁺ or Th cells differentiate further in the peripheral lymphatic organs into effector cells with distinct patterns of cytokine secretion. The initial stimulus is delivered by the T-cell receptor (TCR) and results in the proliferation of the naive T-cell. These activated T-cells (pTh) have only a limited potential of interleukin (IL)-2 secretion, and they acquire the propensity to respond to additional signals for further differentiation. Primary stimuli via the TCR (dose of antigen, intensity and duration of TCR triggering) influence downstream signaling (Ca²⁺, protein kinase C, map kinase, etc.) that regulates transcription factor expression. Expression of GATA-3 leads to Th2, whereas T-bet leads to Th1 differentiation. In the second stage, exposure to cytokines (i.e., IL-4 or IL-12/interferon [IFN]-γ) drives the final steps of differentiation to the Th1 or Th2 pattern of cytokine secretion. NKT, natural killer T-cell; TNF, tumor necrosis factor. (Adapted from Noble A.

Epigenetic Modification of Cytokine Genes

Detailed description of these early events is beyond the scope of this brief review. The reader is referred to reviews of the topic.^{339,348} Transcriptionally inactive gene loci have a condensed chromatin with DNA tightly packed around the nucleosomes. For gene transcription, "open" chromatin is associated with acetylated histones and hypomethylation of DNA. Accessibility of IL4 and IFN- γ genes is initiated promptly after TCR and CD28 activation, but for sustained transcription, STAT6 or STAT4 signaling, and induction, GATA3 and T-bet are required. Within the first few days of Th1 and Th2 differentiation, signs of accessibility of the cytokine gene loci are observed in Th-activated cells. These signs are hypersensitivity to DNAase I and DNA demethylation.

P.298

Maturation of Th1/Th2 Cells

The IL12 and IL4 play a major role in the maturation of Th1 and Th2 cells, respectively. IL12 and IL18 act synergistically to produce IFN- γ from terminally differentiating Th1 cells. IL23 is composed of the p40 subunit of IL12 paired with the IL23 α -chain related to one of the chains of IL12. It binds to IL12 β -chain but interacts with its own IL23R. It activates STAT4 and may act during the induction of Th1 and the production of IFN- γ in cooperation with IL18. The IL27 is produced by APCs and induces proliferation of naive T-cells. It acts together with IL12 in promoting IFN- γ production and is the ligand for the T-cell cytokine receptor in the early development of Th1 cells.³⁴⁹ Th2 maturation is promoted by IL21, which is produced from Th2 cells, and specifically inhibits IFN- γ production and decreases responsiveness of T-cells to IL12, thus amplifying Th2 development.³⁵⁰

IL6 produced by several types of cells, especially APCs, activates transcription by NFAT, leading to production of IL4, which promotes Th2 differentiation. However IL6 also inhibits Th1 development because it up-regulates the suppression of cytokine signaling (SOCS)-1. SOCS, also known as STAT-induced STAT inhibitor, belongs to a family of regulators of cytokine production. SOCS1 inhibits IFN- γ production and the development of Th1 cells. Thus, IL6 plays a dual role in Th1/Th2 differentiation through induction of IL4 and SOCS1.³⁵¹ IL10 has also been reported to promote Th2 differentiation, but its main effect is in suppressing Th1 cells.

Another cytokine with double regulatory function is IL18. IL18 is produced from macrophages and synergizes with IL12 for IFN- γ production from NK-cells and T-cells. In collaboration with IL2, it promotes Th1 differentiation in activated T-cells.³⁵² Overproduction of both cytokines induces severe inflammatory disorders. In addition to its function as a Th1 inducer and as a proinflammatory cytokine, under certain experimental conditions, IL18 stimulates Th2 cell differentiation, increase of IgE, and allergic manifestations.³⁵³ The role of dendritic cells in humans is not clear as the production of cytokines varies depending on signals received from T-cells.

CD8 T-CELL DIFFERENTIATION

CD8⁺ T-cells produce primarily type 1 cytokines because CD8⁺ T-cells have no requirement for STAT4 signaling via IL12 to develop into Tc1 effectors. The Tc1/Tc2 regulation is mediated by transforming growth factor (TGF)- β with IL4 promoting Tc1 development and cytotoxicity in the presence of TGF- β .³⁵⁴ There is some kind of cross-regulation between CD4⁺ and CD8⁺ T-cells. CD8⁺ T-cells produce relatively high levels of IFN- γ and as a result, enhance Th1 immunity. On the other hand, Th2-cell-derived IL4 stimulates development of Tc2 cells in allergic states.

GENOMIC VIEW OF TYPE 1 AND TYPE 2 DIFFERENTIATION

Application of the new technology of gene expression by gene microarrays on polarized type 1 and type 2 CD4 and CD8 T-cells identified similarities in the broad pattern of gene expression in both CD4 and CD8 T-cells for type 1 and type 2 polarization, but differences were also identified between the two lineages.³⁵⁵ Large numbers of apoptosis-related genes were expressed, particularly in Th1 cells, which correlates with the propensity of these cells to undergo activation-induced cell death.³⁵⁶ A large number of cytokine and growth factor genes are preferentially expressed by either type Th1 or type Th2 cells. Th2 cells resemble Tc2 cells in their cytokine gene profile. Differences are also noted in genes involved in synthesis of cell migration molecules, such as CCR1, CXCR4, and β_7 integrin in Th2 cells and α_4 integrin in Th1 cells. This is something that should be expected because the two Th populations home to different locations.³⁵⁷

THE TH1—TH2 PARADIGM

T lymphocytes constitute a diversified population. Of the two CD4⁺ T-cells, the Th2 activates the B-cells for antibody production and the second, CD4⁺ the Th1, activates macrophages for cell-mediated immunity. The first provides defense against extracellular and helminthic infections. The second acts against intracellular bacterial infections, fungi, and protozoa (Fig. 13.12).

Th1 cells coordinate the activation of macrophages and constitute the most important cellular defense mechanism against intracellular pathogens. Macrophage activation is mediated by IFN- γ , the principal cytokine produced by Th1 cells. Macrophages activated by IFN- γ rapidly kill susceptible intracellular bacteria. They produce TNF- α , which synergizes with IFN- γ . IFN- γ has been used successfully as adjunct to chemotherapy in the treatment of leprosy, tuberculosis, and atypical mycobacteriosis. In induction of Th1 immunity, IL12 is rapidly produced by infected macrophages, which activates NK-cells and stimulates production of IFN- γ , which subsequently induces Th1 differentiation. However, overproduction of IL12, by a positive feedback mechanism triggered by IFN- γ , results in inflammatory responses.³⁵⁸ IL12 production is inhibited by IL10.

There is compelling evidence that the Th1 cells have an essential role in protection from mycobacterial infection. Mice deficient in IL4, a major Th2 cytokine, have a normal response to *Mycobacterium tuberculosis*, whereas increased production of IL4

P.299

correlates with disease progression.³⁵⁹ Mice infected acutely with *M. tuberculosis* are protected by adoptive transfer of Th1 cells with a tenfold reduction in bacterial counts, whereas recipients of Th2 cells suffer from weight loss and lung fibrosis.³⁶⁰

FIGURE 13.12. Th1 and Th2 cells and effector mechanisms against pathogens. See text for details. ADCC, antibody-dependent cell-mediated cytotoxicity; CTL, cytotoxic T lymphocyte; IFN, interferon; Ig, immunoglobulin; IL, interleukin; PMN, polymorphonuclear cells.

Leishmanial disease currently affects some 12 million people in 88 countries. The annual incidence is approximately 2 million new cases. Experimental studies have clearly documented that Th1 response is associated with restriction of the disease and cure, whereas a Th2 response is associated with progressive systemic disease. Balb/c mice are susceptible to Leishmania infection because they are unable to generate a Th1 response, whereas C57Bl/6 mice are resistant to the

infection as a result of strong Th1 response. In Balb/c mice, the draining lymph nodes show elevated transcripts for IL4 but not for IFN- γ .³⁶¹

The most critical unifying effect able to induce resistance has been the successful attenuation of IL4 expression in the draining lymph node of infected susceptible animals during the first 24 hours of infection. The extent of IL12 responsiveness is also a critical determinant for the development of a curative immune response because it induces a Th1 response.³⁶²

Another example of the importance of a balanced Th1/Th2 response is related to the allergic inflammation.³⁶³ The pathophysiologic mechanisms of asthma seem to be based on dysregulation of the Th1/Th2 balanced response with a preponderance of Th2 cytokines. Asthma affects 8% to 10% of the population in the United States and is the leading cause of hospitalization among children younger than 15 years of age, causing an exorbitant financial burden on society. Th2-dominant responses stimulate antibody-mediated responses, activate mast cells and elicit tissue eosinophilia (i.e., the predominant response in the asthmatic airway).³⁶⁴ IL13 is one of the Th2 cytokines, and overexpression of IL13 in transgenic mice induces an inflammatory response with an infiltrate rich in eosinophils and macrophages. Furthermore, it causes airway fibrosis, mucous metaplasia, and airway hyperresponsiveness.³⁶⁵ It is likely that asthma is the result of a dysregulated mucosal immune system and pathologic T-cell response in genetically susceptible individuals.³⁶⁶

CD8⁺ T LYMPHOCYTES

The CD8⁺ T lymphocyte is one of the two professional cytotoxic lymphocytes, the other being the NK-cell. The CD8⁺ T lymphocytes, also known as CTLs, differ from NK-cells in the basic mechanism of target recognition. CTL expresses an $\alpha\beta$ -TCR, recognizing processed peptides presented by MHC class I molecules (pMHC), whereas the NK-cell cytotoxicity is regulated by the C-lectin type of NK-cell receptors (CD94) or members of the killer cell Ig-like receptors (KIRs), which recognize class I HLA allotypes rather than pMHC.³⁶⁷

Two fundamentally different groups of methods of evaluation of target cell lysis have been developed: one evaluates disruption of cell membrane and release of tracers incorporated into the target, and the other evaluates DNA fragmentation resulting from apoptotic nuclear damage. In the first category, the most widely used method has been the release of radioactive chromium, ⁵¹Cr, preloaded into the target.³⁶⁸ More sensitive techniques using fluorescent impermanent dyes have been developed. DNA fragments released from the nuclei are harvested, and a "ladder" pattern is identified.³⁶⁹ Direct comparisons of the cytotoxic potency of different cell populations cannot be made by these methods because the target cell death is not linearly related to the cytotoxic input. Usually, the number of cytotoxic cells required to achieve a given level of target cell lysis is expressed in lytic units, which are inversely related to the effector cell number.

Activation of Cytotoxic T Lymphocytes

For the CTL to become an active effector, the precursor cell must be stimulated by antigen to undergo proliferation and differentiation.³⁷⁰ The activation or priming results from the interaction of the naive CD8⁺ T-cell with professional APCs. Granules are not always visible before activation, but the killing machinery (i.e., perforin, granzymes, and FasL) is delivered immediately upon priming.^{371,372} The granule by electron microscopy is 0.5 to 1.0 μm in diameter and is heterogeneous in its structure.³⁷³ The core is homogeneous and sometimes it is surrounded by double membranes containing the perforin enclosed by a thin membrane.³⁷⁴ Multiple small vesicles surround the core toward the periphery of the granule. Depending on the preponderance of these two components, granules have been distinguished as type I (dominated by the cores) or type II (with dominant multivesicular component but no cores), and other granules in terms of content are intermediate between types I and II. The granules are similar to late endosomes and have the properties of two usually separate organelles: those of the secretory type and those of the lysosomes.³⁷⁵ Similarities with lysosomes include the acidic pH, the mannose-6-phosphate receptor (MPR), and the lysosomal marker, lysosome-associated membrane protein. Endocytic components carrying CD3/TCR, CD8, and MHC molecules reach the perforin-containing granule and are displayed in the outer leaflet of the membrane.

GRANULE CONTENTS

Perforin (Cytolysin)

Perforin is a 65- to 75-kD glycoprotein with patchy homology to C9 complement component. It is synthesized as an inactive precursor, which is cleaved to yield a 60-kD active form.³⁷⁶ The protein consists of two regions: one has homology to complement proteins (C₆ to C₉), and the other is a C-2 domain related to Ca²⁺-binding proteins.³⁷⁷ The C-terminal portion is cleaved by proteolytic enzymes activating the C-2 domains for phospholipid binding.³⁷⁸ The N terminal is involved in interaction with the membrane and polymerization. However, the central portion contains four membrane-

spanning domains, potentially capable of forming amphipathic α helices of β sheets. At the carboxy terminal, a short peptide (propeptide with a bulky glycan attached) is removed, and the remaining perforin monomer undergoes conformational changes in the presence of Ca^{2+} , inserting itself in the membrane. Interaction with other perforin monomers forms the polyperforin pores.^{379,380} and ³⁸¹ At least three to four monomers are needed to form a functional channel, whereas 10 to 20 aggregated monomers are needed to produce a pore visible by electron microscopy.

Granulysin

Granulysin is a member of the saposin^{382,383} family of lipid-binding proteins, related functionally to defensins and other bacterial peptides, but is structurally different. It is active against Gram-positive and Gram-negative bacteria, fungi, and parasites. It disrupts artificial liposomes, damages mitochondria, and activates caspase 9 to induce apoptosis. It probably plays an important role in innate and acquired antimicrobial defenses. It kills extracellular *M. tuberculosis* and decreases their viability inside the cell.³⁸⁴

Granzymes

Granzymes are serine proteases of the chymotrypsin family.^{385,386} The crystal structure of granzyme B has been solved, and its structural similarity with chymotrypsin has been verified.³⁸⁷ On the basis of the gene structure, proteolytic specificity, and biologic function, these enzymes are divided into three subfamilies. They are produced as proenzymes, with an acidic inactivating peptide. During their transport through the endoplasmic reticulum and Golgi apparatus, they are processed so that they are targeted to the secretory pathway. The activation peptide is removed by dipeptidyl peptidase I (DPPI), and a sequence motif interacts with

P.300

proteoglycan in the granule to maintain proper conformation for activation. Granzyme B has a unique specificity among mammalian serine proteases in that it requires aspartic acid as P1 amino acid (i.e., the cleavage leaves a carboxy-terminal aspartic acid). Granzymes are highly positively charged proteins at neutral pH and form complexes with proteoglycans in the granule and extracellularly with polyanionic components.

Calreticulin

Calreticulin is a Ca^{2+} storage protein and carries a sequence that retains it in the endoplasmic reticulum. It co-localizes with perforin and is released together with perforin, which binds to the P-domain of calreticulin. Calreticulin functions as a chaperone protein for perforin and protects the CTL during biogenesis of the granules.³⁸⁸ Fragments of individual calreticulin domains used in lytic assays showed that the Ca^{2+} -binding C-domain, which does not bind perforin, has the strongest capacity for inhibitory activity.³⁸⁹ Lysis, however, is independent of calreticulin's ability to sequester Ca^{2+} . It is suggested that calreticulin stabilizes membranes and thus prevents polyperforin pore formation.

Other Components

Chondroitin sulfate proteoglycans are negatively charged and are exocytosed during target lysis. They probably regulate delivery of the positively charged granzymes.³⁹⁰ The multivesicular domain of the granule is rich in MPR, which is normally absent in mature lysosomes but present in early endosomes.

The DPPI (cathepsin C) is a lysosomal cysteine protease responsible for post-translational processing in the generation of activated myeloid and lymphoid granule serine proteases.

TARGET CELL LYSIS

Secretory Synapse

As we have seen with the CD4 T lymphocyte, recognition of the antigenic determinants by TCR is associated with the formation of the IS. In the synapse, the SMAC is organized by TCR and adhesion molecules. CTL also forms a synapse with the target cells, and within the synapse, there is a defined secretory domain.³⁹¹ LFA-1 and talin form an outer ring of adhesion proteins with a distinct secretory domain in the center and separate from the cluster of the TCR and signaling molecules.³⁹² Electron microscopy shows granules at the point of degranulation. The CTL acquires the hand-mirror configuration during its movement, with the nucleus leading in the front and cytoplasmic organelles trailing behind. The Golgi is apposed tightly to the membrane at the point of contact and the organelles appear to be "streaming" toward the contact site. Confocal microscopy shows that the granules initially cluster behind the MTOC and then go around the MTOC to reach the secretory domain. Intimate interdigitations are visible over a large area, but a thin extracellular space separates the two cells that are held together by gap junctions³⁹³ (Fig. 13.13). Gap junctions exist normally between cells in various tissues and probably serve the function of cellular communication. The nucleus moves away and the granules

take up position next to the area of adherence with the target. Confocal microscopy identifies regions of the secretory synapse where granules are secreted between LCK and talin or CD11a (Fig. 13.9). The granules stream around the nucleus along microtubules and accumulate behind the MTOC and the Golgi apparatus. Then they move around the Golgi and reach the synapse, where secretion occurs between the adhesion ring and the signaling domain. They fuse with the membrane within 4 minutes after contact with the target.³⁹⁴

This fusion marks the beginning of the Ca^{2+} -dependent second stage characterized by striking intracellular changes. The most remarkable of these changes is the re-orientation of the MTOC, which, together with the Golgi, takes a position facing the area of contact with the target.^{395,396} and ³⁹⁷ The Ca^{2+} requirements for lysis may also be due to the Ca^{2+} dependency of the MTOC re-orientation that is a prerequisite for CTL killing.³⁹⁸ Granules attach to and then move along microtubules toward the MTOC and finally are secreted at the MTOC. Disruption of microtubules by certain drugs severely impairs killing.³⁹⁷

For the last stage of granule secretion, a GTP-binding protein, RAB27A, is critical for moving the granules from the MTOC to the synapse.³⁹⁹ In a rare autosomal recessive disease known as Griscelli syndrome, RAB27A is defective. These patients have albinism because melanocytes require RAB27A to secrete melanosomes. WASP, which activates the Arp2/3 complex for actin polymerization, is also required for cytotoxicity.³⁹⁹

Lymphocyte-mediated killing can be confined to two pathways: the perforin-granzyme-mediated and the Fas-mediated pathways.⁴⁰⁰ Independent of the importance of the contribution of each pathway in target cell lysis, the fact is that lysis absolutely requires exocytosis of granules and their contents. Exocytosis requires signaling from PI3-K and ERK. The importance of exocytosis is emphasized by markedly decreased cytotoxicity of CTLs and NK-cells in Griscelli syndrome (a rare autosomal recessive disorder characterized by partial albinism and the ashen mouse). The ashen mice have a profound decrease of cytotoxicity, even though they have normal FASL expression and FASL cytotoxicity.⁴⁰¹ Patients with Griscelli syndrome and the ashen mouse have a loss of function mutation in the RAB27A gene that abrogates the expression of RAB27A GTPase (one of approximately 50 GTPases). RAB27A affects the functions of the dense granules of platelets, melanosomes of melanocytes, and secretory lysosomes of CTLs. In platelets, RAB27A regulates secretion only of the dense granules. Increase of Ca^{2+} is critical for cytotoxicity, which results from extracellular sources, because it does not occur if extracellular Ca^{2+} is removed.⁴⁰²

The Role of Perforin

Perforin was the name given to a protein within the granules that perforates the cell membrane and opens pores, which originally were believed to be the cause of lysis and cell death. The C-terminal domain of perforin is the Ca^{2+} -binding site that initiates the insertion of the molecule into cell membrane.³⁷⁸ The insertion is mediated by exposure of several aspartate residues after cleavage of the C-terminus to yield a 60-kD active form. These residues are presumed to become approximated in three dimensions and bind Ca^{2+} , and the molecule becomes highly reactive for lipids from exposure of amphipathic domains. Some data suggest that perforin actually is inserted into the lipid bilayer with the help of a receptor. NK-cells release a lysolipid, the platelet-activating factor, which binds to its receptor and forms a bridge between the platelet-activating factor receptor and perforin.⁴⁰³

At 37°C, perforin inserts into the membrane, and approximately 20 perforin monomers form a tubular structure (16 nm wide) with a torus in the upper ring,⁴⁰⁴ similar to that formed by the C9 component of complement (Fig. 13.14). Purified perforin causes cell lysis but not the DNA fragmentation and condensation associated with apoptosis, which is a hallmark of target cell lysis by CTLs.⁴⁰⁵ Furthermore, nuclear changes occur before cell membrane damage.⁴⁰⁶ Targeting cell death requires the combined action of perforin and granule-associated granzymes. However, mice deficient in perforin suffer more serious consequences of lack of or diminished cytolytic functions⁴⁰⁷ as compared to mice deficient in granzymes A and B.⁴⁰⁸ It has been assumed that granzymes enter passively through perforin pores (Fig. 13.15). Large pores that allow passive diffusion of the granzymes are formed only with large concentrations of perforin. The pore size formed by small concentrations of perforin does not permit diffusion of

P.301

proteins larger than 8 kD. However, even under these conditions, granzymes (32 to 65 kD) have access to the cytosol, although evidently not by direct diffusion through perforin pores. A lysin from *Listeria monocytogenes* also permits granzyme access to cytosol even in the absence of any measurable plasma membrane damage.⁴⁰⁹

Contact regions of cytotoxic T lymphocyte-target cell conjugates. *Cell Immunol* 1976;25:41-51, with permission.)

The entrance of granzyme B into the cell at low perforin concentrations is suggested to occur, probably as a result of endocytosis ("facilitated access" hypothesis). Perforin endocytosed together with granzyme disrupts the endocytic pathway and releases granzyme for delivery to the nucleus. Support for this interpretation comes from the observation that brefeldin, which interferes with redistribution of proteins out of the endosomal system, inhibited perforin-induced release of granzyme B, blocked its translocation to the nucleus, and inhibited cell death.⁴⁰⁹ Granzyme B is therefore able to enter into the interior of the cell autonomously in the absence of perforin. However, apoptotic death does not occur unless perforin is added.⁴¹⁰ Granzyme binds to MPR, when it is trafficking within the cell at the time of synthesis but also on the surface of the target cell.⁴¹¹ However, MPR is not critical for transportation of granzyme B within the target cell because cells lacking MPR are still subject to apoptosis by granzyme B, which enters the cell by constitutive fluid-phase micropinocytosis^{412,413} or some other, probably specific, receptor.

Endocytosis follows the binding to the receptor, and the granzyme B is detected first within Rab5-positive endocytic vesicles and subsequently in Rab5-negative, novel endocytic compartments that are not identifiable by any of the known endocytic markers.⁴¹⁴ The granzyme B is released to the cytoplasm by a second signal provided by perforin or replication deficient adenovirus (Ad2). From the cytoplasm, the granzyme B reaches the nucleus, initiating the apoptotic pathway.

The localization in the nucleus occurs before the nuclear events of apoptosis, suggesting that nuclear translocation of the granzyme B transmits an apoptotic signal that is communicated to the nucleus.⁴¹⁵

FIGURE 13.14. Lesions (arrows) inflicted on its target by cytotoxic T lymphocytes. Cytotoxic T lymphocytes form punched-out lesions on the membrane of the target similar to those formed by complement. (From Dennert G, Podack ER. Cytolysis by H-2-specific T killer cells. Assembly of tubular complexes on target membranes. *J Exp Med* 1983;157:1483-1495, with permission.)

The Role of Granzymes

Independent of the role played by each of the constituents of the granules, it is absolutely clear that exocytosis is crucial for target cell death. In T-cells, the granules are synthesized when the cells receive activation signals, whereas in NK-cells, the granules are preformed. At least four granzymes are present ubiquitously in human cytotoxic cells (i.e., A, G, H, and K). After their synthesis, the granzymes undergo post-translational modifications and as a result assume an active

conformation. First, the signal peptide is removed and subsequently, a short propeptide which for granzymes A and B is DPPI a cysteine aminopeptidase that can activate several serine proteases.⁴¹⁶ Subsequently they are glycosylated and then sorted by MPR in the Golgi apparatus on the way to the granules.⁴¹⁷ Granzyme B is a serine protease originally defined as an aspartase because it cleaves aspartic acid in the P1 position and is the only granzyme with the preference for proteolytic cleavage of aspartate residues. In this respect, it has a specificity similar to caspases and has an extended substrate specificity with nine amino acids making contact with the substrate. The first substrate of biologic significance of granzyme B was found to be a member of the caspase family.⁴¹⁸ Cleavage of target cell caspases⁴¹⁹ results in the activation of the cellular apoptotic cascade (Fig. 13.16).

FIGURE 13.15. What is the role of perforin in cell lysis? The perforin lesion used to be considered the cause of cell death by osmotic lysis (as with complement) (A). When the granzymes were implicated in the cause of cell death by the apoptotic pathway, it was believed that the pores of perforin allow the entrance of the granzymes into the cell (B). Granzymes, however, can still enter the cell without perforin, but by themselves, they cannot cause cell death (C). Because granzymes enter the cell by endocytosis and are within endocytic vesicles, it is argued that perforin is needed to release them in the cytosol by punching holes in the vesicles (endosomolytic mechanism; D). At this point, it is known that cytotoxic T lymphocytes kill their targets, and for this function, they need at least two of the contents of the granules: the granzymes and the perforin. The exact mechanism, however, is still strongly debated.

Granzyme B activates apoptosis by two distinct pathways: i.e., by directly cleaving its substrates, caspase 3 or caspase 8,⁴²⁰ or by a caspase-independent pathway through mitochondria. Mitochondrial factors enhance extramitochondrial caspase activation and play a central role in the execution of apoptosis, involving disruption of electron transport, energy metabolism, production of reactive oxygen radicals, and the release of apoptotic proteins, such as cytochrome-c.^{421,422}

BCL2 can rescue cells from granzyme-B-mediated cell death, specifically blocking the pathways that operate directly through mitochondrial perturbations. BCL2 suppresses the mitochondrial pathway because it prevents loss of mitochondrial membrane depolarization and inhibits the release of cytochrome c and apoptosis-inducing factor into the cytosol.⁴²³ The mitochondrial apoptotic pathway is triggered by direct cleavage of BID (BH-3 interacting domain)⁴²⁴; it results in translocation of BID to mitochondria, where it interacts with its receptors, BAX (BCL2-associated X protein) and BAK (BCL2-antagonist killer) triggering cytochrome-c release. Cytochrome c then activates apoptosome, which in turn activates caspase 9 and ultimately caspase 3.⁴²⁵ BCL2 apparently blocks granzyme-B-induced apoptosis by acting at an upstream point of the granzyme B pathway, i.e., blocking the translocation of the granzyme to the nucleus.⁴²⁶

Granzyme A

Granzyme A is a tryptase and induces caspase-independent cell death. It concentrates in the nucleus of the targeted cells and degrades histone H1 into small fragments.⁴²⁷ Histone H1 plays

P.303

a critical role in chromatin hypercondensation, which protects genomic DNA from endonuclease digestion. Histone digestion provides a mechanism for unfolding compacted chromatin and facilitating endogenous DNAase access to DNA during T-cell granule-mediated apoptosis. Another target for granzyme A is protein HMG2 (high-mobility group protein 2). HMG2 is a nonhistone protein that binds to the internucleosomal linker region of DNA and to core histones and is involved in critical steps in DNA replication and transcription. It binds preferentially to distorted DNA and unwinds damaged DNA for its repair. It facilitates the assembly of higher-order nucleoprotein structures by bending and looping DNA or by stabilizing underwound DNA. However, the HMG2 is cleaved by granzyme A and thus opens up chromatin and blocks the de novo transcription required for cellular repair responses. Opening up chromatin probably contributes to the observed synergy of granzyme A with granzyme B in the induction of oligonucleosomal DNA fragmentation during CTL lysis.⁴²⁸ Both granzyme A and B directly cleave lamin B,⁴²⁹ a member of the lamin family of proteins that maintain the integrity of the nuclear envelope.

FIGURE 13.16. Cytotoxic T-lymphocyte killing of target cells. The cytotoxic T-lymphocyte killing of its targets is mediated by both the granzyme(s) (Gr), especially GrB, and the perforin, and because both of them share the same intracellular

residence (i.e., the granule), the killing mechanism is known as the granule exocytosis mechanism. GrB activates caspase (Casp)-3, either directly or, most likely, in vivo by cleavage of the proapoptotic member of the Bcl2 family, Bid. The active Bid acts on the mitochondrion and causes opening of the permeability transition (PT) pore of the inner mitochondrial membrane that causes (or is the result of) the collapse of the $\Delta\Psi_m$ (mitochondrial transmembrane potential). $\Delta\Psi_m$ normally results from the asymmetric distribution of protons and other ions on both sides of the inner mitochondrial membrane. It is essential for normal mitochondrial function. $\Delta\Psi_m$ disruption occurs before cells exhibit nuclear DNA fragmentation or aberrant exposure of phosphatidyl serine on the outer cell membrane; therefore, it constitutes probably the earliest common event of the apoptotic cascade. Mitochondrial disruption activates a factor not yet well identified (X) and contributes to amplification of activation of Casp-3 and other Casps subsequently (Casp-6, -7, -8, -9, -10). The factor X may be Diablo (direct inhibitor of apoptosis protein-binding protein), which facilitates processing of Casps through inhibition of inhibitor of apoptosis proteins. The Bid pathway of Casp-3 activation provides a greater lethal threshold of amplification of activation of Casps than the direct GrB activation. In addition to the Casp-dependent pathway (apoptosis), disruption of mitochondria by GrB-activated Bid leads to cell death by necrosis. HSP, heat-shock protein. (From Kroemer G, Zamzami N, Snesin SA, et al. Mitochondrial control of apoptosis. *Immunol Today* 1997;18: 44-51; Heibein JA, Barry M, Molyca B, et al. Granzyme B-induced loss of mitochondrial inner membrane potential [$\Delta\Psi_m$] and cytochrome c release are caspase independent. *J Immunol* 1999;163:4683-4693; Sutton VR, Davis JE, Cancilla M, et al. Initiation of apoptosis by granzyme B requires direct cleavage of bid, but not direct granzyme B-mediated caspase activation. *J Exp Med* 2000;192:1403-1413; and Barry M, Bleackley RC. Cytotoxic T lymphocytes: all roads lead to death. *Nat Rev Immunol* 2002;2:401-409.)

Granzyme A bound to proteoglycans, has been detected in the blood of patients with viral diseases and rheumatoid arthritis.⁴³⁰ In complexes with proteoglycans, it is protected against inactivation by protease inhibitors such as α_2 -macroglobulin and others. However, its role in the blood in these conditions remains unknown. The entry of granzyme A into the nucleus requires the signal from perforin and once inside the nucleus, it binds to insoluble factors because it does not leak out even after the nuclear membrane is permeabilized.⁴³¹

Death Receptor Pathway

Cytotoxic lymphocytes use two pathways for killing their targets: the exocytosis pathway (perforin-granzyme) and a death receptor pathway. Although there are multiple receptors on the cell surface that can initiate an apoptotic cascade, they converge at one point downstream to a common final pathway. The point of confluence is the adaptor molecule FADD (fas-associated death domain). These alternate apoptotic pathways may be considered as the FADD pathway.⁴³² The pathways that converge to FADD are initiated by FAS (CD95), physiologically the most important receptor in the family of TNF receptors. FADD binds and recruits caspase-8, which stands at the apex of the cascade of all caspases⁴³³ and forms the DISC (death-inducing signaling complex).⁴³⁴ Caspase-8 may target the mitochondria through BID or caspase 3, depending on the cell type.^{435,436}

In the FADD pathway, the FASL is not stored even in activated cells, and as a result, it requires the induction of a new ligand after TCR stimulation, which requires 1 to 2 hours after stimulation. The half-life of the ligand is long (2 to 3 hours), and the CTL can kill innocent bystanders (as long as they express the appropriate receptor, FAS) without the need for TCR signaling.⁴³⁷ In this respect, the FADD pathway is much more promiscuous than the perforin pathway. The death receptor pathway is important for CD4⁺ Th1 cells.⁴³⁸

Membrane Morphology of Target Cell Lysis

In the early stages of cell death induced by CTL, plasma membrane components are translocated to intracellular membrane structures, including nuclear envelope and mitochondria. Membrane-bound perforin and the granzymes are internalized at the same time, and it is postulated that, subsequently, perforin releases the granzymes to the cytosol by an endosomolytic action for activation of the caspase pathway (Figs. 13.15 and 13.16). In the early stage, the target does not undergo extensive permeabilization during perforin-dependent CTL lysis.

The first detectable change in the target-cell-surface morphology consists of the formation of small dilatations of the surface

P.304

microvilli, forming small vesicles that eventually expand into large blebs even before ⁵¹Cr release can be detected. Some of the detached vesicles attach to neighboring CTLs, suggesting that they carry some target-specific antigens on their surface (Fig. 13.17).

FIGURE 13.17. Cytotoxic T-lymphocyte-target cell interaction. A-C: Scanning electron microscopy of the formation of the killer cell synapses. Intimate contact is established between the microvilli of the two cells. Compare with the electron microscopic view in Figure 13.13. (B and C from Kalina M, Berke G. Contact regions of cytotoxic T lymphocyte-target cell conjugates. *Cell Immunol* 1976;25:41-51; and A from Grimm E, Price Z, Bonavida B. Studies on the induction and expression of T cell-mediated immunity. VIII. Effector-target junctions and target cell membrane disruption during cytolysis. *Cell Immunol* 1979;46:77-99, with permission.)

THE FUNCTION OF CYTOTOXIC T LYMPHOCYTES

Deficiencies of Granule Contents

Virus-specific cytotoxic CD8⁺ T-cells (CTL) are induced during viral infections (Fig. 13.12) and lyse infected cells during the eclipse phase, i.e., before infectious virus is generated. They kill virus-infected cells before new viral antigens can be detected on the surface of infected cells with antibodies.⁴³⁹ Fas deficiency has no effect on the role of viral clearance, but elimination of both Fas and perforin leads to uncontrolled infection.⁴⁴⁰ Normal mice easily survive a high inoculum (10^6 PFU) of the ectromelia virus, a murine-specific poxvirus. However, perforin-deficient mice succumb with a dose as small as 10 PFU.

Perforin deficiency in mice is associated with increased susceptibility to a variety of infections by viruses, protozoa, (plasmodium, *Trypanosoma cruzi*) and bacteria (i.e., mycobacteria, salmonella, chlamydia, listeria, etc.).⁴⁴¹ Defense

involves not only cytolytic mechanisms but also cytokines (i.e., IFN- γ , TNF, etc.), as well as microbicidal molecules. In the experimental model of lymphocytic choriomeningitis virus infection in mice, a nonlytic viral infection, perforin-dependent cytotoxicity is crucial in the control of the acute stage.⁴⁴² During the chronic stage of this infection, perforin down-regulates CD8⁺ T-cell expansion and prevents immunopathology.⁴⁴³ In perforin-deficient mice, however, the lack of this immunoregulatory control results in expansion of CD8⁺-activated T-cells, with approximately 50% of the animals dying within 2 to 4 weeks as a result of the immunopathologic damage from uncontrollable CD8⁺ proliferation and activation. Infusion of normal CD8⁺ T-cells fully reverses pathology and the associated mortality. This example clearly differentiates between defense and immunopathology, which normally is averted from an “exocytosis”-mediated mechanism of regulation of CD8⁺ cytolytic cells.

In another model involving the *lpr/lpr* mice, which are deficient in the Fas receptor, deficiency of perforin markedly accelerates the spontaneous lymphoproliferative disease, which normally occurs at a slower pace in these mice. This evidence also supports the notion that perforin plays a role in immune regulation, prevention of immunopathology, and autoimmunity. Recently a homozygous loss of function defect in the human perforin gene has been detected that is associated with several clinical manifestations, mainly due to uncontrolled T-cell and macrophage activation with overproduction of inflammatory cytokines. The syndrome is known as familial hemophagocytic lymphohistiocytosis (FHL).⁴⁴⁴ The disease is mapped in chromosome 10q21-22 (i.e., the location of the perforin gene). Overall, the incidence of the mutation is approximately 20% in all FHL patients. For the development of FHL syndrome, a viral infection or a defect of an additional pathway that controls lymphocyte homeostasis is required. Perforin-deficient mice, for reasons unknown at the present time, do not develop symptomatology similar to human FHL. Mice deficient in granzyme B lose the ability to induce DNA fragmentation, even though perforin causes membrane damage. Deficiency of both granzymes A and B causes susceptibility to ectromelia infection,⁴⁴⁵ although cytotoxic lymphocytes with the same deficiency and inability to cause DNA fragmentation are still able to exert a potent antitumor effect.⁴⁴⁶

DPPI, also known as cathepsin (CTSC), is a lysosomal cysteine protease expressed in most tissues, and in CTLs, it is found in the secretory compartment. It belongs to the papain superfamily of proteases and shares similarities to lysosomal cysteine proteases cathepsins B, H, and L. Granzymes A and B become enzymatically active only after cleavage of the N-terminal dipeptide by DPPI and are stored in the lysosomal granules in the active form along with perforin. DPPI knockout mice resemble the perforin-deficient mice: Both fail to cause apoptosis. DPPI deficiency results in failure to activate the granzymes, whereas perforin deficiency fails to deliver the granzymes into target cells.^{447,448} Deficiency of DPPI has been detected in humans with Papillon-Lefèvre syndrome, which is characterized by keratosis palmoplantaris with periodontopathia.⁴⁴⁹ There is premature tooth loss due to periodontal disease and thickening of the skin.

Graft versus Host and Graft versus Leukemia Reactions

Lymphocyte cytotoxicity has been implicated in graft versus host disease after allogeneic bone marrow transplantation, with contribution to the pathogenesis by both the perforin and Fas pathways.^{450,451} and ⁴⁵² It is agreed that cytotoxic lymphocytes contribute to the development of the disease, but there is no agreement about the underlying mechanism. The graft versus leukemia effect, however, seems to be mediated predominantly by the perforin pathway.

Granzyme Inhibitors

An important characteristic of the function of cytotoxic cells is that they successfully avoid the damaging effect of the lethal weapons they deliver to kill their targets. As a matter of fact, the CTLs, after a successful hit, disengage and are directed against another target.

P.305

Some recent observations provided a molecular explanation for their protection from “suicide.” The effector cells contain a potent inhibitor of granzyme B, known as proteinase inhibitor 9.^{453,454} The inhibitor is a serpin, is found in both the cytoplasm and the nucleus, and forms tight complexes with granzyme B but does not inhibit most of the caspases. Serpins are a large family of intracellular and extracellular protease inhibitors. Many viruses encode serpins that block caspases, the enzymes of apoptosis. Inhibitors of granzyme B can be encoded by several viruses. Best described is the poxvirus-encoded cytokine response modifier A (Crm A). Overexpression of Crm A in target cells inhibits CTL-mediated killing, but predominantly through a Fas-mediated pathway. Crm A inhibits granzyme B and several caspases. With several of the steps of CTL cytotoxicity now understood, therapeutic interventions are possible for several of the steps of lymphocyte cytotoxicity in a number of human conditions.

Apoptosis

Despite the wealth of information on the mechanism of this important pathway, there are several areas that are not well understood. Perforin has an indispensable role in the delivery of granzyme B, but certainly not simply as a pore-forming molecule. Granzymes, on the other hand, induce the nuclear changes affecting the DNA (i.e., by apoptosis), but even if they enter the cell in the absence of perforin, they cannot be translocated to the nucleus without perforin.⁴⁵⁵ The mechanism of granzyme delivery by perforin is not clear. It has been postulated that intracellular delivery of granzymes is through an endosomolytic mechanism.⁴⁵⁶ Translocation of a fluorescent probe from the target cell membrane to interior membranes, including the nuclear envelope and mitochondria, is supportive of this prediction.⁴⁵⁷

The relationship of the roles of perforin and granzymes in cytotoxicity was examined in the *gld/gld* (FasL/FasL) mice, which have a FasL deficiency and therefore cannot have Fas-mediated cytotoxicity. The additional deficiency of granzyme B in *gld/gld* mice (i.e., mice with the phenotype GrB *gld/gld*) leads to CTLs with residual cytotoxicity, which can only be perforin-dependent. This can be concluded also from the fact that perforin^{-/-} *gld/gld* CTLs have no residual cytotoxicity.⁴⁵⁸ It is reasonable to conclude that the cytotoxicity, which is independent of granzyme B, is normally partially accounted for by a Fas pathway and partially by a second perforin-dependent mechanism. Finally, inhibitors of caspases block the Fas death pathway, but in CTL granule exocytosis, the target cell lysis is not detectably blocked, although the accompanying apoptotic nuclear damage is efficiently blocked. Thus, caspase inhibitors prevent the hallmark phenotype of apoptosis without affecting cell death, as evidenced by lysis.⁴⁵⁹ At this point, not all the roads used by the CTL that may lead to cell death have been fully explored.

Regulatory T-cells

T reg cells constitute about 5% to 10% of the peripheral CD4⁺ T-cells and express the characteristic phenotype CD4⁺/CD25⁺ (the α -chain of the IL2 receptor). They are also CTLA4⁺ (costimulatory molecule cytotoxic T-lymphocyte antigen-4) and GITR⁺ (glucocorticoid-induced TNF receptor family-related protein).¹⁵⁸ Differentiation of CD4⁺ T reg cells is mediated by interactions of CD4⁺ thymocytes with stromal cells. Some thymocytes acquire MHC II molecules,⁴⁶⁰ which are derived from APCs.⁴⁶¹ T reg cells are enriched in autoreactive cells,⁴⁶² but are resistant to deletion by NS, as compared to conventional CD4⁺ thymocytes.⁴⁶³ The TCRs of T reg cells are of relatively high affinity for autoantigens, and this may facilitate their reactivation in the periphery by self-antigens. However, their affinity is still below the level required to trigger NS. These fundamental differences between the TCRs of T reg cells and the other thymocytes, in terms of specificity (MHC II vs. peripheral tissue antigens), affinity, and the nature of the selecting cell, provides an additional mechanism of protection against autoimmunity (i.e., active peripheral suppression in addition to central tolerance). Selection of T reg cells is mediated by the bone-marrow-derived APCs and not the epithelial cells.⁴⁶⁴ It has been suggested that the TCR affinities of T reg cells are just below the deletion level, permitting them to follow a unique differentiative pathway with regulatory function.⁴⁶⁵ The development and function of natural T reg cells depends on the transcription factor FOXP3, which encodes a new member of the forkhead/winged helix family of transcription factors.⁴⁶⁶ Mutations of the human gene FOXP3 is the cause of the IPEX syndrome (immune dysregulation polyendocrinopathy enteropathy and X-linked syndrome),⁴⁶⁷ an X-linked immunodeficiency syndrome associated with autoimmunity involving multiple endocrine organs, inflammatory bowel disease, and atopic dermatitis. TGF- β maintains a central role in the generation and function of T reg cells.⁴⁶⁸ CD4⁺/CD25⁺ T reg cells may arise from CD4⁺/CD25⁻ T-cells following stimulation of TCR and costimulation with TGF- β .⁴⁶⁹ Once they exit the thymus, the T reg cells depend for their survival, preservation, and function on dendritic cells, which present them with autoantigens.⁴⁷⁰ The continuous exposure to self-antigens will maintain the T reg cells in a state of activation.

A portion of T reg cells arising in the thymus are “anergic,” i.e., in a state of partial or total unresponsiveness.⁴⁷¹ Anergy may follow TCR stimulation without subsequent costimulation. Anergic T-cells are unable to produce IL2 and induce a proliferative response. Naturally arising anergic T-cells upon stimulation suppress effector T-cells but are prone to apoptosis, probably as a result of a continuous antigenic stimulation from self-antigens. Anergic T-cells exert their suppressor function by targeting APCs. The APC brings the anergic-suppressive cell into proximity with the target T-cell, forming a tricellular complex and setting the stage for a T-T-cell interaction.⁴⁷² T-T-cell interaction is the foundation for induction and spreading of the anergic state, otherwise known as infectious tolerance.

$\gamma\delta$ T-CELLS

Commitment to $\gamma\delta$ T-cell lineage takes place in the thymus as discussed earlier in this chapter. (See “T-Cell- $\alpha\beta$ versus T-Cell- $\gamma\delta$ ” and “The Pre-T-cell Receptor.”)

Rearrangements of the human γ and δ genes appear to occur in a developmentally ordered fashion.⁴⁷³ Initially the $\gamma\delta$ TCR repertoire is small inasmuch as it involves rearrangements of a small number of V segments and as a result the junctional diversity is limited.

In human embryos between 8.5 and 15.0 weeks of gestation, the most common V fragments are V δ 2 joined to D δ 3 and V γ 1-8 or V γ 9 with J γ 1. These cells are referred to as the V δ 2 cells. Rearrangements after birth at approximately 4 to 6 months of age involve the joining of other $\gamma\delta$ segments such as V δ 1 to D δ 1 and D δ 2 and the V γ 1 family with the J γ 2 cluster. Postnatally in the thymus, the V δ 2 subset represents 15% and the V δ 1 85% of the $\gamma\delta$ cells, and these proportions remain relatively constant throughout adult life.

It has, however, been questioned whether two distinct subsets of $\gamma\delta$ T-cell subsets exist, or one V9V2 T-cell population exerts multiple effector functions.⁴⁷⁴ Although intrinsic or genetic factors generate $\gamma\delta$ T-cell subsets, extrinsic or environmental factors act further to shape and select specific clones. An enormous selective pressure is exerted on the development of $\gamma\delta$ T-cells throughout life to produce populations of cells that express antigen receptors that are encoded by specific gene segments. The predominance in adult human blood of the V δ 2 to V γ 9 population is explained by such antigen-mediated expansion. These expansions create oligoclonal populations due to selection pressures from environmental microbes and certain edible plants. In contrast to the V γ 2/V δ 2

P.306

(V γ 2 is the same as V γ 9) T-cells which are a major circulating population, the V δ 1 cells account for the vast majority of the $\gamma\delta$ T-cells in tissues such as intestine and spleen.⁴⁷⁵

$\gamma\delta$ T-cell Receptor: Structure and Antigen Recognition

Antigen recognition by the $\gamma\delta$ TCR resembles recognition by antibodies.⁴⁷⁶ The V and C domains are organized into "Ig folds" (i.e., approximately seven β strands packed face to face in two antiparallel β sheets, constrained by intradomain disulfide bonding). The V regions are subdivided into framework and hypervariable regions, which have three CDRs. The orientations of V γ and V δ are similar to the relative orientations between the V domains in the Fab Ig fragment or the $\alpha\beta$ TCR. However, the CDR3 of V δ is diverse in length and composition (8 to 21 amino acids), a range similar only to the IGH@ (3 to 25). Furthermore the CDR3 loops of the $\gamma\delta$ TCR protrude above the rest of the molecule creating clefts between them; these strikingly distinguish them from the equivalent loops of the $\alpha\beta$ TCR, which are flat and bind to pMHC, and from the antibodies that bind large proteins.⁴⁷⁷

The $\gamma\delta$ TCR exists as a complex with the CD3 polypeptide chains and recognizes antigens with a wide distribution, by a mechanism fundamentally different from that of $\alpha\beta$ TCRs; i.e., antigen is not processed and there is no MHC restriction.^{476,477,478} and ⁴⁷⁹ Examples of nonprotein substances are pyrophosphates and alkyl-amines found in bacteria, plant, or animal cells,^{480,481} and ⁴⁸² and bacterial and mammalian homologs of heat-shock protein 60 kD (HSP-60).⁴⁸³ Human peripheral blood V γ 2V δ 2 cells are present in large numbers in lepromatous lesions reactive with monoalkyl compounds of mycobacterial cell walls. The most potent compound is monoethylphosphate, which stimulates cytotoxic activity of these cells and the phosphate group is very important in their recognition by the $\gamma\delta$ TCR. Alkyl-amines, derived from plant food products or from bacteria also stimulate V γ 9V δ 2⁺ T-cells⁴⁸² and the aminobiphosphonates that inhibit osteoclastic bone resorption, particularly in cancer patients, can also stimulate V γ 9V δ 2 cells.⁴⁸⁴ The V γ 9⁺ T-cells respond to superantigens, such as staphylococcal enterotoxin A.⁴⁸⁵ Some mucosal $\gamma\delta$ T-cells interact with MHC-encoded proteins, MICA and MICB,⁴⁸⁶ through the NKG2D C-type lectin receptor.⁴⁸⁷ MICA and MICB class I molecules identify stressed cells and have a very restricted pattern of expression, primarily limited to intestine. MICA and MICB do not present peptides because the peptide-binding groove is of limited size.⁴⁸⁸ These molecules may function in innate immunity as important targets for V δ 1⁺ cells for elimination of stressed cells.⁴⁷⁵ Some V δ 1⁺ cells recognize the nonpolymorphic CD1C member of the CD1 family of molecules, expressed on APCs, that presents lipid and glycolipid foreign antigens to T-cells.⁴⁸⁹ These $\gamma\delta$ cells activated in response to CD1C produce IFN- γ and direct $\alpha\beta$ T-cells to Th1 differentiation. Furthermore they are cytotoxic, express granulysin, and they could lyse infected dendritic cells via the perforin pathway and kill released bacteria by granulysin. Therefore their role is significant in host defense before antigen-specific T-cells have differentiated.⁴⁹⁰

Direct recognition of CD1C may represent a bridge between innate and adaptive immunity in a similar fashion to recognition of CD1D by murine and human NK⁺ $\alpha\beta$ T-cells,⁴⁹¹ which polarize T-cells to a Th2 phenotype. The CD1C-restricted $\gamma\delta$ T-cells promote the maturation of myeloid-derived dendritic cells, which are able to present antigens to CD4⁺ T-cells. This function of $\gamma\delta$ T-cells is important because they stimulate rapid accumulation of mature dendritic cells,⁴⁹² early during microbial invasion; at the same time they secrete IL12 to drive T-cell polarization to the Th1 type.

$\gamma\delta$ T-cell Function

The recognition of antigens by the $\gamma\delta$ TCR is more akin to that of antibodies and does not need antigen processing and presentation. The V δ 1 and V δ 2 cells are believed to represent separate lineages with different developmental pathways and tissue distribution.⁴⁹³ Most of the $\gamma\delta$ T-cells with intraepithelial localization are V δ 1, whereas the V δ 2, about 5% of all T-cells, are detected in the peripheral blood. The V γ 9/V δ 2 T-cells release proinflammatory chemokines⁴⁹⁴ and provide protection against mycobacteria by directly killing infected macrophages⁴⁹⁵ as well as extracellular bacteria by granulysin and perforin.⁴⁹⁶

Persistent chronic disease correlates with a decline or disappearance of mycobacteria-reactive $\gamma\delta$ T-cells.⁴⁹⁷ This contributes to the prevention of chronic inflammatory disease by directly killing activated macrophages.⁴⁹⁸ This function of $\gamma\delta$ T-cells may be facilitated by the expression of CCR5, the receptor for the chemokine RANTES (MIP-1 α) produced by macrophages.⁴⁹⁹ The evidence of a role of $\gamma\delta$ cells against cancer is still circumstantial.⁵⁰⁰ Their mucosal localization plays an immunoregulatory role in IL10-mediated low-dose oral tolerance induction, but not in the induction of systemic tolerance.⁵⁰¹ In nonobese diabetic mice with spontaneous insulinitis and diabetes, administration of insulin intranasally induces IL10 secreting suppressor $\gamma\delta$ T-cells.⁵⁰²

In patients with rheumatoid arthritis⁵⁰³ or in collagen-induced arthritis, $\gamma\delta$ T-cells accumulate in the synovium, their role depending on the stage of the disease.⁵⁰⁴ The $\gamma\delta$ T-cells in defense, immune regulation, and surveillance, are critical in their role as a "sentinel" between innate and adaptive immunity.⁵⁰⁵

A population of TCR- $\gamma\delta$ cells resides within the intestinal epithelium and these intraepithelial lymphocytes may have an extrathymic origin (bone marrow),⁵⁰⁶ express a CD8 $\alpha\alpha$ homodimer⁵⁰⁷ and are important in maintaining self-tolerance.⁵⁰⁸ These TCR- $\gamma\delta$ lymphocytes are "educated" by thymic stroma and are dendritic in morphology.⁵⁰⁹

NATURAL KILLER CELLS: MORPHOLOGY, CYTOCHEMISTRY, AND SURFACE MARKERS

NK cells originally described on a functional basis according to their capability of killing certain tumor cells in the absence of prior stimulation are of hematopoietic origin. They are a discrete population of cytolytic lymphocytes implicated in several activities *in vivo*, such as activity against tumor cells, resistance to viral infections, and regulation of hematopoiesis.^{510,511} NK-cells are a heterogeneous population with respect to phenotype and target specificity. Although the majority of the CD-56⁺ NK-cells are CD-3⁺, small numbers of CD-45⁺ cells have been detected and large granular lymphocyte (LGL) leukemias with the same phenotype have been reported.⁵¹² LGLs are large cells with pale blue cytoplasm and a high cytoplasmic-to-nuclear ratio with azurophilic granules. These cells constitute 2% to 6% of the peripheral white cells and approximately 10% to 15% of the peripheral blood lymphocytes. They are larger than the typical lymphocytes (10 to 12 μ m) with a larger amount of cytoplasm that contains peroxidase-negative granules (Fig. 13.18). The α -naphthyl acetate esterase distribution is diffuse, similar to that found in monocytes, and is different from the dotlike pattern of T lymphocytes. LGLs do not adhere to surfaces and have no phagocytic activity. Ultrastructurally, they are heterogeneous in terms of size and the density of the granule matrix.⁵¹³ The granules are located next to the Golgi apparatus, which also contains several smooth membranes and coated vesicles. The granules have an electron-dense center surrounded by a layer of lesser opacity. Like the granules of CTL, the NK-cell granules contain perforin and granzymes, both important for their cytotoxic function⁵¹⁴ and may be present in various forms, such as smooth or coated, depending on the stage of cell activation. LGLs are phenotypically and functionally heterogeneous (i.e., CD56⁺/CD3⁺/CD8⁺) and 80% to 90% of them

P.307

are CD16⁺ and others CD57⁺/CD3⁺/CD8⁺/TCR- $\alpha\beta$ ⁺. Both populations are cytolytic, but the CD57⁺ cells are T (or NK-like) cells that are non-MHC restricted. The CD56⁺ population is sometimes known as NK-LGL, whereas the CD57⁺ population is known as T-LGL and both are CD2⁺ and CD7⁺. The separation of the two cell types is not absolute, and we often detect an intermediate cell population that is CD56⁺/CD57⁺. The relationship of these cells to those expressing only one of the two markers is not known. Clonal diseases have been described from both the NK-LGL and T-LGL lineages with distinct clinical syndromes.

FIGURE 13.18. Natural killer cell morphology and ultrastructure. A: Natural killer cell is characterized by large amounts of pale blue cytoplasm and the presence of azurophilic granules. B: By electron microscopy, the granules in the cytoplasm appear heterogeneous in terms of size and density (arrows). A few scattered mitochondria are present. C: The granule consists of an electron-dense center that contains the perforin and may be enclosed by a thin membrane. Surrounding the core is a layer of lesser opacity containing the granzymes. The granules of the cytotoxic cells are probably derived from two separate organelles—those of secretory granules and those of lysosomes—and are sometimes called granulosomes. (From Zucker-Franklin D, Greaves MF, Grossi CE. Atlas of blood cells, 2nd ed. Philadelphia: Lea & Febiger, 1988, with permission.)

Ontogeny of Natural Killer Cells

Phenotypic Studies

The presence on NK-cells of some markers (CD2, CD7) characteristic of T-cells raised the question of common ontogenetic origins between these two lymphocytes. However, interference with T-cell development, as in athymic or severe

combined immunodeficiency (SCID) mice⁵¹⁵ or in mice with targeted disruptions of RAG, has no impact on NK-cell development. It is conceivable that the two lineages derive from a common progenitor with separation of their developmental pathways.

Some evidence for a common T/NK precursor has been obtained^{516,517} and relates to expression of cytoplasmic CD3 γ , δ , and ϵ . Cytoplasmic expression of CD3 γ , δ , and ϵ proteins has been detected in fetal NK-cells,⁵¹⁸ and overexpression of CD3 ϵ blocks T/NK-cell development without affecting other hematopoietic lineages.⁵¹⁹ Based on the expression of CD56 progenitors of NK-cells have been identified in the thymus within the triplenegative (TN) thymocyte population⁷⁴ and a common T/NK-cell precursor was detected among the CD-34⁺ TN population.⁵²⁰ The common progenitor has a CD45/CD5 phenotype and becomes an NK-committed cell with loss of the capacity for T-cell differentiation with the expression of CD56. The common precursor is present among TN thymocytes that are CD34⁺ and become CD34⁻ as the cell is committed to NK lineage. NK-cell differentiation requires a combination of stem cell factor, IL7, and IL2 in the presence of a stromal feeder layer. Precursors of NK-cells, that can differentiate into DP (CD4⁺/CD8⁺) thymocytes, have also been identified in fetal thymuses of mice⁵²¹ if they remain in contact with the thymic stroma, or into NK-cells if they are removed from the thymic microenvironment. This again supports the notion that the thymus is not essential for NK-cell development. The common T- and NK-cell progenitor in fetal mouse thymus is CD117⁺/CD44⁺/CD25⁻/NK1.1⁺ and shows commitment to NK lineage with loss of CD117 expression.⁵²² The overall scheme of differentiation in fetal mouse thymus suggests that multipotent precursors entering the thymus first lose B-lymphoid potential as they up-regulate NK1.1 and commit to a T/NK lineage. Then CD25 is up-regulated, CD117 is down-regulated, and cells commit to T- and NK-cell lineages, respectively.

Bone marrow is also an important location of NK-cell progenitors which are CD34⁺/CD7⁺ and differentiate to mature NK-cells either in the presence⁵²³ or absence of stromal cells.^{524,525} and ⁵²⁶ The progenitors express CD34 and CD7 and cytokines such as stem cell factor, IL2, and IL7 are essential, for their differentiation.

Cytolytic activity against NK-cell targets is detected at the time of CD56 expression. Mature NK-cells can be stimulated by IL2 for further enhancement of cytotoxic activity, increase of cytotoxic granule content, expression of adhesion molecules, and acquisition of properties attributed to lymphokine-activated killer cells. Other cytokines, such as IL7 and IL12, have similar effects, albeit to a lesser degree than IL2. The common lymphocyte precursor in the bone marrow with the CD-34⁺/CD-10⁺/CD-45RA⁺ phenotype is able to develop into NK-cells in vitro.⁵²⁷ Uncommitted hematopoietic progenitors are CD-34⁺/CD-38⁻, but up-regulation of CD38 indicates enrichment of cells committed to a particular hematopoietic lineage. CD34⁺/CD38²⁺ progenitors in fetal thymus develop into T-cells, but CD34⁺/CD382⁺ progenitors in fetal liver have no T-cell precursor activity. This population has no TRD@ rearrangements and no pre-TCR- α chain expression and develops in vitro into NK-cells through an intermediate stage of CD3⁻/NKR-1⁺/CD34⁺/CD56⁻.^{528,529} A similar NKR-1⁺/CD56⁻ population has been detected in cord blood and develops into mature CD56⁺ NK-cells in the presence of IL12.⁵³⁰

Natural Killer Cell Functional Studies

The cytokine environment regulates NK-cell maturation for the two distinct human NK-cell populations, one producing IFN- γ and the second IL13. IL-4 regulates the size of the IL13 population primarily by inducing their proliferation, whereas IL12 has minimal effects on the proliferation of IFN- γ + NK-cells. Cells with the CD161⁺ (NKR-P1)/CD56⁻ phenotype produce IL13 but not IFN- γ and have no perforin-mediated cytotoxicity.⁵³¹ CD161 is encoded by the NK-gene complex including CD69 and CD94. The CD161⁺CD56⁻ cells produce IL13 and differentiate to phenotypically mature IFN- γ - producing cells in the presence of IL12 and feeder cells. As cells mature they pass through an intermediate stage of IL13⁺/IFN- γ + NK-cells and eventually acquire the mature irreversible phenotype IFN- γ +/IL13⁻ CD56⁺.⁵³² The molecular defect of X-linked SCID conclusively demonstrated that cytokines are critical for T- and NK-cell development.^{533,534} These X-SCID patients present with a severe block of T- and NK-cell development, whereas normal or even elevated numbers of B-cells are

P.308

present. The cause of the disease is the lack of the common γ c-chain shared by several interleukin receptors (i.e., IL2, IL4, IL7, IL9, and IL15). The most important among these interleukins is IL7, which promotes development of human thymocytes (and, in the mouse, B lymphocytes also). Deficiency of Jak3, a tyrosine kinase associated with the γ c-chain, also blocks NK-cell development.⁵³⁵ Other data suggest a critical role for IL15.^{536,537} Of the transcription factors, the Ikaros family is required for transcriptional regulation of NK-cell development.^{538,539}

Natural Killer Cell Receptors

NK-cells are one of the important cellular components of innate immunity, with the mission to defend the body immediately against pathogens or in the early stages of tumor development. As a consequence, the recognition molecules

or receptors of the NK-cells are displayed on the cell surface without the need of assembly, i.e., rearrangements from multiple DNA segments after the antigenic encounter.^{540,541,542,543,544} and ⁵⁴⁵ Another important difference from other receptors such as BCRs or TCRs is that NK receptors do not directly recognize pathogens or their products but the quantitative change of MHC molecules induced as a result of the infection. In humans, three distinct families of genes have been defined that encode for receptors of HLA class I molecules. One family belongs to the Ig superfamily and is composed of KIRs. The second family is structurally Ig-like, named Ig-like transcripts (ILTs). ILTs are expressed mainly on B, T, and myeloid cells, but some members are also present on NK-cells. They are also called LIRs for leukocyte Ig-like receptors. The third family consists of C-type lectin receptors. C-type lectins are a superfamily with homologous modular carbohydrate recognition domains (CRDs) that bind carbohydrates in a Ca^{2+} -dependent manner.⁵⁴⁶ The proteins of this family of NK receptors form group V outside of a total of seven groups. The C-type lectin receptors, however, have structural differences from the other (more than 200) members of the superfamily, and it has been proposed that it be renamed as a new family of C-type lectin-like NK-receptor domains.⁵⁴⁷ The human lectin-like receptor gene complex is on chromosome 12p13.1 and the genes for the Ig-like receptors are in chromosome 19g13.4.

The Leukocyte Immunoglobulin-like Receptors

NK cells express Ig-like receptors, known as “KIRs”, shown to be involved in regulation of adaptive cytotoxic T-cell responses.

The KIRs have two or three Ig-like domains and hence are designated KIR2D or KIR3D receptors, respectively⁵⁴⁸ (Fig. 13.19 and Table 13.2). The cytoplasmic domains of the KIRs can be either long (L) or short (S), corresponding to their function, either inhibitory or activating, respectively. The inhibitory receptors contain one or two immunoreceptor tyrosine-based inhibitory motifs, or ITIMs (I/V/L/S)-X-Y-XX-(L/V) (where X denotes any amino acid).⁵⁴⁹ When tyrosine (Y) is phosphorylated, it recruits and activates SHP-1 phosphatase, leading to inhibition of signaling. Activating receptors do not signal directly but must associate noncovalently (via a salt bridge linking the transmembrane regions) with other signaling adaptor molecules that have ITAMs in their cytoplasmic domain (consensus sequence, -Y-X-X-L-X₆₋₈-YXXL/I).⁵⁵⁰ NK-cells express three ITAM-bearing transmembrane proteins: ζ , Fc ϵ R1 γ , and DAP12. The first two are present as homodimers or heterodimers, whereas DAP12 is exclusively a disulfide homodimer. (The KIRs in the CD designation are known CD158a-m and CD158z. See Table 13.2 and Appendix A for details.)

A fundamental difference between recognition by KIRs and TCRs is that the KIRs recognize more than one MHC allele. They do this by recognizing conserved residues within the polymorphic regions of MHC, whereas TCR recognizes the polymorphic residues. In addition, KIRs display a precise specificity for a particular MHC allotype. This is achieved by variations in single amino acids of KIR molecules.⁵⁵¹

The ligands for KIRs are alleles of all three MHC class I molecules, HLA-A, HLA-B, and HLA-C, which can confer protection from lysis by NK-cells. Generally, KIR3D receptors recognize HLA-A and -B, whereas KIR2D receptors recognize HLA-C alleles. A number of techniques have been used to study the binding and specificity of the receptors. No other molecule is necessary for binding except the HLA alleles.^{552,553} and ⁵⁵⁴ Crystal structures of some KIR receptors with their ligands have been solved. The KIR2DL2 in complex with HLA-Cw3 and peptide shows that KIR binds in nearly orthogonal orientation across the α 1 and α 2 helices of HLA-Cw3. It contacts positions 7 and 8 of the peptide, but most contacts are between the KIR and conserved HLA-C residues.⁵⁵⁵

Allotypic specificity is determined by the interaction between Lys44 of KIR2DL2 and Asn80 of the HLA-Cw3. In general, the peptides play a minimal role in the interaction, a point that strikingly distinguishes TCR-MHC from the KIR-MHC interactions.⁵⁵⁶ LIR-1 is a member of the LIR family (LIR-1 to LIR-8) expressed on monocytes, B-cells, dendritic cells, and some NK-cells. LIRs have two to four extracellular Ig-like domains and ITIMs in the cytoplasmic region; therefore, engagement with MHC molecules protects target cells from lysis. The first amino terminal domain of LIR-1 binds to the nonpolymorphic α 3 domain of MHC I, an interaction that is more similar to that of CD4 with the MHC II than to that of KIRs. LIR-1 also recognizes the human cytomegalovirus protein UL-18, which has a structure similar to MHC I and associates even with β_2 -microglobulin and host peptides. LIR-1 binds to this human cytomegalovirus protein with an affinity that is more than 1,000-fold higher than the host MHC I. This mechanism illustrates an example of viral subversion of host defenses and protection of infected cells from lysis⁵⁵⁷ because the binding of LIR-1 to UL-18 sends an inhibitory signal.

C-type Lectin-like Receptors

The members of the C-type lectin-like receptor family are either homodimers (the large murine family Ly-49A-W, CD69, and NKR-P1) or heterodimers, which consist of an invariant chain CD94 and a second subunit from the NKG2 family members A, B, C, and E.⁵⁵⁸ The function of the heterodimeric proteins depends on the cytoplasmic regions of the variant

chains (i.e., whether long [NKG2A,B] or short [NKG2C,E], corresponding to inhibitory or activating functions, respectively). The inhibitory subunits have one pair of ITIMs in the cytoplasmic region, whereas the activating subunits associate with the ITAM-containing adaptor molecule DAP12. The NKG2D (KLRK1) protein forms a homodimer (does not pair with CD94) and is an activating receptor. Each subunit is composed of an extracellular C-type lectin-like domain known also as an NK-receptor domain or NKD. The NKD, however, binds proteins and not carbohydrates, which are the ligands for the classical C-type lectins, and furthermore, their structure differs from the classical C-type lectins.⁵⁵⁹ C-type lectin-like NK-receptor domains include other important molecules of innate immunity, macrophage mannose receptor, collectins (i.e., pulmonary surfactants), and so forth. The ligands for CD94/NKG2 proteins are the nonclassical HLA-E molecule, which binds peptides from the leader sequence of the HLA-A, -B, -C, and -G molecules.^{560,561} Expression of HLA-E depends on the presence of the signal peptides, thus providing a safe strategy for NK-cells to monitor the presence of polymorphic HLA molecules⁵⁶² because absence of HLA-E would indicate absence of some of the HLA-A, -B, or -C. HLA-E is also capable of binding the signal sequence of heat-shock protein HSP60. HSP60 is present in all living cellular organisms⁵⁶³ and serves as a mitochondrial chaperone. HSP60 levels are increased in response to stress stimuli (i.e., temperature increase, nutrient deprivation, exposure to toxic chemicals, inflammation, etc.). HSP60 protects these cells from harmful stimuli, but at the

P.309

same time, the HLA-E/HSP60 peptide is not recognized by the inhibitory receptor, CD94/NKG2A, and these cells are eliminated by NK-cell activation.⁵⁶⁴

FIGURE 13.19. Natural killer (NK) cell receptors. The NK-cell receptors in humans structurally belong to two different families: one family has immunoglobulin (Ig) domains in the extracellular region and are known as killer Ig receptors (KIRs) and the other family has a C-type lectin-like domain. The C-type lectin domain recognizes oligosaccharides (and sometimes polypeptides), but the binding is directly mediated by Ca^{2+} , hence the term C-type lectin. However, the NK-cell receptors with the C-type fold lack the Ca^{2+} -ligating elements and thus have been termed C-type lectin-like. (See Kogelberg H, Feizi T. New structural insights into lectin-type proteins of the immune system. *Curr Opin Struct Biol* 2001;11:635-643.) The NK-cell receptors in both families are functionally divided into inhibitory and activating. The labyrinthine jargon of the NK-cell receptors becomes simpler with the acquaintance of some rules: The inhibitory KIRs have either two or three Ig domains in the extracellular region (i.e., 2D or 3D) and a long or short cytoplasmic tail (i.e., 2DL

or 2DS and 3DL or 3DS). Those with long cytoplasmic tails are inhibitory, whereas those with short tails are activating. Thus, the receptor KIR 2DL is an inhibitory receptor with two Ig domains, whereas the receptor KIR 3DS is an activating receptor with three Ig domains. (See more details in text and in Table 13.2.)

In humans the ligands for the NKG2D receptor are the MHC class I-related molecules MICA and MICB, which are up-regulated in virally infected cells and many tumors.^{565,566} They are minimally expressed in normal tissues but up-regulated in stressed cells.⁵⁶⁷ MICA is composed of two structural domains: one in the form of a platform formed by α_1/α_2 and the second in the form of a C-type Ig-like α_3 domain.⁵⁶⁸ The NKG2D receptor binds orthogonally to the MICA platform in a way similar to the docking of TCR on pMHC (see above).⁵⁶⁹ For signaling, it uses the adaptor protein DAP10, which has no ITAMs but contains the sequence YINM and propagates signaling through PI3-kinase and is thus less susceptible to the SHP-1-coupled receptors. The NKG2D receptor in mice (Kirk1) may associate with another adaptor protein, DAP12 (also known as KARAP), which recruits protein tyrosine kinases.⁵⁷⁰ Through DAP12, it can activate ZAP70 or SYK protein kinases through the ITAM of DAP12 and the p85 subunit of PI3-K. Thus depending on the availability of the adaptor partners, NKG2D may mediate costimulation in T-cells and/or activation in NK-cells.⁵⁷⁰ Furthermore, the functional outcomes of NKG2D stimulation depend on ligand density, cytokines, or the presence of inhibitory ligands.⁵⁷¹ Another family of ligands for NKG2D contains proteins that bind the UL16 cytomegalovirus protein, known as UL16-binding proteins (ULBP).^{572,573} The ULBP possess α_1 and α_2 domains but differ from MIC and MHC I in lacking the α_3 domain, and they are GPI-anchored proteins without β_2M protein. Binding to the NKG2D receptor has been demonstrated by blocking of ULBP binding by anti-NKG2D antibodies.⁵⁷⁴ The presence on NK-cells of receptors that recognize infected or abnormal (malignant) cells provides a new platform for developing strategies for immunotherapy of malignancy.⁵⁷⁵

The major breakthrough in the regulation of NK-cell function came with the formulation of the “missing self” hypothesis^{576,577} (Fig. 13.20). This hypothesis states that NK-cells can recognize and selectively lyse targets that fail to express self-MHC I antigens. The validity of the hypothesis has been demonstrated in multiple in vivo and in vitro systems as summarized.⁵⁷⁶ The basic premise is that when appropriate MHC I molecules are expressed, lysis of the target is inhibited, but when the target is deficient in MHC I expression, the target is lysed. Specific inhibitory receptors engaged with normal MHC I molecules prevent activating receptors to kill the target. Cells that have lost a normal MHC I expression (“missing self”; i.e., tumors or infected cells) are unable to deliver an inhibitory signal to NK-cells and

P.310

become susceptible to lysis. Cells susceptible to lysis by NK-cells as a result of deficiency of MHC I molecules could be protected by transfection of MHC I alleles. This experiment provided formal demonstration of the validity of the missing self hypothesis. However, NK-cells under persistent stimulatory signals, below the level of full activation, become hyporesponsive or “anergic” (i.e., chronic stimulation induces loss or responsiveness to NK-cells [disarming model]).^{578,579} Another possibility (arming model) assumes that MHC class I inhibitory receptors induce functional maturation and in their absence the NK-cells remain immature (i.e., hyporesponsive).

TABLE 13.2 NATURAL KILLER CELL RECEPTORS AND CD DESIGNATION

A	KIRs	B	LIRs/ILTs
CD158a	KIR2DL1	CD85a	LIR3 (ILT5)
CD158 b1/b2	KIR2DL2/L3	CD85b	ILT8
CD158c	KIR2DS6	CD85c	LIR8
CD158d	KIR2DL4	CD85d	LIR2 (ILT4)
CD158 e1/e2	KIR3DL1/S1	CD85e	LIR4 (ILT6)
CD158f	KIR2DL5	CD85f	ILT11
CD158g	KIR2DS5	CD85g	ILT7
CD158h	KIR2DS1	CD85h	LIR7 (ILT1)
CD158i	KIR2DS4	CD85i	LIR6
CD158j	KIR2DS2	CD85j	LIR1 (ILT2)

CD158k	KIR3DL2	CD85k	LIR5 (ILT3)
CD158z	KIR3DL7	CD85l	ILT9
		CD85m	ILT10

Note: See also Figure 13.20 for structural classification. (Designations were assigned during the seventh HLADA Workshop, Harrogate, UK, June 2000.)

ILT, immunoglobulin-like transcript; KIR, killer cell immunoglobulin-like receptor; LIR, leukocyte immunoglobulin-like receptor.

From Mason D. CD antigens 2001. *Immunology* 2001;103:401-406, with permission.

FIGURE 13.20. Natural killer (NK) cell cytotoxicity: the missing self. NK-cell cytotoxicity is a delicate balance between activating receptors and inhibitory receptors. Both (whether of the immunoglobulin SF or C-type lectin) have HLA class I specificity, although some receptors recognize nonmajor histocompatibility complex molecules. The presence of activating receptors against normal cells causes no problem as long as the NK-cells possess at least one inhibitory receptor, the signal of which is always dominant. However, with alterations of the structure of a class I molecule or complete loss of the molecule, the binding of the inhibitory receptor is abolished and the activating signal remains unopposed. This is the essence of the missing self hypothesis. KAR, killer-activating receptor; KIR, killer Ig receptor. (From Kärre K. How to recognize a foreign submarine. *Immunol Rev* 1997;155:5-9.)

The effector functions of the NK-cell receptors are controlled by the transmembrane and cytoplasmic regions. The inhibitory receptors have ITIMs in their cytoplasmic tails and recruit SHP-1 phosphatase. Activating receptors have a short cytoplasmic region, but for signaling, they borrow the function of ITAMs by associating with adaptor molecules such as DAP12 (TYROBP). Association is mediated by a positively charged residue of the receptor and an oppositely charged (i.e., aspartate) residue of the adaptor.⁵⁸⁰ Further research into the regulation of NK-cell function by the NK receptors is expected to expose new initiatives for investigating tumor immunosurveillance^{581,582} and autoimmunity.⁵⁸³ In hematology specifically, the manipulation of receptor-ligand interactions may help in allogeneic bone marrow transplantation to prevent leukemia relapse and graft versus host disease.^{584,585} and ⁵⁸⁶

Cytotoxicity of Natural Killer Cells

Two major mechanisms are used by NK-cells to kill target cells and both require contact with their targets. One pathway involves proteins released from granules by the process of exocytosis such as perforin (see section "Cytotoxic T Lymphocytes") or serine proteases, the granzymes with various substrate specificities. The other pathway involves engagement of death receptors (e.g., FAS/CD95) on target cells, with their cognate ligands (FASL) on NK-cells.⁵⁸⁷ Engagement of the NK-cell with its targets is mediated by the NK-cell receptors (see above).

Natural Resistance

NK-cells are one of the main effectors of innate immunity. Their role against viral infections has been well documented.⁵⁸⁸ NK-cells selectively lyse virally infected cells but spare noninfected cells. The mechanism of natural resistance against viral infections may involve direct lysis of the infected cells or production of TNF- α , which stimulates NK-cell activity. A patient with selective deficiency of NK-cells has been described who had life-threatening viral infections.⁵⁸⁹ NK-cells also play a role against certain intracellular parasites, such as *Toxoplasma gondii*. Production of TNF- α and IL12 activates NK-cells for production of IFN- γ , which is important for macrophage activation in the defense against intracellular parasites.⁵⁹⁰

Regulation of Adaptive Immunity

NK-cells enhance responses of B- and T-cells during the early stages of an immune response. As a result of stimulation by IL12, produced by macrophages in response to infectious agents, NK-cells produce large amounts of IFN- γ .⁵⁹¹ IFN- γ acts on macrophages and enhances their antigen-presenting function by increasing expression of class II antigens. IFN- γ is important in directing T-cell differentiation to Th1 cytokine responses. Induction of predominantly Th1 responses leads to enhancement of cell-mediated immunity. Finally IFN- γ activates macrophages enhancing their microbicidal function.

Natural Killer Cells: Malignancies and Bone Marrow Transplantation

NK-cells provide surveillance against tumor cells and virus-infected cells.⁵⁶⁵ In patients with X-linked lymphoproliferative disease⁵⁹² or deficient NK activity,⁵⁹² there is a high incidence

P.311

of cancer.⁵⁹³ Nude mice are T-cell deficient, but have normal NK activity, and no increased susceptibility for development to malignancies. There is a positive correlation between NK-cell activity and survival time without metastasis in patients with solid tumors.⁵⁹⁴ Decrease of NK-cell activity has been detected in patients with malignant lymphoma, in patients before relapse of leukemia, and also in women with breast cancer and metastasis to regional lymph nodes. Acceptance of organ grafts in the F1 progeny of inbred strains of mice results from the fact that the F1 animals express co-dominantly the class I antigens from both parents, and therefore, the F1 T-cells recognize them as self but reject bone marrow stem cells from either parent.^{595,596} This is known as hybrid resistance mediated by NK-cells but not T-cells.

After bone marrow transplantation the NK-cells engraft during the first few weeks.^{597,598} In one third of the patients after autologous or allogeneic bone marrow transplantation, a minor NK subpopulation (CD56⁺/CD16⁻) was markedly expanded (up to 40% of peripheral blood lymphocytes).⁵⁹⁹ NK activity helps the acceptance of the graft by controlling viral infections, eliminating leukemic cells, or stimulating hematopoiesis.⁵⁹³

Regulation of Hematopoiesis

Existing evidence suggests that NK-cells exert both inhibitory and stimulatory effects on hemopoietic progenitors. These effects are mediated predominantly by the release of cytokines from NK-cells rather than by cytotoxicity.

Strong evidence exists that an increase in the number of LGLs is associated with anemia or granulocytopenia. NK-cells inhibit in vitro granulocytopenia in the granulocyte-macrophage colony-forming cell assay.⁶⁰⁰ NK-cells also exert a promoting effect on hematopoiesis, however, and the net effect may actually depend on the stage of maturation of the progenitor cells.⁶⁰¹

In some patients with neutropenia, there is an increase of NK-like cells in the bone marrow but not in the peripheral blood.

These cells can be identified only by immunophenotyping.⁶⁰²

Decidual Natural Killer Cells

A unique subset of CD56^{bright} NK-cells accumulates in the maternal decidua in direct contact with fetal trophoblasts.⁶⁰³ These NK-cells are not derived from peripheral blood and produce IL8 and interferon-inducible protein-10 chemokines. They secrete a variety of angiogenic factors, induce vascular growth in the decidua, and possess low or even inefficient cytotoxic abilities and overall orchestrate developmental processes in the fetal-maternal interface.

Natural Killer Cell Proliferations

Artificially five to seven times the normal number (250 to 450/ μ l), is believed to represent a lymphoproliferative disease of LGL if it persists for longer than 3 months.⁶⁰⁴ Some of the most common clinical presentations are fever, infections, neutropenia, anemia, and thrombocytopenia. Mortality was associated with moderately elevated counts of LGLs (2,000 to 3,000/ μ l) and very high counts (more than 7,000/ μ l), which indicates that LGL proliferations are, in general highly heterogeneous.

Cytogenetic abnormalities have been detected, and in LGL cases that are CD57⁺ (and therefore express TCRs), rearrangements of TRB@ genes are detected in most of the cases.⁶⁰⁵ Because these cases are also associated with widespread involvement of several organs, such as the spleen, liver, and bone marrow, the term LGL leukemia has been proposed. The predominant phenotype of the LGL is CD57⁺ (HNK-1⁺)/CD3⁺ and these patients often have rheumatoid arthritis, neutropenia, and splenomegaly, a combination resembling Felty syndrome. Anemia and thrombocytopenia are not uncommon, and serologically, rheumatoid factor, antinuclear antibodies, hypergammaglobulinemia, and immune complexes are detectable.

Two major subtypes have been distinguished in terms of clinical presentation and the phenotype of the cells.^{606,607} and ⁶⁰⁸ The LGLs in type A, also known as T-LGLs, are CD57⁺/CD3⁺/CD8⁺/CD2⁺, and those in type B, also known as NK-LGLs, are CD56⁺/CD3⁺/CD8⁺/CD2⁺. Patients with T-LGL (CD57⁺) often may have neutropenia (84%), rheumatoid arthritis, and autoantibodies. However, these clinical and serologic findings in patients with T-LGL could not be confirmed in other studies.⁶⁰⁹ NK-LGL leukemias are observed in younger patients and run an aggressive course.⁶¹⁰ The most characteristic clinical presentation is hepatosplenomegaly and involvement of the gastrointestinal system with ascites. The course of the disease is acute, and often the patients die within 1 to 2 months after diagnosis.

NATURAL KILLER T-CELLS

Natural killer T-(NKT) cells have been identified as a novel lymphocyte lineage, which, in humans expresses the cell-surface marker CD161 (NKR-PIA) structurally related to several other proteins encoded by the NK-gene complex, including CD94, NKG2, and CD69.⁶¹¹ Because α -glycosphingolipids are not detected in mammals, the α -Gal-Cer probably mimics self-antigens that are recognized by NKT-cells.

The NKT-cells express an invariant V α -14 receptor (V α -14i TCP), which is used only by the NKT-cells but not by T-cells. The expression of an invariant TCR suggests that the selection is mediated by a monomorphic rather than polymorphic MHC molecule.⁶¹² The NKT-cells are selected from DP CD4⁺/CD8⁺ thymocytes expressing CD1D.⁶¹³ Their thymic CD4⁺CD8⁺ V α 14i precursors, recognize endogenous CD1D-associated glycolipids on other CD4⁺CD8⁺ thymocytes and are selected to undergo a maturation program involving sequential expression of CD44 and NK-related markers such as NK1.1.⁶¹⁴ After their selection, the V α 14i precursors are exported and acquire the NKT phenotype in the periphery.⁶¹⁵ They migrate to the liver and from there to sites of inflammation responding to stimuli, i.e., chemokines and glycolipids. They have a surface phenotype characteristic of recently activated or memory T-cells, even when the cells are obtained from cord blood,⁶¹⁶ consistent with the postulated autoreactivity of the NKT-cells.

Inhibitory receptors prevent unchecked autoreactivity for CD1D DCs.⁶¹⁷ The NKT-cells expressing V α 24 in their TCR play a critical role in immune responses, inhibition of tumor development, and protection from autoimmune disease development.^{618,619} These cells have cytolytic function and rapidly induce cytokines after stimulation and activate other cells (i.e., NK-cells, T-cells, B-cells, and macrophages).

In humans the CD4⁺ V α 24i cells preferably produce IL-4, which is believed to regulate Th1/Th2 differentiation,^{620,621} but the Th1 versus Th2 polarization is more complex and depends on additional factors such as the number of antigenic stimulations with a shift to Th2 after multiple challenges.^{622,623} Th2 cytokine prevents the development of type I diabetes in mice with genetic predisposition,⁶²⁴ as well as allergic encephalomyelitis in another strain susceptible to the

development of this disease.⁶²⁵ In experimental autoimmune diseases that develop spontaneously, there is a direct correlation between the development of the disease and the decline of V α -14 cells.⁶²⁶

Selective reduction of V α 24 cells has also been shown in patients with systemic sclerosis,⁶²⁷ systemic lupus erythematosus, rheumatoid arthritis,⁶²⁸ and type I diabetes.⁶²⁹ Stimulation of NKT-cells by α -Gal-Cer in animals triggers secretion of large amounts of cytokines (IFN- γ , IL4, IL2, IL5, etc.).⁶³⁰ The fact remains, however, that NKT-cells promote Th2 responses and suppress Th1-dominant autoimmunity.⁶³¹

P.312

Others have found that NKT-cells are not critical in the IL12-mediated rejection of tumors,⁶³² and it appears that the conflicting results in the literature about the role of NKT in tumor responses are due to complex factors, including the types of tumors and their microenvironment, and functionally different subsets of NKT-cells.⁶³³ NKT-cells have been implicated in protective immunity against several pathogens, i.e., mycobacteria⁶³⁴ and malaria parasites.⁶³⁵ In conclusion, NKT-cells are phenotypically and functionally heterogeneous, endowed with cytolytic and cytokine secretion functions and regulation of several functions of the immune response that are related to host defenses against infections, autoimmunity, and tumor immunity.

They have been called “nonconformist” and “unconventional” because they are suited to get involved in such a great variety of homeostatic disequilibrium conditions of the host.

Th17 CD4⁺ Cells

Effector CD4⁺ T-cells develop in response to cytokines elicited from cells activated during an immune response. as in the development of Th1 and Th2. Another CD4 T-cell lineage known as Th17, represents an additional CD4⁺ T-cell effector cell, characterized by a distinct profile of effector cytokines such as IL17, IL17F, and IL6.⁶³⁶ In the absence of IFN- γ and IL4, IL23 induces naive precursors to differentiate to Th17 cells.⁶³⁷ TGF- β is critical for up-regulation of the IL23 receptor, thus conferring responsiveness to IL23.⁶³⁸ IL6 probably is also needed in cooperation with TGF- β for Th17 cell development from naive T-cells.⁶³⁹ Others, however, have shown that TGF- β alone is a critical factor for differentiation of IL17-producing effector cells.⁶⁴⁰ The role of IL23 may be important for stabilizing the Th17 phenotype in chronic inflammation⁶⁴¹ and control of certain pathogen-induced diseases not covered by Th1 and Th2.⁶⁴²

Chapter 14

Effector Mechanisms in Immunity

Frixos Paraskevas

MAJOR HISTOCOMPATIBILITY COMPLEX

The function of the immune system is under genetic control¹ and molecular genetic studies have helped to elucidate the mechanism of gene regulation of immune functions.² The genes that regulate immune functions are found in the chromosomal region of the major histocompatibility complex (MHC) involved in defining histocompatibility for transplantation, and these antigens have been given specific names in different species, i.e., human leukocyte antigens (HLAs) in humans and histocompatibility-2 or H2 in the mouse.

The HLA complex extends approximately over 4,000 kilobases (kb) on the short arm of chromosome 6, i.e., 6p21-3, whereas the H2 complex is located on chromosome 17 and occupies a segment that is halfway between the centromere and the telomere. Approximately 180 genes have been located within the HLA region and the number grows constantly with the increase in sensitivity and sophistication of techniques of molecular biology.

The complex is divided into three regions: (a) the class I region occupies the most distal (telomeric) end of the short arm of the chromosome and spans approximately 1.8 megabases (Mb); (b) the class II region (approximately 1 Mb) occupies the most centromeric end of the chromosome; and (c) the class III region is between the other two regions² (Fig. 14.1).

Class I Region

Of the polymorphic class I genes HLA-A, HLA-B, and HLA-C, the HLA-B is the most centromeric and HLA-A is the most telomeric; the HLA-C is between the two but closest to HLA-B. There are several nonclassical class I or Ib genes that include HLA-E, HLA-F, HLA-G, HLA-H, HLA-I, HLA-J, HLA-K, and HLA-L, as well as several pseudogenes and gene fragments.^{2,3,4,5} Pseudogenes give products that do not associate with β_2 microglobulin (β_2m), probably as a result of deleterious mutations, and the gene fragments are not expressed because the genes are severely disrupted. In the human MHC class I region, which spans 1.8 Mb from the MICB gene to the HLA-F gene at the telomeric end of the HLA region, there are 118 genes (73 known and 45 new genes), i.e., one gene for every 15.2 kb. The G+C content on average is 45.8%⁶ and contains three classical HLA class I genes, HLA-A, HLA-B, and HLA-C; three nonclassical class I genes, HLA-E, HLA-F, and HLA-G; and two of the nonclassical MHC class I chain-related (MIC) genes MICA and MICB. The class I region also contains 50 non-HLA genes. A number of diseases including Behçet syndrome, ankylosing spondylitis, ulcerative colitis, Takayasu arteritis, and Hashimoto thyroiditis, are associated with a particular class I allele. The large-scale genomic sequencing has greatly facilitated the clarification of gene organization and identification, as well as mapping of the disease-susceptible genes.⁷ A total of 758 microsatellite repeats have been identified consisting of two, three, four, or five nucleotides. They can be used as markers for mapping the exact location of the disease that is associated with the HLA genes. Class I genes

are composed of eight coding sequences or exons that are separated by noncoding sequences or introns. Of the eight exons that correspond to the domains of the protein the first encodes the hydrophobic N-terminal precursor or leader sequence and the second, third, and fourth exons encode the three extracellular domains. A fifth exon encodes the hydrophobic transmembrane segment and the basic residues that act as an anchor. The sixth and seventh exons are small, coding for the cytoplasmic domain of the molecule. The second and third exons are the most polymorphic whereas the fourth exon is the most conserved.

Class II Region

The MHC class II molecule consist of two chains, α and β , each having two extracellular domains $\alpha 1$, $\alpha 2$ and $\beta 1$, $\beta 2$ and a transmembrane domain, which anchors the molecule to the cell membrane.⁵ A peptide-binding groove formed by the $\alpha 1$ and $\beta 1$ domains of the molecule presents the foreign peptides to $CD4^+$ lymphocytes. The nonclassic molecules are detected in internal membranes such as lysosomes. The human class II molecules were originally defined by mixed lymphocyte cultures and because participation of class I, HLA-A, HLA-B, and HLA-C was excluded, the new region was called HLA-D and its specificities were defined with serological reagents obtained from multiparous women. The HLA-D (DR) is located on the centromeric (left) side of the HLA-B and consists of three subregions which in the direction of the telomere are HLA-DP, HLA-DQ, HLA-DR. The genes of the class II region have a 40% G, C content with only one gene for every 25 kb, i.e., much lower in density than class I (15.2/kb) or class III (14.3/kb) regions. The α chain is composed of five exons and the β chain consists of six exons. The sequence of the α chain contains five regions: i.e., (a) signal sequence, (b) $\alpha 1$ domain, (c) $\alpha 2$ domain, (d) transmembrane region and cytoplasmic tail, and (e) an untranslated 3' region. By comparison with murine class II genes, considerable gene expansion has apparently taken place in the evolution of human MHC. Many more α and β chains are in the human class II region and the DR molecule is homologous to the murine E molecule whereas the human DQ molecule is homologous to the murine A molecule.

The genes encoding the α and β chains of class II molecule are designated A and B, respectively, and a DR contains one A gene, three B genes, and pseudogenes.⁸ The α chain can associate with two different β chains to give two different molecules. In the DQ and DP subregions, only one set of genes (A and B) is expressed, and the genes in the other set are pseudogenes. Not all class II molecules that are encoded by these genes are polymorphic. For example, the DR α chain is not polymorphic, and the DP α shows only limited polymorphism.

Within the class II region, several genes encode proteins that are related to antigen processing. Two of them, PSMB9 and PSMB8 (previously known as LMP2 and LMP (for large multifunctional protease), are subunits of the proteasome that cleaves peptides from antigens that are present in the cytoplasm to be transported and loaded on class I molecules.⁹

Also close to these genes are the TAP1 and TAP2 genes (transporters associated with antigen presentation), which encode the proteins that transport the peptides from cytosol across the endoplasmic reticulum (ER) membrane to be loaded on class I.¹⁰ The DR subregion has several haplotypes. The DRA gene is the most telomeric of all class II genes.

The DQ subregion has two pairs of DQ genes, but one of them is nonfunctional. The DP also has two pairs of genes, but only one is expressed, and the others are pseudogenes. Within the class II region are the genes for the nonclassical molecules DMA and DMB, which are distantly related to classical loci (approximately 30% amino acid identity) and must have duplicated from them at an early stage. There are no polymorphic variations in humans in the DM gene. The DN and DO genes, as does DM, may play a role in peptide editing.¹¹

P.314

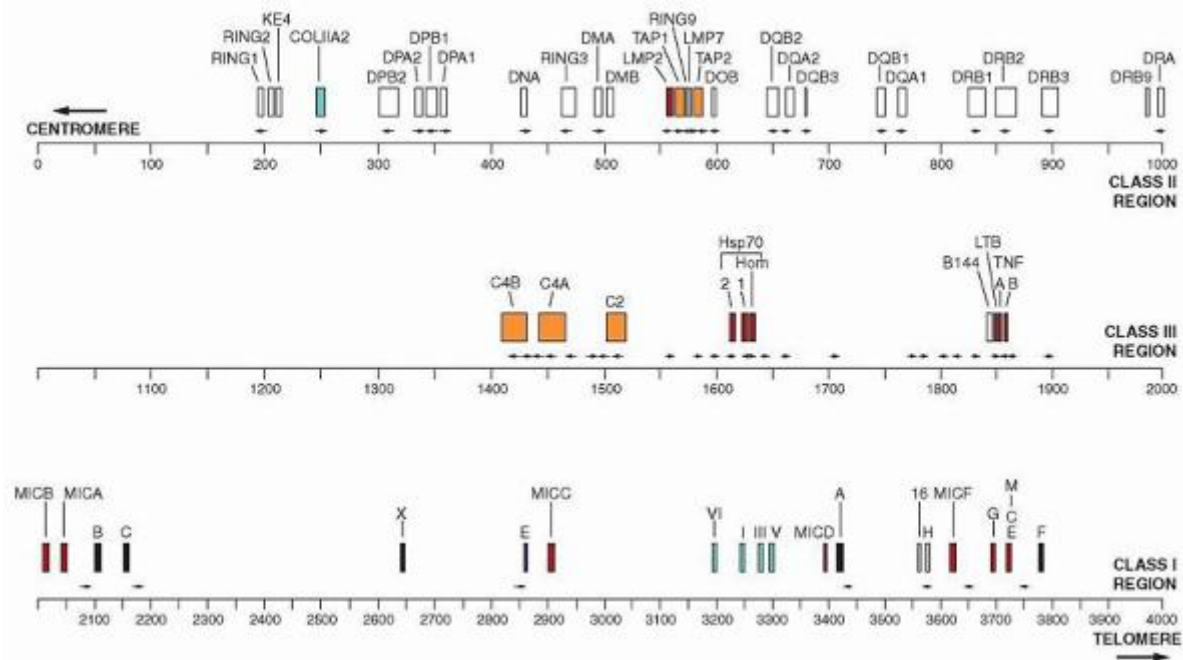

FIGURE 14.1. The human major histocompatibility complex contains genes that are grouped in three regions. Closest to the centromere is the class II region, followed by the class III region, and finally the class I region. Within the class II region are proteasome genes and TAP-1 and TAP-2 genes. The class II genes are located from the centromere in the order DP, DQ, and DR. The class III region contains genes of the complement system heat-shock protein 70, tumor necrosis factor- α , and tumor necrosis factor- β . The class I region contains the genes for the α chain of the HLA-A, HLA-B, and HLA-C molecules and the genes that encode the newly discovered class Ib molecules, such as HLA-E, HLA-F, HLA-G, HLA-H.

Other genes in the class II region are antigen-processing genes. They constitute a cluster of four genes. Two of them, TAP1 and TAP2, are adenosine triphosphate (ATP)-binding cassette (ABC) transporters (for structure and function, see section “Antigen Processing and Presentation”). The proteasome genes, PSMB9 and PSMB8, are both members of the catalytic subunit of proteasome (see section “Antigen Processing and Presentation”).

Class III Region

The class III genes encode proteins that do not participate in antigen presentation, such as the genes of certain components of the classical and alternative complement pathways (C4, C2, and B), as well as the genes of tumor necrosis factor TNFA and TNFB, HSP70 and the 21-hydroxylase-producing gene (CYP21A2). Telomeric to the class III region is a group of genes that encode the proteins involved in inflammation or infection, such as the tumor necrosis factor (TNF)- α , TNF- β (LTA), and LTB cytokines. It has been proposed that this region should be named the class IV region.¹²

The genes of class I and class II regions are present in multiple alleles or, in other words, alternate forms that are defined by distinct DNA sequences. The combination of all HLA-I and HLA-II alleles is known as the haplotype. Because the HLA genes are expressed co-dominantly, each individual therefore inherits two haplotypes. Each class I locus has several alleles, and, according to an adopted nomenclature, each allele is defined by its locus, an asterisk, and a four-digit number. The number that defines the allele relates to the serologically defined antigen that is detected on a molecule that is synthesized by the allele (first two digits) and allows discrimination between closely related alleles (last two digits). For example, the B27 locus has at least seven identifiable alleles, which are defined as HLA-B*2701 through HLA-B*2707.

Major Histocompatibility Complex Class II Molecules

Class II molecules are encoded by the MHC genes HLA-A, HLA-B, and HLA-C. Another group of molecules that are structurally homologous to the class I molecules (44% to 82%) has been detected. These molecules are known as class I-b¹³ to distinguish them from the classical class-I molecules that are now called class I-a. Some of the class I-b molecules are encoded by the MHC-linked genes, HLA-E, HLA-F, and HLA-G, whereas others, such as CD1 and certain CTMV genes, are encoded by non-MHC genes. The MHC class II molecule is a heterodimer consisting of an alpha (α) and a beta (β) chain both encoded by the MHC, whereas the class-I molecule is a heterodimer consisting of an α -chain and the β 2m of 12 kD¹⁴ (Fig. 14.2). The α chain is divided into three extracellular domains, α_1 , α_2 , and α_3 . Except for the domain that is most distal to the membrane (α_1), the other two consist of a loop that is formed by a disulfide bond. The transmembrane portion

consists of hydrophobic residues and terminates in five amino acids, including three arginines (Arg) and one lysine (Lys) that anchor the molecule to the membrane. The variable residues are clustered in seven sequences,¹⁵ three of which are in the α_1 domain and four of which are in the α_2 domain. The α_3 domain is highly conserved. Amino acids 223, 227, and 229 in the α_3 domain are critical for interaction with CD8.¹⁶

The structure of β_2m consists of one Ig domain with one disulfide bond and is highly homologous between species and homologous to the CH₃ domain of human Ig and to the α_3 domain of the class I molecule to which it is noncovalently associated.

The L chain plays an important role in the transport of the α chain, because cells that are derived from patients with Burkitt lymphoma, who are unable to synthesize β_2m , do not express

P.315

HLA antigens. All three extracellular domains of the α chain are in contact with β_2m .¹⁷

FIGURE 14.2. Structure of class I and class II major histocompatibility complex molecules. The class I molecule is a heterodimer of a heavy chain or α chain and a noncovalently associated light chain, β_2 microglobulin (β_2m). The α chain consists of three domains: the N terminal α_1 , followed by α_2 and an immunoglobulinlike α_3 domain. The β_2m protein is homologous to the CH₃ immunoglobulin domain, located underneath the α_1 domain. The class II molecule is a heterodimer of two chains, α and β . The N-terminal polymorphic domain from each chain forms the peptide groove.

β_2m is present on all cells, and small amounts are shed into body fluids. Because of its low molecular weight, it is filtered out rapidly by the glomeruli, but it is re-absorbed from the kidney tubules and then catabolized. In patients with kidney diseases in whom tubular function is impaired, increased amounts of β_2m are detected in the urine. It is also found in increased quantities in the serum and in other fluids from individuals with certain malignancies, such as lymphomas and myelomas.

The crystallographic structure of HLA class I markedly helped the understanding of the function of the molecule.¹⁸ β_2m and the α_3 domain form the base that supports the α_1 and α_2 domains. Each of the α_1 and α_2 domains consists of four antiparallel β strands and one α helix. This structure is similar to that of the class II molecule shown in Figure 14.3. Seeing them from the top, the way the T-cell receptor (TCR) does, the juxtaposition of the two domains isolates a longitudinal cavity, which is commonly known as the groove, which is 30 Å long and 12 Å wide in the middle. Its floor consists of the β -pleated sheets of the α_1 and α_2 domains ("intramolecular dimer"), and the side walls are two α helices, one each from the α_1 and α_2 domains. The MHC I groove tapers at both ends to a width of approximately 5 Å and then is blocked completely by bulky amino acid side chains (Tyr84 and Trp167), which are conserved in virtually all class I MHCs.¹⁷ It is lined by a series of pockets (A to F), which are sites of interaction with the peptide.

The polymorphism of the class I molecule is particularly concentrated in the groove,¹⁹ and yet certain residues are strongly conserved among virtually all class I molecules. These residues surround, on the left and right ends of the groove, the first and last pockets (A and F), which bind the N terminus and C terminus of the peptide, respectively. The other pockets line the central portion of the groove and are also involved in peptide binding.²⁰ Many of the MHC side chains that contribute to the formation of the pockets are polymorphic, and, as a result, the architecture of the pockets varies among the class I molecules. In some molecules, a bulky side chain may block a pocket that is open in another molecule. In other molecules, a smaller polymorphic amino acid may extend the size of the pocket.²¹ This may explain the fact that there are sequence restrictions on the final residue of the peptides.²² A given groove can bind hundreds or even thousands of different peptides, which are identical or homologous at only a few side-chain positions.^{22,23} Side chains from the MHC residues protrude into the groove from the α helices and the β sheet and form an irregular surface along the length of the groove, so that side pockets extend out from the main cavity.²⁴

FIGURE 14.3. Drawing of a major histocompatibility complex (MHC) class II molecule-peptide complex. The MHC class II molecule forms a groove with walls that are made by α helices from the $\alpha 1$ and $\beta 1$ domains and a floor by β -pleated sheets formed by antiparallel β strands from each chain. The peptide is usually long (15 to 25 residues) and projects from both ends, which are not closed (as with MHC class I molecules).

A class I molecule usually accommodates within the groove peptides that are nine amino acids long and that bind with an affinity that is 100- to 1,000-fold higher than longer or shorter peptides. The binding of the peptides is mediated by certain amino acids that are known as anchor residues (sequence-dependent binding). The set of anchor residues that binds to a certain MHC molecule is known as a sequence motif. It allows the identification of peptides within a complex immunogen that are likely to bind to class I MHC. Hydrogen bonds between the peptide and conserved MHC I side chains provide stability to the peptide binding, which is sequence-independent.²⁵ A prominent kink or arch is found approximately one third of the way from the N terminus, which lifts the peptide up, away from the main floor.

The arch that is formed by the peptide contributes to the antigenic specificity of the complex, despite the fact that 73% to 83% of the peptide surface is buried by the MHC in the complex. A number of side chains that do not affect the binding of the peptide to the MHC contribute strikingly to the TCR binding (flag side chains).²⁶ Antigenic specificity is provided not only by the flag side chains, but also by the conformational flexibility of the

P.316

peptide. Peptides that differ in length are usually accommodated by buckling at the center of the cleft.

In many different peptides, the flag side chains are prominently exposed at the surface of the complex and provide TCR with a direct access to the antigenic identity of the bound peptide. The upward-pointing orientation of flag side chains, such as P1 and P4, is conserved in many different HLA-A2-peptide complexes. Some peptides are sandwiched between the MHC and the TCR and make contact with both molecules.

In conclusion, the requirements to satisfy the vast and exquisite specificity of the TCR are provided by the peptide-MHC complex, which is formed with only a small number of nonvariable MHC molecules. The peptide binding is contributed to peptide-MHC complex formation by sequence-dependent binding and is supplemented by sequence-independent interactions of the primary anchor side chains in specific MHC pockets. These interactions, although constraining the conformation of class I-bound peptides at both ends, leave the center relatively free to adopt a conformation that optimizes the secondary anchor and other interactions with the MHC molecule. The MHC molecule is a remarkable tool with which evolution has achieved so much by so little.

Class II Molecules

The second group of MHC genes, the class II genes, encode glycoproteins that regulate cell interactions in the immune response. The genes reside in the D region of the MHC in humans and in the I region of the MHC in the mouse. The class II proteins are also referred to as Ia antigens (immune response antigens). They are not as widely distributed as the class I molecules. They are found in high concentrations on B lymphocytes and on a subpopulation of macrophages, as well as on dendritic cells (DCs). On T cells, small quantities are detectable under conditions that are associated with T-cell activation in vitro or during the course of certain diseases. However, human T cells may acquire Ia antigens from other cells, and murine T lymphocytes acquire Ia antigens passively from macrophages.²⁷ A variety of cell types expresses Ia antigens in response to interferon (IFN)- γ including vascular endothelial cells,²⁸ melanoma cells, and brain astrocytes.

The human class II molecule is a heterodimer of two noncovalently linked proteins, an α chain (34 kDa) and a β chain (29 kDa).²⁹ Each chain can be divided into four domains, two of which form the extracellular region in each chain, and the third and fourth correspond to the transmembrane segment and the intracellular part of the chain, respectively. With the exception of the α_1 domain, the other three domains (α_2 , β_1 , and β_2) are loops that are formed by disulfide bonds. The α_2 and β_2 domains are homologous to the Ig constant domain. The human DR, DQ, and DP β chains and the DQ α chains are polymorphic, and only the DR α chains and DP α chains seem to be invariant (Ii).

The assembly and expression of class II molecules involves a third chain that is known as Ii (CD74),³⁰ which is encoded by a gene on chromosome 5. Complementary DNA clones have been isolated, and the amino acid sequence indicates that the Ii chain is a type II transmembrane protein; that is, the N terminal is inside the cell. When synthesized in the absence of MHC class II molecules, the Ii chain exists as a trimer or even as a hexamer.³¹ The complex of the Ii chain with the class II α and β chains is a nonamer that consists of a core of three Ii chains, each one associated with an α and β class II dimer.³²

However, a peptide from the N terminal two thirds of the I chain, which is known as a class II associated invariant chain peptide (CLIP), inhibits the binding of the antigenic peptides to the class II molecule.³³ The assembly of the class II Ii chain complex occurs in the ER. Class II α/β dimers that are formed in the absence of the Ii chain are poorly expressed on the cell surface and remain in the ER, as they cannot maintain their normal folded structure. In the assembly of multimeric proteins, certain ER-associated proteins stabilize the partially folded subunits, thus preventing aggregation. These proteins are known as chaperons.³⁴

Another ER-resident protein that associates with class II chains is calnexin.³⁵ The class II molecule is transported to the Golgi apparatus and enters the endosomal-lysosomal system, where it is loaded with an antigenic peptide on its way to cell surface expression³⁶ (see section "Processing Antigen for Class II Presentation").

The polymorphism of the class II molecule is localized in the α_1 and β_1 domains. HLADR, HLA-DQ, and HLA-DP have three hypervariable regions in their β_1 domains, whereas the α_1 domain of HLA-DQ has only one hypervariable region.³⁷ The CD4 molecule interacts with amino acids 134 to 148 of the β_2 domain.^{38,39}

The crystallographic structure of the HLA-DR1 molecule reveals similarities with the structure of the HLA class I molecule.⁴⁰ The α_1 and β_1 domains form the peptide-binding groove (Fig. 14.3). As with the class I molecule, the floor is the β -pleated sheet, and the walls are the α helices from the α and β chains. The first two hypervariable regions are found on the floor, whereas the third hypervariable region is on the α helix of the β chain. The class II groove can accommodate longer peptides (10 to 25 residues), because, in contrast to the class I groove, it is open on both ends.⁴¹ Long peptides, which range from 15 to 25 residues, can bind in an extended conformation, projecting out of both ends of the groove. This contrasts with class I peptide binding, in which mostly nonamers bind with extended, but kinked, conformations, and the N and C termini of the peptides are bound to groove pockets. In class I molecules, the residues at the end of the groove are conserved, imposing tight binding for the peptides, but in the class II molecules, conserved residues are located at different intervals along the groove, making the peptide-binding side chain independent. The peptides in class II bind through the central region, and their N- and C-terminal ends protrude from the open ends of the groove.⁴⁰

Evidence from crystallographic studies indicates that the class II molecules exist as tetramers on the cell surface.⁴² Therefore, the geometry of the TCR-MHC peptide interaction places the complementarity-determining region (CDR)-3 loops of the $V\alpha$ and $V\beta$ chains of TCR in contact correspondingly with the N- and C-terminal ends of the peptide, whereas the CDR-1 and CDR-2 loops are in contact with the β_1 and α_1 domains. Ligand-induced dimerization of receptors is a general feature for cell activation and involves most of the known receptors.

MAJOR HISTOCOMPATIBILITY COMPLEX MOLECULES: NONCLASSICAL

Class I: Human Leukocyte Antigen-E, Human Leukocyte Antigen-F, and Human Leukocyte Antigen-G

The nonclassical class I HLA molecules are HLA-E, HLA-F, and HLA-G, and are also known as class Ib, to distinguish them from class Ia (HLA-A, HLA-B, and HLA-C). They constitute one group of the class Ib molecules, the other being the CD1 molecules, a non-MHC-linked group with genes that are located in chromosome 1. Class Ib molecules show limited polymorphism, and although their tissue expression is low, they play a significant role as molecules of antigen recognition.^{42,43} They form heterodimers with β_2m and have conserved key residues that interact with CD8.

Human Leukocyte Antigen-E

The structure of HLA-E is similar to that of the class Ia molecules,⁴⁴ with the β_2 and CD8 interaction sites being conserved.
P.317

The size of the HLA-E groove is structurally similar to that of the classical molecules. It preserves the crucial positions within the groove, of certain residues that determine the preference for binding the peptide. Peptides occupy all the pockets and as a result the HLA-E keeps the peptide tightly bound. The secure fastening of the peptides reinforces the favorable selection of a specific peptide.⁴⁵

The leader peptides of class Ia HLA molecules enter the cytosol after they are cleaved from the coding sequence and are then transported to the inside of the ER by the TAP transporter, to be loaded onto HLA-E.⁴⁶ Detection of HLA-E on the cell surface of $CD56^+CD16^+$ natural killer (NK) cells can be achieved accurately with HLA-E tetramers⁴⁷ (further information regarding HLA-tetramers can be found in Appendix A). The tetramers react with the CD94/NKG2A receptors, and HLA-E is a major ligand for this inhibitory receptor on NK cells⁴⁸ (see Chapter 13). Recognition of HLA-E by this receptor inhibits activation of NK cells and thus protects cells from being killed by the cytotoxic NK cells.⁴⁹ Because HLA-E is expressed with the leader peptides of MHC class I molecules, its presence on the cell surface sends signals to surveilling NK cells that there is no "missing self," that is, an absence of MHC class I molecules, and thus protects cells from being killed by NK cells. Rare $CD8^+$ T cells have been detected that bind HLA-E directly through the TCR.⁵⁰ Subversion of the protective mechanism that is conferred by HLA-E has been demonstrated with cytomegalovirus (CMV).

The leader peptide of the CMV glycoprotein gpUL40 is the same as the class Ia leader peptides, and, as a result, it binds to HLA-E.⁵¹ Although CMV down-regulates MHC class I expression on infected cells, thus rendering them susceptible to lysis by NK cells ("missing self"), it concomitantly up-regulates HLA-E, thus inhibiting lysis. This mechanism represents an escape route for CMV.

Another example of subversion of HLA-E function is the binding of heat-shock protein, HSP60, signal peptide.⁵² HSP60 is present in all normal cells and in eukaryotic cells and serves as a mitochondrial chaperon. Stress stimuli, such as heat, nutrient deprivation, toxic chemicals, and inflammation, up-regulate HSP60. Binding of the HSP60 signal peptide to HLA-E results in loss of its recognition by the CD94/NKG2A receptor and renders stressed cells susceptible to NK-cell lysis.

Human Leukocyte Antigen-F

The structure of HLA-F is not known in great detail, but some predictions have been made based on the known structure of HLA-E and the sequence analysis of HLA-F.⁴³ HLA-F tetramers stain monocytes and bind to Ig-like transcript (ILT) 2 and ILT4.^{47,53} ILT molecules, also known as leukocyte Ig-like receptors, are structurally and functionally related. They recognize HLA class I allotypes, rather than individual peptide-MHC complexes, and are expressed on monocytes, macrophages, and DCs. HLA-F is retained intracellularly, empty, but reaches cell surface after acquisition of its ligand.⁵⁴

Human Leukocyte Antigen-G

HLA-G shows limited polymorphism, restricted tissue distribution, and low levels of expression and therefore belongs to the nonclassical MHC molecules. In the HLA-G gene, all of the regulatory elements of HLA class I genes are missing, thus suggesting that its expression and distribution are uniquely regulated.⁵⁵ HLA-G is expressed strongly in extravillous cytotrophoblasts, endothelial cells of fetal vessels, and in other tissues, such as the thymus. It is not detected in syncytiotrophoblasts. Messenger RNA (mRNA) of HLA-G is detected in peripheral blood T and B cells, keratinocytes, fetal liver, and other cells.⁵⁶ Tetrameric complexes of HLA-G bind to monocytes, especially the CD16⁺ subpopulation, and react with ILT2 and ILT4 receptors, but they do not bind T, B, or NK cells.^{47,57}

The HLA-G gene transcribes six different transcriptional isoforms, membrane bound and soluble forms.⁵⁶ The complete transmembrane isoform HLA-G1 consists of three extracellular domains, whereas isoforms HLA-G2, HLA-G3, and HLA-G4 have one or two domains.

The peptide-binding pocket residues determine the specificity of the molecule. The isoforms HLA-G2 and HLA-G3 lack the α_2 domain and, as a result, do not bind peptides. They also do not bind the CD8 molecule and are therefore unable to present peptides. The HLA-G molecule has an antigen-presenting potential, but, because of the limited diversity of the peptides and its low polymorphism, the function of the molecule is rather restricted. However, it may still be sufficient, considering the limited species of viruses that infect the placenta.⁵⁶

Other than antigen-presenting functions, HLA-G may be more important for its role during pregnancy. HLA-G exerts inhibitory functions by several mechanisms. First, it binds directly to CD94/NKG2A, which is an inhibitory receptor^{58,59}; second, it binds to receptor KIR2DL4 on all NK cells that inhibit lysis of cells that express HLA-G⁶⁰; third, the leader peptide of HLA-G binds to HLA-E, which interacts with the inhibitory receptor CD94/NKG2A. HLA-G is strongly expressed in the placenta, and these inhibitory mechanisms are important for the protection of the fetus.

Class II: Human Leukocyte Antigen-DM and Human Leukocyte Antigen-DO

Human Leukocyte Antigen-DM

There are two nonclassical II proteins with their genes within the class II region, HLA-DM, with two genes, HLA-DMA and HLA-DMB on the centromeric site of TAP and PSMB genes. DMA and DMB encode the α and β chains of the DM molecule,⁶¹ which is detected in all class II expressing cells and is up-regulated by IFN- γ , together with classical class II molecules. Class II molecules associate with the Ii chain after they enter the ER and form nonameric complexes ($\alpha\beta Ii$)₃. Through the CLIP, the Ii chain prevents class II molecules from binding peptides within the ER (see details in the following discussion). The heterodimer DM is formed in the ER, and, by the time class II molecules pass through the endosomal system on the way to the cell surface, the DM protein has already arrived there by a multivesicular system that is known as the MHC class II compartment (MIIC). It is retained in MIIC by a tyrosine (Tyr)-based targeting motif (YTPL) that is located in the cytoplasmic tail of the β chain. DM transiently binds directly to the HLA class II-CLIP complex⁶² and induces the release of CLIP, whereas DM remains associated with the class II molecule until the peptide to be loaded has been found and is safely in place within the groove.⁶³

DM rescues empty HLA-II molecules from denaturation and loss of their peptide-binding capacity. Both HLA-II and DM are in an "acidic" environment, and conformational changes of both molecules seem to facilitate their interaction.⁶⁴

Another important function of the DM molecule after the removal of CLIP and maintenance of an intact three-dimensional structure of the class II molecule is the editing of peptide loading. Editing implies a selection, from a variety of available peptides, of a good peptide, which is defined by the stability of its interactions within the groove.⁶⁵ Intrinsic stability is determined by multiple hydrogen bonds between the peptide backbone and the conserved residues of the binding groove and by the anchor side chains and the specificity pockets.⁶⁶ The mechanism of the ultimate release of DM from HLA-II is not clear. It appears that DM binds more stably to an empty HLA-II than to one that contains a peptide.⁶⁷

Human Leukocyte Antigen-DO

The genes that encode the α and β chains of the DO molecule are similar to the class II genes. The DO proteins have a more

restricted distribution and are detected in B cells, DCs, a melanoma cell line, and cortical and medullary epithelial cells in the thymus.⁶⁸ Upon completion of its synthesis, DO associates with DM, and the tetramer is transported mainly to lysosomes, in which most of it is localized.^{69,70} The lysosomes that contain DO also contain class II molecules. Loading of peptides to class II is slower in the presence of DMDO tetramers, suggesting that DO is a negative regulator of DM function,⁷¹ and overexpression of DO results in accumulation of MHC class II-CLIP complexes at the cell surface. The regulation of peptide presentation by DO limits only one of the mechanisms of antigen uptake—that is, by free fluid phase—whereas membrane Ig-mediated uptake is augmented.⁷²

Major Histocompatibility Complex Class I Chain-Related Genes and Proteins

A distinct family of genes, the last and final to be detected within the MHC class I region, is known as MIC.⁷³ MICC, MICD, and MICE are in close proximity to HLA-E, HLA-A, and HLA-F, respectively. MICE and MICG are between HLA-G and HLA-F, and MICF is centromeric to HLA-G. MICC, MICE, MICF, and MICG are pseudogenes. MICA and MICB are unusually large genes (11 to 13 kb) compared to an average of 3.5 kb for HLA-A to HLA-G genes. However, their overall genomic structure parallels those of the other MHC genes and of the Ig superfamily genes in general, in which distinct functional domains are encoded by separate exons. The crystal structure of MICA shows that the molecule has a general configuration of a class I molecule, that is, a membrane proximal Ig-like C-type domain, and an α_3 domain that, with two distal α_1 and α_2 domains, together form an eight-stranded antiparallel β -pleated sheet bordered at the edges by two α helices.⁷⁴ The groove is less spacious than that of class Ia molecules, i.e., 10 Å within the first four β strands and 7 Å across the second four β strands (compared with >18 Å of classical MHC-I and 14.4 Å for CD-1). The most striking finding is that the groove is oriented down toward the membrane,⁷⁵ so that the whole molecule appears as a wilting flower.⁷⁶ Another major difference from other MHC molecules is the lack of β_2 m binding, due to restructuring of the interface of binding, which ablates the interaction.⁷⁶ The surprising findings about the structure of these proteins were matched by equally surprising findings about their function. The MIC proteins are recognized by the $\gamma\delta$ T cell, especially the V δ -1 cell, but not by the $\alpha\beta$ T cells.⁷⁷

In addition, MICA is the ligand for NKG2-D activating receptor of NK and $\gamma\delta$ T cells, triggering cytolytic responses against epithelial tumors that express MIC-A.⁷⁸ NKG2-D is the most common NK-cell receptor that is known, but it may require a synergistic action by a TCR.⁷⁹ The polymorphic residues are concentrated in the α_2 domain,⁷⁴ which apparently is re-oriented after binding with the ligand NKG2-D.⁸⁰ This ligand-induced re-positioning of the MICA molecule brings the α_1 - α_2 platform with the same polymorphic residues in contact with the NKG2-D receptor. This receptor-induced conformational change is probably facilitated by the coil of the α_1 to α_3 domains.

A number of disease associations have been detected with MIC alleles, such as ankylosing spondylitis, Behçet syndrome, psoriasis vulgaris, and Kawasaki disease. MICA and MICB are up-regulated under stress and in many gastrointestinal tumors. Pancreatic carcinomas express MICs, and their level in the serum of patients is elevated.⁸¹ Soluble MIC unimpairs NKG2-D-mediated immunity (see Chapter 13); i.e., it interferes with T- $\gamma\delta$ cells and NK cells.⁸² In summary, the MICA and MICB polymorphic HLA-like molecules present several unresolved enigmas. Their distribution is relatively restricted to epithelial and endothelial tissues (not on T or B cells) keratinocytes as well as monocytes⁸³ and their expression is associated with some form of stress. In spite of their polymorphism, they are recognized by $\gamma\delta$ T cells in a genetically unrestricted manner.

CD1 System: Genes and Proteins

One of the first monoclonal antibodies, which was made after the discovery of hybridoma technology,⁸⁴ was specific for a protein that later was given the first number, CD1, when the CD nomenclature was introduced at the First International Workshop on Human Leukocyte Differentiation Antigens, which was held in Paris in 1982.

The CD1 family consists of four proteins, CD1a, CD1b, CD1c, and CD1d that are encoded by genes CD1A, CD1B, CD1C, CD1D, and CD1E, which is not transcribed. The genes are located on chromosome 1q22-23, and the proteins that they encode have significant homology to MHC class I and II proteins. They are divided into group 1, which contains CD1a, CD1b, CD1c, and CD1e and group 2, which contains CD1d.

CD1 molecules represent an ancient family of antigen-presenting molecules, and the fact that they are homologous to the MHC molecules suggests that both evolved from a common ancestor with subsequent diversification. CD1 consists of three extracellular domains, α_1 , α_2 , and α_3 . The α_1 domain has minimal, if any, homology to MHC I, whereas with the other two, homology is approximately 35%, which is still far below the average of 70% between different class I proteins.

All CD1 proteins are transmembrane and associate with β_2m , which is necessary for folding and membrane expression.⁸⁵ The crystal structure of mouse CD1d1 shows a remarkable similarity in overall shape to MHC class I proteins.⁸⁶ The α_1 and α_2 domains form a groove with β -pleated sheets that is different from that of the MHC molecules, with three channels, A, C, and F', and a distinct tunnel, which is designated T'.

Another difference between CD1 and MHC is that the CD1 groove is formed by hydrophobic residues, so it is unlikely to form hydrogen bonds with the peptide; furthermore, it is also closed at both ends as well as covered for much of its length.

A complex of CD1b with ligands has been crystallized, and its structure has been solved⁸⁷. The total volume of the groove (220 Å³) and the four interconnected channels are occupied by the two alkyl groups necessary for stable ligand binding.

Mycobacterial mycolates, which are large molecules that play a crucial role in the survival of mycobacteria in the intracellular environment, have been the first characterized ligands for CD1b.⁸⁸ Lipids with three alkyl groups, such as triacylglycerols that are found in atherosclerotic plaques, are presented by CD1, are expressed on macrophages of the atherosclerotic lesions, and activate T cells.⁸⁹ The role of this mechanism in the formation and evolution of such lesions remains to be determined. The CD1 molecules are antigen-presenting molecules for lipids: i.e., bacterial as well as self-glycosphingolipids.⁹⁰ The CD1d molecule presents a number of endogenous glycolipids, tumor-derived lipids as well as nonlipid molecules to NKT cells.⁹¹ The presentation of these molecules has immunopotentiating effects that might be of some utility for the treatment and prevention in certain disorders. The CD1 molecules mediate T- (or NKT-) cell activation, following antigen presentation by CD1-expressing DCs.⁹² Endotoxin binding to TLR4 receptor induces CD1 expression on DCs, promoting T-cell activation.⁹²

UL-16-binding Proteins

The UL-16-binding proteins (ULBP) are novel class I-related surface proteins whose identification was based on their ability to bind the UL-16 glycoprotein of the human CMV.⁹³ The family has three members, ULBP1, ULBP2, and ULBP3, and their genes are located on chromosome 6q25 and not within the MHC complex. However, sequence alignments show clearly that the ULBPs belong to the MHC class I family. The ULBP proteins are glycosyl phosphatidyl inositol (GPI)-linked, do not have the α_3 domain of class I MHC, and do not associate with β_2m . Expression of ULBPs or the MICs on target cells confers susceptibility to NK-cell killing. The ULBP

P.319

transduces signals that override the negative signal generated by an inhibitory receptor. ULBP messages are expressed by a variety of cells, tissues, and tumors. The ULBPs are ligands for the homodimeric NKG2-D C-type lectin receptor,^{94,95} which is expressed not only on NK cells, but also on T cells and activated macrophages.⁹⁶ The cytoplasmic domain of NKG2-D is short, and, as a result, signaling is delivered by the DAP-10 adaptor protein that is associated with NKG2-D (see Chapter 13). DAP-10 binds to the p85 subunit of phosphoinositide 3-kinase (PI3K) and adaptor Grb2, transmitting downstream signals from NKG2-D through Janus kinase 2 and Akt activation pathways.⁹⁵ NKG2-D delivers co-stimulatory signals to T cells,⁷⁹ stimulates proliferation, and induces increased production of cytokines and other activation-associated molecules.⁹⁴ UL-16 mediates an additional evasive function of the human CTMV by inhibiting MICB expression, because it binds directly to MICB, causing its intracellular retention.⁹⁷ Metalloproteases mediate proteolytic shedding of ULBP2 from tumor cells, which interferes with NKG2-D-mediated cytotoxicity and thus may facilitate tumor escape from immunosurveillance.⁹⁸

Furthermore, soluble ULBP proteins down-regulate NKG2-D expression on NK cells, further interfering with NK-cell-mediated attack on cancer cells.⁹⁹

ORIGINS OF THE MAJOR HISTOCOMPATIBILITY COMPLEX

The human MHC is close to 4 Mb long, with approximately 180 to 200 genes, which traditionally has been divided into three regions: starting from the centromere to the telomere, class II, class III, and class I. During evolution, genetic events, such as insertions, duplications, deletions, inversions, conversions, and translocations, have introduced modifications, but the conserved genes have escaped identification with ancestral chromosomal regions. Genes that arose within a species by duplication are termed paralogous genes, and the chromosomal segment that contains the duplicated genes is termed the paralogous region. In the late 1990s, it was realized that three other chromosomes, 1, 9, and 19, have genes that are organized in the same manner as the MHC.^{100,101}

Some gene families, such as NOTCH and PBX, are represented in all four chromosomal paralogous regions, whereas others are represented in only two or three. Two hypotheses have been proposed for the explanation of these observations: (a)

All four paralogous regions arose from large-scale chromosomal duplication^{102,103}; and (b) the paralogous regions arose from independent duplications of genes, which were brought into proximity by selective forces (the functional clustering hypothesis).¹⁰⁴ It is possible that chromosomal duplication may have played a primary role, and functional clustering may have played only a minor one.

The hypothesis proposes that the “block duplication” that generated the four paralogous regions took place before the emergence of jawed vertebrates. Because all vertebrates have four paralogous regions, the duplication from one ancestral region must have occurred twice. It is postulated that the first occurred before the emergence of jawless fishes, which have two paralogous groups, and the second occurred before the emergence of jawed vertebrates. In the vertebrates, the gene order within each region is poorly conserved, probably as a result of structural rearrangements over the 500 million years since the second duplication. The hypothesis of “block duplication” draws severe criticism from others, who have data from phylogenetic analyses of individual gene families that are considered to be inconsistent with this hypothesis.¹⁰⁵

Class Ia genes cluster with class Ib genes but have risen independently by gene duplication from classical genes.

Furthermore, the polymorphism of MHC molecules is localized within the peptide-binding region. Within this region, the number of nonsynonymous nucleotide substitutions (amino acid-altering) far exceed the synonymous (silent or neutral) substitutions, whereas the opposite is true of the rest of the molecule. Because the synonymous substitutions are almost neutral, it is evident that polymorphism is supported by a form of natural selection, which favors peptide-binding region diversity. Other genomic evidence from *Xenopus laevis* (frog) indicates that, in this amphibian, there are class I, II, and III genes, which are linked.¹⁰⁶ Similarly, in cartilaginous fish (sharks), the most primitive organisms with a MHC, the gene structures and sequence variations are impressively similar to those in humans. Sharks also share with humans the MHC class I and class II linkage¹⁰⁷ that is common to all amphibian, bird, and mammalian species.¹⁰⁸ The proposed primordial MHC (proto-MHC) consists of the linkage group class I-PSMB9-PSMB8-TAP2-BRD2-RXR-class I and several genes that are involved in the preparation of class I presentation, that is, PSMB8 and PSMB9 (for proteasome) and TAP2 for peptide transporter. It is likely that, with further genomic sequencing analyses and phylogenetic tree analyses, the nature and composition of the proto-MHC will be determined. For many years, the HLA haplotype has been considered to be the most important genetic marker of susceptibility to many diseases. It has been found that the strongest disease associations are with alleles at multiple loci rather than with individual alleles. The expression of alleles from multiple loci has been called the ancestral haplotype (AH). AHs are conserved genomic sequences that are separated by recombination hotspots. For example, the 8.1 AHs (A1, CW7, B8, CHAQ0, DR3, and DQ2) are associated with multiple immunologic diseases.^{109,110} No single gene predisposes to all diseases, but different regions of 8.1 AH are associated with diseases such as insulin-dependent diabetes, systemic lupus erythematosus (SLE), gluten-sensitive enteropathy, dermatitis herpetiformis, common variable immunodeficiency and IgA deficiency. The AH 8.1 is also associated with rapid loss of CD4⁺ T cells and impaired survival after human immunodeficiency virus (HIV) infection. The precise immunologic mechanisms that give rise to such diverse diseases are not completely known. The AH 8.1 also affects the balance of cytokines with low interleukin (IL)-2 and IFN- γ and normal IL-4 production, with a bias toward the T-helper cell (TH) 2 type of immune responses.

ANTIGEN PROCESSING AND PRESENTATION

Antigen-presenting Cells

The development of humoral and cell-mediated immunity depends on complex cellular interactions that involve lymphocytes and nonlymphoid cells. Activation of lymphocytes by antigen requires its processing and presentation by another cell that is commonly known as an antigen-presenting cell (APC; Table 14.1). Macrophages promptly capture foreign substances, and antigen processing and presentation were first demonstrated there. Other APCs are the DCs (see section “Dendritic Cells”) and B lymphocytes.

Processing Antigens for Class I Presentation

Antigen processing begins in the cytoplasm with an ATP-dependent, proteolytic machine that is known as a proteasome, which is highly conserved from yeast to mammals.^{111,112,113,114,115} Most of the MHC class I presented peptides are generated outside the endosomes and lysosomes, and the energy required is supplied by ATP. The proteolytic subunit of the proteasome is a large cylindrical structure of 20S, which is arranged in four stacked rings. Based on structural analysis, the 20S proteasome is composed of two types of sequences, α and β . The two central rings of the 20S proteasome are composed of seven distinct, but homologous, β subunits,

which surround a central chamber in which proteolysis occurs (Fig. 14.4). The other two outer rings are made of α subunits, which form openings from which substrates enter and leave. Isolated subunits have no proteolytic activity, therefore the subunits must assume a precise conformation in the β ring to be active. It has been determined that the proteolytic mechanism depends on the hydroxyl group of the N-terminal threonine (Thr) of the β subunits. This mechanism of proteolysis by the proteasome is distinct from that of any other known protease. The function of the α subunits may be related to the formation of a scaffolding for the self-assembly of the β rings,¹¹⁶ as well as facilitation of the entry of the substrates.

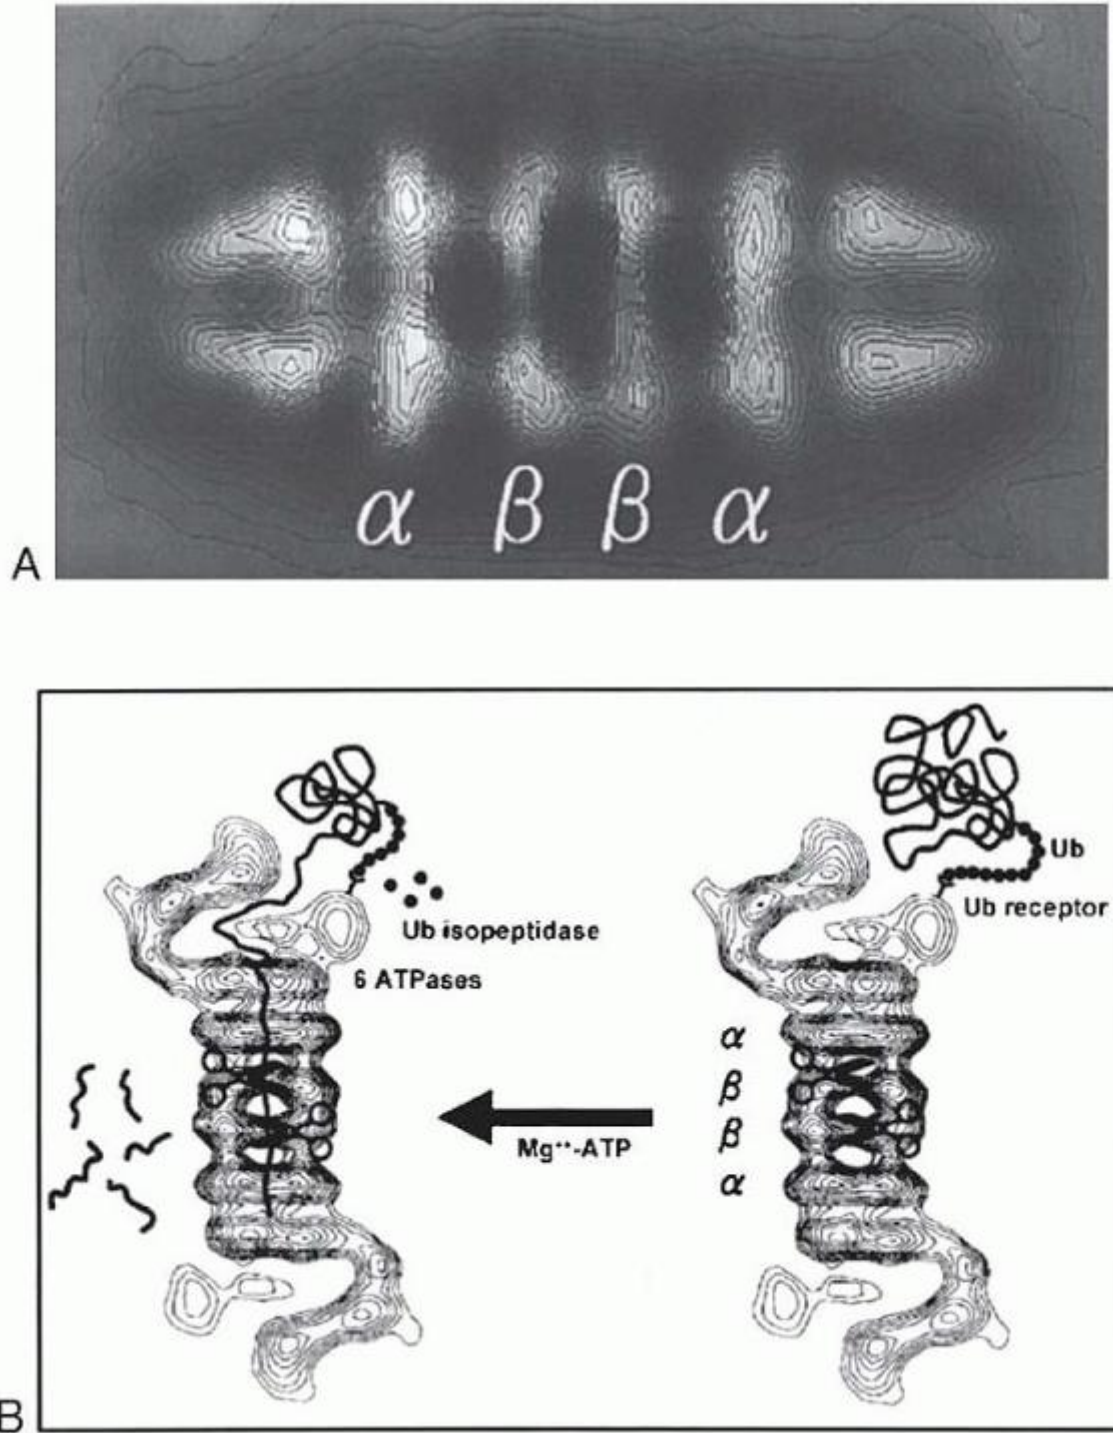

FIGURE 14.4. The proteasome. A: The 26S proteasome consists of a central unit (20S proteasome) composed of seven α and seven β subunits, arranged in four rings in the order $\alpha\beta\beta\alpha$. The central unit performs the catalytic functions. On each side of the central cylinder is a regulatory unit. B: Proteins to be degraded are first coupled to ubiquitin (Ub), which binds to an appropriate receptor in the regulatory unit that directs the protein to the central canal (“digestive tract”) of the proteasome. ATP, adenosine triphosphate. (From Tanaka K, Tanahashi N, Tsurumi C, et al. Proteasomes and antigen processing. *Adv Immunol* 1997;64:1-38, with permission.)

The 20S (650-kDa) proteasome is capped on each side by a 19S (700-kDa) regulatory complex to form the 26S (2,000-kDa) proteasome^{113,115} with proteolytic activity. Each 19S cap contains approximately 20 distinct subunits. It has been known as

PA700 proteasome activator, because, in the presence of ATP, it associates with the 20S particle and stimulates peptidase activity. In the absence of P700, the 20S particle cannot degrade ubiquitinated proteins. At least six of the P700 subunits are putative ATPases and account for the ATP requirements in proteasome-mediated proteolysis. These ATPases have one or two nucleotide-binding domains (NBDs) (“AAA modules”) and function as chaperons in diverse cellular processes. The size of the 19S regulatory complex, or antechamber, is $\sim 59 \text{ nm}^3$ and is large enough to retain unfolded proteins in a “ready to eat” state before they enter the “execution chamber.”¹¹⁷ The 26S proteasome has a dumbbell shape, with the 20S proteasome as a cylinder in the center and the two PA700 V-shaped subunits attached on each end. IFN- γ induces expression of three β -type subunits, two of them encoded by genes, PSMB8 and PSMB9, within the class II region, and a third one, PSMB10 (MECL1), which is encoded outside the MHC.¹¹⁸ IFN- γ also down-regulates three of the normally constitutively expressed subunits. The net result of IFN- γ stimulation is the exchange of three constitutive β subunits by those that are IFN- γ -inducible and that are incorporated into the 20S proteasome.¹¹⁹ This function of IFN- γ changes the activity of the immunoproteasome.

Another regulatory complex, PA28 (11S), a 200-kDa conical structure, also forms a cap at either end of the 20S proteasome¹²⁰ and stimulates multiple peptidase activities with faster kinetics. The PA8 consists of two components, α and β , which are structurally related to the Ki antigen, a nuclear antigen that is detected by autoantibodies in patients with SLE. Ki antigen is now renamed PA28 γ . The PA28 at the two ends of the 20S proteasome consists of a heterohexameric complex with alternating α and β subunits. PA28 proteasome is not involved in the initial cleavage of proteins but, rather, degradation of polypeptides of intermediate size. It is thought to work after the initial action of the 26S proteasome.

P.321

How from a long polypeptide or a protein, the specific peptide that precisely fits to the groove of the MHC is generated is a tantalizing question. These specific peptides are embedded within the polypeptide chain and in order to be extracted, two precise cuts are needed, one at the N terminal (start) and one at the C terminal (end). The importance of proteasomes for the generation of MHC class I-restricted peptides is widely recognized.^{121,122}

Antigen processing in the cytoplasm does not generate the final product in exactly one step. The view that proteasome makes the C-terminal cut is favored by several studies.^{123,124} According to this view, the proteasome releases intermediates with a precisely cut C-terminal end but with an extended N-terminal end. Proteasome cleaves peptides on the carboxyl side of basic and hydrophobic residues of substrates. This specificity satisfies an important requirement for the binding of peptide to the MHC class I groove; that is, basic and hydrophobic residues normally serve in anchoring the peptide in the groove. In addition, the C terminally cut peptides are also more efficiently transported by the TAP transporter.

N-terminal trimming is necessary to produce the antigenic peptide and may occur by aminopeptidases in the ER.¹²⁵ It is estimated that the 26S proteasome generates an antigenic peptide from an intact protein with an efficiency of one peptide for every 20 molecules that are degraded.¹²⁶ The peptides generated are 3 to 22 residues long, but only 20% are in the range that is favored for high-affinity binding (8 to 10 residues).¹²⁷ The crystal structure of the proteasome has revealed that the distance between active Thr residues of adjacent β subunits is approximately 28 Å. This distance determines the length of the generated peptides.

The ubiquitin proteolytic pathway has a crucial role in the degradation of short-lived and regulatory proteins that are important in a variety of cellular processes. Proteolytic cleavage by the proteasome requires the conjugation of the substrate by ubiquitin.^{128,129} The ubiquitin (8.5 kDa) is one of the most conserved proteins in evolution and is activated to a high-energy thioester bond at its C terminal by an activating enzyme, E1. After activation, one of several E2 enzymes (ubiquitin carrier proteins) transfers ubiquitin to an E3 protein (ubiquitin protein ligase) to which the substrate protein is specifically bound. This E3 protein covalently attaches ubiquitin to the substrate, at which it binds to ϵ -NH₂ groups of an internal Lys residue. This step is repeated until a polyubiquitin chain is formed, which serves as a recognition marker to the 26S proteasome. After degradation, ubiquitin molecules are released to participate in another cycle of proteolysis.¹³⁰ Substrates linked to ubiquitin may have different fates within the cell, depending on to which residue of the ubiquitin they are attached.¹³¹ Substrates linked to lysine 48 (K48) usually are directed for proteolysis, whereas K63-linked proteins signal several other, nonproteolytic intracellular pathways, such as kinase activation, protein trafficking, ribosomal protein synthesis, and others.

Rescue of proteins from degradation is mediated by de-ubiquitinating proteases or ubiquitinating specific proteases, the majority of which are cysteine proteases.¹³² These enzymes remove the (poly)ubiquitin from proteins, before their translocation into the catalytic chamber of the proteasome.¹³³

The proteasome exhibits three distinct peptidase activities that are associated with β subunits. One is chymotrypsinlike because it hydrolyzes peptides after a large hydrophobic residue, a second is trypsinlike because it cleaves after basic residues, and a third hydrolyzes after acidic residues. Occupancy of the chymotryptic site by a peptide substrate allosterically activates cleavages by the postacidic site, which in turn inhibits the chymotryptic site. By these cycles of activation-inhibition, the proteins are cleaved in pieces and are propagated for further fragmentation by other active sites.

Peptide Transport

Peptides that are generated by the proteasome must be transported across the ER membrane to meet the MHC class I molecules at which they are synthesized (Fig. 14.5).^{134,135,136} and ¹³⁷ The first indication that peptides are actively transported to the interior of the ER came from the study of mutant cell lines that had low MHC class I expression and could not present antigen, although their capacity to synthesize the molecules was intact. In the absence of peptides, the class I molecule cannot maintain its quaternary structure, folds up, and is incapable of moving along the constitutive pathway to the cell surface. Two genes have been identified within the MHC complex that encode the transporters of cytosolic peptides.¹³⁸ They are called transporters associated with antigen presentation (TAPs). Transfection of these genes to the mutant lines that were mentioned previously corrected their defect in antigen presentation. Profound defects in MHC class I-restricted antigen presentation were detected in humans lacking TAP2¹³⁹ and in mutant mice lacking Tap1.¹⁴⁰

The TAP proteins are members of the ABC family that is found in prokaryotes and eukaryotes.¹⁴¹ In mammals, the ABC proteins are grouped into four subfamilies: the glycoproteins, the cystic fibrosis transmembrane conductance regulators, the peroxisomal membrane proteins, and the TAP proteins. From the genomic structure of the human TAP1 and TAP2 genes, it is predicted that the TAP1 protein has 10 transmembrane-spanning segments. The sixth segment is joined to the seventh and the eighth is joined to the ninth by hydrophilic cytoplasmic segments.¹³⁴ The NBD, which is located in the cytoplasm, is large and consists of several modules. Two are involved in nucleotide binding (Walker motifs), and three others are hydrophilic. The direction of transport varies.

P.322

Some members (such as P-glycoprotein) transport their substrates away from the NBD, and others transport their substrates toward the NBD. The TAP proteins are functional only as heterodimers and are located in the ER and the cis-Golgi.¹⁴² In addition to the ATP-binding site,¹⁴³ a peptide-binding site is formed by both subunits.¹⁴⁴ Peptide binding is ATP-independent, but its transport is ATP-dependent.¹⁴⁵ It is of interest that peptides with 7 to 12 residues and a C terminus are transported more efficiently, and those are precisely the requirements for optimal binding by the class I MHC molecule.¹⁴⁶ Because peptides are usually rapidly degraded in the cytoplasm, it is suggested that they may be carried from the proteasome to the TAP proteins by chaperon proteins, such as those of the HSP70 family. Genes that encode such proteins have been found in the MHC region.¹⁴⁷ Peptide binding to TAP precedes its translocation across the ER membrane, and TAP acts as a peptide channel permitting the diffusion of peptides across the membrane. Most data, however, are consistent with the transporter function, that is, binding followed by translocation. ATP binding releases the peptide as a result of conformational changes of the NBD.

FIGURE 14.5. Processing and presentation for major histocompatibility complex (MHC) class I. Peptides (approximately 8 to 10 amino acids long) are generated by proteolysis within the proteasome. The protein to be degraded is first ubiquitinated. Ubiquitin (U) is attached by a covalent bond to the ϵ -NH₂ group of a lysine residue by an enzyme complex. The peptides are carried across the membrane of the endoplasmic reticulum (ER) by the transporter associated with antigen presentation (TAP) to be loaded on the groove of MHC class I molecules. The nascent α chain of MHC retains its proper conformation by calnexin (C) and after the addition of the β 2 microglobulin (β 2m) chain by calreticulin (Crt). When the peptide passes inside the ER and lands on the MHC groove, with the help of tapasin (T), calreticulin is relieved from its chaperon duties, because the peptide stabilizes the MHC conformation. ATP, adenosine triphosphate; TCR, T-cell receptor.

An important question related to class I antigen presentation is the mechanism by which viral proteins or tumor antigens, which are synthesized within the ER, are targeted to the cytosol to be handled by the processing machinery. There is an ER retrograde pathway that transports proteins from the ER to the cytosol.¹⁴⁸ Until these proteins are assembled and folded

properly, they are retained within the ER by calnexin or calreticulin. Misfolded or aberrant proteins are released for proteasomal degradation.¹⁴⁹ However, the ER possesses proteolytic activity, that is, aminopeptidases that may also process N terminally extended precursors of antigenic peptides for loading to MHC class I molecules.

Assembly and Loading of Class I Molecules

The size restriction for peptides to bind to class I molecules is 8 to 10 residues. The restriction is imposed by the structure of the MHC class I groove, which is closed at the two ends. The class I α chain and β_2m are synthesized on membrane-associated ribosomes and are inserted co-translationally into the ER through a specialized structure known as the translocon. N-Glycosylation takes place in the ER during the translocation process. HLA-A, HLA-B, and HLA-C have a single N-glycosylation site. The ER chaperon, BiP, a HSP70 homolog, interacts with proteins during this stage and, through ATP regulation, provides the energy that is required for the movement of the protein through the ER membrane. BiP binds with free HLA heavy (H) chains.¹⁵⁰ Calnexin is the most important chaperon and binds to newly synthesized free class I α chain,^{151,152} but not to the heterodimer (Fig. 14.5).

Calnexin is a transmembrane lectin and binds to N-linked glycans that bear a single glucose after removal by glycosidases of the extra glucose residues. How calnexin facilitates folding is not known, but the glucose is removed by a glycosidase II and calnexin is released. If the MHC class I molecule has not achieved its proper folding, a second glycosylation cycle follows with another attempt at refolding. Removal of calnexin permits the MHC class I molecule to leave the ER. Another chaperon that has been detected by some studies is calreticulin, which is a soluble homolog of calnexin.¹⁵³ Both recognize Asn-linked glycans bearing a terminal glucose residue, an intermediate in oligosaccharide maturation present on incompletely folded ER glycoproteins. The successive addition and removal of this glucose residue results in cyclical calnexin or calreticulum interactions with substrate proteins until they are correctly folded and assembled. Calreticulin promotes folding of HLA class I molecules to a state in which at low temperatures they spontaneously acquire peptide-binding capacity.¹⁵³

The TAP heterodimeric proteins transport the cytosolic peptides that are generated by the proteasome across the ER membrane. They bind to MHC class I molecules through an additional component that is called tapasin (TAP-associated glycoprotein).¹⁵⁴ Tapasin is a transmembrane glycoprotein that has an ER retention signal in the cytoplasmic region. The gene that encodes tapasin is in the centromeric end of the human MHC region. Tapasin probably forms a bridge between TAP and MHC class I molecules¹⁵⁵ (Fig. 14.5). However, tapasin also stabilizes class I molecules in the absence of peptides by occupying the groove, a function that is performed by the Ii chain in class II MHC molecules. In addition, tapasin is involved in peptide loading¹⁵⁶ and also influences the peptide selection.¹⁵⁷

An additional molecule that associates with MHC class I molecules at the assembly stage is ERp57, an enzyme that ensures the correct formation of intrachain and interchain disulfide bonds.¹⁵⁸ ERp57 is a thiol-dependent reductase and a cysteine (Cys) protease. As a protease, it may play a role in the trimming of peptides, because it remains attached to the complex until the time of the peptide loading.

The order and kinetics of the assembly of the various components of the loading complex is as follows^{159,160}: H chain β_2m heterodimers can be recovered within 4 minutes after translation, and the peptide joins 2 minutes later. Shortly after the synthesis of the H chain, one disulfide bond forms in the α_2 domain, and a second forms in the α_3 domain. Disulfide bond formation is necessary for β_2m binding and peptide loading. The β_2m is required for physical support of the peptide-binding groove.

Calnexin may be bound to a nascent H chain, but calnexin dissociates as β_2m binds to the H chain, and calreticulin is taken up by the heterodimer. The other half of the complex is being assembled in the meantime; that is, TAP forms a complex with tapasin, and both are joined by calnexin and ERp57. When the two halves of the final complex join together, calnexin dissociates, and the final loading complex is complete. Loading of the peptide at this point releases the MHC class I- β_2m heterodimer for the secretory pathway to reach the cell membrane. Presentation of certain proteins such as those derived from viruses is presented very rapidly to CD8⁺ T cells. It was proposed that antigenic peptides originate from defective ribosomal products (DRiP hypothesis)¹⁶¹ from a specialized machinery consisting of immunoribosomes.¹⁶²

Presentation of Exogenous Antigen by Major Histocompatibility Complex Class I Molecules

The class I MHC system evolved to identify cells that bear peptides that derive mostly from infectious agents. The vast majority of peptides that are presented by MHC I derive from proteins that are synthesized by the cell's own ribosomes. The proteins or polypeptides that generate these peptides are referred to as endogenous, whereas peptides that derive from proteins or micro-organisms that are phagocytosed are termed exogenous. It has been widely accepted that endogenous antigens trigger a CD8⁺ class I-restricted response, whereas exogenous antigens activate CD4⁺ class II-restricted cells. However, several examples over the years have detected class I-restricted CD8⁺ T-cell responses with dead

phagocytosed viruses, bacteria, transplants, dead cells, and others, which were handled by the immune system as exogenous antigens and were targeted to the endocytic system.¹⁶³ This has been known as cross-priming, which was originally described in mice that were immunized with cells that expressed minor histocompatibility antigens. Today, it is also known as cross-presentation. Hepatitis B surface antigen, given by the exogenous route and submitted to efficient endolysosomal processing, can lead to peptide-loaded MHC class I molecules.¹⁶⁴ Sometimes peptides derived from internalized particulate material have access to ER or peripheral phagosomes with membrane contributions from the ER, which then are loaded to MHC class I molecules.¹⁶⁵ Cross-presentation also occurs by “immunoproteasomes,” i.e., proteasomes enriched in proteasome proteolytic subunits (PSMB9 and PSMB9) by the action of INF- γ .¹⁶⁶ The

P.323

nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, NOX2, maintains an alkaline milieu of the phagosomes of DC predisposing to peptide presentation rather than protein degradation, which occurs by proteases in the highly acidified lysosomes of neutrophils.

Cross-presentation by APCs of antigens that are chaperoned by HSP (heat-shock proteins) is described by Shrivastava et al.¹⁶⁷ HSPs are highly conserved peptide-binding molecules that control the folding of proteins and prevent their aggregation. HSP70 that is complexed with a variety of synthetic peptides is taken up by APCs and elicits CD8⁺ T-cell class I-restricted antitumor cytolytic responses.¹⁶⁸ The HSP-peptide complexes are internalized by a receptor-mediated mechanism and are subsequently processed by a proteasome and TAP-dependent mechanism or through the endosomal route.¹⁶⁹ This is a highly efficient mechanism whereby antigens that follow an exogenous route induce strong CD8⁺ responses against tumors or viruses.¹⁷⁰ Peptides that are introduced into the cytosol induce a strong class I-restricted response only if they are chaperoned by HSP, but not alone.¹⁷¹ Receptors for HSP have been detected on CD11b⁺ cells,¹⁷² and, recently, the receptor for all HSPs was identified to be the CD91 protein¹⁷³ (see Appendix A). The CD91 is receptor for α_2 -macroglobulin and, with calreticulin, binds and stimulates uptake of apoptotic cells¹⁷⁴; together, they act as receptors for the collectin family and regulate the clearance of organs in the removal of apoptotic cells and cell debris.¹⁷⁵ It is postulated that HSP-peptide complexes that are given by the exogenous route might be used in the future to elicit protective immunity against cancer or viruses.¹⁷⁶

Although macrophages, DCs, and B cells have been reported to be able to mediate cross-presentation, the evidence collectively suggests that the most important cell is a DC. Interactions between CD4 and CD8 T cells that interact with the same APC are apparently needed.¹⁷⁷ Cross-priming is involved, predominantly in response to virus infection, cancer cells, and histoincompatible tissues. Although cross-priming is associated with an immune response, depending on the nature of the antigen (e.g., normal healthy cellular antigens), cross-presentation leads to the opposite of the immune response: cross-tolerance.

Antigen Processing for Class II Presentation

Biosynthesis of Major Histocompatibility Complex Class II Molecules

Expression of class II MHC molecules is restricted mainly to certain cell types, such as macrophages, DCs, and B lymphocytes. However, MHC class II molecules can be induced in other cells by IFN- γ . Regulation of MHC class II molecule expression occurs at the level of transcription. Many factors that regulate their expression are DNA binding and are ubiquitously expressed.¹⁷⁸ An important mediator is the MHC class II trans-activator molecule (CIITA), which is not a direct DNA-binding molecule and is detected in cells that express class II molecules constitutively or after induction with IFN- γ . CIITA is essential for the activation of MHC class II promoters that have the SXY regulatory module, i.e., a module consisting of certain motifs known as S, X, and Y boxes,¹⁷⁹ as well as for the expression of the Ii chain and HLA DM molecules. The MHC class II molecules and Ii chain are co-translationally inserted into the membrane of the ER through a signal peptide. The Ii is a type II membrane protein: the NH₂ terminus is on the cytosolic face of the ER and rapidly forms trimers through interactions of its luminal sequences.¹⁸⁰ It also associates with three MHC class II molecules, added sequentially, forming nonamers.³⁶ A central region of the Ii, which is termed CLIP, occupies the peptide-binding region of MHC class II and prevents peptide loading to MHC class II in the ER. Furthermore, the MHC class II-Ii association conceals a motif that retains Ii into the ER, and, as a result, the nonamer complex moves to the Golgi apparatus.¹⁸¹ Leucine (Leu) signals in Ii bind the AP-1 and AP-2 adaptors,¹⁸² but more than one sorting mechanism probably exists, depending on the cell type. The MHC class II-Ii complexes are targeted to late endosomes,^{183,184} possibly with an intermediate stopover, on the cell membrane or on the early endosome. Permanent localization in the early endosomes (by exchanging the cytoplasmic tail of Ii with that of transferrin receptor) blocks class II presentation, indicating that late endosomes or

lysosomes provide the appropriate milieu for class II presentation.¹⁸⁵ The CLIP has also been shown to mediate interaction of the Ii chain with MHC class I molecules.¹⁸⁶

Generation of Antigenic Peptides for Class II Major Histocompatibility Complex Presentation

Proteolytic breakdown of exogenous antigen in the endocytic pathway is essential for peptide loading. Specific uptake involves endocytosis and phagocytosis, mediated by various receptors in different cells, such as the B-cell receptor (BCR) in B cells and mannose receptors and Fc receptors in macrophages. The mannose receptor recognizes patterns of carbohydrates on the surface of the cell wall of infectious agents, and this increases dramatically the efficiency of class II-mediated presentation by DCs (Fig. 14.6).

The endocytic route that is taken by endocytosed foreign material consists of a complex network of compartments that vary in morphology, physiochemical properties, and content. Three major regions, however, can be distinguished: the early endosomes, with slightly acidic pH, are barely proteolytic; the late endosomes are more acidic and contain some components that are classically used as markers of lysosomal compartments, LAMP1 and LAMP2, and the lysosomes that have a low pH and are rich in hydrolytic enzymes. This route is intersected by another route that originates in the trans-Golgi network (TGN). This route is taken by molecules that come out of the ER, and, depending on specific signals such as dileucine or mannose 6-phosphate, they follow the secretory pathway on the way to the cell membrane or secretion. Foreign antigens that enter the endocytic pathway are subject to gradual proteolysis, which may generate peptides that are suitable for receptive MHC class II molecules.¹⁸⁷ Antigens follow different routes in the endocytic pathway, and antigen processing is different.¹⁸⁸ "Exit tracks" from the endocytic pathway join the constitutive secretory pathway for reaching the membrane. Proteolytic activities along the endocytic pathway are acquired progressively.

Acidification is an important factor for protein unfolding, and, as the pH decreases progressively, it influences several steps in the processing of incoming antigens and in peptide loading, such as protease activity, MHC class II molecule aggregation, peptide receptivity, and function of chaperons HLA-DM and HLA-DO.

Antigen processing is carried out primarily by proteases, and most of the lysosomal proteases are known as cathepsins. The final peptide that is suitable for loading onto MHC class II molecules is prepared by the action of the protease alone or with the assistance of the MHC molecule. A protease-guided initial step breaks down large proteins into smaller polypeptide chains, which may be partially accessible to MHC class II molecules. At this point, MHC class II-guided processing allows the protease to trim down unnecessary protrusions outside the binding site.¹⁸⁹

Several proteases exist within the endocytic system, endoproteases and exoproteases, and some cooperation between them is anticipated.¹⁹⁰ It appears that the first key protease is a Cys endopeptidase that cleaves after Asn residues.¹⁹¹ Once this enzyme takes the first step, other enzymes complete the digestion for the generation of peptides.

P.324

FIGURE 14.6. Processing and presentation for major histocompatibility complex (MHC) class II. Pathogens or their products are captured by phagocytic or dendritic cells and are carried to the interior of the cell enclosed within endocytic vesicles. A: Endocytosis is mediated through the mannose receptor (MR) or the B-cell receptor (BCR), or, depending on the method of entrance, they end up within typical phagosomes or early endosomes (EEs). The endocytic pathway is relatively complex, which is reflected in changes of their composition and pH. There is a dramatic morphologic change from a simple vesicle to multilamellar and multivesicular compartments that are known as MHC class II compartments. The endocytosed material is targeted to vesicles with class II MHC: early peptide loading compartment (EPLC) and late peptide loading compartment (LPLC). Their conformation and groove are maintained by the invariant (Ii) chain in EPLC and HLA-DM in

LPLC. The MHC class II molecule is synthesized in the endoplasmic reticulum (ER), and its conformation is stabilized by the chaperon protein Ii chain. A region of Ii termed class II-associated invariant chain peptide (CLIP) occupies the groove and prevents the collapse of MHC class II molecules. MHC class II molecules and Ii exist as nonamers. The complex moves out of the ER, passes through the Golgi apparatus, and reaches the EPLC, where the Ii chain is proteolytically destroyed but CLIP remains in the groove. Exchange of CLIP with the antigenic peptide is catalyzed by the nonclassical HLA-DM protein. In the last step of this long and tortuous path, the MHC class II-peptide complex is delivered to the plasma membrane by the EPLC vesicle, where it interacts with the appropriate T-cell receptor on CD4⁺ T cells. B: Proteolysis of the Ii chain is mediated by cathepsins, which cleave at a cysteine or aspartic acid residue. LE, late endosome.

Peptide Loading on the Major Histocompatibility Class II Molecule

As indicated earlier, the MHC class II molecule arrives in the endocytic system as a nonamer with the Ii chain. The CLIP region of Ii is inserted in the peptide-binding groove and prevents interaction with ER-resident proteins or other proteins on the way to the endosomes. CLIP also keeps the MHC class II molecule stable until the time of peptide loading. The precise location of the peptide loading within the endocytic system has been debated for a long time. Electron microscopic studies demonstrate that the MHC class II molecule is found throughout the endosomal pathway, including mannose 6-phosphate-positive late endosomes and in late endosomes and lysosomes, a compartment that is rich in MHC II but negative for the mannose 6-phosphate receptor, which is known as MIIC.¹⁹² This compartment consists of vesicles 200 to 300 nm in diameter with heterogeneous morphology, such as multivesicular, multilamellar, and tubulovesicular. Various functional stages of MIICs are distinguished on the basis of the Ii detection; for example, in some of them the intact Ii chain is detected, in others only the aminoterminal region is detected, and, in still others the Ii chain is absent. Loss of the Ii chain is associated with a change from multivesicular to multilamellar MIIC.¹⁹³ Another endocytic compartment, known as the CIIV (for class II vesicles), from a B-cell line, is similar to MIIC. Both are considered to be sites for peptide loading. The MIIC compartment is set aside from the remaining endosomal vesicles, and several endocytic markers are absent. These vesicles receive newly synthesized MHC class II molecules by virtue of the targeting motif of the Ii chain. Once they arrive, the Ii targeting motif is removed (C-terminal region), and the MHC II-Ii complex is retained within the MIIC for prolonged periods of time.^{193a} The MIIC is particularly abundant in DCs which are the professional APCs.

The first step in the peptide loading is the digestion of the Ii chain in the MHC class II-Ii chain nonamer complex (Fig. 14.6). The carboxyterminal region of Ii is cleaved by a protease that releases an MHC class II-Ii trimer.¹⁹⁴ Ii degradation occurs in an orchestrated fashion until only the CLIP remains attached to the MHC class II molecule. Proteolysis proceeds in two stages, and, for proteolysis of the second intermediate, different cathepsins are used in different APCs. Of the lysosomal enzymes, cathepsin S plays an essential role in the degradation of Ii in B cells and DCs, and its absence has major consequences for the onset of humoral immune responses.¹⁹⁰ Cathepsin L, on the other hand, is expressed on thymic epithelial cells.¹⁹⁵

Removal of CLIP from the peptide-binding groove and subsequent loading with antigenic peptide is catalyzed by the nonclassical class II HLA-DM, which binds directly to MHC class II-CLIP complex,⁶¹ near the N terminus of MHC class II.¹⁹⁶ It is thought that the DM induces a transitional "open" state to the MHC class II groove that releases CLIP. This occurs by disruption of a few hydrogen bonds between MHC class II and CLIP.¹⁹⁷ It is intriguing that HLA-DM does not interact with MHC class II that is associated with intact Ii chain.

The HLA-DO molecule is a negative regulator of HLA-DM, and, when it is overexpressed, it results in an accumulation of MHC-CLIP complexes.

MHC class II-peptide complexes are transported to the cell surface by vesicles, the movement of which depends on the cytoskeletal elements. MIIC transport is microtubule-dependent.¹⁹⁸ Microtubules are assembled from $\alpha\beta$ tubulin heterodimers in the microtubule organizing center and extend toward the periphery. A large family of motor proteins, known as kinesins, mediate transport of vesicles of the secretory pathway, cytotoxic granules, lysosomes, and the like. On microtubules, kinesin transports vesicles toward the positive end of the microtubule (the end away from the microtubule organizing center, toward the cell periphery). Another group of proteins, dynein, creates motion toward the negative end of the microtubule.¹⁹⁹ Thus, dynein is important to keep vesicles around the nucleus, because inhibition of its function shuttles all the vesicles to the cell membrane. How and when the vesicular movement is regulated is unknown. In monocytes, IL10 triggers positioning of MIIC in the cell, but in B cells, the BCR performs this function. The signal for kinesin to transport the mature MIIC—i.e., the MIIC that is loaded with the peptide—to the cell surface is unknown. It is also intriguing that only MHC class II-peptide complexes are detected on the cell surface, not the other contents of the MIIC vesicle.

Antigen Presentation by CD1

CD1 was first identified in human cortical thymocytes but later was detected on other cells, such as on antigen-presenting DCs, and CD1a is expressed on Langerhans cells (LCs), which are specialized DCs in the epidermis.²⁰⁰ CD1c is detected on a subset

P.325

of peripheral blood B cells and B cells of the marginal zone, and CD1d is expressed in intestinal epithelia and in a wide variety of hematopoietic cells. The members of the CD1 family are antigen-presenting molecules, and, after their synthesis, they must first reach an appropriate vesicular compartment for peptide loading on the way to the cell surface. There are striking differences in the intracellular distribution of the CD1 isoforms.^{201,202} CD1a is found mainly on the cell surface but also in early endosomes^{203,204} and in LCs that are present in the Birbeck granules. Together with CD1d, CD1b accumulates in the late endosomes and lysosomes, whereas CD1c is found in the early endosomes (transferrin receptor-positive). The ratio between surface expression and intracellular concentration also varies among the isoforms. The differential expression of the isoforms is regulated by a Tyr-based motif in the intracellular region that is present in all isoforms except CD1a.^{205,206} This sequence, YXXZ (Y, Tyr; X, any amino acid; and Z, an amino acid with bulky side chains), interacts with a member of the cytosolic adaptor proteins AP-1 through AP-4.²⁰⁷ AP-2 is positioned in the TGN and mediates delivery from the TGN to the endosomal-lysosomal system, whereas AP-2 is localized in the plasma membrane, where it directs proteins to clathrin-coated pits that lead to the entrance into the endocytic pathway. The AP-3 is implicated in the sorting of proteins from the TGN to endosomes and lysosomes. The AP proteins determine the specificity of destination for the CD1 molecules, but the binding to a specific AP member is determined by the residues that surround the Tyr-based motif.²⁰⁸ The YXXZ motif is essential for localization in the endosomal and lysosomal compartments, because mutations that are introduced into the sequence inhibit presentation of mycobacterial glycolipids to T cells.²⁰⁹ Although the YXXZ motif predicts the final destination, it does not indicate the route that is to be followed. The CD1d first follows a direct route from the ER to the cell surface, where, through the YXXØ motif (Ø, phenylalanine), it binds to AP-2. It is subsequently internalized and is directed to the MIIC compartment.²⁰⁹ MIIC overlaps considerably with lysosomes and may represent a fusion product between endosomes and lysosomes. CD1d is associated with the li chain, which directs CD1d to the same compartment independently of the Tyr-based motif.²⁰⁹ The li chain needs to be degraded by cathepsin S to allow loading of the CD1d and to be directed to the cell membrane.^{210,211}

The antigens that are presented by CD1 molecules are lipids and glycolipids (Fig. 14.7). Mycolic acids are a class of long chain, branched, free fatty acids and constitute the predominant component of the thick outer layer of the mycobacterial cell wall. They confer the acid-fast staining property on mycobacteria. They contain approximately 80 carbon atoms and are known to be required for mycobacterial survival. In addition to mycolic acids, two glycolipids, lipoarabinomannan (LAM) and lipomannan, are large molecules that contain 20 to 100 glycosyl residues and are also presented by CD1 molecules.²¹² Other antigens include selected phosphatidylinositol mannosides and glycosylated mycolates, including glucose monomycolate.

Mycobacteria are taken up by phagocytosis and reside within nonacidified phagosomes (due to a paucity in the vacuolar H⁺ ATPase). Therefore, they are restricted in their capacity to fuse with late endosomes and lysosomes. The macrophage mannose receptor that has been implicated in glycolipid uptake by APC²¹³ is absent from mycobacterial phagosomes.

The mechanism of distribution of various mycobacterial antigens to the subcellular compartments is not well understood. LAM has been found in late endosomes and lysosomes, either by being released from the phagosome or after uptake from the extracellular environment by the mannose receptor.²¹³ Nevertheless, mycobacterial antigens are distributed throughout the endocytic system after their release from the phagosome.^{214,215} Antigens that are released from phagocytosed mycobacteria reach various compartments of the endocytic lysosomal system, where all CD1 isoforms, that is, CD1a, CD1b, and CD1c, gain access to mycobacterial glycolipids at these different sites (Fig. 14.8). CD1a and CD1c sample the antigens in phagosomes that are arrested in the early endosomal stage, whereas CD1b samples antigens in phagosomes that are arrested in the late mature phagolysosome stage. The CD1 molecule binds the lipid antigens by accommodating the first two lipid tails within the hydrophobic groove, whereas the hydrophilic caps (sugars) are exposed to the solvent and contact the TCR directly.²¹⁶ The buried surface of the groove, as determined from crystallographic studies, is 1,400 Å, which could optimally accommodate a lipid with 32 carbons. However, some of the antigens that are presented by CD1 are 44 carbons long, and the mycolic acids are 80 carbons long. Presentation of large lipids takes hours (trafficking to late endosomes), whereas the same antigens with shorter chains are presented rapidly but inefficiently from the cell membrane.²¹⁷ DCs specialize in the presentation of lipids with long alkyl chains, whereas nonprofessional APCs present preferentially short chain glycolipids. The acidic environment of the late endosomes and lysosomes is an

important factor in the interaction of the large lipid antigens with the groove. The properties of the CD1b protein are dramatically altered in an acidic pH to facilitate the interaction with its ligands. There is a reversible unfolding of the α -helical portions of CD1 in an acidic pH, which permits the direct binding of the hydrophobic portions of the molecule, thus burying the alkyl chains.^{218,219} The depth, enclosed nature, and hydrophobicity of the interior of the CD1 groove is well adapted to carry out antigen presentation of lipids and amphipathic glycolipids, for which the hydrophobic component is sequestered within the groove, whereas the carbohydrates are left outside to interact with the TCR.

APC alters the structure of glycolipids by removing terminal glycosyl residues from certain glycolipids, resulting in the exposure of epitopes that are reactive with TCR.²²⁰ Glycosylation also generates new antigens, as is the case of glycosylation of mycolic acids during mycobacterial infections, with the use of glucose from the host and a mycobacterial enzyme.²²¹ Glycolipid processing generates a large variety of lipid ligands for presentation by CD1 proteins.²²²

In addition to bacterial glycolipids (i.e., LAM) and glucose monomycolate, CD1b molecules recognize self-glycosphingolipids, such as GM1 ganglioside.²²³ Several of these gangliosides can bind to CD1b, and, in striking contrast to bacterial glycolipids, the self-glycolipids bind on the cell surface without the need of the late endosome and lysosome acidified environment.²²⁴ Five or more oligosaccharide groups are required to stimulate TCR recognition with a large component of the ligand that is exposed. Apparently, these gangliosides act as blockers to prevent harmful autoreactivity. The number of these autoreactive T cells increases in multiple sclerosis.²²³

CD1 System in Microbial Immunity

The protective value of CD1-mediated immunity is currently under intensive investigation.^{225,226,227} The CD1⁺ cells correlate with the level of immunity to *Mycobacterium leprae* and are present in the lesion tenfold more abundantly in the tuberculoid form (immunologically responsive) than in the lepromatous form (immunologically unresponsive). Low numbers of CD1⁺ cells correlate with low granulocyte-macrophage colony-stimulating factor (GM-CSF) levels and high IL10 levels, which inhibits GM-CSF secretion. GM-CSF is a key differentiating factor for mature CD83⁺ DCs.^{218,228} CD1-restricted T cells contribute to intracellular bacterial infections, such as *M. tuberculosis*, based on high levels of IFN- γ secretion and strong cytolytic activity.

The CD1 isoforms broadly survey the endocytic system over pathways that are distinct from those of MHC class I and MHC class II molecules, and, furthermore, they are restricted to presentation of an important class of antigens, lipids, that are not covered by the MHC molecules. Among them, CD1c is particularly

P.326

P.327

important, because it is expressed on LCs (in the absence of CD1b) and B cells (without CD1a or CD1b).²²⁹

FIGURE 14.7. Microbial glycolipid presentation to T cells. The CD1 molecule, an orphan family of major histocompatibility complex (MHC)-like molecules, presents long carbon-chain glycolipids from mycobacteria and other similar pathogens, to natural killer T cells (NKT), T-cell receptor (TCR)- $\gamma\delta$, and TCR- $\alpha\beta$ cells, linking innate and adaptive immunity. The CD1 molecules are expressed in various compartments of the endocytic system, providing a broad surveying mechanism for the detection of intracellular mycobacterial infections. Localization of CD1 molecules depends on endosomal targeting sequences for loading of glycolipids. The glycolipids in general consist of a hydrophilic head of carbohydrate molecules and one or two lipid tails. The head interacts with the TCR, whereas the lipid tails are accommodated within the large groove of the CD1 molecules, penetrating into two deep pockets. Ag, antigen; α -Gc, α -galactosylceramide; GMM, glucose monomycolate; H-1 PIP, hexosyl-1-phosphoisoprenoid; LAM, lipoarabinomannan; M- β 1-PhDo, mannosyl- β 1-phosphodolichols.

FIGURE 14.8. Migration of dendritic cells. A: A Langerhans cell, migrating through the labyrinthine space of the dermis, guided by chemokine signals that are received by its chemokine receptors. B: The Langerhans cell penetrates into the dermis through a hole (between the two groups of arrows) in the basement membrane (asterisk). (From Romani N, Ratzinger G, Pfaller K, et al. Migration of dendritic cells into lymphatics—the Langerhans cell example: routes, regulation and relevance. *Int Rev Cytol* 2001;207:237-270, with permission.)

DENDRITIC CELLS

DCs, as their name indicates, are characterized by their long and elaborate cytoplasmic branching processes (the Greek word dendron means “tree”). The adaptive immune system, under evolutionary pressures, developed cells with exquisite specific receptors for sensing components of pathogens, so as to be able to generate molecular and cellular effector mechanisms for their elimination. Sensing of the pathogens or their products requires their breakdown (processing) and presentation by cells of the innate immunity. Foremost among the APCs are the DCs.^{230,231,232} DCs are a highly heterogeneous group that resides in most peripheral tissues at sites at which the body interfaces with the environment (i.e., skin, intestine, respiratory mucosa). Although DCs, as do other hematopoietic cells, ultimately derive from bone marrow progenitors, partially differentiated precursors are outside the bone marrow, such as peripheral blood, cord blood, and thymus. Such progenitors that are exposed *in vivo* to bacterial or inflammatory products, cytokines, and the like, differentiate to more mature cells with DC morphology and function. This large plasticity of DC development has created confusing and sometimes contradictory results. Basically, there are two lines of differentiation from stem cells, one along myeloid lineage and another along lymphoid lineage, thus the generation of two prevailing terms: myeloid DC and lymphoid DC. DC precursors circulate in the peripheral blood with a monocytic phenotype $CD14^+CD11c^+CD13^+$. These cells, cultured *in vivo* in the presence of GM-CSF and IL4, give rise to the DCs that are considered as myeloid DCs. However, the same precursors cultured with fibroblasts differentiate to macrophages.²³³ IL6 that is released from fibroblasts in contact with the monocytic precursors up-regulates the macrophage colony-stimulating factor receptors. This switches differentiation to macrophages by an autocrine mechanism, based on the secreted macrophage colony-stimulating factor. Progenitors from cord blood that are considered lymphoid, with the potential to differentiate into NK cells, could give rise *in vitro* to phenotypically and functionally potent DCs under stimulation with various cytokines.²³⁴ *In vitro* studies may not represent the normal *in vivo* pathways of differentiation, but they nevertheless provide evidence that, *in vivo* also, partially differentiated cells of different lineages may choose a DC differentiation pathway when they are exposed to appropriate conditions. The stimuli for DC differentiation vary widely, from inflammatory microbial products²³⁵ to simply crossing endothelial barriers. DCs that develop within the thymus are $CD8^+$ and are considered to be of lymphoid origin. However, it has been documented that even myeloid DCs can express CD8, so CD8 expression does not define lineage origin.^{236,237} Origin from lymphoid precursors was suggested by unique DCs known as plasmacytoid T cells or plasmacytoid monocytes. These cells have a typical plasma cell-like morphology; lack expression of myeloid markers; and

are CD11c-, CXCR3⁺, and L-selectin (CD62L)⁺. DCs are heterogeneous with respect to their phenotype, anatomic distribution, and function.

Functionally, DCs have been distinguished into two groups, DC1 and DC2; the former derive from myeloid monocytes (pre-DC1), and the second derive from a plasmacytoid DC precursor (pre-DC2).²³⁸ This separation correlates with functional differentiation. Myeloid DCs from monocytes that are activated by the CD40 ligand (CD40L) produce large amounts of IL-12 and induce preferentially T_H1 development. Lymphoid DC2s from plasmacytoid precursors produce lower amounts of IL12 and preferentially induce TH2 development.^{239, 240} Another study, however, reached opposite conclusions,²⁴¹ suggesting that the two DCs represent two separate evolutionary traits. The pre-DC1s express the Toll-like receptor (TLR)-2 and TLR4, and preDC2s express TLR7 and TLR9.²⁴²

Pre-DC1s are strongly positive for mannose receptor and rapidly produce large amounts of proinflammatory cytokines, such as TNF- α , IL6, and IL12, in response to ligands of TLR2-bacterial glycoproteins. Pre-DC2s produce IFN- γ in response to ligands of TLR9-bacterial DNA.²⁴³ The origin, response to stimuli, and pathways of differentiation of DCs vary greatly, depending on conditions that are still poorly understood.

The precursors of DCs from bone marrow progenitors move to the periphery as immature DCs and take position at crucial sites of potential entry of pathogens. Once they capture antigens and are exposed to stimuli, they mature and migrate to regional lymphoid organs to present antigens and to activate the adaptive immune responses by presenting antigens that are brought from the periphery. DCs are the professional APCs in immunity.

Migration of Dendritic Cells

DCs are cells that are continuously on the move from the moment they come out of the bone marrow to settle in various organs and tissues as immature DCs. In these locations, they are easily exposed to antigens and invading pathogens, and, now as mature activated DCs, they migrate to the lymphoid organs. Each of these pathways is orchestrated by distinct sets of molecules and receptors, foremost among them being the chemokines and their receptors.

Circulating monocytes and immature DCs express receptors for inflammatory chemokines (CXCR1, CCR1, CCR2, and CCR5), as well as receptors for bacterial and complement chemoattractants (receptor for N-formyl-methionyl-leucyl-phenylalanine-R and C5a-R),²⁴⁴ and, in response to such mediators, they develop into DCs.²⁴⁵ The crossing of the blood wall by DC precursors is mediated by a DC-specific adhesion molecule that is known as DC-specific intercellular adhesion molecule-3 (ICAM3) grabbing nonintegrin (DC-SIGN or CD209). DC-SIGN is a novel cell surface C-type lectin that is expressed on DCs, binds ICAM3, and mediates interactions between DCs and T cells.²⁴⁶ The extracellular region of DC-SIGN has a C-terminal, C-type carbohydrate recognition domain, particularly for mannose. DC-SIGN interacts with ICAM2 on the endothelial cells and establishes shear-resistant contacts with blood vessel walls for the transmigration of the DCs.²⁴⁷ The DC-SIGN-ICAM2 interaction is involved in the bloodborne DC precursor exit into peripheral tissues and in tissue mature DCs to peripheral lymphoid tissues. In the skin and epithelia of lung, intestine, and so on, immature DCs are exposed to stimuli that trigger their maturation, such as cytokines (TNF- α and IL1) and microbial products (e.g., lipopolysaccharide, LPS).

The mature DCs change to a new phenotype (MHC II³⁺, costimulatory and adhesion molecules positive) and acquire new migratory capacity. As a result, they migrate to the T-cell areas of the regional lymph nodes. DCs first down-regulate CCR1 and CCR5 (receptors for macrophage inflammatory protein [MIP]-1 α and MIP-1 β), up-regulate CCR7, and become responsive to secondary lymphoid tissue chemokine (SLC) and Epstein-Barr virus-induced molecule 1 ligand chemokine (ELC), the ligands for CCR7.^{248,249} Maturing DCs first move from their interstitial location to afferent lymphatic capillaries, where SLC is secreted from the endothelial cells and is carried to draining lymph nodes. The migratory pathways of the LCs, the DCs of the epidermis, provide a vivid example of the exquisite regulation of DC migration (Fig. 14.8).²⁵⁰

The LC precursors, CD11⁺ and CD1a⁺,²⁰⁰ are recruited into dermis, depending on the selectin expression of the dermal blood vessels.²⁵¹ These cells express the CCR6 receptor, which binds the inflammatory chemokine MIP-3 α (CCL-20), which is produced by keratinocytes of the epidermis.^{252,253} The LCs remain in the suprabasal layer, physically connected to neighboring keratinocytes by homotypic interactions that are mediated by E-cadherin, which is expressed by keratinocytes and LCs. Concomitantly, the CCR6 is down-regulated and the CCR7 is up-regulated, which

P.328

allows the LCs to move toward the lymphatic vessels in response to SLC. The basement membrane of the skin, however, stands as a barrier to their migration. LCs penetrate the lamina densa, which consists of type IV collagen and is digested by

the matrix metalloproteinase of LCs. They cross the dermis and reach the abluminal side of the vessels. Entry into the lymphatic vessel is poorly understood, but P-glycoprotein may be involved.

LCs are carried by the lymph and acquire morphology that is known as a veiled cell as a result of their broad sail-like membranous sheets. Entering the lymph node, they settle in the dependent areas in response to SLC (CCL21) and ELC (MIP-3 β , CCL19), ligands for the CCR7 receptor. SLC is produced by the endothelial cells of the high endothelial venule, and ELC is produced by DCs or other cells in the paracortex.²⁵⁴ The LCs that settle in the paracortex are known as interdigitating dendritic cells (IDCs).

Accumulation of DCs around tumors follows the same mechanisms and depends fully on the interaction between chemokines released by tumors and the appropriate receptors on DCs²⁵⁵.

Dendritic Cell Functions

DCs are best known for their efficient antigen presentation function. They capture antigens and pathogens, which they internalize and process for antigen presentation. DCs use a variety of receptors to take in antigens, such as receptors for Fc and complement, macrophage-scavenger receptors, mannose receptors, and DEC-205. However, of all the receptors that the DCs use to endocytose pathogens, the best studied is the DC-SIGN receptor that binds to HIV.²⁵⁶ HIV is not endocytosed by the DC, but the DC-SIGN binds to gp120 envelope glycoprotein, and the DC transfers the HIV to the lymphoid organs, where it enhances infection of T cells that express CD4 and chemokine coreceptors. DCs are efficient APCs for the class II-restricted pathway, but endocytosed antigens can also be diverted to the class I-restricted pathway. This is known as cross-priming or cross-presentation (see section "Presentation of Exogenous Antigen by Major Histocompatibility Complex Class I Molecules"). Immature DCs are crucial for this mechanism of presentation.

Interaction with pathogens by immature DCs not only prepares naive T cells for priming, it also activates immature DCs for maturation. This is mediated by signaling receptors, such as the Toll-like receptors of innate immunity (i.e., TLR2, which is involved in response to Gram-positive bacterial components, or TLR4, which interacts with LPS in response to Gram-negative bacteria). An interesting example of the diversity of responses to a single bacterial protein by immature DCs is the bacterial cell wall protein OmpA (from *Klebsiella pneumoniae*). This protein triggers maturation signaling of immature DCs through the TLR2 receptor, endocytosis via a receptor-dependent mechanism, and cross-priming of antigen-specific CD8⁺ T cells (in the absence of CD4⁺ T-cell help).²⁵⁷

DCs, however, are not simply antigen-delivering cells for lymphocytes. They play a key role in the maintenance of T and B lymphocyte pools in the absence of exogenous antigen. For T cells, this function depends on the high density of MHC class II molecules.²⁵⁸ It is postulated that the MHC class II molecules display self-peptides, and the interaction generates and transmits signals that are sufficient for the survival of T cells and could be traced from the cell surface to the nucleus (increase of IL12R β_2 chain and IFN- γ mRNA). Contact between DCs and naive T cells in the absence of antigen is established by the interaction of DC-SIGN (DCs) and the ICAM3 (T cells).²⁴⁶ This strong interaction allows the establishment of interactions with other adhesion molecules to form the immunologic synapse. These synapses are antigen-independent and induce local Tyr phosphorylation, small Ca²⁺ responses, and long-term survival.²⁵⁹

DCs can regulate differentiation of naive B cells. In the initiation of the antibody response, a three-cell interaction takes place among T, B, and D cells with various combinations of cell-surface-expressed molecules. This gives time to B cells to process and present peptide through the class II MHC molecules, for a cognate T- and B-cell interaction.²⁶⁰ DCs directly modulate growth and differentiation of B cells and enhance IgG and IgA secretion by 30- to 300-fold, and through IL2 production stimulate IgM production. IL2 is a key cytokine that is produced early after DC stimulation by maturation signals.²⁶¹

Dendritic Cells in Human Disease

DCs accumulate in the joints of rheumatoid arthritis patients and within psoriatic plaques, which express high levels of CD1b and CD1c, and are active stimulators of autologous T-cell proliferation. In contact allergy, hapten-modified proteins are processed by LCs that migrate to draining lymph nodes and initiate immune responses. A similar pathway is taken by DCs in the respiratory airways that capture and process inhaled antigens in asthma. The DCs are significantly higher in asthmatics. Targeting DCs may be an important new therapeutic approach for asthma.

In human parasitic infections, immature DCs can phagocytose the organism and restrain parasite replication in dermal infiltrates.

The role of DCs as potentiators and initiators of antiviral immune responses is well documented, especially in stimulating recall of cytotoxic T lymphocyte responses. Nevertheless, viruses still survive within DCs and subvert the immune response by down-regulation of MHC class I molecule expression, induction of immunosuppressive cytokines (IL10), or down-

regulation of immunostimulatory cytokines (IL12). In the pathogenesis of HIV disease, the DCSIGN acts as a dendritic-specific HIV-1-binding protein that does not need a coreceptor and promotes binding and transmission of HIV-1 to T cells rather than entry to DCs. The virus is retained in an infectious state but is not allowed to enter the DC. DC-SIGN literally presents HIV to T cells in a nonprocessed infectious form. Various carcinomas display a heavy infiltrate of DCs with high MHC class II molecule expression that is associated with better prognosis. DCs have been used in trials in cancer therapy. Prospects for future successful DC immunotherapy are promising.²⁶² T-cell immunity can be induced, even in patients with advanced stage IV melanoma, by vaccination with antigen-pulsed mature monocyte-derived DCs.²⁶³ When the DCs are loaded with MHC class II molecule-binding melanoma peptides, strong tumor-specific T_H1 responses were elicited.

In a large body of literature regarding animal models, DCs that were loaded with tumor-associated antigens were able to induce antitumor immunity.²⁶⁴ Measurements of CD8⁺ T cells by using MHC tetramers help quantify antigen-specific responses.²⁶⁵

Langerhans Cells

LCs were first observed in the epidermis by Langerhans and can be identified only by means of special stains that make use of the affinity of the cell for heavy-metal ions or the uptake by the cell of L-dopa, dopamine, and noradrenaline.²⁶⁶ The demonstration of a formalin-resistant and sulfhydryl-dependent ATPase is a reliable and specific technique for identifying LCs. Their ultrastructure was first described by Birbeck et al.,²⁶⁷ who also described a characteristic granule that bears Birbeck's name.

LCs constitute 3% to 8% of all cells in the epidermis and are present in all parts of the skin, esophagus, and cervix; they are not found in the cornea, trachea, stomach, or bladder. In humans, the number of LCs per unit of skin varies between 40,000 and 100,000/cm². Their precursors originate in the bone marrow, and in the mature stage they are located in the suprabasal layers of the skin, within the epidermis, where they can be distinguished from keratinocytes on the basis of absent desmosomes and tonofilaments and from melanocytes by the absence of melanosomes.

P.329

The long dendritic processes form a continuous network. The nucleus is irregular and lobulated. The cytoplasm is clear and contains microfilaments and multivesicular bodies, as well as the unique Birbeck granule, which is rod-shaped with periodic striations, giving it the appearance of a zipper. LCs are present in the dermal lymphatics, the marginal sinus, and the paracortex of draining lymph nodes, which suggests that these cells are mobile (see the previous discussion).

Mature LCs express a granule-associated antigen, E-cadherin,²⁶⁸ and HLA-D antigens. Ultraviolet irradiation depletes the skin of LCs and blocks the induction of contact sensitivity.

Veiled Cells

Veiled cells are present in the afferent lymph and resemble LCs.²⁶⁹ Their name derives from the possession of long, actively moving processes or veils that are approximately 100 nm thick. The veils do not contain organelles, and their movement must therefore be generated at a distance. Their nucleus is highly convoluted, and the cytoplasm contains bundles of microfilaments. Only approximately 4% of veiled cells contain a Birbeck granule, but all possess a large vacuole under the cell surface. They elicit a strongly positive response when they are tested for ATPase, and they resemble LC in the content of other enzymes. They are not actively phagocytic, but they possess Fc receptors.

After contact sensitization, Langerhans-like cells appear in the dermal lymphatics, and an increase in the number of veiled cells in the lymph that drain the area is noted. Once they are in the lymph node, most veiled cells localize in the T-cell-dependent areas, where they may function as interdigitating cells. Some veiled cells enhance the response of T lymphocytes to mitogens. Their function possibly consists of transporting antigens into the paracortical area, where they present them to T lymphocytes. Thus, a cellular chain for antigen transport exists in which more than one cell type takes part. Starting from the floor of the subcapsular sinus, antigen is localized first in cells that have the appearance of LCs, but, in deeper regions of the cortex, a second cell with morphologic characteristics of veiled cells has been identified.²⁷⁰ These two cells are similar to the cells that are known to migrate from skin areas to the paracortex.²⁷¹

Interdigitating Dendritic Cells

The T-cell-dependent areas of the lymphoid organs contain substantial numbers of DCs that are known as IDCs.²⁶⁹ They have a clear cytoplasm and an irregularly shaped nucleus and extend long dendritic processes to contact T cells. They

express MHC class II antigens but do not express receptors for the Fc fragment of Ig and complement. IDCs are positive for CD83 and the S100b protein (cytoplasm). The name usually is reserved to describe cells that lack Birbeck granules.

Many common features are shared by IDCs and DCs from other compartments (e.g., skin and splenic white pulp). This led to the view that a single DC system exists in which the peripheral nonlymphoid organs' DCs migrate to the T-cell-dependent areas and become IDCs.²⁷² This has been shown by labeling DCs that are isolated from the spleen of mice and injecting them into footpads. The labeled cells migrated to the periarteriolar sheath of the spleen or the paracortex of the lymph node.²⁷³ DCs from skin that is painted with hapten migrate within 24 hours to the lymph nodes.²⁷⁴

Similarly, Leishmania parasites that are injected into the skin are found within IDCs in the T-cell areas of the lymph nodes, probably as a result of uptake of the parasites by skin DCs that migrated to the lymph nodes to become IDCs.²⁷⁵ In patients with skin allergies, one finds Birbeck granules in some IDCs of local lymph nodes. Also, the T-cell areas stain strongly for CD12, a marker that is expressed on LCs. This evidence supports the notion that LCs migrate from areas of the skin to the T-cell areas of regional lymph nodes. Transportation of antigen from the periphery to lymph nodes is not only characteristic of the skin DC but is also a function that is performed by intestinal DCs and other DCs in the periphery.

Follicular Dendritic Cells

Follicular dendritic cells (FDCs) are found in the follicles and germinal centers (GCs) of lymph nodes and were identified by a distinct dendritic pattern of antigen localization in the follicles. Antigen trapping in the follicles requires antibody with an intact Fc fragment and complement. The antigen that is so trapped persists for long periods, in contrast to the antigen that is captured by the medullary macrophages. Cytologically, the FDCs have an irregular nucleus, a narrow rim of cytoplasm, and filiform dendrites, giving the cell a sunburstlike pattern. On their surface, they express Fc and C3 receptors and MHC class II antigens.

Electron microscopic studies have identified two FDC types: FDCs with filiform dendrites, which mature to FDCs with beaded dendrites.²⁷⁶ After secondary immunization, FDCs form spherical particles called iccosomes (immune complex-coated bodies; Fig. 14.9). The iccosomes are formed through interactions of the two FDC types. One cell binds immune complexes, and the second cell, with beaded dendrites, binds to the areas of the complexes. Thus, the bead becomes coated with the complexes and the cytoplasmic membrane of the first FDC that carries the complexes. At this stage, the bead is filled with immune complexes and is subsequently detached as iccosomes that are dispersed among the cells of a developing GC. This process constitutes what is called the alternative antigen presentation pathway,²⁷⁶ to distinguish it from the more conventional antigen capture and presentation.

Antigen complexes are poor immunogens because they deliver a down-regulatory signal to the B cell that is related to the phosphorylation of the immune receptor Tyr-based inhibitory motif on the B-cell Fc receptor. However, the FDC strongly expresses FcR, and it is conceivable that, as FDC binds to complexes, it limits the available Fc on the complexes for binding to the FcR on B cells. FDC also delivers co-stimulatory signals to B cells, probably through complement-derived fragments, C3dg and C3d, which are associated with the FDC-bound complexes. Complement fragments bind on B cells to complement receptor 2 (CR2, CD21), which is a member of the CD19/CD21/CD81 (TAPA1) complex, a coreceptor of the B-cell antigen receptor (see Chapter 12).²⁷⁷ Thus, the FDC-associated complexes colligate the antigen BCR and the CD19/CD21/CD81 coreceptor, providing two signals for B-cell stimulation.

The CD21 exists in two isoforms, one long and one short. FDCs selectively express the long isoform of CD21, whereas the short molecule is expressed by B cells. CD21 on FDC most likely participates in binding of complexes. The FDC-dependent B-cell stimulation is enhanced by IL2.

FDC traps and retains large numbers of retroviral particles,²⁷⁸ which markedly alter the function of FDC and the anatomy of the follicle. Infected FDC brings the virus and CD4⁺ T cells together, promoting their infectivity. The antigen presentation function of the FDCs is lost, and, eventually, the cells are destroyed.

There are two views on the origin of FDCs: one proposes a hematopoietic origin, whereas the other proposes a mesenchymal/fibroblast origin. FDCs have a fibroblastic morphology and express certain molecules, such as vimentin and desmin, which are found in mesenchymal tissues. FDCs are also found in areas of chronic inflammation.²⁷⁹ As yet there is no convincing evidence for either theory. For the time being, FDCs continue to be defined as the cells in the follicles of lymphoid organs that have the property to trap complexes of Ig and antigen. The reticulum cells within the GCs were thought to be different from those in the mantle, but, by ultrastructural studies, DCs in GCs and those of the mantle zone (or primary follicles) are considered to be of the same family.²⁸⁰

FIGURE 14.9. Follicular dendritic cell and iccosomes. A: Scanning electron micrograph that illustrates a follicular dendritic cell (arrow) with beaded dendrites. Each dendrite contains several iccosomes. B: Transmission electron micrograph of a lymphocyte from the germinal center with two iccosomes in contact with its surface (arrows). (From Szakal AK, Kosco MH, Tew JG. A novel *in vivo* follicular dendritic cell-dependent iccosome-mediated mechanism for delivery of antigen to antigen-processing cells. *J Immunol* 1988;140:341-353, with permission.)

T-B-CELL INTERACTIONS

Immune responses are regulated by the dose and the localization of antigen.²⁸¹ Furthermore, for T and B lymphocytes that need to collaborate, recognition of antigen by their antigen receptors is not sufficient to activate them, but a second signal (co-stimulation) is required. T lymphocytes are in the paracortical areas, and the most abundant APCs in the paracortex are the IDCs.

The complexity of the mechanisms that are involved in activation of naive T cells *in vivo* was elucidated with TCR transgenic T cells.²⁸² When antigen is injected in the absence of an adjuvant, T-cell activation does not take place or is too small in intensity and short in duration and therefore is nonproductive. DCs, which are interspersed in the tissues behind the physical barriers of the body, are Nature's adjuvants, and although they are immature, they are still phagocytic and able to capture pathogens or their products. Under these conditions and with stimulation by inflammatory cytokines, DCs transform into mature DCs, and although they may have lost their phagocytic capacity, they have acquired two new important properties. First, they change their chemokine receptors to migrate to the T-cell areas of the draining lymph nodes. In addition, they acquire co-stimulatory molecules (CD80 and CD86), adhesion molecules (CD48 and CD58), and class II MHC molecules that are loaded with peptides from newly internalized antigens expressed on the cell membrane. In addition to these molecular immunologic changes, morphologic signs of their activated state become apparent, with long cytoplasmic dendrites reaching out between T cells. This morphologic appearance contributed to their name as IDCs. Inflammatory cytokines, such as TNF- α , that are released from activated macrophages contribute to the activation of DCs^{283,284} and up-regulate CD40 expression on DCs,²⁸⁵ which further promotes interaction with CD40L⁺ T cells.²⁸⁶

Activated DCs lead to significant immune responses, whereas immature DCs can be tolerogenic, as has been shown with healthy human volunteers. Immature DCs inhibit CD8⁺ T-cell immunity to viral peptide-specific IL10-producing T cells.²⁸⁷ In contrast, mature DCs (triggered by a mixture of macrophage products, such as IL1 β , IL6, TNF- α , and prostaglandin E₂) induce functionally superior CD8⁺ T cells and polarize CD4 T cells toward IFN- γ production.

Maturation stimuli direct co-stimulatory molecules and MHC class II-peptide complexes to membrane microdomains ("lipid rafts"), where they are able to interact more efficiently with the CD28 and TCR as the DCs and T cells form the immunologic synapse (see Chapter 13).^{288,289} This is the first cognate interaction, which takes place between DCs and T cells in the paracortical area and results in full activation of T cells (Fig. 14.10). Co-stimulatory signaling amplifies the TCR signaling as much as 100-fold, as T cells respond to lower doses of antigen (~100-fold lower dose). The co-stimulatory pathway up-regulates bcl-xL and prevents Fas-mediated apoptosis of newly activated T cells. Co-stimulation enhances production of IL2 from activated T cells and induces expansion of antigen-specific T cells.

The factors that drive these two processes are the levels of MHC class II-peptide complexes and, therefore, the TCR stimulation and the intensity of co-stimulation; both are related to the stability of the synapse.^{290,291,292} Recurrent and sustained exposures to antigen and to polarizing cytokines are essential for differentiation of CD4⁺ T cells.²⁹³ Early withdrawal of antigenic stimulation arrests differentiation, even in the continued presence of cytokines. For TH1 differentiation, prolonged signaling is required to induce appropriate epigenetic modifications to maintain high levels of T-bet expression (Chapter 13, see section “TH1 and TH2 Differentiation”).

An important aspect of T-cell differentiation involves antigen selection of a TCR-restricted repertoire. This was clearly shown in the immune response against pigeon cytochrome C, in which the specificity is determined by the CDR3 of the TCR α chain. Of eight preferred CDR3 features that are rapidly selected early during the response, only one (TCR- α 93 glutamic acid) existed to any significant extent before immunization. This TCR restriction and clonal dominance is antigen-driven and is propagated by expansion of one or a few clones from the postthymic repertoire.

This selective T-cell expansion for effector and memory function takes place in the T-cell zone, before the GC reaction. Inflammatory cytokines, particularly IL1 or TNF- α , also mediate some of these effects through CD28 co-stimulation by up-regulating expression of CD80 and CD86 on DCs.

After the peak of clonal expansion, the number of antigenspecific T cells falls owing to cell death, which may occur via Fas-dependent or activation-induced cell death. For the antibody response to continue, T and B cells, which are specific for different

P.331

P.332

epitopes of the same antigen, must move from their separate locations to meet. Of the surviving activated T cells, most of them move out of the lymph node as memory T cells, but a small portion migrates to the edges of the paracortex next to the follicle, and B cells also move to the same location.^{294,295}

FIGURE 14.10. Chance and necessity: the germinal center reaction. Antigen (Ag) captured in the periphery by dendritic cells (DCs) is brought to the regional lymph nodes to be presented to naive T cells (t) (synapse I). Clonally selected naive T cells become activated by interleukin (IL)-2 (T). They up-regulate the CXCR5 receptor, respond to BLC chemokine that is secreted from follicular cells, and move toward or even inside the follicle. In the border between the paracortex and the mantle of the follicle, they interact with B cells. The interactions are not yet well characterized in vivo. Some B cells process antigen and may present it to T cells that are selected by DCs (synapse II) (1). B cells may have been selected by the same antigen but for a different epitope. B and T cells may bind to the same immunogen but on different epitopes (“carrier effect”; synapse II) (2). Synapse II promotes differentiation of plasma cells that secrete immunoglobulin (Ig) M. B cells move inside the follicle to the pole that is adjacent to the T-cell zone (dark zone) and begin intensive proliferation. They are Ig-negative and are called centroblasts. B cells undergo mutations in the V gene at a high rate (somatic hypermutation) and change their IgM to another Ig class (class switch). When proliferation subsides, centroblasts move to the center of the germinal center—i.e., the light zone—and are known as centrocytes (Ig-positive). Their B-cell receptor (BCR) is submitted to the scrutiny of antigen-antibody complexes on dendrites of DCs of the densely populated light zone. In most centrocytes, somatic hypermutations have decreased or destroyed the affinity of their BCR and enter the pathway

for apoptosis. Their corpses are removed by macrophages known as tingible body macrophages (TBM). If the affinity is increased, they are given the green light for survival and growth (BAFF, IL-6, IL-4, CD40-CD40L). Surviving cells have higher affinity than their predecessors (affinity maturation). They receive signals from germinal center DCs or follicular T-helper cells (TFH). Depending on the instructions that are received, some centrocytes go down memory lane, whereas others become plasma cells. Two genes are most influential in the regulation of germinal center reaction: B-cell lymphoma 6 (BCL-6) in the early phase represses all genes that regulate the second state; the B-lymphocyte-induced maturation protein-1 (Blimp-1) is released from repression when BCL-6 is down-regulated by high-affinity BCR signals. Blimp-1 regulates plasma cell differentiation. b, naive B cell; B, primed, antigen-specific B cell; BAF, B-cell activating factor of the TNF family; BM, bone marrow; CIITA, major histocompatibility complex class II trans-activator molecule; IDC, interdigitating dendritic cell.

Chemokines and their receptors are the main regulators of primary immune responses, setting the stage for the main players as well as orchestrating their performance. CCR7 is the most important for organizing the appropriate microenvironment to make the initial interaction possible.²⁹⁶ As multiple cells contribute to an immune response, change in the chemokine receptor program regulates the second stage in the cell interactions for antibody synthesis. CCR7 is the receptor for chemokines SLC (6CKine, exodus2, and CCL21) and ELC (MIP-3 β , exodus3, and CCL19). SLC is secreted by the cells of high endothelial venules and mediates the crossing of T cells to the lymph nodes. ELC is secreted by stromal cells of the paracortex and attracts naive T cells to settle within the T-cell areas (see Chapter 11). DCs in the peripheral tissues up-regulate CCR7 expression as part of their maturation and are guided to the paracortical areas. The CXCR5 is the receptor for chemokine BLC (CXCL13), which is secreted by stromal cells in the follicles and attracts B cells that cross the high endothelial venules to settle in the follicular area. Activated CD4⁺ T cells up-regulate CXCR5 and migrate to the follicles.^{297,298,299,300,301} Whether the T-cell-B-cell interaction takes place on the paracortical side²⁹⁵ or the follicular side²⁹⁴ of the T-cell-B-cell border is not clear. The fact is that the two cells physically interact (second cognate interaction), forming a synapse by adhesion molecules and supported by co-stimulatory molecules, including the inducible costimulator (ICOS) on activated T cells and its counterreceptor B7-h on B cells.³⁰²

GERMINAL CENTER REACTION

Interaction of B cells with activated T cells initiates their proliferation and migration into the area within the primary follicle, which is now called the secondary follicle. Some of the activated B cells differentiate at the edge of the T-cell zone into plasma cells, secreting IgM and migrating to the medullary cords and on to the bone marrow. Plasma cell differentiation in this area could also be induced in a T-cell-independent way, especially from antigens known as T-cell-independent antigens. The IgM antibody is part of the early phase of antibody production.³⁰³ The remaining antigen-specific B cells are recruited within the follicle and rapidly expand to form the germinal centers.³⁰⁴ GCs are formed as a result of the expansion of one or a small number of B cells and are therefore monoclonal or oligoclonal. The expanding population of B cells fills the FDC network,³⁰⁵ and although T cells facilitate their formation, GCs may be formed in the absence of T-cell signals for certain antigens.³⁰⁶ Multiple steps of mutation and selection are the main driving forces in the formation of the GCs, and recirculation of positively selected centrocytes is quite unlikely.³⁰⁷ CD27 is important for GC formation by two distinct mechanisms. T cells support formation of GC as a result of interaction of CD28 (T cells) with CD27 (B cells) (centroblast expansion) and, in addition, CD27⁺ T cells may be interacting with CD70 on B cells.³⁰⁸ The GCs are oligoclonal and with a cell cycle time of the dividing B cells of approximately 6 hours, the number of accumulating blasts within 3 days is of the order of 1 to 1.5×10^4 . During this exponential growth, the small recirculating B cells are excluded and are pushed aside to form the familiar mantle that surrounds the GC. By the time the B blasts finish their exponential growth, they have filled the FDC network that is close to the T-cell zone, which is known as the dark zone, and the B blasts are known as centroblasts. Centroblasts are Ig⁻ and give rise to nondividing Ig⁺ cells, which are known as centrocytes, which occupy the center of the follicle or the light zone. The light zone has been divided into an apical (FDC CD23²⁺) and a basal component (FDC CD23⁻; Fig. 14.11).

FIGURE 14.11. The germinal center. Dark zone, centробlasts in cell cycle. Light zone, strong expression of CD23 on dense follicular dendritic cell (FDC) network. Mantle, loose FDC network.

Several important events for the life of B cells take place in the GCs: clonal expansion, somatic hypermutation (SHM) resulting in affinity maturation, Ig class switch, and generation of memory B cells and plasma cells. All naive B cells express the CXCR5 receptor for chemokine CXCL13 (BCA-1, B-cell attractant [chemokine 1]), which is secreted constitutively by cells within the DC network in the follicular area. Furthermore, the DC-specific chemokine CD-CK1 (CCL18, also known as PARC) preferably attracts CD38⁺ mantle-zone B cells toward the FDC and may well provide the initiation signal for the formation of GCs.³⁰⁹ Responsiveness to the CXCL13 is also shown by a minor subpopulation of memory CD4⁺ T cells that express the CXCR5 receptor for the CXCL13 chemokine and, as a result, are attracted to the follicles; they are known as follicular T-helper cells (T_{FH}).^{297,298} The expression of CXCR5 is transient and occurs during T-cell activation but before their proliferation. The CXCR5⁺ T cells constitute only a minor proportion of peripheral T cells. They also express the CC-chemokine receptor 7 (CCR7) and L-selectin (CD62L), allowing a steady-state re-circulation through secondary lymphoid organs.²⁹⁹ Several molecules expressed on T_{FH} cells mediate help to B cells, but crucial among them are CD40L (CD40 ligand or CD154) and ICOS (inducible T-cell co-stimulator), which interact with CD40 and the ICOS-ligand (ICOS-L), respectively, on B cells. Another important molecule of T_{FH} is SAP (its name derives from its association with an activation molecule known as SLAM [CD150], or signaling lymphocytic activation molecule). A significant member of TFH undergoes apoptosis, as shown by gene expression profiling.³⁰⁰

The FDCs are strongly positive for CD21 and CD23 and form a dense network in the light zone. In the dark zone, they are weakly positive for CD21 and negative for CD23, and they form a light network. The FDCs express the long isoform of CD21, which is the only specific marker for human FDCs, whereas the B cells express only the short isoform. FDCs trap immune complexes and present antigen to B cells, although the B cells can undergo somatic mutation and memory cell formation, even in the absence of complexes,³¹⁰ probably by other signals that are received from FDCs, which support B cells in the immune response in several ways. Engagement of CD21 in the BCR by complement in the antigen-antibody complexes augments the stimulation that is delivered by FDCs.³¹¹ Furthermore, engagement of the FcγRIIB on DCs diverts binding of the complexes from the same receptor on B cells. FcγRIIB is an inhibitory receptor, and, thus, by trapping the complexes, the FDCs protect B cells from inhibition.³¹¹

There is cross-talk between FDC progenitors and B cells, because B-cell signals contribute to FDC maturation and network development. LT-α, LT-β, and TNF-α from B cells, and TNFR-1

P.333

expression by some nonbone-marrow-derived cells lead to FDC cluster formation in the lymphoid organs.³¹²

Because FDCs have no phagocytic activity and do not synthesize MHC class II molecules, they are unable to present peptides that are complexed with the MHC after processing of internalized antigens. However, there are two other ways that FDCs perform their antigen-presenting function. Cytochemically, antigen has been detected on FDCs along filiform or beaded dendrites. The beads, like pearls on a string, are particles that contain the immune complexes called iccosomes (immune complex-coated body), which are usually detected in the early phase of the formation of the GCs.²⁷⁶

Complement in the complexes binds to CD21 on FDC and delivers a crucial signal that dramatically augments the B-cell stimulation resulting from binding of the antigen to BCR. FDCs have no phagocytic activity and do not synthesize MHC class II molecules, and therefore they are unable to process antigen for presentation.³¹³ MHC class II, however, has been detected on the surface of FDCs in the form of microvesicles that contain MHC class II molecules and other antigens that are foreign to the FDC.³¹⁴ These vesicles are exosomes that are enriched in MHC class II molecules and members of the tetraspan family (i.e., CD37, CD53, CD63, CD81, and CD82; see Appendix A). The exosomes derive from multivesicular endosomes that are released by B cells with specificity for attachment to DCs and the ability to stimulate CD4⁺ T cells.^{315,316} This is an interesting example of cell communication, antigen processing, and presentation for T-cell activation. FDCs therefore have a dual mission for B-cell response within the GCs: antigen processing and presentation to B cells, and promotion of B-cell differentiation and isotype switching.^{317,318}

In addition to FDCs, T cells have a critical role in GC formation, primarily for the late stages of GC reaction and not during the initial development.^{319,320} GCs that are induced in the absence of T cells are of short duration, and the V genes of the antibodies do not undergo hypermutation. The GCs abort dramatically at the time when T cells normally select the high-affinity B cells.³¹⁹ The demise of the GCs at this point is a fail-safe mechanism to prevent autoreactive B cells from escaping into the periphery, with development of autoimmunity.

In the dark zone, lymphocytes are densely packed, and only fine FDC processes penetrate this area. The FDCs in the dark zone are CD23⁻ and only weakly CD21⁺. The centroblasts are in rapid cell cycle and do not increase in number, but they give rise to a progeny of centrocytes that are nondividing and express surface Ig. Centrocytes are located in the light zone and are CD21 strongly positive and CD23 moderately to strongly positive. In this stage of the evolution of the GC, the B cell is selected for survival or death, based on the affinity of the antigen receptor as the cell emerges from changes induced by hypermutation (see the following discussion).

B Cells in Germinal Centers: Struggle for Survival

Proliferation of B cells in the GCs is stimulated by antigen, but different mechanisms regulate the proliferation in the two GC zones, dark versus light. The paucity of T cells in the dark zone suggests that this early, expansive B-cell phase is supported by strong stimulatory signals from complement-containing immune complexes, FDC-B-cell cognate interactions, and soluble factors from FDCs.³²¹ In the light zone, T_{FH} cells play a more important role and, although the density of FDCs is much higher, some FDCs are inhibitory for B-cell activation. GCs develop within 4 to 6 days after primary immunization, and centroblasts in the dark zone continue to maintain a high output of centrocytes for 7 to 14 days and undergo SHM that results in antigen receptor diversification.

The decision between life or death, a process known as selection, takes place within the light zone as the B cell emerges from the dark zone. The mechanism of selection is not yet clear, but antigen that is trapped on FDCs is used to “test” the affinity of the BCR of the centrocytes. A key determinant for selection is the CDR3, which has a major contribution to diversity and affinity of the receptor. Structurally identical receptors are handled differently if variations in CDR3 exist between them, and such variations drive the selection process.³²² The vast majority of these random mutations is deleterious to antigen binding and destroys or diminishes the affinity of the BCR that existed when the antigen-specific B blast entered the dark zone from the paracortex-follicular border. These cells are negatively selected and are diverted to apoptosis.

Other cells have acquired autoreactivity, and these cells receive no signals from FDCs and therefore die from “neglect.”³²³ Of the cells in which BCR expresses reactivity with antigen, some emerge from the mutational process with high affinity, and only those are positively selected to achieve affinity maturation. Affinity maturation was discovered 42 years ago³²⁴ but remained poorly understood until somatic diversification of BCR genes in the GCs was demonstrated.³²⁵ Affinity maturation signifies the increase of the affinity of antibodies between those that are produced early after primary immunization (low affinity) and those that are produced 2 weeks after immunization or, better, after secondary immunization (high affinity). Affinity maturation is associated with somatic diversification that occurs during hypermutation. As shown by studies in mice, the D and J regions of the H chain (16 amino acids long) of the antibodies that are synthesized 7 days after immunization have no residue changes that could be attributed to mutations. However, by 14 days the antibodies carry somatic mutations that have resulted in increase of the affinity.³²⁶ Positive selection of these high-affinity antibodies constitutes affinity maturation.

Survival of the Fittest

One of the puzzling phenomena related to the life of B cells after their release from the bone marrow is the fact that approximately 70% of them do not reach maturation and die. B-cell survival and maturation relies on the delivery of signals, most importantly through BCR, and survival depends on a mechanism of positive selection.³²⁷ The immature B cells that leave the bone marrow undergo a progressive maturation process that takes the cell through three stages, known as transitional stage type 1 (T1), type 2 (T2), and type 3 (T3).³²⁸ T1 cells are IgM^{hi}, IgD⁻, CD23⁻, and CD21^{lo}, and T2 cells are IgM^{hi}, IgD^{hi}, CD23⁺, and CD21^{hi}.³²⁹

Although the location and mechanism by which this huge number of B cells perish have not been identified, it is possible that a prime location is the light zone, in which the mechanism of cell death is by apoptosis as a result of a BCR that is incapacitated by hypermutation.

B cells require and receive multiple signals from different cells and molecules for survival. The cognate interaction between FDCs and B cells provides signals through antigen presentation (albeit weak), as well as through several receptor-ligand pair interactions, such as ICAM-lymphocyte function-associated antigen-1, vascular cell adhesion molecule-1-very late antigen-4, and CD23-CD21.³³⁰

In addition, DC stimulates B-cell proliferation and Ig synthesis, which are mediated by the CD137-ligand system.³³¹ CD137 is a member of the TNF receptor family that is expressed by FDCs and stimulates the CD137 ligand-expressing B cells by reverse signaling.

Germinal Center B Cell

An important B-cell survival factor that is known as the B-cell activation factor member of the TNF family (BAFF or TNFSF13B) promotes maturation of B cells and prolongs their survival and, under certain conditions, B-cell growth.^{332,333} BAFF forms a trimerlike TNF, like other members of the family, but its unique

P.334

feature is the presence of two Mg²⁺ ions. The gene for TNFSF13B (BAFF) is located in human chromosome 13q32-34, a location that is frequently involved in translocations in Burkitt lymphoma. BAFF exists as a membrane-bound form and as a soluble form. It is closely related (approximately 50% similarity) to another TNF family member, a proliferation-inducing ligand (APRIL). Both BAFF and APRIL bind to two receptors, B-cell maturation antigen (TNFRSF17) and transmembrane activator, and calcium modulator and cyclophilin ligand interactor (TNFRSR13B or TACI), with high affinity, but preferences by the ligands have been detected,³³⁴ with BAFF being associated more often with TACI than with TNFRSF17.³³⁵ A third receptor, called BAFFR (TNFSF13C), selectively binds BAFF and not APRIL. However, a basic amino acid sequence close to the NH2 terminus of APRIL binds to proteoglycans in the extracellular matrix or cells and produces its oligomerization. It is probably an APRIL-specific receptor.³³⁶ TNFSF17 (previously known as BCMA), TNFRSF13B, and TNFSF13C (BAFFR) are located on human chromosomes 16p13.1, 17p.11.2, and 22q13.1-13.3, respectively.

Structural analyses of the three receptors and the phenotypes of mice that are deficient in each one have shown that TNFSF13B (BAFF) transmits the survival signal to transitional cells through the TNFRSF13C (BAFFR) and not through TNFRSF17 (BCMA) or TNFRSF13B (TACI).³³⁷ All three receptors are devoid of death domains, and BAFFR is devoid of TNF-receptor-associated factor (TRAF)-binding domains. TRAFs are adaptor proteins that mediate transmission of downstream signaling in the activation of nuclear factor kappa B (NFκB) and mitogen-activated protein kinase (MAPK) pathways. TNFRSF17 (BCMA) however, activates NFκB through binding of TRAF5 or TRAF6, but not TRAF2.³³⁸

NFκB is associated with a strong antiapoptotic function that regulates the end stages of B-cell maturation, Ig class switching, GC organization, and other processes.^{339,340,341} In the absence of the TRAF-binding domain, TNFRSF13C (BAFFR) uses the C-terminal sequence for survival signaling. Replacement of the last C-terminal amino acids results in loss of BAFFR function and of peripheral blood B cells in mice (strain A/WySn).³⁴²

The mechanism of action of TNFSF13B (BAFF) is not stimulation of B-cell proliferation but promotion of survival, probably by increasing BCL2 expression.³⁴³ Loss of signaling by NFκB blocks up-regulation of BCL2. Mice that are deficient in Rel and Rela, which are members of the NFκB family of transcription factors, have a block of B-cell maturation and are similar to mice that lack Tnfsf13b or Tnfrsf13c. BCL2 expression rescues these mice from B-cell deficiency.³⁴⁴ TNFSF13B acts on the T2 transitional stage of B-cell maturation and on marginal-zone B lymphocytes. In mice that are transgenic for Tnfsf13B, the T2 and marginal-zone compartments of B cells are enlarged. The effect of TNFSF13B on various transitional stages of B cells is regulated by different downstream mediators, but mainly by up-regulation of the antiapoptotic genes A1 and

BCLXL in marginal-zone cells. The net result is a proportional increase in the survival of the cells that traverse each stage.³⁴⁵

TNFSF13B and TNFSF13 (APRIL) regulate B-cell survival and activation,³⁴⁶ and disturbances of their function may lead to important disorders such as autoimmunity^{347,348} and malignancies.^{348,349}

Patients with SLE, rheumatoid arthritis, and Sjogren syndrome have elevated levels of TNFSF13B in their sera^{350,351} as well as in their synovial fluids,³⁵² suggesting that TNFSF13B plays a role in autoimmunity. B cells with strong self-reactivity, however, are deleted before they express TNFSF13B receptor,³⁵³ a mechanism that provides protection against B-cell autoimmunity. TNFSF13B is produced by malignant B cells and is an essential autocrine survival factor in B-cell malignancies.³⁴⁹ Myeloma cells express TNFSF13B and TNFSF13 at levels higher than normal B cells and also co-express TNFSF13B receptor and TNFRSF13B (TACI), thus promoting their survival and proliferation.³⁵⁴

In some of these patients, the TNFSF13B and TNFSF13 have been found in the serum in the form of active heterotrimers.³⁵⁵ The pathogenetic relationship between these two members of the TNF family and the levels of various autoantibodies was shown by the fact that their levels were correlated with titers of the autoantibodies in Sjogren syndrome, such as the levels of Ig, rheumatoid factor, and anti-skin-sensitizing antibody.³⁵⁶

Chronic infection may lead to sustained release of TNFSF13B and emergence of autoreactivity. TNFSF13B therefore appears to be critically involved in certain antibody-mediated autoimmune diseases. Most studies have concentrated on the roles of TNFSF13B and TNFSF13 on B cells. However TNFSF13 also acts on T-cell survival by a mechanism that involves up-regulation of BCL2³⁵⁷ and TNFSF13B; although it does not appear to deliver a typical survival signal, it nevertheless acts on T-cell co-stimulation.³⁵⁸

TNFSF13 is up-regulated in many tumors (colon, prostatic carcinoma) and promotes tumor growth,³⁵⁹ but a soluble form of TNFRSF17 and TNFRSF13B counteracts the action of TNFSF13 and inhibits tumor growth.³⁶⁰ The enhancement by TNFSF13 of tumor growth may be due to up-regulation of BCL2 or signals that are delivered by inflammatory cells in the neighborhood of the growing tumors by cells, such as monocytes (which express TNFSF13), that provide optimal conditions for growth of some tumors, such as Burkitt lymphoma.³⁶¹

The tumor-promoter function of TNFSF13 contrasts to functions of many other TNF-related ligands. The difference in the level of expression of TNFSF13 between normal and neoplastic cells is dramatic. Because adenocarcinoma cells lack any detectable expression of TNFRSF17 or TNFRSF13B, it is likely that another TNFSF13 receptor exists in these tumors. Because TNFSF13B and TNFSF13 promote the survival of B cells and the development of autoimmunity, the inflammatory milieu of an autoimmune reaction supplies paracrine signals for the development of malignancies on an autoimmune background,³³⁵ a connection that was identified clinically many years ago.³⁶²

Follicular T-Helper and Germinal-center B Cells

The CD4⁺CD45RO⁺ recently activated T cells in the blood cross into the lymph nodes, and, because they have down-regulated CCR7 and have acquired instead the CXCR5 receptor, they respond to the call from DCs in the GCs, that is, to chemokine CXCL13 (BLC and BCA-1).²⁹⁷ In the GCs, they become known as T_{FH} cells. In this location, TFH cells express high levels of CD40L, a co-stimulatory molecule that is required for B-cell activation and Ig class switching, as well as for the induction of ICOS (inducible co-stimulator). CD28 is required for naive T cells to differentiate into effector GC T cells and for subsequent primary antibody response. Secondary B-cell responses and continuous B-cell activation depend on the CD28 homolog, ICOS; that is, T-cell help is delivered for B cells in an orderly sequence of interactions.³⁶³ The importance of ICOS for sustained B-cell proliferation is reflected in the Icos-deficient mice that have no GCs after secondary immunizations.

Memory T_H cells, after repeated antigenic challenges, emerge with restricted V-region genes and preferred CDRs that confer peptide specificity.³⁶⁴ The memory T cell acquires a functional potential of cytokine secretion early in the primary response, but the delivery of these functions is highly regulated and complex.

T-cell memory is an "operational property of the whole animal or immune system,"³⁶⁵ and, under this broad definition, the requirements for its maintenance and the delivery of specialized functions, although precisely regulated, depend on complex microenvironmental influences.

B-cell proliferation and differentiation are down-regulated by cytotoxic T-lymphocyte-associated protein-4 (CTLA4), a negative regulator for B-cell proliferation. CTLA4 is sequestered in a late or post-Golgi endosomal compartment and is available for rapid delivery to the cell surface, where it interacts with B7 ligands.³⁶⁵ Interaction with B7 causes phosphorylation of one of

the Tyr-containing sequences of CTLA4 that binds the SRC homology 2 (SH2) domain of the Syk phosphatase. Syk dephosphorylates signaling molecules in the vicinity of TCR, dampening or inhibiting completely the TCR signaling pathway.³⁶⁶

CD40 and CD40 Ligand (CD154) Interactions

CD40 and CD40L (CD154) are members of the TNF superfamily and play a crucial role in T-dependent and T-independent humoral immune responses. The CD40 gene is localized in chromosome 20q12-13.2. CD40 is homologous to the TNF receptor, and CD40L is homologous to TNF. (For details of the structure and expression of CD40 and CD154 (CD40L), see Appendix A).

CD40 is expressed on DCs and B cells, and CD154 is expressed on T cells. The CD40-CD154 interaction is critical for T-cell activation and development of the T_H1 and T_H2 responses.^{367,368} The extracellular region contains four Cys-rich domains, and the intracellular region contains distinct sites for binding the adaptor proteins, TRAF1, TRAF2, TRAF3, TRAF5, and TRAF6, and a separate site for direct binding of JAK3 (the Janus family of protein Tyr kinases).

CD40 engagement delivers signals along two broad pathways: TRAF-dependent and TRAF-independent. TRAFs are adaptor proteins that link the receptor to signaling molecules and mediate specific biologic responses. The specific functional outcomes of CD40 engagement extend to a huge territory of cell biology in general and of B cells specifically, such as clonal expansion, activation, chemokine and cytokine secretion and responsiveness, Ig production, and Ig class switch.

The reader is referred to the reviews that were cited previously. The functions that are induced by CD40 engagement are the result of activation of several transcription factors, more importantly, NF κ B, AP-1, and c-AMP response element. Ligation of CD40 on B cells results in proliferation or apoptosis, depending on the differentiation state of the B cell, particularly by linking to different TRAF adaptor molecules. CD40 induces homotypic adhesion between B cells through expression of lymphocyte function-associated antigen-1-ICAM1, or CD23-CD21. The same molecules can also mediate interactions between B cells and T cells or DCs.

Important contributions of CD40-CD154 interactions in humoral immunity are the regulation of APC functions, GC formation, Ig synthesis, and Ig class switch.³⁶⁹ A central role in several of these functions of CD40 is played by the duration of expression of the ligand of CD40 by the T cells.³⁷⁰ Some memory T cells have pre-formed CD154 that can be rapidly expressed on the surface after T-cell activation.

Expression of CD154 for a limited time allows B cells to terminally differentiate and secrete antibody. T_H1 -differentiated cells express CD154 for >3 days and suppress antibody production, whereas activated T_H2 memory cells express CD154 for <12 hours and allow antibody to be produced.³⁷⁰ Expression of CD154 on T cells is reciprocally regulated by cytokines; although IL12 sustains CD154 expression, IL4 represses CD154 expression. It is clear now that prolonged engagement of CD40 inhibits secretion of Ig.³⁷¹

Multimers of TRAF3 and TRAF5 mediate the signals for T-dependent humoral responses.

Signaling events from CD40 engagement without TRAF involvement are still unclear. CD40 ligation leads to phosphorylation of several protein Tyr kinases, such as LYN, BLK, BTK, and SYK. JAK3 binds directly to CD40, but the role of signaling by this pathway remains controversial. BTK leads to expression of CD80 and CD86 after CD40 ligation.

In general, signaling through TRAFs seems to be more important for the CD40-mediated functions.

IMMUNOGLOBULIN CLASS SWITCH

Class or isotype switch refers to the change of the H chain of the antibody molecule by the constant domains of another H chain class. When the antibody changes to another Ig class, it still retains the entire L chain and the V domains of the H chain. In other words, the antibody retains the same specificity for antigen but changes all effector functions that are determined by the H chain domains, such as complement fixation and phagocytosis.³⁷² The change involves a recombination of H chain alleles that results in deletion of DNA. It is called switch recombination, because it occurs between the switch (S) regions. Class switch affects all Ig classes except IgD, which has no S region of its own and is co-expressed with IgM by termination of transcription and RNA processing. Switch recombination occurs in mature B cells after exposure to antigen, T-dependent or -independent; simply by T-cell signals alone in the absence of antigen (i.e., CD40 and CD40L); or by cytokines. Transcription initiates within the promoter of the intronic (I) exon, proceeds through the S region, and terminates in the 3' end of the C_H allele, at the poly (A) site of secreted or membrane C_H allele (Fig. 14.12).

A unique sequence 5' to each I exon determines the selectivity of the switch recombination, acting as the site for binding of a series of regulatory proteins that are expressed after activation. The I region targets class switching to specific S regions that initiate transcription,³⁷³ and an intact I region is required for recombination. The factors that initiate recombination confer accessibility of the switch recombinase to the C_H locus (accessibility model).³⁷² Basically, what accessibility means is that the gene that undergoes switching must be transcriptionally active and therefore accessible. Although accessibility allows transcription, which is targeted to a specific S region to be initiated, it is not the only operating mechanism in class-switch recombination (CSR).³⁷⁴

Understanding of CSR took an unexpected turn with the discovery that CSR and SHM are mediated by the same or similar mechanisms.^{375,376,377} An enzyme known as activation-induced cytidine deaminase (AID) is an RNA-editing enzyme that is induced after cell activation.³⁷⁸ RNA editing is a post-translational modification of RNA. The type of editing that occurs in mammalian cells involves deamination of a base, which converts it to

P.336

another base (e.g., cytidine to uridine or adenosine to inosine). Usually, the editing enzyme is associated with other proteins, forming an editing complex or editosome. AID is structurally similar to the RNA-editing enzyme, APOBEC-1, which deaminates deoxycytidine. APOBEC1 is involved in editing of the mRNA for apolipoprotein-B, generating a new mRNA that encodes a protein, which is an essential component of chylomicron. B-cell activation is important for the induction of CSR recombinase and the selection of the target S region. Both of these events are absolute requirements for CSR.

FIGURE 14.12. Class-switch recombination (CSR). In CSR, the surface immunoglobulin (Ig) M of the B cells is replaced by an Ig of another class. The IgM gene, which is located in the variable region of the heavy chain (VH) proximal end of the constant region of the light chain (CH) gene cluster (A) is replaced in that position by a gene of another class. In the 5' side of each CH gene is the S region (switch; A), followed by a specific intronic (I) promoter, which regulates cytokine-induced transcription of the target gene. The intronic enhancer (E_μ) makes S_μ accessible for recombination with other downstream S regions ("accessibility model"). Beyond accessibility, an enzyme known as activation-induced deaminase (AID; Fig. 14.13) is involved in CSR. The contribution of AID is not yet clarified, but AID deficiency in mice blocks CSR

completely, although germinal center reaction is still intact. The S region of the new Ig gene is brought in juxtaposition to μ , and the intervening sequence is looped out (B). The new CH is brought in next to the VH (C). The new Ig has the same specificity (VH) but possesses different biologic functions that are dictated by the CH.

Activation of the B cell usually occurs through BCR or CD40/CD40L or a cytokine. CSR has always been considered highly dependent on CD40L, and IgG, IgA, and IgE production is severely impaired in the X-linked hyper-IgM (HIGM) syndrome (see section "Hyper-IgM Syndrome"). The CSR activation through CD40/CD40L is T-cell-dependent, because CD40 signaling depends on its ligation by the CD40L that is expressed on T cells. Viral glycoproteins and bacterial LPSs can stimulate IgG and IgA production in the absence of CD40L-expressing T cells. A more physiologic T-independent CSR is induced by DCs through BAFF and APRIL.³⁷⁹

Cytokines direct switching for certain Ig classes; IL4 directs switching to IgG4 and IgE, whereas IFN- γ antagonizes some of the effects of IL4 on germline transcription. TGF- β increases IgA transcripts followed by IgA switching.

The S region is removed by splicing, leaving the 5'-I_HC_H-3' germline RNA. Upstream (i.e., 5') of the I exons are sequences that are considered as sites of cytokine action, which generate DNAase-hypersensitive sites to be used for germline transcription.

For example, IL4, which is a switch factor for IgE, binds to the IL4 receptor and activates the Jak kinases. The Jak kinases induce the signal transducer and activator of transcription (STAT)6, which binds to IL4-responsive elements found upstream of the IgE gene and switch on for IgE transcription.

The S regions used for CSR consist of tandemly repetitive units with many palindromic, that is, inverted, repeats. Therefore, CS recombinase may recognize the secondary structure of the S region DNA rather than the primary sequence. In this respect, it differs from V(D)J recombinase, which targets consensus heptamer and nonamer sequences around the V, D, and J segments. In CSR, the germline transcripts and AID are not sufficient to induce class switch, as was originally thought,³⁸⁰ but transacting factors may play a role.^{374,381} These trans-acting factors are thought to act as docking proteins that recruit AID to the S regions.^{382,383} and ³⁸⁴

The initial event in CSR is a double-strand break (DSB) and produces 3' or 5' overhangs. If, for example, the class switch is between the IgM constant gene and the IgA-1 constant gene (Fig. 14.12) the CSR brings the IgA heavy-chain gene close to the V (V_HDJ_H) gene. Thus, after the IgM/IgA class switch, the IgA antibody has the same specificity as the IgM. The intervening DNA sequence between the μ and α regions forms a circular structure that is looped out.³⁷⁶ The circular DNA that is looped out includes the I promoter of the target S region, which is driven by specific cytokine stimulation before the CSR. This I promoter is still active in the looped-out DNA and directs production of transcripts, termed circular transcripts, which depend on the expression of AID. Circular transcripts may be used as a hallmark of active CSR⁴⁰⁸ and were detected in the majority of patients (14 of 20) with CLL. This indicates that some cells of the clone are able to differentiate in vivo along the pathway that induces CSR³⁸⁵ by stimuli provided from bystander immune cells. The DSB repair machinery is recruited to repair the DNA breaks. Because the S regions are heterogeneous in nature, the joining of the DNA is completed by the nonhomologous end-joining (NHEJ) system. Mutations in the NHEJ system inhibit class switch.³⁸⁶

NHEJ is a process that rejoins DNA breaks with the use of little or no homology. There are five proteins that operate in NHEJ: KU86 (XRCC5), and DNA-dependent protein kinase (DNAPK). DNA-PK consists of a catalytic subunit (DNA-PK_{CS}) and a DNA-binding component that is called Ku, itself a heterodimer of 70- and 80-kDa polypeptides. The protein kinase activity of DNA-PK is activated when Ku binds to altered DNA structures, such as DSB, nicks, or hairpin loops.³⁸⁷ The discovery of the mechanism of CSR is a major advance in our understanding of the complexity of mechanisms that are used by the immune system in the diversification of genetic information to meet the needs and challenges caused by pathogens,^{376,388,389} and it is even more intriguing that the same machinery used for CSR is also used for a second diversification mechanism that takes place in the GCs, SHM.^{375,376,390}

SOMATIC HYPERMUTATION

The first diversification of genetic information in B lymphocytes takes place in the bone marrow during B-cell development. It involves the building of a BCR by random selection of a few DNA segments that are joined by V(D)J recombination. The assembly of these segments constitutes the combinatorial diversity (CD). CD is enhanced further by the addition during the repair of the cut ends of the DNA of palindromic and nongermline nucleotides that generate another level of diversity, the junctional diversity. (See Chapter 12, Fig. 12.5.)

When the IgM⁺ B lymphocyte moves out of the bone marrow to the real world of the secondary lymphoid organs, it finds itself ill-prepared to meet the existing challenges. It further diversifies its BCR during the evolution of the immune

response within the GCs by two additional mechanisms: antibody CSR and SHM. Both of these pathways of diversification use similar mechanisms, with a prominent role played by an enzyme known as AID, which functions as a deaminase and is induced after cell activation. Although the same enzyme, AID, functions in both CSR and SHM, different domains of AID mediate each of these two processes.³⁹¹ Mutations in the N-terminal region of AID causes SHM deficiency and CSR is retained, whereas changes in the C terminal cause loss of CSR activity but not SHM. In addition to its enzymatic activity, AID acts as a docking platform by its C terminus that is specific for CSR.³⁹² Under conditions of stimulation of murine splenic B lymphocytes (e.g., LPS or IL4, which do not induce SHM), large numbers of mutations were detected in the 3' subregion of the S μ region.³⁹⁰ The S μ mutations are independent of the CSR, because they are detected in the S μ of switched and unswitched alleles. These mutational changes of S μ have been considered similar to the mutations that are introduced by SHM during B-cell activation in the GCs.³⁹³ Comparison of the amino acid sequence of L chains from mouse myeloma proteins with the sequence of the same gene from bone marrow B cells (germline) confirmed that the amino acid differences occurred as a result of mutations.³⁹⁴ SHM is the mechanism by which the affinity of antibodies increases after antigen stimulation, a phenomenon that was discovered in the late 1960s and has been known as affinity maturation.

The mutations are largely confined to the V domains^{395,396} and occur in the framework regions as well as the hypervariable regions. They also tend to occur on some residues (hotspots) more often than on others. Hotspots of SHM overlap with the CDRs, which contact the antigen directly. However, the SHM mechanism does not seem to target a specific sequence, because SHM has even been detected in other molecules, such as the BCL6 gene,³⁹⁷ CD79A (Ig α), and CD79B (Ig β) genes,³⁹⁸ and CD95,³⁹⁹ or even in completely artificial sequences that are inserted into an IGK α transgene.⁴⁰⁰ Mutations are introduced in the variable region of the Ig genes at a rate of $\sim 10^{-3}$ mutations per base pair per division, which is 10^6 -fold higher than spontaneous mutation rate in somatic cells. Comparison of the mutability of triplets shows that some are targeted more often than others. For each of the triplets, one can calculate an expected ratio of replacement (R) to silent (S)

P.337

mutations. For example, in triplets that encode glycine (Gly), six of the nine possible nucleotide substitutions result in an amino acid replacement mutation that gives an R:S value of 2 (6/3). In the case of histidine, eight of nine possible substitutions generate an amino acid exchange, and the ratio is 8 (8:1). Evolution has selected for CDRs in which the codon usage leads to a high ratio of R:S mutations. Those are mutations that are likely to affect the antibody-binding site, and the R:S value in the CDR is used as a marker for affinity maturation. No specific targeting mechanism is likely to exist. SHM assisted by AID may occur in other genomic locations,⁴⁰¹ and it is not specific for the Ig genes. Accordingly, AID and the SHM machinery may be a genomewide mutator.⁴⁰² The Ig genes seem to be more highly mutated than the rest of the genome during the affinity maturation process in the GCs. In addition, they are more highly transcribed and have a higher density of DGYW hotspots than other genes.

The process of SHM occurs during the period in which the B cell undergoes a high rate of divisions (approximately one every 6 hours); this period is observed in the dark zone of GCs and is also linked to transcription, with which it is positively correlated.⁴⁰³ GCs have been considered the centers of hypermutation,⁴⁰⁴ although in lymphotoxin- α -deficient mice that lack GCs, mutations can still be induced with strong antigenic stimulations.⁴⁰⁵ The nature of the signals that are necessary for SHM is not well understood. CD40/CD40L interaction is important for the development of GCs and for proliferative activity, both of which are requirements for SHM. Under conditions in vitro that allow SHM to take place, three signals have been identified to be required: signals from anti-Ig, anti-CD40, and anti-CD38.⁴⁰⁶

With the use of several phenotypic markers, the B lymphocytes have been separated into different groups that represent different stages of B-cell differentiation. The majority of the B cells in humans expresses IgM (as much as 90%) and can be distinguished into IgM⁺/IgD⁺, IgM⁺/IgD⁻, and IgM⁻/IgD⁻ groups.

The IgM⁺/IgD⁺ do not carry mutations, except for a subpopulation that expresses CD27.⁴⁰⁷ IgM⁺/IgD⁺ B cells are newly released from bone marrow and are considered still antigenically inexperienced. The two other groups, IgM⁺/IgD⁻ and IgM⁻/IgD⁻, have mutations and therefore belong to their post-GC lymphocytes.⁴⁰⁸

Mechanism of Hypermutation

The hypermutation domain—the region in which mutations occur—spans 1.5 to 2.0 kb downstream of the Ig promoter (Fig. 14.12). The frequency of the mutations increases in the 5'-to 3'-direction, peaks over the V(D)J recombination site, and then decreases toward the J-C junction. The 5' boundary near the promoter is sharp, but the 3' boundary near the enhancer region is less well defined. The I enhancer is the only sequence in the Ig gene cluster that is irreplaceable and

must be in the correct orientation. The need for the enhancer provides the explanation of the strong correlation of SHM with the transcription process. The mutation rate is 10^{-3} to 10^{-4} base pairs per generation, that is, six orders of magnitude higher than the spontaneous mutations.³²⁶ The mutations are usually point mutations, but insertions, deletions, or duplications also occur.^{408,409} Although mutations are limited within the boundaries of 1.5 to 2.0 kb, they tend to exhibit a characteristic nucleotide substitution preference, which affects not only the primary sequence but also secondary structures, such as hairpin loops, which are encoded by palindromic motifs. In spite of these preferences, the sequence of the V gene itself does not initiate the mutation, because artificial substrates hypermutate successfully.⁴¹⁰

Two steps have been considered important for SHM: (a) DNA cleavage, which results in DSBs and (b) DSB repair, which is done by an error-prone mechanism.⁴¹¹ It is recognized that (a) DSBs occur in hypermutating sequences (hotspots), (b) they are coupled to transcription, (c) they depend on the presence of the Ig enhancer, and (d) they correlate with the appearance of nearby mutations.^{412,413} The DSBs are restricted to cells that have completed or almost completed DNA replication and need to be repaired before the end of cell division. In eukaryotes, there are two DNA repair mechanisms, homologous and NHEJ, each of which is used in distinct phases of the cell cycle. The NHEJ is used in the G₁ to S phase, and the homologous recombination is used in the late S to G₂ phase.

In V(D)J recombination, the DNA breaks occur in the G₁ phase and are repaired by the NHEJ that is activated in the same period of the cell cycle. SHM occurs during the G₂ phase,⁴¹⁴ when a sister chromatid is present, and homologous recombination is active, whereas NHEJ occurs in the absence of such a template. The precise phase of the cell cycle for introduction of mutations, however, is not yet agreed on, because they have also been detected during the G₁ phase.⁴¹⁵ For SHM, the AID is necessary, because AID deficiency impairs SHM. The relationship of AID to the DSBs is not clear, and AID probably makes no contribution to their generation,⁴¹⁶ because, according to some evidence, AID acts after their occurrence.⁴¹² Furthermore, DSBs occur with the same frequency in rearranged and germline genes, and yet SHM is preferentially attracted to the rearranged genes,⁴¹⁷ which suggests that DSBs do not express any functional affinity for AID attraction. AID has landed on the stage of SHM only recently, evokes considerable wonder, and attracts massive attention. AID's activity is well understood, but its role in SHM remains elusive.⁴¹⁸

Another approach in the search for answers for the SHM mechanism concentrates on polymerases.⁴¹⁹ Most mutations in SHM are point mutations, but deletions, insertions, or duplications of DNA segments are also common. These changes are recognized as the signature for a DNA polymerase (pol) and are considered as strong evidence against an SHM mechanism that invokes a basemodifying enzyme or chemical DNA modification. Based on these arguments, the SHM could be the result of a DNA polymerase with poor discriminatory capacity for bases. Such a polymerase could be one of the Y family of DNA polymerases—pol ζ, pol ε, pol ι, pol κ⁴²⁰—that are specialized for bypassing DNA lesions (translesional polymerases). Some of these polymerases have been implicated in SHM.^{421,422,423} and ⁴²⁴

Pol ε is significantly error-prone when it copies normal DNA and makes, on average, several more mistakes than a stringent polymerase.⁴²⁴ Patients with a null mutation of POLH (pol ε) present a variant form of xeroderma pigmentosum with a propensity for skin malignancies.⁴²⁵ These sloppy polymerases have the capacity to bypass a DNA lesion, which may otherwise bring the DNA replication to a halt and the cell to its death. However, during the replication of normal DNA, they are notoriously unfaithful in the selection of bases.

AID may function in signaling processes or in editing key molecules in B-cell differentiation in the GCs (see section “Hyper-IgM Syndrome”), at the mRNA level, or by direct alteration of the target V gene, at the level of the RNA transcript. However, some recent results point out another pathway that is opened to AID in CSR and SHM. AID, as mentioned earlier, is a deaminase that converts deoxycytosine (dC) to deoxyuracil (dU; Fig. 14.13A-C). This conversion takes place during transcription of target genes and affects only the nontemplate DNA strand that is exposed as single-stranded DNA during the elongation reaction. This evidence supports once more the direct relationship of transcription and mutations that are linked by the deamination function of AID.⁴²⁶ As a result of this function, AID creates a dU/deoxyguanosine (dG) mismatch or lesion in the DNA, which needs to be repaired. A major mechanism in the resolution of the lesion is excision of the uracil, which can be accomplished by several enzymes, one of them being a uracil-DNA glycosylase (UNG).⁴²⁷ UNG is the major DNA glycosylase in the mouse that processes programmed dU/dG lesions in the Ig genes.⁴²⁸ If the dU that is created by AID is removed by UNG, an abasic site (AP) is generated (Fig. 14.13D).

P.338

If the base excision repair (BER) mechanism arrives first, ahead of the replication fork, a nick or a gap is created, which is filled quickly by the high-fidelity pol δ or pol ε, and no mutations take place. However, if the replication fork wins the race to the lesion, the high-fidelity polymerases are stalled (Fig. 14.13E), and an error-prone polymerase, such as pol ζ, pol ε, or

pol ι , places a base across from the AP site. If the polymerase continues its error-prone function, it introduces many more errors, that is, mutations.⁴²⁹ In mice that are deficient for UNG, the class switch is markedly impaired. This indicates that the AP that is created from removal of dU by the UNG is essential for CSR. The generation of double DNA breaks follows through interference with BER assembly by the CSR machinery.

FIGURE 14.13. Somatic hypermutation. The immunoglobulin M of B cells is of low affinity and has been selected before exposure to antigen. The need to improve the affinity is satisfied by another round of B-cell receptor diversification in the

germinal centers, after exposure to antigen. In the dark zone of the germinal centers, mutations are introduced in the V gene at a rate 1 million times faster than natural mutations; thus it is called somatic hypermutation (SHM; see the text for details). During SHM, double-strand breaks occur in the DNA, as well as rapid gene transcription. Furthermore, for SHM, the immunoglobulin gene promoter is essential, as is an enzyme, activation-induced deaminase (AID). AID removes the NH₂ group of deoxycytosine (dC) (A), forming deoxyuracil (dU) (B). The change generates a dU/deoxyguanosine (dG) mismatch (B). The lesion may be repaired by the base excision repair (BER) (C), and mutation is prevented. However, dU may be removed by another enzyme, uracil-DNA glycosylase (UNG). In this case, the DNA strand remains in one spot that is unoccupied by any base (abasic lesion) (D). High-fidelity DNA polymerases (pols) (i.e., δ or ϵ) are stalled at the abasic lesions, and a promiscuous error-prone pol (i.e., ζ or ϵ) takes over. It usually places a deoxyalanine (dA) on the sister chromatid, opposite to the abasic lesion (E). The positioning of thymidine (T) opposite dA repairs the lesion, but pol continues over the lesion (translesional pols), altering the bases downstream. This generates a cluster of mutations that are close to the dU excision. As a result, one of the daughter cells is normal (F), whereas the other (with the abasic lesion) has mutational changes (E). VH, variable region of the heavy chain.

The function of AID involves introduction of potentially mutagenic changes,⁴³⁰ which have been detected in various experimental systems' non-Ig genes. Ubiquitous and constitutive expression of AID in transgenic mice causes T-cell lymphomas, with TCRs and Myc genes expressing several mutations.⁴³¹ These mutations preferentially occurred in hypermutation hotspots, and were biased toward G-C pairs, which is an AID sequence preference. AID also induces MYC-IGH@ translocations in B cells lacking p53 tumor suppressor.⁴³² AID activity in these experiments indicates that under certain circumstances it may induce chromosomal translocations.

In contrast to normal B cells, in B-CLL cells AID transcripts have been detected constitutively even though the cases were classified as unmutated.⁴³³ However, when B-CLL cases with Richter's transformation were examined, AID expression and SHM activity were higher than in nontransforming B-CLL.⁴³⁴ The oncogenic potential of AID has been verified in transgenic mice that develop T-cell lymphomas.⁴³¹

In conclusion, the AID appears to be important for somatic diversification of Ig genes, but the question remains whether AID can unite all the gene changes, such as SHP, CSR, and gene conversion,⁴³⁵ required in life, or if AID needs more than one other aid.⁴³⁶ To this point, it is interesting that AID deaminates dC on single-stranded DNA, but it requires the action of RNase.⁴³⁷ As of today, this is the latest aid that comes to AID's help.

GENOMIC VIEW OF GERMINAL CENTER REACTION

The study of the GC reaction by conventional, morphologic, and functional methods has provided a clear picture of the central position of the GC in the differentiation of B cells and the function of humoral immunity. Microarray technology carries our understanding to the last frontier,⁴³⁸ the genes that are involved in initiation and evolution of the reaction. Findings by this approach confirm what is known: the naive, antigenically inexperienced B cell does not divide and does not make Ig but is poised to respond to antigen. Indeed, naive B cells express genes that are inhibitory of proliferation (CDKN1A, also known as WAF1), as well as growth expression (BIN1 and BOK) genes. They also express mRNA for early-response genes (JUN and ZFP36L2, also known as ERF2), CCND1 (cyclin D1), and CCND2 (cyclin D2) that function during the transition from G₁ to S phase.

The change from naive B cell to centroblast is as striking at the gene level as it is with the techniques that have been used thus far. The centroblast expresses the vast majority of proliferation-associated genes, as well as those that regulate the cell cycle and mitosis. One of the unexpected results was the lack of expression of c-myc proto-oncogene, which is known to be associated with cell proliferation. Genes that regulate apoptosis are up-regulated, whereas antiapoptotic genes (BCL2) are down-regulated. Studies of gene expression do not detect significant differences between centrocytes and centroblasts, although these two populations have distinct functional characteristics. It is suggested that one of the two populations may be heterogeneous. The light zone contains detectable subpopulations by phenotype or by the expression of transcription factors.

In general, the global gene profile of naive B cells is that of suppression, actively maintained by notable inhibitors of signal transduction.⁴³⁹ However, the GC B cell is characterized by a proliferation signature, which includes activation of genes that participate in various stages of cell cycle, such as cyclin, cyclin-dependent kinase (cdk), and CDC2, which drive cells through the G₂ and M phases. Additionally, other genes that organize the mitotic spindle are also activated.⁴⁴⁰ Somewhat atypical is the lack of MYC expression, a gene known for its proliferative function. Lack of MYC expression⁴³⁸ is reflected by the down-regulation of

sets of genes involved in energy metabolism that are transcriptionally regulated by MYC.

The lack of MYC function may be due to the expression of the human homolog to the mouse MXD3 (MAD3) gene, which forms dimers with MYC and thus blocks its function as a transcriptional activator.

The GC B cells are thus poised to undergo apoptosis, which takes place extensively in the light zone, after hypermutation. Well-known antiapoptotic genes, such as BCL2 and BCL2L1 (BCL-XL), which are targeted by the NFκB transcription factor, are poorly expressed. Not only are antiapoptotic genes suppressed, but expression of proapoptotic genes, such as BIK (member of the BCL2 family), constitute part of the GC B-cell signature.

The BCL6 gene is highly expressed during the GC reaction that promotes the differentiation within GCs but is down-regulated during plasmacytic differentiation.⁴⁴¹ Mice that are deficient in Bcl6 fail to develop GCs and are deficient in affinity maturation, with a reduction in antibody responses. BCL6 represses CD40L-induced and NFκB-dependent gene transcription of B7-1, a co-stimulatory molecule that is essential for T-cell-B-cell interactions.⁴⁴² Mice that are deficient in Bcl6 not only cannot develop GCs, their memory B cells also have no VH mutations.⁴⁴³ Because Bcl6 appears to be a major promoter of GC reaction, the question that is raised is what are the signals that oppose Bcl6 signaling and bring GC reaction to a halt. The BCR signaling opposes BCL6 transcription,⁴⁴⁴ probably directing BCL6 degradation by proteasomes as a result of its phosphorylation by MAPKs.⁴⁴⁵ The hypermutated high-affinity BCRs interact in the light zone with antigen, and the signals that are generated are sufficiently strong to phosphorylate BCL6, leading to its degradation and bringing GC reaction to a halt. Important molecules that have been kept suppressed, such as B lymphocyte-induced maturation protein 1 (PRDM1 or BLIMP1), initiate plasma cell differentiation (see the following discussion). With BCL6 degradation, PRDM1, a major plasma cell differentiation factor, is up-regulated and completes the end stage of the GC reaction.

POST-GERMINAL CENTER DIFFERENTIATION

After somatic diversification in the dark zone, the centroblast moves into the light zone as a centrocyte-expressing surface Ig that has undergone SHM. The centrocytes are submitted to the selection procedure by antigen that is carried on the dendrites of the dense FDC network in the light zone. The majority of centrocytes is destined to die, because the mutational changes are detrimental to affinity and avidity. Loss or diminished binding to antigen leads to programmed cell death, and those dead centrocytes are rapidly removed by macrophages, which are now called tingible body macrophages. Some of the centrocytes may be recycled once more through the dark zone for further clonal expansion, diversification, and selection.

This recycling provides, once more, the opportunity for reaching the highest affinity peak. In the light zone, the selection process separates the fittest B cells (high affinity) for survival and the unfit (poor or no affinity) for death (negative selection). Positive and negative selection may work in concert, so that, among the positively selected high-affinity B cells, those with autoreactivity are deleted⁴⁴⁶ by apoptosis, because overexpression of BCL2 in B cells allows the survival of autoreactive B cells.⁴⁴⁷ The products of several genes participate in the regulation of the selection processes. The protein tyrosine kinase Lyn plays a rate-limiting role in BCR triggering through phosphorylation of CD22, an inhibitory molecule that recruits SHP-1 to the BCR-CD22 complex.⁴⁴⁸ The transcription factor Aiolos maintains B cells at low reactivity levels, because, in mice that are deficient in Aiolos, there is an increase of serum Igs, autoantibody production, and the development of B-cell lymphomas.⁴⁴⁹

CD21 appears to be necessary for the survival of GC B cells with high-affinity BCRs. CD21 is a complement receptor (CR2) and, as a component of the CD19/CD21/CD81 coreceptor, mediates the binding of complement-containing immune complexes to B cells and provides a survival signal for B cells.⁴⁵⁰ The CD19/CD21 coreceptor is a major regulator of B-cell function in humoral immunity, for fine tuning of signals that are received by the BCR.⁴⁵¹ Simultaneous ligation of BCR and the CD19-CD21 complex (i.e., with antigen-antibody-complement complexes) significantly lowers the threshold of antigen that is required to trigger B-cell activation by antigen alone through the BCR. (See Chapter 12, Fig. 12.12.)

The centrocyte that has been positively selected is poised for commitment to one of the two pathways of differentiation: memory B cell or plasma cell, depending on whether the normally delivered signals are properly received.

Memory B Cells

Centrocytes can be diverted to the memory B-cell pool by positive signals or by the lack of negative signals. The CD40/CD40L interaction or IL4 stimulation⁴⁵² belongs to the first category. The apoptotic pathway that normally deletes centrocytes belongs to the second category. Apoptosis normally deletes centrocytes that have emerged from the dark zone with nonfunctional or low-affinity receptors. Interference, therefore, with the apoptotic pathway blocks negative selection and results in accumulation of heavily mutated B cells that bring forward a "bad" memory of the primary

response. Thus, overexpression of BCL2, an antiapoptotic protein, interferes with negative selection and diverts centrocytes to the memory pool.⁴⁵³ Similarly, the lymphoproliferative mutation that incapacitates the FAS receptor results in accumulation of heavily mutated B cells.⁴⁵⁴ These changes disrupt the anatomic organization of lymphatic organs with the development of autoimmune lymphoproliferative disease.

Memory B cells are long-lived and do not secrete antibody until they are challenged again. In such a secondary antigenic challenge, they respond to much smaller doses of antigen, expand clonally, and produce 7 to 10 times more antibody than the antigen-inexperienced B cells.⁴⁵⁵ Memory B cells have undergone an Ig class switch, and expression of Ig classes can be used for their classification, as well as for the classification of other markers, such as CD27⁴⁵⁶ or CD148.⁴⁵⁷

The mechanism that maintains the memory B-cell pool is unknown. Antigen is not required to keep them alive, and, according to an hypothesis that has some appeal, B-cell memory (and, for that matter, T-cell memory) is maintained by idiotypic-anti-idiotypic interactions between B cells.⁴⁵⁸ Such interactions take place between B cells that have been antigenically stimulated, therefore their BCR carries distinct idiotypes that are specific for this clone. These idiotypes are structures (protein sequences) within the antigen-binding site that are specific for this particular BCR. Other B cells that respond to these idiotypes express a BCR with anti-idiotypic properties. Interaction between idiotypic cells (memory cells for the primary antigen) and antiidiotypic B cells, according to this hypothesis, stimulates enough proliferative activity to maintain the B-cell memory pool. Such interactions may also link and maintain T-cell memory within a pan-lymphocyte idiotypic-anti-idiotypic web.

Plasma Cells

The purpose of the B cell's life is to make antibodies after it reaches maturity, a stage of differentiation that is characterized morphologically by the development of an elaborate ER and functionally by the synthesis of Ig that is released extracellularly. Since the detection and description of the plasma cell (see Chapter 11), clinicians and scientists have become quite familiar with the

P.340

morphology, ultrastructure, and physiology of the plasma cell. The new techniques of molecular biology and genomics identify the genes that bring about this spectacular morphologic and functional transformation (Fig. 14.14).

The earliest signs of the plasma cell differentiation are detected within the GCs when the positively selected centrocytes choose one of the two pathways that are available to them. A small number of centrocytes express a partial plasma cell phenotype CD138 (syndecan-1); the transcription factor PRDM1 (BLIMP1); and down-regulation of BCL6 and PAX5.^{459,460} These precursors exit the GCs and migrate to the bone marrow, where they develop into plasma cells, secreting high-affinity antibodies. They are probably

P.341

the same cells that are detected on bone marrow smears,⁴⁶¹ surviving with signals that are delivered by marrow stromal cells,⁴⁶² and are able to secrete antibody in the absence of antigen for several months.⁴⁶³ These post-GC plasma cells should be distinguished from pre-GC plasma cells that secrete IgM antibody, which are generated in the early stage of the primary response.

FIGURE 14.14. Lymphocytes and plasma cells. Morphologic and functional differences between lymphocyte and plasma cells. A: Morphology: routine staining. B: Immunoglobulin production and expression: B-cell surface versus plasma cell intracellular immunoglobulin. a: Fluorescence. b: High-resolution autoradiography. GA, Golgi apparatus; Mi, mitochondrion.

IL6 is particularly effective in driving high-affinity B lymphocytes to plasma cell differentiation.⁴⁶⁴ Before the acquisition by B cells of plasma cell characteristics, the cell loses expression of MHC class II molecules, CD19, CD20, CD22, and CD45,⁴⁶⁵ and up-regulates CD38 (the highest density of all stages during B-cell development) and CD138 (or syndecan-1).⁴⁶⁶ CD38 is a transmembrane type II protein (i.e., NH₂ terminal intracellular), which is the ectoenzyme nicotinamide adenine dinucleotide (NAD⁺), converting NAD⁺ to adenosine diphosphate ribose (glycohydrolase activity; see Appendix, CD38). CD138 binds to hepatocyte growth factor, which is produced by mesenchymal cells and stimulates myeloma cell growth (see Appendix, CD138). Among transcription factors, PAX5 is down-regulated, whereas PRDM1 is up-regulated.⁴⁵⁹

The BCL6 proto-oncogene exerts a negative effect on plasma cell differentiation, because it suppresses genes that are critical in the promotion of their differentiation. BCL6 is a pox virus zinc finger (POZ)/zinc finger (ZF) protein, which contains six Krüppel-type ZF motifs at the terminal end and a POZ motif at the N-terminal end. Therefore, it belongs to the POZ domain and Krüppel-like family (POK) of proteins.⁴⁶⁷

The ZF proteins contain cysteines and histidines that are spaced at regular intervals with a zinc atom that is coordinated between two cysteines and two histidines. ZF proteins are folded in nine loops, with an Ii Leu and a Tyr or Phe that is located in each loop and is important for the DNA binding. The zinc binds to the consensus core sequence TTCCT (A/C) GAA that is found in several BCL6 target genes, but it also mediates protein-protein interactions, notably with class II histone deacetylases (HDACs), JUN transcription factor, and the like. The POZ domain is a protein-protein interaction motif that is conserved in evolution and is found in many transcription factors, oncogenic proteins, ion-channel proteins, and so on. POZ proteins are involved in critical cellular processes, such as development, oncogenesis, apoptosis, and transcription. The most common property of the POZ domain is repression of transcription, based on its ability to recruit the HDAC.

Histone acetylation is mediated by a histone acetyltransferase complex. Acetylation destabilizes the nucleosomal structure by neutralizing the positively charged Lys residues of the N-terminal tail domain of core histone and increases the accessibility of DNA to transcriptional regulatory proteins.^{468,469} Therefore, acetylation plays an important role in the regulation of gene expression and in DNA replication and repair. Deacetylation has the opposite effect. There are two classes of enzymes that deacetylate histones: Class I (HDAC1, HDAC2, HDAC3, and HDAC8) is detected in yeasts and similar organisms, and class II (HDAC4, HDAC5, HDAC6, HDAC7, HDAC9, and HDAC10) is detected in vertebrates. BCL6 recruits class II HDAC4, HDAC5, and HDAC7, forming complexes through the N-terminal POZ domain and the C-terminal ZF region.⁴⁷⁰ BCL6, lacking four of the six ZF proteins, loses entirely its ability to recruit the HDACs. It is likely that this interaction exerts the transcriptional repression of BCL6.⁴⁷¹ Several genes are targets for BCL6, such as CD40, IL4, PRDM1 (BLIMP1), CD80 (B7- 1), and CCND2 (cyclin D2; Fig. 14.15). Point mutations of CREBZF (ZF) indicate that ZF-3, ZF-4, ZF-5, and ZF-6 abolish DNA binding and the ability of BCL6 to bind to its cognate cis element. BCL6 represses genes that are activated by STAT6 or NFκB,⁴⁴⁶ thus regulating IL-4 signaling and IgE production. BCL6 competes with STAT6 for the same DNA-binding sites and thus inhibits specific STAT6-dependent gene transcription. Bcl6^{-/-} mice have dysregulation of IgE production and develop type T_H2 inflammation of the heart and lungs.^{441,442}

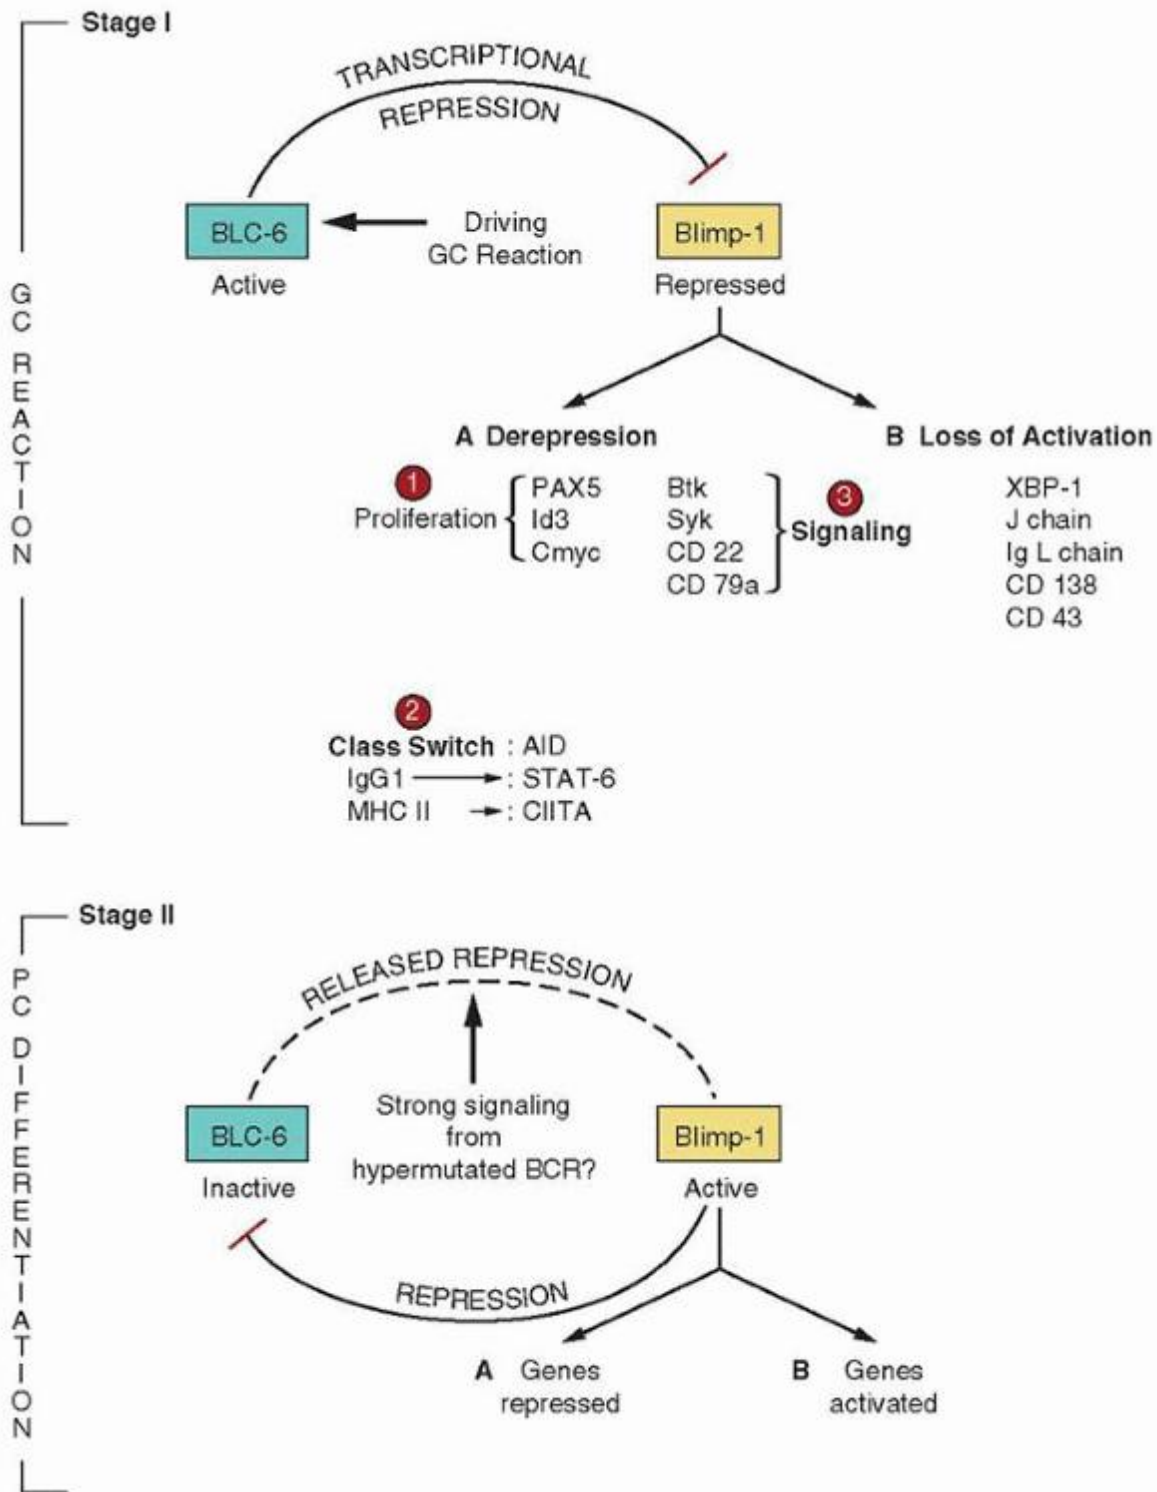

FIGURE 14.15. Gene regulation of germinal center (GC) reaction. Several genes, by their expression or repression, contribute to the molecular and cellular processes that take place within the GCs. More than any others, two genes virtually conduct the GC orchestra: B-cell lymphoma 6 (BCL-6) and B-lymphocyte-induced maturation protein-1 (Blimp-1). BCL-6 is a repressor gene that is identified in diffuse large B-cell lymphomas. It represses several genes and, importantly, Blimp-1 (stage I). As a result, BCL-6 releases from repression all genes that are normally repressed by Blimp-1 (A). The net result is “activation” of genes for proliferation (1), class switch (2), somatic hypermutation, and signaling B-cell molecules (3). BCL-6 is down-regulated, probably by strong signals that are delivered by hypermutated high-affinity B-cell receptors (BCRs; stage II). Loss of BCL-6 function releases Blimp-1 from repression. Genes that are active during the first stage I are

now repressed, whereas genes that are important for plasma cell (PC) differentiation are activated, such as XBP-1 and immunoglobulin L chain. Thus, the GC reaction and the generation of antibodies are finely tuned, basically by a repressor loop between the two master genes BCL-6 and Blimp-1. AID, activation-induced deaminase; CIITA, major histocompatibility complex class II trans-activator molecule; MHC II, major histocompatibility complex class II; STAT, signal transducer and activator of transcription.

Suppression of STAT3 by BCL6 blocks plasma cell differentiation through inhibition of PRDM1⁴⁷² (Fig. 14.15). This function of BCL6 is, at least partially, critical in the role of BCL6 in B-cell differentiation, the block of terminal plasma cell differentiation to maintain proliferation and hypermutation for affinity maturation (i.e., maintenance of GC reaction). BCL6's function is curtailed by signals from high-affinity BCRs that are initiated from interactions with antigen in the light zone. If BCL6 function achieves constitutive independence through chromosomal translocations, it may lead to B-cell lymphomas. When BCL6 is down-regulated, it releases suppression of PRDM1, a transcriptional repressor that is important for plasma cell differentiation. The genes that are repressed by Blimp are shown in Figure 14.15. Several of the biologic characteristics of plasma cells are explained by the repressor function of PRDM1 (BLIMP1). PRDM1 represses MYC and inhibits proliferation⁴⁷³ and also represses the PAX5 gene, releasing XBP1 from PAX5 repression, which is needed for plasma cell formation.⁴⁷⁴ PRDM1 also releases PAX5-mediated inhibition of H chain and J chain⁴⁷⁵ synthesis.

Plasma cells have lost the antigen-presenting function of their parent B cells. This is due to loss of MHC class II expression as a

P.342

result of repression of the gene that encodes the CIITA, which is required for MHC II expression in B cells.⁴⁷⁶

PRDM1 (BLIMP1) is the master regulator gene of the plasma cell differentiation program. Genes that are regulated by it are direct targets or are regulated by other PRDM1 target genes. Its basic function is repression of transcription, which is active or passive. Factors that act as passive repressors interfere with transcriptional activators by competing with their binding site on the promoter or by binding directly to the activation domain of the activator. In active repression, the repressors interact directly with the components of the transcription machinery or recruit co-repressors, such as the HDACs. PRDM1 is an active repressor that is associated directly with HDACs and carries them to the promoters it binds.⁴⁷⁷ HDACs bring alterations in the chromatin structure, which underlines the basic mechanism of PRDM1 function. Another co-repressor for this gene is a complex of the Groucho family proteins.⁴⁷⁸

GENETIC DEFECTS OF CLASS-SWITCH RECOMBINATION

The interaction between CD40L (CD154), expressed on activated T cells and CD40 on B cells, is required for terminal B-cell differentiation. Signaling through CD40 leads to B-cell proliferation and its rescue from apoptosis. Mutations of CD40LG result in the X-linked syndrome that is characterized by lack of GCs in lymphoid organs and the inability of B cells to undergo switch recombination; as a result IgG, IgA, IgE are absent or markedly decreased.⁴⁷⁹ Men who are affected with HIGM syndrome are susceptible to bacterial infections but also experience *Pneumocystis carinii* pneumonia and *Cryptosporidium* intestinal infections, usually observed in T-cell deficiencies.⁴⁸⁰ Lack of interaction between T cells and macrophages leads to defective macrophage activation, probably the basis for opportunistic infections.^{481,482} Some patients with HIGM1 syndrome have a few IgM⁺/IgD⁺ B cells that express CD27, a memory B-cell marker and have SHM. HIGM1 is due to mutations in the gene that encodes CD40L (CD40LG).⁴⁸³

Carriers of HIGM1 are considered to be asymptomatic, because expression of CD40L, even in only a small fraction of T cells, is sufficient for effective immunity. A female carrier has been described with HIGM1 syndrome as a result of extreme lyonization of the normal X chromosome.⁴⁸⁴ This patient was the sister of a boy who was affected with HIGM1 syndrome, and only 5% of T cells were CD40L⁺.

A second HIGM syndrome with autosomal recessive inheritance (HIGM2) has normal CD40L but does not undergo CSR *in vitro* in the presence of CD40 agonists.⁴⁸⁵ CD40 gene sequence and CD40 expression are normal. The defect of HIGM2 is linked to chromosome 12p13, where the AICDA gene also maps. Patients with mutation of AID lack CSR and SHM and have lymph node hyperplasia with giant GCs.⁴⁸⁶ The cells in these GCs are proliferating B cells that co-express IgM, IgD, and CD38, a phenotype that was previously described as characteristic of the GC founder cell subset.⁴⁸⁷ Some mutations are predicted to lead to truncated forms of AID by generating stop codons; other missense mutations are localized within the putative cytidine deaminase catalytic region of the protein. The phenotype of HIGM2 is similar to the phenotype of mice with deficiency of AID.⁴⁸⁸

In a group of 13 patients with HIGM syndrome and normal CD40L, all patients had AID mutations, five of them with a missense mutation of Arg112 His, which indicates that Arg112 is the hotspot for mutations.⁴⁸⁹ Levels of IgG, IgA, and IgE were undetectable, and SHM was impaired, which shows that AID is indispensable in CSR and SHM. Another group of 14 patients of French Canadian descent from Quebec, Canada, had a C-to-T transition in codon 112, resulting in the substitution of Arg with Cys. These patients inherited the genetic defect from a common founder.⁴⁹⁰ In contrast to HIGM1 syndrome, patients with HIGM2 have bacterial, but not opportunistic infections.

Mutations of the AICDA gene do not account for all cases of autosomal recessive HIGM1 syndrome. Mutations in the CD40 gene, which lead to lack of CD40 expression, cause an autosomal recessive form of immunodeficiency with HIGM, which is characterized by lack of CSR, impaired memory B lymphocytes and defective SHM (HIGM3).⁴⁹¹ One patient was detected at 4 months of age with severe respiratory distress because of *P. carinii* infection. Two other patients experienced recurrent respiratory infections early in life.

CYTOKINES IN B-CELL DIFFERENTIATION

The structure and function of the main cytokines that are involved in B-cell differentiation and their receptors are briefly described here. Some of the cytokines have similar structural features and have been divided into two groups, type I and type II.

Type I cytokines consist of four α helices (A, B, C, and D) that are connected by long loops. If the molecule is viewed in the direction from the NH₂ to the COOH terminal, the orientation of the A and B helices is up, and the orientation of the C and D helices is down (i.e., up-up-down-down). Depending on the length of the helix, they are distinguished as short chain or long chain. Cytokines with short chains include IL2, IL3, IL4, IL5, IL7, IL9, IL13, IL15, and SCF, and those with long chains include erythropoietin, thrombopoietin, IL6, IL11, leukemia inhibitory factor (LIF), and oncostatin. Only the short chain cytokines have β -sheet structures in the AB and CD loops. There are intrachain disulfide bonds to maintain the overall tertiary structure, but the number varies; for example, IL2 has one disulfide bond and IL4 has three. The sequences in helices A and D are the most conserved in evolution, and these helices make contacts with the receptors. The receptors of the cytokines that are discussed here have a characteristic cytokine-binding domain (CBD) that consists of two fibronectin type III (FnIII) domains. The N terminal contains four conserved cysteines that form two disulfide bonds and the membrane-proximal conserved sequence WSXWS (Trp-Ser-X-Trp-Ser, where X is any amino acid). The cytokine receptors use several signaling pathways. Briefly described here is the JAK-STAT pathway, which mediates most of the cytokine effects.

The biologic properties of the ILs described here are listed in Table 14.2.

Jaks and Signal Transducers and Activators of Transcription

The Janus family of kinases, which is known as JAK (“just another kinase”), has been given the name of the Roman god, Janus, the god of gates and doorways and the god of all beginnings and endings, who had two faces. JAKs also have two tandem domains, a kinase, and a pseudokinase.⁴⁹² Each molecule consists of seven homology domains, which are termed JAK homology (JH) domains. JH1 is the catalytic domain and has the features of a TYR kinase domain, whereas the N terminal binds to cytokine receptors. Mutation of the conserved LYS in subdomain II that binds ATP abrogates kinase activity. JAKs are apparently interdependent in their function, because they form homo- or heterodimers with other members of the family when the receptors with which they associate form homo- or heterodimers. Certain domains are used as cytokine receptor-specific binding sites. For example, JAK1 uses JH7 and JH6 for binding to IL2RB and IL4RA, but the binding to IFN α R β L and IL10RA requires another domain.⁴⁹³ The Jak-3 kinase is rapidly phosphorylated by IL2 and binds to the γ c chain through the JH6 and JH7 domains, whereas the JAK1 associates with the β chain.

P.343

TABLE 14.2 BIOLOGIC ACTIVITIES OF CYTOKINES

		Effects on:		
Cytokine	Produced	B Cells	T Cells	Macrophages
IL-2	T _H 1	Growth	Growth	—
IL-4	T _H 2	Growth	Growth	Activation

		↑ Major		
		histocompatibility	complex activation	
		↑ Immunoglobulin E		
IL-5	T _H 2	Differentiation	—	—
		↑ Immunoglobulin A		
IL-6	T _H 2	Growth	Costimulation	—
		Differentiation		

IL, interleukin; T_H, T helper cell; ↑, increased.

STATs are latent cytosolic transcription factors with an acronym that accurately reflects the speed of their activation and the urgency of their biologic function, in agreement with the STAT (“at once”) order for immediate action in clinical medicine and emergency rooms. There are seven known mammalian STAT proteins that were conserved in evolution from primitive eukaryotes to humans.⁴⁹⁴ The important structural features of STATs are the SH2 (SRC homology 2) domain and the DNA-binding domain.⁴⁹⁵ The SH2 domain is used to bind to phosphorylated TYR and is used for their dimerization. After phosphorylation of their single TYR (Y-P), they form homodimers or heterodimers, based on the interaction of the Y-P with the SH2 domain of another molecule of a similar or different STAT. Dimerization unmasks a nuclear localization signal that permits STATs to enter the nucleus and bind to DNA.⁴⁹⁵ STATs must take six steps for the full expression of their function: (a) bind to Y-P, (b) become phosphorylated themselves, (c) dimerize, (d) translocate to the nucleus, (e) bind to DNA, and (f) participate in gene transcription. STATs bind to Y-P of cytokine receptors or Y-P of a STAT that is already bound to the receptor or directly to a JAK.

The DNA-binding domain in the C terminal in some STATs contains a SER whose phosphorylation is important for transcriptional activity. JAKs and STATs constitute an important signaling pathway for cytokines. All IFNs and cytokines activate one or more STATs. Because there are more cytokines than STATs, it is not possible for each cytokine to have its own STAT. However, cytokines form groups that share the same STATs. For some STATs that are activated by many cytokines (STAT3, STATA, and STAT5B), their unique actions cannot be mediated by STATs alone, but require a combination of other transcription factors. In addition to transcription regulation, some STATs recruit other signaling components. STAT4 and STAT5 are two of the most important STATs in the STAT pathway, primarily because of their role in TH cell differentiation. STAT3 and STAT1 have a primary role in the function of IL5 and IFN-γ, respectively, in defense against infectious agents.⁴⁹⁶

Interleukin-2 and Interleukin-2 Receptor

IL2 and IL2R were the first to be isolated, and, although IL2 was originally thought to be only a T-cell growth factor, subsequent studies demonstrated that it acted on several types of cells, including B cells and NK cells.⁴⁹⁷ IL2 belongs to the short-chain four-α-helical bundles. IL2R consists of a complex of three polypeptide chains: the IL2RA, IL2RB, and γc (common) chains. The γc chain is shared by receptors of several ILs, such as IL4, IL7, IL9, and IL15.

IL2RA binds IL2 with low affinity (dissociation constant $K_D = 10^{-8}$), whereas, in association with IL2RB, it forms an intermediate-affinity complex ($K_D = 10^{-9}$), and all three subunits form the high-affinity receptor ($K_D = 10^{-11}$). The IL2RB subunit has two pairs of conserved cysteines that are close to the N-terminal end and the sequence WSXWS in the membrane-proximal end of the extracellular region, which is characteristic of type I cytokine receptors.

The intracellular region has the Box1-, Ser (S)-, acidic (A)-, and proline (H)-rich regions. The extracellular region of the γc chain has an N-terminal domain with two pairs of cysteines, and the second membrane-proximal domain contains the highly conserved WSXWS motif. The α and β subunits are expressed only on lymphocytes, but, after activation, they are also expressed on macrophages. The γc chain is detected in several other hematopoietic cells.⁴⁹⁸

The contributions of each of the three chains to IL2 binding are not quite clear. The α chain is necessary to form, with the other two chains, the high-affinity IL2R, whereas the γc chain contributes three loops from the extracellular region (including two of the cysteines) to the IL2 and IL7 binding.⁴⁹⁹ IL2 expresses lectin properties and binds to the β chain in a Ca²⁺-independent manner to oligomannosidic N-glycans (5 to 6 mannose residues). It is proposed that by this mechanism IL2 links the β chain of IL2R with CD23.⁵⁰⁰ The β and γc chains are certainly the signal-transducing components of the IL2R. Signaling through the IL2R follows several paths to the nucleus (Fig. 14.16). One pathway is

the RAS-MAPK cascade that is initiated by the phosphorylation of the Shc adaptor protein.⁴⁹⁷ A second is the PI3K activation, and a third one is through the JAK-STATs.

FIGURE 14.16. Interleukin (IL)-2 signaling. The IL-2 receptor complex consists of three polypeptide chains: α , β , and γ . High-affinity binding of IL-2 requires all three chains. The β chain is associated with Jak 1 kinase, Src kinases (e.g., Lck), and Syk. Jak 1 phosphorylates tyrosines of the C-terminal region of the β chain, which become docking sites for signal transducer and activator of transcription 5 (STAT-5). One of them links to the adaptor protein Shc, which connects to the Ras pathway and mitogen-activated protein kinase (MAPK) activation. Jak 1 also connects with phosphoinositide 3-kinase

(PI3K) and the downstream signaling that is mediated by phosphoinositides. Jak-3 is associated with the γ c chain and probably with β chain. It probably activates Jak 1 and Syk. IL-2 and IL-2R signaling induces multiple and prolonged T-cell responses, such as immediate responses, transcription factors that activate genes for cell cycle, and cytokine release. Later induction of integrins supports T-cell migration and interactions with other cells. IL-2 was the first cytokine to be discovered and retains a commanding role in the regulation of several aspects in T-cell life. NF- κ B, nuclear factor- κ B.

The A region of the β chain is associated with members of the SRC family and PI3K. The H region mediates activation of the JAK family of TYR kinases that activate STATs.⁵⁰¹ The most membrane-proximal TYR (Y) 338 is involved in the phosphorylation of the adaptor protein, SHC1, which is linked to the RAS pathway. The two membrane-distal TYR Y322 and Y510 associate the β chain with the JAK1 kinase,⁵⁰² which interacts with the PI3K. This pathway leads to maximal T-cell proliferation.⁵⁰³ IL2 and several others are associated with the JAK-STAT signal transduction pathway. The JAK3 kinase is rapidly activated by IL2, and, through the JH7 and JH6 domains, it binds to the γ c chain,⁵⁰⁴ whereas JAK1 is associated with the β chain.⁵⁰⁵ Understanding the mechanism of T-cell progression through the cell cycle has been advanced by the discovery of rapamycin, a potent immunosuppressant.⁴⁹⁷ Rapamycin is a macrocyclic lactone that is derived from the filamentous bacterium *Streptomyces hygroscopicus*⁵⁰⁶ and has structural similarities to another powerful immunosuppressant, FK506, or tacrolimus. Both substances bind to a family of intracellular receptors, FK506-binding proteins (FKBPs), which are peptidyl-prolyl isomerases; that is, they catalyze the cis-trans interconversion of peptide bonds that contain proline. The complexes of FK506 and FKBP in T cells inhibit calcineurin, a Ca^{2+} -regulated Ser-Thr phosphatase, which plays a crucial role in the activation of gene transcription by IL2. However, the rapamycin-FKBP complexes do not bind to calcineurin but to another protein that is called the target of rapamycin (TOR).⁵⁰⁷ This protein is expressed in *Saccharomyces cerevisiae*, and it provides resistance to the potent antifungal action of rapamycin.

The protein TOR is apparently needed for the transition of T cells from G_1 to S phase. Transition of the cell from G_1 to S phase is regulated by G_1 cyclins and their associated cdk, which assure the orderly progression from G_1 to S phase. IL2 stimulates the synthesis of three cyclins, D2, E, and A.⁵⁰⁸ These cyclins form complexes with CDKs, which sequentially (D2-complexes followed by E-complexes and then A-complexes) lead the cell from G to S phase. Rapamycin affects the assembly and function of all three cyclin-CDK complexes. The D2-complexes function by phosphorylating their substrate, the retinoblastoma protein, which normally is phosphorylated at a low level and restricts the G_1 -to-S transition. The function of cyclin-CDK complexes is regulated by another set of proteins called kinase-inhibitory proteins (KIPs),⁵⁰⁹ which bind and inhibit the kinase activities of the cyclin-CDK complexes. The IL-2R delivers a signal for KIP down-regulation, whereas rapamycin prevents the IL2-induced reduction of KIP.

The TOR protein regulates the p70^{56K} protein, which is present in mammalian cells, and, as a protein kinase, phosphorylates various intracellular substrates that are involved in protein synthesis and cell cycle control. T-cell activation by antigen induces within the first 30 minutes a number of transcription factors (e.g., FOS, NFAT, and NF κ B; immediate response). These factors in turn activate the transcription of cytokine genes, such as IL2, IFN- γ , IL4, and IL5 (early response). IL2 stimulates T-cell clonal expansion and dictates proliferation of antigen-selected T cells. Antigenic stimulation induces IL2R's expression and secretion of IL2 and other cytokines.⁴⁹⁸ Cross-linking of surface Ig leads to IL2R expression on B cells and responsiveness to IL2. IL2 stimulates proliferation of B cells and Ig secretion and mediates the switch from the membrane form to the secretory form of the μ chain, allowing formation of pentameric IgM molecules. Therefore, IL2 is critical for primary immune responses that are characterized by the production of IgM antibodies. IL2 stimulates secretion of other cytokines, such as IL4, IL5, and IFN- γ , preparing the stage for isotype switch and the maturation of the antibody response. Antigen activation of T cells initiates a series of waves of gene activation that is coordinated by TCR signaling and IL2 secretion, with the expansion of the role of T-cell cytokines in B-cell proliferation, antibody secretion, affinity maturation, and class switch (late response).

X-linked Severe Combined Immunodeficiency

The γ c chain gene of the IL2R is located in chromosome Xq13, which is also the locus for X-linked SCID. X-linked SCID patients are phenotypically identical: T^- , B^+ , and NK^- .⁵¹⁰ Of a large group of patients with SCID, γ c deficiency accounted for 42%, and Jak-3 deficiency accounted for approximately 6% of the cases.⁵¹¹ This form of SCID is associated with severe defects in T-cell development and lack of peripheral T and NK cells. Patients have severe persistent infections of the upper respiratory and gastrointestinal tracts by CTMV, fungal, and bacterial pathogens and require bone marrow transplantation to survive. B-cell levels are normal or elevated in the T^- , B^+ , and NK^- SCID cases. With the exception of two large deletions, the γ c mutations are missense mutations involving one or a few nucleotides. Five mutational hotspots have been identified in exons that encode part of the extracellular domain.⁵¹² In patients with autosomal SCID, a single amino acid substitution, Y100C, in the JH7 domain of JAK3 prevents the interaction of JAK3 with the receptor.⁵¹³

Interleukin-4 and Interleukin-4 Receptor

The IL4 is one of the small four-helix bundle cytokines with four α helices, A, C, B, and D, two end-to-end long loops, and a short β sheet that is packed against the B and D helices.⁵¹⁴ It has biologic activity that is species-specific, in spite of the fact that the main binding residues are conserved.

IL4 is a pleiotropic cytokine that is produced by CD4⁺ T_H2 cells, NKT cells, $\gamma\delta$ T cells, basophils, and mast cells, and it is essential for T_H2 differentiation (see Chapter 13). IL4 binds with high affinity to the IL4RA, and this complex recruits the γ c chain (Fig. 14.17). IL4 binding induces a conformational change in the receptor, forming a structural mosaic in the binding interface. The interacting residues are grouped into three clusters,⁵¹⁵ with the first two clusters consisting of a nucleus of polar groups that are surrounded by hydrophobic side chains. They have been compared to the avocado fruit, in which a nucleus is enveloped by an oily shell. The first cluster is around Glu9, and the second cluster is around Arg88 of IL4 and Asp72 of the IL4RA.

The third cluster steers and accelerates the binding of the IL4 with the receptor.⁵³⁹ The first and second clusters show cooperativity and additive properties, which reinforce the binding to higher affinity.⁵¹⁶ IL4R consists of a complex of two proteins, IL4RA and the γ c chain. The IL4RA has two FnIII domains. The N terminal (D1) has the conserved disulfide bonds of an Ig fold, whereas the second domain (D2) has no disulfide bonds; both have unique structural features.⁵¹⁷ A membrane-proximal WSXWS domain maintains the favorable conformation for cytokine binding. The cytoplasmic region has the box 1 motif (prolinerich) and an acidic region that is adjacent to box 1 that interacts with SRC TYR kinases. Ligand binding causes heterodimerization of the α and γ c chains and activation of JAK1, JAK2, and JAK3 kinases,⁵¹⁸ the first two associating with IL4RA and the last associating with γ c.

Activation of Tyr kinases that are associated with the IL-4R leads to phosphorylation of the five tyrosines of the cytoplasmic region of IL4RA,⁵¹⁴ which function as docking sites for SRC kinases. The functions of IL4RA are mediated by distinct domains in the cytoplasmic region. The first, most membrane-proximal domain contains the Y497 (Y1), which interacts with the IL4 phosphotyrosine substrate (4PS), a 180-kDa protein related to insulin receptor substrate 1 (IRS1) that is phosphorylated and generates proliferative signals.⁵¹⁹ It is interesting that 4PS was found to be homologous to a cytoplasmic protein, which is used as a substrate for the insulin receptor. Insulin binding to the insulin receptor results in rapid autophosphorylation of the receptor, which is a

P.345

receptor protein kinase. The receptor subsequently phosphorylates cytoplasmic substrates that link to downstream signaling pathways. One such major substrate of the insulin receptor is the IRS1. 4PS, which is homologous to IRS1, has been called IRS2.⁵²⁰ IRS1 and -2 bind to the sequence (⁴⁸⁸PL-[X] 4 NPXYXSXSD⁵⁰²) around Y497 of the IL4R, which is highly homologous to a sequence in the cytoplasmic regions of the insulin receptor, and of the insulin growth factor-1 receptor, both of which activate IRS1 and -2. This sequence is critical for transducing signals through the insulin receptor and IL4RA and was termed the insulin IL4 receptor or I4R motif (Fig. 14.17). The IRS2 has a phosphotyrosine-binding domain, which binds to the I4R motif of the IL4RA and insulin receptor. IRS1 and -2 become phosphorylated when they bind to phosphorylated IL4RA and act as a docking site for several SH2-domain-containing signaling molecules. Among such signaling molecules are the PI3K that generates phosphoinositides, which in turn activate Akt and protein kinase C (PKC), which are important in cell growth and survival.

FIGURE 14.17. Interleukin (IL)-4 signaling. IL-4 binds to a receptor, which consists of two chains, α and γ c. The α receptor has two extracellular fibronectin III domains (Fn; D1 and D2), with features of a cytokine receptor homology domain, which is seen in type I cytokine receptors. D2 is characterized by the WSXWS motif (amino acid letter code: W is tryptophan, S is serine, and X is any amino acid) that is implicated in folding and transport of the receptor. The binding of IL-4 to the α chain is mediated by three discrete clusters. Two of them are known as avocado clusters because they consist of a central core of polar groups that is surrounded by a hydrophobic (oily) shell. The third cluster is dominated by electrostatic interactions and stabilizes the complex. The α chain associates with Jak-1 and the γ c chain with Jak-3. Distinct domains of the cytoplasmic tail of the α chain mediate the multiplicity of IL-4 function. A unique feature in the IL-4R α chain is its association with a protein known as IL-4 phosphotyrosine substrate (4PS), which links to phosphoinositide 3-kinase (PI3K) and downstream signaling for cell growth and survival. 4PS also connects to the Ras pathway for mitogen-activated protein kinase (MAPK) activation. 4PS binds to a unique sequence of IL-4R α that is shared by the insulin receptor. In the insulin receptor, this motif binds a protein-linking signaling pathway, which is known as insulin receptor

substrate 1 (IRS-1). 4PS of the IL-4R α is homologous to IRS-1 and has been called IRS-2. Jak-3 phosphorylates tyrosines of the α chain that are used by the signal transducer and activator of transcription 6 (STAT-6) for binding. This phosphorylation is regulated by SHIP phosphatases, which are associated with the C-terminal part of the α chain. STAT-6 induces the suppressor proteins, suppressors of cytokine signaling (SOCSs), which inhibit Jak-3 activation. GTP, guanosine triphosphate; PTB, phosphotyrosine-binding domain.

The adaptor protein Shc binds to the phosphorylated IL4RA chain and links through GRB2 to RAS pathway activation. STAT6 is the primary STAT that is activated by IL4 stimulation, leading to expression of IL4-responsive genes. STAT6 plays an important role in IL4-induced responses, and, for IL4 signaling to be maintained, STA-6 undergoes continuous cycling.⁵²¹ When STAT6 is deactivated in the nucleus, it is exported back to the cytoplasm, where it becomes available for another cycle of phosphorylation and reactivation. STAT6 (together with STAT4) is the most important STAT in the immune response to sepsis, mainly because of its role in T_H differentiation. STAT6 is essential for T_H2 differentiation on activation by IL4.

The phosphorylated C-terminal immunoreceptor tyrosinebased inhibitory motif of the IL4RA acts as docking site for SHP-1 and SHP-2 phosphotyrosine phosphatases. The former is expressed primarily in hematopoietic tissues, whereas the latter is expressed in several other tissues. Another phosphatase, SHIP, regulates the PI3K signaling pathways.

The JAK-STAT pathway is also subject to regulation by a family of newly discovered suppressor proteins termed suppressors of cytokine signaling (SOCSs).⁵²² There are four members in the SOCS family: SOCS1, SOCS2, SOCS3, and CIS (cytokineinducible SH2-containing protein). The SOCS proteins have an SH2 domain in the center, an N-terminal-variable region, and a region of homology at the C terminus, which is termed the SOCS box, with a unique sequence and an unknown function. Five families (20 members) have been identified with a sequence that is homologous to the SOCS box, but the rest of their structure is different.⁵²³ SOCS proteins are not constitutively present in the cells but are induced only after cytokine stimulation. The mechanism of their action is different among the members of the family. SOCS1 binds to the catalytic domain of JAK2 kinase, whereas CIS competes with signaling molecules, such as STATs, for binding to STAT binding sites.⁵²⁴ SOCS1 and SOCS3 inhibit IL4-dependent STAT6 activation by binding to JAK1.^{525,526}

IL4 activates the RAS-MAPK pathway through interaction of IRS2 with the GRB2 protein. The RAS pathway, and other small guanosine triphosphatases (GTPases) that are related to RAS, are regulated by the RAS GTPase activating protein, which activates the GTPase activity of RAS. Down-regulation of RAS is controlled by a molecule termed IL-four receptor interacting protein, which binds to the IL4R motif of IL4RA and, through RAS GTPase activating protein, inactivates the RAS GTP active form.

Functions of Interleukin-4 in T-cell-B-cell Interactions

IL4 plays a central role in differentiation of naive T cells to T_H2 cells capable of producing IL4, IL5, IL10, and IL13 (see Chapter 13). Thus, IL4, through T_H2 differentiation, controls humoral immunity. IL4 increases MHC class II expression in B cells, DCs, and macrophages, thus enhancing their class II antigen presentation, and up-regulates the CD23 expression of B cells. IL4 promotes activation and viability of B cells. A major role of IL4 in B-cell function is in the class switch, as it induces the switch to IgG1, IgG3, IgG4, and, most important, IgE. In this respect, it plays a major role in allergic reactions and protection against helminthic infestations.

The mechanism of promotion of CSR by IL4 is through up-regulation of AID.⁵²⁷ AID is required for CSR and hypermutation (see section "Immunoglobulin Class Switch"). CD45 has recently been defined as a Janus phosphatase,⁵²⁸ which negatively regulates IgE CSR in human B cells through inhibition of IL4-induced (plus anti-CD40) IgE germline transcription.

Interleukin-5 and Interleukin-5 Receptor

IL5 was originally described as a T-cell-replacing factor or B-cell growth factor 2. It affects the terminal differentiation of B cells and is a single polypeptide of a total of 134 amino acids with a molecular weight of 30 to 40 kDa.⁵²⁹ Its tertiary structure reveals

P.346

two domains with a cytokine fold (four α helices and two β sheets), as is seen in GM-CSF, IL2, and IL4. The IL5 gene is found on chromosome 5.

The IL5 receptor is expressed on B cells, eosinophils, and certain cell lines. It consists of an α chain and a β chain. The β_c chain is shared by GM-CSF and IL3 receptors and is functionally analogous to other common chains that are shared by several cytokines, such as the gp130 of the IL6 family and the common γ chain of the IL2 receptor family. The β_c chain

consists of 880 amino acids with four extracellular domains that are related to the FnIII domains, a single region, and the intracellular region.⁵³⁰ The four extracellular domains consist of seven β strands (A through G), which form two cytokine receptor modules. The membrane proximal module contains the recognition contact sites for the α chain.⁵³¹ The membrane proximal cytoplasmic region shows similarities to the sequences of box 1 and box 2 of other receptors and serves in recruitment of members of the family of JAKs. The cytoplasmic region also contains several TYR residues that are phosphorylated after cytokine binding. Binding of the cytokine induces dimerization of the receptor through free Cys that is present in the α subunit and in the first domain of the β_c chain. The disulfide bonds that are formed involve the α chain of one receptor with the β_c chain of the second receptor and vice versa. Dimerization is essential for the Tyr phosphorylation of the receptors. Because the β_c chain is shared by different cytokines, there are sites that are specific for shared interactions.

Detailed studies of the function of IL5 on mouse B cells have concluded that IL5 stimulates production of IgM, IgG1, and IgA, and induces IgA production; therefore, it acts on B cells that are committed to IgA secretion. IL5 synergizes with IL4 in augmenting IgM secretion of human B cells and with IL2 for IgG, IgG, and IgA secretion. The effects of IL5 are detected on activated B lymphocytes.

IL5 plays a unique role in the production, activation, and localization of eosinophils,⁵³² which are seen in patients with asthma and helminthic infestations. IL5 is detected in some patients with severe exacerbations of asthma,⁵³³ and it is conceivable that exacerbations are associated with activation of T cells that secrete IL-5. Local expression of IL5 was detected by in situ hybridization in mucosal bronchial biopsies, which was correlated with the number of infiltrating eosinophils.⁵³⁴

Interleukin-6 and Interleukin-6 Receptor

IL6 is a cytokine with pleiotropic activities that is produced by a great variety of cells (Table 14.3) and plays a central role in immunity and inflammation. IL6 induces (a) terminal differentiation and Ig secretion of B cells; (b) growth promotion of B cells, plasma cells, and myeloma cells; (c) support of colony formation by stem cells; (d) induction of acute-phase response (APR) proteins; (e) differentiation and activation of T cells and macrophages; and (f) neural differentiation. It is also involved in the pathology of several diseases, such as rheumatoid arthritis, proliferative glomerulonephritis, and multiple myeloma. At least 11 different activities are known, with an equal number of acronyms; these turned out to be mediated by the same molecule, which was called IL6. IL6 is a member of a family of structurally and functionally related cytokines that includes IL11, LIF, oncostatin M (OSM), ciliary neurotrophic factor (CNTF), and cardiotrophin-1. Redundancy of function is a result of the sharing of the signal-transducing component of gp130.

IL6 is a glycoprotein that belongs to the long chain, four- α -helical bundle of cytokines^{535,536} and binds to the IL6R-gp130 complex (see the following discussion) but, in addition, has the intriguing property of a lectin that interacts with a trisaccharide (HNK-1 or CD57)⁵³⁷ (see Appendix, CD57). CD57 is a sulfated trisaccharide that is carried by N-glycans, that is, complex polysaccharides. It has been identified in the nervous system as a major target of peripheral neuropathies in patients with lymphomas.

TABLE 14.3 INTERLEUKIN-6 PRODUCTION

Producing Cell Inducer

B cells	IL-4, IL-1, and TNF- α
T cells	Phytohemagglutinin and tissue plasminogen activator
Macrophages	IL-6, interferon- γ , granulocyte-macrophage colony-stimulating factor, IL-1, and LPS
Endothelial cells	LPS, interferon- γ , IL-1, IL-4, and TNF- α
Fibroblasts	IL-1, TNF- α , and LPS
Keratinocytes	IL-1, IL-4, and phorbol myristate acetate
Osteoblasts	IL-1, TNF- α , and LPS
Kupffer cells	IL-1, TNF- α , and LPS

IL, interleukin; LPS, lipopolysaccharide; TNF, tumor necrosis factor.

IL6R consists of an extracellular region with one Ig-like domain (C2-type) and two FnIII domains, which form the CBD, which is characteristic of the class I cytokine receptors. The first FnIII domain has two disulfide bonds, whereas the second

has the sequence WSXWS.⁵³⁸ IL6 binds to the IL6R-gp130 complex by three contact sites. Site one is located in the loop that connects helices A and B of the IL6 and interacts with the D2 domain of IL6R. Site two is located at the C terminus of helix D of IL6, and interacts with the D2 domain of gp130.⁵³⁹ A third site interacts with the N-terminal Ig-like domain (D1) of gp130. gp130 is the signal transduction component of the IL6-gp130 complex, because the cytoplasmic region of IL6R is short.^{540,541,542}

The gp130 protein has an extracellular region that consists of six domains. D2 and D3 have the features that are characteristic of the CBD of class I cytokine receptors. D1 is an Ig-like domain, whereas D4 to D6 are FNIII domains. IL6 induces the formation of a hexamer that consists of two molecules each of IL6, IL6R, and gp130. The crystal structure of gp130 shows that the uncomplexed receptor assumes an L-shaped quaternary structure with limited flexibility.⁵⁴³ gp130 associates with other cytokines, such as OSM, LIF, and CNTF. The crystal structure shows that there is little domain reorientation of the ligand-binding domains, indicating that the overall structure is adaptable to bind multiple cytokines.⁵⁴³ The gp130 protein also has an N-glycan that carries the HNK-1 epitope,⁵⁴⁴ which interacts with IL6. The lectin activity of the IL6 is necessary for the initial signal transduction.⁵⁴⁴

Binding of IL6 to the IL6R-gp130 complex triggers signal transduction, which follows two pathways: the SRC protein tyrosine kinases and the JAKs⁵⁴⁵ (Fig. 14.18). Activated JAKs phosphorylate several TYR (Y) residues of the gp130 cytoplasmic region, which then become docking sites for signaling molecules that possess SH2 domains.^{546,547} The second membrane-proximal Y recruits the SHP-2 phosphatase, leading to the activation of MAPK. Activation of the SRC kinase, HCK, phosphorylates adaptor molecules that link to the GRB2, SOS, RAS pathway to MAPK activation.⁵⁴⁸ This pathway mediates proliferative signaling and, at the same time, through activation of SHP-2 phosphatase, dephosphorylates PYK2 and blocks dexamethasone-induced apoptosis of myeloma cells.⁵⁴⁹

Any of the four most distal TYR residues mediates STAT3 activation. The STAT3 structure is similar to that of other STATs: an N-terminal tetramerization domain, a central DNA-binding domain, a conserved SH2 domain (which binds to the cytokine receptor or another STAT molecule for dimerization), followed by a conserved Y and a C-terminal transactivation domain. STAT3 is the major STAT in IL6 signaling.⁵⁵⁰ IL6 signaling is down-regulated by SOCS1 (see the previous discussion), which is induced via activation of STAT3.⁵⁵¹ Another mechanism of IL6R

P.347

down-regulation involves endocytosis of gp130, after IL6 binding. It is mediated by a dileucine motif after phosphorylation of a SER residue in the cytoplasmic tail of the gp130 protein⁵⁵² (Fig. 14.18).

FIGURE 14.18. Interleukin (IL)-6 and IL-6 receptor (IL-6R) signaling. The IL-6 binds first to IL-6R α (site I). This binary complex forms a composite site that is termed site II, which interacts with the cytokine-binding domain (CBD) of gp130 (which includes domains D2 and D3), forming a trimolecular complex. Recruitment of site III on the immunoglobulinlike activation domain (IGD; i.e., D1 of the gp130) results in the formation of higher-order activation complexes (i.e., a hexamer), which is

fully active (gene transcription). High-affinity binding to the N-terminal domains of gp130 (D1 to D3) is not sufficient for receptor activation. The membrane-proximal (D4 to D6) domains of gp130 are necessary for activation, as they facilitate appropriate spacing (especially D5) of the cytoplasmic components of gp130. gp130 is the signaling component of the complex and recruits Jak-1 and Jak-2 kinases, with Jak-1 having an essential role. Jaks bind to box 1 and box 2 of the membrane-proximal cytoplasmic regions. The N-terminal domain of Jaks comprises a 4.1-ezrin-radixin-moesin domain, which is crucial to link Jak with the receptor. Proteins 4.1 is a large family of proteins that link the membrane of the cell with the cytoskeleton. Jaks phosphorylate tyrosines (Y), which then act as docking sites for signal transducer and activator of transcription (STAT) 3 factors. On dimerization, STAT-3 is translocated to the nucleus, binding to DNA through its DNA-binding domain. STAT-3 is phosphorylated on serines by PKC- δ kinase. Phosphoinositide 3-kinase (PI3-K) is recruited on phosphorylated tyrosine 657. The other important signaling pathway involves activation of SHP-2 phosphatase, which interacts with Grb2-SOS adaptor proteins and leads to Ras activation and the ERK1/2-mitogenactivated protein kinase (MAPK) cascade. STAT-binding sites are in close proximity with binding sites of other transcription factors. MEK, mitogen-activated extracellular signal-regulated kinase; PIP, phosphatidylinositol phosphate.

Interleukin-6 in T- and B-cell Interaction and Myeloma

On T cells, IL6 acts as an activation, growth, and differentiation factor. It can replace co-stimulatory signals from APCs to stimulate IL2 secretion and T-cell proliferation (Table 14.4). IL6 is the most important growth factor for B cells (normal and malignant). It is a potent stimulator of terminal B-cell differentiation and antibody formation. The role of IL6 in multiple myeloma has been extensively studied.⁵⁵³ It is involved in proliferation of plasmablasts and differentiation into mature plasma cells, acting by an autocrine or paracrine mechanism. In addition to its proliferative activity, it blocks the apoptotic pathway (see the previous discussion). The gp130 protein is activated sometimes in the absence of direct ligand binding, i.e., independent of IL6R and IL6. IFN- α induces tyrosine phosphorylation of gp130 in myeloma cell lines that are responsive to IL6.⁵⁵⁴ The question is raised whether receptor cross-talk may be a common theme in the biology of multiple myeloma. The human herpes virus (HHV)-8 is associated with all forms of Kaposi sarcoma (KS) as well as primary effusion lymphoma. It is found in the lymph nodes of a high proportion of patients with multicentric Castleman disease, a polyclonal plasmacytosis that is characterized by hyperplastic lymphadenopathy.^{555,556} IL6 is present at elevated levels in KS and multicentric Castleman disease lesions, and IL6 promotes the growth of KS cells in culture. HHV-8 encodes a homolog of human IL-6 that is known as viral interleukin-6 (vIL6), which acts as a mitogenic factor and induces intracellular signaling that is generally the same as IL6. vIL6 induces receptor dimerization and forms complexes with IL6R and gp130.^{557,558} Signaling by vIL6 may be dependent or independent of the IL6RA.

TABLE 14.4 INTERLEUKIN-6 FUNCTIONS

Target	Function
B cells	Production of IgM, IgG, IgA Growth of plasma cells
T cells	Activation Growth Differentiation
Hematopoietic progenitors	Induce progression from G ₀ to G ₁ phase Enhance survival Stimulate proliferation Enhance megakaryopoiesis Macrophage differentiation
Hepatocytes	Acute-phase protein synthesis
Skin	Stimulates proliferation of keratinocytes
Blood vessels	Increase permeability
Neuronal cells	Proliferation of astrocytes

Survival of cholinergic neurons

Ig, immunoglobulin.

One of the most striking responses to injury and inflammation is the APR. APR consists of alterations in several serum proteins that are known as acute-phase proteins (APPs), which are synthesized mainly by the liver. The response involves more than 1,000-fold increases in C-reactive protein and serum amyloid A and moderate increases in fibrinogen, α -1 antitrypsin, complement factor B, and others. The biosynthesis of these proteins takes place in the liver and is regulated by a factor that was known as hepatocytes stimulating factor, which later was shown to be IL6. Several other cytokines, such as IL1, TNF- α , IL11, and TGF- β , are also capable of inducing APP from the liver. In addition to induction of APP, other systemic responses are associated with APR, such as fever and release of ACTH. These responses are also mediated through IL6.

IL6 has multiple other effects, such as bone remodeling, proliferation of keratinocytes, increase of endothelial cell permeability, and proliferation of astrocytes.

P.348

Interleukin-10 and Interleukin-10 Receptor

The search for a product of T_H2 cells that would inhibit proliferation, effector function, and even development of T_H1 cells resulted in the discovery of a factor that inhibited cytokine synthesis. This cytokine synthesis inhibitory factor was called IL10. It is produced by T_H2 clones and inhibits the synthesis of IFN- γ from the T_H1 clones.⁵⁵⁹

The primary structure of IL10 was determined from a complementary DNA that was isolated from T_H2 cells. It has four α helices and is expressed as a noncovalent dimer.⁵⁶⁰ The IL10 gene is located on chromosome 1. It expresses strong homology to an open reading frame in the Epstein-Barr virus genome.

In addition to T cells, IL10 is produced by macrophages in response to LPS, by B cells, especially after Epstein-Barr virus transformation,⁵⁶¹ and by keratinocytes, especially after exposure to ultraviolet light.

IL10 strongly stimulates proliferation of B cells, especially after cross-linking of CD40 by anti-CD40 antibody,⁵⁶² and this effect is synergistically enhanced by IL4. IL10 induces B-cell differentiation that is activated by anti-CD40 antibodies, with the production of large amounts of IgM, IgG, and IgA antibodies. This activity is antagonized by IL4 but is enhanced by TGF- β , especially for IgA secretion.⁵⁶³ In general, the effects of IL4 and IL10 on proliferation and differentiation of B cells account for much of the noncontact help that is provided during T-cell-B-cell interactions in antibody responses. As a suppressor cytokine of cell proliferation and cytokine response, IL10 plays an important role in tolerating exogenous antigens, especially in immunotherapy of allergy.⁵⁶⁴ It selectively inhibits the CD28-mediated co-stimulatory pathway and, as a result, inhibits T-cell responses that are initiated by engagement of a small number of TCRs, a situation that is critically dependent on CD28 co-stimulation. Blocking of CD28 co-stimulation depends on inhibition of CD28 tyrosine phosphorylation, which is the initial step in co-stimulation by CD28. IL10 regulates cyclo-oxygenase-2 expression and reduces production of prostaglandins that act directly on cyclo-oxygenase-2 expression or through regulation of inflammatory cytokines.⁵⁶⁵

IMMUNOGLOBULIN STRUCTURE

Antibodies are Igs that are produced by B cells in response to foreign antigens; therefore, they have the property of binding specifically to the antigen that triggered their production. Igs constitute the fraction of plasma proteins, originally defined as γ -globulins, because they were located behind the α - and β -globulins, as a result of their slow electrophoretic mobility. When it was shown that these γ -globulins are products of cells of the immune system, they were given the name immunoglobulins.

Antibodies have two fundamental properties for defense against pathogens: they bind specifically to the antigen that is responsible for their induction by one part of their molecule and then dispose the captured antigen with the cooperation of other molecules (complement) or cells (phagocytes) of the immune system.

Primary Structure: One Polypeptide from Two Genes

One of the most revolutionary hypotheses in the recent history of molecular biology was proposed for the structure of the antibody molecule: the Ig molecule is encoded by two different sets of genes.⁵⁶⁶ The C-terminal region is encoded by one gene that is selected from a small group of genes, whereas the N-terminal region is encoded by two or three genes that

are selected from a large number (hundreds) of genes. The Ig molecule consists of two short or light (L) chains and two long or heavy (H) chains, which are held together by disulfide bonds.

The two L chains are of equal length, each consisting of 214 amino acids. The H chains vary in length; the shortest is the γ 1 chain, which is made of 446 amino acids, and the longest is the μ chain, which is made of 567 amino acids. A striking feature of the primary structure of H and L chains is the considerable variation at the N-terminal end of the chains, compared to a significant degree of homology at the C-terminal end. The former region is known as the variable or V region and the latter as the constant or C region. In L chains, the V region of the light chain (V_L) constitutes one half of the chain (amino acids 1 to 107), and the remaining part of the chain is the constant (C_L) region of the light chain. The L chains are encoded by a V and a J allele (N-terminal half) and a C allele (C-terminal half). For L chains, the V allele contributes amino acids 1 to 95, and the J allele contributes the remaining 13 amino acids. The V region of the H chains is encoded by three alleles, V_H , J_H , and D (see Chapter 12). For the V_H region, the V_H allele encodes amino acids 1 to 94, and the remaining amino acids are encoded by the D_H and J_H genes. The rest of the chain is divided into three constant regions, C_{H1} , C_{H2} , and C_{H3} , for IgG, IgA, and IgD, and four constant regions for IgM and IgE.

Within the V regions are three short stretches of amino acid sequences that show extreme variability and are therefore known as hypervariable regions. Hypervariable regions contain amino acids that are in contact with the antigen, and, in the primary structure of the molecule, these regions are separated by long stretches of less variable amino acid sequences. However, these hypervariable regions are in close proximity to each other when the molecule assumes its functional tertiary structure. Amino acid sequences that are not part of the hypervariable regions form the framework regions and constitute 80% of the V region.

Secondary Structure: Immunoglobulin Fold

Results from crystallographic studies confirm that the Ig polypeptide chain is folded back and forth on itself in opposite directions (antiparallel), forming a sheet, which is known as the β -pleated sheet, and is arranged as a sandwich (or β barrel), with a hydrophobic center. This is known as the Ig fold (Fig. 14.19). Each strand bends in a hairpin fashion when it changes direction. Almost all bends contain a Gly that is highly conserved.

Tertiary Structure: Immunoglobulin Domain

The intrachain disulfide bonds divide each chain into globular structures of approximately 100 to 110 amino acids that are known as domains. The IgG molecule has four V-region domains, one C_L per L chain and three C_H per H chain. Considerable homology exists among the V domains and among all the C domains. The degree of homology suggests that domains originated from one primordial gene and evolved independently rather than as a group comprising a single H chain. Each Fab fragment (see the following discussion) has four domains: the V_L and V_H interact to form the V module, and the C_L and C_{H1} interact to form the C module. Each domain is made of two β -pleated sheets (x and y), one consisting of three, the other of four, antiparallel strands that are labeled A through G. In each of the two V domains, there are two additional strands that are called C' and C'' . The sheets are held together by one Li disulfide bond and by interactions between the strands A-B-E and D for the C modules and C-C-F and G for the V module. The hypervariable regions correspond to the hairpin loops that link the strands as they turn around to run in the opposite direction, which are called complementarity-determining regions (CDRs) (Fig. 14.19). Each V domain has three CDRs, for a total of six in the V module. They are known, in sequence order along the polypeptide chain, as L1, L2, and L3 for the V_L domain, and H1, H2, and H3 for the V_H domain. The length of each CDR varies considerably, both as a function of usage of the V allele, mainly affecting CDR1 and -2, and as a consequence of junctional diversity, i.e., additions of amino acids during V(D)J recombination that affect the CDR3 (see Chapter 12). All six CDRs contribute to the formation of each combining site. Because of their positioning in the free end of the

P.349

V module, they are endowed with some mobility, which may be important for binding with the antigen. In the Fab fragment, they form a cavity that is 15 Å long, 6 Å wide, and 6 Å deep. The strands correspond to conserved sequences that are known as framework (FR) sequences. Each V domain has four conserved FR sequences, FR1 through FR4. The Ig fold is not unique to the Ig molecule but is also found in other molecules, such as the $\alpha\beta$ and $\gamma\delta$ TCRs; the class I and class II MHC molecules; the CD2, CD3, CD4, and CD8; and the β_2m , which represents a free domain. Several other proteins have Ig-like domains that form the Ig superfamily.

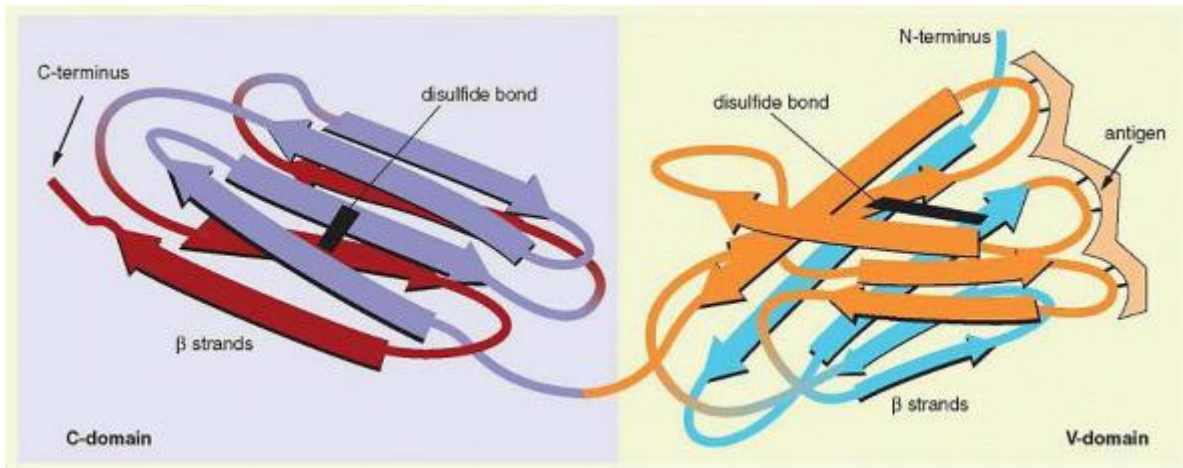

FIGURE 14.19. Tertiary structure of a light chain that depicts the variable (V) and constant (C) domains. Each domain is composed of two sheets that are formed by strands of polypeptide chains that possess the basic β -pleated structure. In each sheet, the strands run in alternating directions (antiparallel). The strands are shown as broad arrows, pointing in an N-terminal-to-C-terminal direction. The strands that belong to the same sheet are blank or hatched. Stretches of polypeptide chains that connect the strands form loops. Three of these loops in the V domain include the complementarity-determining regions (CDR), which are involved in antigen binding. The strands are identified by letters, A to G, starting from the N-terminal end. The V domain contains two additional strands C' and C'' (which are not shown in the diagram as broad arrows). Interactions between the VL and VH sheets contribute to the formation of a cylindrical V module that contains the antigen combining site. The black bars represent the disulfide bonds.

Quaternary Structure: Immunoglobulin Monomer

The Ig molecule consists of four polypeptide chains, which are held together by disulfide bonds and noncovalent interactions⁵⁶⁷ (Fig. 14.20). Two of the chains have a molecular weight of 53 kDa (IgG) or 75 kDa (IgM) and are known as H chains. The other two chains have a molecular weight of 22.5 kDa and are known as L chains. The former determine the major Ig class of the molecule: IgG, IgM, IgA, IgD, and IgE. The respective H chains are designated by Greek letters: γ (IgG), μ (IgM), α (IgA), δ (IgD), and ϵ (IgE). Within each class are subclasses: four for IgG (1, 2, 3, and 4), two for IgM, and two for IgA. The H chains are distinguished by isotypes to identify antigenic determinants that are shared by all individuals of a given species. Humans have 10 loci for constant region genes and, therefore, 10 isotypes that correspond to the total number of what otherwise are known as subclasses: $\mu 1$, $\mu 2$, δ , $\gamma 1$, $\gamma 2$, $\gamma 3$, $\gamma 4$, $\alpha 1$, $\alpha 2$, and ϵ . There are only two types of L chains, kappa (κ) and lambda (λ). The L chains of the λ type exist in four isotypes ($\lambda 1$, $\lambda 2$, $\lambda 3$, and $\lambda 4$). Any given Ig molecule has two κ chains or two λ chains but never one of each type. The κ -to- λ ratio varies between species: in humans it is 70:30, whereas in the mouse it is 95:5.

The hinge region is located between C_{H2} and C_{H3} and is rich in proline residues. Cysteines form the inter-heavy chain disulfide bonds. Because of its unique amino acid sequence, this region does not fold well and thus becomes susceptible to enzymatic attack. The hinge region also affects the flexibility of the molecule and other properties, such as complement binding. IgM and IgE have no hinge region but instead have an extra C domain.

Disulfide bonds are important because they maintain the association of the four chains and divide the Ig molecule into functional domains. The H and L chains are held together by interchain disulfide bonds. Each L chain is attached to the H chain by one disulfide bond, with the exception of human IgA2, which contains no disulfide bond between H and L chains. The disulfide bond is formed between C-terminal cysteine of the κ chain or the penultimate cysteine in the λ chain and the cysteine that is closest to the middle of the H chain.

The two half-molecules are held together by interchain disulfide bonds between the two H chains. The number of these bonds varies among classes: the IgG1 molecule has two, whereas IgG3 possesses 15. Disulfide bonds exist within each chain (intrachain). All L chains have two bonds, and all γ and α chains have four bonds; μ , δ , and ϵ chains have five bonds. Because the cysteines that form the intrachain bonds are separated by 40, or even 70, amino acids, the bond can be formed only if the two cysteines are brought into apposition by looping the intervening sequence. The regularity of the distribution of the intrachain disulfide bonds formed the basis of the domain hypothesis, in which the Ig molecule is separated into distinct functional regions.⁵⁶⁸

Carbohydrate Moiety

Carbohydrate chains are of variable length and shape. The number of these chains varies among isotypes: 2 in IgG molecules, 10 in IgM molecules, 16 in IgA molecules, and 12 in IgE molecules. The carbohydrate chains are attached to the C_{H2} domain, forming a bond between the first carbon of asparagines and the sugar N-acetylglucosamine (GlcNAc). Procedures that interfere with the glycosylation of the α and ε chains prevent the secretion of IgA and IgE molecules.

Enzymatic Fragments

Treatment of the Ig molecule with papain generates three fragments. Two of these fragments are identical; each contains one antigen-binding site and thus they are known as Fab (fragment antigen binding).⁵⁶⁹ The third piece, which is known as Fc (fragment crystallizable), mediates fixation of Ig molecules to skin and other cells (macrophages and lymphocytes), fixes complement,

P.350

and mediates transport of the Ig molecule across the placenta. Digestion of the Ig molecule with pepsin yields one large piece, with a molecular weight of 100 kDa. This divalent fragment, which is known as F(ab)₂, consists of two Fab fragments, each capable of binding antigen. The Fc fragment is digested by pepsin into small peptides (Fig. 14.21).

FIGURE 14.20. Basic arrangement of the polypeptide chains, the enzymatic fragments, and their domain structure of the immunoglobulin G molecule. Locations for structures that are defined as idiotypes, allotypes, and isotypes are shown, as

well as the position of the carbohydrate (CHO). Various domains are shown on the left side.

Combining Site

The antigen-combining site is located near the tip of the two arms on the Y-shaped Ig molecule.^{570,571} The size of the combining site was determined initially by Kabat, using antidextran antibodies that reacted with oligosaccharides of different lengths. Maximal inhibition of the binding was obtained with an oligosaccharide that consisted of six isomaltohexose molecules. The structure of the combining site has also been studied by means of affinity labeling. With this technique, the hapten is linked to a chemical group that interacts with the amino acids that are closest to those that form the combining site. This method helped demonstrate that H and L chains participate in the formation of the combining site. The antigen-binding V module may be viewed as a stable, packed FR structure with six superimposed flexible CDRs. Molecular biologists have now constructed hybrid genes that combine FR and CDR from different Igs. Upon transfection to lymphoid cell lines, these genes produced antibodies with the specificity of the CDR donor.⁵⁷²

Idiotypes and Allotypes

Antibodies and myeloma proteins possess determinants that are characteristic for each antibody or myeloma protein and are known as individually specific antigenic determinants or idiotypes. Idiotypes can be detected by means of antisera. Some anti-idiotypic antibodies detect determinants that are restricted to a single Ig (individual, or private, IdI), and other antibodies detect determinants that are present in antibodies or myeloma proteins other than those that are used for immunization (public, or cross-reactive, IdX). Idiotypic determinants, which are known as idiotopes, have also been classified according to their location in relation to the combining site: α -idiotopes are located outside of the combining site; β -idiotopes are close to the site, so that the binding of the anti-idiotypic antibody interferes with the binding of the antigen; and γ -idiotopes are formed by the site itself.⁵⁷³

In addition to CDR, the idiotope-determining region (IDR) can be defined, not on the basis of amino acid sequence variability, but as a surface-variable structure that is complementary to a structure on the V region of another Ig molecule. Although all CDRs are also IDRs, the partial overlap between these two kinds of regions suggests that IDRs outnumber CDRs.⁵⁷³ IDRs, therefore, are functionally involved in antigen recognition, as well as in recognizing and being recognized by other Ig molecules. This functional attribute of IDR is central to the network theory of immune regulation of Jerne.^{574,575}

Allotypes are allelic variants of Ig polypeptide chains that segregate in Mendelian fashion in outbred populations. Allotypes that vary by one or a few amino acids are simple allotypes, whereas those that are characterized by greater differences are complex allotypes. In humans, Ig allotypes have been well characterized for all subclasses of the IgG (γ) H chains (Gm allotypes), for IgA (α) H chains (Am allotypes), and for the κ chains (Km allotypes). The H chain allotypes of different H chain isotypes are inherited together as a group, which is sometimes referred to as a haplotype.⁵⁷⁶

IMMUNOGLOBULIN FUNCTION

Immunoglobulin G

IgG is the major Ig in humans and constitutes approximately three fourths of the total Ig (Table 14.5). The serum concentration varies from 8 to 16 g/L in adults, but the intravascular pool accounts for less than one half the total body IgG; approximately 55% is found

P.351

widely distributed within the extravascular space. The total body content is in excess of 1 g/kg of body weight. IgG molecules have a half-life of 21 days and therefore have the longest lifespan.

FIGURE 14.21. Proteolytic fragmentation of the immunoglobulin G molecule by papain and pepsin. Papain hydrolyzes the molecule to the N-terminal side of the interchain disulfide bonds and releases three fragments of approximately equal

size, two Fab and one Fc. Pepsin acts on the C-terminal side of the disulfide bonds and forms one large divalent fragment (F[ab']₂); the Fc is fragmented to small peptides and one larger fragment known as pFc'.

The four isotypic subclasses of IgG molecules are distributed as follows: IgG1, 66%; IgG2, 23%; IgG3, 7%; and IgG4, 4%. These antigenic differences are the result of variations in amino acid sequences of the carboxy-terminal parts of the γ chains. All four types of molecules are found in any given normal serum, but individual molecules contain only a single type of γ chain. The IgG subclasses carry numbers of disulfide bonds that are arranged in different ways. The hinge region is also strikingly different among the subclasses; the longest is in IgG3 and supports certain functions of the Fc fragment.

Biologic Properties

Most of the antibodies that are found in secondary antibody responses to antigen are IgGs. IgG is selectively transferred across the placenta, thereby giving a measure of protection to the newborn⁵⁷⁷ (Table 14.5).

Some biologic properties of IgG proteins, and particularly those that are mediated by the Fc fragment, are distinctly subclass-specific. IgG1 and IgG3 react most readily with C1q, the first component of complement, and therefore activate complement most efficiently. IgG2 is less reactive, and intact IgG4 proteins are completely unreactive. The binding of Fc to macrophage and granulocyte Fc receptors is most efficient with IgG1 and IgG3, and this reaction is important in the process of opsonization. Anti-Ig antibodies (rheumatoid factors) react most readily with IgG1, IgG2, and IgG4 proteins and not at all with IgG3 proteins. IgG3, on the other hand, has a tendency to aggregate,⁵⁷⁸ a property that probably is also responsible for the affinity of the molecule for C1q. Aggregation of IgG3 may lead to clinically significant hyperviscosity states, especially in patients with IgG3 myeloma. In addition, IgG3 is selectively retained in the sera of some patients who have generalized hypogammaglobulinemia.

TABLE 14.5 PROPERTIES OF IMMUNOGLOBULINS

Properties	IgM	IgG	IgA	IgD	IgE
Subclasses	2	4	2	—	—
Molecular weight (kDa)	950	150	150 to 300	185	190
Heavy chain	μ	γ	α	δ	ϵ
Light chain	κ, λ	κ, λ	κ, λ	κ, λ	κ, λ
Percent carbohydrates	10-12	4	10	12	12
Survival ($t_{1/2}$ days)	5	21	6	3	
Complement fixation					
Classical	+++	+	-	-	-
Alternative	-	-	+	+	+
Cross placenta	-	+	-	-	-
External secretions	+	+	+++	-	+
Cytophilic for:					
Macrophages	\pm	+++	-	-	-
Mast cells	-	\pm	-	-	+++
Serum concentration (g/L)	1.5	11.0	2.4	0.03	<0.005
Percent of total Ig	5	80	15	-	-

Ig, immunoglobulin; +, weak; +++, strong; -, negative; \pm , borderline.

Some antibody activities are subclass-specific. Thus, anti-Rh antibodies are usually IgG1 or IgG3; antifactor VIII antibodies are often restricted to IgG4, and other antibodies, such as antidextran and antilevan, have been found to be IgG2.

Immunoglobulin A

The IgA class of antibodies can be divided into two separate systems of Ig.⁵⁷⁹ One system, IgA1, provides IgA antibodies for the circulation and the internal secretions, such as the aqueous humor of the eye, the cerebrospinal fluid, and the synovial, amniotic, pleural, and peritoneal fluids. These IgA antibodies probably are synthesized by nonmucosal lymphoid tissues. The other system, IgA2, is found in external secretions, such as saliva, tears, bile, and colostrum, as well as secretions of the respiratory tract, the gastrointestinal tract, the seminal vesicles, the cervix, and the urinary tract. The IgA of external secretions is, for the most part, not derived from the blood but is produced locally by plasma cells that are situated in proximity to the epithelial mucosa. It is the predominant Ig in external secretions, although smaller amounts of IgM and IgG also may be found.

In the serum, 85% of IgA molecules are monomers, with a molecular weight of 170 kDa and a sedimentation coefficient of 7S; 9S, 11S, and 13S polymers make up the remainder. Approximately 1% is secretory IgA (sIgA); this percentage increases in association with a variety of mucosal inflammatory diseases. The serum concentration of IgA is in the range of 2 to 3 g/L, with a half-life of 6 days. Monomeric IgA is composed of two H (α) and two L chains. The α chains of IgA1 and IgA2 subclasses are strikingly different in the hinge region. Certain bacterial proteases cleave IgA1, but not IgA2, into Fab and Fc fragments. These IgA1 proteases are

P.352

exquisitely specific. In the IgA2 subclass, the H and L chains are not held together by a disulfide bond.

sIgA is a large molecule with a molecular weight of 390 to 400 kDa. It consists of two IgA molecules that form a dimer and two additional non-Ig components, which are known as the J chain and the secretory component (SC).⁵⁸⁰ The J chain joins two IgA molecules through a disulfide bond to form a dimer, whereas the SC is the extracellular part of the polymeric Ig receptor (pIgR), which remains attached to IgA after trans-epithelial crossing (Fig. 14.22).⁵⁸¹ The epithelial cells in the glands and basolateral crypts of the gastrointestinal and upper respiratory tracts produce the full-length (100-kDa) pIgR located in the nonserosal surface of the epithelial cells. It consists of five V-type Ig-like domains in the extracellular region, a transmembrane, and a 103-amino acid intracellular region. Binding of polymeric IgA (pIgA) to the first extracellular domain of the pIgR is followed by endocytosis and transcytosis across the epithelial cell.⁵⁸² The initial step is through clathrin-coated pits and requires two cytoplasmic tyrosines of pIgR and phosphorylation of serine 726. The endocytosed complex is delivered first to RAB⁺ basolateral early endosomes and then on to RAB17⁺ common recycling endosome. In this compartment, the complex is sorted and directed to the apical plasma membrane.

The IgA dimer is released on the luminal side of the epithelial cell, with the extracellular portion of the pIgR (i.e., the SC) still attached, forming the sIgA.^{583,584} During transcytosis, disulfide bonds form between pIgR and pIgA. The J chain is essential for the transport of IgA, and expression of the J chain by plasma cells is particularly critical for the overall function of sIgA in mucosal surfaces.⁵⁸⁵ A disulfide bond between the J chain and the IgA monomer is sufficient for IgA dimerization. IgA polymers are also formed that retain high affinity for free SC. The SC protects the IgA from intracellular digestion by proteolytic enzymes. The SC is more efficient than IgR in providing protection because, as a result of its carbohydrates, it is able to anchor the sIgA to mucus within infected areas, in contrast to the random distribution of pIgR. Furthermore, pIgR can be used by some bacteria (e.g., *Streptococcus pneumoniae*) to gain access to the transcytosis pathway. The IgA transport system is unique in that, in contrast to other pathways, it does not lead to degradation of its ligand, the IgA molecule. The IgA and the asialo glycoprotein transport of hepatocytes occupy the same compartment inside the cell, yet each follows distinct pathways subsequently.

FIGURE 14.22. A: Dimer of immunoglobulin A (IgA). The J chain is linked through disulfide bonds with the C α 3 domains of the monomers. The secretory piece attaches through disulfide bonds to the Fc fragments of the monomers. B: IgA dimers. (Courtesy of Dr. K. H. Roux.)

Biologic Properties

Although IgA is incapable of fixing complement or acting as an opsonin, the sIgA molecule, together with complement and lysozyme, is capable of killing *Escherichia coli*. IgA does not activate complement, except in its aggregated form and even then it activates complement only through the alternate pathway. Like other Igs, sIgA is capable of blocking bacterial adherence to mucosal surfaces, thereby preventing colonization. It may also act as a blocking antibody to reagenic reactions on mucosal surfaces and may prevent the absorption of antigenic molecules from the lumen of the gut.

Surprisingly, most IgA-deficient individuals appear to be fairly healthy and not overly susceptible to upper respiratory tract infections. IgA antibodies against intrinsic factor have been reported in the gastric secretions of patients with pernicious anemia. It has been proposed that IgA may serve as a carrier of antigens from the blood to the mucosal sites, providing an

explanation of how antigens find their way into external secretions through the SC transport system. Perhaps the mucosal synthesis of IgA makes it particularly suitable for removal of dietary and microbial antigens that are absorbed from the gut. More recently, receptors for the Fc portion of IgA were identified on peripheral and alveolar macrophages, lymphocytes, and neutrophils.⁵⁸⁶ Through such receptors, IgA participates in antibody-dependent, cell-mediated cytotoxicity reactions.

Immunoglobulin M

IgM antibodies are proteins with a molecular weight of 850 kDa that sediment predominantly at 18S to 19S but also at 22S, 26S, and 35S (Table 14.5). Because of their size, IgM molecules are referred to as macroglobulins. Their rate of synthesis is only 1/20 of that of IgG, whereas their fractional catabolic rate is two to three times that of IgG, which accounts for the relatively short survival (half-life of 5 days) and low serum levels (0.8 to 3.0 g/L) of IgM.

IgM macromolecules are composed of five identical subunits called IgM monomers, each of which consists of two μ (H) chains and two L chains (Fig. 14.23A). The L chains may be κ or λ and are identical to those of other Ig. The H chains, on the other hand, have some unique structural features. Whereas human γ chains vary in length from 446 to 450 amino acid residues, μ chains contain in excess of 500 residues and have a correspondingly higher molecular weight of approximately 70 kDa. In addition, μ chains appear to consist of a variable region and four constant regions, in contrast to the three constant regions of γ chains. Similar to γ chains, however, each region (constant and variable) contains a loop of approximately 60 amino acids with an internal disulfide bridge that is flanked on either side by approximately 20 amino acids. Carbohydrates account for 10.7% of the molecule by weight and are distributed over five sites within the constant region: one within the Fd region, one in the hinge region, two within Fc, and one near the COOH terminus. They affect the conformation and other properties of the molecule but do not contribute directly to antibody specificity. Two subclasses of IgM (IgM1 and IgM2) have been identified on the basis of antigenic differences within the μ chain.

In the intact IgM molecule, five monomers are assembled in a star-shaped configuration, with the carboxy terminal (Fc pieces) being joined at the center through disulfide bonds, whereas the antigen-binding sites (Fab pieces) extend toward the periphery.

P.353

The molecule appears to have a great deal of rotational freedom, and, although it is bound to particulate antigen, it may take on the appearance of a staple or a spider (Fig. 14.23B), with its legs (Fab pieces) extending toward the plane of the antigen (a cell surface) and its body consisting of closely linked Fc fragments that protrude from the center, thus making it ideally suited for complement fixation (Fig. 14.24).

FIGURE 14.23. A: Immunoglobulin M (IgM) pentameric molecule. The IgM molecule is composed of five subunits that are held together through disulfide bonds. In the polymerization of the subunits, the J chain is involved. (From Roitt IM, Brostoff J, Male DK. Immunology, 2nd ed. St. Louis: Mosby, 1989, with permission.) B: By electron microscopy, the IgM

molecule appears star-shaped (a). When it is bound to antigen, such as the flagellum of *Salmonella*, it assumes the crab or staple form (b: 1-4), a model of which is shown in c. (From Feinstein A, Munn EA. Conformation of the free and antigen-bound IgM antibody molecules. *Nature* 1969;224:1307-1309, with permission.)

Because the IgM molecule consists of five subunits, each with two antigen-combining sites, there are 10 combining sites per IgM pentamer. A single J chain has been found attached to the IgM pentamer by disulfide bridges. IgM monomers do not have J chains.

FIGURE 14.24. Immunoglobulin M (IgM)-C1 esterase interaction. On the surface of pathogens, IgM assumes the staple (as seen sideways) or crab conformation. Whereas the Fabs touch the surface of a pathogen, or immune complexes deposited on tissues, the Fc fragments form a plateau on which C1q finds space to touch down with the heads of the arms. The C1r-C1s tetramer weaves between the arms as a necklace. Recognition of patterns by C1q creates a conformational shakeup, which is transmitted to the catalytic domains of C1r, which is activated. In turn, C1r activates the C1s, which performs the esterase functions of the whole complex, C1 esterase.

Biologic Properties

Macroglobulins are restricted mostly to the intravascular pool. Little if any IgM crosses the placental barrier, and the amount that is present at birth is almost entirely of fetal origin. Detectable levels of IgM may be synthesized by the human fetus by as early as the 20th week of gestation, but high levels of IgM at birth usually are indicative of intrauterine sepsis.

On cell surfaces, a single molecule of IgM readily fixes complement, whereas antibody doublets are required for fixation of complement by IgG. IgG is efficient at 4°C and 37°C, however, whereas IgM is inefficient at the lower temperature. Binding of C1q to IgM has been assigned to both C μ 3 and C μ 4 domains. Mutations that involve a single amino acid in the C μ 3 domain abolishes complement fixation.

Specific macrophage receptor sites for the Fc region of IgM have been described in animal systems. Such receptors may play a critical role in the process of phagocytosis of immune complexes.

IgM antibodies are the first to be produced in a primary immune response, to be replaced subsequently by IgG antibodies. However, certain types of antibody responses remain mostly IgM, including those against LPS and the heterophil (Forssman) antigens. Wassermann antibodies, isohemagglutinins, cold agglutinins, and antibodies to the O antigens of Gram-negative bacteria are usually IgM.

Immunoglobulin M Monomer

IgM monomer (7S IgM) is the predominant Ig on the B-cell surface. Naturally occurring 7S to 8S IgM monomers also have been identified in normal sera, and higher concentrations of monomers occur in association with various diseases, including SLE, Waldenström macroglobulinemia and other hypergammaglobulinemic states, congenital rubella, and immune deficiency disorders, such as ataxia telangiectasia and dysgammaglobulinemia. In some

P.354

instances, IgM monomers possess antibody activity against blood-group substances or cell nuclei (antinuclear factors). IgM monomers may be related to more primitive Ig and appear to be synthesized as such, rather than to represent an in vivo or in vitro breakdown product of IgM.

Immunoglobulin D

IgD is found in low concentration (3 to 400 mg/L) in normal serum. It consists of two H (δ) chains and two L (κ or λ) chains, has a molecular weight of 180 kDa, and sediments at 7S. It appears to be catabolized rapidly (half-life 2.8 days), is confined largely to the intravascular space, and does not cross the placental barrier. The IgD has three constant region domains and an unusual hinge region, which is strikingly different from the hinge regions of other Ig. It is longer than the γ_1 , γ_2 , and α_2 hinges and has a highly charged C-terminal half. Its unusual structure makes it extremely susceptible to proteolytic cleavage. IgD is a major surface Ig of peripheral blood lymphocytes.

IgD plays an important role as antigen receptor in B-cell activation. It is expressed during certain periods of B-cell differentiation. IgD may function as an antigen receptor that is capable of triggering antibody production, whereas binding of antigen to IgM leads to tolerance. Both receptors, however, are capable of inducing proliferation and differentiation of B lymphocytes.

Immunoglobulin E

Reaginic antibodies, which mediate acute and sometimes lifethreatening allergic reactions in atopic patients, belong to this distinct class of Igs.^{586a} IgE molecules also have two H (ϵ) chains and two L chains. They have a molecular weight of 200 kDa and a sedimentation coefficient of 8.2S, and they contain 12% carbohydrate. The ϵ chains are approximately the same size as the μ chains, with four constant region domains totaling approximately 550 amino acids. Each molecule has 15 half-cysteines, eight of which form intrachain disulfide bonds within the four constant domains. The formation of two interchain H-H bonds between two noncomplementary regions, that is, between C ϵ 1 and C ϵ 2 and between C ϵ 2 and C ϵ 3, is unique to ϵ chains. Carbohydrates are found throughout the chains. All six oligosaccharide units are N linked to Asn. The survival of IgE molecules in the serum is shorter than that of any other Ig (half-life 2.4 days), and their serum concentration is in the range of 0.1 to 0.7 mg/L, with a mean of 0.3 mg/L. Higher concentrations may be found in the sera of patients who have asthma, hay fever, eczema, Wiskott-Aldrich syndrome, and helminthic infestations. IgE-forming plasma cells are found most commonly in the respiratory, gastric, and intestinal mucosa and in the regional lymph nodes, but a few are noted in the spleen and in other lymph nodes. Thus, IgE, like IgA, is classified as an slg.

Biologic Properties

IgE antibodies are capable of sensitizing basophils and mast cells. The Fc portion of the IgE molecule fits into specific receptor sites on the cell surface. When bivalent or multivalent antigens bind at least two adjacent IgE molecules, the mast cell or basophil is triggered to degranulate, thereby releasing vasoactive substances, especially histamine and slow-reacting anaphylaxis substances, which are responsible for such clinical manifestations as wheal-and-flare reactions, bronchospasm, small-vessel dilation, and shock. Reduction of the disulfide bonds destroys the ability of the molecule to bind to the Fc receptor, and heating of the IgE at 56°C inactivates its cytotoxic activity. This inactivation is associated with loss of antigenic determinants in the C ϵ 3 and C ϵ 4 domains, suggesting that these regions are important for binding to the receptor.

J Chain

The J (joining) chain has been detected in association with polymeric forms of serum and slgA, as well as with the IgM pentamer.⁵⁸⁰ This chain has a molecular weight of 15 kDa. It is attached to IgA or IgM polymers by disulfide linkages. It is

not detectable by antisera while the polymers are in their native state, but it becomes readily accessible if the polymers are dissociated. In contrast to the secretory piece, J chains are produced by plasma cells and appear to play a key role in the process of polymerization of Ig, serving as a clasp or zipper to fasten the last two monomeric components of a plg together.

The complete amino acid sequence has been inferred from cloned genomic DNA. The chain is larger than previously determined, containing 137 amino acids. Many cysteine residues are scattered throughout the molecule. Of the 137 amino acids in mouse and human J chains, 106 are identical (77%). This characteristic, plus the fact that the C-terminal regions of the μ and α chains are also conserved, suggests that the polymerization of Ig molecules has been conserved in evolution, probably because they confer advantages in defense mechanisms in that they aggregate complex pathogens more effectively.

COMPLEMENT

The name complement was introduced by Paul Ehrlich and J. Morgenroth, because it was thought to complete the activity of the antibodies from which it could be distinguished by its particular properties. It is now recognized that complement represents a multimolecular system and is activated by three different pathways, the classical, the alternate, and the lectin, with the final lytic or effector function being carried out by a common pathway. This final common pathway leads to the formation of the membrane attack complex (MAC).

Classical Pathway

The classical pathway is initiated by two functional units: the recognition unit, which consists of three proteins, C1q, C1r, and C1s; and the activation unit, which consists of C2, C3, and C4⁵⁸⁷ (Fig. 14.25). The MAC is activated by the classical pathway by the generation of three complex enzymes with proteolytic activity, the formation of which requires the association of two or more proteins.⁵⁸⁸ Not all Ig classes are capable of binding to C1q; IgG1 and IgG 3 bind readily, whereas IgG4 does not bind at all. Complement binding to the IgG subclasses is determined by the flexibility of the hinge that prevents steric interference between Fab and C1q binding. IgG3, with the longest hinge region, is the most efficient of all IgG subclasses. Exposure of the C1q-binding site of IgM molecules is optimal when the molecule assumes the staple configuration as it binds to the antigen (Fig. 14.24). This site is hidden in the native form of IgM by the closeness of the subunits. IgM has the strongest binding ability because one C1q molecule that is bound to one IgM antibody is capable of lysing an erythrocyte, whereas two IgG molecules in close proximity are required to achieve the same effect. Ig antibodies that are bound to independent epitopes can activate the complement cascade in this way. Depending on the epitope density, activation occurs when at least 800 IgG molecules bind to the cell. For this reason, IgM antibodies are considerably more efficient lysins.

Step 1: C1 Esterase (C1)

C1 esterase is a complex that is assembled from three proteins: C1q (recognition subunit), C1r, and C1s (catalytic complex).⁵⁸⁹

C1q: Recognition Unit of C1s

All activators of the complement cascade recognize the C1q, which consists of a total of 18 polypeptide chains, six of each of the

P.355

three different types, A, B, and C.^{590,591,592} All polypeptide chains are equal in length, and each is comprised of a short N-terminal region that is involved in the formation of A-B and C-C interchain disulfide bonds. It is followed by collagenlike sequences, which consist of repeating triplets X-Y-Gly, a collagenlike motif (X is often a proline; Y is usually hydroxyproline or hydrolysine). These sequences are not found in human serum proteins but are present in collagen fibrils. At the beginning, three heterotrimers (each consisting of A, B, and C polypeptide chains) associate, forming a stalk. Because of the interruption of the collagen sequence, the

P.356

triplets dissociate into six radiating arms (Fig. 14.26A). At the C-terminal end, each arm ends in a globular head, which consists of heterotrimers of protein domains known as C1q modules. When viewed by electron microscopy, the C1q resembles a bouquet of flowers (Fig. 14.26B).

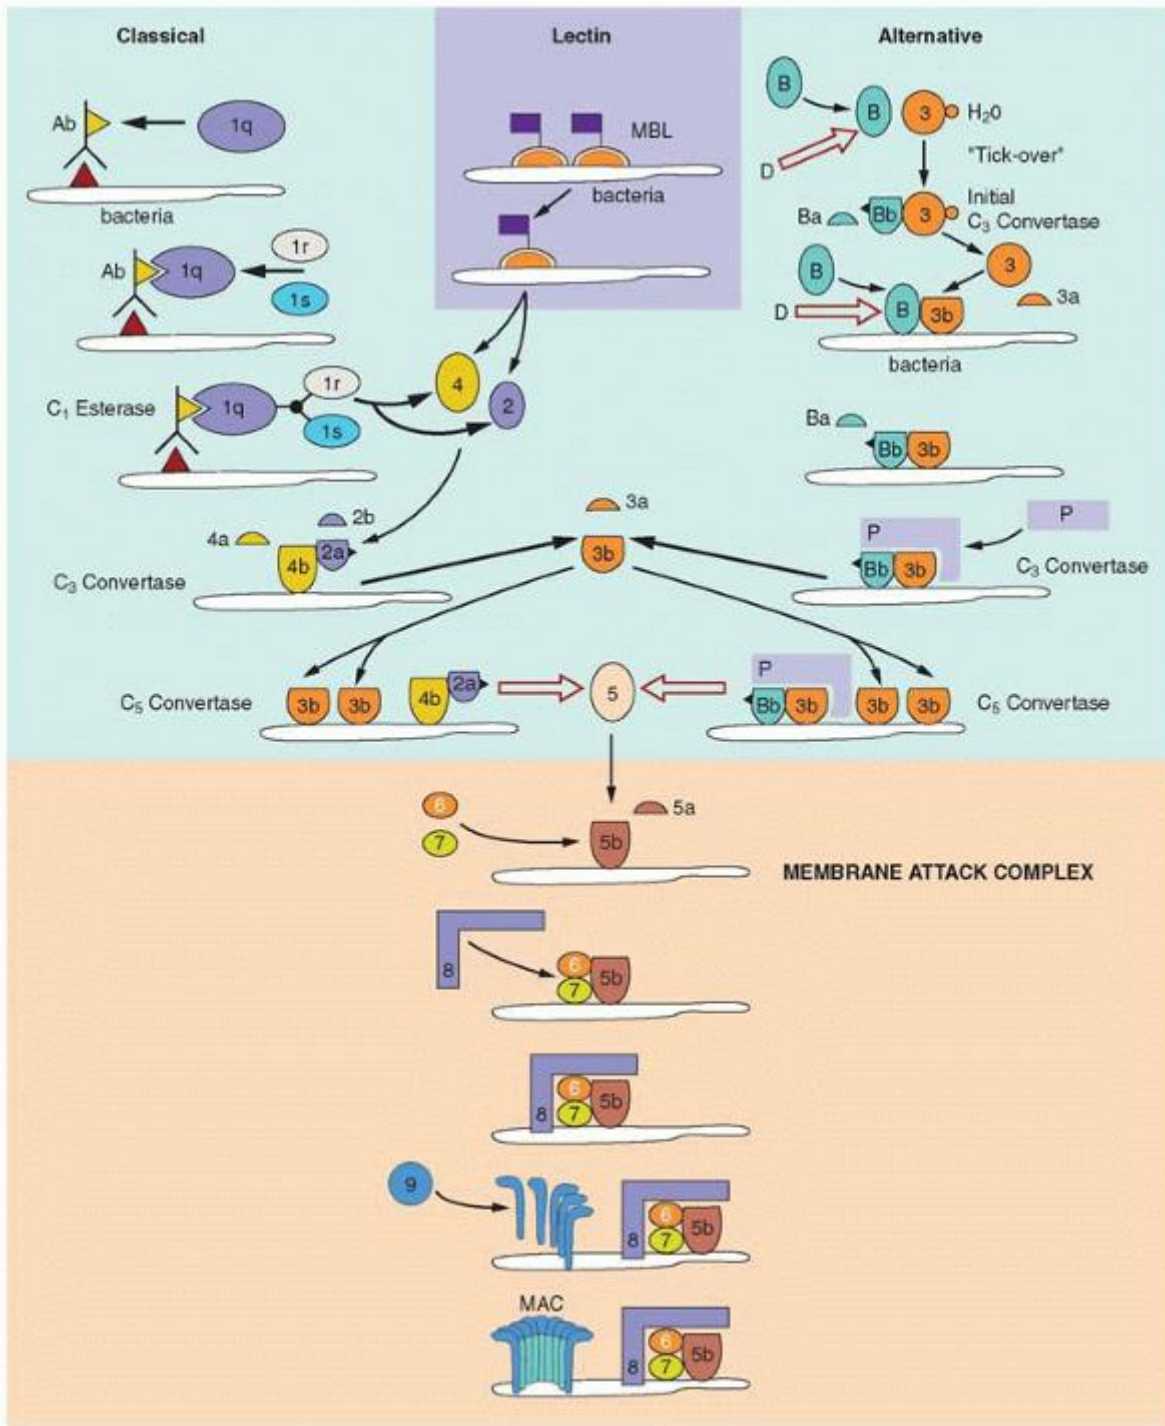

FIGURE 14.25. The complement (C) pathways. The hemolytic function of the C is activated by three pathways, which converge to the same final common pathway (see the text for details). The classical pathway uses C1q as the recognition molecule, which generates sequentially three enzymatic functions: C1 esterase, C3 convertase, and C5 convertase. The alternative pathway initiates activation by a “tick-over” mechanism in the absence of antibody and again generates similar enzymatic functions as the classical pathway. The lectin pathway is triggered by a receptor, mannose-binding lectin (MBL), which, through carbohydrate binding, activates the MBL-associated serine protease (MASP) esterases. A MASP cleaves C4 and C2, generating the same C3 convertase as the classical pathway, which it joins at this point. All pathways converge to the same membrane attack complex (MAC) pathway, which they initiate by cleaving C5.

FIGURE 14.26. A: C1q molecule. Each of the six subunits is made of three polypeptide chains that form a triple helical strand. The N-terminal ends have a collagenlike structure and are packed together, forming a central stalk (a); halfway, they bend and separate from each other (b) to end at the C-terminal end in a globular domain (c) that binds to the immunoglobulin. B: Electron micrographs of the C1q molecule (upper) and bird's eye view (lower). (From Knobel H, Villiger W, Isliker H. Chemical analysis and electron microscopy studies of human C1q prepared by different methods. *Eur J Immunol* 1975;5:78-82.)

Modules of the C1

gC1q Module. Most of the C1 activators, such as immune complexes, β -amyloid fibrils, and HIV, are recognized by the globular heads of C1q.⁵⁹³ Each head is composed of trimers of the gC1q domain, which is detected not only in C1q but also in type VIII and type X collagens and several other proteins.⁵⁹⁰ The gC1q modules bear structural features that are seen in members of the TNF family.⁵⁹⁴

CUB Module: C1r-C1s Uegf Bone Morphogenetic Protein-1 Module. The acronym CUB was given from the detection of this module for the first time in the sea urchin protein, Uegf, and the human bone morphogenetic protein-1. The CUB modules of C1r and C1s surround the single epidermal growth factor (EGF) module and a pair of complement control protein (CCP) modules. CUB modules are detected in proteins that are involved in developmental processes. They contain four cysteine residues, forming two disulfide bonds, except the N-terminal CUB module of C1r and C1s, which has only two cysteines.

Epidermal Growth Factor Module: Epidermal Growth Factorlike. EGF-like modules are detected in diverse proteins that are involved in processes such as blood coagulation and cell adhesion. They have six cysteines that form three disulfide bonds. In C1r and C1s, the EGF module has characteristic consensus sequences with residues Asp and Asn that are hydroxylated and are involved in Ca^{2+} binding.

Complement Control Protein Module. The CCP module is detected in complement receptors and other CCPs. Their consensus sequence consists of aromatic and hydrophobic residues and four cysteines. The crystal structure has been solved and shows six β strands around a hydrophobic core.⁵⁹⁵ The modules are ellipsoidal with the β strands aligned along their long axis, with N and C termini at opposite ends.

Serum Protease Domain

The target bonds in the substrates for cleavage by the C1 esterase have one Arg residue. Indicative of its trypsinlike enzymatic specificity is the Asp residue that is found close to the substrate-binding site. Arginyl bonds, such as Arg-isoleucine (Ile), are the targets in the autoactivation of C1r and in the activation of C1s by C1r. Arg-containing bonds are also cleaved in C4 and C2 by the active C1s. C1s esterase activity is expressed only by the multimolecular complex, which is a tetramer that is formed by two C1r and two C1s. Therefore, the enzymatic activity depends on protein-protein interactions among the four components of the esterase, which are facilitated by Ca^{2+} .⁵⁹⁶ Ca^{2+} brings together one CUB and one EGF module to form a compact structure.⁵⁹⁷ During the formation of the tetramer, interactions are flexible to allow a single C1r to cleave the neighboring and the distant C1s.⁵⁹⁸

C1r and C1s

The C1r and C1s are single polypeptide chains of approximately 85 kDa, with a SER protease activity. In the proenzyme form, they are single glycoproteins, which are activated by cleavage of a single Arg-Ile bond, forming a two-chain active enzyme. They are composed of two CUB modules,⁵⁹⁹ an EGF-like module, two CCP modules, and a C-terminal chymotrypsinlike SER protease domain (Fig. 14.27).

Assembly of C1 Esterase

The first enzymatic activity of the C cascade is assembled from five components, one C1q, two C1r, and two C1s (Fig. 14.27). The C1r-C1s tetramer, in isolation, is a linear structure, with the C-terminal domains responsible for the catalytic function and the N-terminal domain involved in the Ca^{2+} -dependent protein interactions. In the linear form, the two C1r catalytic domains are in the center, whereas those of the C1s are at the two ends. In the assembly of the C1 esterase, which is the first enzymatic activity of the classical complement cascade, the linear tetramer assumes a compact figure-eight conformation. In this configuration, all four catalytic domains of C1r and C1s are brought into juxtaposition under the cone that is formed by the arms of the C1q. The proteininteraction domains are located outside the arms of C1q.^{600,601}

Activation of C1 esterase occurs upon recognition by the globular heads of C1q of pattern target sites (e.g., antibody bound to pathogen surfaces and immune complexes). This binding generates transient conformational changes, which activate C1r by disrupting the C1r homodimer. Activated C1r in turn breaks an Arg-Ile bond, activating C1s.⁵⁹⁶ These transient "earthquakes" do not bring about the collapse of the elaborate C1 esterase edifice, because C1r and C1s are associated tightly with the C1q collagen arms by the CUB-EGF modules that were discussed previously.

C1s is a highly specific enzyme, but, within the mechanical constraints that are imposed by the superstructure of the whole assembly, it requires some degree of freedom of mobility for its interaction with the substrate. These requirements are provided by the CCP modules, especially CCP-2, which is linked by a flexible hinge to the CCP-1 module. This allows CCP-2 to act as a handle and a spacer, to amplify the shift that is required for the serine protease domain.^{595,601}

C1q-binding Proteins

In addition to its function in C activation, C1q binds to other proteins that are sometimes called receptors, mediating other C1q functions.^{602,603} There are two types of surface proteins that bind to C1q. One binds to the collagenous portion of C1q (cC1q

P.357

receptor), and the other binds to the globular heads (gC1q receptor). Some of these proteins are transmembrane, whereas others are intracellular, such as calreticulin (CALR) and the gC1q-binding protein (gC1qR, now known as C1QBP). The C1q structure bears similarity to the proteins of the collectin family, which includes the mannose-binding lectin (MBL), the pulmonary surfactant protein A, and conglutinin. However, the collectins are C-type lectins and bind carbohydrates, whereas the heads of C1q recognize protein patterns on immune complexes.

FIGURE 14.27. C1 esterase assembly. The C1 esterase is a complex that consists of one C1q molecule (recognition component) and a tetramer of two C1r and two C1s. The tetramer in isolation assumes a linear form: C1s-C1r-C1r-C1s. It weaves among the arms of the C1q in a necklacelike way and assumes a figure eight. This arrangement allows access of the catalytic domain of the C1 in the zymogen form to be in contact with the active catalytic domain of C1r for C1s to be activated. Both C1rs have access to both C1s. The flexibility of the tetramer allows changes in their relative position, so that the active C1s sites have access to C4 and C2 for their cleavage and formation of the C4a-C2b C3 convertase. The CUB and EGF modules of C1r are connected by a flexible loop and form a high-affinity Ca^{2+} -binding site that is involved in the interaction with C1s. The CUB-EGF pair interacts with the C1q arm. When the heads of C1q interact with a pattern of sites on the surface of a target, a conformational stress that is transmitted through the arms of C1q triggers the C1r catalytic domain and results in its activation. CCP, complement control protein.

The term C1qR has been used loosely, sometimes without hard evidence that the receptor triggers cell signaling that leads to some cellular functions.⁶⁰³ The gC1qR is expressed on myeloid cells⁶⁰⁴ and microglial cells,⁶⁰⁵ in which it mediates chemotaxis and phagocytosis, and in platelets,⁶⁰⁶ modulating their function in injured vascular sites. Calreticulin is a Ca^{2+} -binding protein that is located primarily in the ER of most nucleated cells. It has been found that calreticulin binds C1q and therefore qualifies as cC1qR, but the significance of this interaction remains elusive.

Step 2: C4 and C2 Complex: C3 Convertase

C3 convertase is formed by the interaction of two fragments from the C4 and C2 components of complement. Complement component 4 circulates in the blood as a disulfide-linked heterotrimer that consists of α (93 kDa), β (75 kDa), and γ chains (33 kDa). C3 and C5 components share a similar structure that is considered to be evolutionarily derived from one ancestral gene. The C3 and C4 components share an internal thioester bond, which is formed between a cysteine and a glutamine, which are two residues apart.⁶⁰⁷

C4 is synthesized as a single polypeptide chain but is later hydrolyzed, giving rise to the three constituent chains. C1s activates C4 by splitting the α chain, releasing the C4a fragment from the N-terminal end of the chain. The thioester bond, which is normally hidden in the C4b fragment, is exposed, reacts with an NH_2 or OH group of the surrounding molecules (Fig. 17.28), and deposits C4b on the surface of potential targets for C attack.

C2 is a single chain protein of approximately 100 to 110 kDa, with a distinct structure that consists of three globular regions: three N-terminal CCP domains, a single von Willebrand factor (vWF) domain in the center, and a serine protease domain in the C terminus.⁶⁰⁸ CCP modules are highly compact structures, folding independently into a β barrel (e.g., two interacting antiparallel β sheets), that form an ellipsoid structure. Loops that connect the β strands protrude from the module and may function as the ligand-binding sites. The vWF type A module consists of five parallel β strands and a short antiparallel strand that form a central twisted core, which is surrounded by seven amphipathic α helices.⁶⁰⁹ Cleavage of C2 by C1s occurs in the N-terminal region of the vWF domain, which results in the generation of two fragments, a larger (70-kDa) C2a, consisting of most of vWF and SP domains, and a smaller (30-kDa) C2b fragment (CCP-1, CCP-2, and CCP-3). Fragmentation of C2 exposes a C4b-binding site that is located on the C2b fragment, which interacts with C4b. C4b-C2a complex formation depends on Mg^{2+} ions, which are coordinated by residues in the metal ion-binding MIDAS (metal-ion-dependent adhesion site) motif of the vWF modules, which is also present in several integrins (see Appendix A, CD61). By electron microscopy, the C2a fragment appears as a two-lobed structure that links the C4b and C3b fragments in the final C5 convertase (see the following discussion). The C4b-C2a complex is a Ser esterase with an esterolytic activity and with the C3 as the natural substrate.⁶¹⁰

Step 3: C3b-C4b-C2a Complex: C5 Convertase

C3 Component

The C3 component of complement is the most abundant in the serum (1.2 mg/ml) and occupies the most critical position in all three C cascades. The prevailing hypothesis is that a gene that was common for all three components, C3, C4, and C5, originated from an ancestral α_2 -macroglobulin gene. Subsequent duplication formed the C4 and C3-C5 genes, and a second duplication formed separate C3 and C5 genes.

C3 comprises an α chain (110 kDa) and a β chain (75 kDa), which are connected covalently by a single disulfide bond. It is synthesized as a single protein and is modified post-translationally by a furinlike enzyme, which removes a sequence of four arginines.⁶¹¹

Another disulfide bond within the α chain connects the N and C terminals (Fig. 14.28). C3 convertase cleaves the α chain at a site that is close to the N terminus, generating two fragments: a small C3a (9 kDa) and a large C3b (176 kDa). The C3b consists of the remaining α chain, which is linked by the disulfide bond to the intact β chain. Cleavage of the α chain of C3 by the C3 convertase exposes the thioester bond, which, in the intact molecule, is well protected within a pocket in the α chain, with a half-life of 231 hours. In the metastable C3b fragment, the bond is exposed, with a half-life of 60 microseconds. These differences strikingly express the extraordinary reactivity of the thioester bond for certain groups on the cell surfaces. The thioester bond participates in a chemical transacylation reaction that results in the attachment of C3b on OH or NH_2 groups on cell surfaces, complex carbohydrates, or immune complexes that are within a radius of 600 Å from the point at which it was generated. Attachment of C3b is not

P.358

discriminatory between self- and nonself-surfaces but is regulated by CCPs (see the following discussion). The selection, however, of the OH groups on the sites of binding is quite restricted.⁶¹² C3b expresses multiple sites for binding to other

complement proteins, which determine its fate. C3b is deposited on and around the C4b-C2a complex, binding through the thioester bond. The deposition produces an enzyme with a change in the specificity from C3 to C5, generating the C5 convertase.⁶¹³ C3b is also deposited on other previously deposited C3b molecules, forming C3b-C3b dimers. The C3b-C4b and C3b-C3b form high-affinity binding sites for C5 and probably, the role of these dimers is to hold the substrate in a rigid position for efficient cleavage of C5. It also appears that the C3b-C3b-IgG complexes function as better precursors of convertases than monomeric C3b.

FIGURE 14.28. C3 degradation. The C3 component not only contributes to the classical pathway in the formation of the C5 convertase, it also, as a result of fragmentation, provides parts of its molecule for other important functions. For example,

C3a serves as an anaphylatoxin, C3b serves as a ligand for the CR1 receptor (CD35), C3d serves as a ligand for CR2 receptor (CD21), iC3b serves as a ligand for CR3 receptor (lymphocyte-function-associated antigen-1 integrin, CD11b/CD18) and for CD11c/CD18 integrin. (Courtesy of Dr. J. D. Lambris. From Sahu A, Lambris JD. Structure and biology of complement protein C3, a connecting link between innate and acquired immunity. *Immunol Rev* 2001;180:35-48, with permission.)

C3 Fragmentation

C3 is fragmented by several enzymes that generate a variety of functionally active fragments (Fig. 14.28). The activation of C3 by the C3 convertase cleaves the peptide bond between residues 726 and 727 (Arg-Ser) and generates a small C3a (9 kDa) and a large C3b (176 kDa) fragment. C3a is the N terminal of the α chain that functions as anaphylatoxin. C3b consists of the remaining α chain (α') and the entire β chain, which are linked by the disulfide bond. C3b is inactivated by further proteolysis by factor I and one of the co-factors. The first cleavage occurs between residues 1,281 to 1,282 of the α' chain and generates the inactivated C3b or iC3b₂, which is the ligand for CD11b-CD18 integrin (see Appendix A). A second cleavage by factor I separates a small fragment C3f (2 kDa) from the α' chain and yields another inactivated C3b or iC3b₂. Factor I, with CR1 or factor H as co-factor, cleaves the α chain once more, at residues 932 and 933, to yield C3dg and C3c. The C3dg fragment is a ligand for CD21 (CR2), a component of the coreceptor complex CD19-CD21-CD81 on B cells (see Chapter 12). C3dg is cleaved by a protease into C3g and C3d fragments.

Alternate Pathway

The alternate complement pathway represents an important natural defense mechanism that is independent of the immune response (Fig. 14.25). Activation of the alternative pathway involves three components: C3, B factor, and D factor. Polysaccharides (zymosan), bacterial products, aggregated human IgA, cobra venom factor, and many other substances are activators of the alternative C cascade. The mechanisms that initiate this pathway have been the subject of much debate. The enzyme that cleaves C3 contains C3b as one of its components, which is the product of a previous C3 cleavage. The origin of the first C3b becomes a puzzling problem. Normally, the C3 continuously generates a low level of a functionally C3b-like form by a "tick-over" mechanism. The mechanism for the tick-over is not a proteolytic process, but involves the spontaneous hydrolysis of the thioester bond by H₂O and the formation of a metastable C3 (H₂O). The hydrolysis occurs *in vitro* at 37°C at a rate of 0.005% per minute.⁶¹⁴ The C3 (H₂O) is an uncleaved C3 molecule and yet has the conformation and function of a C3b in the presence of Mg²⁺, which provides a site for binding of the B factor.

Factor B

Factor B (90 kDa) has a similar structure to C2: it consists of three CCP modules, a vWF type A module, and a serine protease domain that are all connected by short amino acid sequences. By electron microscopy, it appears as a three-lobed structure, presumably with each module corresponding to one of the lobes.

Factor D

Factor D is a Ser protease with only one known substrate, factor B. The single Arg²³³-Lys²³⁴ bond of factor B becomes susceptible to the enzymatic activity of factor D only when it forms an Mg²⁺-dependent complex with C3b. It is the only enzyme in blood that is able to catalyze this reaction and is therefore absolutely required for alternative-pathway activation.

P.359

The concentration of factor D in the blood is 1.8 ± 0.4 $\mu\text{g/ml}$, the lowest of any complement protein, which makes factor D the limiting factor in the activation of the alternative pathway. It is a single chain protein (24 kDa) and is structurally similar to pancreatic serine proteases. It circulates in blood in a zymogen or profactor form⁶¹⁵ converted to the mature enzyme as a result of conformational changes. However, this first step generates a "resting" enzyme because of an inhibitory sequence loop, which prevents its activation. The active enzyme conformation is induced after binding to the substrate in a second step.

Factor D has a structure that is similar to other members of the serine proteases: the polypeptide chain is folded into two antiparallel β barrels. Each barrel consists of six β strands with the same topology in all members.⁶¹⁶ Efficient catalysis requires three amino acids, Asp¹⁰², His⁵⁷, and Ser¹⁹⁵, forming the "catalytic triad," and the positioning of the three residues is crucial for the synergistic action that is required for hydrolysis of the target bond. In the bottom of the substrate specificity pocket is an Asp residue, which places factor D in the category of the trypsin subfamily of serine proteases and cleaves an Arg-Lys bond of its single natural substrate, factor B.

Properdin

Properdin is one of six plasma glycoproteins that collectively comprise the alternative pathway of complement. It was first described by Pillemer et al.⁶¹⁷ as a novel plasma protein that activated complement in the absence of immune complexes. Properdin consists of a single chain (53 kDa), which by electron microscopy appears as a rodlike structure that forms cyclic dimers, trimers, and tetramers.⁶¹⁸ The monomer consists of an N-terminal region of no known homology, followed by six thrombospondin type 1 repeats (TSRs) of approximately 60 amino acids.⁶¹⁹ Repeats of this type have been identified in the cell adhesion molecule thrombospondin and in a variety of other proteins, including thrombospondin types 1 and 2 (TSP-1 and TSP-2), C6 through C9, and the circumsporozoite protein of malaria parasites.⁶²⁰

Removal of TSR5 prevents binding to C3b and sulfatide, whereas, with the removal of TSR4, properdin is unable to stabilize the C3b-Bb complex but is still able to bind C3b and sulfatide,^{621,622} while it exists only as a monomer or a dimer. Absence of TSR3 does not affect any of the functions of properdin, including the formation of the polymers. TSR5 is important for polymer formation, because, in its absence, no cyclic polymers are detected. Properdin, as does thrombospondin, binds sulfated glycoconjugates and sulfatide with especially high affinity when it is activated. Properdin significantly contributes to linking innate and adaptive immunity. It is synthesized by endothelial cells, especially under turbulent blood flow conditions,⁶²³ and mRNA has been detected in neutrophils, monocytes, and T cells. In response to chemoattractants C5a or IL8, neutrophils discharge their properdin content promptly, as well as C3 and factor B, which they store within their granules. Factor D is supplied locally by blood, which completes the list of the components that are essential for activation of the alternative pathway. T cells and monocytes participate in the process, because they also secrete properdin, factor B, and C3. Activation-produced fragments C3d and iC3b are essential B-cell activation factors,⁶²⁴ thus linking with the adaptive immune system.

Activation of the Alternate Complement Pathway

In the presence of Mg^{2+} , C3 (H_2O ; also referred to as iC3) binds factor B, which is cleaved by factor D into a large Bb and a small Ba fragment (Fig. 14.25). The Bb forms a complex with the iC3, which is termed the initial C3 convertase. Although the iC3-Bb complex is destroyed on host surfaces by factor H and factor I (see the following discussion), C3b fragments that are deposited on foreign surfaces associate with factor B in the presence of Mg^{2+} . The C3b-B complex activates factor D, which cleaves factor B into Bb and Ba fragments. The distinction between activator and nonactivator surfaces is not clear. An activator surface is one that allows binding of factor B to C3b in preference of factor H (see the following discussion), thus activating the alternative pathway, and the opposite is true for nonactivators. Nonactivators can be converted to activators by removing sialic acid. A widely used activator is cobra venom factor, which binds to factor B and forms a stable C3 convertase. The factor is functionally analogous to C3b but is related structurally to C3c. It is used to deplete serum of C3 in a variety of experimental situations and is resistant to inactivation by factors H and I.

The C3b-Bb is stabilized by the serum protein properdin, which amplifies the cleavage and deposition of more C3b molecules^{625,626} to form the C5 convertase. The serine protease activity of the C3b-Bb complex, which is located in the Bb component, accelerates deposition of C3b fragments (C3b amplification), a unique feature of the alternative pathway, on and around the C3b-Bb complex. Some will form C3b-C3b dimers, which have a high affinity for C5 self-amplified C5 convertase⁶²⁶ and switch cleavage from C3 to C5, thus initiating the formation of the cytolytic C5b-9 complex. As the activation continues, at the outer ring of this circle, monomeric C3bs form more C3 convertases with factor B, which in turn deposits a new crop of C3bs, forming a new generation of C3b-C3b dimers, that is, C5 convertases. These cycles of successive outward deposition of C3 and C5 convertase activities continue until all surfaces are covered or the supply of individual components is exhausted.

Lectin Complement Pathway

The lectin pathway is an important humoral mechanism of innate immunity. It is activated by pattern-recognition receptors, such as MBL, which interacts with carbohydrates⁶²⁷ (Fig. 14.25).

MBL is a member of the collectin family, which includes the lung surfactant proteins, SP-A and SP-D, and a protein that is localized in the hepatic cell cytosol, CL-L1. Collectins are composed of a C-terminal lectin domain (carbohydrate recognition domain) and a neck region that connects to the collagenlike region, followed by a short cross-linking region that contains two to three cysteines. The neck region forms an α -helical coiled-coil structure, which initiates the formation of a trimer. In blood, MBL is found as multimers (i.e., dimers to hexamers). MBL is a C-type lectin, as it requires Ca^{2+} for binding to a carbohydrate ligand.

Associated with MBL are four serine proteases that are known as MBL-associated serine proteases (MASPs): MASP1, MASP2, MASP3,^{628,629} and sMAP or MAP-19, a truncated form of MASP2. MASP2 and sMAP are encoded by a single gene, but two different mRNAs are generated by alternative splicing.⁶³⁰ All MASP proteases have a modular structure that is

identical to C1r-C1s: a CUB domain, an EGF-like domain, a second CUB domain, two CCP domains, and a serine protease domain. The serine protease domain is homologous to the chymotrypsinogen family. An Asp residue in the substrate specificity pocket indicates trypsinlike substrate specificity. MASP's association with MBL is mediated by the CUB-EGF domain and is Ca^{2+} dependent.⁶³⁰ The MASP proteases are activated when MBL binds to conserved pathogen-associated sugar arrays that form molecular patterns, which are shared by broad classes of pathogens.⁶³¹

When MASP is activated, it cleaves C4 and C2, and the C4b fragment binds covalently to the microbial surface or the lectin itself and becomes the focus for C2 binding and activation. The remaining cascade is identical to that of the classical pathway (Fig. 14.25).

MBL binds mannose-acetyl glucosamine or GlcNAc, which are also ligands for other types of GlcNAc-binding lectins, which are termed ficolins and are present in the serum. Ficolins contain

P.360

collagenlike and fibrinogenlike domains. They bind to GlcNAc through the fibrinogenlike domain. They are associated with MASPs and sMAP and have the capacity to activate the lectin complement pathway.⁶³² In the serum, there are two types of ficolins, which are named L-ficolin and H-ficolin (Hakata antigen).^{633,634}

The recognition that is mediated by MBL and ficolins in complement activation is detected as far back in evolution as the ascidians, our closest invertebrate relatives. It indicates that the complement pathway has been important in innate immunity since before the evolution of adaptive immune systems in jawed vertebrates.

Membrane Attack Complex

C5

C5 (191 kDa) consists of two polypeptide chains, α (115 kDa) and β (75 kDa). C5 convertase selectively cleaves an Arg-Leu bond^{74,75} of the α chain, generating C5a, a potent leukocyte chemotactic peptide that consists of 74 amino acids and has considerable structural homology with C3a and C4a, the other two anaphylatoxins. The remaining larger fragment, C5b, in its nascent state constitutes the nucleus for the MAC. It possesses a metastable binding site with specificity for C6. By electron microscopy, C5 has the shape of a heart or of an ellipse, but the heart-shaped form is related to the elliptical type by rotation.⁶³⁵ The binding sites for C6 and C7 are located in the α chain of C5b. Interaction with C5b involves the C terminus of C6, specifically the C6c fragment that consists of two factor I modules (FIMs).

C6

C6 is a single polypeptide chain (104 kDa), which, by trypsin digestion, can be separated into an N-terminal region (C6a) with some homology to C8 and C9 and a C-terminal region (C6b) with homology to factor H and factor I. Several disulfide bonds separate discrete segments of C6, which is structurally homologous to a variety of other proteins. Overall, the primary sequence is a patchwork, with several modules that are involved in protein-protein interactions (Fig. 14.29). Starting from the N terminus, there are several domains: two tandem TSP-1s, a class A low-density lipoprotein receptor (LDLR), an extended central segment that is referred to as the membrane attack complex perforin (MACPF) domain with homology to perforin, an EGF, a third TSP-1, two CCPs, and two FIMs, which are related to those in the H chain of the complement control factor I.⁶³⁶ The FIMs are specific C5-binding modules, and yet they are not absolutely necessary, probably because other hydrophobic interactions also contribute to the C5 and C6 interactions. As devices that facilitate C5 and C6 interactions, FIMs make a greater contribution to the classical pathway in which C5b density is not as high as it is in the alternative pathway, because fewer C5bs are formed in the classical pathway, and C5b half-life is shorter.⁶³⁷

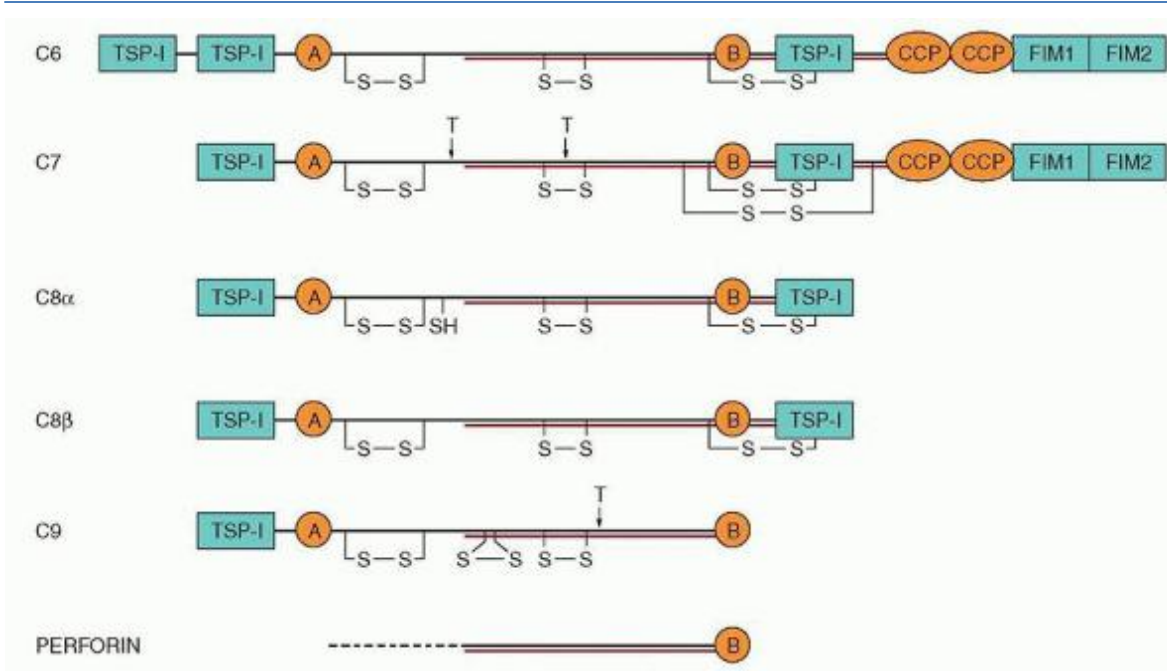

FIGURE 14.29. Structural organization of the C6 through C9 complement components. The last five complement components (C6 through C9) are structurally and genetically related proteins and form the membrane attack complex family. They all have a similar modular structure. In the middle of each molecule is a sequence-designated membrane attack complex perforin to emphasize its similarity with perforin. Membrane attack complex perforin is the portion of the molecule that is inserted in the membrane to form the pore. C8 γ is the sixth component, which is not modular and differs structurally from the others. It is considered that the perforin gene gave rise first to the C9 gene, which evolved in retrograde, followed by the appearance of the genes for the other proteins. The modules in the C6 and C7, which are not shared by C8 and C9 (i.e., complement control protein [CCP] and factor I module [FIM]) are used to interact with C5. A, low-density lipoprotein receptor class A; B, low-density lipoprotein receptor class B (or epidermal growth factor precursor module); TSP-1, thrombospondin 1.

The secondary structure of C6 is a mixture of α helices and β sheets. The α helices reside in MACPF, which is free of disulfide bonds. By transmission electron microscopy, C6 appears as a sickle.

C7

C7 is a single polypeptide (97 kDa), which, like C6, is a mosaic of several modules that are found in other proteins. Starting from the N terminus, C7 has one TSP1, one LDLR type A (LDLRA), a second TSP1, two CCPs, and two FIMs. Its secondary structure is high in β sheets (38%), and, by electron microscopy, it appears as a flexible elongated molecule (151-59-43 Å).⁶³⁸ The three components C5-C6-C7 in a fluid phase form rosettes as a consequence of radial aggregation. However, the complexes on a phospholipid area insert themselves, anchoring by the stalk, whereas the Cys-rich segments fasten the complex for the assembly of the MAC. The C5b-7 complex does not traverse the phospholipid membrane and does not cause lysis. The long flexible stalk of C7 provides greater surface area for interaction within the membrane.

P.361

C8

The C8 component consists of three chains: α (64 kDa), β (64 kDa), and γ (22 kDa), all being encoded by separate genes. The C8 α and C8 γ are linked by a single disulfide bond, and the C8 α -C8 β heterodimer is associated noncovalently with C8 β through a binding site on the C8 α chain.⁶³⁹ The α chain interacts with C9, directs the insertion into the membrane of the first C9 in the formation of MAC, and interacts with lipids, thus becoming accessible to MAC formation. Note that together with the membrane protein CD59, they inhibit MAC formation in homologous cells and protect them from lysis.

The C8 β chain has three binding sites for C8 α , the C5b-7 complex, and membrane lipids. For binding of C8 β to the C8 α - γ complex, the N-terminal TSP1, LDLRA, and the MACPF segment are most important, and, furthermore, they mediate the incorporation of C8 into the MAC.⁶⁴⁰

The C8 α and β chains are structurally related and are members of the MAC family, whereas the C8 γ chain is a member of the lipocalin family, which is unrelated to the MAC family.⁶⁴¹ The lipocalins are widely distributed proteins that are involved in the transport of small lipophilic substances, such as retinol and pheromones, but C8 does not bind retinol. They all share the same folding pattern, which is known as the lipocalin fold. Strikingly, C8 γ is the only protein from a different family among the 35 proteins of the complement system. Furthermore, C8 γ is not absolutely required for the expression of C8 activity by the α and β chains, but it enhances their function.⁶⁴² The crystal structure of C8 γ has been solved and confirms its lipocalin fold and, furthermore, identifies its structural relationship to the neutrophil gelatinase, a protein that is released from the granules of activated neutrophils.⁶⁴³ Overall, it forms a calyx with a distinct large hydrophobic cavity at the base of the calyx for ligand binding.

C9

Complement component C9 is a single polypeptide chain (71 kDa) that has a modular structure that is similar to that of the other members of the MAC family: an N-terminal TSP1; an LDLR-A; the extended central sequence MACPF, which is homologous to perforin⁶⁴⁴; and an EGF module in the C-terminal end. C9 is endowed with the capacity to polymerize spontaneously in a circular fashion and to create tubules.

Membrane Attack Complex Formation

The C5b-7 complex binds to the cell membrane, and, although it inflicts no harm on the cell, it marks it for subsequent assault by C8 (Fig. 14.25). The C5b-8 complex appears foliaceous by electron microscopy, with branched structures radiating from the central pedicle, but, on smaller phospholipid vesicles, C5b-8 monomers appear as long rodlike structures that are 250 Å wide.⁶⁴⁵ The C8 α chain mediates binding and self-polymerization of C9 to form MAC.⁶⁴⁶ The N-terminal TSP1 and LDLRA modules are the principal binding sites for C9 with the cooperative function of MACPF domain. MACs are heterogeneous in size, probably as a result of their composition, and the number of the C9 subunits may vary from 1 to 18, whereas all other components contribute only one molecule.⁶⁴⁷

The final molecular weight of the MAC therefore varies between 66 and 1,850 kDa. The average C9 binding capacity per C8 molecule is 15.4 molecules. C9 polymerizes spontaneously, but the C5b-8-induced rate of C9 polymerization is 10,000-fold greater. Self-associating C9 complexes develop new antigenic determinants that are not present in the monomer. C9 is inserted into the membrane through its C-terminal region, and disulfide bonds stabilize the complex. Electron microscopically, the polymerized C9 appears as a cylinder that extends 120 Å above the cell surface. The extracellular hydrophilic end terminates in an annulus that is 30 Å thick, with an inner diameter of approximately 100 Å⁶⁴⁵ (Fig. 14.30). The C5b-8 is attached firmly to the C9 cylinder and actually extends 160 to 180 Å above the annulus. The annulus, which is seen with computer-assisted programs, appears to be made of whorls⁶⁴⁸ (Fig. 14.30).

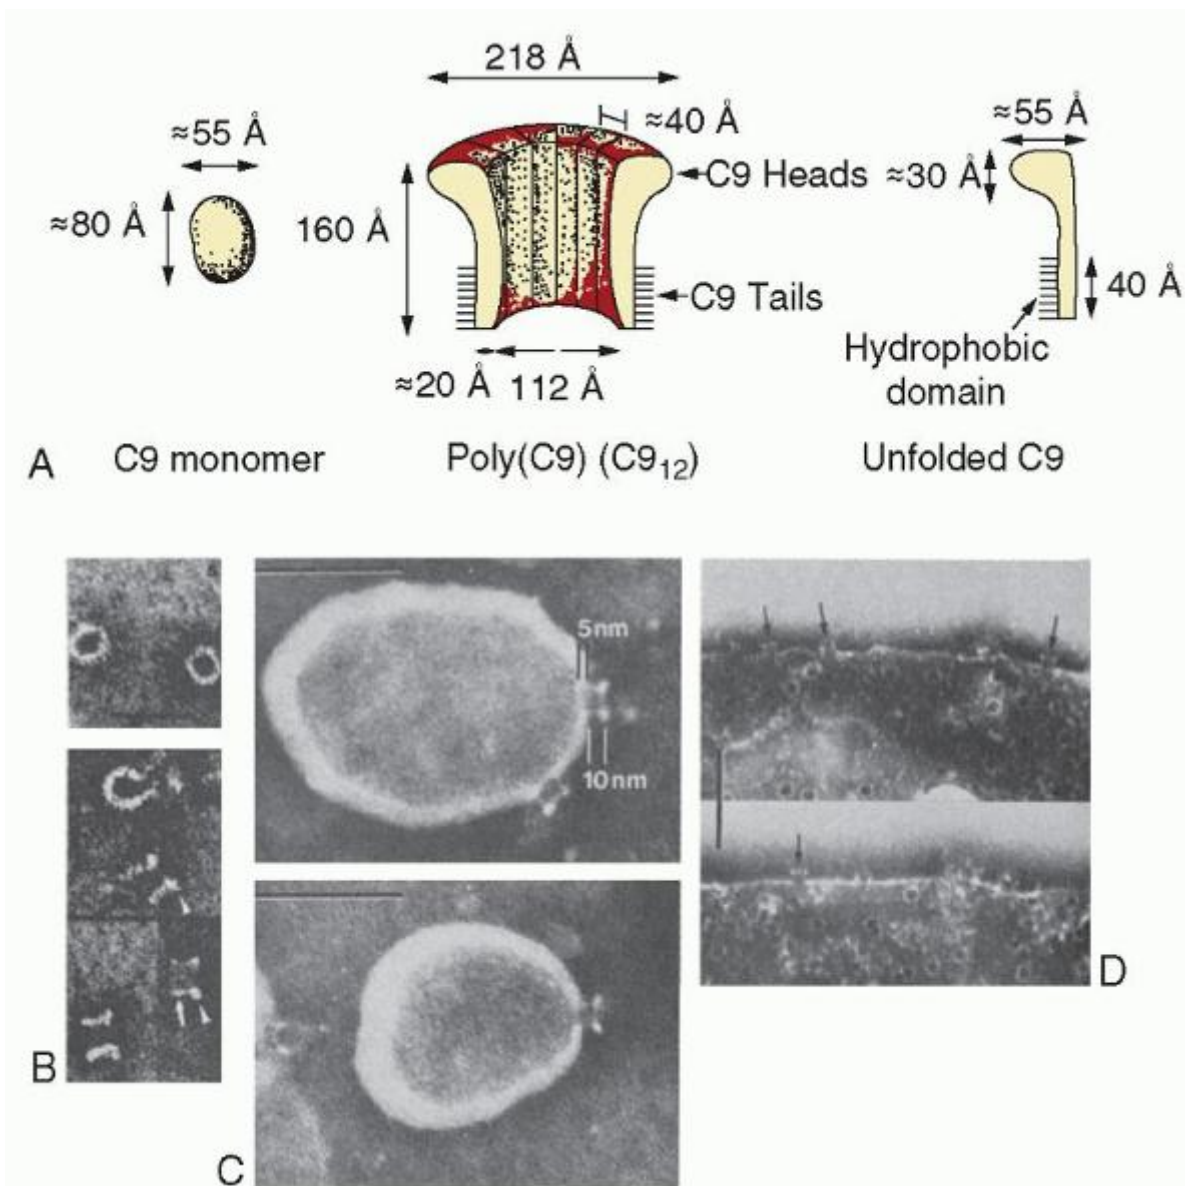

FIGURE 14.30. A: C9 molecule in its monomeric form, folded (left) or unfolded (right) and in its polymerized form (center) as a tubular structure that is seen on cell membranes. B: Poly C9 as ring structures (top view) or tubules (side view). (Courtesy of Dr. E. R. Podack. From Podack ER, Tschopp J. Polymerization of the ninth component of complement (C9): formation of poly(C9) with a tubular ultrastructure resembling the membrane attack complex of complement. *Proc Natl Acad Sci U S A* 1982;79:574-578.) C: Lipid vesicle with a typical cylinder that is formed from polymerization of C9 (side view). The cylinder penetrates the wall and protrudes to the outside, above the surface of the vesicle. D: Lesions that are induced by complement on sheep red blood cell membranes clearly show cylindrical structures of the membrane attack complex and its penetration into the membrane (arrows). (Courtesy of Dr. S. Bhakdi. From Bhakdi S, Trantum-Jensen J. Molecular nature of the complement lesion. *Proc Natl Acad Sci U S A* 1978;75:5655-5659.)

Because the height of the monomeric C9 is only 80 \AA , and the poly C9 cylinder is 160 \AA , the C9 must be unfolding and must transform into a rodlike structure. Thus, the formation of the cylinder by polymerization of C9 molecules involves the transformation of a hydrophilic C9 monomer into an amphiphilic C9 polymer.

The N-terminal part of C9 does not participate directly in polymerization and is located in the upper rim of the cylinder.⁶⁴⁸ The MACPF domain traverses across the thickness of the cell membrane, forming the wall of the cylinder. The C terminal part of C9 returns back up near the rim, indicating that polymerization transforms a straight ellipsoid C9 into a U shape.⁶⁴⁹

C9 aligns with other molecules side by side, like staves of a barrel forming a volutelike structure (i.e., a capital of an Ionianstyle Greek column). Not all agree with the cylinder model of MAC. Others suggest that MAC proteins cause a distortion of the phospholipid bilayer, thus creating "leaky patches."⁶⁵⁰

REGULATION OF COMPLEMENT ACTIVATION

A large number of proteins, known as complement control proteins, are involved in the regulation of complement activation (Table 14.6). This complex regulatory system is best understood

P.362

if we consider the stages of complement activation that are regulated or whether CCPs exist in fluids versus cellular surfaces. CCPs exert regulation mainly by accelerating dissociation of the convertases, a function that is known as decay-accelerating activity (DAA), or by acting as co-factors to the serine protease factor I, a function that is known as co-factor activity (CA). Some regulators are able to serve as both decay accelerators and co-factors, such as factor H, C4-binding protein (C4bp), and complement receptor 1 (CD35).

TABLE 14.6 REGULATORY PROTEINS OF COMPLEMENT

Factor	Location	Function
Initiation step		
C1 inhibitor	Serum	Inactivates C1r and C1s
Amplification step		
Factor I	Serum	Fragmentation of C3b and C4b
Membrane cofactor protein	Membrane	Cofactor for factor I in degradation of C3b Prevents C3 convertase formation
Decay-accelerating factor	Membrane	Dissociates preformed C3 and C5 convertases
C4 binding protein	Serum	Accelerates decay of C4b as cofactor for factor I Impairs uptake of factor B by C3
Factor H	Serum	Cofactor for factor I in C3b cleavage Promotes cleavage of C3b Impairs uptake of factor B by C3b
Complement receptor 1	Membrane	Displaces Bb from C3b
Properdin	Serum	Stabilizes C3 convertases
Membrane attack		

S protein	Serum	Blocks fluid-phase membrane attack complex
CD59	Membrane	Blocks membrane attack complex on cells

Control of the Initiation Step

C1 Inhibitor

C1 inhibitor (C1 INH) is a heavily glycosylated α -globulin with a molecular weight of 105 kDa. It is synthesized in the liver and by blood monocytes. Its gene is located on chromosome 11. C1 INH belongs to the superfamily of serpin proteins (serine protease inhibitors).⁶⁵¹ The inhibitor possesses a site that is structurally similar to the substrate, and, when a protease binds to this site and cleaves a peptide bond, it forms a covalent bond that results in a stable complex between the inhibitor and the enzyme. C1 INH inhibits activation of the classical and alternative pathways. It binds to C1r and C1s, forming stable complexes that prevent them from acting as an esterase. It also binds to the C1r-C1s complex and causes rapid dissociation of the C1 esterase. In the alternative pathway, it prevents factor B from binding to immobilized C3b. Cleavage of factor B by factor D is markedly inhibited when C3b is incubated with C1 INH.⁶⁵² A genetically inherited deficiency of C1 INH is manifested by recurrent acute attacks of circumscribed edema. Hereditary angioneurotic edema (HAE) may cause death from laryngeal edema. The mortality rate that is associated with this condition has been reduced with androgen therapy. This disease assumes two forms. In most (85%) cases (type 1 HAE), the inhibitor is present in reduced concentrations, whereas in the second form (type 2 HAE), it is present in normal concentrations, but is biologically inactive.

Control of C3 and C5 Convertases

The C3 convertase cleaves C3 to C3b and C3a, whereas the C5 convertase cleaves C5 and initiates the final stage that ends with the formation of MAC. These amplification steps are regulated by seven proteins: three of them are present in the serum (C4BP, factor H, and factor I), and four are cell membrane proteins [MCP, decay-accelerating factor (DAF or CD55), CR1, and CR2]. The overall function of these proteins is to prevent formation of the two convertases on self cells. Except for factor I, all other proteins belong to a structurally related family of proteins that is known as the complement control proteins. The genes are clustered on the long arm of chromosome 1q32.

A striking structural feature that is common to these proteins is the multiple homologous cysteine-rich domains, a 60 amino acid sequence referred to as CCP repeats.⁶⁵³ The CCP module or repeat has four li cysteines, an li tryptophan and highly conserved prolines, glycines and hydrophobic residues.⁶⁵⁴ The number of CCP domains are 30 in CR1, 20 in factor H and 4 in CD55. The 60 amino acid unit represents an ancestral domain that gave rise to the complement genes through duplication and splicing. The CCP domains are found in other complement proteins, such as C1r, C1s, C2, and factor B, as well as in noncomplement proteins, such as IL-2 receptor, haptoglobin, and coagulation factor XIII. Each CCP domain has a hydrophobic core that is interlaced with β strands connected by protruding loops, possessing a privileged position for interactions with other proteins. The control of the convertases is achieved by two mechanisms: (a) by dissociating the convertase to its individual components (DAA) and (b) by proteolytic degradation of C4b or C3b components as a result of the CA of the RCA proteins that act as co-factors for the serine protease, factor I. Some proteins have DAA and CA activity in the serum (C4BP, factor H) or cell surface (CR1), whereas others possess only one activity for the C4b and C3b components.

Regulators on Cell Surfaces

Membrane Co-factor Protein (CD46)

The extracellular region of membrane co-factor protein (MCP) consists of four CCP domains that contain the binding site for C3b and C4b and a region that is rich in serines, threonines, and prolines. The serine, threonine, and proline region is O-glycosylated and provides protection from proteolysis. A portion of this region may be removed by alternative splicing, which generates two of the four MCP isoforms. Two alternate forms of cytoplasmic regions contribute to the formation of another two MCP isoforms. MCP is present in almost all cells examined, except for red blood cells. Sites for C3b binding are in CCP2, CCP3, and CCP4 domains. The C3b and C4b binding sites have residues that bind to both complement

components as well as others that are specific for each component.⁶⁵⁵ MCP acts as co-factor for the serine protease factor I for inactivation of C4b that is deposited on self-tissues.⁶⁵⁶ MCP in the maternal-fetal interface protects the fetal tissue from attack by the maternal complement. It is found on the inner membrane of the spermatozoa and may play a role in protecting the sperm against C3b deposition. MCP is a receptor for several pathogens. The measles virus binds to an extended surface of MCP that encompasses the area from the top of CCP1 to the bottom of CCP2.⁶⁵⁷ The measles virus binding to CD46 is more like that of polio virus to its receptor: a wider open area that is flexibly hinged between CCP1 and CCP2 domains.⁶⁵⁸ This leaves the virus still exposed to immune attack. It contrasts with the narrow, recessed binding site or canyon in the case of HIV and rhinoviruses.⁶⁵⁹ The

P.363

M protein of *Streptococcus pyogenes*,⁶⁶⁰ which causes serious suppurative skin infections (e.g., cellulitis, necrotizing fasciitis), binds directly to CCP3 and CCP4 domains at a site that is distinct from the C3b-binding site. MCP mediates adherence of group A streptococci to keratinocytes.⁶⁶¹ HHV-6 also uses CD46 as a receptor and binds to CCP2 and CCP3.⁶⁶²

Decay-accelerating Factor (CD55)

DAF contains four CCP domains and is attached to the membrane by a GPI anchor. Its molecular weight is between 70 and 80 kDa, depending on its glycosylation. Soluble forms exist in body fluids that may arise from the action of a phospholipase on the membrane form. It is expressed on all hematopoietic cells, endothelial and epithelial cells, and cells of the gastrointestinal, genitourinary, and central nervous systems. Erythrocytes possess approximately 3,000 DAF molecules, and, among the lymphoid cells, the NK cells appear to be deficient in DAF. Neutrophil activation results in enhanced expression of DAF (from 10,000 to 20,000 molecules per cell). It is present in a soluble form in many body fluids, including plasma, tears, saliva, urine, synovial fluid, and cerebrospinal fluid.

DAF accelerates the decay of C3 convertase for the classical and alternative pathways but prevents its formation (Fig. 14.31). Regulation by DAF involves separate sites for the two convertases as well as common sites for both.⁶⁶³ For the alternative C3 convertase, DAF acts on the type A domain (vWF type A domain) of the Bb component.⁶⁶⁴ Classical C3 convertase is regulated by a site that is located in the CCP2-CCP3 domain junction, which consists of three consecutive lysines and a hydrophobic patch.^{665,666} DAF is used as receptor by many pathogens, such as several types of echoviruses, enteroviruses, and *E. coli*. It constitutes a functional component of the LPS receptor complex.⁶⁶⁷ CD55 is the ligand (counterreceptor?) of CD97, the prototype of a large seven-span transmembrane family (as many as 2,000 members) with variable numbers of EGF domains and sequence homology to the G-protein-coupled peptide hormone receptors.^{668,669} CD97 is associated with inflammation and is detected in malignancies.

Complement Receptor 1

Receptors for complement components or their breakdown products are expressed on many cells and tissues. They mediate various effector functions listed in Table 14.7. Some of the functions of complement receptors that are related to the regulation of complement activation are briefly reviewed. The complement receptor type one (CR1, C3b/C4b receptor, CD35) was the first to be discovered as the receptor for immune adherence, a fundamental event in the initiation of the immune response. It is a polymorphic membrane protein of 190 to 280 kDa composed of 2,039 residues and present on all peripheral blood cells except platelets, NK cells, and most T cells.⁶⁷⁰ CR1 is expressed on kidney podocytes and FDCs. Cell membrane expression of CR1 is up-regulated by chemotactic peptides, such as C5a, endotoxin, and cytokines. Blood cells at resting state express only 5% to 10% of the total cellular CR1 at the plasma membrane, whereas the remaining CR1 is found intracellularly. The red blood cells express 100 to 400 receptors per cell, and the leukocytes have 10,000 to 50,000 receptors per cell. However, because the number of red cells is approximately 1,000 times more than white cells, they possess more than 85% of the total CR1 that is available in the blood.

FIGURE 14.31. A, B: Decay activity on cell surfaces. A: Decay-accelerating factor (DAF, CD55) is a GP I-anchored protein, which dissociates formed C3 convertase complex, as well as prevents its formation. B: Factor H is a serum protein that expresses DA activity by attacking C3 convertases on self surfaces. It binds to the C3b-Bb complex and displaces factor B irreversibly. C, D: Co-factor activity. C: Membrane co-factor protein (MCP, CD46) is a cell membrane protein, which contains binding sites for C3b and C4b. It acts as co-factor for factor I to cleave both proteins. It is also the measles virus receptor. D: The C4b-binding protein (C4BP) is a serum protein that acts as a co-factor for factor I for cleaving C4b.

TABLE 14.7 CELLULAR DISTRIBUTION AND FUNCTION OF RECEPTORS FOR COMPLEMENT COMPONENTS

Receptor	Cell Type	Functions
C1q	Neutrophils	Respiratory burst
	Monocytes	—
	B cells	—
	Null cells	Enhanced antibody-dependent cell-mediated cytotoxicity
CR1	Macrophages	Enhanced phagocytosis
	Neutrophils	Same as macrophages
	B cells	—
	T cells	—
	Red blood cells	—
	Eosinophils	—
	Epithelial cells: kidney	—
CR2	B cells	Activation
CR3	Similar to CR1	Similar to CR1
Factor H	B cells	Secretion of factor I
	Monocytes	Respiratory burst

	Neutrophils	—
C5a	Mast cells	Histamine release
	Neutrophils	Chemotaxis, increased adhesiveness Enhancement of CR1 expression
	Macrophages	—
C3a/C4a	Mast cells	Histamine release

From Fearon DT, Wong WW. Complement ligand-receptor interactions that mediate biological responses. *Ann Rev Immunol* 1983;1:243, with permission.

CR1 contains 30 CCP domains with three sites for C4b binding and two sites for C3b binding. The CCP15 domain is critical for C4b binding and, together with the CCP16 domain, is required for C3b binding.⁶⁷¹ The CCP domains are arranged in larger domains that are known as long homologous repeats, with each one containing seven CCPs. It is likely that this arrangement facilitates the binding of CR1 with clusters of its ligands. There are four allotypes of CR1 (A through D). CR1, one of the most versatile RCAs, possesses DAA and CA, which are restricted to reducing the complement activity on cells that have absorbed immune complexes. The DAA of CD35 is mediated by CCP1 to CCP3 domains for the classical and alternative pathways.⁶⁷² In the classical pathway, CR1 inhibits the uptake of C2 by C4b as well as displaces C2a from C4b2a C3 convertase and from C4b2a3b C5 convertase. It also promotes the cleavage of C4b to C4c and C4d by factor I and the

cleavage of C3b to iC3b (ligand of CR3) and C3dg (ligand of CR2) by factor I. In the alternative pathway, the CR1 impairs uptake of factor B by C3b and displaces Bb from C3bBb C3 convertase. Complexes that are bound to erythrocytes are eliminated in the spleen. Conversion of C3b to fragments leads to binding of the complexes to macrophages and monocytes that possess CR3 or to lymphoid follicular areas in which all three CR are expressed.

The CR1 has the capacity to inhibit complement activation on cells and tissues other than those in which it is expressed (extrinsic protection), whereas DAF and MCP protect only the cells on which they are expressed (intrinsic protection). CR1 facilitates phagocytosis which in the absence of other ligands does not occur with resting neutrophils or monocytes. However, activation of these cells up-regulates CR1 expression and alters its function, so that phagocytosis of C3b-coated particles may occur. Soluble human CR1 inhibits complement-dependent tissue damage and reduces inflammatory responses.

Regulators in Body Fluids

Factor H

Factor H is a soluble glycoprotein that is present in blood at concentrations of 0.3 to 0.5 mg/L. It is a single polypeptide chain of 150 kDa with a highly elongated shape. It is composed of 1,213 amino acids that are assembled in 20 CCP domains. Factor H synthesis in the liver and in other extrahepatic sites (myeloblasts) is regulated by IL6.⁶⁷³

The main functions of factor H are (a) binding to the α chain of C3b, blocking the amplification cycle in the alternative pathway (tick-over), and preventing the generation of C3 convertase, C3bBb; (b) binding to the C3bBb enzyme and irreversibly displacing the Bb component (DA activity); and (c) acting as co-factor for factor I and enhancing its affinity for C3b. By these three activities, factor H prevents formation of the C5 convertase and, thus, the generation of MACs by the alternative pathway. Factor H possesses an impressive number of discriminatory functional sites. Its 20 CCP domains and its long and flexible structure allow factor H to scan a large surface area. The affinity of factor H for C3b is affected by the properties of the cell or tissue surface. Carbohydrate-rich polymers that are found on yeast and bacterial cells prevent binding of factor H to C3b, thus enabling the complement activation to react against these pathogens. Removal of sialic acid from sheep erythrocytes prevents binding of factor H to C3b and allows activation of complement.

Factor H binds to polyanions and blocking of this site enhances its affinity for C3b.⁶⁷⁴ The propensity of factor H to bind on polyanions, such as heparin on host tissues, may function as a protective mechanism against the alternative complement pathway.⁶⁷⁵ The discriminatory ability of factor H depends on its differential binding to various types of surfaces to which C3b has been initially deposited (Fig. 14.32). The nonactivating surfaces have sialic acid and other negatively charged glycosaminoglycans to which factor H binds through domain CCP20. The same domain is important for binding within approximately 30 Å from the C3d attachment site, indicating that the binding sites of factor H for polyanion and C3d

overlap.⁶⁷⁶ It is possible that discrimination by factor H occurs by a joint recognition of C3 and polyanions. The CCP11 to CCP20 domains are important for binding to activator surfaces,⁶⁷⁷ but the DAA or CA varies among these CCPs, depending on the nature of the surface on which C3b has been deposited. It appears that factor H uses different CCP domains, individually or in combinations, for recognition of C3, host, or foreign tissues. The CCP1 to CCP4 domains are used to bind intact C3b, the CCP6 to CCP10 domains are used for binding C3c within the C3b, and the CCP16 to CCP20 domains are used for the C3d part of the C3b.⁶⁷⁸

Recently, single-base mutations or base pair deletions have been demonstrated in sporadic and familial cases of hemolytic uremic syndrome (HUS).⁶⁷⁹ HUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure in affected individuals and is classified as diarrheal (D+ HUS) or nondiarrheal (D- HUS) and as sporadic or familial.

FIGURE 14.32. Self-/nonself-discrimination by factor H. A: Factor H prevents alternative complement activation by blocking the amplification cycle of the alternative pathway. It enhances its affinity to C3b as a result of binding to certain polyanions (negatively charged glycosaminoglycans) on self surfaces. Binding to C3b invites factor I to fragment C3b (cofactor activity). B: On pathogen surfaces, factor B expresses a higher affinity to deposited C3b and, with a lack of appropriate carbohydrate ligand for factor H, forms the alternative C3 convertase.

A set of 12 missense mutations in the CCP domains between CCP16 through CCP20 is associated with HUS. Nine of them are in CCP20 and are inferred to lead to a functional defect.⁶⁸⁰ The positions of these mutations correspond to basic residues that are involved in binding to heparin. It is suggested that these mutations interfere with the normal function of factor H to bind to sulfated glycosaminoglycans and to prevent the activation of the alternative complement pathway.

These experiments of nature strongly imply that the host-versus-foreign discrimination by factor H resides in CCP20 and is lost by these mutations.⁶⁸¹ Lack of host recognition results in uncontrolled complement activation and, eventually, renal failure.

Mice that are deficient in factor H develop membranoproliferative glomerulonephritis as a result of uncontrolled activation of the alternative complement pathway.⁶⁸² Factor H consists of several members; factor-H-like protein 1 (FHL-1) or reonectin, shares the complement regulatory functions with factor H and interacts with heparin. It contains the first seven of 20 CCP domains of factor H and has four unique residues that are attached to the terminal end.⁶⁸³ Both factor H and FHL-1 are synthesized by the same gene, but their transcripts are differentially regulated. They are produced by the liver, monocytes, and neuronal cells. Other members of the family are factor-H-related (FHR) proteins 3 and 4 (FHR-3 and FHR-4)⁶⁸⁴ which bind to C3b and particularly to C3d fragment.⁶⁸⁵

C4B-binding Protein

The C4b-binding protein (C4BP) is a regulator of the classical complement pathway C3 convertase. C4BP possesses CA and DAA. It consists of eight subunits that radiate from a central core in a spiderlike formation (Fig. 14.33). The peripheral end of each subunit is capable of binding one C4 molecule. Each of the seven

P.365

subunits known as α chains has a molecular weight of 75 kDa, and the eighth subunit, known as a β chain, is 45 kDa. They are flexible, 33 nm in length, and are linked together by disulfide bonds near the carboxy termini. In addition to the most common form of C4BP, $\alpha_7:\beta_1$, there are two other minor forms, $\alpha_7:\beta_0$ and $\alpha_6:\beta_1$. The α chains are composed of 549 amino acids divided into eight CCP domains, with 58 residues left in the C terminus to form the disulfide bond with the other α chains in the core region. The β chains have three CCP domains and are attached by a disulfide bond in a similar way to the α chains. The genes for C4BP are within the gene cluster of the other RCA proteins. The C4b binding site is localized in the CCP1 and CCP2 domains of the α chain, in a cluster of positively charged amino acids.⁶⁸⁶ The same region is also important for binding to heparin, Bordetella pertussis, and the M-protein of *S. pyogenes*, *Neisseria gonorrhoeae*, and *E. coli*.

FIGURE 14.33. Electron micrographs of the C4b (A) and the C4b-binding protein (B) that form complexes with C4b (C). (Courtesy of Dr. B. Dahlback. From Dahlback B, Smith CA, Muller-Eberhard HJ. Visualization of human C4b-binding protein and its complexes with vitamin K-dependent protein S and complement protein C4b. Proc Natl Acad Sci U S A 1983;80:3461-3465, with permission.)

C4BP is synthesized in the liver under stimulation of IL6 and TNF- α and is present in the blood at a concentration of 0.2 mg/L. The mechanism of control of the classical pathway by C4BP depends on the binding to C4b and the displacement of C2a from the C4b2a convertase (DAA), as well as its function as a co-factor for cleavage of C4b by factor I. Dissociation of

C2a from the classical pathway C3 convertase destroys its activity and prevents rebinding of the C2a to C4b. C4BP acts also as co-factor for cleavage of C3b by factor I.⁶⁸⁷

Protein S binds with high affinity to the β chain of C4BP.⁶⁸⁸ Protein S of the coagulation pathway is a vitamin-K-dependent anticoagulant protein. It acts as the co-factor for activated protein C that inactivates factor Va and is also the direct inhibitor of factor Xa. The concentration of free protein S is determined by the concentration of C4BP, as 50% or more of protein S is bound to C4BP. Protein S that is bound to C4BP is unable to participate in the anticoagulant protein C system. It is critical that the balance between free and C4BP-bound protein S is maintained stable, because lack of free protein S leads to thrombosis. Protein-S-bound C4BP is probably localized on negatively charged surfaces that are found in platelets and apoptotic cells. Conditions with elevated C4BP (autoimmune diseases) may be associated with increased clotting tendency as a result of increased binding of protein S to C4BP.

Factor I

Factor I is a serine protease that mediates proteolytic degradation of C3b, iC3b, and C4b only if a co-factor binds to the substrate to promote the binding of the enzyme. These co-factors for C3 and C4 degradation on host cells are MCP (Fig. 14.31), and, to a lesser extent, CR1, whereas in plasma the co-factors are C4BP and factor H (Figs. 14.31 and 14.32). Factor I is constitutively active and essential for control of the fluid and cellular complement reactions. Genetic deficiency of factor I leaves the generation of C3 convertases uncontrolled, leading to incapacitation of the complement system as a result of the continuous low-level conversion of C3. Fragmentation by factor I of C3 and C4 determines the specificity of their derivatives for CR1, CR2, and CR3. Factor I is a two-chain disulfide-linked protein that is synthesized from a single-chain precursor. The H chain is 50 kDa, and the L chain is 38 kDa in molecular mass and has the Ser esterase domain. The H chain is composed of three different types of modules that are derived from different gene superfamilies. One module, which is also found in C6 and C7, is from members of the follistatin family of the extracellular matrix, a second type is a scavenger-receptor cysteine-rich module, and the third type are two LDLR-A modules.

The only known substrates for factor I are C3b and C4b. C3b is cleaved at Arg¹³⁰³-Ser¹³⁰⁴ and Arg¹³²⁰-Ser¹³²¹. For this cleavage, the co-factors are factor H, MCP, and CR1. C4BP acts as a co-factor for cleavage of C4b and C3b. C4b is cleaved at Arg¹³³⁶-Asn¹³³⁷. In general, for C3b and C4b and all subsequent fragments, factor I acts on the C-terminal side of an Arg.

Control of the Membrane Attack Complex Assembly

Protein S

Protein S is identical to vitronectin (serum spreading factor). It is a 75- to 80-kDa protein that is synthesized from a single polypeptide chain that is subsequently cleaved to give the mature polypeptide as a single or double chain protein. At the NH₂ terminus, there is a somatomedin B domain (containing eight cysteines) followed by a linear sequence, which contains the RGD sequence

P.366

that is responsible for the binding of integrins. Two domains of the S protein have homology to hemopexin. The C terminus is rich in basic residues that mediate the binding of S protein with sulfated polysaccharides.

Protein S binds to the metastable C5b-7 complex and prevents the formation of MAC. Because MAC in the process of its formation can be inserted on any cell membrane, the most important function of S protein is the protection of the cells of the body that may be attacked by MAC as innocent bystanders. Protein S acts through its heparin-binding site, which prevents the polymerization of C9. The protein S is important in cell matrix interactions, and, through its multiple binding sites, it participates in several other functions of adherence, phagocytosis, the coagulation cascade in which it interacts with thrombin.

Clusterin (Cytolysis Inhibitor)

Clusterin is an 80-kDa protein composed of two chains (α and β). The gene is located on chromosome 8p21-p12. It is present in a variety of tissues and in the serum at concentrations of 35 to 105 $\mu\text{g/L}$. It forms complexes with lipoproteins and binds to C7, C8b, and C9, to inhibit MAC formation.⁶⁸⁹

Clusterin is involved in several other poorly understood functions. It has been found to be up-regulated in injured tissues and in Alzheimer's disease, as well as in tissues undergoing apoptosis.

Control of Deposited MAC: CD59

CD59 is an 18- to 20-kDa protein that inhibits MAC formation.⁶⁹⁰ It has been known by a variety of other names, such as homologous restriction factor 20, membrane inhibitor of reactive lysis, and protectin. It is a GPI-anchored protein and is widely distributed in human tissues and most body fluids (see the following discussion). CD59 expression is lacking in patients with paroxysmal nocturnal hemoglobinuria (PNH).

Conclusion

The RCA proteins exert several important functions in the regulation of complement activity: (a) they prevent complement activation in the blood (factor H and C4BP); (b) they interfere with the assembly and function of convertase activity on cell membranes (DAF and MCP), protecting the cells of the body from complement attack; (c) they transport and clear immune complexes (CR1); and (d) they mediate transmembrane and intracellular trafficking (CR1) and transmembrane signaling (CR2).

The CCP units that are characteristic of the members of the proteins of the RCA gene cluster are present also in C1r, C6, C7, factor B, properdin, and noncomplement proteins, such as coagulation factor XIII and IL2 receptor. The 60 amino acid unit represents an ancestral domain that gave rise to the complement genes through duplication and splicing with domains from the serine protease gene family.

ANAPHYLATOXINS

Activation of the complement cascade leads to the release of important inflammatory factors that are known as anaphylatoxins: the C3a, C4a, and C5a molecules. Their amino acid sequence varies from 74 to 78 residues. The cysteines are conserved in all anaphylatoxins and form three disulfide bonds that stabilize the conformation and form the core of the molecule. The C terminus forms the active site, with the C-terminal Arg being essential for function. Under physiologic conditions, the molecule is folded or compact.

The C-terminal end protrudes from the core and is considered to be the active site of the molecule that mediates biologic activities. Removal of the last Arg (C5a desArg) results in a loss of spasmogenic activity, but the chemotactic and other neutrophil activation functions are retained. The N-terminal region of C5a binds to its high-affinity receptor on neutrophils, which spans the membrane seven times with the N terminus on the extracellular side.⁶⁹¹ It belongs to the rhodopsin family of receptors, the members of which are linked to G proteins. Binding of C5a to its receptor on neutrophils induces a variety of responses, depending on its concentration, such as chemotaxis, granule secretion, up-regulation of adhesion molecules, changes of cytoskeleton, and activation of NADPH oxidase.

All anaphylatoxins are cleaved rapidly in the serum by carboxypeptidase-N, an enzyme that removes the C-terminal Arg that is found on all three anaphylatoxins. The main biologic function of anaphylatoxins is related to their ability to increase vascular permeability as a result of mast-cell degranulation. Anaphylatoxins also cause serious lung injury because of their capacity to recruit and sequester leukocytes in the pulmonary circulation. Anaphylatoxins also mediate production of oxygen and nitrogen-derived radicals, leukocyte margination, release of granule-associated proteolytic enzymes and capillary leakage, all components of an inflammatory response.

COMPLEMENT COMPONENT DEFICIENCIES

C1 Esterase Inhibitor: Hereditary Angioneurotic Edema

HAE is an autosomal dominant disease that afflicts persons of all races with no sex predominance.⁶⁹² It manifests as recurrent attacks of intense, massive localized edema without pruritus and in the absence of any identifiable initiating event. Gastrointestinal and respiratory systems are most commonly involved with upper airways symptoms, including risk of asphyxiation. There are two types of HAE: type 1 (80% to 85% of cases) caused by decreased production of C1 INH and type 2 (15% to 20%) caused by a functionally impaired C1 INH (C1 esterase inhibitor).

C1 INH belongs to the same family as α 1-antitrypsin; antithrombin IFN- γ and IL6 stimulate its synthesis and release from the liver and monocytes. The main function of C1 INH is prevention of autoactivation of the complement cascade. It also inactivates coagulation factors XIIa, XIIf, and XIId and activated kallikrein. The mechanism of action involves formation of irreversible covalent bonds with the substrates.

Under physiologic conditions, small quantities of factor XII are autoactivated to factor XIIa and trigger the contact system, which cleaves prekallikrein to kallikrein; this cleaves kininogen, generating excessive release of kinins especially bradykinin. This pathway normally is blocked by C1 INH, which inhibits factor XIIa. In the absence of the normal control function of C1 INH, not only is factor XIIa not inhibited, but kallikrein also generates plasmin from plasminogen, activating factor XIIa for more kallikrein as well as activation of the C1 esterase.

Deficiency of Other Early Complement Components

Homozygous deficiencies of the early components of the classical pathway are associated with SLE,⁶⁹³ and the severity of the associated disease is greatest with C1q deficiency. This is caused by failure of C1q synthesis or synthesis of a dysfunctional molecule. C4 deficiency is associated with early onset of severe SLE. C2 deficiency is the most common homozygous complement deficiency in whites; C3 deficiency is associated with recurrent pyogenic infections, and deficiency of factor H has been associated with membranoproliferative glomerulonephritis.

P.367

Paroxysmal Nocturnal Hemoglobinuria: Deficiencies of Decay-accelerating Factor (CD55) or Clustering (CD59), or Both

PNH is an acquired hematopoietic stem cell disorder, which is manifested by intravascular hemolysis, venous thrombosis, aplastic anemia, myelodysplasia, and leukemia. The defect is the result of somatic mutations that consist of deletions, insertions, or point mutations of the PIGA (phosphatidyl inositol glycan complementation class A) gene, which is involved in the synthesis of GPI.^{694,695}

The GPI anchor consists of three components: (a) phosphoethanolamine (PEA), (b) a glycan core formed by three mannose molecules and one GlcNAc, and (c) PI.

Glycosyl Phosphatidyl Inositol Biosynthesis

GPI synthesis involves multiple steps and takes place in the ER (Fig. 14.34). Initially, GlcNAc is attached to PI, by the GPI-N-acetyltransferase, a complex enzyme that is composed of at least six proteins encoded in genes located on the short arm of the X chromosome:^{696,697,698} and ⁶⁹⁹ PIGA, PIGH, PIGC, PIGQ, PIGP, and DPM (dolichol phosphate mannose).

In humans, there is only one PEA, which is added to the third mannose. PIGO is responsible for such a reaction, and its function is stabilized by PIGF. PIGN is involved in the addition of PEA to the first mannose. Once the synthesis of GPI is complete, it is transferred to the protein by a transamidase complex. This complex consists of PIGK (GPI8), a small protein that is a protease, and PIGT (GPI16), PIGS (GPI17), and GPAA1-GAA1 proteins.⁷⁰⁰ These proteins interact physically with each other, but PIGT is the most important for the stability of the complex. The protein to have the GPI attached is first processed by removing the N-terminal leader peptide. The protein bound on the luminal side by a C-terminal peptide is translocated to the transamidase complex in the presence of the BiP chaperon. The C-terminal peptide of the protein is removed, and the transamidase complex attaches the GPI through the ethanolamine head to the newly exposed C terminal (ω site). This C-atom is linked to the amino group of PEA, which is attached to the third mannose by an amide bond.

Paroxysmal Nocturnal Hemoglobinuria: Immunopathology

The biochemical defect of PNH occurs in the first step of GPI synthesis and results from mutations in the PIGA gene. Because PIGA is on the X chromosome, one mutational event is sufficient to cause the disease.^{701,694} Cell proteins that are anchored by GPI are missing from PNH hematopoietic cells, and some of the clinical manifestations are due to loss of GPI-anchored proteins. Lack of CD55 alone is not responsible for the hemolytic component of the disease, because individuals with the Inab phenotype in which CD55 is absent have only slightly increased sensitivity. CD59, which binds to C3 and prevents binding and subsequent polymerization of C9, accounts for the intravascular hemolysis and, possibly, thrombosis in PNH.⁷⁰²

In addition to hemolysis, thrombosis is an important manifestation of PNH. Thrombosis is probably caused by the release of microparticles from platelets with procoagulant activity, such as particles that are rich in factor Va, factor Xa, and the prothrombinase complex. Endothelial cells are stimulated to express tissue factor and may contribute to thrombosis. Furthermore, lack of the urokinase plasminogen activator receptor (uPAR CD87), a GPI-anchored protein, is absent. Normally, it binds urokinase on the surface of granulocytes and monocytes, converting plasminogen to plasmin-initiating fibrinolysis and its lack may promote thrombosis. An important, albeit still unanswered, question is the relationship of PNH to bone marrow aplasia or myelodysplasia and the development of acute myelogenous leukemia. Normal stem cells from patients with PNH show diminished proliferative potential in vitro compared to mutant PNH CD34⁺ stem cells.⁷⁰³ The PNH clone with a proliferative advantage expands and dominates the normal cells. It has been suggested that PNH is expressed only when normal hematopoiesis is impaired and when the PNH clone dominates hematopoiesis. This is supported by some evidence that a tiny proportion of PIGA progeny exists in normal individuals.⁷⁰⁴

FIGURE 14.34. Biosynthesis of glycosyl phosphatidyl inositol (GPI). GPI consists of three components: (a) phosphatidyl inositol (PI), (b) glycan (made of one N-glucosamine and three mannose molecules), and (c) one phosphoethanolamine

(PEA). GPI anchored is synthesized in the endoplasmic reticulum and to proteins, expressing a signal that is encoded in the C-terminal sequence. The signal sequence is cleaved to expose the GPI attachment site (ω site). The first of several steps (1) in GPI biosynthesis attaches N-acetyl glucosamine (GlcNAc) to PI, by the enzyme GlcNAc transferase. The acetyl group is removed in the second step (2) by a deacetylase. Subsequently, three mannose (M) molecules are added by different mannose transferases (3) (attachment bonds differ), and, finally, the PEA molecule is attached by a PEA transferase. The attachment of the completed GPI to the protein is mediated by a transamidase complex. The first enzyme, GlcNAc transferase, is a complex of at least five gene products (see the text for details). Phosphatidyl inositol glycan complementation class A (PIG-A) performs the catalytic function of the enzyme, and mutations in this gene result in paroxysmal nocturnal hemoglobinuria.

Deficiencies of Terminal Complement Components

Deficiencies of the terminal complement components, such as C7, have been detected in several countries, whereas C6 has been detected primarily in blacks in the United States and in South Africa, and the majority of C9 deficiencies have been found in

P.368

Japan.^{693,705,706} and ⁷⁰⁷ C6 deficiency has been defined as quantitatively zero C6 (C6Q0) or subtotal C6 (C6SD), when C6 is structurally abnormal but hemolytically active.⁷⁰⁸

Deficiencies are due to single-base deletions or mutations that lead to premature stop codons. In C6 deficiency there is a tendency for mutations in exon 6⁷⁰⁷ with defects in an area that is adjacent to a sequence that contains seven Gs and a string of six Ts.⁷⁰⁹ Carboxy terminally truncated C6, which results in a shorter dysmorphic, but functionally active, molecule, has been detected in South African families.⁷¹⁰ Complement component C6 deficiency is associated with *Neisseria* infections often being recurrent.⁷¹¹

Infections with serogroup B are the major problems in these patients; these infections limit the usefulness of the available vaccine, which is not directed against this group. Other infections have also been detected in homozygous C6 deficiency, such as SLE, Still disease, and glomerulosclerosis.⁷¹²

THE COMPLEMENT SYSTEM

The origins of the complement system, i.e., the C3 and a protein similar to B factor, can be traced to sea urchins.^{634,713,714} The scidians (sea squirts), or tunicates, occupy an intermediary position between invertebrates and vertebrates.

Two lectins that correspond to mammalian MBL, ficolins, two mannan-binding lectin serine proteases (MASP), the C3 and its receptor the B factor, have been identified in ascidians. These findings indicate that a lectinlike pathway precedes the development of the classical pathway, which seems to emerge only at the stage of cartilaginous fishes at the same time as the appearance of the adaptive immunity. Mannose-binding protein-associated serine protease-2 (MASP2), is an enzyme which in humans is encoded by the MASP2 gene involved in the complement system. MASP2 is very similar to the C-1s molecule, of the classical complement pathway, and they are thought to have a common evolutionary ancestor. When the carbohydrate-recognizing heads of MBL bind to specifically arranged mannose residues on the surface of a pathogen, MASP2 is activated to cleave complement components C4 and C2 into C4a, C4b, C2a, and C2b.

Chapter 15

Megakaryocytes

Amy E. Geddis

Megakaryocytes are large polyploid cells within the bone marrow that produce circulating platelets. Platelets are small anucleate cells that play an essential role in hemostasis, both serving to plug holes in blood vessels and initiate coagulation. To function in this role, platelets have unique properties, including the ability to adhere to injured blood vessels and to other platelets, undergo dramatic shape change, release granules containing vasoactive and thrombogenic substances, and modulate the phospholipid content of their external membrane. Platelets also release agents that promote wound healing. Based on the adult blood volume (5 L), the number of platelets per microliter of blood ($\sim 2 \times 10^5$), and their circulatory half-life (10 days), it can be calculated that each day an adult human produces 1×10^{11} platelets, although in times of increased demand, platelet production can rise tenfold or more. The process of megakaryocyte and platelet formation is complex and only partially understood. This chapter discusses the molecular mechanisms underlying the development of megakaryocytes and platelets, as well as disease states that have illuminated our understanding of megakaryopoiesis.

HISTORICAL PERSPECTIVE

Platelets were described by Addison in 1841 as “extremely minute ... granules” in clotting blood¹ and were termed platelets (blutplättchen) by Bizzozero, who also observed their adhesive qualities as “increased stickiness when a vascular wall is damaged.”² The same elements were identified by microscopic examination of blood smears by Osler and Schaefer and by Hayem in the late nineteenth century.^{3,4} Duke, a student of James Homer Wright's, associated low platelet counts, or thrombocytopenia, with clinical bleeding that could be corrected by transfusion.⁵

Megakaryocytes are rare polyploid cells within the bone marrow, representing approximately 0.05% of nucleated cells. Although Howell coined the term megakaryocyte as early as 1890, it was not until 1906 that James Homer Wright put forth the hypothesis that blood platelets are derived from the cytoplasm of megakaryocytes,^{6,7} and the basic elements of thrombopoiesis were established. Many years later in the early 1990s, c-Mpl, the cellular homolog of the v-Mpl (myeloproliferative leukemia retrovirus) oncogene, was identified and proposed to be a hematopoietic growth factor receptor.^{8,9,10} and¹¹ Shortly thereafter, thrombopoietin (TPO) was cloned based on its properties of binding to and stimulating growth of c-Mpl-bearing cells; subsequent characterization of the cytokine revealed it to be the major growth factor promoting megakaryopoiesis.^{12,13,14,15} The availability of TPO was a major step forward in megakaryocyte and platelet biology as it facilitated expansion of megakaryocytes for further study as well as dissection of the signaling pathways regulating megakaryocyte proliferation and survival.

This chapter focuses primarily on mammalian species. However, it is worth noting that in nonmammalian vertebrates, such as fish and birds, the hemostatic equivalent of platelets is served by nucleated thrombocytes,¹⁶ and polyploid megakaryocytes are not present. The purpose of megakaryocyte polyploidization in the process of platelet development is not understood but it is speculated that this allows for increased expression of the proteins that are needed for the production of large numbers of platelets.¹⁷

MEGAKARYOPOIESIS AND THE HEMATOPOIETIC STEM CELL

Megakaryocytes, like cells of all blood lineages, are derived from the hematopoietic stem cell (HSC). HSCs are also very rare cells within the bone marrow, estimated to represent approximately 0.01% of total nucleated cells. Identified in 1961 by Till and McCullough,¹⁸ key properties of HSCs include the capacity for prolonged quiescence, self-renewal, and ultimately expansion and differentiation into the total diversity of blood cell types. Although megakaryocytes are terminally differentiated cells, they share a number of characteristics with HSCs.¹⁹ For example, both megakaryocytes and HSCs express the integrins CD41 (integrin $\alpha 2b$) and CD61 (integrin $\beta 3$). The integrin $\alpha 2b\beta 3$ complex forms a fibrinogen receptor that is one of the defining markers of the megakaryocyte lineage, but is now known to be expressed much earlier in hematopoiesis, including on HSCs.^{20,21} and²² In addition, expression of integrin $\beta 3$ in association with integrin αv identifies a population of cells with enhanced long-term repopulating activity in transplantation assays.²² Several

transcription factors share key roles in both HSC and megakaryocyte development, including SCL/TAL1, RUNX1, GATA, and ETS family members (discussed below). Strikingly, even the global transcriptional profiles of HSCs and early megakaryocytic/erythroid progenitors (MEPs) are highly similar.²³

In addition to similarities in cell surface protein and gene expression patterns, both HSCs and megakaryocytes require TPO for their growth and survival. The importance of TPO and its receptor c-Mpl for the function of HSCs was suspected when knockout mice, lacking either TPO or c-Mpl, were noted to be deficient in progenitors of all hematopoietic lineages. Transplantation experiments in mice confirmed that in the absence of an intact TPO-c-Mpl axis, HSCs are unable to compete with wild-type cells, either due to reduced numbers or expansion potential, although the mice do not develop bone marrow failure.^{24,25,26,27,28} In humans, mutations that eliminate c-Mpl function are the basis of congenital amegakaryocytic thrombocytopenia (CAMT). Children with CAMT are born with isolated thrombocytopenia and a paucity of megakaryocytes, but typically progress to trilineage bone marrow failure within the first decade of life, providing evidence of an essential and nonredundant role of TPO for the HSC.²⁹

TPO has been demonstrated to contribute to both HSC quiescence and expansion in various experimental settings. In mice, the absence of TPO or c-Mpl leads to acceleration of HSC cell cycling and eventual HSC exhaustion, suggesting that TPO is required for HSC quiescence and self-renewal.³⁰ One potential mechanism

P.372

by which TPO enhances HSC quiescence is by up-regulation of cyclin-dependent kinase inhibitors.^{30,31} In addition, TPO affects the interactions between the HSC and the bone marrow niche. HSCs are maintained in a quiescent state through interactions with TPO-producing osteoblasts.³¹ Although both outside-in and inside-out signaling, TPO triggers a conformational change of integrin $\alpha\beta 3$ to its high-affinity state, and binding of $\alpha\beta 3$ to its extracellular ligand within the niche results in phosphorylation of tyrosine 747 (Y747) of the integrin $\beta 3$ tail, which cooperates with TPO signals to inhibit cell cycling and maintain HSC long-term repopulating activity.³²

TPO can also promote HSC expansion. In vitro, single cell experiments demonstrated that TPO supports the survival of HSCs, and in addition promotes their proliferation if either stem cell factor (SCF) or interleukin (IL)-3 is also present.³³ TPO also cooperates with vascular endothelial growth factor (VEGF) through an autocrine mechanism; TPO increases VEGF expression in primitive murine hematopoietic cells through induction of hypoxia-inducible factor (HIF)-1 α , and TPO in conjunction with VEGF promotes proliferation of hematopoietic progenitors.³⁴ In human embryonic stem cell models, the combination of TPO and VEGF enhances the generation of CD34⁺ cells.³⁵ In addition to HIF-1 α , TPO increases the expression and function of HOX family members. TPO-induced p38 MAPK enhances HOXB4 expression, a homeobox factor that promotes HSC expansion.^{36,37} TPO-induced MAPK also leads to phosphorylation of MEIS1 which binds to and facilitates nuclear translocation of HOXA9.³⁸ As with HOXB4, disruption of HOXA9 in animal models also leads to HSC defects.³⁹ Finally, Lnk, an adaptor protein that modulates TPO-induced STAT5, AKT, and p38 MAPK signaling, negatively regulates self-renewal of HSCs. Lnk-deficient HSCs are hypersensitive to TPO and have enhanced long-term repopulating activity due to increased self-renewal.⁴⁰ Although the mechanisms remain incompletely understood, clinical studies are examining the possible applications for TPO-receptor agonists in expanding HSCs in patients with acquired aplastic anemia with promising preliminary results.⁴¹

MEGAKARYOCYTE DEVELOPMENT

In current models of hematopoiesis, the HSC can either undergo symmetric divisions, resulting in self-renewal, or asymmetric divisions, in which the daughter cells become progressively committed to a specific hematopoietic lineage. Lineage commitment is marked by characteristic gene expression patterns and modulated by hematopoietic cytokines (Fig. 15.1). Specific multipotent and megakaryocytic progenitors can be defined using semi-solid colony assays. More recent strategies have used fluorescence-activated cell sorting approaches to identify progenitors and committed cells prospectively based on cell surface protein expression patterns^{42,43} (Table 15.1). The earliest multipotent progenitor that has been isolated is the committed myeloid progenitor, which gives rise to the colony-forming-unitgranulocyte-erythroid-macrophage-megakaryocyte (CFU-GEMM). From the CFU-GEMM arises a bipotential progenitor with both megakaryocytic and erythroid potential, the MEP.^{44,45,46} and⁴⁷ Identified within the CD34⁺CD38^{low} cell population of progenitor cells,⁴⁶ murine MEPs have been further defined as existing within the CD150⁺CD9^{lo}endoglin^{lo} fraction of Lin⁻cKit⁺IL7R α ⁻Fc γ RII/III^{lo}Sca1⁻ cells.^{48,49} Megakaryocyte-lineage-committed progenitors in contrast were included in the CD150⁺CD9^{hi}endoglin^{lo} fraction. The most primitive committed megakaryocytic cell is the megakaryocytic burst-forming unit, which resembles a small lymphocyte and forms a colony of 40 to 500 cells in semi-solid assays. The megakaryocytic colony-forming unit (CFU-MK) is a more mature progenitor that will form a colony of 3 to 50 cells in semi-solid assays.

Whereas all megakaryocytic progenitors can be recognized by staining for CD41 and, in murine cells, acetylcholinesterase, only CFU-MK express HLA-DR. Though this represents the classical model of megakaryocytic differentiation, it has been proposed that an alternative pathway exists in which the MEP can arise directly from the HSC.⁵⁰

Precursors that are committed to the megakaryocyte lineage undergo further maturation before they are capable of platelet production. As they differentiate, megakaryocytes express specific cell surface proteins, become polyploid, develop a complex cytoplasm containing granules and a system of demarcation membranes, and ultimately form proplatelet processes (Fig. 15.2). Historically, the developmental stages of megakaryocytes have been described based on morphologic criteria including the quality and quantity of the cytoplasm and the size, lobulation, and chromatin pattern of the nucleus. Thus, cells can be categorized as promegakaryoblasts and stage I megakaryoblasts, stage II promegakaryocytes, stage III mature megakaryocytes, and stage IV megakaryocytes preparing to release platelets from their cytoplasm. Stage I megakaryocytes account for approximately 25% of all megakaryocyte lineage cells in a normal marrow. They are 6 to 24 μm in diameter and contain a relatively large, minimally indented nucleus (2 to 4 N) with loosely organized chromatin and multiple nucleoli and scant basophilic cytoplasm containing a small Golgi complex, a few mitochondria and α -granules, and abundant free ribosomes. Although the cytoplasm is scant, the demarcation membrane system (DMS) that is characteristic of more mature cells has already begun to form. This early, proliferative megakaryocytic cell is also sometimes termed a megakaryoblast and, in rodent hematopoiesis, is characterized by intense staining for acetylcholinesterase. Stage II megakaryocytes also represent approximately 25% of marrow megakaryocytes. They measure 14 to 30 μm in diameter, with a lobulated nucleus of 8 to 64 N and more abundant polychromatic cytoplasm. Ultrastructurally, the cytoplasm contains more abundant α -granules and organelles, and the DMS begins to expand at this stage of development. The remaining 50% of morphologically recognizable megakaryocytes in the marrow are stage III/IV megakaryocytes. These cells are very large (40 to 60 μm in diameter) with abundant mature cytoplasm. The DMS is prominent, and the multilobulated nucleus becomes more compact and is often eccentrically placed. Stage IV megakaryocytes may display proplatelet processes. It has been calculated that it takes approximately 72 hours for stage III and stage IV cells to develop from stage I megakaryocytes.

Starting in early megakaryocytes, expression of characteristic cell surface proteins, including integrin $\alpha 2\text{b}\beta 3$ and GPIb/IX, becomes functionally important. Integrin $\alpha 2\text{b}\beta 3$ is an integral transmembrane protein that acts as a receptor for fibrinogen. Of the two subunits, only integrin $\alpha 2\text{b}$ is megakaryocyte lineage specific. Loss of integrin $\alpha 2\text{b}\beta 3$ leads to Glanzmann thrombasthenia due to failure of the defective platelets to engage fibrinogen during aggregation. The two subunits of integrin $\alpha 2\text{b}\beta 3$ are synthesized in the endoplasmic reticulum and form a Ca^{2+} -dependent complex immediately on translation, a step necessary for membrane expression. Subsequently, the α -subunit is cleaved into heavy and light chains and modified with carbohydrate before transfer to the cell surface, demarcation, and α -granule membranes.^{51,52} Megakaryocytes and platelets contain approximately twice the amount of integrin $\alpha 2\text{b}\beta 3$ in granules as is present on the cell surface, the granule compartment serving as a mobilizable pool that is exteriorized on platelet activation.

The GPIb/IX complex is developmentally expressed only slightly later than integrin $\alpha 2\text{b}\beta 3$ and forms a receptor for von Willebrand factor (vWF).²¹ Although known for its role in binding vWF, GPIb α also is an important structural component in platelets through its interaction with the cytoskeletal protein filamin A. Filamin A, in turn, promotes clustering and activation of GPIb, thus regulating its function in platelet aggregation.^{53,54} Absence of

P.373

the GPIb/IX complex results in Bernard-Soulier syndrome (BSS), an autosomal recessive macrothrombocytopenia with severe platelet dysfunction; mutations of filamin A are also associated with macrothrombocytopenia but GPIb surface expression is normal.⁵⁵ Except for minor expression in endothelial cells,⁵⁶ GPIb is a megakaryocyte-specific protein. GPV is also expressed in complex with GPIb and GPIX in a 2:2:1 (Ib:IX:V) stoichiometric ratio^{57,58}; however, GPV is not required for the function of the GPIb/V/IX complex in binding vWF. Genetic elimination of GPV has little effect on platelet adhesion⁵⁹ and no mutations of GPV have been associated with BSS.⁶⁰ Rather, GPV appears to function as a target of thrombin, possibly playing a role in platelet activation.^{61,62}

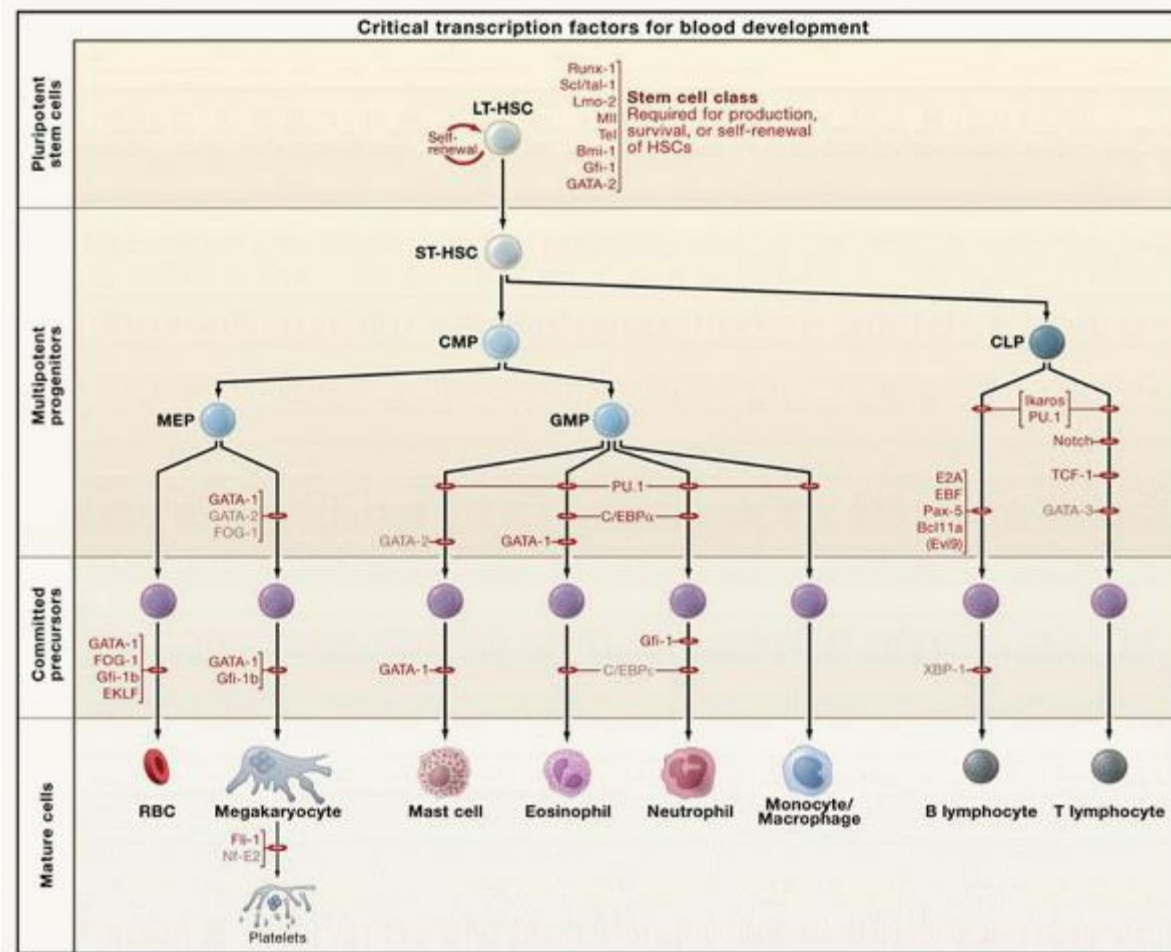

FIGURE 15.1. Hematopoietic cell development. Transcription factors regulate the differentiation of the HSC to produce committed progenitors and mature blood cells. The MEP is a bipotential precursor that gives rise to both erythroid and megakaryocytic lineages. Whereas GATA1 and FOG1 are required for both erythropoiesis and megakaryopoiesis, EKLF favors red cell development and FLI1 promotes megakaryopoiesis. With permission from Orkin SH, Zon LI. Hematopoiesis: an evolving paradigm for stem cell biology. Cell 2008;132:631-644.

FIGURE 15.2. Mature megakaryocytes (A) Bone marrow megakaryocyte visualized by Wright's stain. Note the multilobated nucleus. (B) Electron micrograph of a mature megakaryocyte, showing cytoplasmic alpha granules (A), mitochondria (m),

and demarcation membranes (dm). There appear to be separate nuclei with nucleoli (n), but these represent two lobes of a single nucleus visible in this section.

One of the most characteristic and intriguing features of megakaryocyte maturation is the development of polyploidy. As they mature, megakaryocytes switch from mitotic cell cycling to endomitosis, or DNA replication in the absence of nuclear or cytoplasmic division (Fig. 15.3). Endomitosis begins late in stage I megakaryoblasts, after sufficient diploid cell divisions have occurred to expand the number of megakaryocytic precursor cells, and is completed by the end of stage II megakaryocyte development.^{63,64} This carefully controlled process (i.e., cells are polyploid, rather than aneuploid) results in cells containing DNA content from 8 to 128 times the normal chromosomal complement in a single, highly lobated nucleus. Endomitosis is not simply the absence of mitosis, but rather an aborted mitosis.⁶⁵ The cell-cycle kinetics of endomitotic cells is also unusual, characterized by a short G₁ phase, a normal or modestly prolonged DNA synthesis phase, a short G₂ phase, and a very short endomitosis phase.⁶⁶ During the latter, megakaryocytic chromosomes condense, the nuclear membrane breaks down, and centromeres form mitotic spindles on which the replicated chromosomes assemble. However, after initiation of anaphase with chromosomal separation and cleavage furrow formation, the furrow regresses, the spindle dissociates, and the megakaryocyte re-enters the G₁ phase as a polyploid cell.^{65,67} Attempts at biochemical analysis of this process have come from leukemic cell lines and normal cultured megakaryocytes. Hypotheses for the mechanisms triggering polyploidy in megakaryocytes have included deficiencies of cyclin B, altered cytoskeletal dynamics, a defect of the chromosomal passenger proteins, and malfunction of the contractile ring. Early interest focused on the M-phase cyclin-dependent kinase cyclin B-cdc2. Also termed mitosis-promoting factor, the amount of cyclin B and the activity of the cyclin B-cdk1 complex rise through the cell cycle until mitosis, where they fall abruptly due to proteosomal degradation of cyclin B. As the major departure from normal cell-cycle behavior in megakaryocytes occurs during the M phase, it was proposed that endomitosis might result from impaired activation of cyclin B-cdc2 kinase, as suggested in several cell line models.^{68,69} and ⁷⁰ However, results from normal murine and human megakaryocytes argue for normal mitotic kinase activity during endomitosis. Using TPO to expand primary megakaryocytes *in vitro*, two groups have demonstrated the presence of functional cyclin B and cdc2 in endomitotic megakaryocytes^{65,71} as well as a normal metaphase checkpoint mechanism.⁷² Although the combined deletion of cyclin D1, D2, and D3 in mouse models did not specifically affect megakaryocytes,⁷³ deletion of cyclin E did impair megakaryopoiesis as well as trophoblast development,⁷⁴ suggesting that cyclin E plays a role in endomitosis.

Endomitosis in Megakaryocytes

Diploid cell

Polyploid cell

FIGURE 15.3. Endomitosis in megakaryocytes. (A) Mitosis in a megakaryocytic precursor: chromatids (blue) are arranged in a single metaphase plate, microtubules (red) form a bipolar spindle. (B) Endomitosis: chromatids are arranged in two

metaphase plates and the spindle is multipolar.

Alterations in regulation of the microtubule cytoskeleton have also been proposed as fundamental in triggering endomitosis. Stathmin is a microtubule-depolymerizing protein that is important for the regulation of the mitotic spindle. As cells enter mitosis, the microtubule-depolymerizing activity of stathmin decreases, allowing microtubules to polymerize and assemble into a mitotic spindle. Reactivation of stathmin in the later stages of mitosis is necessary for the disassembly of the mitotic spindle and the exit from mitosis. Interfering with stathmin expression disrupts the normal mitotic spindle and leads to aberrant mitotic exit.⁷⁵ Thus it has been hypothesized that alterations in stathmin expression underlie endomitosis in megakaryocytes. In support of this view, expression of stathmin is decreased in higher ploidy megakaryocytes,⁷⁶ and studies in the erythroleukemia cell line K562 show that inhibition of stathmin expression enhances polyploidy, whereas overexpression of stathmin inhibits the transition from a mitotic cycle to an endomitotic cycle and reduces formation of multipolar mitotic spindles.^{76,77} Whether down-regulation of stathmin leads to polyploidization in megakaryocytes or is a result of it is not known. Proper activation and localization of

P.375

the chromosomal passenger proteins have also been examined as a potential point of departure from the mitotic cell cycle in megakaryocytes. These proteins, including INCENP, survivin, and Aurora Kinase B, form a complex that localizes to the centrosome prior to anaphase and then shifts to the microtubules of the midbody and cleavage furrow.⁷⁸ Elimination of individual members of the passenger protein complex in organisms as diverse as *Drosophila* and mammals leads to the abrogation of proper cell division and the formation of a cellular syncytium containing a large nuclear mass.^{79,80} and⁸¹ Work in cell lines initially suggested that megakaryocytes might be deficient in survivin or Aurora kinase B.^{82,83} However, subsequent examination of primary megakaryocytes revealed that Aurora kinase B as well as associated passenger proteins are active and appropriately localized in both diploid and polyploid megakaryocytes.⁸⁴ Further observation of endomitosis by live cell microscopy demonstrated that endomitotic megakaryocytes assemble cleavage furrows that begin to contract and then regress; this fact suggests that the "defect" in endomitosis is beyond anaphase and involves the function of the contractile ring in cytokinesis.^{85,86} Confocal microscopy confirmed poor localization of RhoA and the actin/myosin complex to the cleavage furrow in endomitotic megakaryocytes. In support of the role of RhoA in endomitosis, expression of Ect2 and GEF-H1, guanine exchange factors that activate RhoA during cytokinesis, is decreased in polyploidizing cells, and forced overexpression of Ect2 and GEF-H1 blocks endomitosis.⁸⁷ Recent work indicates that nonmuscle myosin IIB heavy chain, whose expression is controlled by Runx1, is also down-regulated during megakaryocyte maturation, and that loss of myosin IIB expression inhibits the return of 4 N cells to the diploid state.⁸⁸ It is likely that there are multiple alterations in the cell cycle of megakaryocytes that are involved in the process of endomitosis.

Another important aspect of megakaryocyte maturation is the development of the DMS. Initially described more than 30 years ago,⁸⁹ what begins as invaginations of the plasma membrane ultimately becomes a highly branched interconnected system of channels that course through the cytoplasm. The use of electron-dense tracers indicated that the DMS is in open communication with the extracellular space,^{52,89,90} in comparison with the rough endoplasmic reticulum which is contiguous with the nuclear membrane. Over the 72 hours it takes for stage III and stage IV cells to develop from stage I megakaryocytes, the DMS grows by approximately 25-fold. The mature DMS contains phosphatidyl inositol-4,5-P₂ (PI-4,5-P₂), a phospholipid that is usually associated with the plasma membrane, and PI-4,5-P₂ promotes actin polymerization by activating Rho-like guanosine triphosphatases (GTPases) and Wiskott-Aldrich syndrome (WASp) family proteins.⁹¹ The purpose of the DMS has been disputed for nearly 20 years⁹²; initially, it was thought to compartmentalize the cytoplasm of the mature megakaryocyte into platelet territories, which ultimately fragment into mature platelets along the cleavage planes so formed, but recent evidence suggests that the DMS provides the necessary membrane required for the formation of proplatelet processes and may promote actin polymerization.⁹¹

Two specific types of granules are characteristic of mature megakaryocytes and platelets. The more abundant α -granules first begin to form adjacent to the Golgi apparatus as 300- to 500-nm round or oval organelles in stage I and II cells. α -Granules contain multiple proteins with functions in coagulation and angiogenesis. Three distinct compartments are recognized in α -granules: (a) a central electron-dense nucleoid containing fibrinogen, platelet factor 4 (PF4), β -thromboglobulin, transforming growth factor (TGF)- β 1, vitronectin, multimerin, and tissue-type plasminogen activator; (b) a relatively lucent peripheral zone containing tubules and vWF (an arrangement akin to Weibel-Palade bodies found in endothelial cells); and (c) the granule membrane containing many of the critical platelet receptors for cell rolling (P-selectin, also termed CD62p), firm adhesion (gpIb/V/IX), and aggregation ($\alpha_{IIb}\beta_3$ integrin). In platelets, proteins present in α -granules arise from de novo megakaryocyte synthesis (e.g., gpIb/V/IX, gpIV, $\alpha_{IIb}\beta_3$ integrin, vWF, P-selectin, β -

thromboglobulin, and platelet-derived growth factor), nonspecific pinocytosis of environmental proteins (e.g., albumin and IgG), or cell surface membrane receptor-mediated uptake from the environment (e.g., fibrinogen, fibronectin, and factor V).^{93,94} Dense granules are less numerous and contain the vasoconstrictive 5-hydroxytryptamine, the nonmetabolic pool of adenosine triphosphate and adenosine diphosphate (ADP), calcium, and magnesium, and they have a fundamental role in hemostasis. Although α -granules contain multiple proteins with opposing functions, proteins with specific functions may be released selectively in response to certain agonists. For example, ADP and PAR1 stimulate the release of angiogenic factors such as VEGF, whereas thromboxane A2 and PAR4 stimulate the release of antiangiogenic factors such as endostatin.^{95,96} Therefore, current models propose differential secretion of granule contents in response to different agonists, although the mechanisms by which this selectivity is achieved are still unclear.

Throughout megakaryocyte development, the cytoplasm acquires a rich network of microfilaments and microtubules. Toward stages III and IV, these proteins accumulate in the cell periphery, creating an organelle-poor peripheral zone. Biochemically, the megakaryocyte cytoskeleton is composed of actin, α -actinin, filamin, nonmuscle myosin, β 1 tubulin, talin, and spectrin. Spectrin plays an important role in stabilizing the DMS and proplatelet processes.⁹⁷ β 1 tubulin is expressed exclusively in megakaryocytes and platelets and is critical for proplatelet formation; over 90% of microtubules in the mature megakaryocyte are composed of the β 1 isoform.^{98,99} At the onset of proplatelet formation, blunt pseudopodia are formed, and β 1-tubulin-containing microtubules assemble into thick bundles below the plasma membrane¹⁰⁰ (Fig. 15.4). The pseudopodia elongate, bend, and branch to form proplatelets, and the microtubules form bidirectional linear arrays with terminal loops composed of 8 to 12 microtubule coils at the proplatelet tips.¹⁰¹ Dynein powers microtubule sliding and proplatelet elongation, whereas actin and myosin are involved in proplatelet bending and branching.^{100,102} Granules and organelles such as mitochondria traffic on these microtubule "tracks" to accumulate within the tips that will ultimately be released to become circulating platelets.¹⁰³ The coiled microtubules at the proplatelet tip become the marginal band that maintains the discoid shape of the platelet.^{100,104} RanBP10 binds to microtubules and functions as a GEF for Ran, stabilizing microtubules and facilitating granule transport.^{105,106} Remodeling of the megakaryocyte cytoskeleton is essential for proplatelet formation, and mutations affecting cytoskeletal proteins, including regulators of actin (WASp), filamin A, β 1-tubulin, and nonmuscle myosin heavy chain IIA form the basis of several of the inherited thrombocytopenia syndromes.^{55,107,108,109}

Platelets are derived from the megakaryocyte cytoplasm. It has been estimated that each megakaryocyte gives rise to 1,000 to 5,000 platelets^{110,111} and¹¹² before the residual nuclear material is engulfed and eliminated by marrow macrophages.¹¹³ Stage IV megakaryocytes are wholly engaged in platelet formation. Careful microscopic studies have localized marrow megakaryocytes to the abluminal surface of sinusoidal endothelial cells. Fully mature megakaryocytes develop cytoplasmic processes constricted at platelet-sized intervals that extend through the endothelial barrier into the sinusoidal lumen, where platelets are released.¹¹⁴ It is likely that both integrin-mediated cell-cell interactions and extracellular matrix degradation are required for this process.^{115,116} and¹¹⁷ It is also possible that the final stages of megakaryocyte fragmentation occur in the lung, at least for some megakaryocytes. Howell and Donahue reported in 1939 that platelet levels in pulmonary venous blood exceed those found in the pulmonary artery, suggesting platelet production in the lung.¹¹⁸ Whether this represents the migration and fragmentation of intact megakaryocytes in

P.376

the lung or merely the final size reduction of large fragments of megakaryocyte cytoplasm that are also released into the blood¹¹⁹ is not clear. Lung megakaryocytes have been characterized by Slater et al., who believe they contribute substantially to blood platelet production.¹²⁰ However, in preclinical studies of TPO, Kaushansky et al. did not detect any denuded megakaryocyte nuclei in the lungs of mice which at the time of sacrifice had platelet counts as high as 4 million/mm³.¹²¹ One study found that dog lungs contain 2.5 megakaryocytes/cm² tavassoli¹²²; extrapolation of these data would suggest that human lungs contain approximately 6,000 megakaryocytes, only enough to account for a small proportion (<0.1%) of daily platelet production. Moreover, cultured megakaryocytes can form functional platelets in vitro by generating proplatelets in the absence of endothelial surfaces or the pulmonary circulation,¹⁰⁰ and the release of proplatelet fragments into bone marrow sinusoids has been visualized in living mice.¹²³ Thus, the role of pulmonary bed platelet production remains controversial.

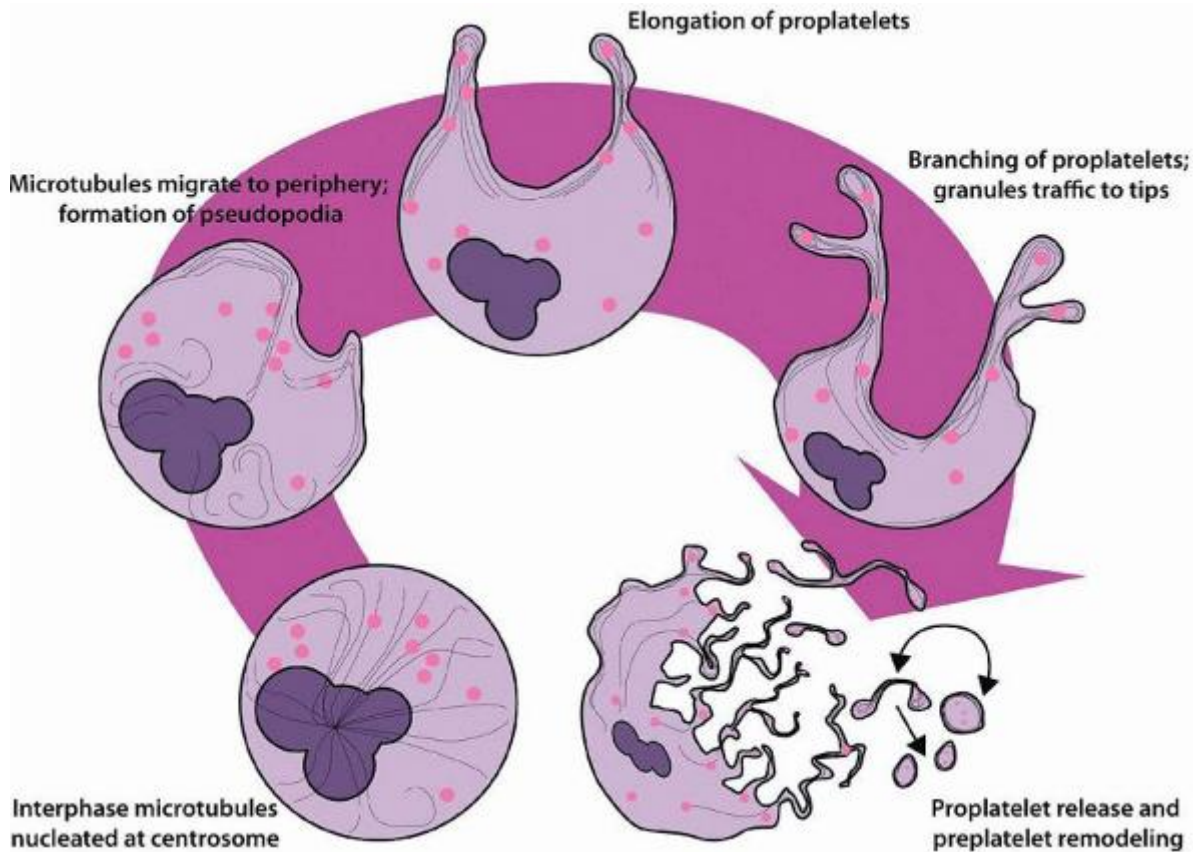

FIGURE 15.4. Proplatelet formation in mature megakaryocytes. Noncentrosomal microtubules migrate to the cell periphery where they form bundles. Pseudopodia form and elongate into proplatelet processes, and the microtubules form bidirectional tracks within the processes that terminate in coiled ends. Granules and other organelles traffic along the microtubules and accumulate in the tips. Proplatelet processes are released and continue to remodel in the circulation, alternating between barbell-shaped proplatelets and large preplatelets, before the proplatelets finally divide into individual platelets.

Notably, the proplatelets and platelets released in experimental models are larger than typical circulating platelets. In addition, it has long been recognized that patients with disorders of increased platelet production, such as immune thrombocytopenia, have relatively large circulating platelets. Thus, it has been proposed that once released into the circulation, these larger platelet precursors undergo further remodeling.^{124,125,126} Using an *in vitro* model, Thon et al. demonstrated that platelet precursors shift back and forth between two morphologic states, discoid preplatelets and barbell-like proplatelets.¹²⁶ Spectrin stabilizes the bridge between the ends of the barbell form.⁹⁷ Furthermore, these precursor platelets can be observed to divide or undergo fission. Shear forces in the circulation likely contribute to the cleavage of barbell-shaped proplatelets into individual platelets, although it has been postulated that mechanisms similar to those driving cell separation in cytokinesis may also be involved.

Programmed cell death represents not only the end of the megakaryocyte life cycle and proteins that regulate the intrinsic apoptosis pathway influence megakaryocyte survival. Apoptosis has also been proposed to play a role in megakaryocyte functions such as proplatelet formation. Early studies found that focal activation of caspases accompanies megakaryocyte maturation and overexpression of Bcl2 inhibits proplatelet formation, suggesting that localized apoptosis is required for platelet shedding.¹²⁷ However, a recent study found that targeted deletion of caspase 9, the initiator caspase in the intrinsic apoptotic pathway, has no effect on proplatelet formation.¹²⁸ Additional data support the alternative hypothesis that inhibition of apoptosis in mature megakaryocytes is necessary for proplatelet formation. In mouse models, targeted loss of Bcl-xL in megakaryocytes leads to caspase activation and failure of proplatelet formation and release of morphologically abnormal, large platelets.¹²⁹ Whereas isolated loss of Bcl-xL primarily affects mature megakaryocytes at the point of proplatelet formation, combined deletion of Bcl-xL

and Mcl-1 has even more profound effects, with severe impairment of megakaryopoiesis in embryos lacking both apoptotic regulators.¹³⁰ In addition, Bcl-xL inhibits apoptosis in circulating platelets. Mutation or pharmacologic inhibition of Bcl-xL leads to reduced platelet life span in mice.^{129,131} Apoptosis of aged platelets is mediated by Bak and Bax, whose activity is normally controlled by Bcl-xL; genetic deletion of Bak and Bax prolongs platelet survival and renders platelets resistant to the effects of Bcl-xL inhibition.¹²⁹ Mutations of Bcl-xL or Mcl-1 have not been described in humans; however, a proapoptotic mutation of cytochrome c has been identified in a family with autosomal dominant thrombocytopenia.¹³²

TRANSCRIPTIONAL REGULATION OF MEGAKARYOPOIESIS

Several themes are emerging in models of transcriptional regulation of hematopoietic differentiation that are relevant to the discussion of megakaryopoiesis. Lineage priming refers to the concept that the HSC is competent to express multiple genetic programs and lineage choice is the consequence of progressive silencing of alternative possibilities.^{133,134} Similarly, anticipatory regulation refers to the concept that differentiation-associated transcription factors are already bound at target promoters in HSCs, allowing for low-level expression that increases with differentiation.²³ Thus, as previously discussed, several transcription factors associated with megakaryocytes, as well as other lineages, are also expressed at low levels in HSCs, as well as in bipotential megakaryocytic/erythroid cells. As cells start to differentiate, lineage-specific transcription factors promote their own expression while suppressing factors that would favor other cell types, thus reinforcing lineage choice. For example, GATA1 activates its own promoter to increase its expression, and simultaneously inhibits PU.1, favoring megakaryocytic/erythroid differentiation, whereas in other cells, PU.1 might dominate, repressing the megakaryocytic/erythroid program and favoring myelopoiesis.^{135,136,137} Transcription factors do not act in isolation, however, but are typically present as components of cross-regulatory multiprotein complexes; their function may vary depending on the other factors that are present.

Recent studies have identified five core transcription factors, SCL/TAL1, GATA1, GATA2, RUNX1, and FLI1, as the promoters of hematopoietic genes in primary megakaryocytes. Genes next to regions bound by all five factors were highly enriched for known regulators of megakaryocytic differentiation or function.¹³⁸ Additional factors of importance in megakaryopoiesis include NF-E2, FOG1, HOX family proteins, GFI-1b, and c-Myb. Mutant forms of several of these factors or their downstream targets have been found in inherited thrombocytopenia syndromes or leukemias. In addition, there is emerging recognition of the role of noncoding RNAs in megakaryocytic differentiation.

SCL/TAL1: Stem cell leukemia/T-cell acute lymphoblastic leukemia gene 1, or SCL/TAL1, is a basic helix-loop-helix transcription factor that is essential for early hematopoietic specification as well as definitive differentiation of the erythroid and megakaryocyte lineages.¹³⁹ Loss of Scl/Tal1 expression in adult mice leads to defects in megakaryocyte cytoplasmic maturation and thrombocytopenia.^{140,141} In addition, progenitor cells from Scl/Tal1-deficient mice are unable to generate megakaryocytes in vitro.^{142,143} Among the transcriptional targets of SCL/TAL1 important for megakaryopoiesis are NF-E2 and MEF2C. Scl/Tal1 directly binds regulatory elements of Mef2C in megakaryocytic cells, and the platelet phenotype of Mef2C- knockout mice is similar to that of Scl/Tal1-deficient animals.¹⁴⁴ In human CD34⁺ hematopoietic progenitor cells, expression of MEF2C increases with megakaryocytic differentiation.¹⁴⁵ SCL/TAL1 has multiple partners, including E2A and LMO2. E2A binds canonical DNA elements called E-boxes represented by the motif CANNTG. E-boxes are frequently found along with GATA-binding motifs within the regulatory elements of erythroid and megakaryocytic cells.^{146,147} LMO2 is a LIM domain containing protein that forms a multiprotein complex with GATA1, SCL/TAL1, E2A, and another LIM domain protein LDB1^{146,148,149} and ¹⁵⁰; the complex is critical for early hematopoietic specification.^{139,148,151} LDB1 can self-associate to form oligomers and may bind multiple GATA1 molecules simultaneously, thus facilitating long-range interactions between GATA-bound sites.^{152,153} and ¹⁵⁴

GATA1: GATA1 is a zinc finger transcription factor critical in both erythroid and megakaryocytic development, with target genes including HBB (encoding β -globin), ALAS1, BCL2L1, NFE2, GP1BB, and GP9. Gata1 deficiency in mouse models leads to arrest of erythroid maturation at the proerythroblast stage and severe anemia,¹⁵⁵ as well as defects in megakaryocyte maturation with hyperproliferation of low ploidy cells, impaired endomitosis and formation of the DMS, and release of large hypogranulated platelets.^{156,157} GATA-binding motifs (T/A)GATA(A/G) are found in the regulatory elements of nearly all erythroid and megakaryocytic genes.^{158,159} Furthermore, the co-occurrence of ETS and GATA motifs was significantly associated with expression of the megakaryocytic program over the erythroid program.¹⁶⁰ GATA1 can function either as a transcriptional activator or repressor, depending on its binding partners. GATA1 contains two zinc fingers; the C-terminal zinc finger is responsible for high-affinity DNA binding, whereas the N-terminal finger stabilizes the interaction and binds to the co-factor FOG1.¹⁶¹ In addition to FOG1,¹⁶² GATA1 has interactions with other megakaryocytic core factors, including RUNX1 and FLI1.^{163,164,165} FOG1 contains 9 zinc fingers, 4 of which mediate interactions with GATA1.¹⁶⁶ In mouse models, deletion of Fog1 results in a more severe defect in megakaryopoiesis than does deletion of Gata1,^{167,168} supporting the

conclusion that although GATA1 is required for erythroid lineage commitment, FOG1 is required for specification of both erythroid and megakaryocytic progenitors.¹⁶⁸ The interaction of GATA1 with FOG1 and PU.1 is mutually exclusive,¹⁶⁹ thus GATA1 bound by FOG1 may be protected from repression by PU.1, favoring megakaryocytic/erythroid differentiation. Posttranslational modification of GATA1 by SUMOylation of amino acid K137 also disrupts FOG1 binding.¹⁷⁰ FOG1 can promote the function of GATA1 either as an activator or repressor of transcription. FOG1 contains an N-terminal nucleosome remodeling and histone deacetylase complex (NuRD) recruitment domain,¹⁷¹ and can thus bind transcriptional repressors such as HDAC1 and HDAC2. Knockin mice expressing FOG1 mutated within its NuRD domain exhibited thrombocytopenia and anemia, suggesting that FOG1 function in megakaryopoiesis is mediated at least in part through recruitment of NuRD.¹⁷² Although association with NuRD was linked with both gene activation and repression, NuRD binding by FOG1 was shown to repress the mast cell program in megakaryocytic/erythroid cells.¹⁷³ In humans, X-linked inheritance of mutations of GATA1 involving the N-zinc finger, abrogating interaction with FOG1, leads to macrothrombocytopenia and dyserythropoiesis^{174,175,176,177} and ¹⁷⁸ (Fig. 15.5). In Down syndrome, acquired mutations within exon 2 of GATA1 result in alteration of the translational start site and production of a shortened species, GATA1S. GATA1S binds DNA and interacts with FOG1, but lacks the N-terminal activation domain and has a reduced transactivation potential.¹⁷⁹ GATA1S is nearly always present in children with Down syndrome who develop transient abnormal myelopoiesis and megakaryoblastic leukemia and is thought to be an early event in the initiation of leukemogenesis.^{180,181}

GATA2: Closely related to GATA1, GATA2 is an essential transcription factor for HSCs, MEPs, and megakaryocytes, but becomes down-regulated in mature erythroid cells.^{182,183,184} and ¹⁸⁵ GATA2 expression is down-regulated to a lesser extent during

P.378

megakaryopoiesis,^{186,187} and overexpression of GATA2 favors megakaryopoiesis in cell lines.¹⁸⁸ In maturing cells, expression of GATA2 is repressed by GATA1, reinforcing the differentiation program.¹⁸⁹ Thus, in experimental models, deletion of GATA1 is accompanied by overexpression of GATA2.¹⁹⁰ GATA1 and GATA2 have homologous zinc fingers, interact with FOG1, and bind overlapping sets of genes.^{191,192} However, in general, GATA1 and GATA2 have opposite effects at target genes, either activating or repressing transcription. The exchange of GATA2 for GATA1 at regulatory elements during differentiation is referred to as the GATA switch.¹⁹³ Using an in vitro model of megakaryocyte maturation, Dore et al. recently found that as many as 30% of sites occupied by GATA2 are occupied instead by GATA1 in differentiated cells.¹⁶⁰ In contrast to GATA1 which is on the X-chromosome, GATA2 is on chromosome 3 and GATA2 mutations have not been described in human disease.

FIGURE 15.5. GATA1 mutations associated with human disease. Wild-type GATA1 contains an activation domain (AD) and

two zinc fingers (NF and CF) that mediate DNA binding. FOG1 interacts with the amino-terminal zinc finger (NF). Mutations in the N-finger have been discovered in males with macrothrombocytopenia and impaired erythropoiesis, either due to disruption of FOG1 binding or, in the case of R216Q, impaired DNA binding. In Down syndrome, mutations that lead to loss of the AD (GATA1S) promote the development of transient myeloproliferative disorder and megakaryoblastic leukemia.

RUNX1: RUNX1 is a heterodimeric transcription factor of the Runt-domain family, consisting of core-binding factor α -2 (CBFA2) that binds DNA and CBF- β , which does not directly bind DNA.¹⁹⁴ Although RUNX1 is critical for emergence of the HSC during embryogenesis, in the adult it is dispensable for maintenance of stem cells but required for megakaryopoiesis.¹⁹⁵ In cell line and animal models, overexpression of RUNX1 induces megakaryocytic differentiation, whereas RUNX1 deficiency results in proliferation of immature megakaryocytes and thrombocytopenia.^{163,195,196} Mutations leading to haploinsufficiency of RUNX1 cause familial thrombocytopenia with defective megakaryocyte maturation and a striking predisposition to myeloid leukemias.¹⁹⁷ Targets of RUNX1 in megakaryopoiesis include c-Mpl.¹⁹⁸ RUNX family members frequently cooperate with co-factors such as CCAAT box/enhancer-binding protein (C/EBP) α , ETS family members, p300/CBP, and c-Myb.^{199,200} In vitro models have demonstrated cooperation of RUNX1 with GATA1 and ETS family members in the activation of megakaryocytic target genes.^{163,165,201,202} RUNX1 and GATA1 also modulate the activity of the cyclin-dependent kinase positive transcription elongation factor (P-TEFb), thus affecting transcriptional elongation²⁰³; induction of megakaryocytic differentiation correlates with P-TEFb activity.²⁰⁴

NF-E2: NF-E2 is a heterodimeric transcription factor containing a p45 leucine-zipper subunit and a p18 subunit MafG. NF-E2 binds DNA through Maf-recognition elements, but p45 is required for transcriptional activation.²⁰⁵ NF-E2 is essential for the final differentiation of megakaryocytes and for platelet formation, as p45^{-/-} mice are severely thrombocytopenic ($\leq 5\%$ the normal platelet count) despite increased numbers of megakaryocytes.^{206,207} Several target genes of NF-E2 have been identified, including TUBB1 (encoding β 1-tubulin), CASP12 (caspase 12), TBXAS1 (thromboxane A synthase-1), RAB27B, and 3β -HSD 3β -hydroxysteroid dehydrogenase, a mediator of autocrine biosynthesis of estradiol within megakaryocytes.^{99,208,209,210} and²¹¹ Intriguingly, ectopic expression of 3β -HSD in NF-E2-deficient megakaryocytes rescues proplatelet formation.²¹² Platelets in NF-E2^{-/-} mice are spherocytic, due to loss of the integrity of the marginal band, normally comprised of β 1-tubulin.²⁰⁸ NF-E2 is itself a target of GATA1 and SCL/TAL1.¹⁴¹

Homeobox Genes: The homeobox genes, which include HOX and non-HOX genes, play key roles in body pattern development, and they are also expressed in adult HSC and play pivotal roles in their proliferation. In hematopoietic progenitors, TPO promotes expression of HOXB4 as well as nuclear localization of HOXA9 through up-regulation of its co-factor MEIS1.^{37,38} In addition to HOXA9, MEIS1 can interact with PBX1b and PBX2, and the

P.379

complex of MEIS1 and PBX up-regulates megakaryocytic gene expression in cooperation with GATA1 and ETS.²¹³ Meis1^{-/-} mice have a severe abnormality of megakaryopoiesis and lack CD41⁺ cells in the fetal liver.^{214,215} Although its function in megakaryocytes is not understood, mutations of HOXA11 are associated with the congenital thrombocytopenia syndrome amegakaryocytic thrombocytopenia with radioulnar synostosis (ATRUS).²¹⁶

FLI1, KLF1, and c-Myb: Several changes in gene expression accompany the divergence of bipotential MEPs to committed megakaryocytic or erythroid cells. The ETS family member FLI1, in conjunction with SCL and GATA2, controls HSC specification²¹⁷; however, it is also critical for formation of the vasculature and for megakaryopoiesis.^{218,219,220} and²²¹ FLI1 cooperates with GATA1^{222,223} and regulates many genes important for terminal megakaryocytic maturation.^{222,224} Expression of FLI1 influences cell fate decisions in the MEP; increased expression of FLI1 favors megakaryocyte development, whereas FLI1 expression decreases in erythroid cells. In mouse models, loss of Fli1 suppresses megakaryopoiesis, whereas overexpression of Fli1 promotes megakaryocyte development while suppressing erythropoiesis.^{218,225,226} Conversely, KLF1 (or EKLF), a target of GATA1, is up-regulated in erythroid-committed progenitors, but inhibits megakaryopoiesis.^{227,228,229} FLI1 and KLF1 inhibit each other's activity directly through protein-protein interaction,²²⁹ and this cross-antagonism has been suggested to reinforce lineage choice between megakaryocytes and erythroid cells.¹⁶⁸ Indeed, selective disruption of Klf1 in mouse models leads to anemia with thrombocytosis,²³⁰ whereas targeted deletion of Fli1 enhances erythropoiesis.²³¹ Other transcription factors have been identified that act in the MEP, including GFI-1b and c-Myb. Growth factor independence-1B (GFI-1b) is a transcriptional repressor that is essential for both erythropoiesis and megakaryopoiesis.^{232,233} GFI-1b is expressed in the bipotent MEP and inhibits the expression of the TGF- β receptor III (TGFBR3) gene. This disrupts TGF- β /smad2 signaling which otherwise restrains proliferation and differentiation of erythro-megakaryocytic progenitors.²³⁴ The c-Myb gene encodes for a basic helix turn helix transcription factor composed of three functional domains: a DNA binding domain at the N terminus, a central transactivation domain,

and a C-terminal negative regulatory domain. c-Myb has critical roles both during early hematopoiesis and in differentiating cells.^{235,236} Down-regulation of c-Myb accompanies megakaryocytic differentiation, and hypomorphic c-Myb expression increases megakaryopoiesis at the expense of erythropoiesis.^{236,237} Silencing of c-Myb in human CD34⁺ progenitor cells in vitro is associated with loss of KLF1 and LMO2 (<http://bloodjournal.hematologylibrary.org/content/116/22/e99.full>, ref 22) expression and results in commitment toward the monomacrophage and megakaryocyte lineages whereas erythroid differentiation is strongly impaired.²³⁸

Recently, the role of noncoding RNAs has been recognized in hematopoiesis and megakaryocyte differentiation.^{239,240,241} MicroRNAs (miRNAs) are a class of approximately 22-nucleotide noncoding RNAs that have been highly conserved during evolution and modulate protein expression by degrading mRNA or repressing translation. There are over 400 human miRNAs, and several of them have been implicated in megakaryopoiesis using profiling, knockdown, or overexpression assays. In megakaryocytes, miR-155 expression is reduced as cells differentiate toward megakaryocytes, and overexpression of miR-155 inhibits megakaryopoiesis in in vitro and mouse models, potentially by targeting Meis1 and Ets1 transcripts.^{242,243} and ²⁴⁴ In contrast, miR-150 levels increase during megakaryocyte differentiation, but not in erythroid cells.²³⁹ miR-150 targets c-Myb expression. Down-regulation of c-Myb promotes megakaryocytic differentiation at the expense of erythroid cells.²³⁶ TPO induces expression of miR-150, providing another mechanism by which it influences megakaryopoiesis.²⁴⁵ Additional regulatory miRNAs with potential roles in megakaryopoiesis include miR-34a which when overexpressed in CD34⁺ cells increases megakaryocyte colony formation, and miR-27a which targets the Runx1 transcript.^{246,247}

CYTOKINES IN MEGAKARYOPOIESIS

The identification of TPO and its receptor c-Mpl was a major advance in the study of megakaryocytes. The term thrombopoietin was first coined in 1958 to describe the putative primary regulator of platelet production²⁴⁸; the anticipated factor was also referred to as megakaryocyte growth and development factor (MGDF). Over the four decades following its description, evidence both for and against the existence of TPO as a distinct entity was presented.^{249,250} Although not appreciated at the time, a major insight into megakaryocyte biology was provided in 1986 when Françoise Wendling et al. described a murine retrovirus, myeloproliferative leukemia virus, which induced a vast expansion of hematopoietic cells.²⁵¹ The responsible viral oncogene was characterized in 1990,¹¹ and its cellular homolog c-mpl was cloned in 1992.¹⁰ Based on the presence of two copies of the hematopoietic cytokine receptor motif, it was immediately apparent that c-mpl encoded a growth factor receptor. However, its ligand was not known. Using three distinct strategies, four separate groups were able to clone the complementary DNA for the corresponding hormone and reported their results in 1994.^{12,13,14} and ¹⁵ The gene for this c-Mpl ligand was mapped to human chromosome 3q26-28, spans 6 to 8 kb, consists of seven exons, and encodes a predicted 36-kD polypeptide.^{252,253} and ²⁵⁴ The recombinant and naturally occurring cytokines migrate as 70-kD proteins, indicating substantial posttranslational modification, a conclusion verified by the finding of six sites of N-linked carbohydrate and many sites of O-linked carbohydrate.²⁵⁵ Based on its biologic activities, the c-Mpl ligand was termed thrombopoietin (TPO).¹²¹

TPO bears a striking homology to erythropoietin (EPO), the primary regulator of erythropoiesis, within the amino terminal half of the predicted polypeptide.^{12,13,14} and ¹⁵ The two proteins are more closely related than any other two cytokines within the hematopoietic cytokine family, sharing 20% identical amino acids, an additional 25% conservative substitutions, and identical positions of three of the four cysteine residues. However, unlike any of the other cytokines in the family, TPO contains a 181-residue carboxyl terminal extension, which bears homology to no known protein. Two functions have been assigned to this region: it prolongs the circulatory half-life of the cytokine and it aids in the secretion of TPO from cells that normally synthesize it.^{256,257} and ²⁵⁸

The biologic activities of TPO are consistent with a primary role in megakaryopoiesis. Incubation of marrow cells from mice, rats, dogs, nonhuman primates, and humans with TPO leads to an impressive stimulation of megakaryocyte growth in both suspension and semi-solid culture.^{12,121,259,260} Compared to cultures initiated with other hematopoietic growth factors with promegakaryocytic activity such as IL-3, kit ligand (KL), IL-6, IL-11, or leukemia inhibitory factor (LIF), marrow cells grown in TPO contain greater numbers of megakaryocytes, and the cells are larger and more highly polyploid. When administered to animals or humans, TPO stimulates platelet production in a log-linear manner to levels tenfold higher than baseline^{14,256,261,262,263} and ²⁶⁴ without affecting the peripheral blood red or white cell counts. However, perhaps unexpectedly, the number of erythroid and myeloid progenitors and mixed myeloid progenitors in marrow and spleen were also increased in some studies,^{265,266} an effect that is especially impressive when the cytokine is administered to animals after myelosuppressive therapy^{265,267,268} and probably due to the synergy between TPO and the other hematopoietic cytokines circulating at high levels in this condition.

In the hopes of treating patients with thrombocytopenia, a number of clinical trials were conducted with recombinant TPO, using either recombinant human TPO (rHuTPO) or a truncated

P.380

and pegylated form (PEG-MGDF); however, the development of antibodies to PEG-MGDF that cross-reacted with endogenous TPO halted further development of these first-generation agents.²⁶⁹ As an alternative strategy, second-generation agents, the TPO-receptor agonists, were designed that can stimulate c-Mpl but bear little homology to the native protein. These agents include peptibodies that bind the extracellular domain of c-Mpl (Romiplostim) as well as small molecules that bind within the transmembrane domain of c-Mpl at a site distinct from TPO.²⁷⁰ Phase 3 studies have demonstrated the efficacy and safety of TPO-receptor agonists in adults with chronic immune thrombocytopenia,^{271,272} and additional clinical indications are under investigation.

The biologic effects of TPO in vitro and of its administration in vivo strongly suggest that the cytokine plays an important role in hematopoiesis. Based on genetic studies, it is now clear that TPO is the primary regulator of thrombopoiesis. Genetic elimination of c-mpl or tpo in mice leads to profound thrombocytopenia due to a greatly reduced number of megakaryocyte progenitors and mature megakaryocytes and the reduced ploidy of the remaining megakaryocytes.^{24,253} The human disease related to deficiency of c-Mpl is CAMT. In CAMT, autosomal recessive inheritance of nonsense or missense mutations of MPL results in loss of TPO responsiveness.^{273,274,275} Both mice and humans with c-Mpl deficiency also have a HSC defect, with humans developing overt marrow failure. Restoration of Mpl expression in Mpl-deficient mice using transcriptionally targeted vectors results in restoration of the HSC pool and correction of thrombocytopenia.²⁷⁶ Although tpo-knockout mice phenocopy c-mpl-deficient animals, mutations eliminating TPO expression have not been described in humans.

TPO levels in the plasma are primarily regulated by platelet mass, although there is evidence for additional regulation at the level of gene transcription and protein translation. In most experimental and natural cases of thrombocytopenia, plasma concentrations of TPO vary inversely with platelet counts, rising to maximal levels within 24 hours of the onset of profound thrombocytopenia.^{277,278} and ²⁷⁹ TPO is produced at a constant rate by the liver, and to a minor extent the kidney, and once in the circulation its uptake and degradation (and, hence, the level remaining in the blood to affect megakaryopoiesis) are determined by the mass of c-Mpl receptors present on platelets and megakaryocytes.^{279,280,281,282,283} In this way, when platelet levels are high, more TPO is removed from the circulation and there is a compensatory reduction of megakaryopoiesis. Conversely, thrombocytopenia, particularly thrombocytopenia due to decreased platelet production, is associated with increased plasma TPO levels that stimulate megakaryopoiesis (Fig. 15.6). Although TPO expression by the liver is not regulated by thrombocytopenia, other stimuli can enhance TPO production. For example, IL-6 increases TPO expression through enhanced hepatic transcription, accounting for the thrombocytosis that is observed in clinical states of inflammation.^{284,285} In addition, transcription of TPO in marrow stromal cells has been shown to increase in states of thrombocytopenia and platelet proteins such as CD40 ligand, platelet-derived growth factor, fibroblast growth factor, TGF- β , PF4, and thrombospondin may also modulate TPO production from marrow stromal cells.^{280,286,287,288} and ²⁸⁹ The human TPO gene 5' flanking region lacks a TATA box or a CAAT motif and directs transcription initiation at multiple sites over a 50-nucleotide region.²⁹⁰ Reporter gene analysis in a hepatocyte cell line identified an ETS2 transcription factor-binding motif responsible for high-level expression of the gene. Subsequent studies, though failing to confirm ETS factor interaction, identified binding of the C/EBP- δ .²⁹¹ The 5' flanking region also includes binding sites for specificity protein-1, activator protein-2 (AP-2), and nuclear factor- κ B (NF- κ B),²⁵² although the contribution of these transcription factors to TPO gene expression, either under steady-state or stimulated conditions, has yet to be defined.

FIGURE 15.6. Regulation of plasma TPO levels. TPO is produced at a steady-state level by the liver, and to a lesser extent by the kidney. Plasma TPO is bound and internalized by c-Mpl receptors on circulating platelets, reducing the amount that reaches the bone marrow to stimulate megakaryopoiesis. In states of thrombocytopenia, more TPO reaches the marrow and thus platelet production is increased. When platelet levels are high, little TPO is available to stimulate megakaryopoiesis and platelet production decreases.

Although TPO is critically important for megakaryopoiesis, it is not essential, as mice lacking either the cytokine or its receptor retain approximately 10% of normal levels of megakaryocytes and platelets.^{292,293} Thus, other cytokines can support megakaryopoiesis. Prior to the discovery of TPO, it was known that IL-3, granulocyte-macrophage colony-stimulating factor (GM-CSF), and the c-KL (also called stem cell factor or steel factor) support the proliferation of megakaryocyte progenitors in plasma-containing cultures.^{294,295,296,297} and²⁹⁸ IL-3 is a 25- to 30-kD protein produced primarily by T lymphocytes.²⁹⁹ The mature human polypeptide contains 133 amino acids, but significant amounts of N-linked carbohydrate modification account for the larger-than-expected relative molecular mass (M_r) of the cytokine. GM-CSF is an 18- to 30-kD protein also produced by T lymphocytes, but endothelial cells, monocytes, and fibroblasts also produce the protein and, like IL-3, GM-CSF is highly modified with both N-linked and O-linked carbohydrate.³⁰⁰ Although the two polypeptides display essentially no primary sequence homology, their tertiary structures

P.381

are highly related,^{301,302} and the receptors for the two cytokines share a common subunit.³⁰³ However, the physiologic relevance of IL-3 and GM-CSF for thrombopoiesis is uncertain because their administration to mice or humans has only minimal effects on platelet production, and the genetic elimination of either cytokine has no impact on megakaryopoiesis, even in combination with the elimination of other thrombopoietic cytokines.^{304,305}

In contrast to the hematopoietic cytokine family, KL is more closely related to other hematopoietic proteins that use protein tyrosine kinase receptors, such as macrophage colony-stimulating factor and the flt-3 ligand (FL).³⁰⁶ Nevertheless, KL has been shown to stimulate megakaryocyte colony growth when used in combination with other cytokines.^{259,298,307} Moreover, genetic elimination of c-kit reduces megakaryocyte production and the rebound thrombocytosis that occurs after immunosuppressive therapy.^{308,309} and³¹⁰ In addition to early hematopoietic cells, KL also acts on primitive cells of the melanogenic and germ cell systems.^{311,312,313,314,315} and³¹⁶ KL is a dimeric protein composed of two identical noncovalently linked polypeptides; the soluble form monomer contains 165 residues,³¹⁷ derived by proteolytic cleavage of a membrane-bound form of the molecule.³¹⁸ The membrane-bound form is actually more active than the soluble cytokine because cell survival and proliferation signals derived from the former are prolonged in receptor-bearing cells.³¹⁹ Moreover, a naturally occurring mutant allele of the gene (Sl^d), which allows production of the soluble but not the membrane-bound form of KL, results in a phenotype nearly identical to deletion of the entire locus.³²⁰

In the late 1980s and early 1990s, three molecules related by use of a common receptor subunit were characterized that display effects on megakaryocyte production. IL-6, cloned by several groups using multiple assays (hepatocyte growth,

myeloma cell growth, immunoglobulin secretion, and antiviral activity), was found to enhance megakaryocyte maturation. IL-6 is a 26-kD polypeptide widely produced in response to inflammatory stimuli from T-cells, fibroblasts, macrophages, and stromal cells.³²¹ The mature protein is composed of 184 amino acids, contains two disulfide bonds, and displays both N-linked and O-linked carbohydrate modification. Although IL-6 alone does not affect in vitro megakaryopoiesis, it augments the number of megakaryocyte colonies obtained in the presence of IL-3 or KL.³²² In such culture systems, IL-6 primarily exerts a differentiating effect, as its levels correlate with megakaryocyte size and ploidy in long-term marrow cultures, and its neutralization reduces these parameters.^{323,324} The administration of IL-6 to mice, dogs, or humans results in a modest thrombocytosis.^{322,324,325,326,327} and³²⁸ However, genetic elimination of IL-6 does not significantly affect basal platelet production³²⁹; furthermore, studies may be confounded by the effect of IL-6 on TPO transcription.²⁸⁵

IL-11 and leukemia inhibitory factor (LIF) also act in synergy with IL-3 or KL to augment megakaryocyte formation. IL-11 is a 23-kD polypeptide initially cloned from a gibbon marrow stromal cell line as an activity that supported the proliferation of an IL-6-responsive myeloma cell line.^{330,331} LIF was initially cloned as a human IL that induced DA-1 cells to proliferate (hence its alternate name, HILDA) or induced leukemic M1 cells to differentiate.^{332,333} LIF displays a wide range of activities³³⁴ including effects on the liver (initiates the acute-phase response), neurons (induces an adrenergic to cholinergic switch), adipocytes (inhibits lipoprotein lipase), and embryonic cells (maintains pluripotentiality). As do IL-6 and IL-11, LIF enhances megakaryocyte maturation in vitro.^{335,336} Moreover, IL-6 and IL-11 were also found to augment the effects of IL-3 and KL on the proliferation of primitive hematopoietic cells, suggesting that these cytokines augment megakaryocyte development at multiple levels. Consistent with these in vitro findings, the administration of either recombinant IL-11 or LIF to rodents, nonhuman primates, or humans produces a modest thrombocytosis.^{333,337,338,339,340} and³⁴¹ However, genetic elimination of either LIF or the IL-11 receptor has no obvious effect on thrombopoiesis.^{342,343}

Although EPO is considered generally specific for erythrocytes, significant evidence supports its activity in megakaryocytes. EPO and TPO, as well as their receptors, are closely related,^{10,11} and¹² and they display synergy in stimulating the growth of progenitors of both lineages.^{259,344,345} However, despite this similarity there is no promiscuity between the receptors and EPO does not stimulate c-Mpl.³⁴⁶ When the wild-type human EPOR or a mutant human gain-of-function EPOR gene was knocked into the mouse EpoR locus, the mice expressing wild-type EPOR, which is hypofunctional due to reduced affinity of the human receptor for mouse EPO, were not only anemic but also thrombocytopenic.³⁴⁷ Expression of the active EPOR, in contrast, only led to erythrocytosis, perhaps due to down-regulation of endogenous TPO. The synergy between EPO and TPO may in part reflect stimulation of a common progenitor, but some studies support the activity of EPO in committed megakaryocytes.³⁴⁸

Additional factors have been found to influence megakaryopoiesis, including the chemokine SDF-1 and the transmembrane protein Notch. Stromal-derived factor-1 (SDF-1) is the ligand for the 7-transmembrane G-protein-coupled chemokine receptor CXCR4 and it is known to enhance HSC homing to the marrow.³⁴⁹ Several avenues have provided evidence that SDF-1 is important in megakaryopoiesis. CXCR4 is expressed on developing megakaryocytes,³⁴⁹ and mice lacking either SDF-1 or CXCR4 have a deficiency in CFU-MK compared with controls.^{350,351} Infusion of SDF-1 can increase platelet production in tpo^{-/-} or c-Mpl^{-/-} mice.³⁵² CXCR4 is the target of miR146a, and in vitro studies in which miR146a was overexpressed resulted in silencing of CXCR4 and impaired megakaryocytic cell proliferation.³⁵³ Some authors have found that SDF-1 acts together with TPO to enhance proliferation of CFU-MK³⁵⁴; however, its efficacy in mice lacking an intact TPO-MPL axis indicates it also has activity that is independent of TPO. SDF-1 enhances adhesion of integrin $\alpha 2\beta 3$ -positive progenitors to fibrinogen and vitronectin and may promote the migration of megakaryocytic progenitors to the vascular niche for platelet formation.^{352,355,356}

Notch signaling is complex, as there are four single-pass transmembrane Notch receptors (Notch1-4) and five transmembrane ligands (Delta-like-1/3/4, Jagged-1/2). Notch signaling is initiated when the extracellular portion of a Notch receptor binds one of its cognate ligands, resulting in proteolytic cleavage that releases the intracellular domain of Notch from the membrane, allowing it to translocate to the nucleus and stimulate gene transcription. Although previously recognized for its role in T-cell development, Notch has more recently been shown to specify megakaryocyte development from hematopoietic stem and progenitor cells.³⁵⁷ Murine hematopoietic progenitors, cultured in the absence of cytokines on stroma expressing DL1, underwent megakaryocytic differentiation, whereas the same cells cultured on control stroma gave rise to erythroid and granulocyte-macrophage cells.³⁵⁸ Conversely, under megakaryocytic culture conditions, the presence of stromal cells expressing DL4 inhibited the later stages of megakaryocytic maturation without affecting earlier aspects of differentiation.³⁵⁹ The pathways are only partially understood; however, DL1 has been shown to cooperate with HOXB4 in promoting HSC expansion³⁶⁰; because TPO promotes HOXB4 expression,³⁷ this provides an opportunity for synergy between Notch and TPO signaling. In addition, both Notch and TPO signaling result in activation of PI3K and Akt, another potential synergy that would promote megakaryopoiesis.^{361,362}

In addition to positive regulators of megakaryopoiesis, several substances have been shown to inhibit megakaryocyte development. TGF- β is a family of five isoforms, all disulfide-linked homodimers each containing 112 residues.³⁶³ TGF- β 1 is the predominant type of TGF found in hematopoietic tissues; platelet α -granules are a particularly rich source of this cytokine. TGFs are inhibitors of hematopoiesis in general, but particularly of megakaryocyte development.^{364,365,366,367} and³⁶⁸ The two best understood TGF- β growth inhibitory effects are exerted on cell-cycle

P.382

progression. After binding to one of five TGF receptors, two pathways that block cell-cycle progression are activated: pRb is hypophosphorylated,³⁶⁹ antagonizing the effects of G₁-phase cyclin-dependent kinases, and the cell-cycle inhibitor p27 is upregulated, again halting cell-cycle progression at the level of S phase.^{370,371} It should be noted that TGF- β is not inhibitory only for megakaryopoiesis; rather, the cytokine appears to reduce hematopoiesis at many levels.^{372,373} and³⁷⁴ In contrast to its effects on cell proliferation, evidence has been presented that TGF- β might enhance megakaryocyte differentiation by enhancing expression of the cell-cycle inhibitor p15^{Ink},³⁷⁵ an effect that may be due to autocrine production of the cytokine. Additional platelet granule proteins found to inhibit megakaryocyte development include the chemokine PF4³⁷⁶ and β -thromboglobulin.³⁷⁷ PF4 is a CXC chemokine, but unlike SDF-1 it does not act through a G protein-coupled CXCR; instead it forms a tetramer and binds to glycosaminoglycans on cell surfaces and to negatively charged domains of several membrane receptors.^{378,379} PF4 secreted by marrow megakaryocytes may act in a paracrine fashion to down-regulate megakaryopoiesis by binding to lipoprotein receptor-related protein-1 (LRP1).³⁸⁰ Although not demonstrated in megakaryocytes, LRP1 is required for growth inhibition in response to TGF- β in vascular cells,³⁸¹ providing a potential mechanistic link between PF4 and TGF- β . Finally, interferon (IFN)- α inhibits megakaryopoiesis, and its use leads to modest to severe thrombocytopenia in a significant number of patients undergoing therapy for chronic hepatitis.^{382,383} Multiple mechanisms are responsible for the inhibitory effect of IFN- α on megakaryopoiesis, including a direct inhibitory effect of IFN- α on growth-factor-induced proliferation pathways. For example, IFN- α augments double-stranded RNA-activated protein kinase activity, inhibiting translation initiation factor-2 and implicating reduction of the growth-factor-induced protein synthesis necessary for cytokine response.³⁸⁴ Other investigators have reported that the functionally similar cytokine IFN- γ induces expression of the cell-cycle inhibitor p27^{kip1}, arresting cells in G₀/G₁.³⁸⁵ Wang et al. demonstrated that IFN- α induces a suppressor of the cytokine signaling-1 (SOCS1)-based feedback mechanism that negatively regulates TPO signaling.³⁸⁶ Consistent with these findings, TPO-receptor agonists have been used to ameliorate the thrombocytopenia resulting from IFN- α therapy in patients with hepatitis.³⁸⁷ Thus, in addition to the multiple positive mediators of megakaryopoiesis, several cytokines block the process and can lead to thrombocytopenia.

SIGNAL TRANSDUCTION PATHWAYS IN MEGAKARYOCYTES

c-Mpl is a typical hematopoietic receptor containing two cytokine receptor homology domains (marked by the distinctive WSXWS sequence motif), a transmembrane domain, and a cytoplasmic domain that mediates intracellular signaling. The extracellular domain is N-glycosylated, enhancing receptor secretion and cell surface expression.³⁸⁸ c-Mpl is secreted onto the cell surface as a pre-formed but inactive homodimer. Although c-Mpl does not have intrinsic tyrosine kinase activity, it associates with a cytoplasmic tyrosine kinase, Janus kinase (JAK)2 (Fig. 15.7). JAK2 binds to a short motif (termed box1) adjacent to the transmembrane domain of the receptor.^{389,390} Upon binding of TPO to its extracellular domain, c-Mpl undergoes a conformational change that brings the cytoplasmic tails of the receptor and the associated JAK2 closer together, initiating JAK2 kinase transactivation and downstream signaling events.³⁹¹ Experimental manipulation of the receptor has identified three different states of the receptor, inactive, partially active, and active, related by receptor subunit rotation.^{392,393} The state of the receptor depends in part on an amphipathic KWQFP motif at the junction between the transmembrane and cytoplasmic domains; deletion of this sequence experimentally results in a gain of function, in which the mutant receptor can signal in the absence of TPO.³⁹⁴ Naturally occurring mutations within the transmembrane domain (e.g., c-Mpl Ser505Asn, Trp508Ser, and Trp515Leu) also result in a constitutively active receptor and are associated with myeloproliferative disease.^{395,396,397} In addition, small molecule TPO-receptor agonists such as Eltrombopag bind to the transmembrane domain and may promote receptor activation through this type of allosteric mechanism.²⁷⁰ Following ligation, both c-Mpl and the bound TPO are then internalized through endocytosis, limiting the duration of signaling.^{398,399} Whereas a portion of the internalized receptor is degraded in the proteasome, a fraction is also recycled to the cell surface where it can again interact with TPO and participate in signaling.^{400,401} Enhanced proteosomal degradation and reduced receptor maturation and recycling of c-Mpl occurs in cells bearing the constitutively active Jak2 Val617Phe, present in the majority of patients with the myeloproliferative disease polycythemia vera (PV), leading to reduced surface expression of the receptor.^{402,403}

Janus family kinases are critical to megakaryopoiesis. Four JAK kinases have been identified in hematopoietic cells: JAK1, JAK2, JAK3, and TYK2.³⁸⁹ Of the cytokines that affect megakaryopoiesis, IL-3 activates JAK2⁴⁰⁴; IL-6, IL-11, and LIF activate JAK1, JAK2, and TYK2 (although JAK1 is most important)⁴⁰⁵; and TPO leads to JAK2 and TYK2 phosphorylation (although JAK2 is most important).^{406,407,408} and ⁴⁰⁹ Moreover, even members of the receptor tyrosine kinase family that affect megakaryopoiesis, such as KL or FL, activate JAK kinases.^{410,411} Phosphorylation of JAKs leads to their activation, which, in turn, leads to phosphorylation of a number of substrates, including the receptors themselves and reversibly tethered signaling molecules. One of the best studied families of secondary signaling molecules is the signal transducers and activators of transcriptions (STATs); these latent transcription factors dock at P-Tyr residues of cytokine receptors and are phosphorylated by JAKs, and, once so modified, P-STATs dimerize, translocate to the nucleus, and bind to specific genetic elements altering transcription. Both P-Tyr and P-Ser modifications are required to fully activate STATs.^{412,413} Of the cytokines affecting megakaryocyte development, IL-3 and GM-CSF activate STAT5⁴¹⁴; IL-6, IL-11, and LIF activate STAT3^{415,416}; and TPO activates both STAT3 and STAT5.^{417,418,419,420} Among the known targets of the STATs known to play an important role in megakaryocytic cell survival and proliferation are Bcl-X_L and c-myc,^{421,422} and ⁴²³ with STAT1 displaying generally inhibitory effects on cell cycling and STAT3 and STAT5 displaying the opposite effect.⁴²⁴ Phosphorylation of tyrosine residues on c-Mpl by JAK2 creates docking sites for additional signaling intermediates via SRC homology 2 (SH2) domains, including the guanine nucleotide exchange factor Vav, adapter proteins such as Shc and the Gabs, and the phosphatase SHP2. Phosphorylation of JAK2 itself provides additional docking sites, providing binding sites for p85 α and the adaptor protein Lnk.^{425,426} These interactions modulate signaling, activating the RAS-RAF-MAPK and PI3K-AKT pathways, or in the case of Lnk, down-regulating JAK2.^{40,425}

The RAS-RAF-MAPK pathway is critical in megakaryopoiesis.

Activation of MAPK in cell lines promotes megakaryocytic differentiation, and MAPK pathway inhibitors block polyploidization and megakaryocyte maturation in primary cells.^{356,427,428,429,430,431,432} MAPKs are approximately 40-kD Ser/Thr kinases that are highly conserved in all eukaryotic cells from yeast to humans. At least six signaling cascades classified as MAPK pathways have been identified^{433,434} and have been found to mediate cell proliferation, survival, apoptosis, or differentiation. At present, three classes of MAPKs have been identified in megakaryocytes: extracellular stimulus response kinase (ERK) 1 and ERK2 (also termed p44 and p42, respectively); c-jun N-terminal kinase (JNK); and p38 kinase.^{435,436} and ⁴³⁷ MAPK activation requires phosphorylation both on threonine and tyrosine residues present on

P.383

specific motifs (Thr-Xaa-Tyr). Receptors that activate MAPKs do so by activating Ras and initiating a kinase cascade. Thus, for c-Mpl, the adapter molecule Shc is recruited to the tyrosinephosphorylated receptor cytoplasmic domain, which is then phosphorylated by JAK2. Phospho-Shc then recruits the adapter protein Grb2, which activates the guanine nucleotide exchange factor SOS, which then charges Ras with GTP, thereby activating it. Active Ras, in turn, leads to the activation of an MAPK kinase kinase such as Raf-1, which phosphorylates an MAPK kinase such as MEK, which then phosphorylates MAPKs including ERK1 and ERK2. Because cells contain numerous MAPK kinase kinases and MAPK kinases, the potential for cross-talk between different MAPK pathways is large; this potential is reduced considerably through scaffolding proteins that sequester only the corresponding MAPK kinase kinase, MAPK kinase, and MAPK.^{438,439} Virtually every cytokine affecting megakaryocytes activates ERK1 and ERK2.^{411,430,440,441} and ⁴⁴² Alternate pathways to MAPK activation have also been described in platelets,⁴⁴³ and integrin engagement in fibroblasts affects the cellular localization of ERK1/2, exerting a profound effect on its capacity to signal.⁴⁴⁴ Blockade of ERK1 and ERK2 has been shown to reduce cell proliferation in c-Mpl receptor-bearing cell lines and both cell proliferation and the generation of highly polyploid cells in megakaryocytic progenitors,⁴³¹ but, curiously, to enhance proliferation of more primitive megakaryocytic progenitors from cord blood.⁴⁴⁵ The molecular targets of active MAPKs in megakaryocyte progenitors that mediate the effect of ERK1 and ERK2 on cell survival, proliferation, and differentiation are presently a topic of intense research; most studies in other cell systems suggest that ERK affects nuclear transcription factors, such as c-jun, c-myc, and the ets family member Elk-1,^{446,447} which then modulate activity of the cell-cycle machinery. For example, stimulation of ERK1 and ERK2 leads to increased levels of cyclin D in fibroblasts.⁴⁴⁸ The strength and duration of MAPK activation may be important in whether the cell responds by proliferation or differentiation. Transient or acute MAPK activation that occurs in the cell cytoplasm (minutes to hours) is typical of cell-cycle progression and proliferation, whereas sustained MAPK activation into the nucleus (lasting many hours or several days) is characteristic of cell-cycle arrest and differentiation.^{449,450} Activation of the Ras-like small GTPase Rap1 activates the MAPK kinase kinase B-Raf and leads to a sustained activation of ERK1/2 in cell lines.⁴⁵¹ The Rap1 ERK signaling pathway responds to Src kinases and cAMP via activation of PKA and is linked to cell receptors via adaptor and scaffold proteins such as c-Cbl and CrkL. MAPKs also act on additional kinases, including the 90

kD ribosomal S6 kinase and the NF- κ B activator AP-1.^{446,452} Despite their apparent importance, a requirement for either Raf-1 or B-Raf in megakaryopoiesis has not been proven in mouse models.^{453,454} Although TPO activates JNK and p38 in c-Mpl-bearing cells, primary megakaryocytes, and platelets,^{443,455} less is known of their effects on megakaryocyte development.

FIGURE 15.7. Representative pathways in TPO signaling. TPO binds to the homodimeric c-Mpl, leading to a conformational change that leads to transactivation of the associated JAK2 molecules. Active JAK2 then phosphorylates tyrosine residues on the receptor, including Y112 and Y117, which form docking sites for SH2-domain-containing proteins and adaptors. JAK2 phosphorylates STATs 3 and 5, which form homodimers and translocate to the nucleus where they activate transcription. Formation of a complex between SHC, SOS, and GRB2 leads to activation of the RAS/RAF/MAPK pathway. Engagement of p85 through adaptor proteins in conjunction with RAS activation leads to activation of PI3K and its downstream effectors. Negative regulators of TPO signaling, including SOCS, Lnk, Lyn, and PTEN, are shown in red.

P.384

The PI3K pathway also has a critical role in megakaryopoiesis and is activated in response to multiple cytokines, including TPO, IL-3, GM-CSF, KL, and IL-6.^{355,362,411,440,456,457,458,459,460} and ⁴⁶¹ PI3K is a heterodimeric lipid kinase composed of a 110-kD kinase (p110) and an 85-kD (p85) regulatory subunit. PI3K activity is initiated by the engagement of the two SRC homology 2 domains of p85, either by a phosphorylated cytokine receptor (usually in the context of a YXXM or YVAC motif)^{462,463} and ⁴⁶⁴ or an adapter molecule,^{456,457,465,466} and ⁴⁶⁷ resulting in conformational changes allowing activation of p110 and relocation of the kinase to the lipid membrane.⁴⁶⁸ Although p85 interacts directly with some hematopoietic cytokine receptors, the mechanism by which it is activated in TPO signaling is not clear; it may involve interaction with an adaptor molecule.^{457,469} Once in proximity to its membrane lipid substrates and its coactivator, membrane-bound activated Ras,⁴⁷⁰ active PI3K then generates PI 4,5 phosphate (PIP2) and PI 3,4,5 phosphate (PIP3), and pleckstrin homology (PH) domain-containing proteins are recruited to these phospholipids to initiate signaling cascades. Lipid phosphatases, including SRC homology 2-containing inositol phosphatase (SHIP2)^{471,472} and ⁴⁷³ and PTEN,^{474,475} negatively regulate PI3K signaling.

Central to the PI3K signaling cascade is 3-phosphoinositide-dependent protein kinase-1, also known as PDK1. PDK1 is recruited to PIP2 and PIP3 in the cell membrane through its PH domain where it can interact with its effector substrates

including Akt, ribosomal protein p70 S6 kinase (p70S6K), and PKC. Akt is a serine-threonine kinase with multiple targets that have roles in cell survival and growth. TPO promotes phosphorylation and activation of Akt which is blocked by inhibitors of PI3K, and inhibition of PI3K in cell line models as well as in primary megakaryocytes leads to reduced cell survival and proliferation; furthermore, expression of a constitutively active Akt restores proliferation and survival in the presence of PI3K inhibitors.³⁶² Akt promotes cell survival by phosphorylation of the proapoptotic protein Bad. Phosphorylated Bad binds to protein 14-3-3 and is thus targeted for proteolysis, removing its inhibitory effect on the pro-survival protein Bcl-X_L.^{476,477,478} GSK-3 β is also phosphorylated by Akt, leading to inhibition of GSK-3 β activity and enhanced survival and proliferation.^{479,480} Forkhead family members, including FOXO3a, are also phosphorylated by Akt, preventing their translocation to the nucleus where they promote cell-cycle arrest and apoptosis by induction of p27, Bim, Fas ligand, and GADD45. TPO promotes down-regulation of p27 in megakaryocytic cells through a PI3K/Akt/FOXO3a pathway.⁴⁸¹

In addition, PI3K and Akt signaling activate the mammalian target of rapamycin (mTOR) through inhibition of the GTPase TSC2 and subsequent activation of the small GTP-binding protein Rheb.^{482,483} mTOR is a serine-threonine kinase and a member of the PI3K-related kinase family that functions in the regulation of cell size and cell-cycle progression. mTOR controls the phosphorylation status of proteins involved in initiating translational control, including p70S6K and eukaryotic translation initiation factor 4E-binding protein (4E-BP). Multiple signaling pathways converge on p70S6K and it has multiple sites of inducible phosphorylation; however, phosphorylation by PDK1 and mTOR are essential for its activity.⁴⁸⁴ The Ras-MAPK pathway also modulates mTOR activity. TPO induces activation of the mTOR/p70S6K pathway in megakaryocytes, and inhibition of mTOR signaling by rapamycin leads to reduced proliferation of megakaryocytic progenitors and, in some studies, megakaryocyte polyploidization and maturation.^{485,486,487} mTOR signaling may be particularly important in neonatal megakaryopoiesis.⁴⁸⁸

Although JAK2 has been studied the most, other tyrosine kinases are activated by TPO and play a role in megakaryopoiesis. The src family kinase Lyn is activated in TPO-stimulated megakaryocytes.⁴⁸⁹ Mutagenesis experiments identified tyrosine 112 of c-Mpl as critical for Lyn activation.⁴⁹⁰ Unlike JAK2, Lyn negatively regulates megakaryocytic proliferation and differentiation, possibly through inhibition of MAPK and Akt signaling, and lyn^{-/-} mice show increased megakaryopoiesis.^{490,491}

In vivo, megakaryocytes are affected both by soluble cytokines and activation of adhesive receptors in the marrow microenvironment⁴⁹²; similarly, focal adhesion kinase (FAK) activation in platelets requires the co-stimulation of growth factor receptors and integrins. In megakaryocytic cell lines, TPO stimulates phosphorylation of FAK.⁴⁹³ Targeted deletion of Fak in a mouse model resulted in enhanced megakaryopoiesis, with increased numbers of megakaryocytic progenitors, mature megakaryocytes, and circulating platelets. Fak^{-/-} megakaryocytes were impaired in their ability to activate Lyn in response to TPO, but in contrast showed increased activation of MAPK and Akt,⁴⁹³ reminiscent of megakaryocytes from Lyn^{-/-} mice and suggesting that FAK plays a role in the activation of Lyn.

As should be clear from the previous discussion, the megakaryocyte (and probably all hematopoietic cells) uses multiple molecular pathways to affect cell survival and proliferation. Recent work with c-Mpl has helped to clarify the nature and teleology behind this seeming redundancy. Phosphorylation of the penultimate tyrosine residue in the cytoplasmic domain of c-Mpl leads to Shc, STAT3, and STAT5 activation.⁴¹⁹ Moreover, MAPK activation is also thought to emanate from the distal half of the receptor.⁴³⁰ Nevertheless, a truncated form of c-Mpl bearing neither of these regions continues to modestly activate STAT5, MAPK, and PI3K in a TPO-dependent manner,⁴¹⁹ and introduction of a similarly truncated receptor into the germline in place of the full-length receptor affords the resultant mice a normal steady-state platelet count throughout life.⁴⁹⁴ However, these mice do not respond properly to stress; compared with normal mice, platelet recovery after immune-mediated or chemotherapy-induced thrombocytopenia is substantially delayed. Thus, the seeming redundancy in cytokine signaling appears to reflect a capacity of the cell to grade the TPO response into steady-state and emergency thrombopoiesis. A similar conclusion regarding signaling via STAT5 in erythropoiesis has been presented.⁴⁹⁵

The signaling cascades initiated by TPO are of limited duration. Multiple mechanisms exist to govern this process. As discussed above, following initiation of signaling, the ligated c-Mpl is internalized and degraded.^{398,399} and⁴⁰⁰ Another mechanism of feedback inhibition of cytokine receptor signaling is mediated by STAT-mediated induction of SOCS proteins.⁴⁹⁶ At present, five members of this STAT-induced family of signaling proteins have been found to inhibit signaling, either by directly blocking JAK kinase function or by competing for binding to phosphotyrosine receptor-signaling sites with secondary signaling mediators. Hence, when STAT is activated, it ultimately feeds back to inhibit JAK2 signaling. This mechanism can also account for receptor cross-talk (i.e., the ability of one cytokine signal to negatively affect another), because SOCS proteins induced by one receptor can interact with others.^{385,497} The SH2-domain-containing adaptor protein Lnk also binds to and negatively regulates JAK2 that has been phosphorylated in response to TPO. In the absence of Lnk, mice exhibit thrombocytosis and over time develop a myeloproliferative disorder.^{425,426,498}

Naturally occurring mutations that disrupt regulation of JAK2 are associated with the development of myeloproliferative disorders and leukemia.

CLINICAL DISORDERS OF MEGAKARYOPOIESIS

A number of disorders of megakaryopoiesis, including congenital thrombocytopenias and thrombocythemias, as well as acquired myeloproliferative disorders and leukemias, involve mutation of transcription factors and signaling molecules that have been discussed in this chapter as having a role in megakaryocyte

P.385

development (Table 15.2). A brief review of several instructive disorders follows.

TABLE 15.2 GENETIC MUTATIONS IN SELECTED INHERITED PLATELET DISORDERS

Gene	Function	Gain/Change of Function	Loss of Function
MPL	TPO receptor	ET, PMF	CAMT
TPO	Growth factor	ET	
JAK2	Tyrosine kinase	PV, ET, PMF	
HOXA11	Transcription factor		ATRUS
RUNX1	Transcription factor		FDP-PMM
FLI1	Transcription factor		PTS
GATA1	Transcription factor	DS-TMD, DS-AMKL	XLT, XLTT
OTT/MAL	Fusion protein, transcription factor	AMKL	
GPIb/GPIX	Adhesive receptor	Platelet-type VWD	BSS
FLNA	Cytoskeletal protein		Macrothrombocytopenia
MYH9	Cytoskeletal protein		MYH9-related disease
WASp	Cytoskeletal protein		WAS
TUBB1	Cytoskeletal protein		Macrothrombocytopenia
NBEAL2	Vesicle trafficking		GPS
AP3	Vesicle trafficking		HPS
CYCS	Apoptosis regulator	AD thrombocytopenia	

ATRUS, amegakaryocytic thrombocytopenia with radioulnar synostosis; BSS, Bernard-Soulier syndrome; CAMT, congenital amegakaryocytic thrombocytopenia; DS-AMKL, Down syndrome, acute megakaryoblastic leukemia; DS-TMD, Down syndrometransient myeloproliferative disorder; ET, essential thrombocythemia; FDP-PMM, familial platelet disorder with predisposition to myeloid malignancy; GPS, gray platelet syndrome; HPS, Hermansky Pudlak syndrome; PMF, primary myelofibrosis; PTS, Paris-Trousseau syndrome; PV, polycythemia vera; vWD, von Willebrand disease; WAS, Wiskott-Aldrich syndrome; XLT, X-linked thrombocytopenia; XLTT, X-linked thrombocytopenia with thalassemia.

CAMT: CAMT is the quintessential defect of megakaryocyte production, resulting from homozygous or compound heterozygous mutations of MPL encoding c-Mpl.⁴⁹⁹ The clinical course of CAMT confirms the critical role of TPO in both megakaryocytes and HSCs. Although children with CAMT are typically born with isolated thrombocytopenia and deficiency of megakaryocytes, over time they develop pancytopenia and bone marrows performed later in their course will show a severe depletion of megakaryocytes and trilineage hypocellularity.⁵⁰⁰ In addition, children with CAMT are at risk to develop clonal disease including myelodysplastic syndrome (MDS) or leukemia.⁵⁰¹ Serum TPO levels are highly elevated

due to the absence of receptor-mediated uptake.²⁷⁴ Whereas the majority of described mutations are in exons 1 to 3 of MPL, mutations have been described throughout the coding sequence. Mutations that result in complete disruption of the receptor (type I) are associated with an earlier onset of marrow failure (median age 22 months), whereas mutations that encode amino acid substitutions that result in partial receptor function (type II) are associated with transient improvement in platelet counts and a later onset of marrow failure (median age 48 months).⁵⁰⁰

TAR and ATRUS: As in CAMT, thrombocytopenia with absent radii (TAR) also presents at birth with thrombocytopenia, but affected infants have the characteristic finding of bilateral absent radii. Additional skeletal and nonskeletal defects are frequent, including lower extremity, cardiac, renal, and gastrointestinal abnormalities.⁵⁰² Unlike CAMT, thrombocytopenia in TAR tends to improve over the first 2 years of life, and children do not usually develop other cytopenias. TAR remains enigmatic with an incomplete understanding of its genetic etiology, and current evidence suggests a complex pattern of inheritance. Platelets from young patients with thrombocytopenia have impaired responses to TPO and impaired megakaryocyte differentiation, but TPO signaling is restored in platelets from adults.⁵⁰³ No defects in THPO (the gene for TPO), MPL, or JAK2 have been identified.^{504,505} and ⁵⁰⁶ A large study involving 30 patients with TAR identified a common interstitial microdeletion of 200 kb on chromosome 1q21.1 including several candidate genes.⁵⁰⁷ However, in approximately 75% of the patients, the deletion was inherited from an unaffected parent, suggesting that a second genetic change must be co-inherited in order for the phenotype to be expressed. The treatment of thrombocytopenia in TAR is largely supportive, as platelet counts typically improve with age.

ATRUS shares features with both CAMT and TAR. Thrombocytopenia is present at birth, and like TAR, there are radial abnormalities, in this case bilateral fusion of the proximal radius and ulna. However, platelet counts do not improve with age and similar to CAMT, most affected children develop bone marrow failure. Autosomal dominant inheritance of a mutation in the HOX family member HOXA11 was reported in two unrelated families with ATRUS^{216,508}; it is intriguing that mice lacking expression of HOXA11 show skeletal abnormalities but lack a hematologic phenotype.⁵⁰⁹ Additional patients with clinical features of ATRUS have been reported who do not have identifiable mutations in HOXA11,^{510,511} suggesting other loci may also be involved.

RUNX1: Reflecting the role of RUNX1 in hematopoiesis and megakaryocyte development, autosomal dominant mutations resulting in haploinsufficiency of RUNX1 are found in the familial platelet disorder with a propensity for myeloid malignancy (FPD-PMM).^{197,512} In FPD-PMM platelets are normal in size and thrombocytopenia is typically moderate, but bleeding may be more prominent than expected due to associated platelet dysfunction. The major complication of this disorder is not bleeding but the development of myelodysplasia or leukemia. The rate of myeloid malignancies in affected individuals ranges between 20% and

P.386

65% and peaks at the fourth decade of life. T-cell malignancies have been reported as well.⁵¹³ Heterozygous mutations of RUNX1 described in this disorder range from substitutions or large deletions and most commonly affect the RUNX homology domain; although most result in haploinsufficiency, some mutations may have a dominant negative effect. Additional acquired mutations in RUNX1 or karyotypic abnormalities are frequently detected in the malignant clone at the time of acute myeloid leukemia/MDS diagnosis.

GATA1: As discussed above, GATA1 is essential for differentiation of both erythrocytes and megakaryocytes; thus, mutations affecting this transcription factor are associated with red cell abnormalities as well as thrombocytopenia. GATA1 mutations are associated with several phenotypes, including X-linked thrombocytopenia (XLT) with dyserythropoiesis, X-linked thrombocytopenia with thalassemia (XLTT), and rarely congenital erythropoietic porphyria.⁵¹⁴ All mutations described to date are within the N-terminal zinc finger of GATA1; mutations altering the interaction of GATA1 and its co-factor FOG1 are associated with XLT, whereas mutations altering the interaction of GATA1 and DNA are associated with XLTT. Features suggestive of a GATA1 mutation include X-linked recessive inheritance, macrothrombocytopenia, "gray platelets" with deficient alpha granules, red cell abnormalities including dyserythropoiesis or thalassemia, and hyperproliferation of megakaryocytes in the bone marrow. Although inheritance is X-linked, a mild phenotype due to skewed X-inactivation in female family members has been described.⁵¹⁵

FLI1: Although no specific FLI1 mutations have been described in patients with inherited thrombocytopenia, in Paris-Trousseau syndrome there is deletion of the terminal portion of chromosome 11q (11q23), and within the critical deleted region are several genes important to megakaryopoiesis, most notably ETS and FLI1.²¹⁸ Affected infants may have severe thrombocytopenia, congenital heart defects, and neurologic abnormalities.⁵¹⁶ Platelets are normal in size, but Romanovsky staining or electron microscopy reveals abnormal giant alpha granules and may show deficiency of dense

granules.^{517,518} Over time platelet counts improve and can reach near-normal levels, but a bleeding tendency that is out of proportion to the degree of thrombocytopenia frequently remains. Multiple genes are deleted; however, thrombocytopenia in Paris-Trousseau syndrome can be traced to the hemizygous loss of FLI1.⁵¹⁹

Macrothrombocytopenias: Giant platelet disorders include BSS and MYH9-related disease, although other thrombocytopenias are also characterized by large platelets. BSS is an autosomal recessive macrothrombocytopenia with significant platelet dysfunction due to the deficiency of GPIb, the platelet receptor for vWF. GPIb is composed of four subunits, encoded by four separate genes: GPIBA, GPIBB, GP5, and GP9. To date, mutations in BSS have been found in GPIBA, GPIBB, and GP9. Although BSS is classically inherited in an autosomal recessive fashion, the Bolzano mutation (c.515C>T transition in the GPIBA gene) is associated with mild macrothrombocytopenia in the heterozygous state.⁵²⁰ The mechanism of macrothrombocytopenia in BSS has been attributed at least in part to the interaction of GPIb with filamin A, a dimeric scaffolding protein.⁵²¹ This interaction may be critical for maintaining the platelet shape, as platelets from Flna- knockout mice are large and fragile despite normal GPIb expression.⁵²² Macrothrombocytopenia associated with mutation of FLNA has also been described in X-linked periventricular nodular heterotopia.⁵⁵ Gain-of-function mutations of GPIb are also associated with thrombocytopenia, due to inappropriate binding of platelets to vWF and consumption. This disorder resembles type 2B von Willebrand disease and is called platelet-type von Willebrand disease.⁵²³ In contrast to BSS, MYH9-related disease is inherited as an autosomal dominant disorder, and MYH9-related disease is also associated with progressive sensorineural deafness, nephropathy, and cataracts. Prior to discovery of the underlying gene defect, affected patients were diagnosed with various disorders, including May-Hegglin anomaly, Sebastian syndrome, Ebstein syndrome, and Fechtner syndrome.^{108,524,525} MYH9 encodes the heavy chain of myosin IIA, which is active in the organization of the DMS and in proplatelet formation.^{526,527} and ⁵²⁸ Review of the peripheral blood smear may reveal Dohle-like bodies within neutrophils, which represent the abnormal precipitated myosin.

Wiskott-Aldrich Syndrome: Wiskott-Aldrich syndrome is caused by mutations involving the WASp, which is a hematopoietic-specific regulator of actin polymerization encoded on the X-chromosome.¹⁰⁷ The full syndrome is manifested by microthrombocytopenia and impaired T-cell function, with eczema, frequent viral and bacterial infections, autoimmune phenomena, and predisposition to lymphoma.⁵²⁹ Mutations that only partially impair WASp function are associated with a less severe clinical course, typically X-linked microthrombocytopenia in the absence of significant immunodeficiency.⁵³⁰ This has been called X-linked thrombocytopenia or XLT, but it must be distinguished from XLT related to GATA1 mutations.

Granule Disorders: The study of disorders involving platelet α -granules (gray platelet syndrome) or dense granules (Hermansky Pudlak syndrome) has provided insights into the cellular mechanisms involved in granule formation in the megakaryocyte. Gray platelet syndrome (GPS) is characterized by thrombocytopenia with large platelets that appear pale on the peripheral blood smear due to a deficiency of α -granules. Families with X-linked disease are likely to have GATA1 mutations that can phenotypically resemble GPS (see above).⁵³¹ Recently, mutations in NBEAL2 (neurobeachin-like 2) were identified as the genetic cause of autosomal recessive GPS.^{532,533,534} The function of NBEAL2 is not understood but it is a member of a family of proteins that are involved in vesicular trafficking. In Hermansky Pudlak syndrome, defects in the biogenesis and trafficking of lysosome-related organelles, including melanosomes and platelet dense granules, underlie the hypopigmentation and bleeding manifestations characteristic of the disorder. At least seven mutations in human disease, as well as additional mutants in mouse models have been described, involving members of multiprotein complexes that function to regulate formation of, and cargo recruitment into, membrane-bounded transport carriers (AP-3), in the tethering and regulation of fusion between endosomal compartments (HOPS), and the intracellular positioning and movement of late endocytic organelles (HOPS and BLOC-3).⁵³⁵ Both α - and dense granules are deficient in gunmetal mice, in which mutation of Rab geranylgeranyl transferase disrupts membrane remodeling and granule packaging⁵³⁶; the human mutation has not been identified.

BCR/ABL-Negative Myeloproliferative Disorders: BCR/ABL-negative myeloproliferative disorders include PV, essential thrombocythemia (ET), and primary myelofibrosis (PMF). Acquired activating mutations in JAK2, typically Val617Phe but rarely alternative exon 12 mutations, can be found in most patients with PV, and nearly half of those with ET or PMF.^{537,538} and ^{539,540,541} Activating mutations in the transmembrane domain of c-Mpl, including Trp515Leu or Trp515Lys, are also found in a small proportion of patients with PMF and ET.⁵⁴² JAK2 contains two Jak homology domains: JH1, which represents the active kinase domain, and JH2, which lacks kinase activity and negatively regulates JH1.^{543,544} The Val617Phe mutation within JH2 disrupts this negative regulation.⁵⁴⁵ In addition, JAK2 Val617Phe is not downregulated normally by Lnk.⁴⁹⁸

In addition to these acquired conditions, familial thrombocytopenia has also been linked to inherited mutations that alter TPO signaling. The mutation Ser505Asn within the transmembrane domain of c-Mpl was identified in a large Japanese

family with thrombocytosis, and the mutant c-Mpl was shown to confer cytokine independence in a Ba/F3 cell line.³⁹⁵

Mutations

P.387

leading to overproduction of TPO have also been identified in families with thrombocytosis. The TPO gene displays an unusual 5' untranslated region structure. Unlike the majority of genes that initiate translation of the encoded polypeptide from the first ATG codon present in the mRNA, TPO translation initiates at the eighth ATG codon, located within the third exon of the full-length transcript.²⁵² Moreover, the eighth ATG is embedded in the short open reading frame (ORF) of the seventh ATG, a particularly inefficient circumstance for translation initiation.⁵⁴⁶ As such, little TPO protein is produced for any given amount of mRNA. Although it is not yet certain whether this molecular arrangement has physiologic consequences (i.e., if it can be differentially regulated), mutation of the TPO gene in noncoding sequences can lead to enhanced translation efficiency and thrombocytosis.⁵⁴⁷ Four pedigrees of familial, autosomal dominant thrombocytosis have been linked to mutations in the region surrounding the initiation codon. In two families, a single mutation in different nucleotides of the intron 3 splice donor sequence results in alternate splicing of the primary TPO transcript, eliminating the seventh and eighth ATG codons, and in the creation of a new amino terminus by the fusing of the fifth ORF with the TPO coding sequence. This novel TPO mRNA is efficiently translated, resulting in supraphysiologic levels of cytokine production and polyclonal expansion of thrombopoiesis.⁵⁴⁸ In another mutant TPO allele, the deletion of a single nucleotide within the seventh ORF leads to its fusion with the TPO coding sequence and to now-enhanced translation of TPO from the seventh ATG codon.⁵⁴⁹ Finally, another mutation within the seventh ORF leads to its premature termination, preventing its interference with translation initiation from the usual eighth initiation codon⁵⁵⁰ and again enhancing TPO production.

Transient Myeloproliferative Disorder and Acute Megakaryoblastic Leukemia: Approximately 10% to 20% of infants with Down syndrome develop transient myeloproliferative disease (TMD), in which immature megakaryoblasts accumulate in the liver, bone marrow, and peripheral blood. Although almost indistinguishable from acute megakaryoblastic leukemia (AMKL), this disorder undergoes spontaneous remission in most cases.⁵⁵¹ However, approximately 30% of children with a history of TMD go on to develop AMKL within 3 years. Certainly an extra copy of chromosome 21, which contains the gene *RUNX1*, predisposes these children to megakaryocytic proliferative disorders, although the exact role of trisomy 21 is unclear. However, acquired mutations of *GATA1*, resulting in the production of *GATA1S*, have been detected in the majority of Down syndrome patients with TMD and AMKL and represent an early step in leukemic transformation.⁵⁵² Note that *GATA1* mutations are not found in children with AMKL in the absence of Down syndrome, suggesting an important interaction between *GATA1S* and trisomy 21. Instead, a translocation between chromosomes 1 and 22, resulting in the fusion protein *OTT-MAL*, has been detected in AMKL occurring in children without Down syndrome.^{553,554} Expression of the *OTT-MAL* fusion protein in a conditional knockin mouse model led to expansion of multipotent myeloid progenitors, enhanced self-renewal of megakaryocytic progenitors, extramedullary hematopoiesis, and eventual development of AMKL.⁵⁵⁵ Further studies showed that expression of *OTT-MAL* activates *RBPJ*, which normally serves as a transcriptional coactivator of Notch, thus deregulating Notch signaling. The activation of *RBPJ*-mediated transcription by *OTT-MAL* is required for the growth of AMKL cells derived from leukemic animals.⁵⁵⁵

Chapter 16

Platelet Structure and Function in Hemostasis and Thrombosis

Susan S. Smyth

PLATELET STRUCTURE

Structural and Functional Anatomy

Light Microscopy

Light microscopy of Wright-stained smears (Fig. 16.1) reveals platelets as small, anucleate (i.e., lacking a nucleus) fragments with occasional reddish granules, measuring approximately 2 μm in diameter with a volume of approximately 8 fl^1 and exhibiting considerable variation in size and shape. Platelets released from the marrow under "conditions of stress" such as thrombocytopenia and termed stress platelets are large and often beaded in shape, whereas young platelets, recently released from the marrow, are termed reticulated in reference to their RNA content and in analogy to young red cell reticulocytes.²

Electron Microscopy and Subcellular Features

Platelets exist in two distinct forms, resting and activated, with the resting state marked by baseline metabolic activity and the activated form resulting from agonist stimulation (e.g., response to thrombin). By scanning electron microscopy, circulating resting blood platelets appear as flat discs with smooth contours, rare spiny filopodia (Fig. 16.2), and random openings of a channel system, the surface-connected canalicular system (SCCS), which invaginates throughout the platelet and is the conduit by which granule contents exocytose after stimulation.^{3,4} Although the platelet is anucleate, transmission electron microscopy reveals a complex surface and a cytoplasm packed with a number of different subplatelet structures and organelles that are essential to the maintenance of normal hemostasis (Figs. 16.3 and 16.4). Initial descriptions of platelet anatomy stem from studies employing transmission electron microscopy; and platelet structure is classified into four general areas: the platelet surface, membranous structures, cytoskeleton, and granules.

Platelet Surface

Plasma Membrane

The platelet plasma membrane separates intra- from extracellular regions and, in thin sections, exhibits a typical 20-nm-thick trilaminar structure⁵ whose overall appearance does not differ from that of other blood cells.⁶ The platelet membrane is exceptionally complex in composition, distribution, and function, incorporating a number of glycoproteins (GPs) and lipids into its phospholipid bilayer and integrating a variety of extra- and intraplatelet events such as permeability, agonist stimulation, and platelet adhesion, activation/secretion, and aggregation.

The lipid composition of the membrane is distributed in an asymmetric manner, with neutral species located mainly in the outer layer, and anionic forms, such as phosphatidylserine (PS), concentrated on the inner side.⁷ This sequestration of PS, which promotes plasma coagulation by contributing to the prothrombinase complex,⁸ on the inner side of the membrane may account for the fact that resting platelets are essentially nonreactive in terms of thrombin generation.⁹ On the other hand, activated platelets make a major contribution to thrombin formation through the interactions of factors Xa and Va and prothrombin on their surface.^{9,10} The plasma membrane also contains sodium and calcium adenosine triphosphatase (ATPase) pumps, which are important for maintaining ionic homeostasis.¹¹

Platelet Membranous Systems

Platelets have features of muscle-related cells in terms of their high content of actin and their contractile response during activation. Similar muscle-like qualities are found in the two membranous systems of platelets, the SCCS and the dense tubular system, which resemble transverse tubules and sarcotubules, respectively.¹²

Surface-connected Canalicular System

The SCCS, also called the open canalicular system, is fenestrated and contiguous with the surface plasma membrane.^{3,13,14} The SCCS has several prominent functional roles: first, as an internal reservoir of membrane to facilitate platelet spreading and filopodia formation after adhesion;¹⁵ and second, as a storage reservoir for membrane GPs, such as $\alpha_{\text{IIb}}\beta_3$ (GPIIb-IIIa), that increase on the platelet surface after activation.¹⁶ The system also provides a route for granule release during the secretory phase of platelet activation⁴ and serves as a route of ingress and egress for molecules as they translocate between the plasma and the platelet.

Dense Tubules

Unlike the SCCS, the dense tubular system is a closed-channel system consisting of narrow, membrane-limited tubules, approximately 40 to 60 nm in diameter.¹⁷ It contains residual smooth endoplasmic reticulum from the megakaryocyte.^{18,19} Peroxidase,^{20,21} and ²² glucose 6-phosphatase,²³ acetylcholinesterase (in cat, rat, and mouse but not human platelets or megakaryocytes),²⁴ adenylate cyclase, and Ca^{2+} - and Mg^{2+} -activated ATPases²⁵ have been cytochemically demonstrated in the dense tubular system.

This channel system is involved in the regulation of intracellular calcium transport because it has been reported to selectively bind, sequester, and release divalent cations after activation.²⁵

P.390

The dense tubular system is also the site of prostaglandin (PG) synthesis in platelets.^{26,27}

FIGURE 16.1. A human peripheral blood smear stained with Wright-Giemsa. Platelets, indicated by arrows, are interspersed between erythrocytes and a few leukocytes. The pale, grayish-blue cytoplasm contains purple-red granules. Original magnification of 35-mm slide $\times 100$.

FIGURE 16.2. Scanning electron micrograph of unstimulated human platelets. Most are discoid (d) in shape. Many surface indentations, indicated by arrows, are present; these correspond to openings of the surface-connected canalicular system to the external milieu. Magnification $\times 15,000$. (Data from Stenberg PE, Shuman MA, Levine SP, Bainton DF. Optimal techniques for the immunocytochemical demonstration of β -thromboglobulin, platelet factor 4, and fibrinogen in the alpha granules of unstimulated platelets. *Histochem J* 1984;16:983-1001.)

Platelet Cytoskeleton

(See additional cytoskeleton information in the section "Role of the Cytoskeleton in Platelet Function.")

The shape of platelets and their ability to contract and spread depend on an organized cytoskeleton.²⁸ The cytoskeleton can direct platelet shape change, send out extracellular extensions, collect and then extrude secretory granules, and affect surface reactivity (Fig. 16.5). These varied functions are performed by three distinct structures: first, the membrane skeleton, which buttresses the inner side of the plasma membrane; second, the mass of actin and intermediate filaments, which fills the cytoplasm; and third, the circumferential microtubule band, which encircles the substance of the platelet to produce the resting disk-like form.^{15,28} Three different protein filaments/tubules contribute to the overall network: 5- to 6-nm-diameter microfilaments of actin,^{29,30} 10- to 12-nm intermediate filaments of desmin and vimentin,^{31,32} and 25-nm microtubules composed mainly of tubulin.^{33,34} and ³⁵ Together, these filaments, depending on the activation state of the platelet, comprise 30% to 50% of total platelet protein.

FIGURE 16.3. Diagram of a human platelet displaying components visible by electron microscopy and cytochemistry. In addition to membranous components (plasma membrane, surface-connected canalicular system, and dense tubular system), mitochondria, microtubules, and glycogen, four types of storage organelles are identified: α -granules, dense bodies, lysosomes, and microperoxisomes. Whereas the first two can be identified morphologically, microperoxisomes and lysosomes are recognizable only by cytochemical stains. (From Bentfeld-Barker ME, Bainton DF. Identification of primary lysosomes in human megakaryocytes and platelets. *Blood* 1982;59:472-481, with permission.)

Membrane Skeleton

The membrane skeleton was first described more than 30 years ago by electron microscopy^{36,37} and then analyzed biochemically by detergent lysis in Triton X-100.^{28,38} The membrane skeleton contains short actin filaments that connect surface receptors with the bulk of cytoplasmic actin filaments.²⁹ Filamin-A, a component of the membrane cytoskeleton, links the cytoplasmic domain of GPIIb α with actin filaments and also binds integrins. Other components of the membrane skeleton include structural and signaling molecules such as spectrin, talin, migfilin, Src, and small GTPase family members (Table 16.1).^{15,28} Through tight regulation, the interactions of these proteins allow platelets to sense and to respond to environmental cues.

Cytoplasmic Actin and Intermediate Filaments

The bulk of the platelet cytoskeleton consists of a large amount of actin ($M_r = 42,000$) that comprises approximately 25% of total platelet protein.³⁹ Other platelet cytoskeletal proteins, such as tropomyosin and α -actinin, are present in lower amounts (2% to 5% of total platelet protein).^{40,41,42} and ⁴³ The actin exists in soluble, monomeric (G-actin), and filamentous (F-actin) forms and connects to both the membrane skeleton and the microtubules.¹⁵ In resting platelets, approximately 40% of actin is in microfilaments, which are dispersed throughout the cytoplasm and obscured by their small size and the

many other subplatelet structures present, such as granules.⁴⁴ The intermediate filaments are more stable, resistant structures, rich in vimentin, that appear to bear tension within the cytoplasm.³²

Platelet stimulation results in profound changes in cytoskeletal organization. Morphologically, platelets rapidly lose their discoid shape, become rounded, and extend filopodia.^{45,46} With the

P.391

rise in intracellular calcium, the proportion of F-actin increases rapidly to 60% or 70%.⁴⁶ Actin monomers polymerize into filaments at platelet peripheries,^{45,47} and bundles of new filaments form to fill developing filopodia.^{48,49} and⁵⁰ Phosphorylation of myosin light chain results in binding of myosin to actin,^{51,52,53} providing the tension required for granule centralization and retraction of filopodia.⁵⁴ Additional proteins, such as talin and surface $\alpha_{IIb}\beta_3$, join the developing electron-dense actin filaments, and the structure is remodeled through the action of an associated calciumdependent protease, calpain.⁵⁵ The sum of these events in platelet function is critical because the combination of various additions, rearrangements, and remodeling steps underpins shape change and spreading (filopodia and lamellipodia formation), along with platelet secretion and clot retraction.

FIGURE 16.4. Ultrastructure of unstimulated human platelets. Membranous organelles, including the surface-connected canicular system (SCCS) and dense tubular system (DTS), and cytoplasmic organelles, including mitochondria (M), α -granules (G), dense bodies (DB), coated vesicles (CV), and glycogen (GLY), are visualized at the ultrastructural level. Microtubules (MT) are present as cross-sectional and longitudinal profiles at the poles of the discoid platelets.

Magnification $\times 46,000$. Bar = $0.5 \mu\text{m}$.

Microtubules

A circumferential microtubule band that supports the discoid form of the platelet^{33,34} is made of two nonidentical subunit proteins (α - and β -tubulin), associated with microtubule-associated proteins. The 25-nm-diameter microtubule coil lies adjacent to, but does not touch, the plasma membrane.⁵⁶ Platelet microtubules comprise 13 protofilaments of $\alpha\beta$ tubulin dimers and are primarily polymerized in unstimulated platelets. Platelet activation results in microtubule disassembly and then reassembly; such alterations in the marginal microtubule bundle result in platelet shape changes.⁵⁶ Microtubules appear to be key determinates of platelet size⁵⁷ and may be disorganized in giant platelet disorders.⁵⁸

Platelet Granules and Organelles

Platelets possess secretory granules and mechanisms for cargo release to amplify responses to stimuli and influence the surrounding environment. Platelet granule structures include α - and dense granules, lysosomes, and peroxisomes. α -Granules and the dense bodies are the main secretory granules that release cargo (e.g., fibrinogen and adenosine diphosphate [ADP]) upon platelet activation.

FIGURE 16.5. Human platelet cytoskeletons prepared by simultaneous fixation and lysis in Triton X-100 detergent. Single actin filaments, indicated by short arrows, course throughout the platelet cytoplasm. Clusters of filaments, indicated by

long arrows, also are present. Note the microtubule coils at the platelet peripheries (arrowheads). Magnification $\times 30,000$. (From Boyles J, Fox JEB, Phillips DR, Stenberg PE. Organization of the cytoskeleton in resting, discoid platelets: preservation of actin filaments by a modified fixation that prevents osmium damage. *J Cell Biol* 1985;101:1463-1472, with permission.)

Platelet granule secretion begins with a dramatic increase in platelet metabolic activity, set off by a wave of calcium release and marked by increased adenosine triphosphate (ATP) production.⁵⁹ After platelet stimulation by agonists, a “contractile ring” develops around centralized granules,^{5,6} the granules fuse with the surface membranes, and then they extrude their contents.⁶⁰ The molecular events underlying platelet granule release involve many of the same proteins and processes observed in other systems of membrane docking, fusion, and extrusion.^{61,62} Granule secretion in platelets is a graded process that depends on the number, concentration, and nature of the original stimulus/stimuli, either strong (e.g., thrombin and collagen) or weak (e.g., ADP and epinephrine).⁶²

α -Granules

α -Granules, with a cross-sectional diameter of approximately 300 nm and numbering approximately 50 per platelet, are the predominant platelet granules.⁶³ They are approximately spherical in shape, with an outer membrane enclosing two distinct intragranular zones that vary in electron density. The larger, electron-dense region is often eccentrically placed and consists of a nucleoid material that is rich in platelet-specific proteins such as β -thromboglobulin.⁶⁴ The second zone, of lower electron density, lies in the periphery adjacent to the granule membrane and contains tubular structures with adhesive GPs such as von Willebrand factor (vWF) and multimerin,

P.392

along with factor V.^{65,66,67} Platelets take up plasma proteins and store them in their α -granules.^{68,69,70} Select α -granule proteins are discussed below and listed in Table 16.2.

TABLE 16.1 MAJOR PLATELET CYTOSKELETAL PROTEINS

Protein	Molecular Weight	Principal Known Function
Actin	42,000	Major protein constituent of microfilaments; 30% of platelet protein; F-actin binds myosin.
Myosin II	500,000	Binds actin; phosphorylation of light chains contracts microfilaments; 4% of platelet protein.
Talin	235,000	Interacts with α -actinin, vinculin; 2% of platelet protein.
Vinculin	130,000	Interacts with talin; links to actin.
α -Actinin	102,000	Dimer forms a gel with F-actin; promotes actin polymerization.
Actin-binding protein (filamin 1)	260,000	Cross-links actin filaments; links membrane skeleton with glycoprotein Ib-IX complex.
Gelsolin	91,000	Caps and severs actin filaments.
Thymosin β_4	5,000	Binds 1:1 with G-actin monomer and inhibits its polymerization.
Profilin	15,200	Binds 1:1 with G-actin and inhibits its polymerization; adds adenosine triphosphate.
Tropomyosin	28,000	Binds groove on certain F-actins.
Caldesmon	80,000	Regulates actomyosin ATPase and actin bundling.
Myosin light chain kinase	105,000	Phosphorylates myosin, activates its ATPase, and causes contraction.

Calmodulin 17,000 Binds four Ca^{2+} ; activates myosin light chain kinase.
ATPase, adenosine triphosphatase.

Three proteins, β -thromboglobulin, PF4, and thrombospondin, are synthesized in megakaryocytes and highly concentrated in α -granules. The first two, β -thromboglobulin and PF4, show homology in amino acid sequence and share the additional features of localization in the dense nucleoid of α -granules, heparin-binding properties, and membership in the CXC family of chemokines.^{14,71,72,73} and⁷⁴ Together, they constitute approximately 5% of total platelet protein, and they can serve as useful markers for platelet activation in serum or plasma.^{75,76} Thrombospondin may comprise up to 20% of the total platelet protein released in response to thrombin, and likely participates in multiple biologic processes.^{77,78}

vWF is also synthesized by megakaryocytes and is present in the tubular structures of the α -granule peripheral zone, similar to its localization within Weibel-Palade bodies of vascular endothelial cells.^{66,79} Factor V and multimerin, a factor V/Va-binding protein,^{67,80} co-localize with vWF in platelets but not in endothelial cells. Fibrinogen is also found in α -granules, but is incorporated actively from plasma and not synthesized by megakaryocytes.⁶⁹ In fact, small amounts of virtually all plasma proteins, such as albumin, immunoglobulin G (IgG), fibronectin, and β -amyloid protein precursor, may be taken up into the platelet α -granules.^{79,81,82} and⁸³ α -Granules also contain many growth factors, including platelet-derived growth factor, transforming growth factor- β_1 (TGF- β_1), and vascular endothelial growth factor. These signaling molecules may contribute to the mitogenic activity of platelets.^{84,85} A role for platelet α -granule proteins in angiogenesis has been recently reported. Both pro- (e.g., VEGF) and antiangiogenesis proteins (e.g., endostatin) are stored within α -granules. How populations of angiogenesis regulatory proteins may be selectively compartmentalized and released from platelets is an area of active investigation.^{86,87,88,89} and⁹⁰ Likewise, the activation and functions of platelet-derived TGF- β_1 in cardiac fibrosis and other conditions have been described.^{91,92}

Platelet α -granules serve as an important reservoir for $\alpha_{IIb}\beta_3$ that contributes significantly to the surface fibrinogen receptors present on activated platelets.^{93,94,95} The α -granule membrane protein, P-selectin (granule membrane protein-140) is translocated to the plasma membrane after platelet activation.^{96,97} Finally, a number of additional proteins have been located to the surface of α -granules alone, including CD9, platelet endothelial cell adhesion molecule-1 (PECAM-1), Rap 1b, GPIb-IX-V, and osteonectin^{98,99} and¹⁰⁰ (Table 16.2).

The platelets and megakaryocytes of patients with gray platelet syndrome have decreased numbers of α -granules and reduced levels of some proteins. It is proposed that there is incorrect targeting of α -granule proteins to the α -granule in the megakaryocyte in this disease.^{101,102}

Dense Bodies

Dense bodies, numbering approximately five per platelet, are exceptionally electron-dense and easily distinguished by electron microscopy because of their distinctive "bull's-eye" appearance.^{103,104} With an approximate diameter of 250 nm, these granules contain a large reservoir of ADP, a critical agonist for platelet activation that amplifies the effect of other stimuli.¹³² In addition to this nonmetabolic pool of ADP, the dense bodies are rich in ATP, pyrophosphate, calcium, and serotonin (5-hydroxytryptamine), with lesser amounts of guanosine triphosphate (GTP), guanosine diphosphate (GDP), and magnesium.⁷⁴ The adenine nucleotides are synthesized and segregated by megakaryocytes, whereas serotonin is incorporated into dense granules from the plasma by circulating platelets.^{133,134,135} There is more ADP than ATP in dense bodies, and both can lead to adenosine monophosphate (AMP). In turn, AMP can be dephosphorylated to adenosine or cyclized to produce cyclic AMP, an inhibitor of the platelet-stimulatory response. The dense granule membrane contains P-selectin and granulophysin.¹³⁶

Lysosomes

Lysosomes are small, acidified vesicles, approximately 200 nm in diameter,¹⁰⁵ that contain acid hydrolases with pH optima of 3.5 to 5.5, including β -glucuronidase, cathepsins, aryl

P.393

sulfatase, β -hexosaminidase, β -galactosidase, heparitinase, and β -glycerophosphatase. Additional proteins found in lysosomes include cathepsin D and lysosome-associated membrane proteins (LAMP-1/LAMP-2), which are expressed on the plasma membrane after activation).^{106,107} Lysosomal constituents are released more slowly and incompletely (maximally, 60% of the granules) than α -granules or dense-body components after platelet stimulation, and their release also requires stronger agonists such as thrombin or collagen.

TABLE 16.2 MAJOR PLATELET GRANULAR CONSTITUENTS SECRETED WITH ACTIVATION

α -Granule Protein	Comments	Amount/ 10^9 Platelets	Concentration in Platelets >Plasma
Coagulant Proteins			
Fibrinogen	Critical ligand for aggregation	140 μ g	3 \times conc. platelets >plasma
Factor V	Critical cofactor for coagulation	4 μ g	30 \times conc. platelets >plasma
Platelet-Specific Proteins			
Platelet factor 4	Marker for platelet activation	12 μ g	20,000 \times conc. platelets >plasma
β -Thromboglobulin	Marker for activation	10-20 μ g	20,000 \times conc. platelets >plasma
Mitogenic and Angiogenic Factors			
Platelet-derived growth factor	Smooth muscle mitogen	30-100 ng	
Transforming growth factor- β	Complex activation pathway; binds thrombospondin		
Vascular endothelial growth factor	Relatively high concentrations in platelets		
Adhesive Glycoproteins and α-Granule Membrane-Specific Proteins			
Thrombospondin	Multiple complexes	40 μ g	20,000 \times conc. platelets >plasma
von Willebrand factor (vWF)	Role in adhesion	0.3 μ g	100 \times conc. platelets >plasma
Multimerin	Binds factor V; resembles vWF-binding factor VIII; has RDG sequence		
P-selectin	Mediates platelet-leukocyte binding	20,000 copies on activated platelets	
Dense Granule Constituent			
Constituent	Comments	Concentration in Granules (nmol/mg Dense Granule Protein)	Percent Secreted
Adenosine diphosphate	Highly concentrated; a critical mediator of aggregation	630	95% secreted with platelet activation
Adenosine triphosphate		440	40% released with activation
Calcium		2,630	70% secreted with activation
Serotonin		100	95% released with activation

conc., concentration.

Note: A number of additional elements are released or secreted from within the platelet. For example, α -granules also contain the major platelet surface glycoproteins (GPs) GPIIb-IIIa and GPIb-IX along with albumin and immunoglobulin G, adhesive glycoproteins (fibronectin, vitronectin), fibrinolytic components (α_2 -antiplasmin, plasminogen activator), and coagulation-related proteins (high-molecular-weight kininogen, α_2 -macroglobulin). In addition, dense granules contain guanosine triphosphate/guanosine diphosphate and high concentrations of pyrophosphate, phosphate, and magnesium, much of which is secreted with activation. A number of additional proteins are present, some released and some retained in the platelet cytosol, such as a subunit of factor XIII, amyloid β -protein precursor, protease nexin I, and tissue factor pathway inhibitor.

Organelles: Microperoxisomes, Coated Vesicles, Mitochondria, and Glycogen

Peroxisomes are rare, small (90 nm in diameter) granules, demonstrable with alkaline diaminobenzidine as a result of their catalase activity.¹⁰⁸ The structure may participate in the synthesis of platelet-activating factor.¹⁰⁹

Mitochondria in platelets are similar, with the exception of their smaller size, to those in other cell types. There are approximately seven per human platelet, and they serve as the site for the actions of the respiratory chain and the citric acid cycle.¹¹⁰ Glycogen is found in small particles or in masses of closely associated particles, playing an essential role in platelet metabolism.¹¹¹

Platelet Biochemistry and Metabolism

Composition

The platelet is composed of approximately 60% protein, 15% lipid, and 8% carbohydrate by dry weight. Platelet minerals include magnesium, calcium, potassium, and zinc. Platelets contain substantial amounts of vitamin B₁₂, folic acid, and ascorbic acid.¹¹² The concentrations of sodium and potassium within the platelet are 39 and 138 mEq, respectively.¹¹³ This gradient against plasma, apparently distributed in two discrete metabolic compartments, is maintained by an active ion pump, which derives energy from a membrane ATPase of the ouabain-sensitive, Na⁺/K⁺-dependent type.¹¹⁴

Unstimulated platelets maintain a low cytoplasmic Ca²⁺ concentration (~100 to 500 nmol/L) by limiting Ca²⁺ transport from plasma and promoting active efflux of this ion from the cell.¹¹⁵ Two pools of calcium are present in platelets: a rapidly turning over cytosolic pool regulated by a sodium-calcium antiporter in the plasma membrane and a more slowly exchanging pool regulated by Ca²⁺/Mg⁺-ATPase and sequestered in the dense tubular system.¹¹⁶ Platelets are therefore able to transport calcium from the cytosol by moving it against a gradient into the extracellular space or by sequestration in the dense tubular system.

P.394

Energy Metabolism and Generation of ATP

There are several similarities between the energy metabolism of the platelet (Fig. 16.6) and that of skeletal muscle. Both involve active glycolysis and the synthesis and use of large amounts of glycogen,¹¹⁷ and in both, the major mediator of intracellular energy use is an actomyosin-like ATPase. The platelet, like muscle, is metabolically adapted to expend large amounts of energy rapidly during aggregation, the release reaction, and clot retraction.

The major energy source for the platelet is glucose, which is rapidly taken up from the plasma (Fig. 16.6, Step 1). Under basal conditions, 40% to 50% of the absorbed glucose is used to provide energy for synthetic functions or is converted into glycogen. Electron microscopy reveals prominent masses of glycogen in some platelets. The glycolytic pathway with its regulatory enzymes (phosphorylase, pyruvate kinase, hexokinase, phosphofructokinase, and glyceraldehyde 3-phosphate dehydrogenase),¹¹⁷ the citric acid cycle, the pentose phosphate shunt, and the NAD-NADH (nicotinamide adenine dinucleotide-nicotinamide adenine dinucleotide [reduced form]) system are all active in the platelet. Ninety-eight percent of platelet pyruvate is converted to lactate, which leaves the platelet.¹¹⁸ and ^{119,120} In addition to glycolysis, platelets contain enzymes for oxidative phosphorylation and fatty acid oxidation (Fig. 16.6, Step 2).^{121,122}

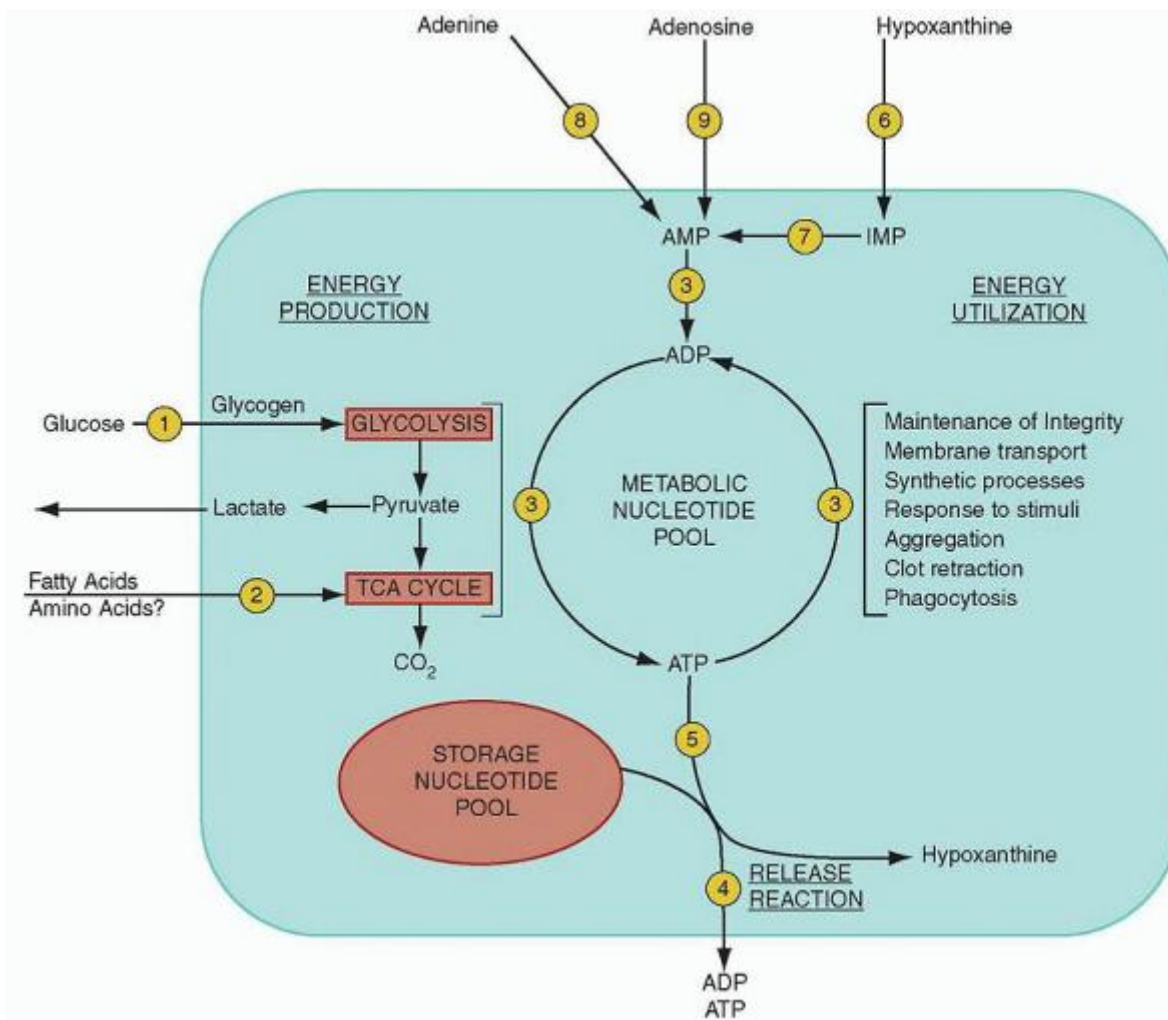

FIGURE 16.6. Simplified scheme of platelet energy metabolism. Platelet energy is derived from the metabolism of glucose and, to a lesser extent, from the metabolism of fatty acids. Energy is provided in approximately equal amounts by glycolysis and the citric acid cycle. The platelet energy reserve is provided by the metabolic pool of platelet nucleotides that is in a state of continuous turnover. This energy is used for the maintenance of the platelets' structural integrity and in the reactions accompanying the response of platelets to stimuli. The granule-bound storage (nonmetabolic) nucleotide pool is discharged during the release reaction. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; IMP, inosine monophosphate. (Adapted from Hirsh J, Doery JCG. Platelet function in health and disease. *Prog Hematol* 1972;7:185-234.)

ATP production in platelets is affected greatly by the suspending medium, chelating agents, and in vitro manipulation of platelets. In plasma, oxidative ATP production by unstimulated platelets is predominant, and all ATP formed by oxidative phosphorylation may be the product of β -oxidation of fatty acids;¹²³ glycogen turnover, the hexose monophosphate shunt, and the citric acid cycle are virtually inactive.¹²⁰ Glycolysis is capable of completely compensating for reduced ATP production when oxidative phosphorylation is inhibited. Platelet stimulation by agents that induce aggregation and release is associated with a marked increase in metabolic activity involving glycogenolysis,¹²⁴ as well as with glycolysis and oxidation to varying degrees.^{117,125}

The total amounts of ATP synthesized by the two pathways are approximately equal because of the greater ATP yield per mole of glucose provided by oxidation.^{118,122} ATP energy is used in unstimulated platelets to maintain homeostatic levels of H⁺, K⁺, Na⁺, and Ca²⁺.^{126,127}

Nucleotide Metabolism and the Nonmetabolic Role for ADP

Adenine nucleotides constitute 90% of free platelet nucleotides and are partitioned into at least two different pools, which undergo minimal interchange (Fig. 16.6).⁹⁷ The metabolic or

cytoplasmic pool makes up 40% of total adenine nucleotides; it is used for the maintenance of various energy-consuming cell functions and is retained during platelet release. In large part made up of ATP, this pool is constantly turning over, as revealed by the rapid incorporation of ^{14}C -adenine and ^{32}P -phosphate into ATP. In unstimulated platelets, the relative concentrations of metabolic AMP, ADP, and ATP are maintained by the enzyme adenylate kinase (Fig. 16.6, Step 3).¹²⁸

The storage pool, which is present in the dense bodies, contains approximately two-thirds of the total platelet nucleotides, mainly in the form of ADP and ATP.¹²⁹ It is metabolically inactive, does not rapidly incorporate exogenous adenine or phosphate, and equilibrates slowly with the metabolic pool.¹³⁰ Nucleotides in this pool are extruded from the platelet during the release reaction (Fig. 16.6, Step 4) and cannot be replenished after release. ATP hydrolysis is required for conversion of G-actin to F-actin, and the resultant ADP becomes associated with F-actin; this small percentage of platelet ADP bound to actin constitutes one-third of the nucleotide compartment.¹³¹ Perhaps as much as 40% of all ATP produced is used during the process of actin treadmilling,¹³² and as much as 7% is used in the turnover of the phosphoinositides PIP and PIP₂.¹³³

The ATP that is broken down to provide energy for the release reaction is not rephosphorylated; rather, it is irreversibly degraded to hypoxanthine (Fig. 16.6, Step 5), which diffuses out of the cell.¹²⁸ This reaction also proceeds slowly in stored normal platelets.¹⁷⁰ Hypoxanthine in the plasma may be reincorporated slowly into metabolic AMP by the salvage pathway (Fig. 16.6, Steps 6 and 7).^{129,134} Platelet stimulation results in marked activation of ATP-producing pathways.¹³⁵ The steady-state level of ATP decreases and hypoxanthine accumulates. In addition, a transient but greatly increased uptake of phosphate by platelets occurs.¹³⁶ Although ATP-requiring processes are activated by platelet stimulation, it is unknown whether or how these are coupled to signal processing in platelets.

Lipid Composition and Metabolism and the Generation of Arachidonic Acid

Phospholipids constitute 80% of total platelet lipid, with neutral lipids and glycolipids comprising the remainder.¹³⁷ The five major phospholipids identified in human platelets are phosphatidylcholine (PC, 38% of total phospholipids), phosphatidylethanolamine (PE, 27%), sphingomyelin (17%), PS (10%), and phosphatidylinositol (PI, 5%).⁸ Studies of platelet subcellular fractions reveal that 57% of total human platelet phospholipids are present in the plasma membrane.¹³⁸ Most of the negatively charged phospholipids (i.e., PE, PI, and PS) are contained in the inner leaflet,^{138,139} and ¹⁴⁰ an asymmetric arrangement that prevents inappropriate coagulation by sequestering the phospholipids that accelerate plasma coagulation (mainly PS) away from the platelet surface. This asymmetry collapses when platelets are activated.¹⁴¹ These same phospholipids (i.e., PS and PE, which interact with coagulation proteins) redistribute with platelet activation and are thereby exposed on the surface to function in promoting clot formation.¹⁴² The asymmetric distribution of phospholipids on the platelet surface appears to be maintained by one or more membrane scramblase enzymes; and a "floppase" has been proposed to reverse the phospholipid asymmetry with activation.

Almost all platelet fatty acids are esterified in phospholipids, leaving only trace amounts in the free form. Platelet phospholipids are enriched in arachidonate, the precursor of prostaglandins, at their "sn-2" position.¹⁴³ After agonist stimulation, phospholipase A₂ activity rises, and arachidonic acid is released from membrane phospholipids, predominantly PC.^{144,145,146} After release, arachidonic acid is oxygenated to form the cyclic endoperoxide intermediate, PGH₂, by cyclo-oxygenase-1, which leads to TxA₂ formation.¹⁴³ The lipoxygenase pathway accounts for a small proportion of arachidonate metabolism, producing mainly 12-HETE (12-hydroxyeicosatetraenoic acid).

Neutral lipids, mainly cholesterol, make up approximately 28% of total platelet lipids. Cholesterol is a major constituent of platelet membranes and is also present in the platelet cytoskeleton.¹⁴⁷ It is synthesized by megakaryocytes but not by platelets. Finally, neutral glycolipids, gangliosides, and ceramides have been detected in platelets.¹⁷⁹

Platelet Microparticles and Kinetics

Microparticles

Platelet microparticles are tiny structures rich in surface PS that are generated during platelet activation and can contribute significantly to the acceleration by platelets of plasma coagulation, specifically factor Xa and thrombin generation.¹⁴⁸ The composition of microparticles varies with the agonist or stimulus (C5b-9, ionophore A23187, thrombin, tissue factor, shear) involved in their formation,^{149,150} and have been found to bind factors Xa, VIII, and Va, along with protein S.^{151,152} Physiologically, microparticles appear to be an important contributor to procoagulant activity as their defect in patients is associated with clinical bleeding.^{153,154}

Platelet Heterogeneity

The normal platelet count varies between 150,000 and 400,000/ μl , and normal platelet size (mean platelet volume) varies between 7.5 and 10.5 fl. Platelets are released into the blood from long proplatelet extensions of megakaryocytes.¹⁵⁵

Young platelets, that is, those recently released by megakaryocytes, are larger and more dense, and undergo remodeling in circulation, in part by shedding some of their surface components. Macrothrombocytopenias may reflect a disturbance in the steps of platelet production,¹⁵⁶ and the properties of large platelets may reflect unique attributes of platelets recently released from the marrow or proplatelets produced under conditions of accelerated or abnormal production.

Platelet Distribution and Survival Kinetics

Labeling

Platelets labeled with ⁵¹Cr (chromate) have been used to estimate platelet lifespan in humans at 8 to 12 days,¹⁵⁷ and the method has been widely validated.¹⁵⁸ Other methods reported for platelet labeling include ¹¹¹In (indium) chelated with 8-hydroxyquinoline and ³²P-labeled diisopropylfluorophosphate, ⁶⁸Ga (gallium).¹⁵⁹ Platelet labeling is not commonly used for clinical evaluations, but all of the published studies give the same approximate values for distribution and survival.

Distribution

Approximately one-third of the total platelet mass appears to pool in the spleen. The splenic pool exchanges freely with the platelets in the peripheral circulation. Transfusion of ⁵¹Cr-labeled platelets into normal subjects results in approximately two-thirds remaining in the circulation—in contrast to nearly 100% in splenectomized patients.^{160,161} In addition, administration of epinephrine, which evacuates platelets from the spleen, increases the peripheral platelet count 30% to 50%.¹⁶² Platelet counts in asplenic patients are not affected by epinephrine. Some studies suggest that the splenic pool consists of the youngest, largest platelets. The mechanism of splenic sequestration has been hypothesized to result from a longer transit time through the splenic cords (which platelets enter because of their small size) or from binding to the reticular and endothelial cells of the spleen.¹⁶³ Pathophysiologic states can result in 80% to 90% of platelets being sequestered in the spleen, resulting in thrombocytopenia. Release of platelets from the lungs after intracardiac administration of epinephrine has been reported.¹⁶⁴ Also, platelet counts rise after

P.396

vigorous exercise, and this rise is not affected by splenectomy.¹⁶⁵ This nonsplenic pool represents approximately 16% of the total platelet mass.

Life Span

Platelet life span, based on the time required to clear labeled platelets from the circulation, has been estimated to be 8 to 12 days in humans. In steady state, when platelet production equals destruction, platelet turnover has been estimated at 1.2 to 1.5 $\times 10^{11}$ cells per day.^{160,166} Recommendations for estimation of platelet lifespan have been published by the Panel on Diagnostic Application of Radioisotopes in Hematology, International Committee for Standardization in Hematology,¹⁶⁶ and multiple models for analysis of platelet lifespan have been proposed.¹⁶⁷ As discussed above, platelets may be removed from circulation by pooling in the spleen,¹⁶¹ the liver, and the lung.¹⁶⁴

Platelet life span is regulated by Bcl-2 proteins.^{168,169} Platelet Bcl-x(L) is required for survival by suppressing Bak. Bak activation results in classic apoptosis pathways that result in mitochondrial damage, caspase activation, and PS exposure. Platelets from Bak-deficient animals live longer than normal,¹⁶⁹ indicating a predetermined program of platelet death.

Interactions beyond Platelets: The Coagulation System

Platelet Interactions with the Plasma Coagulation System

Activated platelets accelerate thrombin generation. The production of factor Xa and thrombin is the result of the coagulation “cascade” in which a series of successive calcium-dependent complexes is generated by the extrinsic and intrinsic pathways.¹⁷⁰ The complex development occurs primarily on phospholipid surfaces.^{171,172} Soluble Xa binds avidly to Va on the surface of activated platelets, indicating that the surface of activated platelets is likely a major site for coagulation reactions.¹⁷³ The precise elements involved in “platelet-based coagulation” remain to be elucidated. Platelet-bound VIIIa may serve as a binding site for IXa and, in addition to factor Va, the effector cell protease receptor-1 (EPR-1) has been identified as a factor Xa-binding site. An additional receptor(s) for IXa may also exist. Whether specific receptors for VIIIa and Va exist or if they bind to exposed PS is not entirely established. Unlike factor V, it is not clear if factor VIII is present within resting, unactivated platelets. Platelets do not appear to take up significant amounts of plasma vWF with bound factor VIII—a clear difference from their active uptake of plasma fibrinogen.⁷⁰

Thrombin can activate factor XI, particularly on platelet surfaces or in the presence of proteoglycans.^{174,175} In this instance, traces of thrombin, generated through tissue factor from sites of cellular injury, activate plasma factor XI (bound to platelets through the presence of prothrombin itself), which, in turn, activates plasma factor IX and leads to a subsequent dramatic increase in thrombin production.^{176,177} and ¹⁷⁸ Such a sequence of events is favored by the presence of platelets that protect any surfacebound reactants from soluble inhibitors. The process may also conserve a small amount of initial thrombin by linking it to immobilized protein substrates, away from plasma inhibitors.¹⁷⁸ The data are consistent with the clinical observation that the amount of platelet factor XI, rather than plasma factor XI, determines the bleeding severity in deficient patients, and the information explains how factor XI can be activated regardless of other contact factors.^{179,180}

This work illustrates that platelets play a multifaceted role in coagulation and emphasizes the fundamental difference between resting platelets with no ability to accelerate coagulation and agonist-activated platelets, which are intensely active participants. Both intact platelets and platelet microparticles may contribute to these processes. Regardless of the exact mechanisms involved, the binding of any coagulation factor to a high-affinity binding site on the platelet plasma membrane concentrates that factor locally and can orient it with respect to other factors. Also, multiple studies show that platelet surface-bound coagulation proteins are generally protected from their usual plasma inhibitors.¹⁸¹ Finally, such binding (e.g., factor Xa to activated platelets) can facilitate the rapid delivery of a potent coagulant and potential agonist to a site of vessel injury, where it may be most valuable in hemostasis.

Platelet Forms of Plasma Proteins

Three factors (factor V, fibrinogen, and vWF) found in platelet α -granules contribute significantly to coagulation (Table 16.3). Platelets have particularly large amounts of fibrinogen, which they do not synthesize, and lesser amounts of vWF, which they do. The origin of FV appears to be a combination of incorporation from plasma and de novo synthesis in megakaryocytes. The bulk of FV (20% of total factor V in blood) is located in the α -granules, and the thrombin-activated form, factor Va, is the major secreted platelet phosphoprotein.^{182,183} The distinct and critical role of FV in hemostasis is underscored by the findings in two kindreds of factor V Quebec, in which a selective defect in α -granule factor V (plasma factor V is nearly normal), probably due to excessive granule-based proteolysis, is accompanied by a severe bleeding diathesis.^{184,185} Platelet fibrinogen constitutes up to 10% of total platelet protein.^{186,187} Platelet vWF is present in relatively large amounts in α -granules, and may play a role in platelet adherence to subendothelium.¹⁸⁸

Other Platelet-associated Coagulation Factors

The numerous platelet proteins that participate in plasma coagulation are listed in Table 16.3. Several additional plasma coagulation factors are associated with platelets, along with a variety of coagulation inhibitors as noted in the following. FXIII is contained in the cytosol and is not organelle-associated; it is a fully active subunit of plasma factor XIII. FXIII makes up 50% of the total amount of factor XIII activity in blood. It has been suggested that it provides a subunit for plasma factor XIII.¹⁸⁹ High-molecular-weight kininogen is present in α -granules and is secreted and expressed on the platelet plasma membrane after thrombin activation.¹⁹⁰ Platelets contain 2.5% of protein S found in whole blood. This protein is synthesized in megakaryocytes, stored in α -granules, and released from platelets on thrombin stimulation.¹⁹¹ Additionally, platelet-dense granules contain polyphosphate at a concentration of approximately 130 mM,¹⁹² which is released upon platelet activation. Polyphosphate, a highly anionic polymer, activates the contact pathway, heightens Va activation, and accelerates thrombin generation.^{193,194} Polyphosphates also incorporate into fibrin clots and may alter clot structure.¹⁹⁴

Protease Inhibitors

All known plasma protease inhibitors¹⁹⁵ are also localized to platelet α -granules. These include α_1 -protease inhibitor, α_2 -macroglobulin, C1 inhibitor, α_2 -antiplasmin, plasminogen activator inhibitor-1, lipoprotein-associated coagulation inhibitor, protease nexin I (thrombin inhibitor), and protease nexin II (factors IXa and XIa inhibitors).

Clot Retraction

When whole blood is placed in a glass tube and simply left to clot for several hours at ambient temperature, clear serum is expressed from the bulk of the fibrin-red cell mass as platelets exert their global contractile potential.¹⁹⁶ Clot retraction in vitro requires the major surface integrin $\alpha_{IIb}\beta_3$ (or GPIIb-IIIa)¹⁹⁷ and

P.397

contractile proteins actin and myosin, including the non-muscle myosin heavy chain IIA.¹⁹⁸ Integrin activation by talin is required for clot retraction,¹⁹⁹ However, beyond these broadly based studies, relatively few additional details are available to translate this dramatic laboratory event into a physiologic mechanism.

TABLE 16.3 PLATELET-ASSOCIATED COAGULATION FACTORS

Protein	Amount Present	Subcellular Localization	Mechanism of Release or Exposure	Proposed Function
Fibrinogen				
Total	5-25 mg/10 ¹¹ platelets ^a			
Surface-associated	0.3-10.0 mg/10 ¹¹ platelets ^{b, c}	Adsorbed to platelet	Not released	Platelet aggregation by adenosine diphosphate
Intracellular	3-7 mg/10 ¹¹ platelets ^a	Membrane α -granules	Secretion	Platelet aggregation by thrombin
Factor V	0.25-0.77 mg/10 ¹¹ platelets ^b	α -Granules	Secretion	Receptor for factor Xa
von Willebrand factor	10-64 units/10 ¹¹ platelets	α -Granules	Secretion	Platelet adhesion
Factor XI	1.2-6.1 units/10 ¹¹ platelets ^a	Platelet membrane	Unknown	Initiation of intrinsic coagulation
Factor XIII	50% of the total in blood ^a	Cytosol	Not released	α Subunit of factor XIII
High-molecular-weight kininogen	60 μ g/10 ¹¹ platelets ^d	α -Granules	Secretion	Contact activation of coagulation

^cQuantitation by electroimmunodiffusion.

^dQuantitation by competitive enzyme-linked immunosorbent assay.

PLATELET ADHESION AND ACTIVATION

Primary hemostasis and arterial thrombosis are the results of a complex series of cell-cell, cell-protein, and protein-protein reactions that involve platelets, leukocytes, endothelium, subendothelial matrix, and plasma proteins, such as fibrinogen, vWF, and others. The consequences of arterial thrombosis include such events as myocardial infarction (MI), unstable angina, and stroke. These clinicopathologic entities and their associated cellular physiologic mechanisms that are outlined in this chapter, collectively account for the largest cause of morbidity and mortality in the Western world.

Platelet adhesion to exposed subendothelium is a complex multistep process that involves a diverse array of adhesive ligands (vWF, collagen, fibronectin, thrombospondin, and perhaps laminin) and surface receptors (GPIb/V/IX, GPVI, integrins $\alpha_{IIb}\beta_3$, $\alpha_2\beta_1$, $\alpha_5\beta_1$, and $\alpha_6\beta_1$).^{200,201,202,203} The specific ligand/receptor players in primary platelet adhesion are largely dependent on the arterial flow conditions present.²⁰⁴ As such, in larger arteries and veins, platelet adhesion to the vessel wall is thought to involve fibrillar collagen, fibronectin, and laminin. There are at least 25 forms of collagen, and several of these are present in the blood vessel wall, while one (type IV) is present in the subendothelial basement membrane.^{205,206} In high shear conditions, platelet tethering is dependent on the unique shear-dependent interaction between GPIb/V/IX and subendothelial vWF, derived either from plasma or released by endothelial cells and/or platelets.²⁰⁷ A tether forms between GPIb and vWF that either halts platelet movement or reduces it such that other interactions can proceed. Subsequent interactions are mediated by GPVI binding to glycineproline-hydroxyproline sites on

collagen and perhaps to exposed laminin.²⁰⁷ The interaction of GPVI with collagen strongly activates platelets such that integrins, including $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$ (GPIIb-IIIa), can engage in high-affinity interactions with ligands.

Following initial platelet adhesion, subsequent platelet-platelet interactions are initially mediated by two receptors, GPIb/V/IX and $\alpha_{IIb}\beta_3$, and their respective contributions are dependent on the flow conditions present. In high shear stress conditions, GPIb/V/IX receptor and vWF ligand action are predominant, with fibrinogen playing a stabilizing role. At low shear conditions, fibrinogen is thought to be the primary ligand supporting platelet plug formation through its interaction with $\alpha_{IIb}\beta_3$, although thrombus formation can take place in the absence of vWF and fibrinogen, so other ligands may also be involved.²⁰⁸

Platelet Glycoprotein Ib Complex-von Willebrand Factor Interaction and Signaling

The interaction of the platelet GPIb "complex" (the polypeptides GPIb α , GPIb β , GPIX, and GPV) with its primary ligand, vWF, is the receptor-ligand pairing that initiates platelet adhesion followed by a cascade of events leading to pathologic thrombosis or physiologic hemostasis. A unique aspect of this receptor-ligand interaction is that it requires the presence of high arterial shear rates to take place, thus explaining the predisposition of platelet-rich "white clots" in the arterial circulation over clots found in the venous circulation, with its relatively lower shear forces, in which clot formation takes place independent of the GPIb complex.

The GPIb complex consists of four transmembrane subunits, each of which is a member of the leucine-rich repeat protein superfamily that participates in cell-matrix interactions throughout nature. Each of the four subunits contains one or more tandem, 24-amino acid leucine-rich repeats flanked by conserved disulfide loop structures at both the N and C termini of the repeats.²⁰⁹ GPIb α is covalently associated with the GPIb β chain through disulfide linkage of cysteine residues, and both of these chains are noncovalently associated with GPIX in a 1:1 ratio and with GPV in a 2:1 ratio (Fig. 16.7). GPIb contains multiple O-linked carbohydrate groups with sialic acid residues. The complex appears as a long rod with globular domains by electron microscopy and is predicted to extend far out from the platelet surface, a feature which may make it sensitive to shear-induced conformational changes.²¹⁰

vWF is a large, multimeric GP that circulates in plasma and is also found in platelets and the Weibel-Palade bodies of endothelial cells. Mature vWF is a 2,050-amino acid subunit that is

P.398

disulfide linked into large multimers. It contains three adjacent A domains in the N-proximal half of the peptide that collectively regulate the adhesion of platelets to subendothelial matrix. In this respect, the A₁ and A₃ domains bind to different matrix collagens, whereas the A₁ domain contains the binding site for the GPIb complex.²¹¹ The A₁ domain is the primary role player in platelet adhesion, because this part of the molecule is believed to change its conformation in response to immobilization and high shear forces, thus making it a high-affinity ligand for the GPIb complex receptor.^{212,213}

FIGURE 16.7. Glycoprotein (GP) Ib complex. GPIb α Disulfide linked to GPIb β is noncovalently associated with GPIX and GPV in the ratio of 2:2:2:1. Phosphorylation sites within the cytoplasmic tails of GPIb α (Ser 609) and GPIb β (Ser 166) are indicated by a circled P. (From Berndt MC, Shen Y, Dopheide SM, et al. The vascular biology of the GP Ib-IX-V complex. *Thromb Haemost* 2001;86:180, with permission.)

The binding site for vWF is present in the N-terminal 282 residues of GPIb. Important to the interactions are a cluster between residues Asp 252 and Arg 293 containing sulfated tyrosine residues and important anionic residues, a disulfide loop between Cys 209 and Cys 248, and an N-terminal flanking sequence of the leucine-rich repeats (LRG). Mutations involving single amino acid residues within these LRGs account for some cases of the congenital bleeding disorder Bernard-Soulier syndrome, in which the GPIb complex binds poorly, or not at all, to vWF. The crystal structure of the N terminus of GPIb α in complex with the A1 domain of vWF reveals an elongated complex with interactions of the globular A1 domain with the concave face of GPIb α .^{214,215}

Unlike other receptors, GPIb does not require platelet activation for its interactions with vWF. In vitro, the interactions of vWF and binding with the GPIb complex occur with generally very low affinity in the absence of shear. The presence of the vancomycinlike antibiotic ristocetin or viper venom proteins, such as botrocetin, promotes the interactions. Mobilization may uncoil vWF to promote interactions with GPIb.²⁰⁴ The addition of shear, in a parallel-plate flow system, results in platelet interaction with subendothelial vWF that occurs in a biphasic fashion.²¹⁶ Likewise, the rate of translocation of platelets from blood to the endothelial cell surface, which is dependent, increases linearly up to wall shear rates of $1,500 \text{ s}^{-1}$, whereas the translocation rate remains relatively constant with the wall shear rate between $1,500$ and $6,000 \text{ s}^{-1}$. Thus, the presence of shear is important for promoting the interactions between the GPIb complex and vWF. Studies of real-time thrombus formation in the absence of platelet GPIb complex and in blood from individuals with severe (type 3) von Willebrand disease²¹⁷ indicate that GPIb and vWF interaction are required for platelet surface interaction at high shear rates ($>1,210 \text{ s}^{-1}$), whereas GPIb deficiency results in poor platelet adhesion at lower shear.

Shear accelerates thrombus formation likely by promoting this receptor-ligand interaction.

Glycoprotein Ib Complex Interaction with Thrombin and Other Molecules

The GPIb complex serves as an α -thrombin binding site on platelets,²¹⁸ although the physiologic relevance of the interactions is not clear. The density of GPIb complexes (~20,000/platelet) far exceeds the number of thrombin binding sites reported on platelets (~6,000/platelet). Both exosites I and II of thrombin have been implicated in the interactions. Two independently solved crystal structures had significant differences.^{219,220} Involvement of exosite I could have important ramifications for thrombin activity, as most substrates need to bind exosite 1 to be efficiently cleaved. Thrombin binding may influence vWF interactions, although this has not been definitively established. Thrombin is also capable of cleaving GPV near the surface to release a soluble fragment.

P.399

Studies have identified interaction of the GPIb complex with ligands other than vWF. These include a study of a reversible association of GPIb with P-selectin, which is examined in more detail in the section "Platelets and Endothelium." The interaction of platelet GPIb with the neutrophil adhesion receptor α M β 2 (Mac-1) is discussed in the section "Platelets and White Blood Cells." Additionally, GPIb reportedly interacts with high-molecular-weight kininogen, factor XII, and factor XI.

Glycoprotein Ib Complex Signaling

When the GPIb complex interacts with its vWF ligand under conditions of elevated shear stress, signals are initiated that activate integrin $\alpha_{IIb}\beta_3$.^{221,222} The pathways involved lead to (a) elevation of intracellular calcium; (b) activation of a tyrosine kinase signaling pathway that incorporates nonreceptor tyrosine kinases such as Src, Fyn, Lyn, and Syk, phospholipase C γ 2, and adaptor proteins such as SHC, LAT, and SLP-76; (c) inside-out signaling through the $\alpha_{IIb}\beta_3$ integrin followed by platelet aggregation; and (d) activation of protein kinase C (PKC), protein kinase G (PKG), and phosphoinositide 3-kinase (PI3K). Other downstream players and events that play roles after GPIb receptor occupancy include: a) the homodimeric signaling protein 14-3-3 and calmodulin, (b) receptor cross-linking, and (c) the immunoreceptor tyrosine-based activation motif (ITAM)-containing proteins Fc γ receptor IIA (Fc γ RIIA) and Fc receptor (FcR) γ chain. Signaling through the GPIb complex can release ADP and generate thromboxane A₂ generation,²¹² which in turn activate integrin $\alpha_{IIb}\beta_3$.

Binding sites for 14-3-3 have been identified in the cytoplasmic domains of GPIb α , GPIb β , GPIX, and GPV, and yeast two-hybrid studies documented in vivo interaction between 14-3-3 ζ and both GPIb α and - β .²²³ Phosphorylation of Ser 166 of the 14-3-3 consensus sequence in the GPIb β cytoplasmic domain is required to permit high-affinity 14-3-3 binding.^{223,224} The GPIb complex appears to physically associate with the 14-kDa FcR γ -chain²²⁵ and with the 40-kDa Fc γ RIIA receptor.²²⁶ Both of these proteins contain nonidentical, but similar ITAM domain sequences and may play roles in signaling by GPIb. The lipid kinase PI3K has been found to play a role in GPIb-IX mediated activation of $\alpha_{IIb}\beta_3$ by participation in complex formation with the GPIb and 14-3-3.²²⁷ Thus, once vWF binds to GPIb-V-IX, signaling complexes form in the vicinity of the GPIb α cytoplasmic tail consisting of cytoskeletal proteins such as 14-3-3 ζ as well as signaling proteins like Src and PI 3-kinase. This process leads to Syk activation, protein tyrosine phosphorylation, and recruitment of other cytoplasmic proteins with pleckstrin homology domains that can support interactions with 3-phosphorylated phosphoinositides and ultimately activation of integrin $\alpha_{IIb}\beta_3$.^{228,229}

Platelet-Collagen Interaction and Signaling

Collagens, one of the most thrombogenic substances in vessels, are very important activators of platelets in the vascular subendothelium and vessel wall, and thus are prime targets for therapeutic intervention in patients experiencing a pathologic arterial thrombotic event such as MI or stroke. Platelets have two major surface receptors for collagen, the immunoglobulin superfamily member GPVI and the integrin $\alpha_2\beta_1$. The former is considered to be the primary player in platelet adhesion, initiating signaling and subsequent platelet activation. In addition to these two surface receptors, the GPIb complex can also be considered an indirect collagen receptor because its subendothelial vWF ligand essentially acts as a bridging molecule between platelets and collagen by fixing itself to the latter, which, in turn, acts as scaffolding for the multimers. Collagen adhesion also results in indirect activation of the protease-activated receptor 1 via MMP-1. Other molecules, such as CD 36, may also sustain collagen interactions.

Glycoprotein VI Receptor

The GPVI receptor, a member of the IgG superfamily,^{230,231,232} is expressed in platelets in close association with the 14-kDa FcR γ -chain, which serves as the signaling subunit for GPVI.^{233,234} The receptor exists as a dimer in stable association with the FcR γ -chain. Expression of GPVI on mouse platelets appears to be dependent on FcR γ -chain expression, and the latter has also been found to be critical for collagen-mediated platelet activation.²³⁴

GPVI has two Ig C2 loops, and the N-terminal loop likely contains the collagen-binding domain.²³⁰ The crystal structure indicates that the GPVI dimers assume a parallel orientation of the collagen-binding domains to fit the helix structure of collagen.²³⁵

GPVI is the main receptor involved in collagen-mediated platelet activation.^{236,237} and ²³⁸ Studies of mice lacking platelet GPVI show that they lose collagen-induced platelet activation due to a defect in platelet adhesion.²³⁹ Thus, GPVI appears to serve as the initial receptor involved in platelet adhesion, and it activates integrin binding. GPVI alone supports adhesion to insoluble collagens, and works with $\alpha_2\beta_1$ to promote platelet adhesion to soluble collagen microfibrils. GPVI can also be engaged by collagen-related peptides (arranged in triple helical structures with sequences similar to collagen) and the snake venom convulxin, which elicit signals through GPVI.

$\alpha_2\beta_1$ Receptor

The first platelet collagen receptor identified was the integrin $\alpha_2\beta_1$ receptor, also known as platelet GPIa/IIa and lymphocyte VLA-2.²⁴⁰ In all α subunits of integrins, seven tandem repeats are localized to the N-terminal end and folded into a sevenbladed β -propeller structure.²⁴¹ The α_2 subunit also contains an I domain between the second and third repeats that includes a metal coordination site for Mg^{2+} that is critical for interaction with collagen.²³⁰ As with other integrins, activation increases the affinity between $\alpha_2\beta_1$ and collagen.²⁴² Currently, $\alpha_2\beta_1$ is believed to mediate stable adhesion following GPIb- and GPVI-initiated interactions with vWF and collagen, respectively.

Platelet-Collagen Signaling

When compared to vWF, collagen is a more efficient substrate when it comes to supporting stable platelet adhesion and thrombus formation. The fact that initial platelet tethering to collagen under high shear flow first requires interaction between vWF and platelet GPIb serves to underscore the importance of the two major collagen receptors, GPVI and $\alpha_2\beta_1$, in promoting platelet adhesion and activation under shear conditions.

Many of the early signaling events that follow GPVI stimulation have been characterized. Synergism between GPVI pathways and those related to other adhesion receptors such as GPIb-V-IX and soluble agonists released by activated platelets are likely necessary for the full repertoire of platelet-collagen signaling. Exposure of platelets to collagen surfaces likely results in GPVI clustering that in turn triggers the tyrosine phosphorylation of the FcR γ chain.²³³ GPVI signaling may also be influenced by its association with glycolipid-enriched microdomains (GEMS, membrane rafts) in the plasma membrane.²⁴³ The GPVI/FcR γ -chain complex leads to platelet activation through a pathway that has many aspects in common with signaling by immune receptors, such as the Fc receptor family (of which Fc γ RIIA is the lone family member found in platelets) and the B- and T-cell antigen receptors (Fig. 16.8). Immunoreceptors like the Fc receptors and the FcR γ chain all have the ITAM (immunoreceptor tyrosine-based activation motif) in common. Tyrosine phosphorylation of the ITAM by Lyn and Fyn of the Src family of tyrosine kinases takes place after activation of GPVI. The phosphorylated Src kinase, in turn, leads to activation of the tyrosine kinase Syk after its autophosphorylation.²⁴⁴ Syk then initiates a downstream signaling

P.400

cascade involving the LAT and SLP-76 adapter proteins, which leads to formation of a signaling complex by virtue of its multiple phosphorylation sites that also act as docking sites, leading to recruitment of additional proteins to the plasma membrane.²⁴⁵ The signaling complex activates cytosolic second messenger-producing enzymes PI3K and phospholipase C γ 2, facilitated by tyrosine phosphorylated LAT.²⁴⁶ PI3K leads to the generation of PI3,4P₂ and PI3,4,5P₃ (PIP₃), and this, in turn, supports recruitment of proteins to the membrane signalosome complex with specific pleckstrin homology (PH) domains, including a member of the Tec kinase family, Btk, along with PIC γ 2.^{247,248} Syk is critical for collagen-mediated platelet activation through the GPVI/FcR γ -chain complex, and knockout mouse studies have shown that absence of this enzyme leads to loss of phosphorylation of LAT, the adapter SLP-76, and PIC γ 2.^{248,249}

FIGURE 16.8. Collagen activates platelets through the same pathway as an immune receptor. Cross-linking of the glycoprotein (GP) VI/Fc receptor (R) γ chain leads to tyrosine phosphorylation of the immunoreceptor tyrosine-based activation motif (ITAM) sequence, enabling recruitment of the tyrosine kinase (Syk) through its tandem Src-homology 2 (SH2) domains. This leads to autophosphorylation and subsequent activation of Syk, which in turn leads to tyrosine phosphorylation of phospholipase Cy2 (PLC γ 2). A large number of proteins are implicated in the regulation of PLC γ 2, as discussed in the text. YP, phosphotyrosine. (From Watson SP. Collagen receptor signaling in platelets and megakaryocytes. *Thromb Haemost* 1999;82:367, with permission.)

PLC γ 2 plays a critical role in aggregation and secretion responses to collagen, as demonstrated in PLC γ 2 knockout mice.^{250,251} The major role of PLC isoforms is concerned with the generation of the second messengers inositol 1,4,5-triphosphate and 1,2-diacylglycerol (DAG), which participate in intracellular calcium homeostasis and activation of many isoforms of PKC. The former process culminates in a robust calcium signal that promotes efficient platelet activation, via $\alpha_2\beta_1$ as well as $\alpha_{IIb}\beta_3$. Along with the proteins noted above, PI3K and its associated second messenger pathway also play a very important role in the regulation of PLC γ 2 through activation of other signaling proteins such as protein kinase B (also known as Akt).²⁵² Platelets contain several isoforms of Akt that are important for normal platelet function and thrombus formation along with granule secretion. Other downstream events include activation of Rap1 and Pyk2.^{251,252,253} and ^{254,255}

In addition to GPVI, the $\alpha_2\beta_1$ receptor also propagates signaling. The use of $\alpha_2\beta_1$ -selective ligands has demonstrated calcium-dependent spreading and tyrosine phosphorylation of several proteins when interaction with platelets takes place, including Src, Syk, SLP-76, PLC γ 2, p38 MAP kinase, ILK, Rac, and PAK.²⁵⁶

Physiologic Inhibition of Platelet Adhesion

Negative regulation of platelets is essential to set the stimulus threshold for thrombus formation, determine final clot size and stability, and prevent uncontrolled thrombosis. The mechanisms behind the negative regulation of platelet activation are described later in the chapter, and in this respect, roles of players such as nitric oxide and prostacyclin have been well characterized. Platelet activation can also be inhibited by signaling through the adhesion molecule PECAM-1 (CD31).^{257,258,259,260} Expressed on a number of blood cells and endothelial cells, PECAM has a wide array of regulatory functions in processes such as apoptosis and cell activation. Following homophilic interactions and/or clustering, PECAM-1 is tyrosine phosphorylated in its cytoplasmic tail ITIM domain (immunoreceptor tyrosine-based inhibition motif) by Src family kinases, and this engenders recruitment of tyrosine, serine/threonine, or lipid phosphatases with resultant kinase-dependent signaling inhibition.²⁵⁸ Phosphorylation of PECAM-1 recruits and activates the SH2 domain-containing protein-tyrosine phosphatase, SHP-2.²⁶⁰ Studies suggest that the PECAM-1/SH-2 complex functions to counteract platelet activating, most particularly for collagen by inhibiting GPVI/ FcR γ chain signaling.²⁶⁰ However, PECAM-1 has also been observed to attenuate G-protein mediated signaling by thrombin and other agonists. The Src family kinase Lyn also inhibits platelet activation by GPVI, and appears to do so independently of PECAM.²⁶¹ Other platelet proteins with ITIM-domains that also inhibit platelet function include carcinoembryonic antigen cell adhesion molecule 1 (CECAM1) and G6B.²⁶²

Platelet Thrombin (Protease-activated) Receptors and Signaling

PARs are G-protein-coupled receptors that use a unique mechanism to convert an extracellular protein cleavage event into an intracellular activation signal. In this case, the ligand is already part of the receptor per se, by virtue of the fact that it is represented by the amino acid sequence SFLLRN (residues 42 through 47) and is unmasked as a new amino terminus after thrombin cleaves the peptide bond between Arg 41 and Ser 42. This “tethered ligand” then proceeds to irreversibly dock with the body of its own receptor to effect transmembrane signaling, as shown in Figure 16.9.

Thrombin signaling in platelets is mediated, at least in part, by four members of a family of G-protein-coupled PARs (PAR-1, -2, -3, and -4) (see previous section for a discussion of the GPIb complex as a thrombin receptor).²⁶³ Human platelets express PAR-1 and PAR-4, and activation of either is sufficient to trigger platelet aggregation.^{264,265} Mouse platelets express PAR-3 and PAR-4.²⁶⁶ PAR-1, -3, and -4 can be activated by thrombin, whereas PAR-2 can be activated by trypsin, tryptase, and coagulation factors VIIa and Xa. Presumably, other proteases are capable of recognizing the active sites of these receptors and can thus also trigger PAR signaling.

PAR-1 is the prototype family member and was the first to be cloned and characterized in the human and hamster.²⁶⁴ A synthetic peptide that mimics the PAR-1-tethered ligand (SFLLRN) is capable of functioning as an agonist by activating the receptor independent of cleavage of the 41-residue N-terminal exodomain.

The mechanism by which G-protein-coupled receptors, such as PAR-1, signal through the G proteins is shown in Figure 16.10. PAR-1 is capable of coupling to members of the G12/13, Gq, and Gi/z families and thus is connected to a significant number of intracellular signaling pathways. The α subunits of G12 and G13 are believed to be involved in mediating platelet shape change,²⁶⁷ and downstream signaling mediators include Rho family members, among others. The α subunit of Gq is needed for platelet secretion and aggregation and participates in activation of PIC β that leads to calcium mobilization and PKC activation.²⁶⁸ The α

P.401

subunit of Gz is a Gi family member that has been speculated to play an epinephrinelike role in human platelets through inhibition of adenylate cyclase.²⁶⁹

FIGURE 16.9. Structure and features of PAR-1. Cleavage of PAR-1 by thrombin between arginine 41 and serine 42 exposes a new N terminus that serves as a tethered ligand. Activation of PAR-1 is followed by a rapid burst of signaling before the receptor is desensitized and, in some cases, cleared from the cell surface. (From Brass LF. Thrombin and platelet activation. *Chest* 2003;124:18S-25S.)

The β - γ subunit counterparts of G proteins involved in PAR signaling are involved in a plethora of activities, including activation of protein kinases, channels, and lipid-modifying enzymes, such as PI3K, which provide attachment for multiple signaling protein complexes close to the inner leaflet of the cell membrane, potentially through surface "hot spots."²⁷⁰ Thus, this vast network of signaling pathways mediated through several G-protein families is in keeping with the pleiotropic roles that thrombin has been shown to exhibit in cellular homeostasis, which extends beyond platelet activation to include endothelial cells, leukocytes, smooth muscle cells, and T lymphocytes, along with physiologic processes such as tissue injury, inflammation, angiogenesis, and embryonic development.

FIGURE 16.10. Signaling through G proteins and G-protein-coupled receptors. Agonist binding to the receptor causes the exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on the guanine nucleotide-binding site of the G-protein α subunit. This causes the dissociation of $G\alpha$ from $G\beta\gamma$, both of which can activate intracellular effectors and ion channels. (From Brass LF. Molecular basis of platelet activation. In: Hoffman R, Benz EJ, Shattil SJ, et al., eds. Hematology: basic principles and practice. New York: Churchill-Livingstone, 2000:1754, with permission.)

Physiologic differences exist between PAR-1 and PAR-4 on human platelets. PAR-1 appears to mediate a substantial portion of thrombin signaling and appears to be most efficient at mediating platelet activation at low concentrations of thrombin, whereas PAR-4 can function in the absence of PAR-1, but only at high thrombin concentrations. The rate of platelet activation through PAR-4 is significantly slower and more sustained than that through PAR-1.^{271,272} Given the importance of this system with respect to normal hemostasis, PAR-4 may serve as a redundant, backup receptor to PAR-1, or it may serve as an important receptor for one or more proteases other than thrombin.

Once activated, PAR-1 is rapidly uncoupled from signaling and internalized into the cell.²⁷³ It is then transported to lysosomes and degraded.^{268,269} Platelets presumably have no need for a thrombin receptor recycling mechanism, because once activated, they are irreversibly incorporated into blood clots. Conversely, in cell lines with characteristics similar to megakaryocytes, new protein synthesis is needed for recovery of PAR-1 signaling,²⁷⁴ and in endothelial cells, sensitivity to thrombin is maintained by delivery of naive PAR-1 to the cell surface from a preformed intracellular pool.²⁷⁵

Subsequent studies employing PAR3 and PAR4 knockout mice have also demonstrated defective thrombus formation under high shear conditions *in vivo*, suggesting the possible existence of shear-based functional differences between protease-activated receptors.^{276,277}

Platelet ADP (Purinergetic) Receptors and Signaling

Evidence that ADP plays an important role in both the formation of the platelet plug and the pathogenesis of arterial thrombosis has been accumulating since its initial characterization in 1960 as a factor derived from red blood cells that influences platelet adhesion.²⁷⁸ ADP is present in high (molar) concentrations in platelet-dense granules and is released when platelet stimulation takes place with other agonists, such as collagen; thus, ADP serves to further amplify the biochemical and physiologic changes associated with platelet activation and aggregation. Inhibitors of this ADP-associated aggregation include commonly used clinical agents, including ticlopidine, clopidogrel, prasugrel, and ticagrelor, proven to be very effective antithrombotic drugs.^{278,279}

Platelet P2Y₁ and P2Y₁₂ and P2X₁ Receptors

Adenine nucleotides interact with P2 receptors that are ubiquitous among different cell types and have been found to regulate a wide range of physiologic processes. They are divided into two groups, the G-protein-coupled superfamily named P2Y and the ligand-gated ion channel superfamily termed P2X.²⁸⁰ Two G-protein-coupled

P.402

(P2Y) receptors contribute to platelet aggregation. The P2Y₁ receptor initiates aggregation through mobilization of calcium stores, and the P2Y₁₂ receptor is coupled to inhibition of adenylate cyclase and is essential for a full aggregation response to ADP with stabilization of the platelet plug. P2X₁ is a third purinergetic receptor present in platelets that may largely recognize ATP.

The P2Y₁ receptor was first cloned in 1993 from a chick brain complementary DNA library.²⁸¹ The P2Y₁ receptor has 373 amino acid residues and the prototype structure of a G-protein-coupled receptor. It is distributed in various tissues such as heart, blood vessels, testis, and ovary.²⁸⁰ P2Y₁ couples to G_{αq}, and platelets from mice deficient in P2Y₁ are unable to change shape or aggregate in response to ADP²⁸²; likewise, platelets from mice lacking G_{αq} do not aggregate to ADP.²⁸³ After the characterization of P2Y₁, it became clear that a second platelet ADP receptor had to exist that was responsible for the inhibition of cAMP production by ADP^{284,285} and that was the target for antithrombotic drugs (at the time, ticlopidine and clopidogrel) that interfered with ADP-activation. The P2Y₁₂ receptor was cloned in 2001 from human and rat platelet complementary DNA libraries using *Xenopus* oocytes.²⁸⁶ The receptor indeed showed the ability to display ADP-mediated inhibition of platelet cyclic AMP (cAMP) formation that was not blocked by P2Y₁ antagonists.

Inhibition of either of the P2Y₁ or P2Y₁₂ receptors is sufficient to block ADP-mediated platelet aggregation, and coactivation of both receptors is therefore necessary, through the G proteins G_q and G_i, respectively, for ADP to activate and aggregate the platelet (Fig. 16.11).²⁸⁷ A series of studies involving the use of selective P2Y₁ and P2Y₁₂ receptor antagonists, a cAMP inhibitor, gene targeting, and G_q and G_i protein agonists that would theoretically activate the two main G-protein pathways associated with ADP stimulation (see below) has led to the conclusion that signaling events downstream of both receptors are needed to elicit full activation.

Studies done with platelets from patients who manifest defective P2Y₁₂, along with experiments involving the study of P2Y₁ receptor function in platelet-rich plasma that has high fibrinogen concentrations, indicate that the P2Y₁ receptor has roles in activation and aggregation in addition to shape change. Platelet shape change is dependent on two separate G signaling pathways, a G_q-linked release of calcium from internal stores, and a G₁₂/G₁₃ link to activation of Rho kinases and Rho guanine nucleotide exchange factors that activate small G proteins.²⁸⁸ The primary role of the P2Y₁₂ receptor in platelet activation and aggregation is to amplify and complete the aggregation response to ADP.^{284,285} Individuals with congenital defects in P2Y₁₂ display a mild to moderate bleeding diathesis. Platelets from P2Y₁₂-deficient mice aggregate poorly, or not at all, in response to ADP, display a shift in the dose-response curves for collagen and thrombin, and lack ADP-induced repression of cAMP levels.²⁸⁹ The bleeding time of homozygous knockouts was markedly prolonged compared with near normal results in heterozygotes.²⁹⁰ Current data indicated that the P2Y₁ receptor elicits a transient platelet response (manifested by a rise in cytoplasmic calcium, shape change, and reversible aggregation), and the P2Y₁₂ receptor, via inhibition of adenylyl cyclase, amplifies the ADP response. The central role of the P2Y₁₂ receptor in the formation and stabilization of thrombi has been demonstrated by the therapeutic efficacy of antithrombotic drugs that are antagonists.^{282,283}

FIGURE 16.11. Current view of the interplay between the platelet P2 receptors. Two G-protein-coupled receptors are involved in adenosine diphosphate (ADP)-induced platelet aggregation, P2Y₁ and P2Y₁₂. The former is responsible for intracellular calcium mobilization, shape change, and transient aggregation, whereas the latter is coupled to adenylate

cyclase (AC) inhibition and is responsible for amplification of platelet aggregation and potentiation of platelet secretion. Both receptors are required for normal platelet response to ADP. A P2X receptor is also present on platelets and is responsible for rapid calcium influx. It therefore synergizes with the P2Y₁ receptor. Both the P2Y₁₂ and P2X₁ receptors have been shown to play key roles in platelet activation and aggregation under high shear stress conditions. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; MLC, myosin light chain; P, phosphorylated; PLC, phospholipase C; Y, phosphotyrosine. (Modified from Gachet C. ADP receptors of platelets and their inhibition. *Thromb Haemost* 2001;86:227, with permission.)

The P2X₁ is an ATP-gated ion channel known to mediate rapid and selective permeability to cations. On platelets, the P2X₁ receptor has been shown to mediate fast calcium entry stimulated by ADP,²⁹¹ although ATP may be the physiologically relevant agonist. P2X₁ is a 399-amino acid protein composed of two transmembrane domains, intracellular N and C termini, and an extracellular loop with 10 conserved cysteine residues.²⁸⁰ At least three P2X subunits are required to constitute a membrane pore. A study of P2X₁-deficient mice has further indicated that this receptor contributes to the thrombosis of small arteries.²⁹² Conversely, increased systemic thrombosis has been reported in mice overexpressing the human P2X₁ receptor.²⁹³

ADP Receptor Signaling

Although considered a weak agonist in comparison to collagen or thrombin, ADP clearly plays an important role in thrombus stabilization, likely by contributing to the recruitment of

P.403

additional platelets to growing thrombi. Aggregation is often reversible when platelets are stimulated by ADP alone. In addition, low concentrations of ADP serve to amplify the effects of both strong and weaker agonists, the latter including serotonin and adrenaline, among others. As noted in the preceding paragraphs, ADP signal transduction downstream from the P2Y₁ receptor leads to a transient rise in free cytoplasmic calcium as a result of mobilization from internal stores, and this is followed by a secondary store-mediated influx, while a concomitant inhibition of adenylate cyclase is initiated by ADP stimulation of the P2Y₁₂ receptor (Fig. 16.11). The G-protein family member responsible for signaling through P2Y₁ to PICβ is G_q, whereas the member responsible for signaling through P2Y₁₂ to inhibit adenylate cyclase is G_i. While ADP-mediated platelet activation via the P2Y₁ receptor incorporates the G_q-dependent PLC-β second messenger pathway, the P2Y₁₂ receptor mediates its postoccupancy signaling through G_i-dependent PI3 kinase activation and subsequent repression of cAMP levels. In addition to the PI3K role, several groups have reported a role for Rap1b in P2Y₁₂ signal transduction. Rap1b is a small GTPase that is highly expressed in platelets, and its ADP-stimulated increased activation is abolished by P2Y₁₂ antagonists and G_i knockout mice.²⁹⁴ Rap1b, in turn, is an important intermediate in activation of platelet integrins.²⁹⁵ P2Y₁₂ activation has been found to play an important role in activation of α_{IIb}β₃. Using P2Y₁₂ knockout mice, Andre et al. noted that platelets activated with PAR-4 or ADP were defective in binding soluble fibrinogen relative to wild-type mice.²⁹⁰

Platelet Activation by Soluble Agonists

α₂-Adrenergic Receptors and Epinephrine

Epinephrine is unique among platelet agonists because it is considered to be capable of stimulating secretion and aggregation, but not cytoskeletal reorganization responsible for shape change. Platelet responses to epinephrine are mediated through α₂-adrenergic receptors,^{296,297} and these responses have been found to vary among individuals, with some donors with otherwise normal platelets manifesting delayed or absent responses.²⁹⁸ The α_{2A}-adrenergic receptor couples to G_{ai} members, most notably G_{αz} in platelets. Epinephrine synergizes with other agonists, although whether ADP or thromboxane is necessary for epinephrine's actions is not entirely clear. Epinephrine may mediate sympathetic stimulation of platelets.

Arachidonic Acid, Thromboxane A₂, and Thromboxane Receptors

After platelet stimulation by a number of agonists, arachidonic acid is generated directly by phospholipase A from its membrane phospholipid precursors (PC, PS, and PI) and indirectly by PLC generation of DAG followed by DAG lipase action. Most platelet agonists are believed to activate this pathway. Three known eicosanoid subsets of biochemical compounds are known to be derived from the formation of arachidonic acid—the prostanoids, leukotrienes, and epoxides. The prostanoids are formed by the cyclo-oxygenase pathway and include endoperoxides and thromboxanes along with prostaglandins. The leukotrienes are formed by the lipoxygenase pathway and the epoxides by the cytochrome

P450 epoxygenase pathway. Although all three of these pathways are present in platelets, most arachidonic acid ends up being metabolized to thromboxane A₂ (TxA₂).²⁹⁹

TxA₂ is produced in platelets from arachidonic acid through the generation of PGH₂ by the enzyme cyclo-oxygenase, which is irreversibly inhibited by aspirin through acetylation of a serine residue near its C terminus.^{300,301} PGH₂ is the parent compound for both biologically active prostaglandins, such as PGE₂ and PGI₂, and TxA₂. The former two compounds act to inhibit platelet activation by generating intracellular cAMP, whereas TxA₂ activates platelets. Although prostaglandin and thromboxane pathways can be present in the same cell, platelets primarily synthesize thromboxane, and endothelial cells mainly synthesize prostaglandins such as PGI₂, which acts as a local vasodilator and thus indirectly opposes platelet activation and vasoconstriction.³⁰¹

Like ADP and epinephrine, TxA₂ is also capable of activating nearby platelets after its release into plasma. It has a very short half-life of 30 seconds before its conversion to the inactive metabolite thromboxane B₂ prevents widespread platelet activation beyond the vicinity of thrombus formation.³⁰² Both arachidonic acid and analogs of TxA₂ have been found to activate and aggregate platelets by mediating shape change and phosphorylation of signaling enzymes, such as PLCβ, PKC, and so forth.³⁰³ The thromboxane receptor (TP) is a member of the seven-transmembrane G-protein-coupled receptor family and has been localized to the plasma membrane. Two isoforms of the receptor have been identified in platelets—TPα and TPβ—and they activate platelets through the G_q pathway to PLCβ and G₁₂/G₁₃ to myosin light chain phosphorylation through activation of Rho kinase.³⁰³ In addition, the α receptor is associated with activation of adenylate cyclase that leads to generation of cAMP, known to inhibit platelet activation, whereas the β receptor inhibits adenylate cyclase activation after its stimulation.

Coordination between Platelet Adhesion Events and Soluble Agonist Stimulation in Thrombus Growth

The mechanism by which soluble agonists coordinate their actions with platelet adhesion-related processes is an important consideration in the context of the steps required to facilitate thrombus growth.³⁰⁴ The application of advanced imaging techniques for visualizing individual platelets and thrombus development in live animals has dramatically improved understanding of the underlying mechanisms.^{305,306} Depending on the type and degree of vessel injury, exposure of collagen and generation of thrombin appear to serve as initiators of thrombus formation. Thrombus propagation appears to be a dynamic process, with platelets adhering and separating from the core. The bulk of the data supports a role for soluble mediators, such as ADP, in the additional accumulation of platelets within the growing thrombus. Rapid blood and high shear exert complex prothrombotic properties (e.g., by enhancing GPIb adhesions) and antithrombotic properties (e.g., by clearing soluble mediators). Within the platelet, initial platelet/vessel wall interactions characterized by contact between platelet GPIb and matrix vWF result in subsequent conformational changes in α_{IIb}β₃. Costimulation of platelets by these adhesion events and soluble agonist receptors may then potentiate and sustain early activation signals initiated by the early GPIb/vWF/α_{IIb}β₃. The costimulation may then lead to arrest of platelets. Once platelets are in close contact, molecules on the surface of one platelet can interact directly with those on an adjacent platelet. These contact-dependent events can promote or inhibit platelet functions.³⁰⁴ Major receptor pairs that amplify signaling include the Eph receptor tyrosine kinase and its ephrin ligands, semaphoring 4D, which reinforces signaling downstream of GPVI. Several adhesion/junction receptors participate in contact-dependent signaling, including PECAM-1, CEACAM1, ESAM, and JAM-A, and the bulk of the evidence indicates that they limit platelet activation and thrombus growth. Platelets also express connexins, which appear to form functional pores in closely attached platelets, but their function remains to be established definitively.³⁰⁷

Physiologic Inhibition of Platelet Activation

One of the many remarkable features of platelets is their ability to remain in a physiologic resting state and resist becoming activated while navigating the heart, arterial, and venous circulations.

P.404

Indeed, the pathologic consequences associated with widespread inappropriate platelet activation are life- and limb-threatening in the settings of well-characterized clinical disorders, such as thrombotic thrombocytopenic purpura and heparin-induced thrombocytopenia. The mechanisms responsible for maintaining the fine balance of keeping platelets in a resting state until they encounter a genuine need to undergo adhesion, activation, and aggregation at the site of vascular injury are nearly as diverse as those responsible for mediating these physiologic phenomena.

Some general mechanisms involved in physiologic inhibition of platelet activation include phenomena such as (a) generation of negative-regulating molecules by the platelet (e.g., cAMP), endothelium (e.g., PGI₂, nitric oxide [NO], heparan sulfate), and at distant sites (e.g., antithrombin); (b) barrier of endothelial cells that prevents direct contact of

circulating platelets with collagen; (c) ecto-ADPase (CD39) expression by endothelial cells that metabolizes ADP secreted from platelets; (d) tendency for blood flow to wash away unbound thrombin and other soluble mediators from the site of platelet plug formation; (e) brief half-life of certain key platelet activators such as TxA_2 ; (f) tight regulation of the affinity state of receptors such as $\alpha_{\text{IIb}}\beta_3$; (g) downregulation of signaling receptors to limit their actions; and (h) inhibitory pathways mediated by ITIM-containing and/or contact-dependent adhesion receptors, such as PECAM, CECAM-1, JAM-A, and potentially others.³⁰⁸ Some of the physiologic and biochemical phenomena related to inhibition of platelet activation are described in the following.

Receptor Downregulation and Desensitization

Signaling through G-protein-coupled receptors present on the surface of platelets is limited by their phosphorylation, which triggers desensitization, that is, uncoupling from G proteins, and internalization via Claritin-mediated endocytosis. G-protein kinases and β -arrestin are central to these processes.³⁰⁹ In addition, G-protein-coupled receptors interact with a myriad of other molecules that finely tune their signaling, including regulators of G-protein signaling (RGS)³¹⁰ and GPCR-associated sorting proteins.³¹¹

Inhibitory Prostaglandins

Generation of the prostaglandins from arachidonic acid metabolism, such as PGI_2 and PGE_2 (at high concentrations), results in inhibition of platelet activation and aggregation, and counterbalances the actions of thromboxanes derived from the same pathway. While PGI_2 and PGD_2 inhibit platelet function at low doses, PGE_2 displays a biphasic response, and inhibits platelet function only at higher concentrations, likely via the EP4 receptor. The inhibitory effects are mediated via G-protein-coupled receptors (IP and EP receptors, respectively) that couple to the α subunits of G_s to regulate adenylate cyclase-mediated generation of cAMP. cAMP levels in platelets are also governed by the activity of phosphodiesterase, the enzyme responsible for cAMP metabolism. This enzyme activity is inhibited by drugs such as the weak antiplatelet agent dipyridamole, the bronchodilator theophylline, and sildenafil, used to treat erectile dysfunction in men.

Raising cAMP levels causes a number of specific changes in platelet function, mediated in large part by activation of protein kinase A (PKA). Targets for PKA include vasodilator-stimulated phosphoprotein (VASP), the IP_3 receptor, which reduces intracellular calcium mobilization, $\text{G}\alpha_{13}$, and the cytoplasmic domain of $\text{GPIIb}\beta$. Phosphorylation of the IP_3 receptor reduces intracellular calcium mobilization, whereas $\text{G}\alpha_{13}$ phosphorylation downregulates TxA_2 signaling. Phosphorylation of $\text{GPIIb}\beta$ may reduce platelet activation through its increased interaction with the 14-3-3 ζ protein. Other targets include small G proteins of the Rho family, filamin, myosin light chain, VASP, and Rap1b.³¹² The net effect is inactivation of signaling pathways and modulation of actin cytoskeletal dynamics to block adhesion, granule release, and aggregation.

Nitric Oxide

NO is generated by endothelial cells and platelets from L-arginine in response to shear stress forces and other platelet agonists, such as thrombin and ADP. The bulk of the evidence suggests that at high concentrations NO functions to inhibit platelet activation through the cyclic guanosine monophosphate (cGMP) second messenger generated by guanylate cyclase activation.³¹³ Elevations in cGMP, by modulating phosphodiesterase activity, can raise intraplatelet cAMP. Paradoxically, low levels of NO may elicit platelet activation pathways. Endothelial NO synthase activity is enhanced during platelet activation, presumably as an additional means for limiting platelet aggregation.

Other Inhibitory Processes of Platelet Activation

Increasingly, a number of surface receptors are being identified that negatively regulate platelet signaling.³⁰⁸ Among these include the immunoglobulin (Ig)-immunoreceptor tyrosine-based inhibitory motif (ITIM) superfamily members, PECAM-1, CECAM-1, and G6b-B. While the ITIM members clearly suppress immunoreceptor tyrosine-based activation motif (ITAM)-associated Fc γ receptor IIa and glycoprotein VI (GPVI)/FcR γ -chain signaling pathways in platelets, they also appear to have broader effects at multiple levels on platelet function.

Platelet Secretion

The extent of secretion of α -, dense-, and lysosomal-granule contents is dependent on the strength of the agonist, occurs in association with platelet activation, and is one of the many downstream consequences mediated by the activation and transport to the internal leaflet of the plasma membrane of PKC. In turn, release of cargo, such as ADP, vWF, fibrinogen, and calcium ions, enhances activation and aggregation. To date, over 300 proteins have been identified that are released by platelets and may alter the local environment and have important downstream consequences.

The strongest responses a platelet can mount to agonist stimulation include activation, secretion, and aggregation. The granule secretory (release) phase is most readily documented in vitro by the “secondary wave” that denotes a second surge of aggregation activity of a fixed number of platelets in response to release of proaggregatory granule contents. These platelets are exposed to an agonist under the controlled in vitro conditions associated with platelet aggregation studies, in which clinical defects in primary hemostasis due to platelet perturbations are further characterized. The secondary wave is typically seen best when the agonist is a weaker one, such as epinephrine, or is a relatively lower concentration of another relatively weak agonist, ADP. These two agonists require both cyclo-oxygenase activity and a primary wave of aggregation to induce secretion at low calcium concentrations.³¹⁴

Several studies suggest that the mechanism by which platelet granules (vesicles) fuse with the cell membrane to release their granule contents involves soluble N-ethylmaleimide-sensitive factor (NSF) attachment protein (SNAP) receptor (SNARE) complexes that are formed between vesicle-associated membrane proteins (VAMPs; v-SNAREs), and proteins in the target membranes (different members of the syntaxin, SNAP, and vesicle-associated membrane protein [VAMP] gene families; t-SNAREs) in a lock-and-key form of docking.^{61,315} These SNARE complexes are crucial for membrane trafficking and fusion events such as secretion and

P.405

exocytosis. In platelets, the specific isoforms VAMP-2, VAMP-3, and VAMP-8 form SNARE complexes with platelet syntaxin 2, 4, and SNAP-23 to mediate platelet secretion.^{61,315} A number of SNARE regulators, such as members of the Munc family, Doc2 α , and tomosyn, regulate SNARE function. Simultaneous with the exocytosis of platelet granules, it is apparent that there is also inward (centripetal) movement of other intracellular contents, and this may play a role in transporting proaggregatory proteins away from the membrane surface and thus serve as another counterbalancing mechanism for limiting the extent of thrombus formation. Examples of this phenomenon include the internalization of fibrinogen from the surface of activated platelets, along with $\alpha_{IIb}\beta_3$ receptors from the surface of resting and activated platelets, as noted earlier.³¹⁶

PLATELET AGGREGATION: $\alpha_{IIb}\beta_3$ RECEPTOR AND ITS SIGNALING MECHANISMS

Platelet aggregation is a complex phenomenon that is the end result of a series of adhesion- and activation-related processes. The molecular mechanisms involved in platelet aggregation continue to be an area of very active research that also periodically reminds us that there is still much to be characterized about this important aspect of platelet function. Essential components of this process include an agonist, calcium, and the adhesive proteins fibrinogen and vWF. Divalent cations, such as calcium and magnesium, are required for platelet aggregation in trace amounts, and these alter the specificity of the integrin $\alpha_{IIb}\beta_3$ for its ligands. Fibrinogen and vWF play dominant roles in platelet aggregation through binding to $\alpha_{IIb}\beta_3$, and also by the ability of the former to generate polymerized fibrin as support for the platelets in a thrombus. The multivalent nature of fibrinogen and vWF allows them to cross-link platelets on binding to $\alpha_{IIb}\beta_3$ on stimulated platelets to initiate platelet aggregation.

The molecular basis of integrin signaling that occurs in platelet $\alpha_{IIb}\beta_3$ is an integral part of thrombus formation and is important in understanding this process. GPIIb (α_{IIb}) and GPIIIa (β_3) were identified as the abnormal proteins present in patients with Glanzmann thrombasthenia in the 1970s.^{316,317} They represent the most abundant receptor on the platelet surface. Like all integrin receptors, this complex is composed of noncovalently linked subunits. Each subunit is encoded by separate genes on the long arm of chromosome 17. Both subunits consist of a large extracellular domain and very short cytoplasmic domains, and together they form a heterodimer. Within their combined extracellular domains is the ligand-binding pocket, with surrounding subunit domains conferring specificity. Equally important are the short cytoplasmic domains critical for transmembrane signaling. These domains act to regulate the affinity of the receptor, transmit intracellular signaling, and anchor the receptor to the cytoskeletal elements.³¹⁸

The signaling pathways of $\alpha_{IIb}\beta_3$ are complex and have been extensively studied. Central concepts of the signaling pathway include inside-out signaling, which involves the processes termed affinity and avidity modulation,^{318,319,320,321} and outside-in signaling, in which messages are transmitted to the inside of the platelet via the events occurring outside the membrane through $\alpha_{IIb}\beta_3$ activation. Primary platelet agonists such as ADP, thrombin, and matrix proteins collagen and vWF affect platelet aggregation through a process known as inside-out signaling. This term denotes an integrin property that involves the binding action of agonists and extracellular matrix ligands to their receptors, leading to activation of numerous platelet functions, including the conformational change of $\alpha_{IIb}\beta_3$ to a high-affinity state, referred to as affinity modulation. The relative contribution of soluble and extracellular matrix stimuli to inside-out signaling likely varies with flow conditions and other factors related to vascular perturbation. For example, GPIb/V/IX function is most relevant under

high shear stress conditions such as those associated with arterioles and capillaries and in stenotic arteries. One of the effects of inside-out signaling on $\alpha_{IIb}\beta_3$ is exposure of the fibrinogen-binding site through signal transduction involving the cytoplasmic domains (Figs. 16.12 and 16.13). The process involves a cascade of intracellular pathways that converge on Rap1, the Rap1-adaptor molecule RIAM, talin, and kindlin. The association between subunit cytoplasmic tails, and likely also the integrin subunit transmembrane domains, maintains the $\alpha_{IIb}\beta_3$ complex in a resting, nonadhesive conformation. Likewise, talin appears to be “auto-inhibited” in resting cells. Inside-out signals release talin auto-inhibition to expose a FERM domain in the talin head. This domain interacts with the integrin β subunit cytoplasmic domains, which causes separation of the integrin tails with consequent changes in the extracellular domains to increase $\alpha_{IIb}\beta_3$ affinity. Activation of $\alpha_{IIb}\beta_3$ also requires kindlin-3, an adaptor protein that interacts with a distinct site on β_3 integrin tails. The precise relationship between talin and kindlin remains to be elucidated.³²²

The crystal structure of the $\alpha_{IIb}\beta_3$ headpiece provides evidence that the receptor can assume different conformations, and complexes of the receptor with the drugs eptifibatide and tirofiban have been reported.³²³ Two major conformational changes of $\alpha_{IIb}\beta_3$ have been reported—headpiece extension and domain swing-out—both of which may enhance integrin ligand binding.³²⁴ Thiol-disulfide exchange may also influence $\alpha_{IIb}\beta_3$ activation.

Avidity modulation, the less dominant action, acts to cluster the $\alpha_{IIb}\beta_3$ heterodimers into oligomers through lateral diffusion.^{325,326} These conversions are critical in allowing $\alpha_{IIb}\beta_3$ to engage soluble adhesive ligands. These ligands contain the classical integrin-recognition sequence RGD, Arg-Gly-Asp, which acts as a bridge between adjacent platelets, allowing aggregation to proceed. In addition, more $\alpha_{IIb}\beta_3$ translocates to the platelet surface membrane from the degranulating α -granule pool, where additional receptors are stored. These changes facilitate irreversible binding to fibrinogen.

FIGURE 16.12. Integrin activation is bidirectional and reciprocal. The $\alpha_{IIb}\beta_3$ complex equilibrates between resting and activated states, the resting state predominating in unstimulated platelets and the activated state in stimulated platelets. Conversion from resting to activated does not imply a single, abrupt change but rather a series of coordinated and linked conformational transitions. A: Inside-out signaling. Agonist-dependent intracellular signals stimulate the interaction of key regulatory ligands (such as talin) with integrin cytoplasmic tails (in this case the β_3 tail). This leads to conformational changes in the extracellular domain that result in increased affinity for adhesive ligands such as fibrinogen, von Willebrand factor (vWF), and fibronectin. Plasma fibrinogen and vWF support platelet aggregation at low and high shear rates, respectively, by bridging $\alpha_{IIb}\beta_3$ receptors on adjacent platelets. Studies in mice deficient in fibrinogen and vWF indicate that plasma fibronectin can also promote thrombus initiation, growth, and stability at high shear rates. B: Outside-in signaling. Extracellular ligand binding, initially reversible, becomes progressively irreversible and promotes integrin clustering and further conformational changes that are transmitted to the cytoplasmic tails. This results in the recruitment and/or activation of enzymes, adaptors, and effectors to form integrin-based signaling complexes. (From Shattil SJ, Newman PJ. Integrins: dynamic scaffolds for adhesion and signaling in platelets. *Blood* 2004;104:1606-1615.)

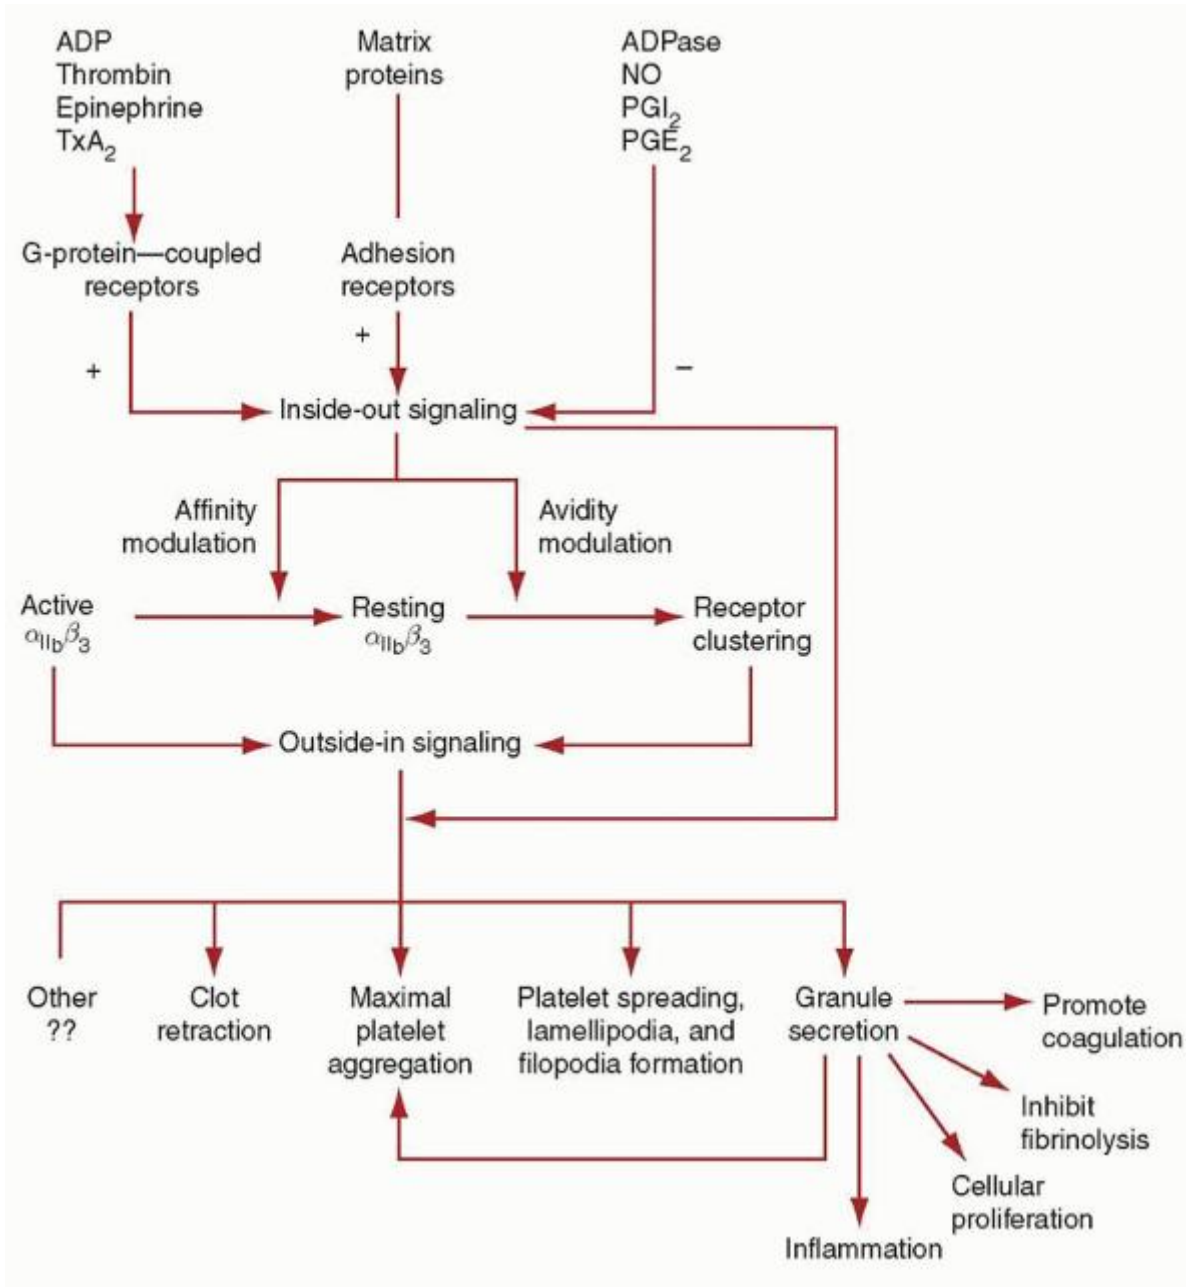

FIGURE 16.13. Schematic illustration of $\alpha_{IIb}\beta_3$ receptor regulation via inside-out and outside-in signaling. ADP, adenosine diphosphate; ADPase, adenosine 5'-diphosphatase; NO, nitric oxide; PGE_2 , prostaglandin E_2 ; PGI_2 , prostacyclin; TxA_2 , thromboxane A_2 . (From Casserly IP, Topol EJ. Glycoprotein IIb/IIIa antagonists—from bench to practice. *Cell Mol Life Sci* 2002;59:481, with permission.)

After ligand binding occurs, a multitude of intracellular signals are generated that are collectively referred to as outside-in signaling. This “contact-dependent signaling” determines the extent to which platelets will spread on a vascular matrix and how resistant to detachment they are.^{318,325} Outside-in signaling occurs in a discrete pattern in which ligand binding initiates integrin clustering and assembly of a “nascent” signaling complex proximal to the $\alpha_{IIb}\beta_3$ cytoplasmic tails, and this is followed by the growth of a larger “actin-based” signaling complex. It can be envisioned that the nascent complex is characterized temporally by (a) activation of Src kinases bound to the β_3 cytoplasmic tail by fibrinogen engaging and facilitating integrin clustering, then (b) recruitment and activation of Syk by Src, then (c) Src and/or Syk phosphorylation of various substrates including adaptor proteins SLP-76 and c-Cbl along with the Rac GTPase Vav; and these substrates in

turn act by participating in signaling to the actin cytoskeleton. As the nascent complex assembles, many additional proteins are recruited that can influence actin reorganization, including Rac, the adaptor Nck, PAK, PI3-kinase, and VASP, an actin-bundling protein. All these signaling events during platelet aggregation are further supported by release of granules induced by the binding of adhesive proteins to the extracellular domain of β_3 . This complex series of events serves as a determinant of the final clot size. Once full spreading and aggregation of platelets occurs, usually within several minutes, focal adhesion kinase is phosphorylated.³²⁶ The PI3K system is activated once $\alpha_{IIb}\beta_3$ is engaged, leading to generation of D3 phosphoinositides. These proteins act to prevent the depolymerization of the actin cytoskeleton, with the result that the platelet aggregate is stabilized. The end result of this outside-in signaling is a stable platelet clot. Not only does the $\alpha_{IIb}\beta_3$ receptor have important roles with respect to platelet function, it affects coagulation and may influence inflammatory processes as well.

Antithrombotic agents that act on the $\alpha_{IIb}\beta_3$ receptor have had a significant impact on clinical outcomes of patients with acute coronary syndromes (ACS) and those requiring percutaneous coronary interventions (PCI).³²⁷ The three parental agents used in the United States are the chimeric monoclonal antibody abciximab, the cyclic heptapeptide (based on the RGD sequence) eptifibatid, and the synthetic nonpeptide tirofiban. Disappointing clinical trial results were seen with the oral $\alpha_{IIb}\beta_3$ inhibitors used for longer term indications, and this even includes an increased all-cause mortality rate. The reasons for these results are not entirely known.

ROLE OF THE CYTOSKELETON IN PLATELET FUNCTION

(See additional cytoskeleton structure information in the section on platelet structure earlier in the chapter.)

Once an agonist has interacted with its platelet membrane receptor and triggered second messenger formation, a key event in platelet activation and subsequent aggregation is the transition of the platelet's shape from the discoid appearance associated with its circulating, resting state to the amorphous, amebalike

P.407

appearance with multiple pseudopodial projections that denote its activation state and readiness to participate in platelet plug formation. The platelet cytoskeleton and its associated signaling proteins are responsible for mediating shape change associated with activation, spreading, secretion, and aggregation. This cytoskeleton is associated with at least 14 different structural proteins that function interdependently as a single unit but can be seen as consisting of three major functional units: (a) a cytoplasmic network consisting mainly of actin, (b) a meshwork of proteins immediately proximal to the cytoplasmic leaflet of the platelet membrane referred to as the membrane skeleton (because they contain surface-associated proteins such as the GPIb complex), and (c) the microtubule coil that encircles the platelet to contribute to its resting, discoid state.

Transmembrane receptors such as GPIb participate in anchoring the platelets to extracellular matrix in the arterial subendothelium through their extracellular domains, while their cytoplasmic domains are almost simultaneously associating with membrane skeletal proteins in response. In doing so, these surface receptors are providing sites at which tension can be generated by intracellular contractile elements that subsequently lead to shape change and activation of signaling proteins.

The cytoplasmic network consists of actin filaments and their associated proteins, referred to as intermediate filaments. In resting platelets, approximately half of the actin is structurally filamentous in nature, and this fraction increases to approximately three-fourths during platelet activation.⁴⁶ During this process, the actin filaments are reorganized into longer filaments after their initial breakdown into smaller units. Simultaneously, myosin is phosphorylated by myosin light chain kinase and then associates with F-actin, with the resultant filament then attaching itself to the α subunit of the GPIb complex through filamin.^{328,329} These filaments are also anchored at sites called focal adhesions, where the tyrosine kinase Fak becomes activated after platelet stimulation. Focal adhesions assemble around the $\alpha_{IIb}\beta_3$ integrin on its conformational change (activation) and so play a very important role in signaling pathways associated with platelet activation by drawing together membrane receptors, the cytoskeleton, and signaling phosphoproteins, such as members of the Src family, PI3K, and Syk, into close physical proximity.³³⁰ Other platelet integrin receptors, such as $\alpha_2\beta_1$, also organize focal adhesions after binding to their respective extracellular ligands.

It was noted in the section on GPIb complex signaling that phosphorylation of Ser 166 in the cytoplasmic domain of the GPIb complex β chain has been observed to be mediated by cAMP-associated activation of PKA and that this phosphorylation reduced interaction of GPIb β and the signaling molecule, 14-3-3 ζ . The phosphorylation of GPIb β has also been demonstrated to have a direct inhibitory effect on actin polymerization.³³¹

The membrane skeleton consists of actin, filamin-A, talin, vinculin, spectrin, cortactin, α -actinin, and several membrane GPs, as noted previously. Filamin-A (previously termed actin-binding protein), a 280-kDa elongated dimer, serves as a scaffold for many proteins, including GPIIb α and is important to the latter's signaling and expression, and together they control platelet size. After platelet activation, cytoskeletal proteins, in particular filamin and talin, are preferentially cleaved by calpains, which are calcium-dependent proteases. Calpain-mediated cleavage of the β 3 tail of $\alpha_{IIb}\beta_3$ may modulate its functions.

The marginal microtubule band maintains a platelet discoid shape and appears to be an essential intermediate in the microtubule-driven process of proplatelet formation and platelet release.³³¹ This single microtubule polymer is wound in 8 to 12 coils in the cytoplasmic periphery and is located just beneath the plasma membrane. About 90% of β -tubulin in the marginal band is of the divergent, megakaryocyte (MK)/platelet-restricted β 1 isoform. β 1-tubulin-null mice show reduced proplatelet formation, thrombocytopenia, and platelet spherocytosis.³³²

PLATELET-CELL INTERACTIONS

Platelets and Endothelium

The mechanisms behind platelet interaction with vWF, collagen, and other subendothelial matrix molecules exposed as a result of damaged endothelium have been well studied and described in earlier sections of this chapter. In addition to these platelet-subendothelial interaction paradigms, platelets (like neutrophils) roll on intact, activated endothelium *in vivo* and then reversibly adhere to it in a process that is dependent on endothelial cell expression of P-selectin.^{333,334} This sequence of molecular interactions is a well-controlled multistep process involving platelet tethering and interaction of platelet P-selectin glycoprotein ligand-1 (PSGL-1) or GPIIb α with endothelial P-selectin ("rolling"), followed by subsequent "firm adhesion" to the vascular wall mediated through β_3 integrins. Platelets rolling on activated endothelium can be inhibited by both anti-P-selectin and anti-GPIIb α antibodies. GPIIb α and PSGL-1 have structural similarities, including similar ligand-binding domains, and both are present on platelets and may interact with P-selectin. Endothelial P-selectin is rapidly expressed on the surface in response to inflammatory stimuli by translocating from membranes of storage granules (Weibel-Palade bodies) to the plasma membrane within seconds.

Along with endothelial P-selectin, vWF expressed on activated venous endothelium promotes platelet adhesion and translocation.³³⁵ When released along the endothelial surface as ultralarge vWF, platelets adhere like beads on a string. Platelets are released by cleavage of vWF by the metalloprotease, a disintegrin-like metalloproteinase with thrombospondin repeats-13 (ADAMTS13), that proteolyzes vWF within the A2 domain under conditions of increased shear stress. Dysfunction in ADAMTS13 function underlies thrombotic thrombocytopenic purpura (TTP). In the absence of ADAMTS13, the platelet beads along the endothelial cells coalesce to form thrombi.

Firm platelet adhesion to intact endothelial cells following rolling is a process dependent on $\alpha_{IIb}\beta_3$ bridging to endothelium that involves endothelial receptors such as $\alpha_v\beta_3$ and intercellular adhesion molecule-1 interacting with platelet-bound fibrinogen, fibronectin, and vWF.^{335,336,337} This firm adhesion is strengthened by inflammatory cytokines, such as RANTES, and additional receptor pairs, such as CD40-CD40L.

Platelets and White Blood Cells

Platelets contribute to leukocyte rolling and extravasation, which are two well-characterized steps involved in the translocation of the latter cell from the circulation to sites of infection.³³⁸ Leukocytes are also capable of tethering and rolling on adherent and activated platelets by interacting with P-selectin expressed on the platelet surface, and they will subsequently display extravasation mediated by activation of Mac-1.³³⁹ The α subunits of certain integrins, such as Mac-1, have been found to contain "insert" (I) domains, homologous to the A₁ domain of vWF. This observation has taken on added interest since it has been shown that Mac-1 is capable of binding to the GPIIb complex and that this interaction requires the I domain of Mac-1 and the leucine-rich repeat region of GPIIb α . The Mac-1-GPIIb complex interaction may be important to initiate and propagate inflammation associated with the progression of atherosclerotic, purely thrombotic, or atherothrombotic processes.

Mac-1 has also been found to associate with other receptors of the platelet membrane, including the junctional adhesion molecule-3 (JAM-3), intercellular adhesion molecule-2 (ICAM-2), fibrinogen bound to $\alpha_{IIb}\beta_3$, and high-molecular-weight kininogen bound to GPIIb α .³⁴⁰ During this adhesive process, the association of platelet membrane PSGL-1 and Mac-1 stimulates the

P.408

release of inflammatory cytokines from platelets, which in turn induces inflammatory cascades in monocytes. This

integrin-, selectin-, and cytokine-based set of coordinated reactions linking neutrophils, platelets, and monocytes leads to circulating activated platelets and platelet-white cell aggregates that promote formation of atherosclerotic lesions.

ROLE OF PLATELETS IN SYSTEMIC DISORDERS

Inflammation and Immunity

The binding of platelets to leukocytes influences important white cell effector responses, such as cell activation, signaling associated with integrin activation, chemokine synthesis, and so forth. Thus, it has become clear that inflammation is capable of leading to local thrombosis, and thrombosis is capable of initiating and propagating inflammation. Leukocyte interactions with platelets result in immediate events, including activation of adhesion receptors, reactive oxygen species generation, and thrombin formation, but also in delayed responses such as alterations in gene expression and protein synthesis. The molecules regulated by platelet adhesion include cyclo-oxygenase 2 and tissue factor expression. Platelets and leukocytes participate in transcellular metabolism of arachidonic acid to generate novel mediators that either cell type alone could not generate. Platelets also stimulate the formation of neutrophil extracellular traps (nets) composed of DNA and proteases. Nets trap and kill bacteria and may also form scaffolds for thrombus formation. Platelets can also promote class switching of B cells through CD40L. The interactions of platelets with leukocytes may regulate the development of intimal hyperplasia, inflammatory lung and bowel disease, and arthritis.

Platelets in Atherogenesis

Atherosclerosis is the major cause of vascular occlusive disorders such as coronary artery disease, stroke, and peripheral arterial disease. Many of the molecular players mediating leukocyte-endothelium interactions that underscore the development of atherosclerosis have also been found to play important roles coordinating leukocyte attachment and transmigration across layers of platelets adherent to injured vascular intima. Animal models have recently provided strong evidence linking platelets to early events of atherogenesis. An atherosclerosis mouse model lacking α_{IIb} exhibited substantial reduction in atherosclerotic lesion formation.³⁴¹ The importance of P-selectin in atherosclerosis lesion formation has been well described.^{342,343} Platelet adhesion has been found to activate endothelial cell nuclear factor- κ B and its regulated genes, many of which play key roles in platelet-leukocyte-endothelium-extracellular matrix molecular events that support inflammatory and proatherogenic phenotypes. This includes events that contribute to lesion maturation such as smooth muscle cell and fibroblast proliferation and promotion of collagen synthesis, among others. Inhibition of COX-1, an enzyme with expression restricted to platelets, in turn inhibits lesion formation in an atherosclerosis mouse model.^{344,247} Another atherosclerosis mouse model demonstrates that prolonged antibody blockade of GPIIb/IIIa leads to reduced arterial leukocyte accumulation in carotid arterial intima and subsequent reduced atherosclerosis lesion formation.³⁴⁵ vWF may also have a role in atherogenesis.³⁴⁶

In contrast to animal data, conclusions regarding the role of human platelets in atherogenesis are not nearly as extensive. Mouse data cannot be unequivocally applied to humans, because mouse platelets differ from human with respect to expression levels of certain surface receptors. Systemic platelet activation in humans has been described in a variety of atherosclerosis disease presentations. Antiplatelet agents do not obviously influence disease progression when applied in the secondary disease prevention setting in humans in which atherosclerosis is likely advanced, as opposed to the possibly preventable progression of early lesions that are present before an initial atherosclerosis clinical event.³⁴⁷

Platelets in Atherothrombosis

The interior of intact atherosclerotic plaques is rich in components that are highly thrombogenic (e.g., collagen types I and III, fibrinogen/fibrin, thrombospondin), and the luminal surface is relatively nonthrombogenic. In contrast to these observations, the thrombotic response to plaque disruption is dynamic. In this respect, thrombosis, repeat thrombosis, and thrombolysis, along with embolization, all occur simultaneously in many patients with acute coronary syndrome, and this is considered responsible for intermittent flow obstructions.³⁴⁸ The initial flow obstruction is acknowledged as being due to platelet aggregation, but subsequent fibrin stabilization is important to the longevity of the early and fragile platelet thrombus.³⁴⁹ As a result of reduced flow caused by the platelet thrombus at the plaque rupture site, an erythrocyte- and fibrin-rich thrombus may form and propagate up and down the artery in both directions.³⁴⁸ There is evidence that alteration of the endothelium such as may occur with early atherogenesis (particularly when under the influence of atherosclerosis risk factors) or plaque disruption may cause the endothelium to generate more mediators that enhance constriction, such as endothelin-1, and fewer mediators that enhance dilation, such as PGI₂ and NO.

Platelets in Vessel Integrity and Development

Platelets are essential to maintain the integrity of the vasculature, although the mechanisms are unknown. Platelets store a number of barrier stabilizing cytokines and growth factors which may be released constitutively or in a stimulus-

dependent manner, including sphingosine-1-phosphate (S1P) is essential for barrier function, ADP, serotonin, VEGF, and thrombospondin. Platelets recruit and promote the differentiation of bone marrow-derived and circulating endothelial progenitor cells, which may contribute to the vessel response to injury. Finally, platelets regulate lymphangiogenesis through interactions between platelet C-type, lectin-like receptor 2 (CLEC-2) expressed by platelets and podoplanin on lymphatic endothelial cells. Disruptions in these interactions in mice result in severe lymphatic vascular defects.

Chapter 17

Platelet Function in Hemostasis and Thrombosis

David C. Calverley

PLATELET ADHESION AND ACTIVATION

Primary hemostasis and arterial thrombosis are the results of a complex series of cell-cell, cell-protein, and protein-protein reactions that involve platelets, leukocytes, endothelium, subendothelial matrix, and plasma proteins, such as fibrinogen, von Willebrand factor (vWF), and others. The consequences of arterial thrombosis include such events as myocardial infarction (MI), unstable angina, and stroke. These clinicopathologic entities and their associated cellular physiologic mechanisms that are outlined in this chapter collectively account for the largest cause of morbidity and mortality in the Western world.

Platelet adhesion to exposed subendothelium is a complex multistep process that involves a diverse array of adhesive ligands (vWF, collagen, fibrinogen/fibrin, fibronectin, thrombospondin, laminin, and vitronectin) and surface receptors (gpIb/V/IX, gpVI, integrins $\alpha_{IIb}\beta_3$, $\alpha_2\beta_1$, $\alpha_5\beta_1$, and $\alpha_6\beta_1$).^{1,2,3,4,5,6,7,8,9,10,11,12} and ¹³ The specific ligand/receptor players in primary platelet adhesion are largely dependent on the arterial flow conditions present.^{5,14} As such, in larger arteries and

veins, platelet adhesion to the vessel wall is thought to involve fibrillar collagen, fibronectin, and laminin. There are at least 25 forms of collagen, and several of these are present in the blood vessel wall, whereas one (type IV) is present in the subendothelial basement membrane.¹⁵ In the high-shear conditions present in smaller arteries, platelet tethering is dependent on the unique shear-dependent interaction between gpIb/V/IX and subendothelial vWF. The subsequent rapid platelet deceleration allows for other ligand-receptor interactions such as collagen and $\alpha_2\beta_1$ that have slower binding kinetics and take on the role of mediating firm platelet adhesion. A metalloprotease, ADAMTS13, cleaves vWF; this cleavage prevents the accumulation of ultrahigh-molecular-weight multimers that would otherwise cause spontaneous platelet clumping and arterial thrombosis.

Following initial platelet adhesion, subsequent platelet-platelet interaction (aggregation) is mediated by two receptors, gpIb/V/IX and $\alpha_{IIb}\beta_3$, and their respective contributions are dependent on the flow conditions present. In high-shear stress conditions, gpIb/V/IX receptor and vWF ligand action are predominant, with fibrinogen playing a stabilizing role. At low-shear conditions, fibrinogen is thought to be the primary ligand supporting platelet plug formation through its interaction with $\alpha_{IIb}\beta_3$. It has been shown that thrombus formation can take place in the absence of vWF and fibrinogen, and this supports the idea that a third ligand directed to the $\alpha_{IIb}\beta_3$ receptor may also exist *in vivo*.¹⁶

Platelet Glycoprotein Ib Complex-von Willebrand Factor Interaction and Signaling

It has long been recognized that the interaction of the platelet glycoprotein (gp) Ib “complex” (including the single-chain polypeptides gpIb α , gpIb β , gpIX, and gpV) with its primary ligand, vWF, is the receptor-ligand pairing that initiates platelet adhesion followed by a cascade of events leading to pathologic thrombosis or physiologic hemostasis. A unique aspect of this receptor-ligand interaction is that it requires the presence of high arterial shear rates to take place, thus explaining the predisposition of platelet-rich “white clots” in the arterial circulation over clots found in the venous circulation, with its relatively lower shear forces, in which clot formation takes place independent of the gpIb complex.

Using a parallel-plate flow cytometer, platelet interaction with subendothelial vWF has been characterized as occurring in a biphasic fashion.¹⁷ In this respect, the rate of translocation of platelets from blood to the endothelial cell surface increased linearly up to wall shear rates of $1,500 \text{ s}^{-1}$, whereas the translocation rate remained relatively constant with the wall shear rate between $1,500$ and $6,000 \text{ s}^{-1}$. This ability to mediate translocation or rolling of the platelet on vWF is contingent on the gpIb complex, and mammalian cells expressing either the full complex or a complex lacking the gpV subunit were able to roll onto vWF in a gpIb α -chain-dependent manner.^{18,19}

It is clear that arterial thrombus formation is contingent on both the presence of high wall shear rates and interaction between the gpIb complex and vWF. Studies involving the endpoint of realtime thrombus formation that involved comparison of blood from both patients with Bernard-Soulier syndrome (which lacks platelet gpIb complex) and severe (type 3) von Willebrand disease versus normal blood led to the conclusion that gpIb and vWF interaction was required for platelet surface interaction at high shear rates ($>1,210 \text{ s}^{-1}$), whereas normal thrombus formation at lower shear rates ($<340 \text{ s}^{-1}$) was possible with blood deficient in either gpIb or vWF.²⁰ In normal blood, thrombus formation was accelerated as shear rate increased, and this served to verify the unique shear flow dependence of this receptor-ligand interaction.

The gpIb complex consists of four transmembrane subunits, each of which is a member of the leucine-rich repeat protein superfamily that participates in cell-matrix interactions throughout nature. Each of the four subunits contains one or more tandem, 24-amino acid leucine-rich repeats flanked by conserved disulfide loop structures at both the N and C termini of the repeats.²¹ gpIb α is covalently associated with the gpIb β chain through disulfide linkage of cysteine residues, and both of these chains are noncovalently associated with gpIX in a 1:1 ratio and with gpV in a 2:1 ratio^{22,23} and ²⁴ (Fig. 17.1).

vWF is a large multimeric glycoprotein that circulates in plasma and is also found in platelets and the Weibe-Palade bodies of endothelial cells. Mature vWF is a 2,050-amino acid subunit that is disulfide linked into large multimers. It contains three adjacent A domains in the N-proximal half of the peptide that collectively regulate the adhesion of platelets to subendothelial matrix. In this respect, the A₁ and A₃ domains bind to different matrix collagens, whereas the A₁ domain contains the binding site for the gpIb complex.²⁵ The A₁ domain is the primary role player in platelet adhesion, because this part of the molecule is believed to change its conformation in response to immobilization and high-shear forces, thus making it a high-affinity ligand for the gpIb complex receptor.^{26,27} It has also been suggested that shear stresses may induce conformational changes in the gpIb complex that may be important in increasing its affinity for vWF.²⁸ Through the simultaneous binding of collagen and platelets, vWF can serve as a molecular bridge between platelets and the subendothelial matrix mediating platelet adhesion to the vessel wall. Thus by associating with matrix proteins vWF mediates rapid and reversible platelet adhesion that promotes the rolling of these cells along the surface of vascular injury.

To further add to the mystery behind the mechanism of shear dependence in gplb-vWF interaction, in vitro activation of vWF and binding to the gplb complex occur with generally very low affinity without shear, whereas this shear-free binding exhibits high affinity in the presence of the vancomycinlike antibiotic ristocetin, and viper venom proteins, such as botrocetin. It is interesting that studies incorporating anti-gplb α and anti-vWF domain A₁ antibodies have suggested that ristocetin and botrocetin each

P.412

appear to use different receptor and ligand-binding sites to facilitate the vWF-gplb complex interaction.^{29,30} and ³¹

FIGURE 17.1. Schematic illustration of the glycoprotein (GP) Ib/V/IX complex and associated proteins. The N-terminal domain of GPIb α contains binding sites for von Willebrand factor (vWF) and thrombin. The cytoplasmic domain of GPIb α contains the phosphorylation-dependent 14-3-3 binding sites, and also the binding site for filamin that links GPIb-IX to the actin cytoskeleton underlining the membrane. The cytoplasmic domain of GPIb β is phosphorylated by protein kinase A (PKA) and this phosphorylation is required for 14-3-3 binding. The membrane proximal region in the cytoplasmic domain of GPIb β and GPIX contains calmodulin-binding sites. From Du, X. Signaling and regulation of the platelet glycoprotein Ib-IX-V complex. *LWW, Curr Opin Hematol* 2007;14:262, Figure 2, with permission.

The binding interaction between vWF and gplb appears to involve at least three distinct regions within the N-terminal 282 residues of gplb. Each of these regions appears to be responsible for either direct binding to vWF or modulating its affinity for the ligand.³² In this respect, one region (His 1 to Glu 282), which includes a cluster between residues Asp 252 and Arg 293 containing sulfated tyrosine residues and important anionic residues, appears to be predominantly responsible for vWF-gplb complex interaction in the presence of botrocetin over ristocetin.^{33,34} and ³⁵

The second region contains the disulfide loop between Cys 209 and Cys 248 along with two naturally occurring mutations (Gly 233 to Val and Met 239 to Val) and two additional mutation sites identified in the laboratory (Asp 235 to Val and Lys 237 to Val) that can individually lead to expression of the pseudo- or platelettype von Willebrand disease phenotype.³⁰ This disorder is associated with a gain-of-function gplb α on platelets that adheres to vWF in the presence of lower concentrations of ristocetin (0.3 to 0.5 mg/ml) than are required for the wild-type phenotype (1.5 g/ml). It is analogous to type 2B von Willebrand disease, in which high-molecular-weight vWF multimers are absent from the plasma, and similar gain-of-function mutations have been localized to the Cys 509 to Cys 695 disulfide loop of vWF exon 28.

The third region includes the N-terminal flanking sequence of the leucine-rich repeat (LRG) motifs and the LRGs themselves. Mutations involving single amino acid residues within these LRGs account for some cases of the congenital bleeding disorder, Bernard-Soulier syndrome, in which the gplb complex binds poorly or not at all to vWF. Evidence using mammalian Chinese hamster ovary cells expressing loss-of-function proteins and anti-gplb α monoclonal antibodies has suggested that the more N-terminal LRGs may play a more direct role in interaction with vWF.³⁶

Glycoprotein Ib Complex Interaction with Thrombin

Recent studies have examined the potential role of the gplb complex in thrombin-mediated platelet activation. The physiologic significance of the interaction of thrombin with the complex has remained relatively controversial. gplb α contains a well-characterized high-affinity binding site for thrombin, and thrombin is also capable of cleaving gpV near the surface to release a soluble fragment.³⁷

Recent studies have suggested that a relationship exists between thrombin binding to the gplb complex and cleavage of the seven-transmembrane G-protein-coupled protease-activated thrombin receptor, protease-activated receptor (PAR)-1 (see section "Platelet Thrombin [Protease-Activated] Receptors and Signaling"), and that accelerated coagulation on the surface of a developing thrombus is a downstream consequence of thrombin-gplb interaction because of enhanced phospholipid exposure.^{38,39} These studies support a procoagulant role of this thrombin-gplb pairing and this activity also plays an important role in the generation of platelet microparticles.^{40,41} In contrast, studies using gpV-null mice have suggested that the gpV subunit may act as a negative regulator of thrombin-mediated platelet activation, whereas data from another study suggest that thrombin-gplb interaction leads to conformational changes in thrombin that reduce its cleavage of fibrinogen.^{42,43}

The phenotype of a gplb α knockout mouse has been reported and was similar in many ways to human Bernard-Soulier syndrome.⁴⁴ This mouse was then capable of having the wild-type phenotype restored by a human gplb α transgene. Future use of this mouse model might be helpful toward further elucidation of the physiologic role of platelet gplb complex interaction with thrombin.⁴⁵ In the meantime, the current data extend further support for a role for the gplb complex as a thrombin receptor on platelets, whereas, recent insights notwithstanding, elucidation of the downstream consequences of that interaction with respect to platelet activation and thrombus formation will remain the subject of further investigation.

Studies have focused on interaction of the gplb complex with activated intact endothelium through ligands other than vWF adherent to subendothelial matrix. These include a study of a reversible association of gplb with endothelial cell P-selectin, which is examined in more detail in the section, "Platelets and Endothelium." The interaction of platelet gplb with the neutrophil adhesion receptor Mac-1 is discussed in the section, "Platelets and White Blood Cells." These interactions may contribute more to inflammatory responses than platelet thrombus formation. The dependence of fibrin-associated platelet procoagulant activity on both the gplb complex and vWF has also been documented.⁴⁶

Glycoprotein Ib Complex Signaling

For some time, controversy surrounded the question of whether the gplb/V/IX complex signals. This was likely a result of variations in experimental strategies that involve differences with respect to vWF preparations, the use of conformational modulators in experimental work such as botrocetin, cell lines used, and other causes. It is reasonable to assume that the receptor is capable of signaling, although a lot of questions remain to be answered, and the many molecules that are known to participate in the process remain to be assembled into a defined pathway.

When the gplb complex interacts with its vWF ligand under conditions of elevated shear stress, there is abundant evidence that signaling pathways are activated that lead to (a) elevation of intracellular calcium; (b) activation of a tyrosine kinase signaling

P.413

pathway that incorporates nonreceptor tyrosine kinases such as Src, Fyn, Lyn, and Syk, phospholipase C (PIC) γ 2, and adaptor proteins such as SHC, LAT, and SLP-76; (c) GTPase activating protein; (d) tyrosine phosphatases (PTP-1B and SHPTP10); (e) inside-out signaling through the $\alpha_{IIb}\beta_3$ integrin followed by platelet aggregation³²; and (f) activation of protein kinase C (PKC), protein kinase G (PKG), and phosphoinositide 3-kinase (PI3K). vWF binding also up-regulates integrin $\alpha_{IIb}\beta_3$ affinity indirectly through stimulation of adenosine diphosphate (ADP) secretion.³³ Other downstream players and events that play roles after gplb receptor occupancy include (a) the homodimeric signaling protein 14-3-3 and calmodulin, (b) receptor cross-linking, and (c) the immunoreceptor tyrosine-based activation motif (ITAM)-containing proteins Fc γ receptor IIA (Fc γ RIIA) and Fc receptor (FcR) γ chain. In addition to the above-mentioned components, the effect of shear force itself on gplb signaling, including the affinity and number of bonds between vWF and gplb, play potentially important roles as well.^{34,35}

Evidence has also been presented suggesting that indirect mechanisms may also be involved in gplb signaling, that are linked to ADP release and/or thromboxane A₂ (TxA₂) generation.^{33,34} The increase in intracellular calcium prompted by vWF-gplb interaction promotes dense granule secretion of ADP, which then activates integrin $\alpha_{IIb}\beta_3$ through the P2Y₁ and P2Y₁₂ purinergic receptors (see the section on "Platelet P2Y₁ and P2Y₁₂ Receptor Roles in ADP-Mediated Activation" later in the chapter).

14-3-3 ζ is among the 10 isoforms of the 14-3-3 family of proteins that is named according to its electrophoretic gel migration position. Functionally, this family has a wide range of activities, including participating as a DNA damage, cell-cycle checkpoint protein, regulation of PKC activity, formation of heterotrimers with the signaling kinase Raf and the guanosine triphosphate exchange factor Ras, and so forth.^{47,48} and ⁴⁹ Binding sites for 14-3-3 have been identified in the cytoplasmic domains of gplb α , gplb β , gplX, and gpV. In this respect, peptide fragments corresponding to overlapping cytoplasmic sequences of the four subunits demonstrated binding in vitro, whereas yeast two-hybrid studies documented in vivo interaction between 14-3-3 ζ and both gplb α and - β .^{50,51} Site-directed mutagenesis and protein-binding experiments confirmed the need for phosphorylation of Ser 166 of the 14-3-3 consensus sequence in the gplb β cytoplasmic domain to permit high-affinity 14-3-3 binding.^{51,52} Findings that have evolved in lieu of the above observations include the binding of fibrinogen to mammalian-cell-transfected $\alpha_{IIb}\beta_3$ in response to vWF binding to co-transfected gplb-IX that was inhibited when the 14-3-3-binding domain was deleted from the gplb-IX transfectant.⁵³ Also, the lipid kinase PI3K has been found to play a role in this gplb-IX dependence of $\alpha_{IIb}\beta_3$ activation through its participation in complex formation with the gplb complex and 14-3-3.⁵⁴ The reason for these associations would be to regulate, in short order, the formation of inositols phosphorylated in the 3-position within the reorganizing cytoskeleton in response to platelet activation (see section "Role of the Cytoskeleton in Platelet Function").³²

Many adhesion receptors initiate signaling through cross-linking, and there is evidence to suggest that the gplb complex may also use this mechanism. The gpV subunit surface expression on platelets is roughly half that of the other three subunits (12,000 vs. 25,000 copies per cell). It has also been suggested that two or more gplb α subunits cluster into a complex with the other glycoprotein subunits.⁵⁵ The fact that there is one gpV subunit available in this complex for every two of the other subunits, and that both actin-binding protein (ABP or filamin; a membrane skeleton protein that associates with gplb α ; see later in the chapter) and 14-3-3 exist as dimers, lends support to the concept of a complex consisting of a pair of gplb α -gplb β -gplX trimers joined noncovalently by a single gpV monomer (Fig. 17.1).

Several studies document a physical association of the gplb complex with the 14-kDa Fc γ -chain⁵⁶ and with the 40-kDa Fc γ RIIA receptor,⁵⁷ suggesting that platelet activation may also occur through gplb-mediated triggering of Src-family-kinase phosphorylation.^{58,59} Both of these proteins contain nonidentical but similar ITAM domain sequences. The Fc γ -chain forms a complex with the gpVI monomer and plays an essential role in collagen-mediated platelet activation, as reviewed in the next section. The Fc γ RIIA receptor is a member of the immunoglobulin (Ig) superfamily and is without a clearly defined physiologic role in platelets. Occupancy of this receptor by the C-terminal Fc domains of immunoglobulin leads to platelet activation, and this is blocked by anti-gplb α antibodies, whereas signaling through vWF is also blocked with anti-Fc γ RIIA antibodies.^{57,60} Both ITAM-containing receptors can be coimmunoprecipitated with gplb,^{56,60} and both have very similar signaling pathways that involve the tyrosine kinase Syk and PIC γ 2.^{61,62} and ⁶³ Although the physical proximities of these three players have recently become apparent, the nature and significance of any physiologic

relationships that exist between the gpIb complex and these two ITAM receptors with respect to vWF-dependent platelet activation remains unclear.

Shear flow studies have demonstrated an important role for calcium signals that in turn promote $\alpha_{\text{IIb}}\beta_3$ activation necessary for stable platelet adhesion to vWF (34,35). This phenomenon occurs independently of extracellular calcium and is thought to involve $\alpha_{\text{IIb}}\beta_3$ -mediated calcium release from intracellular stores. One proposed mechanism to explain this observation involves signaling pathways such as those used by ITAM-bearing receptors, because the enzyme and adaptor protein components used in both $\alpha_{\text{IIb}}\beta_3$ and ITAM signaling are very similar. These components are likely to be important in the positive feedback loop linking $\alpha_{\text{IIb}}\beta_3$ activation and calcium flux under high shear, which in turn promotes the efficient conversion of translocating platelets into firmly adhesive cells.⁶⁴

Once vWF binds to gpIb-V-IX , signaling complexes form in the vicinity of the $\text{gpIb}\alpha$ cytoplasmic tail consisting of cytoskeletal proteins such as 14-3-3 ζ as well as signaling proteins such as Src and PI 3-kinase. This process leads to Syk activation, protein tyrosine phosphorylation, and recruitment of other cytoplasmic proteins with Pleckstrin homology domains that can support interactions with 3-phosphorylated phosphoinositides.^{65,66,67,68} and ⁶⁹

Platelet-Collagen Interaction and Signaling

Collagens are very important activators of platelets in the vascular subendothelium and vessel wall, and thus are prime targets for therapeutic intervention in patients experiencing a pathologic arterial thrombotic event such as MI or stroke. Platelets have two major surface receptors for collagen, the integrin $\alpha_2\beta_1$ and the immunoglobulin superfamily member gpVI . In addition to binding collagen with high affinity, $\alpha_2\beta_1$ binds laminins, E-cadherins, matrix metalloproteins, C1q, echovirus, and rotavirus. In addition to these two surface receptors, the gpIb complex can also be considered an indirect collagen receptor because its subendothelial vWF ligand essentially acts as a bridging molecule between platelets and collagen by fixing itself to the latter, which, in turn, acts as scaffolding for the multimers.

Collagen supports platelet adhesion through interaction with the integrin surface receptor $\alpha_2\beta_1$, although this interaction alone does not support platelet activation.⁷² Laboratory evidence suggests that gpVI and the 14-kDa $\text{Fc}\gamma$ -chain signaling subunit ($\text{Fc}\gamma$ chain) with which gpVI forms a complex are both required for collagen-mediated platelet adhesion and activation.^{61,69,70,71,72,73,74,75,76,77,78,79,80} and ⁸¹ Thus platelet adhesion to collagen is a multistep process. Once exposed to an injured vascular wall, vWF adheres to subendothelial collagen and undergoes a conformational change allowing its A1 domain to bind to GP1b/V/IX under high-shear flow conditions. This rapidly formed bond is quickly broken and re-established and this leads to the platelet rolling along the vascular wall. This

P.414

in turn slows down the platelet and allows the signaling receptor GPVI to bind collagen, more specifically the repeating sequence Gly-Pro-Hyp (where Hyp is hydroxyproline). Both receptors can signal but the role of GPVI is considered predominant in this respect.⁸² A series of signaling events then leads to the inside-out signaling activation of $\alpha_2\beta_1$ and interaction of this receptor with collagen is stable and allows the platelet to form a high-affinity strong adhesive bond with the vessel wall.

The above notwithstanding, of many receptors studied only $\alpha_2\beta_1$ and GPVI have a defined role in platelet-collagen interactions although, in spite of extensive studies, their relative importance with respect to both adhesion and activation continues to be debatable. Problems associated with the isolation of collagen from extracellular matrices and possible but poorly understood differences between human *ex vivo* and mouse *in vivo* experimental systems explain these ongoing unresolved issues.⁸²

$\alpha_2\beta_1$ Receptor

The platelet collagen receptor to be first identified and characterized was the integrin $\alpha_2\beta_1$ receptor, also known as gpIa/IIa , and on lymphocytes as VLA-2 .⁸³ Integrins are a family of α - β heterodimers on the surface of cells that carry out diverse interactions between the cell surface and its environment that ultimately lead to changes in cell behavior in response to the ligand-receptor interaction. In all α subunits of integrins, seven tandem repeats are localized to the N-terminal end and folded into a seven-bladed β -propeller structure.⁸⁴ The α_2 subunit also contains an I domain between the second and third repeats that includes a metal coordination site for Mg^{2+} that is critical for interaction with collagen.⁸⁵ Similar domains are found on the β subunit, although less is known about these, and it appears that the interaction of $\alpha_2\beta_1$ with collagen involves only the I domain of α_2 . The β_1 subunit exhibits a cysteine-rich domain containing CGXC sequences that is close to the membrane surface. This region has protein disulfide isomerase activity responsible for regulating

conformational changes of the β_1 subunit (which, in turn, alters α_2 conformation, increasing its avidity for collagen) in response to inside-out signaling through the cytoplasmic domain.^{86,87}

Glycoprotein VI Receptor

Although the gpVI receptor was identified on the surface of platelets in 1982, its role in collagen-mediated platelet activation was not appreciated until much later.⁸⁸ The human and murine genes were cloned and characterized, and gpVI was found to be a member of the immunoglobulin superfamily.^{81,87,89,90} The expression of gpVI in platelets is very closely associated with that of the 14-kDa FcR γ -chain, which also serves as the signaling subunit for gpVI.^{91,92} Expression of gpVI on mouse platelets appears to be dependent on FcR γ -chain expression, and the latter has also been found to be critical for collagen-mediated platelet activation.^{76,92} gpVI has two Ig C2 loops, and the N-terminal loop likely contains the collagen-binding domain.⁸² It appears that gpVI has a requirement for the quaternary structure of collagen to be in a triple-helical conformation for the two to associate.⁹³

Following the cloning of gpVI, mouse knockout studies have suggested GPVI may be the primary receptor involved in collagen-mediated platelet activation.^{94,95} and⁹⁶ Further studies have enabled the collagen-binding site on gpVI to be characterized.⁹⁷

Studies incorporating collagen-related peptides (arranged in triple helical structures with sequences similar to collagen) and the snake venom convulxin as agonists have been shown to signal by clustering gpVI molecules on the surface.^{73,78,98} However, the idea of gpVI receptor clustering as a platelet activation mechanism applicable to collagen is tempered by consideration of the theoretically much greater distances that would exist between adjacent gpVI-binding sites along fibrillar collagen compared with the larger, noncovalently linked structures of convulxin, in which gpVI-binding site distribution is much different.⁹⁹

Platelet-Collagen Signaling

When compared to vWF, collagen is a more efficient substrate when it comes to supporting stable platelet adhesion and thrombus formation. The fact that initial platelet tethering to collagen under high-shear flow first requires interaction between vWF and platelet gpIb serves to underscore the importance of the two major collagen receptors, $\alpha_2\beta_1$ and gpVI, in promoting platelet adhesion and activation under shear conditions.

Many of the early signaling events that follow gpVI stimulation have been characterized, although synergism between these gpVI mediators and those related to other adhesion receptors such as gpIb-V-IX and soluble agonists released by activated platelets further complicates full elucidation of the players and pathways associated with platelet-collagen signaling.

The gpVI signaling pathway has been found to be essential for collagen-mediated platelet activation, and mouse platelet studies have shown a central role for this receptor in promoting platelet-collagen interaction.^{61,100} Integrin $\alpha_2\beta_1$ also contributes to platelet adhesion through amplification of signals from gpVI.^{101,102} As noted in the last section, exposure of platelets to collagen surfaces is thought to result in gpVI clustering that in turn triggers the tyrosine phosphorylation of the FcR γ chain.⁹¹ gpVI signaling may be influenced by its association with glycolipid-enriched microdomains (membrane rafts) in the plasma membrane, although it is unclear whether gpVI is constitutively associated with the rafts or is recruited.^{103,104} The gpVI/FcR γ -chain complex leads to platelet activation through a pathway that has many aspects in common with signaling by immune receptors, such as the FcR receptor family (of which Fc γ RIIA is the lone family member found in platelets) and the B- and T-cell antigen receptors (Fig. 17.2). Much of what we know about gpVI signaling has been based on earlier work related to immune-receptor signaling.^{105,106}

FIGURE 17.2. Collagen activates platelets through the same pathway as an immune receptor. Cross-linking of the glycoprotein (gp) VI/Fc receptor (R) γ chain leads to tyrosine phosphorylation of the immunoreceptor tyrosine-based activation motif (ITAM) sequence, enabling recruitment of the tyrosine kinase (Syk) through its tandem Src-homology 2 (SH2) domains. This leads to autophosphorylation and subsequent activation of Syk, which in turn leads to tyrosine phosphorylation of phospholipase C γ 2 (PLC γ 2). A large number of proteins are implicated in the regulation of PLC γ 2, as discussed in the text. YP, phosphotyrosine. From Watson SP. Collagen receptor signalling in platelets and megakaryocytes. *Thromb Haemost* 1999;82:367, with permission.

P.415

Immunoreceptors such as the FcRs and the FcR γ chain all have the ITAM in common. Tyrosine phosphorylation of the ITAM by Lyn and Fyn of the Src family of tyrosine kinases takes place after activation of gpVI. The phosphorylated Src kinase, in turn, leads to activation of the tyrosine kinase Syk after its autophosphorylation.¹⁰⁷ Syk then initiates a downstream signaling cascade involving the LAT and SLP-76 adapter proteins, which leads to formation of a signaling complex by virtue of its multiple phosphorylation sites that also act as docking sites, leading to recruitment of additional proteins to the plasma membrane.¹⁰⁸ Transport to the signaling complex and activation of the cytosolic second messenger-producing enzymes PI3K and PLC γ 2 is also facilitated by tyrosine phosphorylated LAT.¹⁰⁹ PI3K leads to the generation of PI3,4P3 and PI3,4,5P3 (PIP3), and this, in turn, supports recruitment of proteins to the membrane signalosome complex with specific plekstrin homology (PH) domains including a member of the Tec kinase family, Btk,

along with PLC γ 2.^{110,111} Syk is critical for collagen-mediated platelet activation through the gpVI/FcR γ -chain complex, and knockout mouse studies have shown that absence of this enzyme leads to loss of phosphorylation of LAT, the adapter SLP-76, and PLC γ 2.^{61,111,112}

Adapters such as LAT are modular proteins without enzyme activity that support protein-protein interaction. Many adapter proteins appear to participate in the regulation of PLC γ 2. These proteins appear to come together in T lymphocytes along with PLC γ 1 to form a LAT/SLP-76 signalosome that is essential for activation of PLC γ 2.¹⁰⁶ SLP-76 is thought to be especially important among adapters in the regulation of PLC γ 2, because its loss results in reduced phosphorylation of PLC γ 2.^{112,113}

Along with the adapter proteins noted above, PI3K and its associated second messenger pathway also play a very important role in the regulation of PLC γ 2 through activation of other signaling proteins such as protein kinase B (PKB) (also known as Akt).^{114,115} One of the two PKB isoforms, PKB β (Akt2), is important for normal platelet function and thrombus formation and leads to impaired alpha and dense granule secretion along with impaired $\alpha_{IIb}\beta_3$ activation when absent.¹¹⁵ Integrin-linked kinase (ILK) is another PI3K downstream effector that interacts with β_1 and β_3 integrin subunit cytoplasmic tails and is considered important in the bidirectional signaling of $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$.^{396,397} It may also be playing a role in regulating PKB.³⁹⁴ Using PI3K inhibitors such as wortmannin and LY294002, studies have demonstrated significantly reduced PLC γ 2 activation through gpVI.^{116,117} and¹¹⁸ These inhibitors have also been shown to block platelet activation through the Fc γ RIIA immunoreceptor, and this demonstrates an additional similarity between signaling pathways of this receptor and the FcR γ chain.¹¹⁹

PLC γ 2 is known to play a critical role in aggregation and secretion responses to collagen, as demonstrated in PLC γ 2 knockout mice and in other studies.^{63,120,121} The major role of PLC isoforms is concerned with the generation of the second messengers inositol 1,4,5-triphosphate and 1,2-diacylglycerol (DAG), which participate in intracellular calcium homeostasis and activation of many isoforms of PKC. The former process culminates in a robust calcium signal that promotes efficient platelet activation. The PKC isoforms make possible the regulatory serine/threonine phosphorylation events needed for activation of $\alpha_2\beta_1$ as well as $\alpha_{IIb}\beta_3$, and interaction of these two integrins with their ligands facilitates a second round of signaling that includes some of the same molecules downstream of gpVI, such as Syk, SLP-76, and PLC γ 2.¹²²

Recent research has led to increased knowledge about $\alpha_2\beta_1$ receptor signaling. The use of $\alpha_2\beta_1$ -selective ligands has demonstrated calcium-dependent spreading and tyrosine phosphorylation of several proteins when interaction with platelets takes place, including Src, Syk, SLP-76, PLC γ 2, p38 MAP kinase, ILK, Rac, and PAK.^{117,123,124} It appears likely that only GPVI and GPIb/V/IX are able to bind collagen and vWF, respectively, without prior platelet activation. Once activation starts, $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$ are able to bind their respective ligands as well.

Other Platelet Adhesion Receptors

Other adhesive proteins present in the extracellular matrix and involved in the interaction between platelets and the subendothelium include fibronectin, thrombospondin, laminin, and vitronectin. Fibronectin is stored in platelet α granules and secreted upon thrombin-mediated platelet activation. Thrombospondin is also stored in platelet α granules. It interacts with fibrinogen, fibrin, fibronectin, and collagen on the platelet membrane and its release during platelet activation might relate to its capability to overcome the antithrombotic activity of physiologic nitric oxide (NO). Laminin is a large glycoprotein and can amplify platelet activation through GPVI binding. Recent data suggest that laminin may also interact with vWF and the GPIb/V/IX complex thereby supporting platelet adhesion under high-shear flow conditions.¹²⁵ The extracellular adhesive protein vitronectin can bind to platelet receptor $\alpha_{IIb}\beta_3$ or the integrin $\alpha_v\beta_3$ and appears to be functionally similar to fibronectin.

Physiologic Inhibition of Platelet Adhesion

Negative regulation of platelets is essential to set the stimulus threshold for thrombus formation, determine final clot size and stability, and prevent uncontrolled thrombosis. The mechanisms behind the negative regulation of platelet activation are described later in the chapter, and in this respect, roles of players such as NO and prostacyclin have been well characterized. Platelet activation and aggregation can also be inhibited by signaling through the platelet endothelial cell adhesion molecule (PECAM)-1 (CD31).^{126,127} This molecule is expressed on a number of blood cells and endothelial cells and has a wide array of regulatory functions in processes such as apoptosis and cell activation. It becomes tyrosine phosphorylated following platelet stimulation by a diverse set of agonists, which suggests that it has a negative feedback role in this setting. Its main ligand is itself, so it has been proposed that interactions between platelet and endothelial PECAM-1 might serve to restrict thrombus growth through the signaling mechanisms below; this is supported by studies involving PECAM-1-knockout mice.^{128,129}

Following homophilic interactions and/or clustering, PECAM-1 is tyrosine phosphorylated in its cytoplasmic-tail ITIM domain (immunoreceptor tyrosine-based inhibition motif) by Src family kinases, and this engenders recruitment of tyrosine, serine/threonine, or lipid phosphatases with resultant kinase-dependent signaling inhibition.^{127,130} The net result is reduced total platelet tyrosine phosphorylation, calcium mobilization, and signaling through PI3K.¹²⁷ ITIM-mediated signaling inhibition through the ITAM domain is not the only mechanism by which PECAM-1 dampens platelet adhesion, because low-density lipoprotein and thrombin-dependent signaling pathways also appear to be downregulated by PECAM-1.^{127,130} Negative effects have also been documented with gplb signaling and platelet FcγRIIA-mediated responses.^{131,132}

Von Willebrand factor multimer size and thus also vWF activity is mainly regulated by the metalloprotease ADAMTS13 and recently other factors have been found to cleave vWF including plasmin and leukocyte proteases.^{133,134} ADAMTS13 cleaves released large vWF multimers into smaller fragments. Different circumstances can induce vWF unfolding thereby exposing the ADAMTS13 cleavage site. These include high-shear flow conditions, denaturing agents such as urea, and mutations seen in von Willebrand disease type 2A. In contrast, reduced ADAMTS13 activity may lead to insufficient vWF processing causing a prothrombotic state such as thrombotic thrombocytopenic purpura (see Chapter 48).

P.416

Platelet Thrombin (Protease-activated) Receptors and Signaling

PARs are G-protein-coupled receptors that use a unique mechanism to convert an extracellular protein cleavage event into an intracellular activation signal. In this case, the ligand is already part of the receptor per se, by virtue of the fact that it is represented by the amino acid sequence SFLLRN (residues 42 through 47) and is unmasked as a new amino terminus after thrombin cleaves the peptide bond between Arg 41 and Ser 42. This “tethered ligand” then proceeds to dock irreversibly with the body of its own receptor to effect transmembrane signaling, as shown in Figure 17.3.

Thrombin signaling in platelets is mediated, at least in part, by four members of a family of G-protein-coupled PARs (PAR-1, -2, -3, and -4; see previous section for a discussion of the gplb complex as a thrombin receptor).¹³⁵ Human platelets express PAR-1 and PAR-4, and activation of either is sufficient to trigger platelet aggregation.^{136,137} Mouse platelets express PAR-3 and PAR-4.¹³⁸ PAR-1, -3, and -4 can be activated by thrombin, whereas PAR-2 can be activated by trypsin, tryptase, and coagulation factors VIIa and Xa but not thrombin.^{139,140} and ¹⁴¹ Presumably, other proteases are capable of recognizing the active sites of these receptors and can thus also trigger PAR signaling.

PAR-1 is the prototype family member and was the first to be cloned and characterized in the human and hamster.^{136,142} A synthetic peptide that mimics the PAR-1-tethered ligand (SFLLRN) is capable of functioning as an agonist by activating the receptor independent of cleavage of the 41-residue N-terminal exodomain.

The mechanism by which G-protein-coupled receptors, such as PAR-1, signal through the G proteins is shown in Figure 17.4. PAR-1 is capable of coupling to members of the G_{12/13}, G_q, and G_{i/z} families and thus is connected to a significant number of intracellular signaling pathways. The α subunits of G₁₂ and G₁₃ are believed to be involved in mediating rearrangement of the actin cytoskeleton and platelet shape change,¹⁴³ and downstream signaling mediators include Rho family members, among others. The α subunit of G_q is needed for platelet secretion and aggregation and participates in activation of PICβ that leads to calcium mobilization and PKC activation.^{144,145} The α subunit of G_z is a G_i family member that has been speculated to play an epinephrinelike role in human platelets through inhibition of adenylate cyclase.^{34,146}

FIGURE 17.3. Structure and features of PAR-1. Cleavage of PAR-1 by thrombin between arginine 41 and serine 42 exposes a new N terminus that serves as a tethered ligand. Activation of PAR-1 is followed by a rapid burst of signaling before the receptor is desensitized and, in some cases, cleared from the cell surface. From Brass LF. Thrombin and platelet activation. *Chest* 2003;124:18S-25S, with permission.

The β - γ subunit counterparts of G proteins involved in PAR-1 signaling are involved in a plethora of activities, including activation of protein kinases, channels, and lipid-modifying enzymes, such as PI3K, which provides attachment for multiple signaling protein complexes close to the inner leaflet of the cell membrane.^{147,148} and ¹⁴⁹ Thus, this vast network of signaling pathways mediated through several G-protein families is in keeping with the pleiotropic roles that thrombin has been shown to exhibit in cellular homeostasis, which extends beyond platelet activation to include endothelial cells, leukocytes, smooth muscle cells, and T lymphocytes, along with physiologic processes such as tissue injury, inflammation, angiogenesis, and embryonic development.⁴⁵

Once activated, PAR-1 is rapidly uncoupled from signaling and internalized into the cell.^{150,151} and ¹⁵² It is then transported to lysosomes and degraded.^{151,153,154} and ¹⁵⁵ Platelets presumably have no need for a thrombin-receptor recycling

mechanism, because once activated, they are irreversibly incorporated into blood clots. Conversely, in cell lines with characteristics similar to megakaryocytes (MKs), new protein synthesis is needed for recovery of PAR-1 signaling^{151,153} and, in endothelial cells, sensitivity to thrombin is maintained by delivery of naïve PAR-1 to the cell surface from a preformed intracellular pool.¹⁵³

Physiologic differences exist between PAR-1 and PAR-4 on human platelets. When antibodies to the thrombin interaction site of PAR-1 are used, platelet activation is blocked at low, as opposed to high, thrombin concentrations.^{154,155} Antibodies that blocked PAR-4 alone had no effect on thrombin-mediated platelet activation. If both receptors were blocked, platelet activation was blocked at both low and high thrombin concentrations,¹³⁸ and so PAR-1 appears to be most efficient at mediating platelet activation at low concentrations of thrombin, whereas PAR-4 functions in the absence of PAR-1 but only at high thrombin concentrations. Because PAR-1 is capable of mediating platelet activation at low thrombin concentrations, the exact role of PAR-4 in human platelet function remains speculative. It has been shown that the rate of platelet activation through PAR-4 is significantly slower and more sustained than that through PAR-1.^{45,156,157} Given the importance of this system with respect to normal hemostasis, PAR-4 may serve as a redundant backup receptor to PAR-1, or it may serve as an important receptor for one or more proteases other than thrombin.

Initial studies addressing the role of thrombin in promoting platelet thrombus formation employing ex vivo perfusion systems pointed toward its importance at low- to intermediate-shear rates (100 to 650 s⁻¹), but not at higher shear rates (>2,600 s⁻¹).^{158,159} Subsequent studies employing PAR3 and PAR4 knockout mice have also demonstrated defective thrombus formation under high-shear conditions in vivo, although suggesting the possible existence of shear-based functional differences between PARs.^{160,161}

Platelet ADP (Purinergic) Receptors and Signaling

Evidence that ADP plays an important role in both formation of the platelet plug and the pathogenesis of arterial thrombosis has been accumulating since its initial characterization in 1960 as a factor derived from red blood cells that influences platelet

P.417

adhesion.^{161,162} ADP is present in high (molar) concentrations in platelet-dense granules and is released when platelet stimulation takes place with other agonists, such as collagen; thus, ADP serves to amplify further the biochemical and physiologic changes associated with platelet activation and aggregation. Inhibitors of this ADP-associated aggregation include commonly used clinical agents such as clopidogrel that have proven to be very effective antithrombotic drugs.^{163,164}

FIGURE 17.4. Signaling through G proteins and G-protein-coupled receptors. Agonist binding to the receptor causes the exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on the guanine nucleotide-binding site of the G-protein α subunit. This causes the dissociation of $G\alpha$ from $G\beta\gamma$, both of which can activate intracellular effectors and ion channels. From Brass LF. Molecular basis of platelet activation. In: Hoffman R, Benz EJ, Shattil SJ, et al., eds. Hematology: basic principles and practice. New York: Churchill-Livingstone, 2000:1754, with permission.

Adenine nucleotides interact with P2 receptors that are ubiquitous among different cell types and have been found to regulate a wide range of physiologic processes. They are divided into two groups, the G-protein-coupled or “metabotropic” superfamily named P2Y and the ligand-gated ion channel or “ionotropic” superfamily termed P2X.¹⁶⁵ Two G-protein-coupled (P2Y) receptors contribute to platelet aggregation. The P2Y₁ receptor initiates aggregation through

mobilization of calcium stores, and the P2Y₁₂ receptor is coupled to inhibition of adenylate cyclase and is essential for a full aggregation response to ADP with stabilization of the platelet plug. P2X₁ is a third ADP receptor present in platelets and has been shown to contribute to aggregation in response to collagen. Both the P2Y₁₂ and P2X₁ receptors have been shown to play key roles in platelet activation and aggregation under flow conditions characterized by high-shear stress.^{166,167}

The P2Y₁ receptor was first cloned in 1993 from a chick brain complementary DNA library.^{168,169} and ¹⁷⁰ Messenger RNA was later found in MK-like cell lines, such as HEL and K562, along with human platelets.¹⁷¹ It was also established that the purported agonist effects of purified triphosphate nucleotides were, in fact, due to their transformation into diphosphate analogs by the ectonucleotidases present at the cell surface of the platelets and brain capillary endothelial cells being studied.^{171,172} The P2Y₁ receptor has 373 amino acid residues and the prototype structure of a G-protein-coupled receptor. It is distributed in various tissues such as heart, blood vessels, testis, and ovary.¹⁶⁵

After the characterization of P2Y₁, it became clear that a second platelet ADP receptor had to exist which was responsible for the inhibition of cAMP production by ADP that, in turn, was unaffected by blocking P2Y₁.^{173,174,175,176,177} and ¹⁷⁸ The P2Y₁₂ receptor was cloned in 2001 from human and rat platelet complementary DNA libraries using *Xenopus* oocytes.¹⁷⁹ The receptor indeed showed the ability to display ADP-mediated inhibition of platelet cyclic AMP (cAMP) formation that was not blocked by P2Y₁ antagonists. The receptor has been localized to certain regions of the brain, such as the substantia nigra and thalamus, in addition to platelets.¹⁷⁹

Platelet P2Y₁ and P2Y₁₂ Receptor Roles in ADP-Mediated Activation

Even at high concentrations ADP is a weak activator of PIC. Thus its role in platelet activation is based more on its ability to activate other pathways. Inhibition of either of the P2Y₁ or P2Y₁₂ receptors is sufficient to block ADP-mediated platelet aggregation, and co-activation of both receptors is therefore necessary, through the G proteins G_q and G_i, respectively, for ADP to activate and aggregate the platelet (Fig. 17.5).¹⁸⁰ A series of studies involving the use of selective P2Y₁ and P2Y₁₂ receptor antagonists, a cAMP inhibitor, gene targeting, and G_q and G_i protein agonists that would theoretically activate the two main G-protein pathways associated with ADP stimulation (see below) has led to the conclusion that a signaling event downstream from G_i is required for the conformational change and subsequent aggregation associated with the α_{IIb}β₃ receptor.^{176,178,180,181,182,183,184,185} and ¹⁸⁶

Studies done with platelets from patients who manifest defective P2Y₁₂, along with experiments involving the study of P2Y₁ receptor function in platelet-rich plasma that has high fibrinogen concentrations, have demonstrated that the P2Y₁ receptor has roles in activation and aggregation in addition to shape change, and that it is fully capable of mounting an aggregation response which is nonetheless transient in nature.^{176,187,188} The P2Y₁ receptor is an absolute requirement for ADP-mediated aggregation based on knockout mouse studies, the demonstration that platelets can become refractory to ADP due to desensitization of the P2Y₁ receptor, and the observation that adrenaline (which activates the G protein G_i that mediates inhibition of adenylate cyclase) does not restore aggregation in the presence of P2Y₁ selective antagonists.^{183,184,185,186,187} and ¹⁸⁸ Platelet shape change is dependent on two separate G signaling pathways, a G_q-linked release of calcium from internal stores, and a G₁₂/G₁₃ link to activation of Rho kinases and Rho guanine nucleotide exchange factors that activate small G proteins.^{143,189,190} The primary role of the P2Y₁₂ receptor in platelet activation and aggregation is to amplify and complete the aggregation response to ADP as well as to other agonists.^{173,174,175,176} and ¹⁷⁷ In the presence of a high ADP concentration, the receptor is also capable of mediating partial platelet aggregation on its own in P2Y₁ and G_q knockout mice, thus proving that α_{IIb}β₃ conformational change followed by aggregation can actually take place in the absence of calcium mobilization and PKC activation.^{184,190} In general terms, it appears that P2Y₁₂ is responsible for acting as an ADP co-stimulus receptor in the presence of low concentrations of other agonists, such as collagen, thrombin, chemokines, or IgG, whereas the P2Y₁ receptor has a specific role early in platelet activation.^{191,192} and ¹⁹³ Another role for the P2Y₁₂ receptor is the potentiation of platelet secretion.^{194,195} Because of its central role in the formation and stabilization of thrombi, the P2Y₁₂ receptor is a well-established target of antithrombotic drugs such as clopidogrel.^{194,196}

Platelets from P2Y₁₂-deficient mice aggregate poorly or not at all in response to ADP display a shift in the dose-response curves for collagen and thrombin and lack ADP-induced repression of cAMP levels.¹⁹⁷ The bleeding time of homozygous knockouts was markedly prolonged compared with near-normal results in heterozygotes.¹⁹⁸

FIGURE 17.5. Current view of the interplay between the platelet P2 receptors. Two G-protein-coupled receptors are involved in adenosine diphosphate (ADP)-induced platelet aggregation, P2Y₁ and P2Y₁₂. The former is responsible for intracellular calcium mobilization, shape change, and transient aggregation, whereas the latter is coupled to adenylate cyclase (AC) inhibition and is responsible for amplification of platelet aggregation and potentiation of platelet secretion. Both receptors are required for normal platelet response to ADP. A P2X receptor is also present on platelets and is responsible for rapid calcium influx. It therefore synergizes with the P2Y₁ receptor. Both the P2Y₁₂ and P2X₁ receptors have been shown to play key roles in platelet activation and aggregation under high-shear stress conditions. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; MLC, myosin light chain; P, phosphorylated; PLC, phospholipase C; Y, phosphotyrosine. Modified from Gachet C. ADP receptors of platelets and their inhibition. *Thromb Haemost* 2001;86:227, with permission.

P2X₁ Receptor

P2X₁ was first discovered in platelets using polymerase chain reaction of transcripts from platelets and MK-like cell lines.^{199,200,201} and ²⁰² This third platelet P2 receptor is an ATP-gated ion channel (as are all other P2X receptors thus far discovered) and is known to mediate rapid and selective permeability to cations. On platelets, the P2X₁ receptor has been shown to mediate fast calcium entry stimulated by ADP.²⁰³ P2X₁ is a 399-amino acid protein composed of two transmembrane domains, intracellular N and C termini, and an extracellular loop with 10 conserved cysteine residues.¹⁶⁵ At least three P2X subunits are required to constitute a membrane pore, and these receptors are typically expressed on excitable cells, such as neurons.

Despite the fact that activation of the P2X₁ receptor alone cannot induce platelet aggregation, it contributes to aggregation in response to collagen.^{204,205} The role of P2X₁ in platelet function seems to be particularly relevant under flow conditions characterized by high-shear stress.^{205,206} and ²⁰⁷ A study of P2X₁-deficient (P2X₁^{-/-}) mice has further indicated that this receptor contributes to the thrombosis of small arteries. P2X₁^{-/-} mice display resistance to the localized arterial thrombosis of mesenteric arterioles triggered by laser-induced vessel wall injury and to the acute systemic thromboembolism induced by infusion of a mixture of collagen and adrenaline.²⁰⁵ Conversely, increased systemic thrombosis has been reported in mice overexpressing the human P2X₁ receptor.²⁰⁸

ADP Receptor Signaling

ADP is considered a weak agonist compared with collagen or thrombin, for example. Aggregation is typically reversible when platelets are stimulated by ADP alone. In addition, low concentrations of ADP serve to amplify the effects of both strong and weaker agonists, the latter including serotonin and adrenaline, among others.^{136,137} As noted in the preceding paragraphs, ADP signal transduction downstream from the P2Y₁ receptor leads to a transient rise in free cytoplasmic calcium as a result of mobilization from internal stores, and this is followed by secondary-store-mediated influx, whereas a

concomitant inhibition of adenylate cyclase is initiated by ADP stimulation of the P2Y₁₂ receptor (Fig. 17.5). The G-protein family member responsible for signaling through P2Y₁ to PICβ is G_q, whereas the member responsible for signaling through P2Y₁₂ to inhibit adenylate cyclase is G_i. The G_i family member associated with P2Y₁₂ appears to be primarily G_{i2} inasmuch as G_{i2} knockout mice have an impaired response to ADP and those lacking G_{i3α} and G_{zα} do not.^{209,210} and ²¹¹ ADP also induces a rapid influx of calcium from the external media through ligand-gated calcium channels.^{212,213} Although partial platelet aggregation without shape change can be seen in P2Y₁ and G_q knockout mice in the presence of high ADP concentrations, the fact that aggregation is not seen at lower concentrations suggests that the G_q-dependent PICβ pathway leading to phosphoinositide hydrolysis and PKC activation is necessary to mobilize calcium after ADP stimulation and is essential for full platelet aggregation to take place in response to ADP.^{144,184,214,215}

Although ADP-mediated platelet activation via the P2Y₁ receptor incorporates the G_q-dependent PIC-β second messenger pathway, the P2Y₁₂ receptor mediates its post-occupancy signaling through G_i-dependent PI3 kinase activation and subsequent repression of cAMP levels. In addition to the PI3K role, several groups have reported a role for Rap1B in P2Y₁₂ signal transduction. Rap1B is a small GTPase that is highly expressed in platelets, and its ADP-stimulated increased activation is abolished by P2Y₁₂ antagonists and G_i knockout mice.^{216,217} and ²¹⁸ Rap1B activation through other receptors such as FcγRIIA and gpVI also appears to have a P2Y₁₂ component.^{217,218} Evidence suggests that ADP-induced Rap1B activation lies downstream of PI3K, because PI3K inhibitors have been shown to inhibit Rap1B activation, although evidence differs as to which isoform is involved.^{216,218}

The same G_i-protein-associated signaling pathway used by platelet ADP receptors has been found to act in a synergistic fashion when it is triggered either through other platelet receptors, or through key downstream players triggered by other receptors, such as PICγ2.^{219,220} It has been suggested that concomitant signaling through the G proteins and tyrosine kinases of other receptor pathways may potentially be seen as a general mechanism in

P.419

which ADP contributes to efficient platelet activation and aggregation.^{191,221} For example, ADP in platelets has been proposed to be an important co-factor of PI3 kinase activation that is stimulated through the PAR-1 thrombin receptor.²²² It is interesting that there is a difference in the ability of ADP to potentiate aggregation through the two platelet thrombin receptors (PAR-1 and PAR-4), in that PAR-1 is more dependent on secreted ADP acting through P2Y₁₂ than PAR-4.^{223,224} Collagen-induced platelet aggregation is similarly facilitated by P2Y₁₂.^{225,226} and ²²⁷

ADP has been implicated as an important co-factor of platelet activation seen in the settings of experimental cross-linking of the FcγRIIA immunoreceptor and in patients with heparin-induced thrombocytopenia.²²⁸ The latter is a disorder in which platelet activation and often serious thrombotic sequelae take place as a consequence of administration of the anticoagulant heparin or low-molecular-weight heparin. In susceptible patients, an autoantibody is generated by the immune system that is directed to a complex on the platelet membrane formed by the heparin molecule and platelet factor 4. The Fc portion of the autoantibody is then capable of activating the platelet through its interaction with the FcγRIIA receptor. Activation of PI3K has been shown to be a central player in these two settings.

P2Y₁₂ activation has been found to play an important role in activation of α_{IIb}β₃. Using P2Y₁₂ knockout mice, Andre et al. noted that platelets activated with PAR-4 or ADP were defective in binding soluble fibrinogen relative to wild-type mice.²⁰¹ Similarly, in humans it has been observed that P2Y₁₂ antagonists such as clopidogrel inhibit P-selectin expression and platelet-leukocyte conjugate formation, whereas aspirin does not.²²⁹

Platelet Activation by Soluble Agonists

α₂ Adrenergic Receptors and Epinephrine

Epinephrine is unique among platelet agonists because it is considered to be capable of stimulating secretion and aggregation, but not cytoskeletal reorganization responsible for shape change. Furthermore, generation of the key signaling enzyme PIC through epinephrine stimulation appears to be dependent on TxA₂ and can thus be blocked with aspirin.²³⁰ It is interesting, however, that epinephrine stimulation in the presence of aspirin is still capable of leading to the conformational change in the α_{IIb}β₃ receptor that precedes fibrinogen binding and platelet aggregation.^{231,232} Similarly, the thrombin inhibitor hirudin has been found to block epinephrine-associated aggregation of washed platelets in one study, suggesting that an element of thrombin co-stimulation of platelets may be necessary to enhance the effects of epinephrine.²³³ In low doses epinephrine is thought to prime platelets for activation with other agonists and the resulting stimulation is stronger than with either agonist alone.

Platelet responses to epinephrine are mediated through α_2 -adrenergic receptors,^{234,235} and these responses have been found to vary among individuals, with some donors with otherwise normal platelets manifesting delayed or absent responses.²³⁶ Potentiation is typically attributed to cAMP formation inhibition.

Arachidonic Acid, Thromboxane A₂, and Thromboxane Receptors

After platelet stimulation by a number of agonists, arachidonic acid is generated directly by phospholipase A from its membrane phospholipid precursors (PC, PS, and PI) and indirectly by PIC generation of DAG followed by DAG lipase action. Most platelet agonists are believed to activate this pathway. Three known eicosanoid subsets of biochemical compounds are known to be derived from the formation of arachidonic acid: the prostanoids, leukotrienes, and epoxides. The prostanoids are formed by the cyclo-oxygenase pathway and include endoperoxides and thromboxanes along with prostaglandins. The leukotrienes are formed by the lipoxygenase pathway and the epoxides by the cytochrome P450 epoxygenase pathway. Although all three of these pathways are present in platelets, most arachidonic acid ends up being metabolized to TxA₂.²³⁷

TxA₂ is produced in platelets from arachidonic acid through the generation of PGH₂ by the enzyme cyclo-oxygenase, which is irreversibly inhibited by aspirin through acetylation of a serine residue near its C terminus.^{238,239} PGH₂ is the parent compound for both biologically active prostaglandins, such as PGE₂ and PGI₂, and TxA₂. The former two compounds act to inhibit platelet activation by generating intracellular cAMP, whereas TxA₂ activates platelets. Although prostaglandin and thromboxane pathways can be present in the same cell, platelets primarily synthesize thromboxane, and endothelial cells mainly synthesize prostaglandins such as PGI₂, which acts as a local vasodilator and thus indirectly opposes platelet activation and vasoconstriction.²³⁹

Like ADP and epinephrine, TxA₂ is also capable of activating nearby platelets after its release into plasma. It has a very short half-life of 30 seconds before its conversion to the inactive metabolite thromboxane B₂ prevents widespread platelet activation beyond the vicinity of thrombus formation.^{240,241} Both arachidonic acid and analogs of TxA₂ have been found to activate and aggregate platelets by mediating shape change and phosphorylation of signaling enzymes, such as PIC β , PKC, and so forth.^{242,243} Signaling events associated with stimulation of the TxA₂ receptor (TxR) farther downstream from PIC β and PKC include activation of p38 mitogen-activated protein kinase and the small heat-shock protein hsp27.²⁴⁴

The TxR is a member of the seven-transmembrane G-proteincoupled receptor family and has been localized to the plasma membrane. The receptor is coupled to the α subunits of the G_q and G₁₂/G₁₃ members of the G-protein family.^{245,246} and ²⁴⁷ One isoform of the receptor has been cloned from placenta (TxR α) and the other from endothelium (TxR β). Both are found in platelets, and platelet activation through the G_q pathway has been found to activate PIC β and G₁₂/G₁₃ regulates myosin light-chain phosphorylation through activation of Rho kinase.^{245,246,248} In addition, the α receptor is associated with activation of adenylate cyclase that leads to generation of cAMP, known to inhibit platelet activation, whereas the β receptor inhibits adenylate cyclase activation after its stimulation.²⁴⁸ Because TxA₂ is a net agonist, the effects of PIC β activation must somehow outweigh those of adenylate cyclase activation, or MK and platelet TxR β receptor expression levels may outweigh those of TxR α receptor expression levels.²⁴⁸ TxR knockout mice have a prolonged bleeding time, do not aggregate in response to TxA₂ agonists, and show delayed aggregation with collagen.²⁴⁹

Coordination between Platelet Adhesion Events and Soluble Agonist Stimulation in Thrombus Growth

The mechanism by which soluble agonists coordinate their actions with platelet adhesion-related processes is an important consideration in the context of the steps required to facilitate thrombus growth.²⁵⁰ The constraint imposed by blood flow on these prothrombotic processes represents the primary means by which platelet adhesion and activation are negatively regulated. These arterial high-shear forces have complex effects on platelet-vWF matrix interactions that are both pro- and antithrombotic in nature. Rapid blood flow also has complex and poorly characterized effects on the formation and clearance of soluble agonists such as TxA₂.

One model to explain these relationships incorporates intraand intercellular calcium signaling phenomena as a central unifying process.²⁵⁰ In this model the initial platelet/vessel wall interaction is characterized by contact between platelet gpIb and matrix vWF with subsequent early platelet $\alpha_{1b}\beta_3$ conformational change, all leading to weak platelet activation. Co-stimulation of platelets by these adhesion events and soluble agonist receptors is

P.420

then needed to potentiate and sustain activation signals initiated by the early gpIb/vWF/ $\alpha_{1b}\beta_3$ interactions, and this co-stimulation leads to deceleration and arrest of platelet movement as the nidus of the thrombus develops. Platelet intracellular calcium is proposed to be the primary second messenger mediating these events, based on evidence

suggesting an inverse correlation between calcium flux and platelet translocation behavior under flow conditions.²⁵¹ Intercellular calcium-related signaling between platelets is then thought to lead to ADP release at the site of contact between platelets, which in turn sustains these $\alpha_{IIb}\beta_3$ -derived calcium signals by a P2Y₁₂-linked signaling mechanism.²⁵²

Physiologic Inhibition of Platelet Activation

One of the many remarkable features of platelets is their ability to remain in a physiologic resting state and resist becoming activated while navigating the heart, arterial, and venous circulations, and splenic microcirculation for an average of 10 days. Over this time, platelets can be expected to remain in a quiescent state while they encounter high-shear forces, what must be frequent collisions with other circulating cells as well as normal endothelium, and relatively profound turbulence associated with arterial branch points and diseased yet physically intact arteries and arterioles. Indeed, the pathologic consequences associated with widespread inappropriate platelet activation are life- and limb-threatening when associated with well-characterized clinical disorders such as thrombotic thrombocytopenic purpura and heparin-induced thrombocytopenia. The mechanisms responsible for maintaining the fine balance of keeping platelets in a resting state until they encounter a genuine need to undergo adhesion, activation, and aggregation at the site of vascular injury are almost as diverse as those responsible for mediating these physiologic phenomena.

Some general mechanisms involved in physiologic inhibition of platelet activation include phenomena such as (a) generation of negative-regulating molecules by the platelet (e.g., cAMP), endothelium (e.g., PGI₂, NO, heparan sulfate), and at distant sites (e.g., antithrombin); (b) direct contact of circulating platelets with collagen prevented by a barrier of endothelial cells; (c) generation of an ecto-ADPase (CD39) by endothelial cells that will metabolize ADP secreted from activated platelets and thus is intended to limit further activation; (d) tendency for blood flow to wash away unbound thrombin from the site of platelet plug formation and hence limit the extent of clot formation; (e) brief half-life of certain key platelet activators such as TxA₂; (f) ability to alter the conformation of a receptor such that it is then able to interact with a specific proaggregatory ligand, as happens with $\alpha_{IIb}\beta_3$ and plasma fibrinogen; and (g) the ability to inactivate switched-on receptors associated with activation through biochemical modification such as phosphorylation or their removal from the platelet surface.

Biochemical modification leads to receptor desensitization and occurs with G-protein-coupled receptors present on the surface of platelets, with the notable exception of PAR-1 because thrombin requires an intact N terminus to activate the receptor.²⁵³ Desensitization of G-protein-coupled receptors is normally mediated through phosphorylation of serine and threonine residues associated with the cytoplasmic side of the receptor by G-protein-coupled receptor kinases.²⁵⁴ The role of phosphorylation of these residues is to uncouple them from their G proteins and then lay the groundwork for internalization of the receptor through the binding of arrestin proteins.^{255,256} Some of the physiologic and biochemical phenomena related to inhibition of platelet activation are described in the following.

Inhibitory Prostaglandins

PGE₂ and PGI₂, along with PGE₁, are examples of prostaglandins generated through the arachidonic acid pathway that inhibit platelet activation and aggregation, which are processes mediated in part by other prostaglandins and thromboxanes derived from the same pathway. The inhibitors carry this out through G-protein-coupled receptors that regulate adenylate-cyclase-mediated generation of cAMP, which in turn activates PKA (or A kinases). PKA then goes on to inhibit other proteins that mediate platelet reactivity through phosphorylation.

The receptors of prostaglandins believed to increase cAMP levels in platelets such as PGI₂ have been described as being coupled to the α subunits of G_s. Conversely, most platelet agonists suppress cAMP formation by inhibiting adenylate cyclase via one or more of the G_i family members that are expressed in platelets.²⁵⁷ In addition to these considerations, cAMP levels in platelets are also governed by the activity of phosphodiesterase, the enzyme responsible for cAMP metabolism. This enzyme activity is inhibited by drugs such as the weak antiplatelet agent dipyridamole, the bronchodilator theophylline, and sildenafil, used to treat erectile dysfunction in men.

Raising cAMP levels causes a number of specific changes in platelet function. These include limitation of phosphoinositide hydrolysis, which is believed to occur through blockade of the inositol 1,4,5-triphosphate receptor and inhibition of the resynthesis of the phosphatidylinositol 4,5-bisphosphate precursor of DAG formation. There is also a smaller increase in the cytosolic free Ca²⁺ concentration in response to agonists and an accelerated uptake of Ca²⁺ into the dense tubular system.^{258,259,260} and ²⁶¹ The targets through which cAMP and PKA reduce platelet reactivity are incompletely understood. They include ABP (filamin), myosin light chain, VASP, and Rap1B. Another PKA substrate is the β subunit of the gplb complex, and this phosphorylation may in turn reduce platelet activation through its increased interaction with the 14-3-3 ζ protein.^{51,52} The 14-3-3 family of proteins exists as homodimers and modulates effector pathways in diverse cell types through interaction with key signaling enzymes.⁴⁸

Plekstrin and Protein Kinase C Inhibition

PKC is an important serine-threonine kinase with protean effector manifestations in platelet signaling. PKC is the receptor for the lipid second messenger DAG, and is a key enzyme in the signaling events that follow activation of receptors coupled to PLC. PKC isozymes phosphorylate multiple cellular proteins at serine and threonine residues. PKC is actually a family of structurally related molecules, and platelets contain at least the α , β , δ , ϵ , ϵ , θ , and perhaps ζ and λ isozymes.²⁶²

Once activated, PKC appears to mediate individual roles that, in some respects, may be considered contradictory in nature. These include positive effects such as mediating secretion and aggregation, as well as negative effects that can be observed when platelets are incubated with phorbol esters before agonist stimulation. Under these circumstances, the agonist effector-mediated responses are reduced or do not occur, particularly if they are mediated by effectors downstream from phosphoinositide hydrolysis, and this phenomenon may represent a form of negative feedback.^{263,264} and²⁶⁵ This is speculated as possibly being due to a shorter duration of signaling for calcium release.²⁶⁶

Several platelet proteins are known PKC substrates, and these include plekstrin (P47), myosin light chain (P20), ABP, and the α subunits of the G proteins G_z , G_{12} , and G_{13} . The precise role of plekstrin in platelets is unknown, although its first and last 100 residues are homologous with domains in molecules with roles in signal transduction. These so-called plekstrin homology domains are speculated to play roles in protein-protein interactions, and so phosphorylated plekstrin may have a role in the negative regulation of PKC. One study suggests that phosphorylated plekstrin may be accomplishing negative regulation of PKC through inhibiting phosphoinositide hydrolysis and the activity of the lipid kinase, PI3K.²⁶⁷ Reduced activity of PI3K leads to reduced phosphorylation of PI-4,5-P2 to PI-3,4,5-P3, a molecule that, in turn, is involved in the activation of the PKC isoforms.²⁶⁸

P.421

Other Inhibitory Processes of Platelet Activation

The $\alpha_{IIb}\beta_3$ receptor on the surface of activated and resting platelets along with the fibrinogen that binds to stimulated platelets expressing the activated form of $\alpha_{IIb}\beta_3$ have been observed to undergo rapid internalization into MK and platelet α -granules.^{269,270} and²⁷¹ It has been speculated that this may represent a mechanism by which platelets not involved in clot formation may be able to return to a resting state.²⁷² The in vivo evidence supporting this unique platelet-inhibitory process is included in a paper describing the transfusion of plasma into an afibrinogenemic patient followed by the demonstration that platelet fibrinogen could be restored faster than new platelets could be produced in the bone marrow.²⁷³

NO is generated by endothelial cells and platelets from L-arginine in response to shear stress forces and other platelet agonists, such as thrombin and ADP. This molecule works to inhibit platelet activation through the cyclic guanosine monophosphate second messenger generated by guanylate cyclase activation. Endothelial NO synthase activity is enhanced during platelet activation, presumably as an additional means for limiting platelet aggregation.

Platelet Secretion

The extent of secretion of α -, dense-, and lysosomal-granule contents is dependent on the strength of the agonist, occurs in association with platelet activation, and is one of the many downstream consequences mediated by the activation and transport to the internal leaflet of the plasma membrane of PKC. Granule contents that are involved in enhancing activation and aggregation of both their own and other platelets in the vicinity include ADP, vWF, fibrinogen, and calcium ions. Platelets contain three types of granules: dense granules contain agonists that amplify platelet activation, α granules contain proteins that enhance adhesion, and lysosomal granules contain glycosidases and proteases with largely unknown function.

The strongest response a platelet can mount to agonist stimulation includes activation, secretion, and aggregation. The granule secretory (release) phase is most readily documented in vitro by the "secondary wave" that denotes a second surge of aggregation activity of a fixed number of platelets in response to release of proaggregatory granule contents. These platelets are exposed to an agonist under the controlled in vitro conditions associated with platelet aggregation studies in which clinical defects in primary hemostasis due to platelet perturbations are further characterized. The secondary wave is typically seen best when the agonist is a weaker one, such as epinephrine, or is a relatively lower concentration of another relatively weak agonist, ADP. These two agonists require both cyclo-oxygenase activity and a primary wave of aggregation to induce secretion at low calcium concentrations.²⁷⁴

Although platelets are anucleate, they contain mRNA and are capable of synthesizing a restricted group of proteins mainly related to inflammation and apoptosis.^{275,276} In addition to this, vesicles are secreted from the membranes of stimulated platelets referred to as platelet microparticles that are enriched with specific membrane proteins which make them significantly procoagulant in settings such as heparin-induced thrombocytopenia, peripheral artery disease, and MI.²⁷⁷

Several studies suggest that the mechanism by which platelet granules (vesicles) fuse with the cell membrane to release their granule contents involves soluble N-ethylmaleimide-sensitive factor attachment protein (SNAP) receptor (SNARE) complexes that are formed between vesicle-associated membrane proteins (VAMPs; v-SNAREs) and proteins in the target membranes (different members of the syntaxin, SNAP-25, and VAMP gene families; t-SNAREs) in a lock-and-key form of docking.^{278,279} Many lines of evidence show that these SNARE complexes are crucial for membrane trafficking and fusion events such as secretion and exocytosis. There is evidence that suggests the specific isoforms VAMP-3 and VAMP-8 form SNARE complexes with platelet syntaxin 4 and that these specific complexes mediate platelet secretion.^{279,280}

Simultaneous with the exocytosis of platelet granules, it is apparent that there is also inward (centripetal) movement of other intracellular contents, and this may play a role in transporting proaggregatory proteins away from the membrane surface and thus serve as another counterbalancing mechanism for limiting the extent of thrombus formation. Examples of this phenomenon include the internalization of fibrinogen from the surface of activated platelets, along with gpIIb/IIIa receptors from the surface of resting and activated platelets, as noted earlier.²⁷²

PLATELET AGGREGATION: $\alpha_{IIb}\beta_3$ RECEPTOR AND ITS SIGNALING MECHANISMS

Platelet aggregation is a complex phenomenon that is the end result of a series of adhesion- and activation-related processes. The molecular mechanisms involved in platelet aggregation continue to be an area of very active research that also periodically reminds us that there is still much to be characterized about this important aspect of platelet function. Essential components of this process include an agonist, calcium, and the adhesive proteins, fibrinogen and vWF. Divalent cations, such as calcium and magnesium, are required for platelet aggregation in trace amounts, and these alter the specificity of the integrin $\alpha_{IIb}\beta_3$ for its ligands.²⁸⁰ Fibrinogen and vWF play dominant roles in platelet aggregation through binding to $\alpha_{IIb}\beta_3$ and also by the ability of the former to generate polymerized fibrin as support for the platelets in a thrombus.^{281,282} The multivalent nature of fibrinogen and vWF allows them to cross-link platelets on binding to $\alpha_{IIb}\beta_3$ on stimulated platelets to initiate platelet aggregation.

The molecular basis of integrin signaling that occurs in platelet $\alpha_{IIb}\beta_3$ is an integral part of thrombus formation and is important in understanding this process. gpIIb (α_{IIb}) and gpIIIa (β_3) were identified as the abnormal proteins present in patients with Glanzmann thrombasthenia in the 1970s.^{283,284} They represent the most abundant receptor on the platelet surface. Like all integrin receptors, this complex is composed of noncovalently linked subunits. Each subunit is encoded by separate genes on the long arm of chromosome 17. Both subunits consist of a large extracellular domain and very short cytoplasmic domains, and together they form a heterodimer. Within their combined extracellular domains is the ligand-binding pocket, with surrounding subunit domains conferring specificity.²⁸⁵ Equally important are the short cytoplasmic domains critical for transmembrane signaling. These domains act to anchor the receptor to the cytoskeletal elements.^{286,287,288}

The signaling pathways of $gp\alpha_{IIb}\beta_3$ are complex and have been extensively studied. Despite this, the terminal effector molecules affecting activation remain unknown. Central concepts of the signaling pathway include inside-out signaling, which involves the processes termed affinity and avidity modulation,^{271,290} and outside-in signaling in which messages are transmitted to the inside of the platelet via the events occurring outside the membrane through $\alpha_{IIb}\beta_3$ activation. Regarding the former, a major knowledge gap exists with respect to how second messengers effect functional changes in $\alpha_{IIb}\beta_3$. As examples, PKC, PI3-kinase, and Rap 1b have been implicated as intermediates in inside-out signaling, but identity of the effector molecules remains to be determined.^{250, 291} Current knowledge regarding these complex pathways has been recently reviewed and is summarized in Figures 17.6 and 17.7.^{285,286,292}

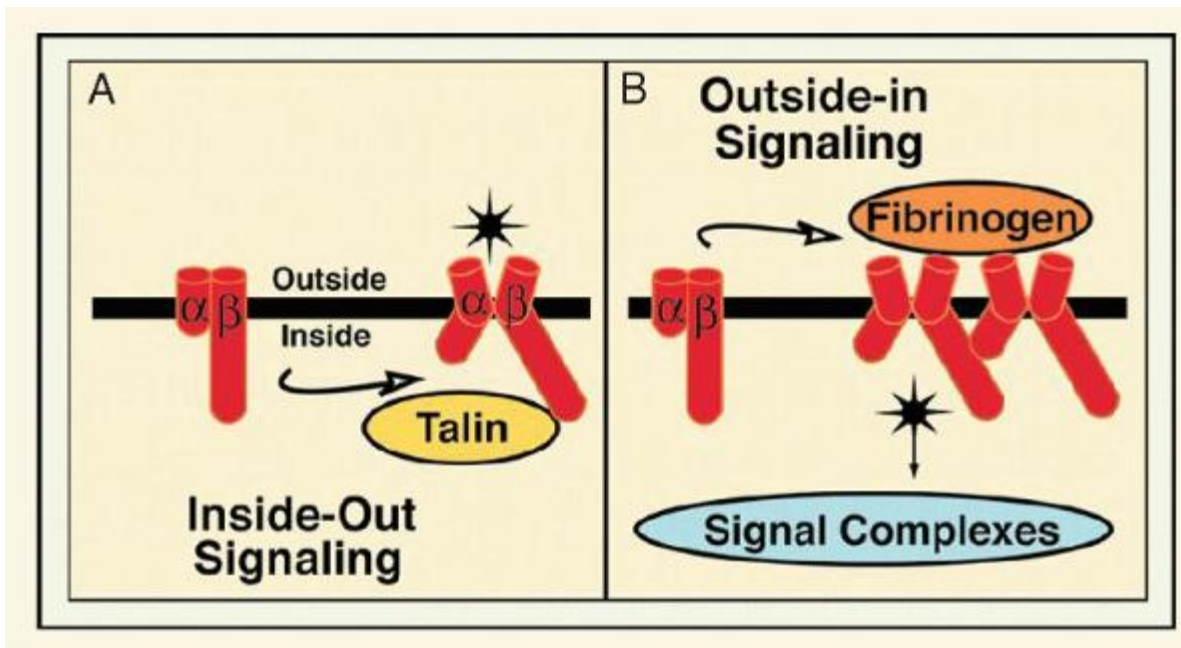

FIGURE 17.6. Integrin activation is bidirectional and reciprocal. The $\alpha_{IIb}\beta_3$ complex equilibrates between resting and activated states, the resting state predominating in unstimulated platelets and the activated state in stimulated platelets. Conversion from resting to activated does not imply a single abrupt change but rather a series of coordinated and linked conformational transitions. A: Inside-out signaling. Agonist-dependent intracellular signals stimulate the interaction of key regulatory ligands (such as talin) with integrin cytoplasmic tails (in this case the β_3 tail). This leads to conformational changes in the extracellular domain that result in increased affinity for adhesive ligands such as fibrinogen, von Willebrand factor (vWF), and fibronectin. Plasma fibrinogen and vWF support platelet aggregation at low and high shear rates, respectively, by bridging $\alpha_{IIb}\beta_3$ receptors on adjacent platelets. Studies in mice deficient in fibrinogen and vWF indicate that plasma fibronectin can also promote thrombus initiation, growth, and stability at high shear rates. B: Outside-in signaling. Extracellular ligand binding, initially reversible, becomes progressively irreversible and promotes integrin clustering and further conformational changes that are transmitted to the cytoplasmic tails. This results in the recruitment and/or activation of enzymes, adaptors, and effectors to form integrin-based signaling complexes. From Shattil SJ, Newman PJ. Integrins: dynamic scaffolds for adhesion and signaling in platelets. *Blood* 2004;104:1606-1615, with permission.

Glycoprotein IIb/IIIa antagonists—from bench to practice. *Cell Mol Life Sci* 2002;59:481, with permission.

Normally, undisturbed endothelium possesses nonthrombogenic properties that can inactivate activated coagulation factors, increase blood flow, inhibit platelet aggregation, and modulate fibrinolysis. Substances that inhibit platelet activation released by the endothelium include PGI_2 , NO, and ADPase. In addition, platelets release PGE_2 that acts to prevent its own activation. These molecules act via the Gs protein pathway that stimulates protein kinases to modulate various enzymes involved in platelet receptor $\alpha_{IIb}\beta_3$ activation (see later).²⁹² They may also act to phosphorylate and inactivate various protein receptor agonists.^{293,294}

Primary platelet agonists such as ADP, thrombin, and matrix proteins collagen and vWF affect platelet aggregation through a process known as inside-out signaling. This term denotes an integrin property that involves the binding action of agonists and extracellular matrix ligands to their receptors, leading to activation of numerous platelet functions, including the conformational change of $\alpha_{IIb}\beta_3$ to a high-affinity state, referred to as affinity modulation. The relative contribution of

soluble and extracellular matrix stimuli to inside-out signaling likely varies with flow conditions and other factors related to vascular perturbation. For example, gplb/v/IX function is most relevant under high-shear stress conditions such as those associated with arterioles and capillaries and in stenotic arteries. Ligand binding is initially reversible and later becomes irreversible in nature.²⁹⁵ Therefore, one of the effects of inside-out signaling on $\alpha_{IIb}\beta_3$ is exposure of the fibrinogen-binding site through signal transduction involving the cytoplasmic domains (Fig. 17.6).^{293,296} Various regulatory intracellular or transmembrane proteins participate

P.423

in this process. Overall, the data provide strong evidence that association between subunit cytoplasmic tails and possibly also between integrin subunit transmembrane domains works to maintain the $\alpha_{IIb}\beta_3$ complex in a resting nonadhesive conformation, and disruption of this state causes separation of the tails with consequent changes in the extracellular domains to increase $\alpha_{IIb}\beta_3$ affinity.^{297,298} Evidence currently suggests that any role for extracellular or transmembrane molecules in affinity modulation is secondary to $\alpha_{IIb}\beta_3$ regulation by intracellular proteins, in particular a 270-kDa dimer named talin that interacts with the integrin cytoplasmic tails.²⁹⁹ The complexity of the mechanisms by which inside-out signaling trigger $\alpha_{IIb}\beta_3$ activation is significant.^{200,201}

Talin is a large protein that has been implicated as a trigger of integrin activation and binds to two sites in the β_3 cytoplasmic tail: the NPLY sequence in the midsegment of the cytoplasmic tail and a sequence in the membrane proximal region.³⁰² Its binding to the latter region may follow the former and may trigger separation of β_3 from the α_{IIb} cytoplasmic tail resulting in activation. Other proteins bind to the NPLY sequence and whether these function as coactivators or suppressors remains to be determined (Chapter 115, ref 303,304). Talin must also be activated to accomplish this and multiple activation pathways have been described.

Avidity modulation, the less dominant action, acts to cluster the $\alpha_{IIb}\beta_3$ heterodimers into oligomers through lateral diffusion.^{305,306} These conversions are critical in allowing $\alpha_{IIb}\beta_3$ to engage soluble adhesive ligands. These ligands contain the classical integrin-recognition sequence RGD, Arg-Gly-Asp, which acts as a bridge between adjacent platelets allowing aggregation to proceed.³⁰⁷ In addition, more $\alpha_{IIb}\beta_3$ translocates to the platelet surface membrane from the degranulating α -granule pool, where additional receptor is stored. These changes facilitate irreversible binding to fibrinogen. An important role for tyrosine kinase- and phosphatase-associated phosphorylation-dephosphorylation in integrin activation exists as assessed by the blockade of fibrinogen binding and platelet aggregation by enzyme inhibitors.^{308,309}

After ligand binding occurs, a multitude of intracellular signals are generated that are collectively referred to as outside-in signaling. This "contact-dependent signaling" determines the extent to which platelets will spread on a vascular matrix and how resistant to detachment they are.^{310,311} Outside-in signaling occurs in a discrete pattern in which ligand binding initiates integrin clustering and assembly of a "nascent" signaling complex proximal to the $\alpha_{IIb}\beta_3$ cytoplasmic tails, and this is followed by the growth of a larger "actin-based" signaling complex. It can be envisioned that the nascent complex is characterized temporally by (a) activation of Src kinases bound to the β_3 cytoplasmic tail by fibrinogen engaging and facilitating integrin clustering, then (b) recruitment and activation of Syk by Src, then (c) Src and/or Syk phosphorylation of various substrates including adaptor proteins SLP-76 and c-Cbl along with the Rac GTPase Vav, and these substrates in turn act by participating in signaling to the actin cytoskeleton.²⁹² As the nascent complex assembles, many additional proteins are recruited that can influence actin reorganization, including Rac, the adaptor Nck, PAK, PI3-kinase, and VASP, an actin-bundling protein.²⁹² All these signaling events during platelet aggregation are further supported by release of granules induced by the binding of adhesive proteins to the extracellular domain of β_3 . This complex series of events serves as a determinant of the final clot size.

Activation of $\alpha_{IIb}\beta_3$ by agonists is very rapid and the platelet can become fully competent to bind fibrinogen/vWF via the receptor within seconds after its initial encounter with agonist. Once full spreading and aggregation of platelets occurs, usually within several minutes, focal adhesion kinase is phosphorylated.^{312,313} and ³¹⁴ The PI3K system is activated once $\alpha_{IIb}\beta_3$ is engaged, leading to generation of D3 phosphoinositides.³¹⁵ These proteins act to prevent the depolymerization of the actin cytoskeleton, with the result that the platelet aggregate is stabilized.³¹⁶ The end result of this outside-in signaling is a stable platelet clot.

In addition to outside-in signaling, following binding of fibrinogen to $\alpha_{IIb}\beta_3$ one or more of a number of other events can be postulated to occur that facilitate platelet aggregation. These include the formation of a dimeric fibrinogen bridge between $\alpha_{IIb}\beta_3$ receptors on adjacent platelets, conformational changes in bound fibrinogen and/or occupied $\alpha_{IIb}\beta_3$, and additional interactions of bound receptor with cytoskeletal elements.^{317,318,319} and ³²⁰

Although fibrinogen is the dominant ligand, other RGD-containing peptides also bind to $\alpha_{IIb}\beta_3$ including vWF, collagen, fibronectin, and vitronectin. Because vWF binds to GPIb/V/IX it is close to $\alpha_{IIb}\beta_3$ which may facilitate their interaction. Thus $\alpha_{IIb}\beta_3$ may also play a role in platelet adhesion particularly in stabilizing cell-matrix interactions.³²¹ Other platelet membrane proteins have also been shown to associate with $\alpha_{IIb}\beta_3$ including CD9 and Gas6³²² and these may play a role in modulating $\alpha_{IIb}\beta_3$ function.

Not only does the $\alpha_{IIb}\beta_3$ receptor have important roles with respect to platelet function, it affects coagulation and the inflammatory process as well. It acts to promote the formation of the prothrombinase complex³²³ and mediates the adhesion of leukocytes to the platelet membrane and endothelium (i.e., vascular inflammation).^{324,325,326} and ³²⁷ This receptor may also have a role in cell proliferation. In this respect, antagonists to $\alpha_V\beta_3$ or to both $\alpha_{IIb}\beta_3$ and $\alpha_V\beta_3$ significantly inhibited intimal hyperplasia after vascular injury in all but 1 of at least 12 animal studies.³²⁸

Platelet Aggregation and Arterial Shear Flow

Until relatively recently platelet aggregation was considered to be comparatively straightforward involving just $\alpha_{IIb}\beta_3$ interacting with fibrinogen as described in the preceding paragraphs. With the recent ability to analyze *in vivo* platelet aggregate formation in realtime, though, it has become apparent that this process is much more complex than previously thought. Platelet aggregation now appears to represent a series of adhesion reactions involving multiple receptors and adhesive ligands such as vWF, fibrinogen, and fibronectin with the contribution of individual receptor-ligand interactions dependent on prevailing blood flow conditions. It has been postulated that at least three distinct mechanisms can initiate aggregation with each mechanism working over a specific arterial shear range *in vivo*.³²⁹ Under low-shear conditions ($<1,000\text{ s}^{-1}$) the predominant mechanism is thought to involve fibrinogen and $\alpha_{IIb}\beta_3$ exclusively and this occurs independent of GPIb/vWF interaction.³³⁰ Subsequent stimulation by locally generated soluble agonists induces platelet shape change and an increase in $\alpha_{IIb}\beta_3$ affinity for fibrinogen. At shear rates between 1,000 and 10,000 s^{-1} platelet-platelet interactions become more vWF dependent with roles for both GPIb and $\alpha_{IIb}\beta_3$ in promoting platelet aggregates. Now a third mechanism initiating platelet aggregation has been identified that occurs when shear rates are very high ($>10,000\text{ s}^{-1}$) and it is interesting that this mechanism does not require platelet activation or the adhesive function of $\alpha_{IIb}\beta_3$ and is mediated by GPIb/vWF bonds.^{286,331} This finding that nonactivated platelets can form large aggregates under very high shear may have important implications behind the mechanism of pathologic thrombus formation in stenosed arteries.

Integrin $\alpha_{IIb}\beta_3$ Antagonists

Antithrombotic agents that act against the $\alpha_{IIb}\beta_3$ receptor are extensive and represent a targeted therapy against the most prevalent platelet surface receptor. They have had a significant impact on clinical outcomes of patients with acute coronary syndromes (ACSs) and those requiring percutaneous coronary interventions (PCIs).

Although many anti- $\alpha_{IIb}\beta_3$ agents have been developed, only a small number are currently approved for clinical use.

Examples

P.424

of approved parenteral agents with various mechanisms of action include the chimeric monoclonal antibody abciximab, the synthetic peptide eptifibatide, and the synthetic nonpeptide tirofiban.

Coller reported on the first mouse monoclonal antibody directed against the $\alpha_{IIb}\beta_3$ receptor,³³² and abciximab was subsequently developed. Abciximab is thought to block access of large molecules to the receptor by steric hindrance and/or conformational effects rather than interacting directly with the arginine-glycine-aspartic acid-binding site of gpIIb/IIIa.²⁸⁵ Within minutes of receiving the standard bolus dose, $\sim 90\%$ of $\alpha_{IIb}\beta_3$ receptors are bound.³³³ Abciximab then slowly dissociates for up to 4 hours, and platelet function can be abnormal for up to 7 days after infusion.³³⁴

Eptifibatide is a synthetic cyclic heptapeptide based on an RGD sequence that blocks all RGD-recognizing integrin receptors. It binds to the ligand-binding pocket of the $\alpha_{IIb}\beta_3$ receptor such that it blocks its interaction with fibrinogen and vWF. It has a very rapid onset of action and a low affinity, leading to quick dissociation. It is approved for use in both the PCI and ACS settings.

Tirofiban is a synthetic nonpeptide tyrosine derivative that mimics the RGD recognition sequence.³³⁵ This agent also acts by blocking the ligand-binding region of the $\alpha_{IIb}\beta_3$ receptor such that it competitively inhibits platelet aggregation. Within minutes, it inhibits platelet aggregation, and it dissociates from the receptor within seconds. It is approved for use in ACS.

Numerous trials have been conducted to evaluate the efficacy of parenteral $\alpha_{IIb}\beta_3$ antagonists (Fig. 17.8).^{285,336} These trials evaluated the drugs in terms of 30-day post-intervention or event episodes of death or nonfatal MIs after PCI or ACS. With

>100,000 patients being evaluated in placebo-controlled trials, the absolute and relative risk reductions in PCI with the use of $\alpha_{IIb}\beta_3$ inhibitors were 2.9% and 34.0%, respectively. The benefit of the $\alpha_{IIb}\beta_3$ inhibitors among ACS patients is maximized in those undergoing PCI.³³⁷ This might relate to the relatively short time period between vessel injury and initiation of therapy. Correspondingly, the risk reductions provided by these agents in the medical management of ACS is more modest and the risk/benefit profile of currently available $\alpha_{IIb}\beta_3$ agents is substantially uncertain for patients with ACS who are not routinely scheduled for early revascularization.³³⁸ Among this particular population, benefit has been found to be highest in those with diabetes mellitus and/or elevated serum troponin levels reflecting microvascular obstruction and myocardial necrosis.^{339,340,341,342} and ³⁴³ Clopidogrel and anticoagulants have essentially curtailed the application of these agents in the non-PCI ACS setting.^{344,345}

After longer-term follow-up of 1 year, the evaluation of IIb/IIIa platelet inhibitor for stenting (EPISTENT) trial demonstrated a significant reduction in mortality after the use of abciximab in PCI. This effect has not been demonstrated with the other mentioned agents, although significantly fewer studies have been performed with them to date. A meta-analysis of the trials performed using tirofiban and eptifibatide in ACS showed no significant difference in mortality with these agents, but did show that there was a significant reduction in endpoints of death/MI, as well as death/MI/revascularization at 48- to 96-hour, 30-day, and 6-month followup periods.³⁴⁶

FIGURE 17.8. Hypothetical model of atherosclerosis triggered by platelets. Activated platelets roll along the endothelial monolayer via gpIb/P-selectin or PSGL-1/P-selectin. Thereafter, platelets firmly adhere to vascular endothelium via β_3 integrins, release proinflammatory compounds (IL-1 β , CD40L), and induce a proatherogenic phenotype of ECs (chemotaxis, MCP-1; adhesion, ICAM-1). Subsequently, adherent platelets recruit circulating leukocytes, bind them, and inflame them by receptor interactions and paracrine pathways, thereby initiating leukocyte transmigration and foam cell formation. Thus, platelets provide the inflammatory basis for plaque formation before physically occluding the vessel by thrombosis upon plaque rupture. From Gawaz M, Langer H, May AE. Platelets in inflammation and atherosclerosis. *J Clin Invest* 2005;115:3378-3384, with permission.

Disappointing clinical trial results have been seen with the oral $\alpha_{IIb}\beta_3$ inhibitors, and this even includes an increased all-cause mortality rate.^{347,348} This could be explained by possible subtherapeutic drug levels leading to platelet activation and/or inflammation. Another explanation is that these agents may leave the receptor activated as they dissociate away.³⁴⁹

ROLE OF THE CYTOSKELETON IN PLATELET FUNCTION

(See additional cytoskeleton structure information in Chapter 16 on platelet structure.)

Once an agonist has interacted with its platelet membrane receptor and triggered second messenger formation, a key event in platelet activation and subsequent aggregation is the transition of the platelet's shape from the discoid appearance associated with its circulating resting state to the amorphous amoebalike appearance with multiple pseudopodial projections that denote its activation state and readiness to participate in platelet plug formation. The platelet cytoskeleton and its associated signaling proteins are responsible for mediating shape change associated with activation, spreading, secretion, and aggregation. This cytoskeleton is associated with at least 14 different structural proteins that function interdependently as a single unit but can be seen as consisting of three major functional units: (a) a cytoplasmic network consisting mainly of actin, (b) a meshwork of proteins immediately proximal to the cytoplasmic leaflet of the platelet membrane referred to as the membrane skeleton (because it contains surface-associated proteins

such as the gplb complex), and (c) the platelet marginal band, which consists of a single peripheral microtubule coil that encircles the platelet to contribute to its resting discoid state.

Transmembrane receptors such as gplb participate in anchoring the platelets to extracellular matrix in the arterial subendothelium through their extracellular domains, whereas their cytoplasmic domains are almost simultaneously associating with membrane skeletal proteins in response. In doing so, these

P.425

surface receptors are providing sites at which tension can be generated by intracellular contractile elements that subsequently lead to shape change and activation of signaling proteins.

The cytoplasmic network consists of actin filaments and their associated proteins, referred to as intermediate filaments. In resting platelets, approximately half of actin is structurally filamentous in nature (with the rest present as globular monomeric G-actin), and this fraction increases to approximately three fourths during platelet activation.³⁵⁰ During this process, the actin filaments are reorganized into longer filaments after their initial breakdown into smaller units and this is thought to be regulated in part by an increase in phosphatidylinositol-4,5-bisphosphonate (PIP₂) that accompanies platelet activation. Simultaneously, myosin is phosphorylated by myosin light-chain kinase and then associates with F-actin, with the resultant filament then attaching itself to the α subunit of the gplb complex through ABP.^{351,352} These filaments are also anchored at sites called focal adhesions, where the tyrosine kinase Fak becomes activated after platelet stimulation. Focal adhesions assemble around the $\alpha_{IIb}\beta_3$ integrin on its conformational change (activation) and so play a very important role in signaling pathways associated with platelet activation by drawing together membrane receptors, the cytoskeleton, and signaling phosphoproteins such as members of the Src family, PI3K, and Syk into close physical proximity.³⁵³ Other platelet integrin receptors, such as $\alpha_2\beta_1$, also organize focal adhesions after binding to their respective extracellular ligands.

The membrane skeleton consists of actin, ABP, talin, vinculin, spectrin, cortactin, α -actinin, and several membrane glycoproteins, as noted in Chapter 16. ABP is a 250-kDa elongated dimer that associates with the cytoplasmic domain of the gplb α chain and acts to link the receptor to actin in the early stages of platelet activation, as noted in the previous paragraph. After platelet activation, calpain, the calcium-dependent protease, is activated in aggregating and spreading platelets and cleaves the link between ABP and gplb. Thus, ABP may be considered a prototype of sorts of membrane skeleton proteins that provides a good example of their important role in terms of interaction with second messengers and other signaling molecules that either may become activated or may act on their substrates after platelet stimulation.

The marginal microtubule band maintains platelet discoid shape and appears to be an essential intermediate in the microtubule-driven process of proplatelet formation and platelet release.⁹⁶ This single microtubule polymer is wound in 8 to 12 coils in the cytoplasmic periphery and is located just beneath the plasma membrane.³⁵⁴ About 90% of β -tubulin in the marginal band is of the divergent, MK/platelet-restricted β_1 isoform. β_1 -tubulin-null mice show reduced proplatelet formation, thrombocytopenia, and platelet spherocytosis.³⁵⁵

PLATELET-CELL INTERACTIONS

Platelets and Endothelium

The mechanisms behind platelet interaction with vWF, collagen, and other subendothelial matrix molecules exposed as a result of damaged endothelium have been well studied and described in earlier sections of this chapter. In addition to these platelet-subendothelial interaction paradigms, evidence has emerged that circulating unactivated platelets have the capacity (as do neutrophils) to roll on intact activated endothelium *in vivo* and then reversibly adhere to it in a process that is dependent on endothelial cell expression of P-selectin.^{356,357,358} and ³⁵⁹ This sequence of molecular interactions is a well-controlled multistep process involving platelet tethering and interaction of platelet P-selectin glycoprotein ligand-1 (PSGL-1) or gplb α with endothelial P-selectin ("rolling"), followed by subsequent "firm adhesion" to the vascular wall mediated through β_3 integrins. gplb α and PSGL-1 have structural similarities including similar ligand-binding domains. P-selectin is also expressed on the surface of activated platelets and is an α -granule component in resting platelets. Endothelial P-selectin is rapidly expressed on the surface in response to inflammatory stimuli by translocating from membranes of storage granules (Weibel-Palade bodies) to the plasma membrane within seconds.

As noted in an earlier section, there are multiple general mechanisms at play in inhibition of platelet activation that involve intact endothelium. It is increasingly recognized that inflammatory stimuli facilitate sustained platelet-endothelial interaction by perturbing these antiadhesion and activation mechanisms and increasing surface expression of endothelial molecules. Adhesion of platelets to inflamed endothelium involves a similar coordinated multistep process as occurs in

hemostasis and thrombosis, including platelet tethering, surface translocation, and firm adhesion.³⁶⁰ In atherosclerosis accumulation of modified oxidized lipoprotein particles in the setting of hyperlipidemia leads to surface expression of endothelial P- and E-selectin as well as endothelial vWF.^{360,361}

Along with endothelial P-selectin, it is not surprising that vWF expressed on activated venous endothelium has also been implicated in platelet adhesion and translocation.³⁶² The precise nature of the relationships between these two endothelial cell molecules and the platelet gplb complex, and the role different shear forces may play in determining which ligand gplb may preferentially associate with, remain to be determined. As noted in the section on "Platelet Aggregation and Arterial Shear Flow", aggregation is currently considered to consist of a series of adhesion reactions involving multiple receptors and adhesive ligands such as vWF, fibrinogen, and fibronectin with the contribution of individual receptor-ligand interactions dependent on prevailing blood flow conditions. Studies using intravital microscopy have confirmed that platelet-endothelium adhesion takes place even under high-shear stress *in vivo*.^{363,364} Platelets rolling on activated endothelium can be inhibited by both anti-P-selectin and anti-gplb α antibodies, and this suggests that platelet gplb/V/IX mediates platelet adhesion to both the subendothelial matrix and the intact endothelium.³⁶⁵ PSGL-1 on platelets has also been shown to mediate platelet rolling on the endothelial cell monolayer under high-shear stress.³⁶⁶

Platelet firm adhesion to intact endothelial cells following rolling is a process dependent on $\alpha_{IIb}\beta_3$ bridging to endothelium that involves endothelial receptors such as $\alpha_V\beta_3$ and intercellular adhesion molecule (ICAM)-1 interacting with platelet-bound fibrinogen, fibronectin, and vWF.^{325,358,367,386} This firm adhesion induces platelet surface P-selectin expression, and whether this selectin plays any role in their interaction with endothelium is unknown. The fact that P-selectin knockout mice have been observed to display impaired hemostasis suggests a potential role in this respect.³⁶⁹

Platelets and White Blood Cells

In addition to the participation of the gplb complex, selectins, and the β_3 integrin in the interaction between platelets and intact endothelium described above, these proteins along with the β_2 integrin receptor Mac-1 ($\alpha_M\beta_2$ or CD11b/CD18) participate in interactions between platelets and leukocytes.³⁷⁰ Platelets contribute to leukocyte rolling and extravasation, which are two well-characterized steps involved in the translocation of the latter cell from the circulation to sites of infection.³⁷¹ Normally, after interaction of endothelial cell P-selectin with leukocyte receptors such as PSGL-1, β_2 integrin activation on the leukocyte mediates increased adhesion to endothelium, followed by extravasation. Neutrophils are also capable of tethering and rolling on adherent and activated platelets through interactions between its P-selectin glycoprotein 1 and P-selectin expressed on the platelet surface, and they will subsequently display extravasation mediated by activation of Mac-1 and lymphocyte function-associated

P.426

antigen 1 ($\alpha_L\beta_2$) which are required to mediate stable leukocyte adhesion.^{372,373} and ³⁷⁴ The α subunits of certain integrins, such as Mac-1, have been found to contain "insert" (I) domains, homologous to the A1 domain of vWF. This observation has taken on added interest since it has been shown that Mac-1 is capable of binding to the gplb complex and that this interaction required the I domain of Mac-1 and the leucine-rich repeat region of gplb α .³⁷⁵ Mac-1 knockout mouse neutrophils were incapable of binding to isolated polypeptide fragments corresponding to the extracellular domain of gplb α (called glyocalicin). For this reason and others, the role of Mac-1-gplb complex interaction could turn out to be important with respect to initiating and propagating inflammation associated with the progression of atherosclerotic, purely thrombotic, or atherothrombotic processes.

Mac-1 has also been found to associate with other receptors of the platelet membrane, including the junctional adhesion molecule-3, ICAM-2, fibrinogen bound to $\alpha_{IIb}\beta_3$, and high-molecular-weight kininogen bound to gplb α .^{376,377,378,379} and ³⁸⁰ These associations have been characterized individually, however, their downstream signaling partners along with any coordinated actions that may exist between the ligand-receptor pairs *in vivo* remain to be determined. During this adhesive process, the association of platelet membrane PSGL-1 and Mac-1 stimulates the release of inflammatory cytokines from platelets, which in turn induces inflammatory cascades in monocytes.^{381,382} This integrin, selectin, and cytokine-based set of coordinated reactions linking neutrophils, platelets, and monocytes leads to circulating activated platelets and platelet-white cell aggregates that promote formation of atherosclerotic lesions.³⁸³

Role of Platelets in Inflammation

The growing list of pathophysiologic processes in which platelets have a proposed role is a reflection of the many different cell types with which they interact. These include endothelial cells, neutrophils, monocytes, dendritic cells, cytotoxic T lymphocytes, malaria-infected red cells, and various tumor cells. In addition to the mechanisms behind interaction of platelets with activated endothelium and white cells described in the last section, platelet activation induces a local

release of alpha granule contents containing various potent inflammatory substances that further enhance the inflammatory response and alter chemotactic, adhesive, and proteolytic properties of endothelial cells. These include chemokines CXCL4 (PF-4), CXCL7 (PBP, β -TG, CTAP-III, and NAP-2), and CCL5 (RANTES), platelet-derived growth factor, IL-1 β , CD40 ligand, TxA₂, leukotriene B₄, and platelet-activating factor.

The interaction between platelets, leukocytes, and the vascular wall can occur in various sequences.³⁸⁴ First, platelets can form aggregates with leukocytes that promote leukocyte recruitment either by activating leukocyte adhesion receptors or by directly serving as a bridging molecule between leukocytes and the endothelium. When adhered to the vessel wall, platelets can attract leukocytes by releasing chemoattractants and providing an adhesive surface for leukocyte adhesion. Thus platelets, leukocytes, and endothelial cells all become activated in a cascadelike fashion.

A key receptor-ligand interaction in these processes includes P-selectin and PSGL-1 (as noted above) that was initially found to be important in rolling interactions between leukocytes and the vessel wall and later found to be important in the recruitment of tissue factor bearing microparticles in thrombosis as well.^{385,386} Using apolipoprotein E-deficient mice, it has been shown that platelet P-selectin plays a critical role in atherosclerosis by promoting leukocyte recruitment on atherosclerosis-prone endothelium.³⁸⁷

A second key interaction involves platelet CD40 ligand, which is related to the tumor necrosis family, and CD40. Once on the activated platelet surface, CD40L increases release of attractants for neutrophils and monocytes, and triggers outside-in signaling by inducing $\alpha_{IIb}\beta_3$ phosphorylation and enhancing thrombus stability.^{388,389} High levels of soluble CD40L are released from platelets in response to thrombosis that then functions as a primary platelet agonist in an autocrine loop with $\alpha_{IIb}\beta_3$ as the primary agonist receptor.

ROLE OF PLATELETS IN ATHEROGENESIS AND ATHEROTHROMBOSIS

Atherosclerosis is the major cause of vascular occlusive disorders such as coronary artery disease, stroke, and peripheral arterial disease. Every year, more than 4 million patients are admitted to hospitals worldwide with ACS, more than 1.5 million of them in the United States.³⁹⁰ Peripheral arterial disease affects up to 12% of the general population and 20% of those older than age 70 years.³⁹¹ The instability associated with atherosclerotic plaque progression enhances vulnerability to disruption or ulceration, and this is associated with secondary deep vessel wall injury and thrombus formation.^{392,393} and ³⁹⁴ Based on extensive laboratory and clinical experience, it is clear that platelet activation and aggregation play an integral role on two fronts: (a) in the cytokine-driven local inflammatory changes associated with plaque formation and growth, followed by (b) thrombus associated with plaque instability (Fig. 17.8).

Platelets in Atherogenesis

The importance of the role of both arterial wall and systemic inflammation in atherogenesis and its later clinical manifestations, along with the molecular interface between inflammation and thrombosis, have been the subject of much recent attention in the literature.^{395,396,397} An increased number of links between thrombosis and inflammatory mediators have been observed, and new roles for platelets in inflammation are becoming apparent.³⁹⁸

Many of the molecular players mediating leukocyte-endothelium interactions have also been found to play important roles coordinating leukocyte attachment and transmigration across layers of platelets adherent to injured vascular intima.^{375,399} In addition, the binding of platelets to leukocytes influences important whitecell effector responses, such as cell activation, signaling associated with integrin activation, chemokine synthesis, and so forth. Thus, it has become clear that inflammation is capable of leading to local thrombosis, and thrombosis is capable of initiating and propagating inflammation.

As noted in the section, "Platelets and Endothelium," platelet adhesion to intact endothelium (as opposed to exposed subendothelium following vascular injury) has been well characterized using intravital microscopy and atherosclerosis animal models, and in some cases, adhesion has been shown to occur even before detectable atherosclerotic lesions are manifested.^{400,401} Animal models have recently provided strong evidence linking platelets to early events of atherogenesis. An atherosclerosis mouse model lacking α_{IIb} exhibited substantial reduction in atherosclerotic lesion formation.⁴⁰² The importance of P-selectin in atherosclerosis lesion formation has been well described.^{403,404} and ⁴⁰⁵ Platelet adhesion has been found to activate endothelial cell nuclear factor- κ B (NF- κ B) and its regulated genes, many of which play key roles in platelet-leukocyte-endothelium-extracellular matrix molecular events that support inflammatory and proatherogenic phenotypes. This includes events that contribute to lesion maturation such as smooth muscle cell and fibroblast proliferation and promotion of collagen synthesis, among others.^{406,407} and ⁴⁰⁸ Inhibition of COX-1, an enzyme with expression restricted to platelets, in turn inhibited lesion formation in an atherosclerosis mouse model.⁴⁰⁹ Another atherosclerosis mouse model demonstrated that prolonged antibody blockade of gplb α leads to reduced arterial leukocyte accumulation in carotid arterial intima and subsequent reduced atherosclerosis lesion

formation.⁴⁰¹ This suggests that vWF may also have a role in atherogenesis.⁴¹⁰

In contrast to animal data, conclusions regarding the role of human platelets in atherogenesis are not nearly as extensive. Mouse data cannot be unequivocally applied to humans, because mouse platelets differ from human with respect to expression levels of certain surface receptors. Systemic platelet activation in humans has been described in a variety of atherosclerosis disease presentations. However, antiplatelet agents have not been found to influence disease progression when applied in the secondary disease-prevention setting in humans in which atherosclerosis is likely advanced, as opposed to the possibly preventable progression of early lesions that are present before an initial atherosclerosis clinical event.³⁶⁰ With respect to the role of NF- κ B noted in the preceding paragraph, one study of patients revealed a marked elevation of NF- κ B in those with unstable as compared to stable angina.⁴¹¹

Platelets in Atherothrombosis

The interior of intact atherosclerotic plaques is rich in components that are highly thrombogenic (e.g., collagen types I and III, fibrinogen/fibrin, thrombospondin), and the luminal surface is relatively nonthrombogenic. In contrast to these observations, the thrombotic response to plaque disruption is dynamic. In this respect, thrombosis, repeat thrombosis, and thrombolysis along with embolization all occur simultaneously in many patients with ACS, and this is considered responsible for intermittent flow obstructions.⁴¹² The initial flow obstruction is acknowledged as being due to platelet aggregation, but subsequent fibrin stabilization is important to the longevity of the early and fragile platelet thrombus.⁴¹³ As a result of reduced flow caused by the platelet thrombus at the plaque rupture site, an erythrocyte- and fibrinrich thrombus may form and propagate up and down the artery in both directions.⁴¹²

Normally blood flow is laminar with adjacent fluid layers traveling parallel to each other but at different velocities due to fluid drag exerted by the vessel wall and this leads to shear forces between adjacent fluid planes. However, at arterial branch points, curvatures, and areas of stenosis these flow profiles develop alterations leading to shear gradients, turbulence, flow separation, and eddy formation and these will influence atherogenesis. Progression of the lesion exacerbates these flow disturbances and so a dangerous cycle of shear-dependent atherosclerosis acceleration can occur.⁴¹⁴ The rate of fluctuation in blood flow has been quoted as the major parameter altering endothelial function and as such cell function responds to flow changes through a variety of mechanotransduction mechanisms.⁴¹⁵ These mechanosensory signaling mechanisms are very sensitive to changes in wall shear stress leading to alterations in cell morphology, gene expression profiles, and increased adhesiveness. Thus at high shear rates as occurs in stenosed atherosclerotic arteries ($>5,000 \text{ s}^{-1}$), shear will directly induce platelet activation and aggregation as noted in the section on "Platelet Aggregation and Arterial Shear Flow," and recent evidence suggests this can occur independently of ADP and TxA_2 which implies shear gradients can promote platelet deposition and initial thrombus growth even in the presence of aspirin and a P2Y_{12} inhibitor.⁴¹⁶

There is evidence that alteration of the endothelium such as may occur with early atherogenesis (particularly when under the influence of atherosclerosis risk factors) or plaque disruption may cause the endothelium to generate more mediators that enhance constriction, such as endothelin-1, and fewer mediators that enhance dilation, such as PGI_2 and NO.^{413,417,418,419} Coronary angioplasty data collected at the time of ACS have shown that transient vasoconstriction often accompanies plaque disruption or fissuring, and thrombosis.⁴²⁰ This vasoconstriction occurs with significant vessel wall damage and is dependent on both platelets and thrombin, with platelet dependence shown to be mediated by serotonin and TxA_2 .^{420,421}

Chapter 18

Blood Coagulation and Fibrinolysis

Kathleen E. Brummel-Ziedins

Stephen J. Everse

Kenneth G. Mann

The opposing forces of fibrin clot formation and dissolution maintain hemostasis and preserve vascular function and integrity. Procoagulant events (platelet adhesion/activation, α -thrombin generation, and cross-linked fibrin clot formation) protect the vasculature from perforating injury and excessive blood loss in a process tightly regulated by plasma and cellular inhibition systems. Subsequent activation of the fibrinolytic system removes the clot, restores blood flow, and initiates tissue repair and regeneration. Hemostasis thus refers to multiple discrete processes that collectively culminate in preservation of vascular integrity. Circulating and adherent cells collaborate with plasma and cell membrane-associated proteins to carry out key roles in both pathways. Hemostasis is not a passive but a continuously active process in maintaining vascular integrity. With vascular perforation, focal interactions initiate procoagulant and fibrinolytic events and initiate tissue repair. Each process must operate in a cooperative fashion, or the entire system is compromised. Thus, balance between the procoagulant, anticoagulant, fibrinolytic, and antifibrinolytic processes is required to prevent extra vascular blood loss, or undesirable intravascular thrombosis.¹

Much of our knowledge of hemostasis has been gleaned and validated from observations of hemostatic and thrombotic pathology; however, much is still not well understood. Epidemiologic studies have expanded our knowledge about key factors that determine risk for venous and arterial thrombosis; however, vascular thrombosis is still the primary cause of death in the United States and Western Europe.² Thus, although the present information base is formidable, investigators continue to examine the processes that contribute to blood coagulation and fibrinolysis. The current concepts governing the roles of protein and cellular components, their structures, functions, and regulations are summarized in the following sections.

ESSENTIAL FEATURES OF COAGULATION

MacFarlane³ and Davie and Ratnoff⁴ provided the first integrated descriptions of the coagulation system. They proposed a "cascade" or "waterfall" sequence of events in which the reactions occur in a defined series leading to prothrombin activation and fibrin clot formation. Each reaction shares a similar mechanism in which an inactive zymogen is converted to an active enzyme. Although some facets of these initial descriptions are still valid, the emerging concept of coagulation and fibrinolysis centers on a complex network of highly interwoven collections of simultaneously occurring processes. Procoagulant, anticoagulant, and fibrinolytic processes occur with many positive and negative feedback loops regulating the processes. These overlapped reactions can be operationally described as five distinct phases: initiation of coagulation, propagation of α -thrombin formation, termination of the procoagulant response, elimination of the fibrin clot, and tissue repair and regeneration. The reactions involved in these five phases share several key features and the nomenclature used to describe the protein components of the reactions is similar.

The proteolytic enzymes and their zymogen precursors are mostly members of the serine protease family that includes chymotrypsin and trypsin with the zymogen and enzyme forms distinguished by an " α " to signify the active enzyme. For example, factor Xa is the active enzyme and factor X is the corresponding zymogen. Factor II, most commonly referred to as prothrombin, is the zymogen that upon activation becomes factor α IIa or α -thrombin. The non-zymogen procofactors factors V and VIII also share this nomenclature, in which the proteolytically activated fully functional cofactor forms are designated factors Va and VIIIa; conversely, the inactivated forms are designated with an "i" subscript (factor Va_i). The

protein cofactors that are cell associated, tissue factor and thrombomodulin, primarily exist in one form and designation. The mechanisms of the individual procoagulant reactions are likewise similar. In each case, a complex consisting of a serine protease, a cofactor protein and Ca^{2+} is assembled on a membrane surface. Each complex enzyme cleaves a zymogen to an enzyme.⁵ The progression from complex to complex results in amplification of product formation.⁶ In blood, the membrane surface is provided by platelets and by other circulating cells and microparticles. The vessel wall also contributes cofactors and membrane to support complex formation. The common features of these membrane-cofactor-protease complexes include target recognition, reaction amplification, regulation, and localization. The response to injury is rapid and ordinarily modulated to ensure a sufficient but not excessive response to the injury.

The initiation of the antihemorrhagic response occurs when the vascular wall is perforated and the antithrombotic nature of the vessel wall is overcome to achieve a prothrombotic state. Membrane surface and subcellular elements, including tissue factor, are presented and initiate the subsequent phases of coagulation. The assembly of the multicomponent procoagulant complexes on membrane surfaces triggers propagation of the coagulation response. The net result of the activities of these complexes (the intrinsic and extrinsic tenase and prothrombinase complexes) is an explosive local expression of α -thrombin. The initial burst of α -thrombin sustains the procoagulant response by activating circulating platelets, the procofactors V and VIII, and the zymogen factors VII and XI.^{7, 8,9,10,11,12,13,14,15} and¹⁶ Thrombin cleaves the fibrinopeptides from fibrinogen and activates factor XIII (to factor XIIIa),¹⁷ a protransglutaminase that, when activated, cross-links (to fXIIIa) and stabilizes the fibrin clot. Tight regulation by antithrombin (AT), tissue factor pathway inhibitor (TFPI), and the dynamic protein C system (thrombin-thrombomodulin) ensures that the response is appropriate to the stimulating injury. The thrombin-activatable fibrinolysis inhibitor (TAFI),^{18,19} a procarboxypeptidase zymogen, thrombin-activated as TAFIa, protects the fibrin clot by downregulating the fibrinolytic system. The propagation phase thus stems blood loss by producing a platelet-rich cross-linked fibrin clot.²⁰ Ultimately, inhibition of the procoagulant enzyme complexes by direct inhibition of the serine proteases and proteolytic inactivation of the cofactor proteins restores homeostasis by limiting coagulation to the site of vascular damage and preventing excessive clot formation.

The plasma proenzyme plasminogen is activated to plasmin by proteases associated with the vascular endothelial cells. Plasmin cleaves the cross-linked fibrin matrix to produce soluble peptides including D-dimer.^{21,22} The mechanism by which plasmin is generated is complex and involves several proteins with key roles throughout the hemostatic response. The solubilization and removal of the fibrin scaffolding of the hemostatic plug is coordinated with the processes of tissue repair and regeneration in part triggered by products of the processes. The extracellular matrix is degraded to allow for cell migration into the damaged area. Vascular cells repopulate the site and recreate the elements necessary to restore the vessel to its (relatively) previously unper-turbed state.

P.429

These steps occur rapidly and in a precise choreographed manner and must be localized to the site of injury. Localization presents challenges because the hemostatic response occurs under conditions of highly variable flow in vascular tubes of various diameters.²³ Localization is controlled on several levels. Endothelial cells actively inhibit coagulation by constitutively synthesizing various anticoagulants and platelet activation inhibitors. Furthermore, the surfaces of inactivated, undamaged blood and vascular cells are not conducive to the assembly and function of the procoagulant protein complexes. Thus, surface availability for procoagulant complex assembly is ordinarily limited by vascular pathology. The activated cell/damaged membrane surfaces may also provide for rapid transfer of intermediate products between complexes; such two-dimensional transfer of intermediates between complexes would increase the rates of complex formation and provide protection from the abundant plasma inhibitors. The essential features of the hemostatic response (recognition, amplification, regulation and localization) ensure that the response is localized to the injury, amplified appropriately according to the severity of the injury, and attenuated to block a systemic reaction.^{24,25}

In contrast to hemostasis, thrombosis is invoked by the presentation of intravascular tissue factor either by damaged endothelium or by an inflammatory cell. The resulting coagulation process is invoked, but in this instance results in the pathology of thrombosis. Vascular thrombotic occlusions composed of platelets and fibrin are significantly influenced by vascular architecture, vascular cell biology, and flow biophysics. In arterial thrombosis, high shear rates make platelet-rich clots (white clots) more apparent, while in the low shear venous circulation, fibrin-rich clots (red clots) are observed. However, it is likely that in both vascular environments, events similar to those associated with the hemostatic process occur.

OVERVIEW OF PROCOAGULANT PATHWAYS: PRIMARY (EXTRINSIC) AND ACCESSORY (INTRINSIC) PATHWAYS

Two procoagulant pathways have been identified which converge at the “intrinsic” fXase (fIXa•fVIIIa) complex (Fig. 18.1). The contact or “intrinsic” pathway is activated by the interaction of blood with a foreign surface. This pathway is activated by the factor XIIa-high-molecular-weight kininogen (HMWK)-prekallikrein complex in association with foreign surfaces including glass, dextran sulfate, or kaolin. The complex catalyst activates factor XI leading to the factor XIa-HMWK complex which activates fIX to fIXa. The “intrinsic” fXase rapidly cleaves fX to fXa.

Factor Xa is directly but less effectively produced by the “extrinsic” fXase, which is composed of plasma-derived fVIIa and tissue factor and expressed when the latter is exposed to blood. The “extrinsic” fXase also activates fIX to fIXa as the reaction progresses. The “extrinsic” fXase also activates fIX to fIXa as the reaction progresses, with suppression of the quaternary complex occurring by TFPI. The “intrinsic” fXase complex is kinetically superior and ultimately produces the majority of fXa.

Since bleeding pathology is not ordinarily associated with defects of the initiation protein complexes of the contact pathway, most investigations conclude that the “extrinsic” pathway is not the primary provider for hemostasis. The “intrinsic” pathway, however, has been implicated in some forms of thrombosis. The primary (“extrinsic”) and accessory (“intrinsic”) pathways, initiated by independent routes, both lead to the activation of factor IX and converge at the “intrinsic” fXase complex (Fig. 18.1). Regardless of the path, the outcome is the formation of the prothrombinase complex and thrombin generation. Each reaction of the primary pathway of coagulation involves the vitamin K-dependent zymogens and serine proteases, cofactor proteins, and Ca^{2+} ions assembled on membranes. The complexes display reaction rates 10^5 to 10^9 times greater than the respective serine proteases alone.⁵

Clinical laboratory tests differentiate between the pathways. The activated partial thromboplastin time (aPTT) initiates coagulation through the accessory pathway, whereas the prothrombin time (PT) assay initiates coagulation through the primary pathway.^{26,27} and ²⁸ The designations of primary and accessory pathways are based on clinical evidence of bleeding diseases. Deficiencies of proteins associated with the “intrinsic” or accessory pathway (factor XII, prekallikrein, and HMWK) exist but are not associated with abnormal bleeding events, even after surgical challenge.^{29,30} and ³¹ However, deficiencies of the protein components of the “extrinsic” or primary pathway (prothrombin and factors V, VII, VIII, IX, and X) can lead to severe bleeding diatheses.^{16,32,33,34} and ³⁵ Factor XI deficiency may also result in bleeding episodes subsequent to trauma or surgery.^{20,36} The role of the accessory pathway is therefore not clearly understood. Factor XI appears to play a role in coagulation,^{21,37} most likely unrelated to its activity in the “intrinsic” pathway, with the contribution of factor XI to hemostasis thought to be due to its activation by α -thrombin. Factor XIa then functions in the propagation phase of α -thrombin generation in association with the primary pathway.^{7,22}

Factor XII, prekallikrein, and HMWK are required for activity of the contact or accessory pathway and deficiencies are reported by the aPTT. Factor XII and prekallikrein are zymogens that are activated to serine proteases, while HMWK is a cofactor. The accessory pathway factors are hypothesized to play a role in disseminated intravascular coagulation (DIC) associated with the systemic inflammatory response syndrome,^{38,39} and may also be involved in the promotion of thrombus stability.^{5,24,40,41} The accessory pathway may also be important in cardiopulmonary bypass because of contact between blood components and synthetic surfaces.³⁹

The importance of the membrane component in coagulation was initially identified by kinetic studies of the prothrombinase complex. In the absence of the membrane surface, the cofactor (factor Va)-enzyme (factor Xa) interaction is relatively weak, with a dissociation constant (K_d) of 800 nmol/L.^{42,43,44} The factor Va-lipid interaction ($K_d = 3$ nmol/L) and factor Xa-lipid interaction ($K_d = 110$ nmol/L)⁴⁵ show higher affinity. However, all of the components must be present to generate the high-affinity factor Va-factor Xa- Ca^{2+} membrane complex, with a K_d of 1 nmol/L.⁴⁶ The fully assembled complex is stabilized through factor Va-factor Xa, factor Va-lipid, and factor Xa-lipid interactions.^{14,47,48} Similar properties have been observed for the fIXa/fVIIIa, TF/fVIIa, and Tm/fIIa complexes.⁴²

The primary pathway of coagulation is initiated or triggered by the interaction of circulating factor VIIa with its cofactor tissue factor.^{49,50,51} In general, the serine proteases associated with hemostasis circulate in their zymogen or inactive forms; however, low levels of circulating factor VIIa are present in blood.⁵² This factor VIIa binds to tissue factor expressed by pathology and initiates the procoagulant response. Free factor VIIa is a poor enzyme with virtually no proteolytic activity, but as a consequence is protected from interacting with the circulating inhibitors in the absence of tissue factor. Tissue factor, an integral membrane protein not normally expressed on vascular cell surfaces, is constitutively expressed on extravascular cellular surfaces^{53,54,55,56,57,58} and thus becomes exposed upon damage to the endothelial cell layer. Tissue factor is also expressed on peripheral blood cells and endothelial cells stimulated by inflammatory cytokines.^{59,60}

Upon interaction of plasma factor VIIa and the injury/pathology presented, tissue factor, the “extrinsic” fXase complex (factor VIIIa-tissue factor) is formed and initiates coagulation by

activating factors IX and X. Factor IXa forms a complex with its cofactor, factor VIIIa, to generate the intrinsic “fXase” complex, and factor Xa combines with factor Va to form the prothrombinase complex. The factor VIIIa-factor IXa complex more efficiently activates factor X to factor Xa, providing a robust source of the enzyme component (factor Xa) of the prothrombinase complex.

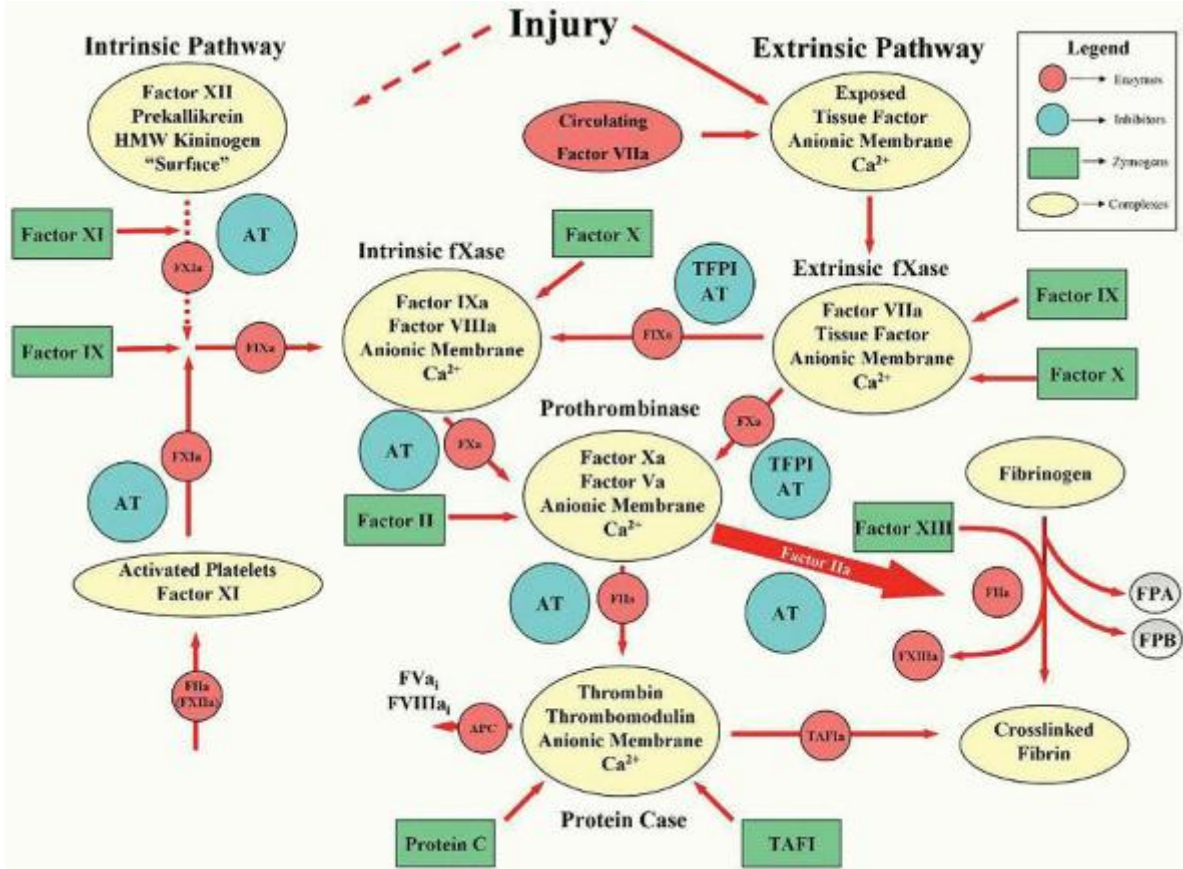

FIGURE 18.1. Overview of hemostasis. There are two pathways to initiate coagulation: the primary extrinsic pathway (shown on right) and the intrinsic (also called the contact pathway) (shown on left). The components of these multistep processes are illustrated as follows: enzymes (pink circles), inhibitors (blue circles), zymogens (green boxes), or complexes (cream ovals). The intrinsic pathway has no known bleeding etiology associated with it; thus, this path is considered accessory to hemostasis. On injury to the vessel wall, tissue factor, a membrane-bound cofactor, is exposed to circulating factor VIIa, forming the extrinsic fXase, a vitamin K-dependent complex. Factor IX and factor X are converted to the serine proteases factor IXa (FIXa) and factor Xa (FXa), which are the enzymatic components of the intrinsic fXase and the prothrombinase complexes, respectively. The combined actions of the intrinsic and extrinsic fXase and the prothrombinase complexes lead to an explosive burst of the enzyme thrombin (FIIa). In addition to its multiple procoagulant roles, thrombin also acts in an anticoagulant capacity when combined with the cofactor thrombomodulin in the protein Case complex. The product of the protein Case reaction, activated protein C (APC), inactivates the cofactors factors Va and VIIIa. The cleaved species, factors Va_i (FVa_i) and VIIIa_i (FVIIIa_i), no longer support the respective procoagulant activities of the prothrombinase and intrinsic fXase complexes. Once thrombin is generated through procoagulant mechanisms, thrombin cleaves fibrinogen (releasing fibrinopeptides A and B [FPA and FPB, respectively]) and activates factor XIII to form a cross-linked fibrin clot. Thrombin-thrombomodulin also activates thrombin-activatable fibrinolysis inhibitor (TAFI) that slows down fibrin degradation by plasmin. The procoagulant response is downregulated by the stoichiometric inhibitors tissue factor pathway inhibitor (TFPI) and antithrombin (AT). TFPI serves to attenuate the activity of the extrinsic fXase, the trigger of coagulation. AT directly inhibits thrombin, FIXa and FXa. The intrinsic pathway provides an alternate route for the generation of factor IXa. Thrombin has also been shown to activate factor XI. The fibrin clot is eventually degraded by plasmin, yielding soluble fibrin peptides (see Fig. 18.17). HMW, high molecular weight.

Deficiencies of the “intrinsic” fXase components factor VIIIa (hemophilia A) and factor IXa (hemophilia B) illustrate the significance of the factor IX activation by the fVIIa/TF complex and the enhanced rate of factor X activation by the intrinsic fXase and the inhibition of the extrinsic fXase by TFPI. Hemophilia A and B are detected using the aPTT. From inspection of Figure 18.1, it would appear activation of factor X by the “extrinsic” fXase should compensate for the lack of factor X activation by the “intrinsic” fXase in hemophilias A and B. However, this compensatory mechanism only occurs during clinical administration of supraphysiologic concentrations of recombinant factor VIIa during replacement therapy for hemophilia with inhibitors. The natural physiologic levels of factor VIIa are not able to provide sufficient levels of factor Xa to support normal coagulation. Factor Xa generation is suppressed to approximately one-half the level observed when factor X is the only substrate presented.^{61,62}

Factor IX, not factor X, appears to be the preferred substrate of the extrinsic fXase. In addition, factor IX α , the intermediate species in factor IX activation, is generated more rapidly in the presence of factor X. Factor IX α activation to the final product factor IXa occurs at a higher rate than factor IX activation, thereby providing a burst of factor IXa to form the intrinsic fXase complex. The low level of factor Xa generated by the tissue factor-factor VIIa complex most likely functions in the activation of factor IX. A model of extrinsic fXase behavior suggests

P.431

that factor IX is converted to factor IX α by the extrinsic fXase or factor Xa-phospholipid complex. Factor IX α is then rapidly converted to factor IXa by the extrinsic fXase.^{61,62} The factor VIIIa-factor IXa complex subsequently activates the major fraction of factor X to factor Xa and provides the enzyme component for the prothrombinase complex. Measurements of second-order rate constants for factor Xa generation by the intrinsic and extrinsic fXase complexes also support this model. The rate of factor Xa generation by the tissue factor-factor VIIa complex is 1/50th the rate of factor Xa generation by the factor VIIIa-factor IXa complex.^{61,62} and ⁶³ Both complexes thus have distinct roles in the procoagulant response.

In summary, the procoagulant response is triggered upon the interaction of factor VIIa with tissue factor, when the latter is exposed and/or expressed as a result of vascular perturbation. The extrinsic fXase generates low levels of factors IXa and Xa during the initiation phase of coagulation. Factor Xa-phospholipid complexes also assist in the activation of factor IX. Factor IXa combines with factor VIIIa on the membrane surface, and the intrinsic fXase accelerates factor Xa generation 50-fold over the extrinsic fXase. The burst of factor Xa overcomes circulating levels of factor Xa inhibitors and initiates maximal levels of prothrombinase complex activity. Prothrombinase activity subsequently leads to a burst of α -thrombin generation and propagation of the procoagulant response.^{61,62}

PROCOAGULANT PROTEINS: ACCESSORY PATHWAY FACTORS AND FACTOR XI

The procoagulant proteins that make up the intrinsic or accessory pathway consist of factor XII, plasma prekallikrein, HMWK, and factor XI. These proteins are responsible for the contact activation of blood coagulation. The physiologic role of the intrinsic pathway is not clearly understood, but does not appear to be essential for hemostasis because individuals deficient in factor XII, plasma prekallikrein, or HMWK do not manifest abnormal bleeding. Factor XI appears to play a more prominent role, unrelated to its activities in the intrinsic pathway, after activation by thrombin.^{7,37} Each of these proteins is described in terms of its gene structure and expression, biochemistry, activation, function, and regulation in regard to hemostasis.

Factor XII (Hageman Factor, Contact Factor)

Factor XII, or Hageman factor (HF), is the zymogen precursor of the serine protease factor XIIa. Factor XII is also known as contact factor for its role in the initiation of coagulation on contact with substances such as glass or kaolin. The contact pathway is the basis for the activated partial thromboplastin time clotting assay. Factor XII circulates in plasma at an average concentration of 40 $\mu\text{g/ml}$ (500 nmol/L)^{64,65} (Table 18.1). Increased levels of factor XII are seen in postmenopausal women using estrogen replacement therapy and during pregnancy. Animal studies also demonstrate enhanced expression of factor XII by estrogen and prolactin.^{66,67} and ⁶⁸ Since a deficiency of factor XII is not associated with any bleeding abnormality, its precise role in hemostasis is at present unknown. Studies show that mice lacking factor XII are protected against arterial thrombosis and stroke.^{40,41,69,70} This suggests that the intrinsic pathway of coagulation is essential for thrombus stability. The components of the contact pathway are also believed to provide a link between coagulation and inflammation,⁷¹ with the multifunctional cellular protein gC1q-R/p33 postulated to play a central bridging role between these two processes.⁷² Misfolded protein aggregates have been implicated in activating factor XII.⁷³

Gene Structure and Expression

Human factor XII is produced by a single gene located on chromosome 5 q33-qter^{74,75} (Table 18.2). The gene for factor XII spans approximately 12 kilobases (kb) and is composed of 13 introns and 14 exons.⁷⁶ The intron/exon gene structure is similar to the gene structures of tissue plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA).⁷⁶ The promoter does not contain the CAAT or TATA sequences common in other genes, but it does contain two LF-A1 transcription elements characteristic of genes with liver-specific expression. The promoter also contains one estrogen-responsive element.^{76,77}

Biochemistry

Human factor XII is synthesized as a precursor protein with a 19-residue signal peptide. The mature factor XII molecule is a 596-amino acid single-chain β -globulin with a molecular weight of approximately 80 kDa.^{78,79,80,81,82} It circulates at a concentration of 40 $\mu\text{g/ml}$ (500 nmol/L) with a half-life ($t_{1/2}$) of 2 to 3 days (Table 18.1). The factor XII molecule is composed of two domains: an NH₂-terminal heavy chain and a COOH-terminal light chain. The heavy chain contains several domain structures: fibronectin type I and type II domains, two epidermal growth factor (EGF)-like domains, a kringle domain, and a proline-rich region (residues 277 to 330) (Fig. 18.2). The light chain contains the serine protease catalytic domain, a region homologous to the B-chain of the enzyme plasmin. The mature factor XII molecule contains approximately 17% carbohydrate. Glycosylation consists of an O-linked fucose at Thr⁹⁰ in the first EGF domain⁸³; N-linked carbohydrates at Asn²³⁰ and Asn⁴¹⁴ in the kringle and catalytic domains, respectively; and six O-linked carbohydrates in the proline-rich region.⁸⁴ The factor XII molecule also contains four zinc ion (Zn²⁺)-binding sites.⁸⁵ Zn²⁺ binding to factor XII likely induces a conformation change that promotes activation of factor XII associated with negatively charged surfaces.^{86,87} and ⁸⁸

Activation

Factor XII undergoes autoactivation on interaction with negatively charged surfaces such as glass, kaolin, dextran sulfate, ellagic acid, celite, or bismuth subgallate,^{89,90,91,92,93,94,95,96,97,98} and ⁹⁹ and on interaction with hydrophobic surfaces.¹⁰⁰ This is likely only an in vitro event triggered by the artificial surfaces used in studies of the contact pathway, although research is ongoing. Although factor XII associates with many physiologically relevant anionic surfaces, including negatively charged phospholipids,^{101,102,103} and ^{104,105,106,107,108,109,110,111,112} and ¹¹³ the autoactivation of factor XII induced by these surfaces in vitro does not appear to represent the mechanism for factor XII activation in vivo.¹¹⁴ Instead, factor XII is most likely activated by a cell membrane-associated proteinase.^{115,116} When factor XII, prekallikrein, and HMWK form a complex on anionic phospholipids of the cell membrane, prekallikrein is cleaved, forming the enzyme kallikrein. Kallikrein then activates factor XII (plasmin activates factor XII as well) via a single cleavage at Arg³⁵³-Val³⁵⁴ to generate an 80-kDa two-chain enzyme, α -factor XIIa (factor XIIa, α -HFa, or HFa), composed of an NH₂-terminal heavy chain (relative molecular weight [M_r] = 52,000) and a COOH-terminal light chain (M_r = 28,000) held together by a disulfide bond (Cys³⁴⁰-Cys⁴⁶⁷) (Fig. 18.2). This cleavage is essential for exposure of the active site in factor XIIa.¹¹⁷ Factor XIIa can then bind negatively charged surfaces and activate factor XI and prekallikrein.^{118,119} Two secondary cleavages can also occur on factor XII: one outside the disulfide bond (Arg³³⁴-Asn³³⁵) and one inside the disulfide loop (Arg³⁴³-Leu³⁴⁴), generating β -factor XIIa (FXII_f, HF_f).^{120,121,122} and ¹²³ β -Factor XIIa has no surface-binding capabilities but is able to activate prekallikrein.^{89,124,125}

Function

Factor XIIa is a serine protease that activates factor XI and prekallikrein by mechanisms dependent on anionic surfaces and the cofactor HMWK.^{118,126} Factor XIIa also activates the C1 component of the complement system.¹²⁷ In addition, factor XIIa downregulates the Fc receptor on monocytes and macrophages,¹²⁸ induces release of interleukin (IL)-1 and IL-6 from monocytes and macrophages,¹²⁹ and stimulates neutrophils.¹³⁰ Although these roles have no apparent impact on normal coagulation, factor XII/XIIa may be an important link between coagulation and inflammation (for review, see Ref. 131). Factor XIIa also activates plasminogen to plasmin, linking the contact pathway to fibrinolysis.¹³²

Regulation

C1 inhibitor is the major inhibitor of both factor XIIa and β -factor XIIa and irreversibly inhibits both enzymes.^{133,134,135} and ¹³⁶ Antithrombin and plasminogen activator inhibitor (PAI)-1 also inhibit factor XIIa.^{137,138} and ¹³⁹ Endothelial cells and eosinophils are reported to produce proteins that inhibit factor XII activation but not factor XIIa activity.^{140,141} and ¹⁴² Amyloid precursor protein likewise is reported to inhibit factor XII activation but not factor XIIa.¹⁴³

Plasma Prekallikrein (Fletcher Factor)

Plasma prekallikrein, or Fletcher factor, is the zymogen form of the enzyme kallikrein. Prekallikrein circulates in plasma at an average concentration of 42 $\mu\text{g/ml}$ (486 nmol/L)^{144,145} (Table 18.1). Approximately 75% circulates in a noncovalent complex with HMWK,^{146,147} and the remaining 25% circulates as free prekallikrein. Like factor XII, prekallikrein is a component of the intrinsic or accessory pathway and serves as a link between coagulation and inflammation. Prekallikrein is also linked to fibrinolytic events. Plasma prekallikrein deficiency is rare and is not associated with

P.433

hemostatic defects except perhaps in deficient individuals with other cardiovascular risk factors.^{148,149}

Gene Structure and Expression

The human prekallikrein gene is located on chromosome 4q34-35, close to the factor XI gene¹⁵⁰ (Table 18.2). The human plasma prekallikrein gene spans 30 kb and contains 15 exons and 14 introns.¹⁵¹ A total of 12 allelic variants have been identified in the 5' proximal promoter and in 7 of the exons. A common polymorphism (30% of the population) leads to an Asn124Ser replacement in the heavy chain of the apple 2 domain of prekallikrein. Two other polymorphisms in the coding region of the protein, His189Pro in the apple 3 domain of the heavy chain and His183Gln, were identified.¹⁵¹ Prekallikrein and factor XI are highly homologous, and both human and rat factor XI prekallikrein genes are located on chromosome 4, suggesting a gene duplication event from a common ancestor.¹⁵² Prekallikrein mRNA has been detected in human kidney, adrenal gland, placenta, and brain, but the liver is considered to be the major site of synthesis.^{153,154} and ¹⁵⁵

Biochemistry

Human plasma prekallikrein is synthesized as a precursor with a 19-amino acid signal peptide. The mature form of the protein, appearing as a doublet of 85 and 88 kDa when analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), is a single-chain fast γ -globulin of 619 amino acids (Table 18.1).^{132,156,157} Prekallikrein contains 15% carbohydrate with five N-linked sugar moieties.¹⁵³ Structurally, prekallikrein contains four tandem repeats, called apple domains, in the NH₂-terminal portion of the molecule (Fig. 18.2). Each apple domain consists of 90 to 91 amino acid residues including six to eight cysteines that are disulfide bonded to form the distinct domain structure.^{153,158} The apple 1 and apple 4 domains mediate the binding of prekallikrein to HMWK.^{159,160} The apple domains of prekallikrein are highly homologous to the apple domains of factor XI. Apple domains have been found only in these two proteins, lending support to a gene duplication event from a common ancestor.^{150,158} The COOH-terminal region of prekallikrein contains the catalytic site.

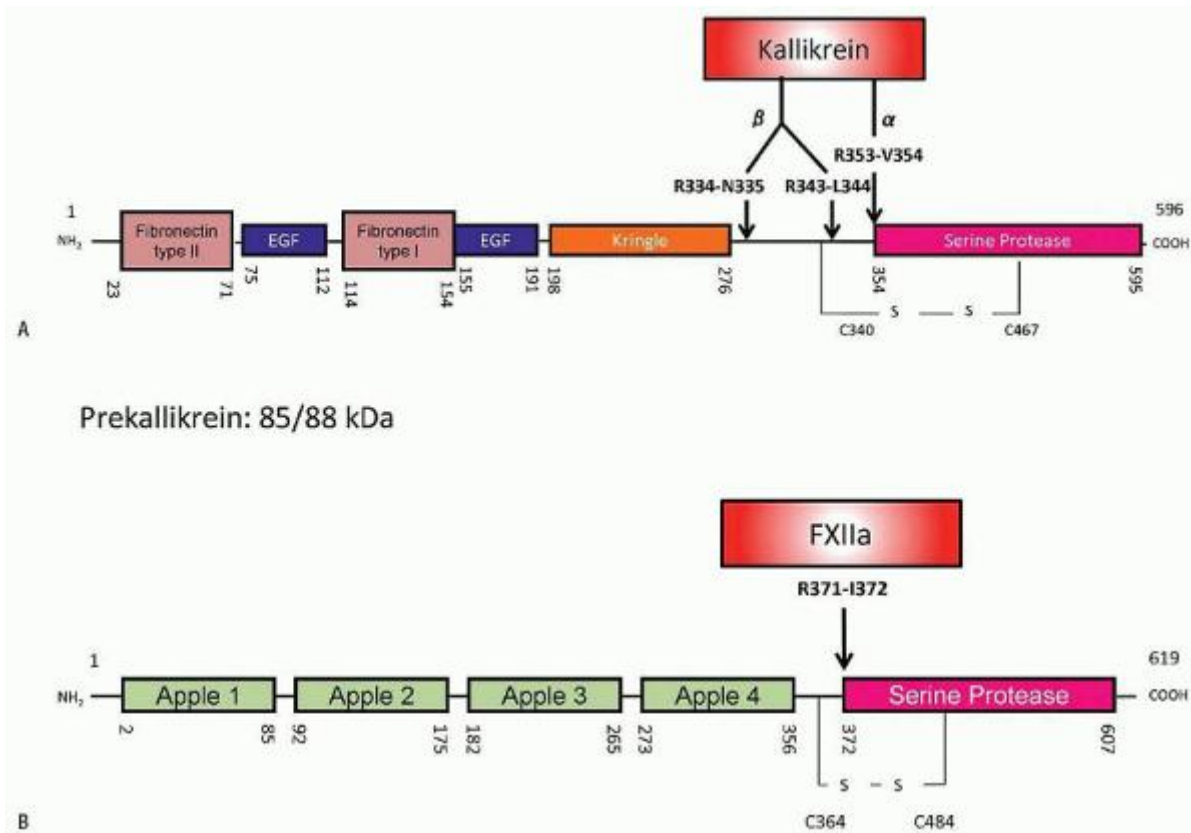

FIGURE 18.2. Schematic representation of the intrinsic pathway (contact) proteins. Factor XII (FXII), prekallikrein (PK), high-molecular-weight (HMW) kininogen, low-molecular-weight (LMW) kininogen, and factor XI (FXI) are shown with their various domains depicted as blocks. Activating proteases are placed in a box above the cleavage sites with the specific amino acid residues of the site shown directly underneath. Key interchain disulfide bonds (S-S) are included. For the kininogens, horizontal arrows indicate the amino acid residues defining heavy and light chain regions of the activated forms of the cofactors. Factor XI is illustrated as a monomer. EGF, epidermal growth factor.

Activation

Prekallikrein is activated by factor XIIa in complex with the cofactor HMWK on an anionic surface (Fig. 18.2). Prekallikrein is also activated by β -factor XII in the absence of a surface.¹⁶¹ The factor XIIa-HMWK complex or β -factor XII catalyzes the cleavage of the Arg³⁷¹-Ile³⁷² bond in prekallikrein. This cleavage is also reported to occur in the absence of factor XIIa when prekallikrein is bound to HMWK on the endothelial cell surface.^{115,162} The enzyme kallikrein is a two-chain molecule composed of an NH₂-terminal heavy chain ($M_r = 53,000$) containing the four apple domains and a COOH-terminal light chain ($M_r = 36,000$ or $33,000$) containing the active site.^{132,153,163,164}

Function

Kallikrein is a member of the trypsin family of serine proteases. In the presence of an appropriate anionic surface and the cofactor HMWK, kallikrein activates factor XII to factor XIIa and proteolyzes factor XIIa to β -factor XIIa. Kallikrein also undergoes autoproteolysis at Lys¹⁴⁰-Ala¹⁴¹ to yield β -kallikrein.^{165,166} Enzyme activity is significantly reduced on conversion of kallikrein to β -kallikrein.¹⁶⁴ Kallikrein cleaves HMWK at two sites to generate the vasoactive nonapeptide bradykinin.^{167,168} Bradykinin is a potent vasodilator and stimulates endothelial cell prostacyclin synthesis, resulting in hypotension.^{169,170} Kallikrein is also an activator of fibrinolytic zymogens and converts both plasminogen to plasmin and pro-u-PA to u-PA.^{132,171,172} In addition, kallikrein has been reported to activate neutrophils and stimulate elastase release as part of the hemostatic and inflammatory responses.¹⁷³

Regulation

C1 inhibitor and α_2 -macroglobulin are the major inhibitors of kallikrein.^{174,175} C1 inhibitor forms a 1:1 stoichiometric complex with kallikrein and abolishes its proteolytic and amidolytic activities.^{175,176,177} and ¹⁷⁸ α_2 -Macroglobulin inhibits the ability of kallikrein to generate bradykinin and partially inhibits amidolytic activity.¹⁷⁶ C1 inhibitor and α_2 -macroglobulin each inhibit equivalent amounts

P.435

of kallikrein in plasma, but C1 inhibitor acts much more rapidly and plays the major role in reducing kallikrein activity.¹⁷⁹ Antithrombin and antithrombin-heparin are slow inhibitors of kallikrein although the antithrombin-heparin-HMWK complex is an effective inhibitor.^{180,181} and ¹⁸² Protein C inhibitor also inhibits kallikrein.^{183,184} and ¹⁸⁵

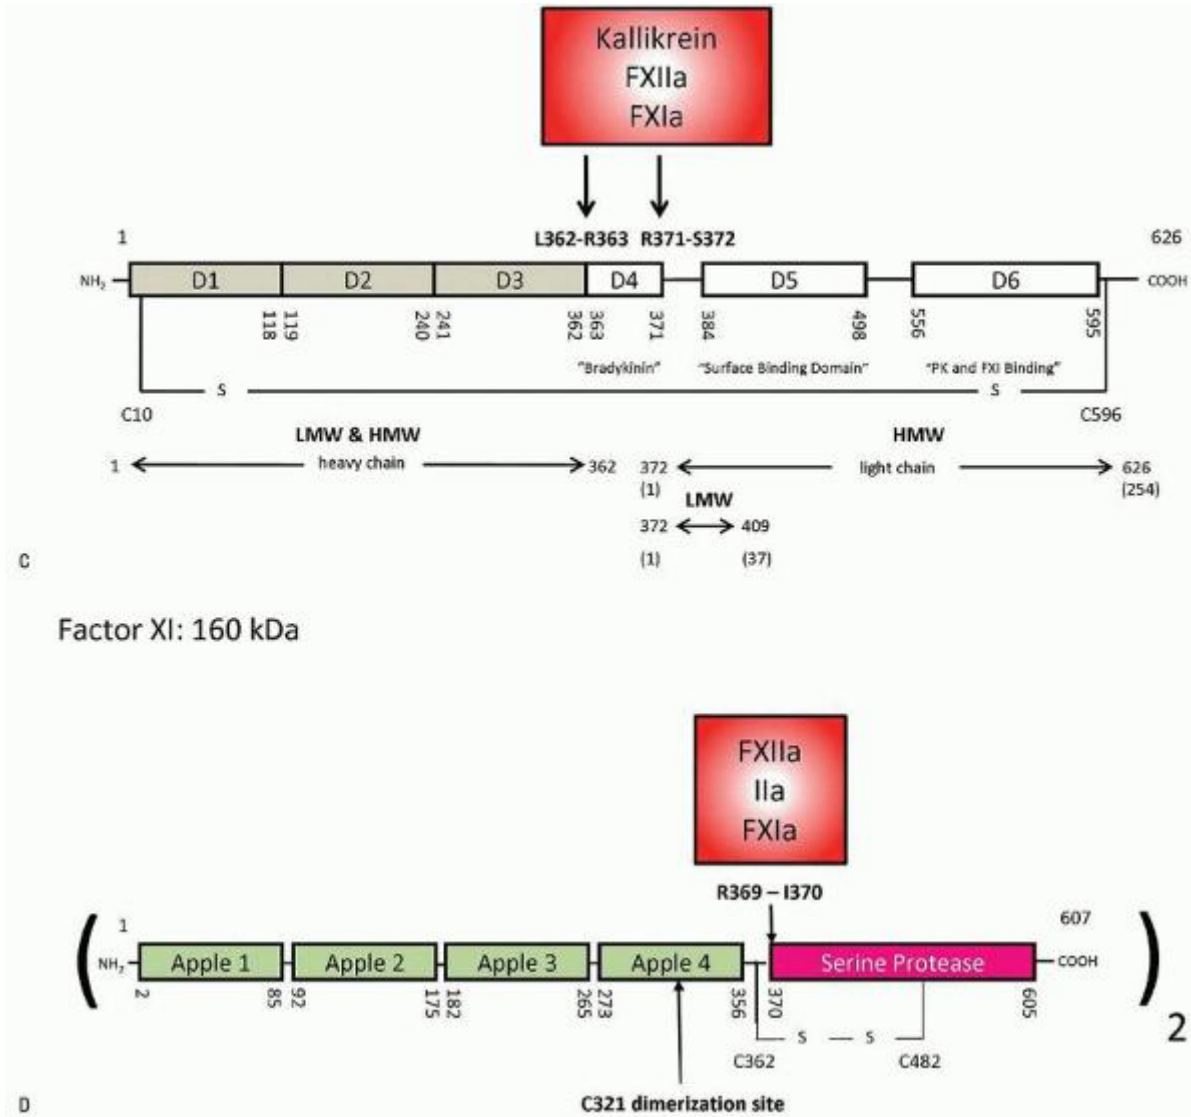

FIGURE 18.2. (continued)

FIGURE 18.2. (continued)

High-Molecular-Weight Kininogen (Fitzgerald Factor, Williams Factor)

HMWK, also known as Fitzgerald factor or Williams factor, circulates in plasma at an average concentration of 80 $\mu\text{g/ml}$ (670 nmol/L)^{186,187} (Table 18.1). HMWK acts as a cofactor for the activation of factor XII and prekallikrein and is the precursor of the vasoactive peptide bradykinin. A second form of kininogen, low-molecular-weight kininogen (LMWK), is also found in plasma. LMWK can be cleaved to yield bradykinin but has no procoagulant activity. LMWK circulates at an average concentration of 90 $\mu\text{g/ml}$ (1,300 nmol/L).¹⁸⁸ Deficiencies of HMWKs and LMWKs are rare and are not associated

with bleeding diatheses.¹⁸⁹ The major established function of the kininogens is to serve as a source of bradykinin and thereby to contribute to a number of vascular events regulated by bradykinin.¹⁹⁰

P.436

Gene Structure and Expression

The two forms of kininogen, HMWK and LMWK, are the products of a single gene^{191,192} located on chromosome 3q26-qter¹⁹³ (Table 18.2). The kininogen gene consists of 10 introns and 11 exons and spans 27 kb.¹⁹² The gene produces messenger RNAs (mRNAs) for the two different forms of kininogen by alternative splicing.¹⁹² HMWK and LMWK share the coding region of the first nine exons and the portion of exon 10 containing the bradykinin sequence and the first 12 amino acids following the COOH-terminal of bradykinin. Exon 10 also codes for a 56-kDa light chain unique to HMWK, whereas exon 11 codes for a 4-kDa light chain unique to LMWK. Human liver contains mRNAs for both HMWK and LMWK^{191,192}; only HMWK is expressed and secreted by human umbilical vein endothelial cells.¹⁹⁴ Estrogen administration¹⁹⁵ and pregnancy¹⁹⁶ increase HMWK levels. Conversely, progesterone treatment reduces kininogen gene expression and plasma kininogen levels.¹⁹⁷

Biochemistry

Human HMWKs and LMWKs are synthesized as precursor proteins containing 18 amino acid signal peptides. The mature form of HMWK is a 120-kDa single-chain α -globulin of 626 residues, whereas the LMWK form is a 66-kDa single-chain β -globulin composed of 409 residues.^{187,188,197} Glycosylation at a number of shared sites (Asn¹⁵¹, Asn¹⁸⁷, Asn²⁷⁶, and Asn³⁸³) and sites unique to HMWK (Thr⁵¹⁵, Thr⁵²¹, Thr⁵²⁸, Thr⁵³⁹, Thr⁵⁵³, Thr⁵⁵⁹, Thr⁵⁷⁵, and Thr⁶¹⁰) presumably accounts for the substantial increase over the masses predicted from the amino acid compositions (70,000 for HMWK and 46,000 for LMWK). The NH₂-terminal heavy chains (residues 1 to 362) of the two forms are identical and consist of three consecutive regions designated domains 1, 2, and 3 (D1, D2, and D3) (Fig. 18.2). Domain 1 has a low-affinity Ca²⁺-binding site.¹⁹⁸ Domains 2 and 3 share homology with cysteine protease inhibitors.¹⁹⁹ Both HMWK and LMWK are potent inhibitors of cysteine proteases such as calpain.^{200,201} Domain 3 also contains a cell-binding region^{202,203,204,205} and²⁰⁶ and is reported to inhibit α -thrombin activity^{203,205,207} and platelet activation.^{205,207,208} The central domain of both kininogens, domain 4 (D4), is the bradykinin region. Domain 4 also contains a cell-binding region²⁰⁹ and a region that inhibits α -thrombin activity.²¹⁰ The two forms of kininogen have different COOH-terminal light-chain regions. The light chain of LMWK (residues 372 to 409) consists of a single domain, domain 5_L (D5_L), with no known function. The light chain of HMWK (residues 372 to 626) is composed of two regions, domain 5_H (D5_H) and domain 6_H (D6_H). Domain 5_H contains additional cell-binding regions^{202,203,206,211,212} and mediates HMWK binding to anionic surfaces, heparin, and Zn²⁺.^{180,181,213,214} Domain 6_H has binding sites for prekallikrein and factor XI.^{215,216} and²¹⁷

Activation

Kallikrein, factor XIIa, and factor XIa cleave HMWK to release bradykinin (residues 363 to 371) (Fig. 18.2). Kallikrein also cleaves LMWK to release bradykinin. Bradykinin release from HMWK yields a two-chain protein composed of the heavy-chain (D1, D2, and D3) disulfide linked (Cys¹⁰-Cys⁵⁹⁶) to the light chain (D5_H and D6_H). This molecule retains procoagulant activity, binding to prekallikrein, factor XI, and anionic surfaces via light-chain interactions^{215,218,219} and induces apoptosis in endothelial cells.²²⁰

Function

The major role proposed for the kininogens is as a source of bradykinin. Bradykinin release provides a key vasoactive agent with a variety of roles and directly links the contact pathway to vascular repair processes. HMWK also functions as a nonenzymatic cofactor in the contact pathway of coagulation. HMWK binds anionic surfaces, prekallikrein, and factor XI, thus enhancing their activation by surface-associated factor XIIa. Although most studies of contact activation make use of artificial surfaces, cell membranes may provide appropriate sites for contact activation in vivo. Many cells contain kininogens and express kininogenbinding sites.^{187,194,221,222,223,224,225} and²²⁶ There is some evidence to support cell membrane-associated contact activation. Prekallikrein bound to HMWK on platelets or endothelial cells can result in the generation of kallikrein by a factor XIIa-dependent^{115,172} or -independent mechanism.¹¹⁵ However, factor XI bound to HMWK on the surface of platelets is not activated to factor XIa.²²⁷ HMWK and its cleaved form exert anticoagulant effects via their inhibitory action on platelet adhesion²²⁸ and aggregation.²²⁹

Factor XI (Plasma Thromboplastin Antecedent)

Factor XI, also known as plasma thromboplastin antecedent, circulates as a homodimer at an average concentration of 5 µg/ml (30 nmol/L)²³⁰ in complex with HMWK²³¹ (Table 18.1). Factor XI is also found in human platelets, and the platelet form accounts for approximately 0.5% of the factor XI antigen in blood.^{232,233,234,235} and ²³⁶ Factor XI is the zymogen precursor of the enzyme factor XIa. Unlike the other members of the accessory or contact pathway, factor XIa has an established role in coagulation as part of a positive feedback loop enhancing α-thrombin generation.^{7,16} Although rare in the general population (~1 in 100,000 individuals),²³⁷ factor XI deficiency is common in the Ashkenazi (European) Jewish population, with approximately 1 in 200 individuals affected by factor XI deficiency.^{238,239,240,241} and ²⁴² Factor XI deficiency can be associated with severe bleeding tendencies²⁴³ after injury or surgical trauma. Spontaneous hemorrhage is not common. Factor XI deficiency is unusual in that bleeding abnormalities vary considerably and range from a complete absence of symptoms to life-threatening hemorrhage.²⁴⁴ The severity of the bleeding complications is also not related to the severity of factor XI deficiency. Individuals with mild deficiency may experience severe hemorrhagic events, whereas individuals with severe deficiency may have no abnormal bleeding.^{238,240,242,245,246,247,248} and ²⁴⁹

Gene Structure and Expression

The gene for human factor XI is located on chromosome 4q35 and spans 23 kb (Table 18.2). The gene contains 14 introns and 15 exons.^{156,250} Although mRNA for human plasma factor XI has been found in liver, pancreas, and kidney,²⁵¹ evidence suggests that the primary site of synthesis is the liver: Plasma factor XI levels decrease in liver disease, and a patient with no history of factor XI deficiency developed a deficiency subsequent to a liver transplant from a factor XI-deficient donor.²⁵² Platelet factor XI is exclusively synthesized in the megakaryocyte.²⁵³ Human platelet factor XI lacks exon 5 and may be an alternative splicing product of the plasma factor XI gene or a product of a gene specific to megakaryocytes.²⁵³

There are three major types of genetic mutations associated with factor XI deficiency: (a) intronic point mutations that interrupt exon splicing^{240,254}; (b) exonic point mutations that lead to mutations in specific amino acids and result in premature polypeptide termination, disruption of dimerization, or reduced protein secretion^{240,254,255,256,257} and ²⁵⁸; and (c) nucleotide deletions that lead to decreased protein synthesis.^{259,260} Two specific exonic point mutations account for the majority of the cases of factor XI deficiency in the Ashkenazi Jewish population. An E117X mutation in exon 5 (type II mutation) introduces a stop codon and results in premature polypeptide termination. The type II mutation accounts for approximately 52% of the cases of factor XI deficiency in the Ashkenazi Jewish population. An F283L mutation in exon 9 (type III mutation) that accounts for 36% of the cases is believed to prevent intracellular dimer formation and protein secretion. These

P.437

mutations are less frequent in the general population.^{239,240,254,258} Approximately 150 mutations have been identified in the factor XI gene with four exhibiting founder effects in specific populations.²⁶¹

Biochemistry

Human factor XI is found in plasma and in platelets. The two forms of the protein are somewhat different and may have different functions as well. Plasma factor XI accounts for most of the factor XI antigen in the human system and is a disulfide-linked homodimer ($M_r = 160,000$), with approximately 5% of its mass made up by carbohydrate (Table 18.1). Each of the two identical polypeptide chains is synthesized with an 18-amino acid signal peptide. The mature polypeptide chain ($M_r = 80,000$) consists of 607 amino acid residues^{232,233} and ²³⁴ and has five potential glycosylation sites, although only Asn⁷², Asn¹⁰⁸, Asn⁴³², and Asn⁴⁷³ are glycosylated.²⁶² Exons 3 to 10 of the plasma factor XI gene encode four NH₂-terminal tandem sequences termed apple domains (apple 1 to apple 4, Fig. 18.2). The apple domains are homologous to the apple domains in human plasma prekallikrein.²⁶² Exons 11 to 15 encode the COOH-terminal catalytic domain. Human platelet factor XI lacks exon 5 and amino acids Ala⁹¹-Arg¹⁴⁴ in the NH₂-terminus of the apple 2 domain. The mature platelet polypeptide chain ($M_r = 55,000$) may form a disulfide-linked tetramer of identical subunits ($M_r = 220,000$) or may be disulfide linked to a platelet plasma membrane protein.^{233,246,253} Plasma factor XI circulates in complex with HMWK.²³¹ Formation of this complex, mediated by the apple 1 domain of factor XI, is required for factor XI to associate with anionic surfaces.²⁶³ The apple 1 domain also contains binding sites for α-thrombin²⁶⁴ and prothrombin.²⁴⁹ The apple 2, apple 3, or both domains mediate the binding of factor IX, the substrate of factor XIa.^{249,265,266,267} and ²⁶⁸ In addition to potentially mediating the factor XIa-factor IX interaction, the apple 3 domain contains binding sites for platelets and heparin.^{269,270} and ²⁷¹ The apple 4 domain contains the site (Cys³²¹) involved in the dimerization process. Dimerization is required for efficient intracellular processing and protein secretion.²⁵⁵ Factor XIa associates with a region of the apple 4 domain as well.²⁷² Polyphosphates have also been proposed as a natural cofactor for factor XI activation in plasma.^{273,274}

Activation

Plasma factor XI is cleaved at an internal Arg³⁶⁹-Ile³⁷⁰ bond to yield a disulfide-linked two-chain activated serine protease (Fig. 18.2). The factor XI homodimer yields two disulfide-linked heavy chains containing the apple domains and two light chains containing the active sites.^{275,276} and ²⁷⁷ Activation of factor XI can be accomplished by factor XIIa and α -thrombin and by autoactivation by factor XIa itself. Activation of factor XI by factor XIIa requires HMWK and an anionic surface. However, deficiencies of factor XII and HMWK do not result in bleeding diatheses, whereas factor XI deficiency is associated with hemorrhage. This suggests that factor XIIa-dependent activation of factor XI, a part of the contact pathway, is not likely to be the primary route of factor XIa generation in hemostasis. The physiologically relevant pathway for factor XI activation in coagulation is believed to involve α -thrombin.^{7,16,278} Factor XI in complex with HMWK binds to the platelet surface via the apple 3 domain.²⁶⁹ The rate of α -thrombin activation of factor XI on the platelet surface is greater than the rates of platelet-supported factor XIIa activation and factor XIa autoactivation.²⁷⁹ Although platelets appear to play a key role in providing the surface for factor XI activation, the precise mechanism of activation of platelet factor XI and its function remain unclear.²⁸⁰

Function

Subsequent to activation, factor XIa remains bound to the surface. Factor XIa is a trypsin-like serine protease that cleaves and activates factor IX in a Ca²⁺-dependent fashion.^{281,282} and ²⁸³ Factor IXa is the enzyme component of the intrinsic tenase complex that provides the burst of factor Xa necessary for normal coagulation. As part of a positive feedback loop, α -thrombin activates factor XI. In turn, factor XIa generates factor IXa, contributing to the high levels of factor Xa that ensure efficient α -thrombin generation.⁷ Factor XI as an antithrombotic target is being explored.^{284,285}

Regulation

Factor XIa is regulated by four serine protease inhibitors or serpins: antithrombin, α_1 -protease inhibitor, C1 inhibitor, and α_2 -antiplasmin.^{133,276,286,287,288,289,290,291,292,293,294,295} and ²⁹⁶ Factor XIa is also reported to be inhibited by PAI-1 and protein C inhibitor.^{139,297} In addition, platelets secrete several factor XIa inhibitors,^{298,299,300,301,302} including protease nexin-2 (PN2). PN2 is a truncated form of the Alzheimer's β -amyloid protein precursor and contains a Kunitztype serine protease inhibitor domain. Platelet-bound factor XIa is protected from inactivation by PN2²⁸¹; however, heparin enhances PN2 inactivation of factor XIa. Factor XIa bound to the surface of endothelial cells that secrete heparan sulfate glycosaminoglycans (GAGs) may be readily inactivated by PN2.³⁰³

PROCOAGULANT PROTEINS: VITAMIN K-DEPENDENT PROTEIN FAMILY

The first identification/description of vitamin K-dependent pro-teins was introduced by Henrik Dam et al. at the University of Copenhagen in the late 1920s.^{304,305} and ³⁰⁶ They demonstrated that chickens fed a lipid-free diet exhibited a hemorrhagic condition. The addition of alfalfa meal or a lipid extract of alfalfa prevented this condition. The active compound, 2-methyl-3-phytyl-1, 4-naphthoquinone (phyloquinone), was subsequently isolated from green plants. Further work performed by Doisy et al.³⁰⁷ in the 1930s showed that vitamin K activity in bacteria is also present as a series of menaquinones, 2-methyl-1,4-naphthoquinones substituted at the 3 position with an unsaturated polyisoprenoid chain. The Nobel Prize was awarded to Dam and Doisy in 1941 for their discovery of the fat-soluble vitamin K.

Simultaneously with the discovery of the vitamin, a naturally occurring antagonist, bishydroxycoumarin (dicumarol), was described. This naturally occurring vitamin K antagonist was identified as a toxic agent in spoiled sweet clover causing hemorrhage in cattle. The increase in clotting time was later identified as a function of decreased prothrombin time.³⁰⁸ This led to the synthesis of several oral anticoagulant analogs and coumarin derivatives, including warfarin.

Vitamin K is essential in the biosynthesis of functional clotting factors. It is the required cofactor for the enzyme catalyzing the conversion of 9 to 13 NH₂-terminal glutamic acid residues to γ -carboxy glutamic acid residues (Gla). The enzyme required for this conversion uses a reduced form of vitamin K.

This specific posttranslational modification allows the vitamin K-dependent proteins to interact with Ca²⁺ and a membrane surface to exert their effect. The modification was initially identified and characterized in bovine prothrombin.^{309,310,311} and ³¹² Gla residues were missing or present in decreased amounts in prothrombin isolated from cattle treated with coumarin derivatives. The vitamin K-dependent proteins present in plasma after treatment with anticoagulants lacked biologic activity due to decreased Ca²⁺-dependent phospholipid binding. Therefore, preventing the formation of Gla residues became a basis for anticoagulant therapy.

Recently, two cDNAs were identified that encode proteins with NH₂-terminal Gla domains.³¹³ Both appear to be integral membrane proteins but bear no other similarity to the vitamin K-dependent proteins beyond the Gla domain. Mineralized tissues

contain two proteins with Gla residues.³¹⁴ Gla has also been found as a component of the toxin peptides from the marine snail *Conus*.^{315,316} and ³¹⁷ The biologic activity of the toxins has been found to depend on the Gla residue(s). The identification of Gla in invertebrates suggests that vitamin K has a much wider range of biologic functions than previously thought. Gas 6 is a novel member of the vitamin K-dependent family of proteins, and when bound to the receptor tyrosine kinase Axl has been shown to mediate cell survival. γ -Carboxylation of Gas 6 is necessary for its function.³¹⁸

The vitamin K-dependent proteins can be divided into two classes: procoagulant (factors II, VII, IX, and X; Fig. 18.3A) and anticoagulant (protein C, protein S, and protein Z; Fig. 18.3B). The vitamin K-dependent proteins are part of a family of serine proteinases (except for protein S and protein Z) related to the trypsin/chymotrypsin superfamily. Sequence homology exists between the proteins at both the gene and the protein level, possibly due to a common ancestral gene.^{319,320} Congenital deficiencies of factors II, VII, IX, and X are associated with bleeding tendencies, whereas protein C and protein S deficiencies are associated with thrombotic tendencies. These proteins are composed of separate domains, each of which is characterized by highly conserved regions that fold, independently from the rest of the molecule, into a characteristic three-dimensional shape. The domains of the vitamin K-dependent proteins are illustrated in Figure 18.3. NH₂-terminal Gla domains (containing from 9 to 13 Gla residues) are followed by either a kringle domain in factor II or an EGF-like domain (EGF) in factor VII, factor IX, factor X, protein C, protein S, and protein Z. Protein S contains a thrombin-sensitive region before the EGF domain. The active site is contained within the serine protease domain for factor II, factor VII, factor IX, factor X, and protein C and becomes functional on specific peptide bond cleavages. Protein S is not a serine protease precursor and instead contains a sex hormone-binding globulin-like domain in the COOH-terminus. Protein Z contains a "pseudo-catalytic domain" in the COOH-terminus and does not function as a serine protease enzyme.

Factor VII: 50 kDa

Factor IX: 55 kDa

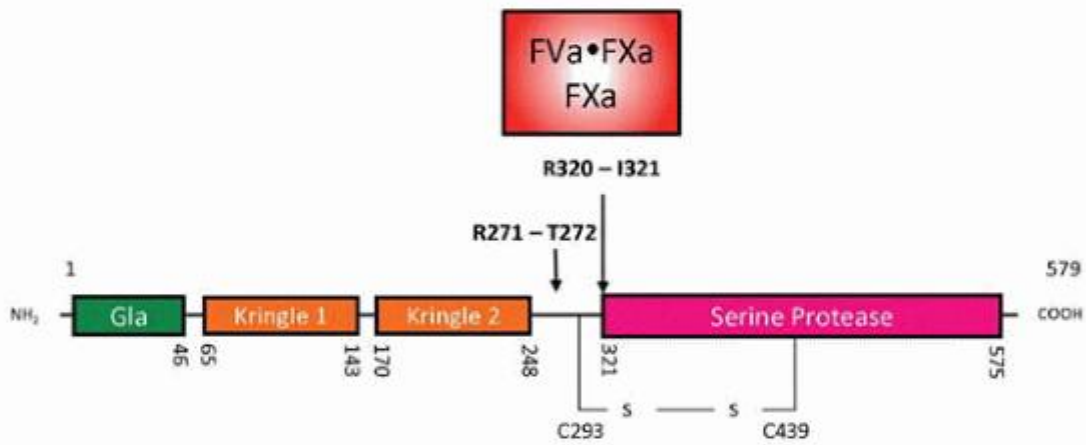

FIGURE 18.3. Schematic representation of the vitamin K-dependent proteins. The building blocks for these proteins include an NH₂-terminal Gla domain with 9 to 13 Gla residues followed by either an epidermal growth factor (EGF)-like domain in factor VII (FVII), factor IX (FIX), factor X (FX), protein C, protein S, and protein Z, or a kringle domain in prothrombin. Protein S contains a thrombin-sensitive region (TSR) before the EGF domain. Active sites are contained within the serine protease domain. Cleavage sites for the conversion of zymogens to their active forms are designated by arrows; activating proteases are placed in boxes above the arrows. Factor IX, factor X, and protein C are activated by proteolytic removal of an activation peptide (AP). Protein S is not a serine protease precursor and instead contains a sex hormone-binding globulin-like domain (SHGB) in the COOH-terminus. Protein Z also contains a “pseudo-catalytic domain” in the COOH-terminus and does not function as a serine protease. For reference, the molecular weight for each zymogen is listed, and disulfide bonds (-S-S-) critical to the integrity of the two-chain zymogens or active forms are presented. A: Panel illustrates the procoagulant vitamin K-dependent proteins factor VII, factor IX, factor X, and prothrombin. B: Panel illustrates the anticoagulant proteins, protein C, protein S, and protein Z. C: Structural ribbon diagram of factor IXa (PDB-ID: 1PFX). Protein C: 62 kDa

FIGURE 18.3. (Continued)

The synthesis of these proteins occurs primarily in the liver followed by secretion into circulation. However, recently, a functional prothrombin gene product has been found to be synthesized by human kidney cells.³²¹ The concentration of circulating zymogens in plasma varies 200-fold from 100 µg/ml for prothrombin to 0.5 µg/ml for factor VII (Table 18.1). Levels present in plasma can be affected by polymorphisms in the promoter or coding region^{322,323} and³²⁴ and aberrant levels are considered a risk factor for ischemic heart disease.³²⁵ Cholesterol and triglyceride levels have also been correlated with plasma concentrations of the vitamin K-dependent proteins.^{326,327} and³²⁸ Liver function in the synthesis of the clotting factors, dietary intake/adsorption of vitamin K, and drug interactions can affect individuals on anticoagulant therapy.^{329,330}

P.440

Protein S: 69 kDa

Protein Z: 62 kDa

B

C

FIGURE 18.3. (Continued)

Clearance ($t_{1/2}$) of the vitamin K-dependent proteins varies from approximately 6 hours for factor VII to 2.5 days for prothrombin (Table 18.1). Once the zymogen is activated to its serine protease form, it is then inactivated by inhibitors and the complex cleared from the blood.

These activated forms of the vitamin K-dependent proteins are key components in the formation of the vitamin K-dependent coagulation complexes: the extrinsic tenase (factor VIIa-tissue factor); the intrinsic tenase (factor IXa-factor

VIIIa); prothrombinase (factor Xa-factor Va); and protein C (thrombin-thrombomodulin) (Fig. 18.4). When all the components for each complex are assembled on the appropriate membrane surfaces (e.g., activated platelets, monocytes, blood cells, or endothelium), the specific reactions occur with rates enhanced by 10^4 to 10^9 -fold over enzyme-substrate alone⁵ (Table 18.3). A simple calculation can illustrate the importance of the rate enhancements achieved through complex assembly (vitamin K-dependent serine protease-cofactor-membrane- Ca^{2+}): If a normal person takes 4 minutes for his or her blood to clot, then in the absence of membrane and cofactor, blood clot formation would take approximately 3.8 years.

Gene Structure and Expression

The family of vitamin K-dependent proteins is mainly synthesized in the liver by hepatocytes. Decreased levels of the vitamin

P.441

K-dependent proteins are indicators of liver dysfunction.^{333,334} Liver transplantation has been shown either to treat vitamin K deficiency³³⁵ or to bring about vitamin K deficiency.³³⁶ The genes encoding all of the vitamin K-dependent coagulation proteins have been sequenced and are seen in Table 18.2. The difference between the vitamin K-dependent protein genes and most other eukaryotic genes is that the 5'-flanking regions lack TATA boxes. Binding sites for liver-enriched or liver-specific (or both) transcription factors, which are important for hepatic expression of these proteins, are contained within the regulatory region of these genes. A common pentanucleotide motif that occurs in a similar location in the regulatory region of the genes encoding factor VII, factor IX, and factor X may be important in their possible coordinate expression.

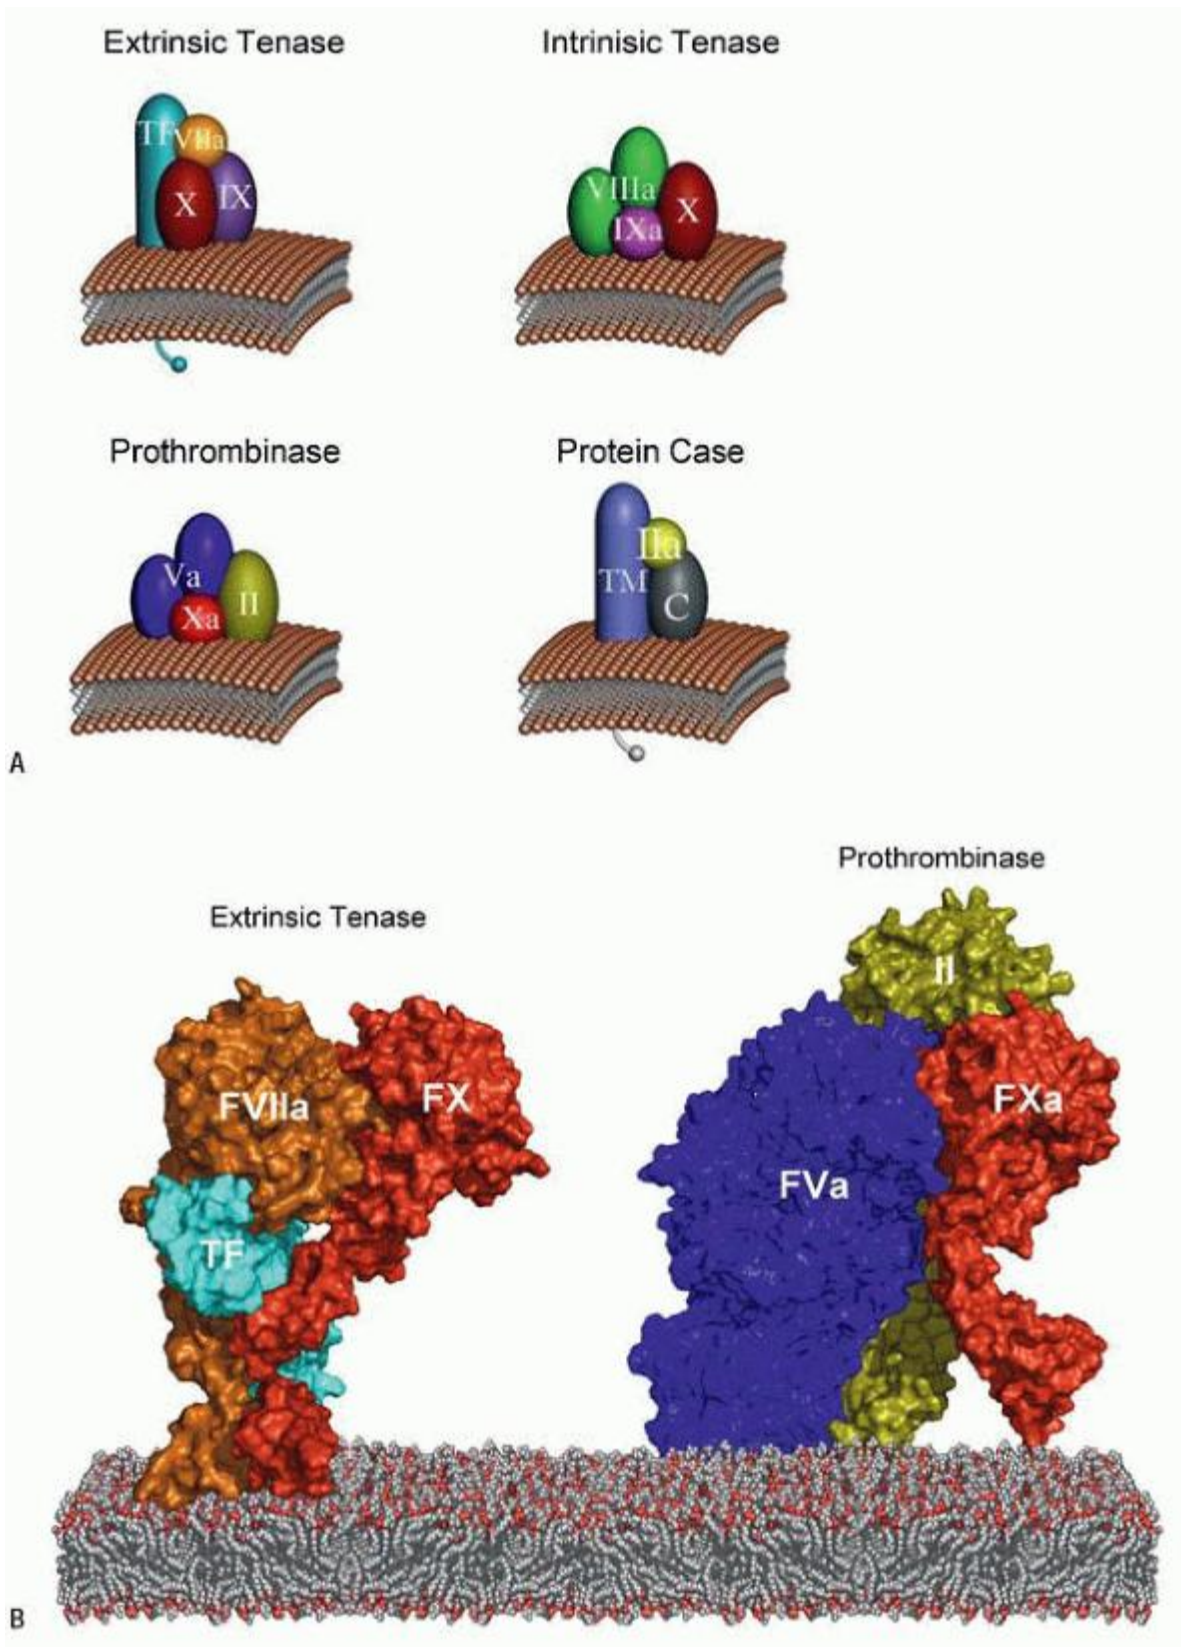

FIGURE 18.4. Vitamin K-dependent complexes. A: Three procoagulant complexes (extrinsic tenase, intrinsic tenase, and prothrombinase) and one anticoagulant complex (protein Cse) are illustrated. Each membrane complex consists of a vitamin K-dependent serine protease (factor VIIa [VIIa], factor IXa [IXa], factor Xa [Xa], or thrombin [IIa]) and a soluble or cell surface-associated cofactor (factor VIIIa [heavy and light chain VIII_H and VIII_L], factor Va [heavy and light chain V_H and

V_I], tissue factor [TF], or thrombomodulin [TM]). Each serine protease is shown in association with the appropriate cofactor protein and zymogen substrate(s) on the membrane surface. The membrane serves as a scaffold for the coagulation reactants, enhancing the reaction rates by 10⁴- to 10⁹-fold. When vascular damage or inflammatory cytokine activation occurs, TF becomes exposed to flowing blood carrying low levels of factor VIIa. The formed extrinsic tenase complex activates the circulating serine protease zymogens factors IX and X. Factor IXa becomes the serine protease for the intrinsic tenase complex, which, with its cofactor factor VIIIa, activates factor X to its active protease form factor Xa. Factor Xa formed primarily from the intrinsic tenase combines with its cofactor factor Va to activate II to IIa on the prothrombinase complex. Cofactor regulation occurs when IIa released from the prothrombinase complex binds to endothelial cell surface protein TM to form the protein Case anticoagulant complex. This complex generates activated protein C, which then proteolytically inactivates factors Va and VIIIa. (From Mann KG. Coagulation explosion. Vermont Bus Graph 1997, with permission.) B: Structural models of extrinsic tenase³³¹ and prothrombinase.³³²

Posttranslational Processing

The vitamin K-dependent proteins are synthesized in the liver as preprozymogens in a process that requires a dietary intake of vitamin K. They are modified posttranslationally at glutamic acid (γ -carboxylation to form γ -carboxy glutamic acid)³¹⁰ and at aspartic acid and asparagine (β -hydroxylation to form erythro- β -hydroxy aspartic acid [Hya] and erythro- β -hydroxy asparagine [Hyn])^{79,337,338}; they are also modified by sulfation at tyrosine residues as well as the addition of sugar moieties (glycosylation).^{337,338} This high degree of posttranslational processing is necessary for the biologic activity of the mature vitamin K-dependent proteins.

P.442

TABLE 18.3 RATE ENHANCEMENT BY VITAMIN K-DEPENDENT COMPLEXES

Complex ^a	Substrates	Fold Enhancement ^b
FVIIa/TF/PCPS/Ca ²⁺	FIX	>1 × 10 ^{9c}
FVIIa/TF/PCPS/Ca ²⁺	FX	3 × 10 ⁴
FIXa/FVIIIa/PCPS/Ca ²⁺	FX	1 × 10 ⁹
FXa/FVa/PCPS/Ca ²⁺	FII	3 × 10 ⁵
FIIa/TM/PCPS/Ca ²⁺	PC	1 × 10 ⁵

F, factor; PC, phosphatidylcholine; PS, phosphatidylserine; TF, tissue factor; TM, thrombomodulin.

^a Complexes are assembled on membranes composed of PC and PS (3:1 molar ratio PC/PS).

^b Rate enhancement is derived from the ratio of catalytic efficiency [number of catalytic events per unit time/Michaelis constant (k_{cat}/K_m)] for the complex to the catalytic efficiency of the free serine protease for a given substrate.

^c No measurable activation of FIXa by FVIIa without TF and the membrane. The catalytic efficiency of the extrinsic tenase toward FIX is reduced relative to FX.

Proteolytic Maturation

The vitamin K-dependent proteins are synthesized in the liver as a single-chain precursor that contains a prepro sequence followed by the polypeptide region. The hydrophobic signal peptide (prepeptide) gets the protein to the endoplasmic reticulum, the first compartment in the secretory pathway. For the vitamin K-dependent proteins to become mature, the polypeptide is translocated out of the first compartment in the endoplasmic reticulum across the lipid bilayer into the lumen of the endoplasmic reticulum. The signal peptide is then removed by a signal peptidase. The propeptide, which plays a role in docking vitamin K-dependent carboxylase,³³⁹ is removed by an endoprotease. The release of the propeptide coincides with γ -carboxylation (Gla formation)³⁴⁰ (Fig. 18.5a). Removal of an internal di- or tripeptide in singlechain factor X and protein C occurs, which converts them to their mature two-chain zymogen form. Several studies

describe the endoprotease that cleaves the propeptide and the internal bonds as furin/paired basic amino acid cleaving enzyme.^{341,342} and³⁴³

Carboxylation and Vitamin K-dependent Carboxylase

The γ -carboxylation reaction is catalyzed by the enzyme γ -glutamyl carboxylase. This enzyme is located in the rough endoplasmic reticulum and requires the reduced form of vitamin K, oxygen, and carbon dioxide.³¹¹ The carboxylation mechanism involves proton abstraction of the γ -hydrogen of the glutamate residues near the NH₂-terminus of the nascent prepro protein (Fig. 18.5B). The generated carbanion at each glutamic acid residue then reacts with free CO₂, forming γ -carboxy glutamic acid. It is this Gla region that mediates the Ca²⁺-dependent binding of the protein to anionic phospholipid surfaces, thereby ensuring close proximity and interaction with other components of the coagulation sequence and with cell receptors for vitamin K-dependent ligands. Without vitamin K, the coagulation protein precursors continue to be synthesized but are not γ -carboxylated. In this form, they are still secreted into plasma but are nonfunctional.

The cDNA for the human γ -carboxylase gene was cloned and sequenced by Wu et al.³⁴⁴ The open reading frame predicts a molecular weight of approximately 87.5 kDa. Glycosylation of the carboxylase probably accounts for its decreased mobility on SDS-PAGE (94 kDa). Vitamin K-dependent carboxylase has been identified in many cell types.³⁴⁵ This supports the notion that vitamin K has a wide range of biologic functions.

The presence of vitamin K is essential to maintain the γ -carboxylation reaction. Vitamin K₁ (phylloquinone) is primarily found in leafy green vegetables and vegetable oils. Additional K activity may be provided by vitamin K₂ (menaquinones) synthesized by intestinal Gram-negative bacteria. Synthetic vitamin K₃ (menadione) has no intrinsic activity until it undergoes in vivo transformation to the active menaquinone form. These K vitamins are 2-methyl-1,4-naphthoquinones with repeating fivecarbon prenyl units at position 3. In vivo, vitamin K is recycled in a microsomal oxidation-reduction system for continued use in the γ -carboxylation reaction. To perform the γ -carboxylation reaction, vitamin K has to be present in its reduced hydroquinone form. As the precursor proteins are carboxylated, vitamin K is oxidized to the epoxide.³⁴⁶ The epoxide in the presence of 2, 3-epoxide reductase, using thiols as the reducing agent, yields the quinone form of vitamin K.³⁴⁷ A subsequent nicotinamide adenine dinucleotide phosphate- or nicotinamide adenine dinucleotidedependent quinone reductase reaction resynthesizes the hydroquinone form. The cycle can thus begin again.

One important target for anticoagulant therapy is the process required for the regeneration of reduced hydroquinone vitamin K. Anticoagulants that effectively block this reaction include warfarin (Coumadin), dicumarol, and phenprocoumon (Fig. 18.5B). These oral anticoagulants are structurally similar to the quinone form of vitamin K, thereby targeting the reductase enzyme and inhibiting the reduction to the requisite hydroquinone form. The affinity of the anticoagulants for the reductase enzymes determines the efficacy of the drug.^{12,348} In the United States, the most widely used oral anticoagulant warfarin (Coumadin) is also used as rat poison. It acts as a competitive inhibitor of oxidized vitamin K and interferes with its reduction. Without the regeneration of the reduced form of vitamin K, the vitamin K-dependent protein carboxylase is unable to convert glutamate to γ -carboxy glutamate. Thus, these drugs indirectly affect carboxylation and can be overcome with excess vitamin K. The level of competitive inhibition achieved in Coumadin therapy among individuals taking the same dose regimen is variable. Factors affecting the efficacy of treatment include liver function in the synthesis of the clotting factors, enhancement of effect from other medications, and dietary intake/adsorption of vitamin K.³⁴⁹ Therefore, proper monitoring of oral anticoagulant therapy is essential with frequently measured PT and corrected assay sensitivity using the international normalized ratio.^{350,351} Several lines of evidence indicate that vitamin K antagonists inhibit not only posttranslational modification on coagulation factors, but also the synthesis of functional extra hepatic vitamin K-dependent proteins potentially resulting in vascular calcification.^{352,353}

Hydroxylation

Hydroxylation in the context of vitamin K-dependent proteins refers to the addition of a hydroxyl group (-OH) to aspartic acid and asparagine residues present in the EGF-like domains. The EGF-1 domains of human factors IX and X, protein C, and protein S contain a homologous aspartic acid residue that is hydroxylated to form erythro- β -hydroxy aspartic acid (Hya).^{79,354,355} Protein S also contains asparagine residues in EGF-2 and EGF-4 domains that are hydroxylated to form erythro- β -hydroxy asparagine residues (Hyn).³⁵⁶ This posttranslational modification to Hya and Hyn occurs by a β -hydroxylase enzyme, a 2-oxo-glutarate-dependent dioxygenase.^{338,357} The mechanism of action involves the recognition of a consensus sequence Cys-X-Asp/Asn-X-X-X-Tyr/Phe-X-Cys-X-Cys.³⁵⁶ The reason for this modification to Hya and Hyn is unclear. No effect has been found on the overall fold of the EGF-1 domain, its affinity, or specificity for calcium.³⁵⁸ These modifications also appear to have no relevance to the biologic activity or macromolecular interactions of the vitamin K-dependent proteins.^{359,360}

FIGURE 18.5. Vitamin K-dependent processes. A: Schematic representation of the synthesis and posttranslational carboxylation pathway of vitamin K-dependent proteins in the endoplasmic reticulum. (From Bovill EG, Malhotra OP, Mann KG. Mechanisms of vitamin K antagonism. Baillieres Clin Haematol 1990;3:555-581, with permission.) B: The mechanism of γ -carboxy glutamate (Gla) generation by a vitamin K-dependent reaction cycle is illustrated. The regeneration of vitamin K hydroquinone by the vitamin K-dependent reductases is inhibited by anticoagulants, as illustrated by Coumadin.

Glycosylation

The addition of a carbohydrate moiety as a posttranslational modification to proteins is referred to as glycosylation. The vitamin K-dependent proteins contain significant amounts of carbohydrate (Tables 18.1 and 18.4). Carbohydrate adducts on Asn, Ser, and Thr residues are found in key domains of these proteins, including the activation peptide of factor IX and factor X; the EGF domains in factor VII, factor IX, and protein Z; and the kringle domain in prothrombin. In most cases, the purpose of these modifications remains unknown. However, differences in the properties of the carbohydrate variants of protein C have been noted.^{361,362}

General Structure/Function Features

The vitamin K-dependent proteins, both procoagulant and anticoagulant, share a common protein domain structure. Each has a tripartite design: an NH₂-terminal γ-carboxy glutamic acid (Gla) domain, a linker region (kringle domains, EGF-like domains [EGF], or a thrombin-sensitive finger region, or all three), and a COOH-terminal domain usually consisting of a serine protease domain (factors II, VII, IX, and X and protein C) (Fig. 18.3). The Gla domain is involved in the Ca²⁺ ion-dependent binding of vitamin K-dependent proteins to anionic phospholipid membranes. The number of domains in the linker region is variable, and, in general, they are involved in protein-protein interactions. The COOH-terminal catalytic domain seen in factors II, VII, IX, and X and protein C is homologous to the pancreatic serine proteases, trypsin, and chymotrypsin. The nonserrine protease domain seen in protein S (a cofactor of activated protein C [APC]) is homologous to sex hormone-binding globulin.³⁶³ Protein Z is an enzymatically inactive homolog of factors VII, IX, and X and protein C.³⁶⁴ A separate review of the Gla, EGF, and serine protease domains is presented below.

TABLE 18.4 BIOCHEMICAL PROPERTIES OF HUMAN ANTICOAGULANT PROTEINS AND THEIR INHIBITORS

Protein	Plasma Concentration			Carbohydrate (%)	Clinical Phenotype ^a		Protein Family	Functional Classification
	Molecular Weight (Da)	nmol/L	Plasma t _{1/2} (days)		HT			
Protein C	62,000	65	4	0.33	23	+	VKD	Proteinase zymogen
Protein S	69,000	300	20	1.75	8	+	VKD	Inhibitor/cofactor
Protein Z	62,000	47	2.9	2.5		±	VKD	Cofactor

+, presence of phenotype; ±, some individuals present with phenotype and others do not; H, hemorrhagic disease/hemophilia; T, thrombotic disease/thrombophilia; VKD, vitamin K-dependent.

“Clinical phenotype: the expression of either H or T phenotype in deficient individuals.

The importance of each of the domains has been uncovered through studies from natural variants that occur in patients with either familial bleeding (i.e., factor IX deficiency/hemophilia B) or thrombotic disease (i.e., protein C deficiency). The situations that can cause a disease state are either deficiency in the level of protein present (cross-reactive material [CRM]-negative) or expressed protein that is present but nonfunctional (CRM⁺). Defects have diverse causes, including mutations that lead to amino acid substitutions in one or more domains, defects in posttranslational modifications, or mutations that introduce stop codons resulting in either no expression or expression of truncated proteins. In the case of combined vitamin K deficiency, a rare hereditary bleeding disorder,^{365,366} two studies have identified a missense mutation in the γ-carboxylase gene that results in a defective γ-glutamyl carboxylase and thus incomplete processing of the vitamin K-dependent proteins.^{367,368}

When a hemostatic disorder characterized by a dysfunctional protein (CRM⁺) is identified, it is through the combination of techniques including protein isolation, in vitro studies, and DNA technology that the root of the defect is elucidated. The importance of domains as functional units and of specific amino acid interactions can be uncovered using recombinant DNA technology. Single amino acid substitutions can be introduced into domains or entire domains removed to determine where the intra- and interprotein interactions take place. Structural information through nuclear magnetic resonance spectroscopy and x-ray crystallography provides amino acid assignments and tertiary structure, thus allowing for precise approaches to site-directed mutagenesis studies. The combination of all these techniques results in a map

P.445

of how the domains are aligned and interact. Further, using computational molecular dynamics, one can predict conformational changes associated with protein-protein, protein-ligand, and protein-surface interactions. Identifying residues directly involved in binding to membranes, metal ions, or small substrates can lead to new drug therapies.

The first x-ray crystal structure of a vitamin K-dependent protein was obtained by Tulinsky's laboratory for prothrombin fragment 1 (factor II, residues 1 to 155) in the presence³⁶⁹ and absence of calcium.^{370,371} These results provided information regarding the entire Gla domain, the connector peptide, and kringle 1. In the absence of calcium, only the connector peptide and the kringle can be visualized in the resulting x-ray crystal analysis. Prothrombin is the only vitamin K-dependent protein with a kringle domain. It is likely that organization of the polypeptide chains of the Gla domain is similar for all vitamin K-dependent proteins. To date, several other vitamin K-dependent protein structures have been elucidated^{372,373,374,375,376,377,378,379,380,381} and ³⁸² (see Table 18.5). Many studies on the individual vitamin K-dependent proteins have been conducted and are detailed under each protein subsection.

All the vitamin K-dependent proteins contain an NH₂-terminal Gla domain, and only factors II, VII, IX, and X and protein C contain a serine protease domain. Factors IX, X, and VII, protein C, and protein S contain EGF domains. Several recent reviews have been written on vitamin K-dependent proteins.^{383,384,385} and ³⁸⁶

Gla Domain

The Gla domain constitutes the first approximately 50 residues of the vitamin K-dependent proteins (Fig. 18.3). The negative charge elicited from the string of Gla residues (9 to 13) contributes to the binding to Ca^{2+} and the generation of the conformation required for binding to anionic phospholipid membranes. This surface in vivo is supplied by activated platelets or other blood cells in response to vascular damage through exposure of the internal face of their cell membranes where it is phosphatidylserine (PS)-rich.^{369,387} In vitro systems that attempt to mimic coagulation mainly use natural or synthetic preparations of PS and phosphatidylcholine, often at a 1:3 molar ratio. Studies have shown that PS exposure is crucial for cells to support the membrane-bound enzymatic reactions and that PS is more effective than other equally charged lipids.^{5,388,389} The striking degree of homology among the Gla domains of the vitamin K-dependent clotting factors suggests that the affinity of the calcium-Gla complexes for

P.446

P.447

phospholipids would also be very similar. However, this turns out not to be the case. The dissociation constants for binding to phosphatidylcholine and PS-containing vesicles vary, with K^d values in the range of 50 nmol/L for protein Z and protein S,³⁹⁰ 100 to 300 nmol/L for factor X and prothrombin,³⁹¹ 15 nmol/L for protein C,³⁹⁰ and 17,000 nmol/L for factor VII.^{390,392} A systematic analysis of the sequence/structural basis for these divergent membrane-binding properties is available.^{382,390}

The mode of interaction between the Gla domain-containing coagulation factors and biologic membranes has been difficult to study and is still a subject for debate. Two models of binding have been presented. One involves the bridging of calcium between specific Gla residues and the negative anionic phospholipid membrane components.^{392,393} A second model involves a major hydrophobic contribution to the membrane binding. X-ray crystallographic^{370,394,395} and³⁹⁶ and nuclear magnetic resonance studies³⁹⁷ have been conducted to elucidate the conformational changes, in the absence and presence of calcium, that occur on Gla domain binding to a lipid membrane. In the absence of calcium, the negatively charged Gla residues appear exposed to the solution, and the hydrophobic residues of the Gla domain are buried in its interior.³⁹⁷ On Ca^{2+} binding to the Gla domain, the conformation is altered to expose the hydrophobic residues, making possible their insertion into the lipid membrane. The hydrophobic patch in prothrombin fragment 1 surrounding the first pair of Gla residues was determined to be Phe⁴, Leu⁵, and Val⁸. Site-directed mutagenesis studies of protein C determined these residues (Phe⁴, Leu⁵, and Leu⁸) to be important in membrane interactions.^{398,399} and⁴⁰⁰ The actual mechanism of membrane binding is still under active investigation.

Epidermal Growth Factor Domain

The Gla domain is followed by two tandem EGF domains (EGF-1 and EGF-2) in factor VII, factor IX, factor X, and protein C and four EGF domains (EGF-1 to EGF-4) in protein S⁴⁰¹ (Fig. 18.3). The first EGF domain (EGF-1) contains the posttranslationally modified amino acid- β -hydroxy aspartic acid in the case of factors IX and X, and β -hydroxy asparagine in the case of protein S.^{337,354,356,402,403} and⁴⁰⁴ An EGF-like domain consists of 40 to 50 amino acids, including six cysteine residues involved in disulfide bond formation. The EGF domains have been evaluated by nuclear magnetic resonance spectroscopy.^{386,405,406,407,408} and⁴⁰⁹ The EGF-2 domains of factor Xa,³⁷⁸ factor VIIa,³⁸⁰ activated protein C,³⁸² and factor IXa⁴¹⁰ have been evaluated by x-ray crystallography. The EGF-like domains are found widely distributed in extracellular and membrane proteins. Proteins containing these domains are involved in blood coagulation, fibrinolysis, complement activation, and microfibril formation in connective tissue and in signal transduction.^{356,411,412} These domains are similar to the archetypal protein, EGF, which contains nine of these domains and is derived from a membrane-bound precursor.

The structure of the EGF-like domains is dominated by β sheets and β turns. Several point mutations in the EGF domain of factor IX have been identified that cause hemophilia B.⁴¹³ Calcium-binding sites have been identified in the NH₂-terminal EGF-like domains isolated from factors VII, IX, and X and proteins C and Z, with K_d values ranging from 1 to 5 mM. This Ca²⁺-binding site is functionally important because vitamin K-dependent proteins that have missense mutations in EGF-1 that disrupt the Ca²⁺-binding site have reduced biologic activity. In these proteins, the second EGF domain does not appear to bind calcium. The NH₂-terminal EGF domain of protein S does not appear to bind Ca²⁺.

The function of the EGF domain is still unclear. One hypothesis is that it serves as a spacer. A consistent elongation of the molecules of factors VII, IX, and X and protein C and protein S has been noted. The distance between the membrane-binding Gla domain and the serine protease domain is crucial to the placement of the active site in an appropriate position relative to the target peptide bond in its substrate.⁴¹⁴ Calcium binding serves a role in the function of these domains. For example, it has been proposed that for appropriate docking of factor VIIa to tissue factor, Ca²⁺ binding to the EGF domain is required.⁴¹⁵ Calcium binding to the EGF domains in non-vitamin K-dependent proteins has been observed in the Notch protein⁴¹⁶ and fibrillin.⁴¹⁷

Serine Protease Domain

The serine protease domain accounts for approximately one-half the mass of each protein. Peptide bond cleavage at specific sites converts the vitamin K-dependent zymogens to their active serine protease forms (Fig. 18.3). These enzymes are serine proteases in the same family as trypsin and chymotrypsin. The mechanism of proteolysis by chymotrypsin involves a catalytic triad, composed of Asp¹⁰², His⁵⁷, and Ser¹⁹⁵ (chymotrypsin numbering). The nucleophilic attack is carried out by the hydroxyl group of Ser¹⁹⁵ with the imidazole ring of His⁵⁷ taking up the liberated proton and the carboxylate ion of Asp¹⁰² stabilizing the developing charge. More extensive elements of structure (i.e., calcium-, membrane-, and cofactor-binding sites) are required for interactions of enzymes and substrates in the coagulation process.

The serine protease domains of all the Gla-containing factors show a high degree of sequence identity with each other and to trypsin and chymotrypsin, cleaving almost specifically at arginyl residues. However, unlike trypsin, which shows little specificity beyond the requirement for arginyl or lysyl residues at the cleavage site, the activated coagulation factors have extended substrate specificity pockets where only a small number of amino acid sequences are recognized by each activated factor. Despite a high degree of structural similarity between the protease domains of protein C and factors II, VII, IX, and X, each of these factors has a highly specific function in coagulation. Some of this discrimination may be mediated by surface loops and other domains away from the substrate-binding pocket that are not highly homologous.

Factor VII (Proconvertin, Convertin)

The vitamin K-dependent single-chain zymogen factor VII ($M_r = 50,000$), also known as proconvertin, circulates in plasma at a concentration of 0.5 $\mu\text{g/ml}$, or 10 nmol/L^{418,419} (Table 18.1). It is synthesized primarily in the liver. The activated two-chain serine protease form, factor VIIa, circulates in plasma at approximately 1% the concentration of its precursor, or 0.1 nmol/L.⁵² The mechanism for the initial activation of this zymogen is unclear. One recently identified candidate is the factor VII-activating protease (FSAP; see section on factor VII-activating protease). The function of factor VIIa is to serve as an initiator of the extrinsic pathway of coagulation when bound to its membrane cofactor, tissue factor. Factor VII has the shortest $t_{1/2}$ of all the clotting factor zymogens (~ 3 to 6 hours).⁴²⁰ Its activated form factor VIIa has a $t_{1/2}$ of 2.4 hours.^{421,422}

Factor VII deficiency is an autosomal recessive disorder with wide phenotypic and genotypic variability.^{423,424,425} and ⁴²⁶ Its incidence in the general population is approximately 1 in 500,000. In a large French-Canadian kindred, the incidence is approximately 1 in 335.⁴²⁷ Bleeding phenotypes can range from mild to severe and include bruising, epistaxis, postsurgical hemorrhage, and cerebral hemorrhage. Severe bleeding is most commonly associated with plasma factor VII levels that are $< 1\%$.⁴²⁸ Patients have prolonged PTs, and the final diagnosis is established by plasma factor VII coagulant activity (VII:C) using factor VII-deficient plasma and animal thromboplastins, immunologic quantitation of factor VII antigen, or both.^{419,429} Treatment of these individuals includes the use of fresh frozen plasma, prothrombin complex concentrates,⁴³⁰ factor VII concentrates (plasma-derived or

P.448

recombinant),⁴³¹ and liver transplantation.⁴³² Due to its short $t_{1/2}$ (~ 3 to 6 hours), therapy with factor VII concentrates is difficult. Recently, the use of recombinant factor VII as a safe and effective treatment for factor VII deficiency has been evaluated.^{433,434} and ⁴³⁵ During the last decade, supraphysiologic concentrations of recombinant factor VIIa have been used clinically for treatment of patients with hemophilia A or B (factor VIII or factor IX deficiency, respectively) and patients undergoing surgical procedures.^{436,437,438,439,440} and ⁴⁴¹ Recombinant factor VIIa has been suggested for treatment

of almost all bleeding disorders.⁴⁴² The mechanism of hemostasis by recombinant factor VIIa is not fully understood, although several hypotheses have been proposed.^{443,444,445,446}

Studies on the molecular basis for factor VII deficiency have led to the identification of several mutations in the factor VII gene. These mutations have been identified in the splice site,⁴⁴⁷ the promoter region,⁴⁴⁸ the EGF domain,⁴⁴⁹ and numerous single base pair (bp) mutations.^{450,451} For more detail, there is a factor VII mutation database available at europium.csc.mrc.ac.uk.⁴⁵² Factor VII deficiency in mice is not lethal at the embryonic stage, but factor VII^{-/-} neonates die from hemorrhage within the first days after birth.^{453,454}

Gene Structure and Expression

The factor VII gene is located on chromosome 13 band q34-qter, consists of nine exons, and spans 12.8 kb^{455,456,457} (Table 18.2). It is located approximately 2.8 kb upstream from the factor X gene. The mRNA encodes a 2.5-kb message.⁴⁵⁸ Alternative splicing of the factor VII gene yields two gene transcripts. One gene transcript contains eight segments as exons, and the second gene transcript contains nine segments as exons. The additional exon, which is unique among the vitamin K-dependent proteins, is in the prepro leader sequence. Factor VII mRNA expression is localized in the liver,⁴⁵⁹ where its expression is 6% of the factor X mRNA level.⁴⁶⁰ Extrahepatic synthesis of factor VII has been observed in human atherosclerotic vessels.⁴⁶¹ The 5'-flanking region of the factor VII gene contains binding sites for the liver-enriched transcription factor hepatic nuclear factor (HNF)-4.⁴⁶² Three potential activation peptide-1 binding sites are also contained in this region. Both genetic and epigenetic modifications in the promoter region of the factor VII gene have been shown to affect plasma factor VIIa levels.⁴⁶³

Biochemistry

Factor VII circulates in plasma as a single-chain zymogen of a molecular weight of 50,000.^{418,456,464,465} Its 406-amino acid structure consists of an NH₂-terminal Gla domain containing ten γ -carboxy glutamate residues, β -hydroxy aspartic acid at position 63,³⁵⁵ an aromatic residue-rich α -helical region, two EGF domains, and a serine protease domain (Fig. 18.3). The NH₂-terminus, along with the serine protease domain, is involved in the metal binding properties of the protein and its interaction with its cofactor tissue factor.^{466,467} and ⁴⁶⁸ The COOH-terminus of factor VII is important in its interactions with factor X.⁴⁶⁹ Structures of factors VII⁴⁷⁰ and VIIa³⁸¹ and the extrinsic tenase⁴⁷¹ have been determined and have been utilized in a variety of ways to enhance our understanding of this protein.

Activation

The single-chain zymogen factor VII is activated to its two-chain serine protease form, factor VIIa, through a single peptide bond cleavage between Arg¹⁵²-Ile¹⁵³ (Fig. 18.3). The resulting protease consists of an NH₂-terminal light chain (M_r = 20,000) containing the membrane-binding Gla domain (ten Gla residues), linked by a single disulfide bond between Cys¹³⁵-Cys²⁶² to a COOH-terminal heavy chain (M_r = 30,000) that contains the catalytic domain. A small amount of activated factor VII (10 to 100 pmol/L) already circulates in the cleaved active two-chain form.⁴⁷² This small portion of plasma factor VIIa has very poor catalytic efficiency in the absence of its cofactor, tissue factor.^{473,474} The cleavage of factor VII to factor VIIa is catalyzed by several proteases, including α -thrombin,⁸ factor IXa,⁴⁷⁵ factor Xa,⁸ autoactivation by factor VIIa,⁴⁷⁶ factor XIIa,⁴⁷⁷ and FSAP.⁴⁷⁸ The endothelial cell protein C receptor has been reported to bind factor VII and suppress its activation by factor Xa.⁴⁷⁹

Function

Factor VII is a crucial zymogen in blood coagulation and can bind to tissue factor with a subnanomolar K_d and become activated by a number of proteases. Once converted to its active serine protease form and bound to its cofactor, the integral membrane protein tissue factor, it forms the extrinsic tenase complex^{480,481} (Fig. 18.4). The enzyme complex is so named because it contains a protein, tissue factor, normally extrinsic to the plasma environment. The extrinsic tenase complex (factor VIIa-tissue factor-membrane surface-Ca²⁺) activates a fraction of the circulating vitamin K-dependent zymogens, factors IX and X, to their serine protease forms.^{45,482,483,484} Thus, it serves to initiate the formation of the intrinsic tenase (factor IXa-factor VIIIa-membrane-Ca²⁺) and the prothrombinase complexes (factor Xa-factor Va-membrane-Ca²⁺). In vitro studies have shown that the rate of activation by the extrinsic tenase complex is significantly greater (~100,000-fold) than the rate of substrate (factors IX and X) activation by the enzyme factor VIIa alone.^{485,486} Factor Xa bound to a membrane surface can activate additional factor VII in a positive feedback loop.^{8,487}

Regulation

Free factor VIIa, unlike other serine proteases of the coagulation cascade,⁴⁷⁴ is not readily inhibited by circulating protease inhibitors, including the antithrombin-heparin complex.^{488,489} This is most likely because of its poor catalytic efficiency when not bound to its cofactor tissue factor. However, when factor VIIa is bound to tissue factor, antithrombin-heparin

exhibits significant inhibition of factor VIIa.^{490,491} and ⁴⁹² Thus, regulation of tissue factor expression is the primary means to control factor VIIa activity. Paradoxically, in normal hemostasis, factor VII (10 nmol/L) is an effective competitor of factor VIIa (0.1 nmol/L) for binding to tissue factor. This competition downregulates the level of enzymatically active complex (factor VIIa-tissue factor), thus suppressing initiation of the clotting cascade. Once the extrinsic tenase complex (factor VIIa-tissue factor-Ca²⁺-membrane) activates factor X to factor Xa, tissue factor pathway inhibitor (TFPI) can form a quaternary complex (factor VIIa-tissue factor-factor Xa-TFPI) with no enzymatic activity⁴⁹³ (Fig. 18.6).

Factor IX (Plasma Thromboplastin Component, Christmas Factor, Hemophilia B Factor)

The zymogen factor IX is a single-chain vitamin K-dependent procoagulant glycoprotein synthesized in the liver, which has also been referred to as plasma thromboplastin component, Christmas factor, or hemophilia B factor. It circulates in plasma ($t_{1/2} = 24$ hours⁴⁹⁴) at a mean concentration of 5 µg/ml, or 90 nmol/L, with a relative molecular weight of 55,000⁴⁹⁵ (Table 18.1). In addition, there may be a pool of noncirculating factor IX, which is readily available to the intravascular space, systemically distributed and sequestered either to the endothelial surface⁴⁹⁶ or subendothelial components, specifically collagen IV.^{497,498} and ⁴⁹⁹ High levels of factor IX have been correlated with an increased risk of venous thrombosis.⁵⁰⁰

Deficiency of this glycoprotein, known as hemophilia B, is considered one of the most common inherited coagulation disorders. The factor IX gene, found on the X chromosome, is a

P.449

sex-linked recessive bleeding disorder that is found in males. The frequency of this disorder in the general population is approximately 1 in 30,000 males.^{495,501} It rarely affects females, but several cases have been identified involving a mutation on the factor IX gene.^{502,503} Acquired hemophilia can also occur due to the generation of autoantibodies.⁵⁰⁴ Many mutations, including large deletions, small deletions, point mutations, and missense mutations, have been identified in factor IX that appear to reduce activity in the presence of normal antigen levels (CRM⁺) or impair synthesis resulting in reduction of both activity and antigen (CRM⁻).^{505,506} Several specific cases and studies are noted: X translocation,⁵⁰⁷ links to factor V^{Leiden},⁵⁰⁸ population studies,^{509,510,511} and ⁵¹² and factor IX Denver.⁵¹³ The point mutation called factor IX Denver results in a 100-fold decrease in the binding affinity of factor IXa Denver for factor VIIIa ($K_d = 9.9$ nmol/L) compared to normal factor IXa.⁵¹³ Mutations in the EGF-1-like domain of factor IX, specifically at Gly⁴⁸, have also been identified in CRM⁺ individuals with hemophilia B.⁵¹⁴ Molecular insights into hemophilia B, as well as hemophilia A, have been formatted in reviews with references to accession numbers and locus identification.^{515,516}

FIGURE 18.6. Regulation of the procoagulant response. Four vitamin K-dependent complexes are illustrated: the extrinsic tenase, the intrinsic tenase, prothrombinase, and protein Case. The procoagulant response is regulated by the stoichiometric inhibitors antithrombin (AT) and tissue factor pathway inhibitor (TFPI). AT inhibits thrombin, factor Xa, and factor IXa that are free in solution. TFPI inhibits both factor Xa and the factor VIIa-tissue factor (TF)-factor Xa complex. Activated protein C (APC) generated from the protein Case complex [thrombomodulin (TM)-thrombin (IIa)] inactivates FVa and FVIIIa by proteolysis of their heavy chains. PC, protein C. Panel A: initiation phase; Panel B: Propagation; Panel C: Termination. (Adapted from Mann KG. Coagulation explosion. Vermont Bus Graph 1997, with permission.)

Hemophiliacs experience prolonged bleeding episodes that can be life threatening and lead to chronic disabilities. The clinical presentation or phenotype is not homogeneous. Severe disease is associated with < 1% functional factor IX, moderate disease with 1% to 5%, and mild disease with 5% to 25%. Female carriers usually have approximately 20% to 50% functional factor IX. Traditionally, treatment for hemophilia B involves plasma-derived or recombinant factor IX.^{517,518} One problem with this therapy is the development of inhibitory antibodies. There is a North American Immune Tolerance Registry to study immune tolerance in hemophiliacs.⁵¹⁹ An alternative treatment in the last decade has been the use of recombinant factor VIIa at supraphysiologic concentrations (~90 µg/kg). These therapies eliminate the immediate danger of bleeding but do not constitute a cure for the patients. The potential for gene-based therapy for the treatment of hemophilia has become a new avenue for investigation.^{520,521,522} and ⁵²³ To date, transgene therapy has proved successful in animal models, and human trials have been initiated as well.^{524,525,526,527,528,529,530} and ^{531,532}

Gene Structure and Expression

The gene for factor IX is located on the X chromosome at position q26.3-27.1, near the factor VIII gene.^{533,534} and ⁵³⁵ The gene contains eight exons and seven introns and has an overall size of 33 kb.^{536,537} Five cis-acting elements have been identified in the promoter region of the factor IX gene.^{536,539} These include binding sites for transcription factor C/EBP,⁵⁴⁰ an HNF-1 binding site,⁵⁴¹ an HNF-4 binding site,⁵⁴² and a site for the D-box binding protein.⁵⁴³ Two essential age-regulatory elements, AE5' and AE3', have been identified in the 5' upstream region of the gene encoding factor IX in transgenic mice.⁵⁴⁴ Together, these elements identify the advancing age-associated increase in factor IX gene expression.

Single point mutations in the factor IX promoter region have been correlated with a rare form of hemophilia B termed hemophilia B Leyden.^{538,545,546} Hemophilia B Leyden is characterized by an altered developmental expression of blood

coagulation factor IX.⁵³⁸ These individuals have increasing levels of factor IX after puberty, or after administration of testosterone, resulting in decreased bleeding instances.^{547,548} Studies in mice support the role of androgen receptor binding to the factor IX promoter in regulating the developmental expression of factor IX.⁵⁴⁹

Biochemistry

The structure of human factor IX consists of 415 amino acids that are separated into a Gla domain (12 Gla residues), two tandem EGF domains (EGF-1 [residues 46 to 84] and EGF-2 [residues 85 to 127]), an activation peptide region, and a serine protease domain^{283,537,550} (Fig. 18.3). Glycosylation in the form of O-linked and N-linked oligosaccharides makes up 17% by weight of the factor IX protein—specifically, O-linked oligosaccharides at Ser⁵³ and Ser⁶¹ in the EGF-1 domain and O-linked and N-linked oligosaccharides at Asn¹⁵⁷, Asn¹⁶⁷, Thr¹⁵⁹, and Thr¹⁶⁹ in the activation peptide region.^{551,552,553} and ⁵⁵⁴ The Gla domains are crucial for binding to anionic lipid membranes through Ca²⁺ interactions. The x-ray crystal structure of human factor IX with Ca²⁺ has shown that EGF-1 binds a single Ca²⁺ with residues Asp⁴⁷, Gly⁴⁸, Gln⁵⁰, Asp⁶⁴, and Asp⁶⁵ functioning as the ligands.^{410,555} Hydrophobic

P.450

interactions⁵⁵⁶ and a salt bridge (Glu⁷⁸-Arg⁹⁴)⁵⁵⁷ between the carboxy end of EGF-1 and EGF-2 have also been identified.³⁷⁹ Ca²⁺ binding and hydrophobic interactions lock the domains in a manner that ensures biologic activity. Several point mutations in the EGF domain give rise to hemophilia B.⁴¹³

Activation

Factor IX activation to its serine protease form, factor IXa, is a two-stage process requiring sequential cleavages at Arg¹⁴⁵ and Arg¹⁸⁰, releasing a 35-residue activation peptide with an approximate molecular weight of 11,000^{558,559} (Fig. 18.3). Physiologic activators of factor IX are either tissue factor-factor VIIa (extrinsic tenase complex)^{482,560} or factor XIa.^{561,562} and ⁵⁶³ The first step in activation is the cleavage by its physiologic activators at the Arg¹⁴⁵-Ala¹⁴⁶ bond, resulting in factor IXa. This cleavage has been shown to be important in its affinity for its cofactor factor VIIIa⁵⁶⁴ and has been identified as a molecular defect in factor IX_{Chapel Hill}.⁵⁶⁵ The second step is cleavage at the Arg¹⁸⁰-Val¹⁸¹ bond, resulting in factor IXα β, the active form, also known as factor IXa. Both cleavages are required for full biologic activity of factor IXa.⁵⁵⁹ In vitro, factor IX has also been shown to be cleaved by factor Xa at Arg¹⁴⁵ on phospholipid membrane surfaces,⁶¹ producing the inactive precursor factor IXα and increasing the overall rate of factor IXa production by tissue factor-factor VIIa. Both cleavage sites, Arg¹⁴⁵ and Arg¹⁸⁰, have been identified as single point mutations in hemophilia B.⁵⁶⁶ The x-ray crystal structure of porcine factor IXa has also been solved.³⁷⁹

A

B

FIGURE 18.7. Profiles of thrombin and factor Xa generation. A: Empirical time course (x-axis: 0 to 20 minutes) of thrombin-antithrombin formation (y-axis: nmol/L thrombin-antithrombin complex) during whole blood coagulation initiated with 5 pmol/L tissue factor.⁵⁶⁹ Data represent means plus or minus standard error of the means for 35 individuals; thrombin-antithrombin levels reach maximum levels of 900 nmol/L (blue diamonds) in this group of normal individuals. Clot time (CT) is shown below with the symbols for each curve. Thrombin generation is divided into two phases: an initiation phase and a propagation phase. When two hemophilia A patients were studied (green squares, red circles), CT was delayed, and the propagation phase of thrombin generation was not present.^{446, 568} By not having factor VIIIa present, the intrinsic tenase complex is unable to generate the additional factor Xa that is required for the burst or propagation phase of thrombin generation. B: Computer simulation of the time course of factor Xa generation on activation of the factor VIIa-tissue factor pathway.⁵⁶⁷ Concentrations are expressed as the relative percentage of factor Xa produced by each catalyst at each time point. The factor Xa that is initially produced is via the extrinsic tenase complex. After CT, the majority of factor Xa generated is via the intrinsic Xase. The clot time represents the time point in the computer simulation at which

calculated thrombin levels are comparable to thrombin levels (~10 nmol/L) measured in clotting whole blood (see Fig. 18.11).

The active serine protease ($M_r = 45,000$) structure is composed of a heavy chain ($M_r = 28,000$) and a light chain ($M_r = 17,000$) covalently associated through a disulfide bond. Factor IXa forms the intrinsic tenase complex with its cofactor factor VIIIa, Ca^{2+} , and a membrane surface primarily supplied by platelets (Fig. 18.4). On formation of this complex, factor X is activated to its serine protease form, factor Xa. Factor IXa (the enzyme) alone without its cofactor (factor VIIIa) has poor amidolytic and proteolytic activity (10^7 -fold less activity).

Function

The main role for factor IXa in blood coagulation is to form the intrinsic tenase complex, which efficiently activates factor X to factor Xa. The complex is so named because the components, including the cofactor, are intrinsic to circulating blood, unlike tissue factor, the cofactor for the extrinsic tenase complex. Both complexes activate factor X to factor Xa. The extrinsic tenase complex (factor VIIa-tissue factor- Ca^{2+} -membrane) catalyzes the initial formation (picomolar amounts) of factor Xa, which ultimately participates in prothrombinase complex assembly and the resulting conversion of prothrombin to thrombin, allowing clot formation to occur. The intrinsic tenase complex (factor IXa-factor VIIIa- Ca^{2+} -membrane) generates the second burst of factor Xa that results in the propagation phase of the activation of prothrombin to thrombin (Fig. 18.7).⁵⁶⁷ The intrinsic tenase complex is kinetically more efficient than the extrinsic tenase complex in generating factor Xa. Factor Xa generation by tissue factor-factor VIIa occurs at

P.451

only 1/50th the rate of factor X activation by the factor IXa-factor VIIIa complex.^{61,62} and ⁶³ Without the intrinsic complex being formed, as occurs in situations like hemophilia A or B, factor Xa is not generated in levels sufficient to produce the propagation phase of thrombin generation (Fig. 18.7).^{446,568,569}

When the competitive substrates factors IX and X are simultaneously presented to the extrinsic tenase complex, factor IXa generation is increased, whereas factor Xa generation is suppressed.^{61,62} This occurs because the factor Xa initially produced cleaves factor IX at Arg¹⁴⁵, producing factor IX α . Factor IX α is a better substrate for factor VIIa-tissue factor than factor IX; the intermediate is converted to factor IX $\alpha\beta$ (factor IXa) by cleavage at Arg¹⁸⁰ by factor VIIa-tissue factor. This cooperative enzymatic action results in factor IX being an improved substrate for the extrinsic tenase complex, whereas factor X activation is suppressed.

Regulation

Plasma factor IXa is primarily inhibited by antithrombin⁵⁷⁰ (Fig. 18.6). In vitro experiments conducted on phospholipid vesicles and cell membranes showed that PN2/amyloid β -protein precursor (PN-2/APP) can also inhibit factor IXa.⁵⁷¹ Interestingly, an insect salivary protein, Prolixin-S, has been shown to inhibit factor IXa generation and the intrinsic tenase complex formation.⁵⁷²

One strategy to improve existing antithrombotic therapies has been to develop factor IXa inhibitors⁵⁷³—including the use of monoclonal antibodies that target factor IX/factor IXa^{574,575} or aptamers targeting factor IXa.^{576,577} Currently, problems exist in using direct thrombin inhibitors to regulate thrombin activity. Targeting the end product of an amplifying cascade results in a narrow window of therapeutic dose, which is difficult to achieve in clinical practice.^{578,579} and ⁵⁸⁰ The advantages of regulating events upstream (factor IX/factor IXa; the intrinsic tenase complex) as an approach to antithrombotic therapy would be to potentially produce a partial reduction in the magnitude of thrombin formation.^{581,582}

Factor X (Stuart Factor)

The zymogen factor X, or Stuart factor, is a vitamin K-dependent glycoprotein that is synthesized in the liver.^{560,583} It circulates in plasma at a mean concentration of 10 $\mu\text{g/ml}$ or 170 nmol/L, and has a $t_{1/2}$ of approximately 1.5 days^{494,584,585} (Table 18.1). In the Leiden Thrombophilia study, a population-based case control study on venous thrombosis, high levels of factor X alone predicted the risk of thrombosis but were not a risk factor for venous thrombosis when the levels of other vitamin K-dependent proteins were taken into account.⁵⁸⁶

Factor X deficiency is a rare autosomal recessive disorder with varied phenotype and genotype. Homozygous factor X deficiency has an incidence of 1 in 1 million in the general population.^{587,588} Whereas heterozygotes are often clinically asymptomatic, the most severely affected homozygous individuals exhibit extensive bleeding early in life. Multiple factor X deficiency cases have been identified, and the gene defects have been elucidated in individuals with bleeding tendencies^{589,590,591,592} and ^{593,594,595} and in an individual without a bleeding tendency,⁵⁹⁶ although mutations within the

catalytic domain are not always consistent with the phenotype of the individual.⁵⁹⁷ As with most deficiencies, the level of factor X expression is indicative of the bleeding response. When factor X levels are approximately 1%, bleeding can include hemarthrosis, soft tissue hemorrhage, and menorrhagia. With functional levels above 15%, bleeding is infrequent and usually mild. Acquired factor X deficiency is rare and is usually associated with lightchain amyloidosis.^{598,599} and ⁶⁰⁰ In amyloidosis, factor X is thought to be adsorbed onto extracellular amyloid fibrils, thereby decreasing the circulating factor X level and increasing bleeding. In these cases, replacement with factor X products is not as effective a therapy for deficiency because it is continuously removed from plasma. Treatment of bleeding from factor X deficiency can involve the administration of fresh frozen plasma or prothrombin complex concentrates. No sure venous or arterial thrombotic event has ever been reported in congenital factor X deficiency.⁶⁰¹

The importance of factor X generation is illustrated by transgenic mice with a total deficiency of factor X. Homozygous deficiency ($f^/-$) results in partial embryonic lethality with signs of massive bleeding.^{453,603} Those mice that survive to term die within 5 to 20 days from fatal neonatal bleeding. The lethality of factor X knockout genotype in mice supports the significance of factor X function in hemostasis.

Gene Structure and Expression

The gene for factor X spans 27 kb, is located on chromosome 13 bands q34-qter, and yields a 1.5-kb mRNA^{455,603,604} and ⁶⁰⁵ (Table 18.2). The gene for factor X is located near the gene for factor VII. Studies to elucidate the liver-specific expression of factor X have included the characterization of the human⁶⁰⁶ and murine factor X promoter.⁶⁰⁷ Using a hepatoma cell line that expresses factor X, the first 279 bp of the 5'-flanking sequence upstream from the first AUG proved to be sufficient to confer maximal promoter activity.⁶⁰⁶ From mutagenesis studies, two protein-binding sites within the 279-bp fragment were identified that are critical for promoter activity: CCAAT (at -120 to -116) and ACTTTG (at -56 to -51).⁶⁰⁶ Factor X also lacks a typical TATA box. In the human factor X promoter, the binding proteins HNF-4 (at -73),⁶⁰⁸ nuclear factor-Y (at -128),⁶⁰⁸ GATA-4 (GATA element at -96),⁶⁰⁹ and the Sp family of transcription factors I footprinted sites (at -165 and -195)⁶⁰⁹ have been identified as playing crucial roles in modulating the activity of the proximal promoter of factor X.

Biochemistry

Human factor X is a vitamin K-dependent glycoprotein of molecular weight 59,000 that circulates in plasma (10 µg/ml or 170 nmol/L) as a two-chain molecule composed of a disulfide-linked light chain ($M_r = 16,500$) and heavy chain ($M_r = 42,000$)^{610,611} (Table 18.1). Its structure contains an NH₂-terminal light chain consisting of a Gla domain (11 Gla residues), with a single β-hydroxy aspartic acid residue, and two EGF-like domains (EGF-1 and EGF-2) (Fig. 18.3). The COOH-terminal heavy chain consists of an activation peptide region and a catalytic (serine protease) domain. Most of the carbohydrate moieties (~15%) are located within the heavy chain⁵⁸⁴ in the activation peptide domain.⁶¹² Ca²⁺ binding in the first EGF domain has been proposed to enhance the structural rigidity of the factor X molecule.⁴⁰⁸ Numerous structures of factor Xa (des Gla)³⁷⁸ have been deposited in the Protein Data Bank, the majority of which are bound to inhibitors and have provided insight into specificity and function.⁶¹³

Activation

Factor X is activated to its serine protease form factor Xa through a cleavage of the activation peptide at Arg¹⁹⁴-Ile¹⁹⁵ (Arg⁵²-Ile⁵³ of the heavy chain) (Fig. 18.3). A 52-amino acid activation peptide is released with a relative molecular mass of 12,000. The resulting catalytic serine protease, factor Xa, has a molecular weight of 48,000 and is composed of a light chain ($M_r = 18,000$) and a disulfide-linked heavy chain ($M_r = 30,000$). The activation of factor X is catalyzed by factor VIIa-tissue factor (the extrinsic tenase complex)⁴⁸³ and factor IXa-factor VIIIa (the intrinsic tenase complex).⁶¹⁴ In vitro studies have determined that factor X has to be bound to the membrane before activation.^{45,615}

Function

The main function of factor Xa is to form the prothrombinase complex (factor Xa-factor Va-membrane-Ca²⁺) (Fig. 18.4).
Factor Xa

P.452

is the serine protease enzyme in the prothrombinase complex that catalytically activates prothrombin to thrombin, the key enzyme in blood coagulation. The prothrombinase complex activates prothrombin to thrombin 10⁵-fold faster than factor Xa alone.⁴² Factor Xa is a unique regulatory enzyme in that it is formed through both the extrinsic tenase and intrinsic tenase complexes (as mentioned in the section on Factor IX). During the initial stages of the hemostatic event, low levels of both factor Xa and factor IXa are generated. Once generated, the limited amounts of factor Xa produced by extrinsic tenase bind to available membrane sites and convert picomolar amounts of prothrombin to thrombin^{37,616,617}

(Fig. 18.7B). This thrombin then activates factor VIII⁶¹⁸ and factor V,⁶¹⁹ allowing the initial formation of the intrinsic tenase and prothrombinase complexes. Thus, the time period in which factor Xa directly generates picomolar amounts of thrombin is referred to as the initiation phase of blood coagulation. The burst or propagation phase of thrombin generation is then obtained from additional factor Xa generated via the intrinsic tenase complex (factor IXa-factor VIIIa-Ca²⁺-membrane) (Fig. 18.7). The intrinsic tenase complex activates factor X at a 50- to 100-fold higher rate than the extrinsic tenase complex.^{61,62} and ⁶³ This burst in factor Xa levels overcomes the levels of factor Xa inhibitors, such as TFPI, and achieves maximal prothrombinase activity and propagation of the procoagulant event.

There is evidence that factor Xa can also trigger intracellular signaling events by increasing endothelial cell cytosolic Ca²⁺ and the release of endothelial cell mitogens.⁶²⁰ Mitogenic activity toward smooth muscle cells⁶²¹ and lymphocytes⁶²² has also been identified. Both factor X and factor Xa have been shown to provoke PAR-2 dependent protective signaling responses in endothelial cells.⁶²³ An alternative initiation of factor X to factor Xa has been identified on stimulated cells of monocytic and myeloid differentiation involving the specific adhesive receptor Mac-1.⁶²⁴ A novel factor Xa receptor, effector cell protease receptor-1, has been identified on the surface of a monocytic cell line.⁶²⁵ A platelet factor Xa receptor has been described as important in mediating prothrombin binding via factor Xa binding to platelet factor Va.⁶²⁶

Regulation

Once assembled, the extrinsic tenase (factor VIIa-tissue factor-Ca²⁺-membrane) is rapidly inactivated along with its product factor Xa through the action of TFPI (Fig. 18.6). The factor Xa active site associates with the COOH-terminus of TFPI^{627,628} to localize the TFPI to the membrane. Once localized, the factor Xa-TFPI complex rapidly inactivates tissue factor-factor VIIa, forming a stable quaternary complex, tissue factor-factor VIIa-TFPI-factor Xa. The factor Xa-TFPI complex has been shown to be elevated in cancer patients.⁶²⁹

Factor Xa is also inhibited by antithrombin⁶³⁰ when not in complex with prothrombinase.^{631,632} Its inhibition is enhanced through the use of heparin, which increases the reactivity of antithrombin with its targets (i.e., factor Xa).

Because factor Xa is a major player in the coagulation cascade, it is a target for regulation by synthetic inhibitors in treating ischemic heart disease and cerebrovascular disease. Many studies are currently underway to develop a new class of antithrombotic agents that target factor Xa.^{633,634,635,636} and ^{637,638,639}

Factor II (Prothrombin)

Factor II, or prothrombin, is a single-chain vitamin K-dependent zymogen that, when activated, yields factor IIa (thrombin), the key enzyme in blood coagulation. The zymogen prothrombin (M_r = 72,000, 8% carbohydrate) is the most abundant of the vitamin K-dependent proteins and circulates in plasma at a mean concentration of 1.4 μmol/L or 100 μg/ml^{640,641} and ⁶⁴² (Table 18.1). Prothrombin is primarily synthesized in the liver with a t_{1/2} of approximately 2.5 days. Low levels of prothrombin expression have been identified in other tissues including brain, diaphragm, stomach, kidney, spleen, intestine, uterine, placental, and adrenal.^{643,644} Increased prothrombin levels have been associated with an increased risk of venous thrombosis.

Human prothrombin deficiency, first described by Quick in 1943,²⁷ is rare because of the autosomal nature of its expression. Prothrombin deficiencies are classified as either hypoprothrombinemia or dysprothrombinemia and occur due to genetic disorders affecting either transcriptional regulation or protein function.^{645,646} These disorders are characterized by variable pathologies extending from mild bruising to clinically severe bleeding.⁶⁴⁷ Homozygotes are characterized by severe bleeding, and heterozygotes either have mild bleeding or are asymptomatic. Prothrombin complex concentrates have been used for prophylaxis and bleeding episodes in individuals with prothrombin deficiency.⁴³⁰ The importance of α-thrombin to hemostasis is demonstrated in prothrombin-deficient mice, which experience embryonic and neonatal lethality.^{648,649} and ⁶⁵⁰

Gene Structure and Expression

The 21-kb human prothrombin gene is located on chromosome 11 bands p11-q12 and has been extensively studied.^{651,652,653,654} The prothrombin gene contains 14 exons and 13 introns⁶⁵² and is transcribed as a prepropeptide of 622 amino acids.^{653,654} The 43-amino acid propeptide mediates posttranslational processing to generate the mature protein of 579 amino acids. The promoter region of the prothrombin gene lacks a TATA box.

Many studies have been conducted on prothrombin gene polymorphisms to determine their relationships to thrombophilia. One common polymorphism is the G20210A transition in the 3'-untranslated region of the promoter. This mutation has been linked to familial thrombosis. The G20210A polymorphism of the prothrombin gene has been associated with elevated prothrombin levels and an increased risk for venous thrombosis.⁶⁵⁵ It is one of the most commonly identified genetic risk factors for thrombosis. An additional polymorphism, A19911G, in the prothrombin gene

has been identified that can modulate the risk of the G20210A polymorphism in developing deep vein thrombosis.⁶⁵⁶ Several reviews have been written on the influence of genetic polymorphisms (including the prothrombin G20210A) and the laboratory diagnosis of thrombophilia.^{657,658} and ⁶⁵⁹

Biochemistry

Initial observations about the structure/function relationship of the prothrombin molecule came about from the partial primary structures of bovine and human prothrombins. Subsequently, the complete primary structure of human prothrombin 2 (residues 272 to 579), which is the precursor of thrombin, was determined.⁶⁶⁰ Finally, the primary structure for bovine prothrombin⁶⁶¹ and human prothrombin⁶⁵⁴ were deduced from isolated cDNAs. The elucidated structure of human prothrombin is characterized by an NH₂-terminal Gla domain (residues 1 to 40 with 10 Gla residues), followed by two kringle domains (kringle 1, residues 65 to 143; kringle 2, residues 170 to 248) and the serine protease precursor domain (residues 272 to 579). Human prothrombin has three N-linked sugar chains—two in the first kringle domain and one in the catalytic domain.⁶⁶²

The first x-ray crystal structure of a blood coagulation protein fragment, bovine prothrombin kringle 1, was determined in Tulinsky's laboratory in 1986.³⁷¹ Kringles have been identified as common motifs in many plasma proteins, including prothrombin, plasminogen, t-PA, urokinase, factor XII, and apolipoprotein A.^{663,664} The kringle 1 domain contains four cysteine residues participating in two disulfide bonds. The role of the kringle 1 domain of prothrombin is still unclear, but it has been suggested that it is

P.453

involved with the interaction of prothrombin and factor Va in the prothrombinase complex.^{665,666} The NH₂-terminal Gla domain and the first kringle domain together are referred to as prothrombin fragment 1. The kringle 2 domain of human prothrombin, located in prothrombin fragment 2 (residues 156 to 271), is similar in sequence and presumably in structure. The kringle 2 domain also binds Ca²⁺ and appears to be the primary region in prothrombin that mediates the interaction of the prothrombin molecule with factor Va in the prothrombinase complex.^{667,668} This latter interaction has been suggested to initiate conformational changes that make reaction sites accessible for enzymatic cleavage of prothrombin.⁶⁶⁹ The sequence of the enzyme α -thrombin is contained within prothrombin 2 (residues 272 to 579).

Activation

Prothrombin is activated to the procoagulant α -thrombin by two cleavages: one at Arg²⁷¹-Thr²⁷² and another at Arg³²⁰-Ile³²¹ by the prothrombinase complex (factor Xa-factor Va-phospholipid membrane-Ca²⁺) (Fig. 18.3). Membrane-bound factor Va serves as the receptor for factor Xa, the catalytic serine protease. The rate of α -thrombin generation by prothrombinase is 3×10^5 -fold faster than the rate for factor Xa alone at potential physiologic concentrations of the proteins.⁴² Recent studies have indicated that the order of these two cleavages differs depending on the cell surface upon which prothrombinase is assembled.^{670,671}

On synthetic phospholipid vesicles, the activation of prothrombin by prothrombinase proceeds through an initial cleavage of prothrombin at Arg³²⁰-Ile³²¹, giving rise to meizothrombin, a twochain disulfide-linked molecule (Fig. 18.8; pathway A, cleavage at 1).⁶⁷² The probable mechanism involves meizothrombin dissociating from prothrombinase with a subsequent rebinding step and conversion to α -thrombin.^{672,673} Meizothrombin expresses some of the activities of α -thrombin. However, meizothrombin has impaired fibrinogen clotting ability compared to α -thrombin.⁶⁷⁴ Meizothrombin is subsequently cleaved at Arg²⁷¹-Thr²⁷² (Fig. 18.8; pathway A, cleavage at 2), yielding the NH₂-terminal half of the molecule, consisting of the Gla domain and two kringle domains (prothrombin fragment 1.2: residues 1 to 271) and α -thrombin. α -Thrombin consists of an NH₂-terminal 49-residue A-chain (residues 272 to 320) disulfide-linked to a COOH-terminal 259-residue B-chain (residues 321 to 579) containing the catalytic triad.

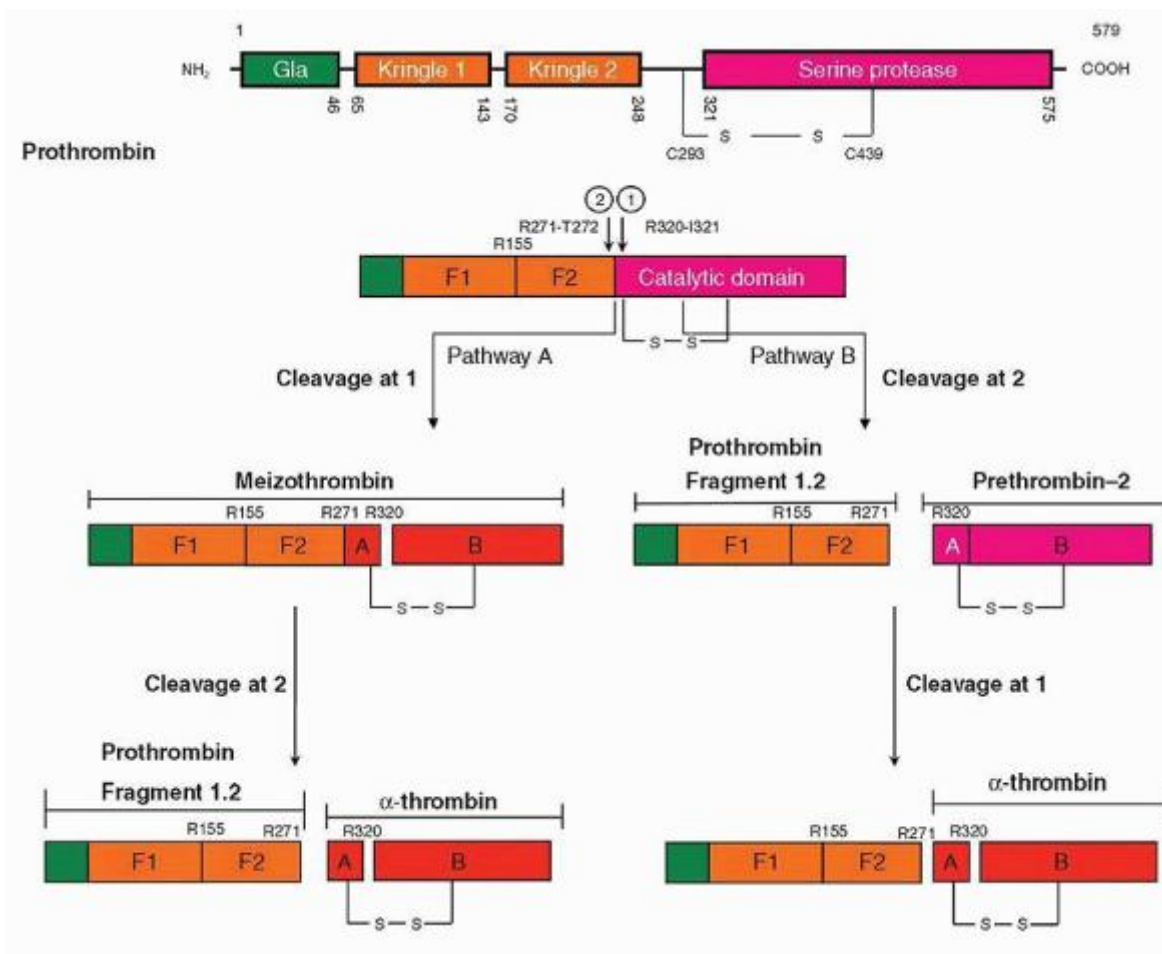

FIGURE 18.8. Schematic representation of the pathways for prothrombin activation. The generation of α -thrombin from its zymogen precursor prothrombin by factor Xa involves the cleavage of two peptide bonds. The reaction begins either via step 1 (cleavage at R³²⁰-I³²¹) or step 2 (cleavage at R²⁷¹-T²⁷²). Cleavage at 1 (R³²⁰), pathway A, produces meizothrombin. Meizothrombin is composed of a prothrombin fragment consisting of fragment 1 (F1, residues 1 to 155: Gla domain + kringle 1), fragment 2 (F2, residues 156 to 271: kringle 2), and residues 272 to 320 (A-chain) linked by a disulfide bond to the catalytic domain (B-chain). Subsequent cleavage at R²⁷¹ (cleavage at 2, pathway A) generates prothrombin fragment 1.2 (F1 and F2) and the disulfide-linked heterodimer α -thrombin (A- and B-chains). In pathway B cleavage occurs first at 2 (R²⁷¹), generating prothrombin fragment 1.2 (F1 and F2) and prethrombin-2. Subsequent cleavage at R³²⁰ produces the A- and B-chains of α -thrombin.

An alternative cleavage pathway occurs when factor Xa alone acts on prothrombin or when prothrombinase is assembled on washed platelets.⁶⁷⁰ In the presence of factor Xa, Ca²⁺, and an appropriate membrane surface, the initial cleavage occurs at Arg²⁷¹-Thr²⁷² and gives rise to prothrombin fragment 1.2 and prethrombin 2 (Fig. 18.8; pathway B, cleavage at 2). Cleavage at Arg³²⁰ in prethrombin 2 (Fig. 18.8; pathway B, cleavage at 2) yields α -thrombin. In contrast to the meizothrombin pathway, the prethrombin 2 intermediate appears not to dissociate from prothrombinase.⁶⁷⁵ Prothrombin fragment 1.2 remains noncovalently associated with α -thrombin. In vitro, α -thrombin is associated ($K_d = 10$ nmol/L) with prothrombin fragment 2,⁶⁷⁶ or the latter's precursor prothrombin fragment 1.2, or both.⁶⁷⁷ In contrast to other vitamin K-dependent proteins, the phospholipid-binding region is no longer covalently attached to the serine protease domain after prothrombin conversion to thrombin.

Thrombin and meizothrombin catalyze cleavage at Arg¹⁵⁵ of prothrombin, yielding a truncated molecule called prethrombin 1 (residues 156 to 579) that lacks the Gla domain. Thrombin can also cleave at Arg²⁸⁴, yielding a truncated α -thrombin species (residues 284 to 579), which is the form of thrombin found in commercial preparations.

The membrane surface that supports the prothrombinase complex in vivo has traditionally been assumed to be primarily provided by platelets, but can also be provided by other circulating blood cells, such as monocytes and lymphocytes, and by vascular endothelial cells.⁶⁷⁸ Since prothrombin activation on platelets proceeds through the prothrombin 2 pathway

and meizothrombin formation has been observed in clotting blood,^{671,679} it appears that prothrombin activation in blood involve both pathways. Prothrombin activation through the meizothrombin pathway has been reported to occur on the subpopulation of red blood cells that express phosphatidylserine on their surface.⁶⁷¹

P.454

Function

α -Thrombin can be considered the central enzyme in blood coagulation in that it contributes to reactions at all levels, allowing for the overall maintenance of vascular fidelity. Its main role is in stemming blood loss through fibrin clot formation.⁶⁸⁰ The series of events that leads up to and occurs after fibrin formation also involves protein activation by α -thrombin. This includes activation of platelets,⁶⁸¹ factor VII,⁸ factor V,⁶⁸² factor VIII,⁶⁸³ factor XI,⁷ and factor XIII.¹⁷ α -Thrombin activity also extends from the procoagulant process to anticoagulation and suppression of fibrinolytic reactions. For example, α -thrombin-thrombomodulin activates the anticoagulant protein, protein C,⁶⁸⁴ and the antifibrinolytic protein, TAFI.³⁶

Relatively minute concentrations of thrombin are generated during the initiation phase of blood coagulation, primarily due to the factor Xa generated from the extrinsic tenase complex (Fig. 18.7). These levels of thrombin, in the range of 0.5 to 2.0 nmol/L, have been shown to be sufficient for the initiation of rapid activation of platelets, factor XIII and factor V, and fibrin formation in an ex vivo whole blood model.⁵⁶⁹ All of these processes occur before the major burst of thrombin generation during the propagation phase of the reaction.

α -Thrombin's role continues into the tissue repair and remodeling phase that is necessary to regenerate damaged vascular tissue. α -Thrombin is a potent mitogen^{685,686} and stimulates cell division in macrophages,⁶⁸⁷ smooth muscle cells,⁶⁸⁸ and endothelial cells.⁶⁸⁹ α -Thrombin also appears to be involved in the growth and metastasis of tumors by promoting angiogenesis,^{690,691} possibly through vascular endothelial growth factor.⁶⁹² The roles that thrombin plays in coagulation and beyond are outlined in a recent review.⁶⁹³

Regulation

In vivo, the activity of the prothrombinase complex has to be tightly regulated to ensure that adequate but limited levels of α -thrombin are generated. If too much α -thrombin is continuously generated, localized clot formation can lead to occlusion or systemic thrombosis. Equally, if too little α -thrombin is generated, hemorrhagic conditions result. Two reaction systems, one covalent and one proteolytic, regulate α -thrombin generation. Antithrombin-heparin (or heparan sulfate) is a potent inhibitor of blood coagulation and inhibits both α -thrombin and factor Xa via covalent interactions.^{694,695} α -Thrombin also participates in its own downregulation by binding to thrombomodulin on the vascular cell surface and converting protein C to APC. This anticoagulant serine protease then cleaves factors Va and VIIIa. These cofactors for the vitamin K-dependent complexes are no longer available for ongoing reactions, thereby eliminating α -thrombin generation. In ex vivo models of blood coagulation, prothrombin levels and antithrombin appear to have the most significant impact on α -thrombin generation.⁶⁹⁶ Increased levels of antithrombin reduce α -thrombin generation by inhibiting α -thrombin activity and preventing positive feedback.⁶⁹⁶ Decreased levels of antithrombin allow for higher levels of prothrombin activation and prolongation of α -thrombin generation.⁶⁹⁶

PROCOAGULANT PROTEINS: PROCOAGULANT COFACTOR PROTEINS

There are two categories of cofactor proteins: the plasma-derived soluble procoagulant procofactors factors V and VIII (and their circulating carrier von Willebrand factor [vWF]), and the cell-associated coagulation cofactor, tissue factor. Factors V and VIII are highly homologous (40% identity), sharing many structural and functional similarities. Tissue factor is a single-chain transmembrane protein that is composed of extracellular, transmembrane, and cytoplasmic domains.

Tissue Factor (Tissue Thromboplastin, CD142, Coagulation Factor III)

Tissue factor, also known as tissue thromboplastin, CD142, and coagulation factor III, is a transmembrane protein that functions as a nonenzymatic cofactor for factor VIIa in the extrinsic tenase complex. In the absence of injury or stimulus, tissue factor is not ordinarily expressed on cellular surfaces in direct contact with circulating blood. Presentation of tissue factor to the circulation is the event that triggers the procoagulant primary pathway of coagulation (Fig. 18.1). There are no known mutations or deficiencies of human tissue factor, leading to the speculation that tissue factor is essential for life. In mice, inactivation of the tissue factor gene to create homozygous tissue factor-null mice proves to be lethal during embryonic development.^{697,698,699,700}

Gene Structure and Expression

The tissue factor gene is located on chromosome 1p21-22^{701,702} and spans 12.4 kb (Table 18.2). The gene contains five introns and six exons.⁷⁰³ Tissue factor expression can be induced in a number of cultured cell types. Fibroblasts express tissue factor on exposure to serum or mitogenic cytokines,^{704,705} as do vascular smooth muscle cells and keratinocytes.^{706,707} Monocytic cells and monocytes isolated from peripheral blood also express tissue factor when stimulated by bacterial endotoxin or other proinflammatory agents.^{706,707} The presence of these cells may be associated with DIC.⁷⁰⁸ In vitro, certain leukemic cell lines constitutively express low levels of tissue factor.^{709,710} and ⁷¹¹ Tissue factor expression by circulating and nonvascular cells plays key roles in cancer, sepsis, and perhaps atherosclerotic plaque formation.^{56,712,713,714,715} and ⁷¹⁶ However, tissue factor in the subendothelial cell layer is proposed to trigger coagulation on exposure to the circulation. Cultured vascular endothelial cells express tissue factor on stimulation by IL-1, tumor necrosis factor (TNF)- α , and bacterial endotoxin.^{706,707} In vivo, there is little or no detectable tissue factor expression on unstimulated endothelial cells. Certain conditions such as sepsis, placental villitis and graft rejection induce tissue factor expression on endothelial cells in vivo.^{708,717,718} and ⁷¹⁹ The mechanism governing tissue factor expression under nonpathologic conditions is presently unknown. Studies of transcriptional control of tissue factor expression in various cell lines have demonstrated that Sp1 sites are important in basal transcription of the tissue factor gene. EGR-1, activation peptide-1, and NF- κ β sites mediate tissue factor expression in response to pathologic stimulation.^{699,720,721,722,723} and ⁷²⁴

Biochemistry

Tissue factor is a single-chain glycoprotein ($M_r = 44,000$)⁷²⁵ of 261 or 263 amino acids (Table 18.1). It is synthesized with a signal peptide of 32 amino acids. The variability in protein size is due to heterogeneity at the NH₂-terminus.^{701,726,727} Tissue factor is a member of the class 2 cytokine receptor superfamily⁷²⁸ and a type I integral membrane protein. The type I designation refers to the location of the NH₂- and COOH-termini. The NH₂-terminus of tissue factor (residues 1 to 219) is extracellular, whereas the COOH-terminus of the protein is intracellular (residues 243 to 263). Tissue factor also contains a hydrophobic membrane-spanning domain (residues 220 to 242) (Fig. 18.9). This domain appears to function solely to anchor tissue factor in the membrane.⁷²⁹ The NH₂-terminal domain of tissue factor is composed of two fibronectin type III domains and is glycosylated at Asn¹¹, Asn¹²⁴, and Asn¹³⁷.⁷³⁰ X-ray crystal structures of tissue factor show that the two fibronectin type III domains are joined at an angle of approximately 120°.^{731,732,733,734,735} and ⁷³⁶ There are also two disulfide bonds (Cys⁴⁹-Cys⁵⁷

P.455

P.456

and Cys¹⁸⁶-Cys²⁰⁹) in the NH₂-terminal extracellular region.⁷³⁷ At least one of the disulfide bonds is required for tissue factor activity. Early studies suggested that glycosylation does not appear to play a key role in determining protein function^{730,738,739}; however, more recent work indicates that glycosylation⁷⁴⁰ and other posttranslational modifications^{741,742} play important roles in modulating tissue factor biological activities. The COOH-terminal cytoplasmic domain is quite short and contains a single cysteine residue (Cys²⁴⁵) that is linked to a palmitate or stearate fatty acyl chain via a thioester bond.⁷³⁷ The COOH-terminus also contains a serine that may be phosphorylated.⁷⁴³ The function of the COOH-terminus and the importance of these two modifications are not clear, as deletion of this domain has no significant effect on tissue factor procoagulant activity.⁷²⁹

FIGURE 18.9. Transmembrane cofactors. A: Schematics of tissue factor and thrombomodulin. Tissue factor is composed of an extracellular domain (residues 1 to 219), a transmembrane domain (residues 220 to 242), and a cytoplasmic domain (residues 243 to 263). Two disulfide bonds (S-S) and the sites of the three carbohydrate moieties (CHO) are identified by amino acid residue. One cysteine (C²⁴⁵) contains a thiol ester linkage to a fatty acid. Tissue factor is the cofactor for factor VIIa in the extrinsic tenase complex and is exposed on the subendothelial surface after injury. Thrombomodulin is an endothelial cell surface glycoprotein composed of five distinct domains. The domain structures include a lectinlike domain (residues 6 to 149), a domain containing six epidermal growth factor (EGF)-like regions (residues 227 to 462), a small

extracellular domain rich in threonine and serine residues (two residues, S⁴⁷² and S⁴⁷⁴, have been identified as sites of chondroitin sulfate adducts), a membrane-spanning region (residues 499 to 521), and a cytoplasmic tail (residues 522 to 557). There are nine known glycosylation sites (CHO) on the thrombomodulin molecule. Thrombomodulin functions as the cofactor in the protein Case complex and assists in the generation of activated protein C. B: Structural ribbon diagram of tissue factor (blue) (PDB-ID: 2HFT)⁷³³ and tissue factor and factor VIIa (green) (PDB-ID: 1DAN).⁴⁷¹ The tissue factor carbohydrate side chains have been added to the structure.⁷⁴⁰

Function

The nonenzymatic cofactor tissue factor can bind either factor VII or factor VIIa in a Ca²⁺-dependent manner and form a highaffinity 1:1 complex. Once bound to tissue factor, the zymogen factor VII is rapidly converted to an active enzyme via limited proteolysis.⁷⁴⁴ The tissue factor-factor VIIa, or extrinsic tenase complex, activates factors IX and X. When tissue factor is exposed or expressed, or both, subsequent to vascular perturbation, low levels of circulating factor VIIa bind to tissue factor, and the extrinsic tenase triggers the procoagulant cascade. Factor VII bound to tissue factor is converted to factor VIIa, augmenting factors IXa and Xa generation. The primary role of the complex is to provide factor IXa and low levels of factor Xa, which serve to promote factor IXa production^{61,62} and^{63,487} and to directly catalyze the conversion of trace amounts of prothrombin to thrombin.

In the absence of tissue factor, factor VIIa is relatively inert. Once bound to tissue factor, the catalytic activity of factor VIIa is increased 20- to 100-fold with low-molecular-weight substrates^{476,745,746} and⁷⁴⁷ and approximately 10⁴-fold with its macromolecular substrates factors X and IX.^{745,747,748} Tissue factor alters the active site of factor VIIa, thus functioning as an allosteric activator of the enzyme.

Although the cofactor is necessary for enzymatic activity, complex formation between tissue factor and factor VIIa does not share the same requirements for an anionic phospholipid membrane surface as the other procoagulant complexes. The membrane dependency of the extrinsic tenase complex arises from membrane-mediated substrate delivery. Both factors X and IX bind to anionic membrane surfaces for efficient two-dimensional transfer to the extrinsic tenase.

An additional role for tissue factor-factor VIIa beyond its activation of the coagulation cascade involves triggering signaling through the G-protein-coupled, protease-activated receptor 2, which is relevant to inflammation and angiogenesis.^{749,750}

Regulation

Tissue factor activity is regulated by controlling its presentation. The common accepted source of functional tissue factor is through exposure of the subendothelium on vascular damage. However, there is controversy regarding the source and presentation of active tissue factor and whether functional tissue factor circulates in blood in healthy individuals or only in those with pathologies.^{751,752,753,754} Tissue factor function has been reported to be under the control of an allosteric disulfide bond.^{750,755,756} Once the tissue factor-factor VIIa complex is formed in the vicinity of an injury, the extrinsic tenase activity is then modulated by TFPI and antithrombin reduction of enzymatic activity.

Factor VIII (Antihemophilic Factor, Factor VIII:Antigen, Factor VIII:Coagulant)

Factor VIII, or antihemophilic factor, is a nonenzymatic procofactor that circulates in plasma in complex with the large multimeric protein vWF. Initially, factor VIII and vWF were thought to be a single entity, and early reports on factor VIII were actually measuring facets of vWF structure and function. The factor VIII protein is designated as factor VIII:Ag (antigen; VIII:Ag is vWF), and its procoagulant function is designated factor VIII:C (coagulant).⁷⁵⁷ Factor VIII circulates at an average concentration of 0.2 µg/ml (0.7 nmol/L; Table 18.1). The ratio of factor VIII to vWF is fairly constant and in the range of 1 molecule of factor VIII to 50 to 100 molecules of vWF monomeric units.^{758,759} vWF acts to regulate the plasma concentration of factor VIII. 1-Deamino-8-d-arginine vasopressin administration elicits an increase in the plasma concentration of vWF and, in turn, increases the plasma level of factor VIII.⁷⁶⁰ vWF also stabilizes factor VIII in plasma. Factor VIII in complex with vWF has a plasma t_{1/2} of approximately 12 hours, whereas factor VIII alone undergoes rapid clearance and has a t_{1/2} of approximately 2 hours.^{761,762,763} and⁷⁶⁴ Deficiency of factor VIII, or hemophilia A, is a well-characterized bleeding disorder linked to the X chromosome. Hemophilia A, therefore, occurs almost exclusively in males and occurs at a frequency of 1:5,000 to 1:10,000 males. Females with one abnormal factor VIII gene are unaffected carriers. The severity of bleeding in hemophilia A patients is correlated with the level of functional factor VIII in plasma.^{765,766} Approximately 50% to 60% of hemophilia A cases are severe, with factor VIII coagulant activity < 1% of normal. Severe hemophilia A is manifested in frequent episodes of spontaneous bleeding into joints, muscles, and internal organs. Factor VIII coagulant activity in the range of 1% to 5% of normal (25% to 30% of patients) results in moderate hemophilia A. In the moderate form, abnormal bleeding is generally linked to any trauma, including minor injury. The remaining patients have 6% to 30% of normal factor VIII activity and exhibit mild hemophilia A. In the mild form, factor VIII deficiency results in bleeding events only subsequent to significant trauma or surgery.⁷⁶⁷

Gene Structure and Expression

The factor VIII gene has been mapped to the long arm of the X chromosome in band q28.^{768,769,770,771,772} The factor VIII gene is 186 kb in length and contains 25 introns and 26 exons.^{9,770,773} The liver and spleen are thought to be the primary sites of factor VIII biosynthesis,^{774,775,776,777,778,779} and⁷⁸⁰ although factor VIII mRNA has been detected in other cell types as well.⁷⁸⁰

Biochemistry

Human factor VIII has a relative molecular weight in the range of 280,000 (Table 18.1). The heterogeneity in molecular weight is due to proteolysis of the protein in circulation or processing,⁸ or both. It is a glycoprotein of 2,351 amino acids that is synthesized as a precursor molecule with a 19-amino acid signal peptide.^{9,781} The sequence of factor VIII is highly homologous to factor V.⁷⁸² The procofactors factors VIII and V are organized into discrete structural domains. The NH₂-terminal heavy chains of both proteins contain the A1 and A2 domains (Fig. 18.10). The COOH-terminal light chains contain the A3, C1, and C2 domains. The heavy and light chains are separated by the B domain. The three A domains of factor VIII are homologous to each other and to the A domains of factor V and ceruloplasmin.^{781,782,782a} The C domains of factor VIII are homologous to each other and to the C domains of factor V. The C domains are also homologous to milk fat globule protein and the A-, C-, and D-chains of discoidin 1.^{784,785} The B domain of factor VIII is not homologous to the factor V B domain, nor do the B domains of either protein share homology with any known proteins.

The factor VIII molecule is secreted as a two-chain heterodimer as a result of intracellular proteolysis at the B-A3 junction (Arg¹⁶⁴⁹). Additional cleavages within the B-chain yield A1-A2-B fragments that are variable in length.^{786,787,788} and⁷⁸⁹ The B domain

P.457

P.458

(residues 741 to 1,649) contains 18 of the 25 potential N-linked glycosylation sites in factor VIII and is highly glycosylated. The murine factor VIII B-chain is also heavily glycosylated, suggesting that glycosylation of the B-chain may be important for protein expression or function, or both.⁷⁸⁹ The B domains of factors VIII and V are excised during activation of the proteins to generate the cofactor molecules factors VIIIa and Va.

Factor VIII: 280 kDa

Factor V: 330 kDa

FIGURE 18.10. Soluble cofactors. A: Domain structures of the soluble cofactors factor VIII and factor V. The disulfide loop structures of factor VIII and factor V defining the α , β , and γ loops are illustrated as bubbles. α -Thrombin (IIa), activated protein C (APC), factor Xa, and Russell viper venom (RVV) cleavage sites are shown with vertical arrows. The linear domain structures (A1-A2-A3-C1-C2) are illustrated with horizontal arrows bracketed by the beginning and ending amino acid number. The B regions (factor V, residues 710 to 1,545; factor VIII, residues 741 to 1,649) are represented by the crosshatched regions. Phosphorylation sites are illustrated by a P inscribed in a circle and the phosphoamino acid, serine (S) or threonine (T), illustrated above or below it. Free cysteine thiols are represented by SH and identified by residue number. B: Crystal structures. Bovine factor Va des-A2 (PDB-ID: 1SDD)865 and human factor VIIIa (PDB-ID: 2R7E).⁷⁸³

FIGURE 18.10. (Continued)

Factor VIII shares homology with the copper ion (Cu^+)-binding protein ceruloplasmin and contains a Cu^+ -binding site in the A1 domain.^{790,791} This site is important for protein function. A similar Cu^+ -binding site in the A3 domain does not appear to play a role in protein function.

Factor VIII also contains binding sites for vWF, anionic phospholipids, factor IXa, and, potentially, factor X. Factor VIII interaction with vWF requires the NH_2 - and COOH -termini of the factor VIII light chain (A3, C1, and C2 domains), although a specific vWF-binding site has been identified at residues 1,673 to 1,684 on the light chain.^{758,792,793} and ⁷⁹⁴ The vWF-binding site is removed from the factor VIII protein by α -thrombin cleavage at Arg¹⁶⁸⁹. A phospholipid-binding domain is located on the factor VIII C2 domain at residues 2,303 to 2,332.⁷⁹⁵ High-affinity factor IXa binding is mediated by the light chain of the factor VIII molecule. The A3 domain contains a high-affinity site for factor IXa localized at residues Glu¹⁸¹¹ to Lys^{1818, 796,797}. Residues 552 to 565 in the A2 domain of the factor VIII heavy chain may also play a role in factor VIII interaction with factor IXa.^{798,799} and ⁸⁰⁰ Mutations within this region have been documented in the hemophilia A mutation database.⁸⁰¹ Specifically, Ser558Phe, Val559Ala, Asp560Ala, and Gln565Arg have been described as CRM⁺ with defective activity resulting in mild hemophilia A. These residues have been shown to be essential for the catalytic efficiency of the factor VIIIa-factor IXa complex while not affecting the binding affinity between the two species.⁸⁰² A model of factor VIII based on the x-ray crystal structure of ceruloplasmin has been used to examine structure/function relationships in the factor VIII molecule.⁸⁰³ This approach has recently been expanded upon by using the x-ray structure of the C2⁸⁰⁴ domain to generate 10 hypothetical models of the intrinsic tenase complex.⁸⁰⁵ Based on homology between factor VIII and ceruloplasmin, the factor IXa binding sites in the A2 and A3 domains are likely located in close proximity on the same side of the factor VIII molecule. A factor X binding site may exist on the COOH -terminus of the factor VIII A1 domain.^{806,807}

Factor VIII also contains several tyrosine residues modified by the addition of sulfate.⁸⁰⁸ The tyrosine sulfate residues enhance α -thrombin cleavage of the procofactor.⁸⁰⁹ In addition, factor VIII contains biantennary complex-type sugar chains with blood group A or H, or both, determinants.⁸¹⁰

Function

The procofactor factor VIII is activated by α -thrombin to generate the cofactor factor VIIIa. Activation by α -thrombin involves cleavages at Arg³⁷² (the A1-A2 junction), Arg⁷⁴⁰ (the A2-B junction), and Arg¹⁶⁸⁹ in the light chain (Fig. 18.10). The resulting molecule contains three separate polypeptide chains: A light-chain region (A3-C1-C2) bound to the NH_2 region of the heavy chain (A1) in a Ca^{2+} -dependent manner and the noncovalently associated A2 region of the heavy chain. Once

formed, the cofactor factor VIIIa binds its serine protease enzyme factor IXa to form the Ca^{2+} - and membrane-dependent complex, the intrinsic tenase (Fig. 18.4). This complex is homologous to the prothrombinase complex. The intrinsic tenase complex catalyzes factor X conversion to factor Xa at a rate several orders of magnitude greater than the enzyme factor IXa alone.^{811,812} Factor Xa generated via the intrinsic tenase complex (factor IXa-factor VIIIa- Ca^{2+} -membrane) yields the propagation phase of α -thrombin generation by raising the factor Xa concentration approximately 100-fold over that achieved by the extrinsic tenase complex (Fig. 18.7B).⁵⁶⁷ Without formation of the intrinsic complex, as occurs in a situation like that of hemophilia A or B, factor Xa is not generated at a level sufficient to produce the propagation phase of α -thrombin generation (Fig. 18.7A).^{446,568,569}

Like the prothrombinase complex, the cofactor (factor VIIIa) interaction with the enzyme (factor IXa) in the presence of divalent cations and an anionic phospholipid surface is a highaffinity interaction with a K_d of 2 nmol/L. The interaction of factor IXa with phospholipid in the absence of its cofactor is of approximately 100-fold lower affinity.^{812,813}

Regulation

Factor VIIIa function is primarily regulated by dissociation of a fragment (residues 373 to 740) containing the A2 subunit from the heterotrimer. Once the A2 subunit is displaced, factor VIIIa

P.459

loses all cofactor function. Dissociation is spontaneous and occurs rapidly under physiologic conditions. Factor IXa stabilizes factor VIIIa, delaying dissociation of the heterotrimer and prolonging the transient activity of factor VIIIa.^{814,815} Factor VIIIa is also regulated by limited proteolysis. Factor IXa cleaves the factor VIIIa A1 subunit at Arg³³⁶ and eliminates factor VIIIa function.^{815,816} and ⁸¹⁷ In addition to factor IXa, the A1 subunit of factor VIIIa is cleaved by factor Xa and α -thrombin.^{11,808,815,818} APC is a key anticoagulant enzyme that likewise cleaves the A1 subunit at Arg³³⁶. APC also cleaves the factor VIIIa A2 subunit at Arg⁵⁶².^{11,819} The APC cleavages occur sequentially with the A1 cleavage first and the A2 cleavage second.⁸²⁰ Factor IXa protects factor VIIIa from APC cleavage at Arg⁵⁶²; however, protein S blocks the protective effect.⁸²¹ Although factor VIIIa is proteolytically inactivated by a number of enzymes, spontaneous dissociation is the key regulator of cofactor function.

Factor V (Labile Factor)

Factor V was first recognized as an unstable plasma component necessary for the generation of α -thrombin.²⁷ Factor V is a large single-chain glycoprotein that circulates in plasma at an average concentration of 6.6 $\mu\text{g/ml}$ (20 nmol/L) (Table 18.1). Factor V is also contained in the α -granules of human platelets, with approximately 18% to 25% of the total factor V present in platelets.⁸²² The identification, role in coagulation, and overall importance of factor V in hemostasis has been discussed in recent reviews.^{823,824} and ⁸²⁵

Congenital factor V deficiency, or parahemophilia, is an extremely rare disorder inherited in an autosomal recessive manner. Patients can exhibit severe bleeding diatheses. Although complete lack of factor V in humans does not appear to be lethal, factor V-deficient mice experience fatal hemorrhage in utero.⁸²⁶ Combined deficiencies of factors V and VIII have also been observed. Interestingly, combined cofactor deficiencies occur more commonly than factor V deficiency alone.^{827,828} Recently, the gene for ERGIC-53, a calcium-dependent lectin that serves as a glycoprotein-sorting receptor between the endoplasmic reticulum and the Golgi complex, has been linked to combined factors V and VIII deficiency.^{829,830} Mutations in this gene in patients with combined hemophilia have been described. Factor V deficiency becomes even more complex when platelet factor V is taken into consideration. Patients have been identified with normal functional levels of plasma factor V, but deficiencies of platelet factor V that result in bleeding disorders.^{822,831,832} and ⁸³³ Lack of platelet α -granules and their contents in storage pool disorders leads to deficiency of platelet factor V.^{831,832} Factor V^{Quebec} is an autosomal dominant bleeding disorder characterized by mild thrombocytopenia, normal levels of plasma factor V, and degraded platelet factor V with very low activity.^{822,833} A database on factor V mutation⁸³⁴ has been compiled by Dr. Hans L. Vos (Hemostasis and Thrombosis Research Center, Leiden University Medical Center, Leiden, The Netherlands; e-mail: h.l.vos@lumc.nl) and is available upon request.

Gene Structure and Expression

The human factor V gene is located on chromosome 1 bands q21-q25⁸³⁵ (Table 18.2). The gene spans approximately 80 kb and consists of 24 introns and 25 exons. Transcription and processing yield an mRNA species of 6.8 kb. The intron-exon structure of the factors V and VIII genes are quite similar, and the genes likely evolved from a common ancestor. The liver appears to be the primary site of factor V biosynthesis.^{782,836,837} While human megakaryocytes express factor V,^{838,839} and ⁸⁴⁰ platelet factor V is likely derived from circulating liver-derived plasma factor V^{841,842,843} and ⁸⁴⁴; however, the source of

platelet factor V has not been definitively determined.⁸⁴⁵ Bovine aortic endothelial cells⁸⁴⁶ and vascular smooth muscle cells⁸⁴⁷ also have been reported to express factor V.

Biochemistry

Human factor V ($M_r = 330,000$)^{848,849,850} and ⁸⁵¹ is a single-chain glycoprotein of 2,196 amino acids derived from a precursor molecule with a signal peptide (Table 18.1 and Fig. 18.10). Factor V consists of an NH₂-terminal heavy chain (residues 1 to 709: A1-A2 domains), a central B domain (residues 710 to 1,545), and a COOH-terminal light chain (residues 1,546 to 2,196: A3-C1-C2 domains). The A domains are homologous to those found in factor VIII and plasma ceruloplasmin; the C domains are homologous to the slime mold protein discoidin.⁷⁸² Like factor VIII and ceruloplasmin, factor V is also a copper-binding protein.⁸⁵²

Factor V undergoes extensive posttranslational modification, including phosphorylation, sulfation, glycosylation, and formation of mixed disulfides between its five free cysteine residues and circulating thiols like cysteine and homocysteine.⁸⁵³ Phosphorylation occurs at sites in the heavy chain, B region, and light chain. Phosphorylation at Ser⁶⁹² affects the rate of inactivation of factor Va by APC.⁸⁵⁴ Factor V is sulfated at a number of sites in the heavy chain (Tyr⁶⁶⁵, Tyr⁶⁹⁶, and Tyr⁶⁹⁸), the B region (Tyr¹⁴⁹⁴, Tyr¹⁵¹⁰, and Tyr¹⁵¹⁵) and the light chain (Tyr¹⁵⁶⁵). The sulfation status of factor V has been related to its function.^{855,856} Carbohydrate accounts for 13% to 25% of the mass of factor V.⁸⁵⁷ The heavy chain has nine potential N-linked glycosylation sites. In the B region, 25 asparagine residues are candidates for modification with carbohydrate; carbohydrate accounts for approximately 50% of the mass of the B region. The light chain of factor V has three N-linked glycosylation sites. Differential glycosylation of Asn²¹⁸² in the C2 domain is reported to be responsible for the factor V1 and factor V2 variants observed in plasma. The two variants have slightly different molecular masses and charges.⁸⁵⁸ Factors Va1 and Va2 are distinguished by functional differences as well. Factor Va1 does not appear to bind to anionic phospholipid as efficiently as factor Va2 and is not as competent a cofactor in the prothrombinase complex as factor Va2.^{857,859,860} and ⁸⁶¹ The presence of an oligosaccharide at Asn²¹⁸² apparently reduces the affinity of factor Va1 for the phospholipid surface and interferes with prothrombinase complex assembly and function. The COOH-terminal fragment of the factor Va light chain (residues 1,753 to 2,183) that contains the Asn²¹⁸² glycosylation site is one of the two regions that mediate membrane association.⁸⁶²

Several models of fragments of factor Va have been generated.^{863,864} The crystal structure of APC-inactivated bovine factor Va (factor Vai), which includes the A1 domain from the heavy chain and the entire light chain, showed a domain organization quite different from previous models of either factor V or factor VIII.⁸⁶⁵ Most notably, the structure places the C1 and C2 domains in a "side-by-side" orientation, in which both C domains can interact with the phospholipid surface. This model has been supported by biochemical experiments.⁸⁶⁶ Recently, homology models have been generated for the prothrombinase complex.⁸⁶⁷

Activation

The procofactor factor V does not bind factor Xa and is essentially completely inactive.⁴² Limited proteolysis of the factor V molecule yields the active cofactor factor Va. Factor Va functions as both a factor Xa receptor and a positive modulator of factor Xa catalytic potential in the prothrombinase complex. Rate enhancements of 300,000-fold derive from the participation of factor Va in the process of factor Xa activation of prothrombin.⁵⁸⁰

α -Thrombin is the primary catalyst of factor V activation in vivo. α -Thrombin cleaves factor V at Arg⁷⁰⁹, Arg¹⁰¹⁸, and Arg¹⁵⁴⁵,⁷⁸² (Fig. 18.10). The α -thrombin-generated form of factor Va is a heterodimer consisting of an NH₂-terminal heavy chain ($M_r = 105,000$ [A1-A2 domains]) linked noncovalently to a COOH-terminal light chain ($M_r = 73,000$ [A3-C1-C2 domains]).^{850,868,869,870} and ⁸⁷¹ The association of the heavy and light chains of factor Va shows a divalent cation dependence. The B domain is excised during proteolysis.^{15,868,870}

P.460

Factor Xa cleaves factor V at Arg⁷⁰⁹, Arg¹⁰¹⁸, and Arg¹⁵⁴⁵, producing a factor Va molecule similar to the factor Va produced by α -thrombin cleavage.^{619,872} Factor Xa cleavage of factor V is less efficient than α -thrombin cleavage,^{619,872} although factor V released from stimulated platelets is partially activated and is more efficiently cleaved by factor Xa than plasma factor V.⁸⁷³

Other enzymes may also activate or partially activate factor V. Platelet calpain,⁸⁷⁴ cathepsin G, and human neutrophil elastase^{875,876} partially activate factor V. The fibrinolytic enzyme plasmin both activates and inactivates factor V.^{877,878} and

⁸⁷⁹ Plasmin cleavage and inactivation of factor V are hypothesized to play a role in hemorrhage subsequent to thrombolytic therapy by decreasing the level of factor Va cofactor activity.⁸⁸⁰

Function

Activation of the procofactor factor V yields the functional form factor Va. Factor Va acts as a cofactor for the serine protease factor Xa in the prothrombinase complex. Factor Va forms at least part of the receptor for factor Xa on platelets and serves to anchor factor Xa to the membrane surface.⁸²³ Factor Va stabilizes the prothrombinase complex and enhances prothrombin activation.^{5,682}

Factor Va Regulation and Factor V^{Leiden}

Factor Va is regulated by proteolytic inactivation by APC. An anionic membrane surface is required for complete cleavage and full inactivation of the cofactor; in the absence of phospholipid, factor Va cleavage is not complete, and the cofactor retains some activity. Protein S, a suggested cofactor for APC, only functions in the presence of a phospholipid bilayer as well. In the presence of a membrane surface, APC cleaves factor Va sequentially at three sites: Arg⁵⁰⁶, Arg³⁰⁶, and Arg⁶⁷⁹. Factor Va is initially cleaved at Arg⁵⁰⁶. Subsequently, the membrane-dependent cleavage at Arg³⁰⁶ results in complete loss of factor Va cofactor activity. An additional APC-mediated cleavage of factor Va fragments occurs at Arg⁶⁷⁹. Loss of cofactor activity coincides with dissociation of the A2 domain of APC-cleaved factor Va in a process similar to the spontaneous dissociation of factor VIIIa.^{881,882}

The importance of this regulatory mechanism is demonstrated by the “APC resistance” syndrome associated with factor V^{Leiden}.⁸⁸³ Individuals with factor V^{Leiden} have a G to A substitution at nucleotide 1,691 in the factor V gene that results in an Arg⁵⁰⁶→Gln mutation at the protein level.⁸⁸⁴ Factor Va^{Leiden} has normal cofactor activity as part of the prothrombinase complex. However, unlike normal factor Va, factor Va^{Leiden} is not readily inactivated by APC. The Arg⁵⁰⁶→Gln mutation hinders the first step in the sequential series of inactivating cleavages by APC. Factor Va^{Leiden} retains cofactor activity and continues to promote α-thrombin generation for an extended period of time. Inactivation of factor Va^{Leiden} by cleavage of the Arg³⁰⁶ bond occurs eventually but is markedly slower than normal factor Va.⁸⁸⁵ The prevalence of the factor V^{Leiden} mutation is approximately 5% in whites.⁸⁸⁶ Individuals heterozygous for factor V^{Leiden} have a sevenfold greater risk of thrombosis than normal individuals, whereas individuals homozygous for factor V^{Leiden} have an 80-fold greater risk of thrombosis.⁸⁸⁷ The risk of thrombosis in individuals with factor V^{Leiden} is also exacerbated by other genetic and acquired risk factors such as protein C or protein S deficiency, or both, and use of oral contraceptives.^{823,888} The effects of factor V^{Leiden} are of considerable interest, as factor V^{Leiden} is the most common prothrombotic risk factor yet identified.^{889,890} and ⁸⁹¹

von Willebrand Factor (von Willebrand Factor: Antigen, Ristocetin Cofactor, von Willebrand Factor Ristocetin: Cofactor)

vWF is a multifunctional protein with several key roles in coagulation. vWF circulates in plasma at an average concentration of 10 µg/ml⁸⁹² (Table 18.1) and is also contained in the α-granules of human platelets.⁸⁹³ ABO blood type has a significant influence on vWF levels, with individuals of types A, B, or AB blood having much higher levels of vWF than individuals with type O blood.^{894,895} vWF is also known for its role in ristocetin-induced platelet aggregation,^{896,897} which is the basis of clinical assays. vWF was first recognized as the missing or defective factor in a severe autosomal dominant bleeding disorder.^{898,899,900} and ⁹⁰¹ von Willebrand disease is fairly common and is estimated to occur in 1% to 2% of the general population.^{902,903,904} and ⁹⁰⁵ vWF is also an acute phase reactant; levels are elevated as a result of stress, pregnancy, or surgical trauma,^{906,907,908} and ⁹⁰⁹ and is a key player in hemostasis.⁹¹⁰

Gene Structure and Expression

The vWF gene is located on chromosome 12 band 12p-12pter and is 178 kb long with 51 introns and 52 exons^{911,912,913} (Table 18.2). A pseudogene with approximately 98% homology to the vWF gene has been mapped to chromosome 22.^{912,913} vWF is expressed only by endothelial cells and megakaryocytes.^{914,915} and ⁹¹⁶ vWF is stored in Weibel-Palade bodies in endothelial cells and in α-granules in platelets.^{917,918} and ⁹¹⁹ There are several regulatory elements that control vWF expression including GATA-binding consensus sequences in the promoter region.⁹²⁰ Endothelial cellspecific expression appears to be regulated by NF1 and Oct-1 binding sites.^{917,920,921,922} and ⁹²³ vWF expression is also regulated by complex signaling pathways that are directed by specific cellular environments.^{921,924,925} and ⁹²⁶ In addition, vWF plasma levels can be regulated through release of vWF from endothelial cell and platelet storage compartments. Platelet activation results in the release of vWF, and endothelial cell vWF release is induced by histamine and 1-deamino-8-d-arginine vasopressin.^{927,928} and ⁹²⁹

Biochemistry

vWF is a large adhesive glycoprotein that circulates in plasma as a heterogeneous mixture of disulfide-linked multimers. The biocycle of vWF comprises a series of steps ranging from regulated expression of the vWF gene in endothelial cells and megakaryocytes to its clearance from the blood.⁹³⁰ vWF is synthesized as a prepro molecule containing a 22-amino acid signal peptide, a propeptide of 741 amino acids, and the mature vWF protein of 2,050 amino acids.^{931,932,933,934,935} and⁹³⁶ The prepro vWF molecule is comprised of internally repeated A, B, C, and D domains arranged in the sequence D1-D2-D'-D3-A1-A2-A3-D4-B-C1-C2. The A repeats share homology with complement factor B, collagen type IV, chicken cartilage matrix protein, and the I domain of the integrin α -subunit.^{937,938} Portions of the C domains are homologous to sequences in procollagen and thrombospondin.⁹³⁹ Prepro vWF undergoes extensive posttranslational modification to yield the mature vWF protein lacking the D1 and D2 domains. The large vWF propolypeptide copurifies with factor VIII and vWF and is designated vWF antigen-II. The mature vWF monomer has a molecular weight of approximately 255,000 based on protein sequence and carbohydrate content.^{931,932,935,936,940} The disulfide-linked multimers range in size from dimers ($M_r = 600,000$) to extremely large multimers of 20 million D. vWF has binding sites for factor VIII, heparin, collagen, platelet glycoprotein (gp) Ib, and platelet gpIIb-IIIa.^{941,942,943,944,945,946,947,948,949,950,951,952,953} and⁹⁵⁴

Function

vWF has multiple functions in hemostasis. vWF stabilizes factor VIII and protects it from inactivation by APC,^{185,955} thus significantly prolonging factor VIII half-life in circulation.^{761,763,764} vWF is a structural protein and is part of the subendothelial matrix. vWF also acts as a bridge between platelets and promotes platelet aggregation. The primary platelet-binding site for vWF is the gpIb-IX-V receptor complex. gpIb-IX-V is an active receptor on

P.461

unstimulated platelets and serves to promote platelet aggregation and adhesion to vWF in the absence of platelet activation.⁴⁰⁰ This is likely a key element in the procoagulant response serving to recruit and localize platelets to the site of damage before the events that induce platelet activation.⁹⁵⁶ Subsequent platelet activation also induces expression of another receptor complex, gpIIb-IIIa. The gpIIb-IIIa complex recognizes a number of adhesive proteins including vWF. gpIIb-IIIa receptor binding of these adhesive proteins creates a strong network of platelets, other cells and matrix components.

Endothelial cells secrete vWF multimers, which are larger than those found circulating in plasma.⁹⁵⁷ The function of these large multimeric forms of vWF is to bind to and agglutinate blood platelets under high shear rates. These large multimers of vWF are degraded by a specific metalloprotease called a disintegrinlike and metalloprotease domain with thrombospondin in type I motifs (ADAMTS)-13.^{958,959,960} In familial and acquired thrombotic thrombocytopenic purpura, ultra-large vWF multimers are correlated to defective ADAMTS-13 activity.⁹⁶¹

PROCOAGULANT PROTEINS: THROMBIN (FACTOR IIa)

The enzyme α -thrombin, or factor IIa, is the central enzyme in blood coagulation and plays myriad roles in hemostasis²³ as well as roles in tissue repair, development, and pathogenic processes.^{649,687,962,963} and⁹⁶⁴ α -Thrombin is the most potent activator of circulating platelets, thus providing the requisite surface for procoagulant activities. α -Thrombin cleaves fibrinogen to generate the fibrin clot,^{680,965,966} and⁹⁶⁷ converts factor XIII to factor XIIIa to crosslink and stabilize the clot,^{17,968} and, in association with thrombomodulin, activates TAFI, which delays dissolution of the fibrin clot.^{36,969} α -Thrombin also acts directly and indirectly to amplify its own production. The procofactors V and VIII are activated by α -thrombin^{682,683,782,970} as are factor XI⁷ and, potentially, factor VII.⁸ In an analysis of a whole blood model of coagulation, a time course of α -thrombin generation and of the protein products of its catalytic activities illustrates that most procoagulant responses to α -thrombin occur during the initiation phase before fibrin formation (Fig. 18.11).⁵⁶⁹ Less than 0.2% of the final α -thrombin produced is required to achieve the activation of its primary substrates in blood. After fibrin clot formation, during the propagation phase, the bulk of α -thrombin is formed (~95%).

FIGURE 18.11. Initiation, propagation, and termination of thrombin generation and the procoagulant response. A: Low levels of thrombin are required to initiate clot formation (initiation phase) and trigger the coagulation cascade response (propagation phase). The enzymes, cofactors, and inhibitors act together to generate a hemostatic response that can be divided into an initiation phase and a propagation/termination phase. During the initiation phase, factors X and IX are converted to their respective serine proteases factor Xa and factor IXa; low levels of thrombin are subsequently generated by factor Xa. This thrombin then can activate platelets and the procofactors factors V and VIII, which stimulate further thrombin generation during the propagation phase. Thrombin generation is attenuated by shutting down the initiation phase by means of the stoichiometric inhibitor of the extrinsic tenase complex, tissue factor pathway inhibitor (TFPI), followed by antithrombin (AT), which directly inhibits thrombin and factors Xa and IXa. B: Time course of early thrombin-antithrombin (TAT) complex formation from whole blood coagulation of 35 individuals is presented: y-axis, TAT (solid line [green diamonds]) and free thrombin [dashed line (blue squares)] concentrations (nmol/L) are shown on a log scale; x-axis, time in minutes.⁵⁶⁹ Arrows indicate the time and TAT concentration at which each of the indicated events (osteonectin [OSN] release, a marker of platelet activation, factor XIII activation [fXIIIa], fibrinopeptide A [FPA] release, fibrinopeptide B [FPB] release, and prothrombin activation) has entered a phase of rapid activation. The percent of total TAT present at the point of activation is shown in parentheses. APC, activated protein C; CT, clot time; PC, protein C; TF, tissue factor. (From Brummel KE, Paradis SG, Butenas S, Mann KG. Thrombin functions during tissue factor induced blood coagulation. *Blood* 2002;100:148-152, with permission.)

In addition, α -thrombin also acts as a mitogen in a variety of cell types^{685,686,687,688} and^{689,971,972,973,974} and⁹⁷⁵; induces the release of cytokines,^{976,977,978,979} and⁹⁸⁰ vasoactive compounds,^{981,982} and⁹⁸³ and chemoattractants⁹⁸⁴ as part of the response to vascular damage; and stimulates events that initiate tissue repair.^{985,986,987} and^{988,989}

α -Thrombin acts to indirectly inhibit its own generation through the protein C anticoagulation pathway, a dynamic inhibitory system. α -Thrombin forms the protein Case complex with its cofactor thrombomodulin, and activates protein C to APC.^{893,990} APC cleaves factors Va and VIIIa, thus inhibiting prothrombinase and intrinsic tenase function and blocking α -thrombin formation. The binding of α -thrombin to thrombomodulin both produces a potent anticoagulant and alters α -thrombin reactivity. Once bound to thrombomodulin, α -thrombin no longer recognizes fibrinogen as a substrate and no longer acts in a procoagulant capacity.^{991,992}

α -Thrombin generation must be tightly regulated to ensure that localized, adequate levels of the enzyme are produced. Markedly decreased levels of α -thrombin due to hypoprothrombinemia or reduced α -thrombin activity due to genetic mutation (dysprothrombinemia) are often characterized by bleeding diatheses.^{993,994} Conversely, elevated levels of α -thrombin promote the risk of thrombosis. A G→A transition at nucleotide position 20210 (G20210A) in the 3'-untranslated region of the prothrombin gene results in elevated plasma levels of prothrombin⁶⁵⁵ and is strongly associated with venous thrombotic events.^{995,996,997} and⁹⁹⁸

Roles in Coagulation

On phospholipids, membrane activation to α -thrombin proceeds through the obligate intermediate meizothrombin. In contrast, on platelets, the reaction has been reported to proceed through prothrombin 2 (see Fig. 18.8).⁶⁷⁰

Most prothrombin activation to α -thrombin proceeds through the obligate intermediate meizothrombin. Both meizothrombin and α -thrombin possess catalytic activity and cleave a variety of

P.462

substrates. Although meizothrombin is a short-lived intermediate in the activation process, it appears to play several important roles in coagulation. Meizothrombin is a potent vasoactive agent and acts on the adrenergic receptor to induce

vascular constriction. The vasoactive potency of meizothrombin is five to seven times greater than that of α -thrombin.^{999,1000} However, the ability of meizothrombin to activate platelets and cleave fibrinogen is greatly reduced compared to that of α -thrombin.^{673,1001} These are major roles for α -thrombin in promoting an efficient and effective procoagulant response. α -Thrombin has long been recognized as the most potent platelet agonist.⁶⁸¹ α -Thrombin induces release of platelet α -granule contents, including a number of procoagulant and adhesive proteins,^{187,893,1002,1003,1004,1005,1006,1007,1008,1009} and ¹⁰¹⁰ and of adenosine diphosphate from the platelet-dense granules. α -Thrombin also triggers the translocation of anionic phospholipid to the outer leaflet of the platelet membrane. α -Thrombin thus provides a cross-linked platelet mesh and an anionic surface appropriate for procoagulant complex assembly and function.

In addition, α -thrombin generates and stabilizes the fibrin clot. α -Thrombin cleaves the Arg¹⁶-Gly¹⁷ bond in the A α -chain and the Arg¹⁴-Gly¹⁵ bond in the B β -chain of fibrinogen, releasing fibrinopeptide A (FPA) and fibrinopeptide B (FPB), respectively.⁶⁸⁰ FPA and FPB release allow formation of overlapping fibrin strands.^{965,966} and ⁹⁶⁷ α -Thrombin cleavage of the 37-residue NH₂-terminal activation peptide of factor XIII generates the transglutaminase factor XIIIa.^{17,968} Factor XIIIa cross-links and stabilizes the fibrin clot by catalyzing the formation of intermolecular γ -glutamyl ϵ -lysyl isopeptide bonds between fibrin molecules.¹⁷ TAFI, also known as plasma carboxypeptidase B or carboxypeptidase U, is likewise activated in an α -thrombin-dependent manner to provide activated TAFI (TAFIa).^{36,969} TAFIa has carboxypeptidase B-like activity and is a key link between the coagulation and fibrinolytic cascades. TAFIa prevents premature clot lysis by cleaving COOH-terminal lysine and arginine residues on fibrin, rendering it a less suitable cofactor in t-PA-dependent plasminogen activation.¹⁰¹¹ At elevated concentrations, TAFIa also directly inhibits plasmin and therefore clot lysis.¹⁰¹¹ In addition, TAFI is a substrate for factor XIIIa and is cross-linked to fibrin and incorporated into the fibrin clot.¹⁰¹² The α -thrombin-dependent processes involved in clot formation and stabilization likely occur simultaneously to generate a mature clot that effectively reduces blood loss.¹⁰¹³

α -Thrombin has other key roles in procoagulant events as well. α -Thrombin activates factor XI^{7,617} and the procofactors factor V, factor VIII,^{682,683,782,970} and potentially factor VII.⁸ Meizothrombin likewise is an efficient activator of factor XI¹⁰¹⁴ and possibly factor V.¹⁰¹⁵ Meizothrombin is thought to function to enhance α -thrombin generation by activating factor XI before its final processing to form α -thrombin.

Roles in Anticoagulation

Although α -thrombin is the central enzyme in the procoagulant response, it is also a key mediator of anticoagulant events as well.¹⁰¹⁶ When α -thrombin binds to the cell membrane-associated cofactor thrombomodulin, the reactivity of α -thrombin is altered. α -Thrombin bound to thrombomodulin no longer cleaves fibrinogen or acts as a procoagulant enzyme.^{991,992} Instead, the α -thrombin-thrombomodulin complex, or protein Case, cleaves protein C to generate the enzyme APC. APC is a potent anticoagulant and inactivates the cofactors factor Va and factor VIIIa.^{991,1017} α -Thrombin activation of platelets also induces the release of anticoagulant and inhibitory proteins from the α -granules.^{299,1018,1019} and ¹⁰²⁰

Roles in Tissue Repair and Regeneration

Tissue repair and regeneration is the final phase of the hemostatic response to injury. Subsequent to lysis of the fibrin clot, multiple cell types choreograph the restructuring of the damaged vasculature. Vascular permeability is increased, and inflammatory cells accumulate at the site of injury. Smooth muscle cells, fibroblasts, and endothelial cells migrate to the site and proliferate. Cellular differentiation, as well as production and remodeling of the extracellular matrix, restores the vascular tissue. α -Thrombin contributes to these processes through a variety of interactions with different cell types. α -Thrombin is a potent mitogen^{685,686,971,972,973} and ⁹⁷⁴ and stimulates proliferation of smooth muscle cells,^{686,688,975} macrophages,⁶⁸⁷ and endothelial cells.^{687,689} The mitogenic effects of α -thrombin are due to direct activation of cellular proliferation or α -thrombin-induced secretion of a variety of growth factors, or both. Platelet activation, an early event in the procoagulant response, results in the release of a plethora of α -granule proteins that regulate cell growth, vascular permeability, and chemotaxis.^{310,1021,1022,1023,1024,1025,1026,1027} and ¹⁰²⁸ α -Thrombin thus mediates multiple aspects of the hemostatic response to vascular injury from the formation and stabilization of the initial fibrin plug to the final stages of tissue repair and regeneration.

Thrombin Receptors

Many of the effects of α -thrombin on platelets and cells are elicited through α -thrombin interaction with receptor molecules in which α -thrombin binds to a receptor and initiates a signal transduction mechanism. The interaction between α -thrombin and the human platelet thrombin receptor, protease-activated receptor (PAR)-1, however, is characterized by a more unusual mechanism in which the receptor is also a substrate for α -thrombin.^{989,1029,1030} PAR-1 is a

425-amino acid transmembrane protein with a large NH₂-terminal extracellular domain.^{989,1030} α-Thrombin cleaves the extracellular region of the receptor at Arg⁴¹, producing a “tethered ligand.” The new NH₂-terminus binds back to and activates the receptor.^{989,1030} PAR-1 is also found on T lymphocytes, monocytes, and endothelial cells and mediates the α-thrombin-induced responses of these cells as well.

Two additional α-thrombin receptors homologous to PAR-1 have also been identified: PAR-3 and PAR-4. PAR-3 is expressed on human platelets and endothelial cells, although at much lower levels than PAR-1.¹⁰³¹ PAR-3 is required for normal α-thrombin-dependent platelet activation in mice,⁷³⁶ but in the human system, the role of PAR-3 appears to be primarily in cellular development. PAR-3 is expressed at high levels on human megakaryocytes, the precursor cells of platelets.⁷³⁶ PAR-4, however, is believed to act in combination with PAR-1 as a dual mechanism to elicit the multiple effects of α-thrombin on human platelets.

Structure/Function Relationships

In vivo, α-thrombin is derived from proteolytic cleavage of prothrombin by the prothrombinase complex (Figs 18.3 and 18.8). Cleavage of the Arg³²⁰-Ile³²¹ bond in prothrombin yields meizothrombin. Subsequent cleavage of the Arg²⁷¹-Thr²⁷² bond gives rise to fragment 1.2 and α-thrombin. Human α-thrombin cleaves its own NH₂-terminus at Arg²⁸⁴-Thr²⁸⁵ to generate a stable α-thrombin molecule. The initial form of human α-thrombin has an NH₂-terminal A-chain of 49 residues, whereas the autocatalytically generated stable protein has an A-chain of 36 residues. The COOH-terminal B-chain of α-thrombin has 259 amino acid residues including the catalytic triad residues His³⁶³, Asp⁴¹⁹, and Ser⁵²⁵.

α-Thrombin is subject to further degradation resulting in stable, degraded thrombin molecules with reduced reactivity.^{1032,1033} and ¹⁰³⁴ These degraded forms are designated β- and γ-thrombin. The degradation of α-thrombin may be autocatalytic or may be due to proteolysis by enzymes other than α-thrombin. Human β-thrombin is generated by cleavage at Arg³⁸² and Arg³⁹³, which deletes a segment of the α-thrombin B-chain.^{1035,1036} Cleavage of β-thrombin at Arg⁴⁴³ and Lys⁴⁷⁴ deletes an additional

P.463

segment of the B-chain and results in formation of γ-thrombin. β- and γ-thrombin retain some activity toward small peptide substrates,^{1000,1037} factor XIII,¹⁰³⁸ antithrombin,¹⁰³⁹ prothrombin,¹⁰⁴⁰ and factor XI.¹⁰⁴¹ However, both β- and γ-thrombin have no significant ability to cleave fibrinogen or protein C.^{640,1039,1042} These proteolyzed forms of α-thrombin have been identified as products of the blood clotting reaction in vivo,⁶⁷⁹ but their mechanism of production and function is unknown.

The stable form of human α-thrombin possesses at least five distinct binding sites for substrates, inhibitors, cofactors, apolar molecules, and sodium ions (Na⁺). The apolar binding site is located near the catalytic center of α-thrombin.¹⁰⁴³ The Na⁺ binding site is in the B-chain, in a cavity formed by three antiparallel β sheets, and appears to play a role in determining whether α-thrombin acts as a procoagulant or an anticoagulant. In the presence of Na⁺, α-thrombin recognizes fibrinogen as a substrate and acts as a procoagulant. In the absence of Na⁺, α-thrombin has increased specificity for protein C and functions in an anticoagulant capacity.^{1044,1045} The binding of Na⁺ therefore appears to mediate the dual nature of α-thrombin as both a procoagulant and an anticoagulant.

Exosite I, the fibrinogen-binding site, is an anion-binding, electropositive site distinct from, but acting in concert with, the active site of the α-thrombin molecule.¹⁰⁴⁵ In addition to fibrinogen, exosite I also recognizes the COOH-terminal domain of hirudin, the hirudin-like region of PAR-1, and the fifth and sixth EGF-like domains of thrombomodulin.¹⁰⁴⁵ Detailed information about exosite I is available from the x-ray crystal structure of the α-thrombin-hirudin complex. In solution, the COOH-terminal domain of hirudin is disordered.^{1046,1047} However, in the α-thrombin-hirudin complex, the COOH-terminus of hirudin inserts into the large groove in the α-thrombin molecule to interact with exosite I. Hirudin also inserts into the active site of α-thrombin.^{1048,1049} and ¹⁰⁵⁰ The high-affinity interaction ($K_d = 2 \times 10^{-14}$ mol/L) between α-thrombin and the inhibitor hirudin is thus stabilized by electrostatic, polar, and hydrophobic interactions.^{1048,1051}

Exosite II is a second electropositive, anion-binding site located on the opposite side of the α-thrombin molecule compared to exosite I. Exosite II recognizes the COOH-terminal region of the B-chain of thrombin and sulfated polysaccharides such as heparin and the chondroitin sulfate moiety of thrombomodulin.¹⁰⁴⁵

The active site of α-thrombin is responsible for mediating interactions with substrate molecules including fibrinogen, protein C, and antithrombin.¹⁰⁴⁵ The active site of α-thrombin is similar to the active sites of trypsin and chymotrypsin. However, unlike the relatively nonspecific pancreatic enzymes, α-thrombin also has secondary binding sites, exosites I and

II, that confer specificity to α -thrombin. For substrates such as fibrinogen, there may be multiple secondary binding sites.¹⁰⁵²

Regulation

α -Thrombin regulates its own production through complex formation with thrombomodulin and activation of protein C (Fig. 18.6). α -Thrombin enzymatic activity is mediated mainly by antithrombin-III. The inhibitory activity of antithrombin is potentiated *in vivo* by cell-expressed heparan sulfate GAGs or by pharmaceutical heparins.^{694,695} Antithrombin inhibits α -thrombin through formation of a covalent complex with the active site of α -thrombin.¹⁰⁵³ α -Thrombin-antithrombin (TAT) complexes are rapidly cleared from the circulation by the liver.¹⁰⁵⁴

α -Thrombin is also inhibited by α_2 -macroglobulin, a broad specificity proteinase inhibitor. α_2 -Macroglobulin does not appear to be a primary inhibitor of α -thrombin, but rather functions as a secondary inhibitor.¹⁰⁰⁰ Unlike antithrombin, α_2 -macroglobulin does not complex with the active site of its target enzymes. Enzymes in complex with α_2 -macroglobulin retain the ability to cleave small peptidyl substrates, although they are unable to cleave large substrates.¹⁰⁵⁵ α -Thrombin interaction with α_2 -macroglobulin involves limited proteolysis of α_2 -macroglobulin. Subsequent to cleavage, α_2 -macroglobulin undergoes a conformation change that traps the enzyme inside the α_2 -macroglobulin molecule.^{1056,1057} The α_2 -macroglobulin-enzyme complexes are rapidly cleared from circulation.^{1058,1059}

ANTICOAGULANT PROTEINS: DYNAMIC INHIBITORY SYSTEM

The protein C pathway provides a dynamic inhibitory system to regulate α -thrombin production.^{1060,1061,1062} The activity of this anticoagulant pathway is directly dependent on the level of α -thrombin production. The protein C activating complex, or protein Case, is a membrane-dependent multiprotein complex similar to the membrane-dependent procoagulant complexes (Figs. 18.4 and 18.6). The key proteins in the protein C pathway are α -thrombin, thrombomodulin, protein C, and protein S.

Protein C

Protein C, first identified as a thrombin inhibitory activity or autoprothrombin II-A,¹⁰⁶³ is the zymogen form of the enzyme APC. Protein C circulates at a concentration of 4 $\mu\text{g/ml}$ (65 nmol/L) with a $t_{1/2}$ of 8 to 10 hours^{1064,1065} and ¹⁰⁶⁶ (Table 18.4). The $t_{1/2}$ of protein C is markedly shorter than most other members of the vitamin K-dependent protein family and is the likely basis of the transient hypercoagulable state subsequent to administration of coumarin-based anticoagulants.^{1067,1068,1069,1070} and ¹⁰⁷¹ Homozygous protein C deficiency is associated with severe thrombotic tendencies and can result in fatal neonatal thrombotic events.¹⁰⁷² Heterozygous protein C deficiency is associated with increased risk of thrombosis.^{1073,1074} and ¹⁰⁷⁵ The mutation in factor V^{Leiden}, which blocks a key APC cleavage site in factor V^{Leiden}, is another defect leading to an alteration in the protein C anticoagulant pathway and predisposition to thrombosis.

Gene Structure and Expression

The protein C gene is located on chromosome 2 bands q14-q21 and spans 11 kb with eight introns and nine exons^{1076,1077} (Table 18.6). The promoter region contains HNF-1, HNF-3, and Sp1 binding sites that promote gene expression.^{1078,1079} HNF-3 is a liver-specific transcription factor.

Biochemistry

Protein C is synthesized in the liver as a single-chain polypeptide with a prepro sequence of 42 amino acids. The prepro protein is subsequently processed to remove the leader sequence and the dipeptide Lys¹⁵⁶-Arg¹⁵⁷. Thus, in plasma, most protein C circulates as a heterodimer consisting of a disulfide-linked (Cys¹⁴¹-Cys²⁷⁷) heavy and light chain.^{1080,1081,1082,1083,1084} and ¹⁰⁸⁵ However, approximately 5% to 10% of circulating protein C is the single-chain form.³⁶¹ The twochain form of human protein C ($M_r = 62,000$) is a 419-amino acid glycoprotein with approximately 23% carbohydrate (Table 18.4 and Fig. 18.3B). The NH₂-terminal light chain (residues 1 to 155; $M_r = 21,000$) contains the Gla domain (residues 6 to 29; nine Gla residues) and a hydrophobic region that connects the Gla domain to two EGF domains (residues 55 to 90 and 94 to 134). The COOH-terminal heavy chain (residues 158 to 419; $M_r = 41,000$) contains the serine protease domain. Residues 158 to 169 constitute the activation peptide domain. A β -hydroxy aspartate residue (Asp⁷¹) in the first EGF domain is required for Ca²⁺-dependent alterations in protein C. Ca²⁺ binding is mediated by the first EGF domain as well as the Gla domain and the serine protease

P.464

domain.^{354,398,402,1086,1087,1088,1089,1090} and ¹⁰⁹¹ Leu⁵ in the NH₂-terminus is important in mediating phospholipid binding.⁴⁰⁰ There are several glycosylation variants (Asn⁹⁷, Asn²⁴⁸, Asn³¹³, and Asn³²⁹) with two to four N-linked carbohydrate

chains.³⁶¹ The major forms, α -protein C and β -protein C, have four and three carbohydrate moieties, respectively. All the protein C carbohydrate variants can be activated, but appear to have different anticoagulant properties and rates of activation.¹⁰⁹² An x-ray crystal structure has been determined for Gla-domainless activated protein C.³⁸²

Activation

Protein C is the zymogen form of the enzyme APC. Protein C is cleaved at the Arg¹⁶⁹-Leu¹⁷⁰ bond, releasing its activation peptide from the heavy chain to generate the active enzyme.^{1093,1094} The α -thrombin-thrombomodulin complex is likely the major physiologic activator of protein C.¹⁰⁹⁵ There are other activators as well. Plasmin activates and then inactivates protein C.^{1068,1096} Meizothrombin also binds thrombomodulin and can efficiently activate protein C.^{674,1097} Factor Xa has likewise been reported to bind to thrombomodulin and activate protein C¹⁰⁹⁸; however, this mechanism has not been confirmed in subsequent studies.^{1099,1100} More recently, glycosaminoglycans have been shown to potentiate factor Xa-mediated protein C activation.¹¹⁰¹ Copperhead snake venom also contains a protein C activator.¹¹⁰²

Function

APC is a serine protease with key anticoagulant functions. The most important anticoagulant role for the protein C pathway is the proteolytic inactivation of factor Va. APC inactivates factor Va via a series of proteolytic cleavages, thus inhibiting the generation of α -thrombin. APC also cleaves and inactivates factor VIIIa, although the spontaneous dissociation of the factor VIIIa A2 domain is the probable physiologic regulator of factor Xa generation. Full inactivation of factor Va by APC requires an anionic phospholipid surface, and the rates of APC inactivation of factors Va and VIIIa are enhanced by protein S.¹¹⁰³

APC also has a profibrinolytic effect. This effect is due to TAFI. TAFI is activated by the α -thrombin-thrombomodulin complex and acts to prolong clot lysis. APC cleavage of factor Va inhibits α -thrombin generation, thus reducing α -thrombin-thrombomodulin-mediated TAFI activation.¹¹⁰⁴ The prolongation of clot lysis by TAFIa likely contributes to the prothrombotic tendencies associated with factor V^{Leiden}.¹¹⁰⁵

The endothelial cell protein C receptor provides cell-specific binding sites for both protein C and APC.^{1106,1107} However, two other coagulation proteases, factors VIIa and Xa, have been shown to bind to this receptor.¹¹⁰⁸ Endothelial cell protein C receptor is downregulated by TNF- α .¹¹⁰⁷ Monocytes appear to express specific binding sites for APC that are distinct from endothelial cell protein C receptor.^{1109,1110} The cell-expressed binding sites may be important in the antiinflammatory

properties of APC.¹¹¹¹ APC blocks the septic shock response in animal models^{1112,1113} and has shown clinical success in severe sepsis patients.^{1114,1115} APC reduces the levels of inflammatory cytokines such as TNF- α .^{1113,1116} The antiinflammatory properties of APC are also due to inhibition of α -thrombin generation and, therefore, inhibition of the proinflammatory properties of α -thrombin.

Regulation

Protein C activation and APC activity are controlled on several levels. Inflammatory agents such as endotoxin, IL-1 β , transforming growth factor- β (TGF- β), and TNF- α regulate protein C activation on endothelial cells.^{1117,1118,1119,1120,1121,1122,1123,1124,1125} and¹¹²⁶ TNF- α is responsible for downregulation of thrombomodulin on the endothelial cell surface.^{1120,1123,1124,1125} and¹¹²⁶ There are multiple other factors that downregulate thrombomodulin as well. APC activity is regulated mainly by the protein C inhibitor or PAI-3.^{1127,1128} and¹¹²⁹

Protein S

Protein S is a vitamin K-dependent protein that is not a serine protease precursor. Protein S circulates at a plasma concentration of 20 μ g/ml (300 nmol/L)^{1130,1131} (Table 18.4). Approximately 40% of protein S circulates in the free form, and the remaining 60% circulates as a 1:1 complex with C4b-binding protein (C4bBP), a regulatory protein of the complement system.¹¹³⁰ Protein S is thought to function as a cofactor for APC in the inactivation of factors Va

P.465

and VIIIa.^{185,1132,1133,1134,1135,1136} and¹¹³⁷ Heterozygous deficiency of protein S increases the risk for developing thrombosis; however, the diagnosis is complicated.¹¹³⁸ The protein S cofactor effect is minimal, however, and does not correlate with the thrombotic pathologies manifested in protein S-deficient patients.^{1139,1140,1141,1142,1143,1144} and¹¹⁴⁵ Protein S has also been reported to inhibit prothrombin activation through several mechanisms.^{696,1146,1147} and¹¹⁴⁸ Although the precise function of protein S is not clear, protein S is important in anticoagulation.

Gene Structure and Expression

The gene for protein S is located on chromosome 3 and spans at least 80 kb^{1149,1150} (Table 18.6). The gene contains 15 exons and 14 introns.^{1149,1151,1152} A second copy of the protein S gene has also been identified; however, this second gene is likely a pseudogene.^{1153,1154} The pseudogene spans approximately 55 kb and differs from the protein S gene in that it lacks exon 1 and has multiple nucleotide substitutions. Protein S is synthesized in the liver^{1155,1156} and by a variety of other cell types including endothelial cells,^{1157,1158} and¹¹⁵⁹ osteoclasts,¹¹⁶⁰ and lymphoid cells.¹¹⁶¹ Protein S is also found in the α -granules of platelets.¹⁰¹⁹

Biochemistry

Protein S ($M_r = 69,000$) is a single-chain glycoprotein with approximately 8% carbohydrate and 11 Gla residues^{584,1162} (Table 18.4 and Fig. 18.3B). Protein S is synthesized with a signal sequence and propeptide region of 41 amino acids.^{1151,1152,1156,1163} The mature form of the protein has 635 amino acids and is organized into eight domains: An NH₂-terminal Gla domain (residues 1 to 45), an aromatic stack, a 29-residue thrombin-sensitive domain (residues 46 to 75), four EGF domains (residues 76 to 242), and a COOH-terminal domain homologous to the sex hormone-binding globulin and androgen-binding protein.^{1164,1165} The Gla domain and EGF domains mediate Ca²⁺ binding.¹¹⁶⁶ The Gla domain is also involved in interactions with phospholipid membranes.¹¹⁶⁷ C4bBP binds to the COOH-terminal sex hormone-binding globulin domain.^{1168,1169} Protein S reversibly self-associates in the absence of Ca²⁺.¹¹⁷⁰

Function

The precise function of protein S in the protein C inhibitory pathway is not clearly defined. Protein S enhances APC inactivation of factors Va and VIIIa in a phospholipid-dependent fashion.^{185,1132,1133,1134,1135,1136} and¹¹³⁷ The interaction between protein S and APC alters the structure of APC and moves the APC active site closer to the membrane surface.¹¹⁷¹ Protein S may also serve directly in an anticoagulant capacity. Protein S has been reported to bind to factor Xa,¹¹⁴⁷ factor VIII,¹¹⁷² and factor Va¹¹⁴⁶ to compete for prothrombinase-binding sites on the membrane surface^{696,1148} and to stimulate the inhibition of factor Xa by TFPI.^{1173,1174} These interactions serve to inhibit prothrombin activation in vitro.¹¹⁷⁵ The C4bBP-protein S complex may inhibit factor X activation as well.¹¹⁷⁶

Protein S also has additional potential roles outside of anticoagulation. Protein S interaction with T cells promotes T cell aggregation and proliferation and may serve to regulate inflammatory processes.¹¹⁷⁷

Regulation

α -Thrombin cleavage of protein S at Arg⁴⁹, Arg⁶⁰, or Arg⁷⁰ in the thrombin-sensitive domain inhibits the ability of protein S to act as a cofactor for APC.^{1136,1178,1179} and¹¹⁸⁰ Protein S activity is also regulated by interaction with C4bBP. The 1:1 complex between protein S and C4bBP neutralizes the anticoagulant capacity of protein S. Approximately 60% of plasma protein S circulates bound to C4bBP.

Protein Z

Protein Z, a vitamin K-dependent glycoprotein, is an enzymatically inactive homolog of factors VII, IX, and X, and protein C.³⁶⁴ Protein Z was first identified in bovine plasma by Prowse and Esnouf in 1977,¹¹⁸¹ and later in human plasma by Broze and Miletich in 1984.¹¹⁸² The name protein Z came about from its being the last of the vitamin K-dependent proteins to elute during anion exchange chromatography.¹¹⁸³ Protein Z circulates in plasma in a complex with protein Z-dependent protease inhibitor (ZPI).¹¹⁸⁴ This inhibitor, ZPI, has been identified as a 72-kDa member of the serpin superfamily.

Reports suggest that protein Z behaves as a negative acute-phase reactant.^{1185,1186} Protein Z levels have been found to be low in newborn infants^{1187,1188} and in individuals with DIC,¹¹⁸⁹ liver disease,¹¹⁹⁰ and amyloidosis.¹¹⁹¹ High plasma levels have been found in individuals on chronic hemodialysis and with idiopathic thrombocytopenic purpura.^{1192,1193} Protein Z levels also appear to be more susceptible to warfarin therapy than other vitamin K-dependent proteins.¹¹⁹⁴

Gene Structure and Expression

The gene for protein Z is located on chromosome 13 at band q34 (Table 18.6). It spans approximately 14 kb and consists of nine exons, including one alternative exon.³⁶⁴ The gene organization is similar to that of the other vitamin K-dependent proteins, factors VII, IX, and X, and protein C.

Homozygous and heterozygous protein Z-deficient mice showed no abnormalities in growth and development. Protein Z deficiency has been reported to be prothrombotic in nature in factor V^{Leiden} mice.¹¹⁹⁵ In general, evidence supports the anticoagulant role of the complex between protein Z and the serpin protein Z-dependent protease inhibitor (ZPI) and the thrombotic consequences of its deficiency.^{1196,1197} and¹¹⁹⁸ Protein Z-deficient mice crossed with factor V^{Leiden} mice did not have viable progeny. Several clinical studies identified diminished levels of plasma protein Z in patients with unidentified bleeding disorders.^{1219,1200} Protein Z has also been identified in liver disease¹¹⁹⁰ and atherosclerosis.¹²⁰¹

Biochemistry

Protein Z has a molecular weight of 62,000 and circulates in plasma at a mean concentration of $2.9 \pm 1.0 \mu\text{g/ml}$ ^{1182,1194} (Table 18.4). The plasma $t_{1/2}$ of protein Z is 2.5 days.¹¹⁹⁴ Structurally, protein Z is similar to factors VII, IX, and X, and protein C, containing a Gla domain (13 residues) and two EGF domains at its NH₂-terminus^{364,1202,1203} (Fig. 18.3B). However, like protein S, protein Z does not function as a protease. The COOH-terminus contains a region homologous to the catalytic domains present in the serine protease zymogens. The catalytic triad is not present in protein Z, except for the conserved Asp residue.^{1202,1203}

Function

Protein Z is a vitamin K-dependent protein that does not function as a serine protease enzyme. Protein Z circulates in plasma in complex with ZPI. The function of protein Z in vivo is still unclear to date.¹²⁰⁴ It has been reported that protein Z inactivates factor Xa by forming a Ca²⁺-dependent complex with factor Xa bound to phospholipid with the help of ZPI.¹¹⁸⁴ Factor IXa has also been reported to be a target for the protein Z/ZPI system.¹²⁰⁵ The overall importance of these protein Z/ZPI activities is unclear.¹¹⁹⁶ In vitro, protein Z has also been shown to have a weak interaction ($K_d = 8.9 \mu\text{mol/L}$) with thrombin that facilitates the binding of thrombin to phospholipid surfaces.¹²⁰⁶ It is also consumed, like all other coagulation factors and inhibitors, during the course of DIC.

P.466

Thrombomodulin

Thrombomodulin is a type 1 transmembrane protein constitutively expressed on the surface of vascular endothelial cells (Fig. 18.9). It is an essential that displays a range of antiinflammatory, anticoagulant, and antifibrinolytic properties.¹²⁰⁷ Thrombomodulin is a high-affinity receptor for α -thrombin and acts as a cofactor for the α -thrombin-dependent activation of protein C and TAFI. Thrombomodulin activity on the surface of endothelial cells is decreased by inflammatory cytokines and may contribute to the hypercoagulation characteristic of inflammatory states. Thrombomodulin is expressed widely during fetal development.¹²⁰⁸ Homozygous thrombomodulin-deficient mice die in utero before the formation of the cardiovascular system, suggesting a potential role for thrombomodulin in mammalian development.¹²⁰⁹

Gene Structure and Expression

The human thrombomodulin gene is located on chromosome 20 band p-12cen and spans 3.7 kb^{1210,1211} (Table 18.6). The gene is unusual in that it lacks introns.^{1212,1213} Thrombomodulin expression has been reported in a variety of cell types, including vascular endothelial cells,^{1214,1215} neutrophils,¹²¹⁶ monocytes,^{1217,1218} platelets,¹²¹⁹ synovial cells,¹²²⁰ and squamous epithelial cells.^{1221,1222} and¹²²³ Vascular expression is limited to endothelial cells. Thrombomodulin activity on the surface of endothelial cells is decreased by homocysteine, lipopolysaccharide, IL-1 β and TNF- α .^{1117,1118,1224,1225,1226} Many of these same inflammatory agents that downregulate thrombomodulin also upregulate tissue factor, contributing to the hypercoagulation associated with inflammation. Hypoxia also downregulates thrombomodulin expression.¹²²⁷ Likewise, thrombomodulin expression is decreased by glucose-modified albumin, which may provide a link to diabetic thrombotic complications.¹²²⁸ Conversely, dibutyl cyclic adenosine monophosphate, retinoic acid, shear stress, and increased temperature (42°C) upregulate thrombomodulin activity on endothelial cells.^{1229,1230,1231,1232} and¹²³³ Upregulation of thrombomodulin expression by TNF- α may involve a consensus sequence of a cyclic adenosine monophosphate response element in the 3'-untranslated region of the thrombomodulin gene.¹²³⁴ Increased thrombomodulin gene transcription due to elevated temperature is mediated by consensus sequence recognition sites for a heat shock element in the 5'-promoter region.¹²³³ Upregulation of thrombomodulin expression in response to elevated temperature may be a protective mechanism to compensate for the procoagulant effects of the inflammatory mechanism.

Biochemistry

Human thrombomodulin is synthesized with an 18-amino acid signal sequence followed by a 557-residue polypeptide chain of the mature protein.^{1210,1212,1213,1235} Thrombomodulin has five different domain structures: An NH₂-terminal domain having weak homology to lectins (residues 6 to 149) such as the asialoglycoprotein receptor,¹²³⁶ six EGF-like domains (residues 227 to 462), a 34-residue region rich in serine and threonine corresponding to potential O-linked glycosylation sites (residues 463 to 497), a 23-residue hydrophobic transmembrane region (residues 499 to 521), and a COOH-terminal domain (residues 522 to 557) containing several potential phosphorylation sites and one free cysteine residue (Cys⁵³⁶) (Fig. 18.9). The fifth and sixth EGF domains support α -thrombin association.¹²³⁸ The region required for efficient protein C activation extends from the linker region between EGF domains 3 and 4 through EGF-6.^{1238,1239,1240} and¹²⁴¹ Ser⁴⁷² and Ser⁴⁷⁴ in the serine- and threonine-rich region are potential sites for chondroitin sulfate addition.¹²⁴² The presence of chondroitin sulfate increases the affinity for α -thrombin more than 10-fold,¹²⁴³ thus increasing the ability of thrombomodulin to block fibrinogen cleavage and platelet activation by α -thrombin.^{1244,1245} The chondroitin sulfate moiety also enhances inactivation of α -thrombin by antithrombin^{1244,1246} and modulates the Ca²⁺ dependence of protein C activation.^{1243,1246} The O-linked sugar domain of thrombomodulin is required for APC generation on cellular surfaces. This domain is extended and rigid and rises approximately perpendicular to the membrane surface. The O-linked sugar domain likely functions to elevate α -thrombin from the membrane surface.¹²⁴⁷ The active site of α -thrombin bound to thrombomodulin is located approximately 65 Å from the membrane surface.¹²⁴⁸

Although no consensus sequence for internalization via coated pit-mediated endocytosis is found in thrombomodulin, coated and noncoated pit-mediated endocytosis has been observed.¹²⁴⁹ Internalization appears to be mediated by the NH₂-terminal lectin-like domain.¹²⁵⁰

Function

Thrombomodulin functions as a cofactor for α -thrombin in the activation of protein C and TAFI. Production of APC by the α -thrombin-thrombomodulin complex is approximately 1,000 times faster than by equivalent concentrations of protein C and thrombin. Once bound to thrombomodulin, α -thrombin's procoagulant activities are neutralized. The high-affinity α -thrombin-thrombomodulin interaction is mediated mainly by exosite I on the α -thrombin molecule. Exosite I also binds fibrinogen, and the interaction of α -thrombin with thrombomodulin therefore blocks fibrinogen binding and cleavage. In addition, thrombomodulin induces conformational changes in α -thrombin.^{1251,1252,1253,1254,1255} and¹²⁵⁶ Overall, the changes that occur on α -thrombin interaction with thrombomodulin reduce the ability of α -thrombin to generate fibrin, and to activate factor V and platelets,^{1257,1258} while increasing the rate of inactivation of α -thrombin by antithrombin.^{1259,1260} and¹²⁶¹ α -Thrombin-thrombomodulin, or protein Case, functions solely in an anticoagulant and antifibrinolytic capacity.

Regulation

There are several potential mechanisms of thrombomodulin regulation on the cell surface. Thrombomodulin expression is downregulated by endotoxin and inflammatory cytokines.¹¹²³ Shear stress, homocysteine, and hypoxia likewise downregulate thrombomodulin expression.^{1226,1227,1232,1262} α -Thrombin may also regulate thrombomodulin activity, although evidence is somewhat controversial. Thrombomodulin-dependent α -thrombin internalization has been

reported.^{1263,1264} and ¹²⁶⁵ However, the α -thrombin-thrombomodulin complex appears to be stable under some conditions.^{1017,1266} In addition, thrombomodulin activity can be regulated proteolytically, mainly by neutrophil elastase.^{1267,1268} Neutrophils decrease thrombomodulin activity via oxidation as well.¹²⁶⁹

ANTICOAGULANT PROTEINS: PROTEINASE INHIBITORS

Proteinases, enzymes that hydrolyze peptide bonds, are found in a wide array of biologic systems, including the blood coagulation process (clot formation and fibrinolysis), digestive system, apoptotic cascades, and the immune system. To keep these systems in balance between activation and inhibition, a complex system of proteinase inhibitors has evolved. In blood, proteinase inhibitors constitute a significant percentage of circulating proteins. In general, proteinases that activate the coagulation and fibrinolytic cascades have highly defined substrate specificities. Coagulation is kept in check through the action of several specific and broad-spectrum proteinase inhibitors. Specific clot formation inhibitors are antithrombin and TFPI. Fibrinolysis-specific

P.467

inhibitors are PAI-1 and α_2 -antiplasmin. Together, specific and broad-spectrum inhibitors function to localize, limit, and control hemostasis.

α_2 -Macroglobulin

α_2 -Macroglobulin is a nonspecific proteinase inhibitor that targets a broad spectrum of protease substrates.¹²⁷⁰ It is present in human plasma at concentrations ranging from 2 to 4 $\mu\text{mol/L}$ (2 to 3 mg/ml) (Table 18.4). α_2 -Macroglobulin can also be found at higher concentrations in extravascular fluids.¹²⁷¹ This protease inhibitor can be produced in a variety of cells including hepatocytes, fibroblasts, and macrophages.^{1058,1272} α_2 -Macroglobulin is also found in several species including the horseshoe crab.¹²⁷³

Reduced levels of serum α_2 -macroglobulin in humans have been observed in individuals with chronic obstructive lung disease¹²⁷⁴ and cancer metastasis.¹²⁷⁵ In humans, no absolute deficiency has been reported to date, leading to the suggestion that such a congenital deficiency is incompatible with survival. The inactivation of the mouse α_2 -macroglobulin gene results in viable mice that produce normal-sized litters but are more resistant to endotoxin challenge.¹²⁷⁶ In a later study, it was suggested that this phenotype in mice functions as a neutralizer of transforming growth factor- β and as an inducer of nitric oxide synthesis.¹²⁷⁷

Gene Structure and Expression

The gene encoding human α_2 -macroglobulin spans approximately 48 kb and consists of 36 exons and 35 introns¹²⁷⁸ (Table 18.6). It is located on chromosome 12p12.3-13.3.^{1279,1280} and ¹²⁸¹ The α_2 -macroglobulin gene is a single copy gene in the human genome. α_2 -Macroglobulin is synthesized in the liver as a pro- α_2 -macroglobulin, which contains a 23-residue signal peptide. Three transcription initiation sites, including a TATA box, a TATA-like structure (ATAAA), and a potential HP-1 binding site, have been identified in the liver.¹²⁷⁸

Biochemistry

Human α_2 -macroglobulin circulates in plasma as a tetramer with four identical single-chain subunits with an individual relative molecular weight of 180,000 and a total relative molecular weight of 735,000.^{1279,1282,1283} An unusual feature of this protein is that multiple forms may be found in various species and may appear only during acute-phase reactions.^{1058,1271,1272} A dimeric form termed pregnancy zone protein has been found in human plasma at peak levels during the last trimester. Therefore, this protein may be found in human plasma composed of either two or four identical subunits.^{1284,1285}

α_2 -Macroglobulin has a unique mechanism by which it achieves broad specificity.¹²⁸⁶ The initial step involves the "bait region" of α_2 -macroglobulin.¹⁰⁵⁷ This region consists of a 25-amino acid sequence that has sequence motifs appropriate for many proteases.¹²⁸⁷ After proteolysis in this bait region, α_2 -macroglobulin undergoes conformational changes that trap the proteinase inside the molecule.¹⁰⁵⁷ The crystal structure of human α_2 -macroglobulin displays a large central cavity capable of containing one or two average-sized proteases.¹²⁸⁸ These conformational changes have been referred to as a slow to fast transition.^{1056,1057} The active site of the substrate proteinase is not found in complex with the inhibitor. Studies have shown that the entrapped proteinase is no longer able to interact with macromolecular substrates, inhibitors, and antibodies, but still appears to retain its ability to react with small substrates and inhibitors.¹⁰⁵⁷ These complexes are rapidly cleared from the circulation by the endocytic α_2 -macroglobulin receptor also known as the low-density lipoprotein

receptor-related protein (LRP). This receptor is found on most mast cells and tissues. The proteinase inhibitor complex has an approximate $t_{1/2}$ of 2 to 5 minutes.¹⁰⁵⁸

Another important feature of α_2 -macroglobulin is the presence of a β -cysteinyl- γ -glutamyl thiol ester.^{1289,1290} Studies have shown that these thiol esters may directly react with small nucleophiles, such as ammonia or methylamine; induce a conformational change; and prevent proteinase binding.¹²⁹¹ The conformational changes associated with proteolysis of the bait region generate a thiol ester more susceptible to nucleophilic attack, with the result that surface Lys residues of the trapped proteinase can react with it and become covalently linked to α_2 -macroglobulin. Binding studies in vitro have identified specific high-affinity receptors for α_2 -macroglobulin-proteinase complexes on many cell types, including fibroblasts, macrophages, and hepatocytes.¹⁰⁵⁹

Function

One role for α_2 -macroglobulin is to inhibit a broad range of proteinases. It is distinctive in its capacity to inhibit members from each of four mechanistic classes of proteinases (serine, cysteine, and aspartic proteinases, and metalloproteinases). α_2 -Macroglobulin functions as a secondary inhibitor to serine proteinases in plasma by inhibiting thrombin, kallikrein, and plasmin.^{1292,1293} It may also be important in preventing thromboembolic events when there is a congenital deficiency of antithrombin or sepsis.^{1294,1295} α_2 -Macroglobulin also inhibits various growth factors and cytokines, including TGF- β ,¹²⁹⁶ IL-1 β ,¹²⁹⁷ IL-6,¹²⁹⁸ acidic fibroblast growth factor,¹²⁹⁹ basic fibroblast growth factor,¹²⁹⁹ TNF- α ,¹³⁰⁰ and IL-2.¹³⁰¹ Polymorphisms identified in α_2 -macroglobulin have been thought to play a role in Alzheimer disease.^{1302,1303} and ¹³⁰⁴ Overall, the biologic role of α_2 -macroglobulin in vivo is still being elucidated.

Tissue Factor Pathway Inhibitor

TFPI, formerly called extrinsic pathway inhibitor or lipoprotein-associated coagulation inhibitor, is a multivalent, Kunitz-type plasma proteinase inhibitor. TFPI modulates tissue factor-dependent coagulation in vivo by rapidly inhibiting the extrinsic tenase complex (factor VIIa-tissue factor) as soon as it is formed^{1305,1306} and ¹³⁰⁷ (Fig. 18.6). It circulates in plasma at approximately 0.1 $\mu\text{g}/\text{ml}$ ¹³⁰⁸ as a heterogeneous collection of partially proteolyzed forms^{1309,1310} and ¹³¹¹ (Table 18.4). Ninety percent of circulating TFPI is found associated with lipoproteins, primarily low-density lipoprotein.^{1310,1312,1313} Parenteral TFPI is cleared from the circulation primarily by the liver and has an unusually short $t_{1/2}$ (minutes) compared to other proteinase inhibitors.

Many reviews of TFPI have been published.^{1314,1315,1316,1317} and ¹³¹⁸ The importance of TFPI in blood coagulation has been best illustrated through transgenic mice that have a complete deficiency (-/-) of TFPI. This deficiency is incompatible with birth and survival.¹³¹⁹ However, this lethality in mice can be rescued by heterozygous or homozygous factor VII deficiency.¹³²⁰ This implies that diminishing the level of factor VII lessens the need for TFPI-mediated inhibition of the factor VIIa-tissue factor coagulation pathway during embryogenesis.¹³²⁰ When mice are generated that have a combined heterozygous TFPI deficiency and homozygous apolipoprotein E deficiency, they exhibit a greater atherosclerotic burden.¹³²¹ These observations suggest a role for TFPI in protection from atherosclerosis and as a potential regulator of thrombosis.

To date, there are no known human TFPI-deficient individuals described, which suggests that human embryos with TFPI^{-/-} genotype fail to develop. A role for TFPI in preventing thrombosis and other cardiovascular diseases is currently under intensive clinical and in vitro investigation.¹³²² One application for recombinant TFPI is in the area of sepsis in which patients frequently have reduced TFPI levels.^{1323,1324}

Gene Structure and Expression

The human TFPI gene has been localized to chromosome 2 bands q31-q32.1^{1325,1326} and ¹³²⁷ (Table 18.6). It spans 85 kb, over half of which

P.468

consists of the 5' noncoding region. The coding region is distributed over nine exons¹³²⁸; mature TFPI contains three Kunitz domains that are encoded on separate exons. The gene specifies a protein of 304 amino acids; the first 28 residues comprise a signal peptide. Two variants of TFPI (isoforms α and β) arising from alternative splicing have been identified; the variable region involves residues 210 to 251 of the primary gene product, spanning a large portion of the third Kunitz domain. TFPI is expressed constitutively by cultured endothelial cells, and its level of synthesis is hardly affected by endotoxin or inflammatory cytokines.^{1311,1329} TFPI is not expressed by hepatocytes. TFPI is found bound to low- and high-density lipoproteins located within platelets or noncovalently associated with endothelial cell heparin sulfate

proteoglycans.¹³⁰⁸ TFPI is catabolized in the liver and kidney by uptake/degradation via the low-density LRP or its homologs.¹³³⁰

Biochemistry

TFPI (M_r = 40,000) is a single-chain glycoprotein of the Kunitz proteinase inhibitor family.^{1331,1332} As isolated, the COOH-terminus of TFPI displays some degradation. Structurally, mature full-length TFPI (276 amino acids in the α isoform) consists of an acidic NH₂-terminal region, three tandem Kunitz-like serine protease inhibitor domains (K1 to K3), and a positively charged COOH-terminal region^{1330,1331} (Fig. 18.12). The tandem Kunitz domains are essential for the function of TFPI.¹³⁰⁸ The Kunitz 1 inhibitor domain (residues 26 to 76) binds factor VIIa-tissue factor. The second Kunitz domain (residues 97 to 147) of TFPI binds the factor Xa active site. The Kunitz 3 domain (residues 189 to 239) of TFPIα binds protein S, and the protein S mediated potentiation of factor Xa inhibition by TFPIα involves protein S-Kunitz 3 interaction.¹³³³ Heparin binds at two heparin-binding sites: a high-affinity site in the COOH-terminal basic region and a low-affinity site between Gly²¹² and Phe²⁴³ in the third Kunitz domain.^{627,628,1334}

Tissue factor pathway inhibitor (TFPI): 40 kDa

Antithrombin (AT): 58 kDa

FIGURE 18.12. Soluble stoichiometric inhibitors. Tissue factor pathway inhibitor (TFPI) contains three Kunitz domains. TFPI inhibits the serine protease factor Xa (FXa) directly and tissue factor-factor VIIa complex in a factor Xa-dependent mechanism, shutting down the extrinsic pathway of coagulation. Kunitz 1 domain binds factor VIIa, Kunitz 2 domain binds factor Xa, and Kunitz 3 binds protein S, with this interaction reported to enhance the activity of TFPI.¹³³³ The COOH-terminus of TFPI contains a basic region, the cell-binding domain, which binds to heparin. Antithrombin (AT) contains two intrachain disulfide bonds (-S-S-) in its NH₂-terminus and one in its COOH-terminus with a carbohydrate-rich domain (CHO) in between. Asn¹³⁵ is not glycosylated in the β form of AT. The region of interaction between the active sites of target proteases and AT is illustrated as a circle (reactive center loop) above the reactive site bond R³⁹³-S³⁹⁴. Heparin binding occurs in the NH₂-terminus, involving interactions with residues R⁴⁷, K¹¹⁴, K¹²⁵, and R¹²⁹, and enhances the rate of inhibition of certain serine proteases.

TFPI contains three potential N-linked glycosylation sites (Asn¹¹⁷, Asn¹⁶⁷, and Asn²²⁸), with one or more of these oligosaccharides sulfated during expression by cultured endothelial cells.¹³³⁵ Two O-linked glycosylation sites have also been identified (Ser²⁰² and Thr²⁰³). A significant proportion of TFPI molecules in the blood is truncated to variable extents at the COOH-terminal end (some lacking most of the third Kunitz domain) and has compromised inhibitory activity.¹³³⁶ In

contrast, TFPI released by heparin infusion is full length and more active than the truncated forms.¹³³² The inhibitory activity of TFPI is enhanced by heparin.

P.469

The normal plasma concentration of TFPI is 0.1 µg/ml. TFPI α is found either associated with lipoproteins, such as low- and high-density lipoproteins or lipoprotein(a), complexed noncovalently to endothelial cell heparan sulfate proteoglycans¹³³⁷; or associated with endothelial cell surfaces via a glycosyl-phosphatidylinositol (GPI) anchor.^{1315,1316} On heparin administration, TFPI is released from endothelial cells, primarily microvascular, causing a two- to 10-fold increase in circulating TFPI levels.^{1332,1338,1339} TFPI release on heparin therapy is responsible for the observed elevation in PT and raises the possibility that a portion of the antithrombotic effect of the polysaccharide may be mediated by TFPI. GPI-anchored TFPI α is not released by heparin therapy and represents the largest in vivo pool of TFPI. A minor pool of TFPI (~10% of total TFPI in blood) is located within platelets and is released after dual stimulation by collagen and thrombin.¹⁰²⁰ TFPI β has Kunitz 1 and Kunitz 2 domains and a unique C-terminal region that contains a GPI-anchor sequence.¹³¹⁶

The qualitative and quantitative properties of TFPI can be altered both by the genotype of an individual and by environmental factors. This is illustrated by in vitro experiments in which factor V^{Leiden} is combined with reduced levels of TFPI. Factor V^{Leiden}, when combined with TFPI levels that are at the low end (50%) of the normal range, can produce an unregulated propagation phase of thrombin generation in a synthetic plasma system.¹³⁴⁰ In a control with normal factor V, the propagation phase of thrombin generation is attenuated substantially at the tissue factor concentrations used in this experiment (i.e., it is near threshold). With factor V^{Leiden} and low normal TFPI, the propagation phase of thrombin generation is equivalent to a situation in which the protein C regulatory system is totally dysfunctional. This observation suggests the risk of thrombotic pathology. An in vivo parallel to this in vitro experiment has been reported by Eitzman et al.,¹³⁴¹ who showed that factor V^{Leiden} (+/+) mice with reduced levels of TFPI (+/-) died of thrombosis.

Function

TFPI is the principal stoichiometric inhibitor of the extrinsic pathway (factor VIIa-tissue factor) of coagulation (Fig. 18.6). The extrinsic pathway generates low levels of the serine proteases, factor IXa (~1 pmol/L), and factor Xa (~10 pmol/L).⁵⁶⁷ As soon as the proteases are formed, factor Xa can activate prothrombin to generate thrombin, and factor IXa can combine with its cofactor factor VIIIa and form the intrinsic tenase complex to generate more factor Xa. This is followed by the formation of the prothrombinase complex (factor Xa-factor Va), which converts prothrombin to thrombin. The TFPI mechanism allows the factor VIIa-tissue factor complex to initiate factor Xa formation but then suppresses high levels of factor Xa product formation by this complex. TFPI is the principal regulator of the initiation phase of thrombin generation⁵⁶⁷ (Fig. 18.11).

The actual mechanism involves a rapid interaction between the second Kunitz domain of TFPI with the factor Xa active site; localization of the complex to the membrane surface is mediated by the Gla domain of factor Xa.^{628,1342,1343} Once surface bound, the factor Xa-TFPI complex rapidly inactivates tissue factor-factor VIIa. This complex formation depends on the binding of the first Kunitz domain of TFPI to the factor VIIa active site. These interactions together form a stable quaternary complex, tissue factor-factor VIIa-TFPI-factor Xa. Ethylenediaminetetraacetic acid (EDTA) can readily dissociate this inhibited quaternary complex. Protein S enhances TFPI α inhibition of factor Xa¹¹⁷³; although whether this affects TFPI α suppression of the factor VIIa-tissue factor complex is controversial.¹³⁴⁴

Inhibition of factor VIIa-tissue factor by TFPI is not completely dependent on the presence of factor Xa because the factor IXa-TFPI complex can also bind to and inhibit factor VIIa-tissue factor. However, the binding affinity of TFPI for factor IXa is significantly less than for factor Xa. The physiologic relevance of this route of inhibition is thus debatable because high plasma concentrations of TFPI are required. At normal plasma concentrations, this multicomponent interaction of TFPI allows basal function of the factor VIIa-tissue factor complex but inhibits it after more extensive activation occurs.

When combined with the stoichiometric inhibitor antithrombin, a synergistic regulatory effect of blood coagulation occurs by inducing kinetic "thresholds" such that the initiating tissue factor stimulus must achieve a significant magnitude to propel thrombin generation.¹³⁴⁵ Tissue factor concentrations below the threshold concentration are ineffective in promoting robust thrombin generation because of the cooperative influence of the inhibitors; concentrations in excess of the threshold yield robust and almost equivalent thrombin generation. In a similar fashion, TFPI and the dynamic protein C-thrombomodulin-thrombin system cooperate to provide a threshold-limited, synergistic inhibition of thrombin production.¹³⁴⁶ In this instance, TFPI slows the initiation phase, whereas the APC system reduces the availability of the cofactors factors Va and VIIIa, thereby shutting down the propagation phase of thrombin generation (Fig. 18.11).

Regulation

TFPI administered intravenously to rats and mice is cleared rapidly from the circulation by liver hepatocytes, which recognize its COOH-terminal region (third Kunitz domain and basic COOH-terminus).^{1347,1348} and ¹³⁴⁹ TFPI is cleared by the promiscuous endocytic receptor, low-density LRP. Several lines of evidence suggest that TFPI binding to heparin-like sites on the cell surface may precede its catabolism by LRP. In addition, TFPI appears to be important for factor Xa catabolism. TFPI-factor Xa complexes are cleared by a liver receptor that is distinct from LRP.

ANTICOAGULANT PROTEINS: SERINE PROTEASE INHIBITOR SUPERFAMILY (SERPIN)

Inhibitory serpins are irreversible covalent suicide protease inhibitors. These inhibitors target serine proteases, a family of proteolytic enzymes sharing common active site architectures and common catalytic mechanisms. Key features of these enzymes include a nucleophilic serine hydroxyl moiety that attacks the carbonyl group of the targeted bond and the formation of a transient acyl-enzyme intermediate between the enzyme and the NH₂-terminal part of the substrate polypeptide. In vivo, when a serpin successfully reacts with a protease, catalysis of serpin proteolysis is arrested at the acyl-enzyme stage, and the serpin-enzyme complex is cleared from the circulation by specific receptormediated processes. Members of this multigene inhibitor family include antithrombin, heparin cofactor II, α₁-proteinase inhibitor (also known as α₁-antitrypsin), C1 esterase inhibitor, protein C inhibitor, PAI-1, α₂-antiplasmin, protein Z-dependent protease inhibitor, and protease nexin-1. Plasminogen activator-1 and α₂-antiplasmin are discussed in detail in the section on Inhibitors of the Fibrinolytic System, and protein Z-dependent protease inhibitor is discussed briefly in the section on Protein Z. Serpins function in diverse physiologic processes including blood coagulation, fibrinolysis, complement activation, angiogenesis, apoptosis, inflammation, neoplasia, and viral pathogenesis^{1350,1351} and ¹³⁵² (Table 18.7). When a member of the serpin family is either deficient or dysfunctional, several biologic disorders are evidenced, including thrombosis,^{1353,1354} emphysema,¹³⁵⁵ lupus erythematosus,¹³⁵⁶ liver disease,¹³⁵⁷ and dementia.¹³⁵⁸

In the past two decades, advances have been made to further understand the mechanism of action of serpins.^{1053,1359,1360,1361,1362,1363,1364,1365,1366} and ^{1367,1368,1369,1370} Serpins in uncleaved states

P.470

(native or latent) and cleaved states have been crystallized.^{1367,1371,1372} Achievement of the first crystal structure for a serpin-protease complex (α₁-antitrypsin-trypsin)¹³⁷³ has confirmed the physical displacement of the tethered protease: The conformation of α₁-antitrypsin in the complex is superimposable with that of the isolated cleaved α₁-antitrypsin. The crystal structure also revealed that the translocated, tethered protease has undergone an overall 37% loss of structure with its catalytic site radically disrupted.

TABLE 18.7 SERPIN INHIBITORS

Serpin	System(s) Regulated	Target Protease(s)	Deficiency State
Antithrombin	Coagulation	Thrombin, FXa, FIXa, kallikrein ^a , FXIa, and FVIIa ^b	Thrombosis Thrombosis in some individuals
Heparin cofactor II	Coagulation	Thrombin	None reported
Protein C inhibitor	Coagulation	APC, kallikrein	Pulmonary emphysema
α ₁ -Proteinase inhibitor	Inflammation	Elastase	—
	Tissue remodeling	Cathepsin G	—
	Coagulation	APC, FXIa, and FXa	—
Plasminogen activator inhibitor-1	Fibrinolysis	Tissue-type plasminogen activator, urokinase-type plasminogen activator	Bleeding

α_2 -Antiplasmin	Fibrinolysis	Plasmin	Bleeding
C1 esterase inhibitor	Complement	C1r, C1s	Angioedema
	Contact factors	FXIIa, kallikrein	—
	Coagulation	FXIa	—
Protease nexin-1	Coagulation	Thrombin	None reported

APC, activated protein C; F, factor.

^a Reaction also requires the presence of high-molecular-weight kininogen.

^b Antithrombin-heparin inhibits factor VIIa only when bound to tissue factor.

Inhibitory serpins share a similar backbone structure but expose a variable reactive site loop. This loop binds to the catalytic groove of the target proteases. Serpin specificity derives in part from the sequence of the reactive site loop and also from secondary binding sites.^{1374,1375} Initially, the reaction of a serpin and serine protease involves formation of a noncovalent Michaelis complex between the exposed reactive site loop and the protease active site. Exosite interactions between the two molecules, or in some cases, exosite binding of a cofactor, induce structural changes that increase the availability of the reactive site loop. Reversible complex formation is followed by reaction of the active site serine residue of the protease with the serpin "bait" peptide bond to form an acyl-enzyme intermediate. Trapping of this covalent complex between the reactive site loop and the protease appears to involve a process that both physically translocates the reactive loop-protease complex approximately 71 Å from the initial docking site and induces a general disordering of the protease's conformation with consequent loss of any further catalytic activity.¹³⁷³ The energy for translocation and structural alteration of the protease derives from the insertion of the proteolytically released reactive site loop of the serpin into β sheet A of its central core. A kinetic partitioning of serpin-protease reactions between stable inhibited complexes and mixtures of regenerated enzyme and proteolyzed serpin reflects the relative rates of reactive site loop insertion versus deacylation.¹³⁷⁶ A number of recent reviews have been written on the known serpin conformations and their biologic significance.^{1350,1377,1378,1379,1380,1381,1382,1383} and ¹³⁸⁴

Antithrombin

Antithrombin is a member of the serpin proteinase inhibitory family and circulates in blood as a single-chain glycoprotein²⁹⁶ (Table 18.4). Its $t_{1/2}$ is approximately 61 to 72 hours.^{1385,1386} Other names for antithrombin include antithrombin-heparin cofactor and heparin cofactor. Despite its name, antithrombin inhibits not only thrombin, but also many of the other enzymes in the coagulation pathway. Congenital antithrombin deficiency exhibits an autosomal dominant pattern of inheritance, with an incidence of 1:2,000 to 1:5,000.¹³⁸⁷ The complete absence of antithrombin is lethal. Individuals with this deficiency have partial expression of antithrombin and are prone to thromboembolic disease.¹³⁸⁸ Inherited deficiency is categorized by either quantitative defect with a reduction in antigen and activity (type I) or qualitative with reduced antithrombin functional activity and normal antigen levels (type II).¹³⁸⁹ These defects are caused by a variety of mutations that include insertions, deletions, and missense mutations.^{1390,1391,1392} Function can be compromised by mutations in the thrombin-binding domain or the heparin-binding domain. Unstable variants of antithrombin have been identified in families with severe episodic thrombotic disease. Acquired antithrombin deficiency occurs in patients with sepsis or severe traumatic shock.^{1393,1394} Therefore, studies are being conducted on the use of antithrombin as an agent for treating coagulation abnormalities associated with sepsis or other inflammation disorders.^{1395,1396}

Gene Structure and Expression

The gene encoding antithrombin is located on chromosome 1 in the q23-q25 region¹³⁹⁷ and spans 13.5 kb of genomic DNA¹³⁹⁸ (Table 18.6). The gene is composed of seven exons and six introns.¹³⁹⁸ The mechanisms underlying antithrombin gene expression are not well established. It is primarily expressed in the liver with low levels detected in the brain and kidney. Cis-acting elements and trans-acting factors have been identified that regulate constitutive expression of the human antithrombin gene.¹³⁹⁹

Biochemistry

Human antithrombin is a single-chain glycoprotein ($M_r = 58,000$) that circulates in blood at a concentration of approximately 140 $\mu\text{g/ml}$ (2.4 $\mu\text{mol/L}$).^{296,1400} It circulates as two glycoforms,

P.471

α and β variants, that contain identical polypeptide backbones but differ in carbohydrate content and heparin affinity.¹⁴⁰¹ The antithrombin α variant is the predominant form (~90%).¹⁴⁰² The structure of antithrombin α consists of 432 amino acid residues, with three disulfide bonds and four sialylated oligosaccharides at Asn⁹⁶, Asn¹³⁵, Asn¹⁵⁵, and Asn¹⁹² (Fig. 18.12). The carbohydrate residues account for 15% of the total mass.^{1402,1403,1404,1405} The antithrombin β variant is not glycosylated at Asn¹³⁵. Antithrombin β binds heparin more tightly than does antithrombin α and is observed to preferentially accumulate on the vessel wall when heparan sulfate proteoglycans are exposed.¹⁴⁰⁶ The reactive site peptide bond is Arg³⁹³-Ser³⁹⁴.

The first x-ray crystal structure of antithrombin that was determined was a cleaved form that diffracted to 3.2 Å resolution.¹⁴⁰⁷ Significant differences between structures of antithrombin and another serpin, α_1 -antitrypsin, were identified in the NH₂-terminal region that defines the heparin-binding site. Since then, several x-ray crystal structures of intact antithrombin have been solved to 2.6 to 3.0 Å.^{1408,1409} and ¹⁴¹⁰

Function

Antithrombin has a broad spectrum of inhibitory activity with most of its target proteases participating in the coagulation cascade. It is primarily an inhibitor of the serine protease thrombin as well as factor Xa, factor IXa, factor VIIa-tissue factor, factor XIa, factor XIIa, and plasma kallikrein.^{1411,1412} and ¹⁴¹³ Antithrombin plays a key role in maintaining hemostasis. Antithrombin also displays antiproliferative and antiinflammatory properties that primarily derive from its ability to inhibit thrombin. In addition, latent or cleaved forms of antithrombin have antiangiogenic activities.¹⁴¹⁴ Heparins and heparan sulfates potentiate these reactions and are used in the treatment of thrombosis.¹⁴¹⁵ When antithrombin is complexed with heparin, its rate of inhibition of several coagulation proteases is accelerated by up to 10,000-fold.

In general, binding of heparins to antithrombin improves its reactivities with proteases in two ways: (1) By inducing conformational changes in antithrombin, including better presentation both of the reactive center loop and of exosites on antithrombin that interact with target enzymes; and (2) by enabling a template effect, whereby binding of enzyme and antithrombin to the same heparin molecule improves the likelihood of the interaction.

The mechanism of inhibition involves reaction of the active site of the enzyme with a peptide loop structure (reactive center loop, Fig. 18.12) of the serpin to form a tight, equimolar (1:1) complex. Inactivation is suspected to proceed through covalent bond formation between antithrombin and the protease, followed by inactivating structural rearrangements of both antithrombin and the protease. However, the exact mechanism of inhibition of serine proteases by antithrombin is uncertain. In the case of factor Xa inhibition, crystallographic data indicate that heparin-induced conformational change in antithrombin permits contacts between antithrombin and the active site and two exosites of factor Xa.¹⁴¹⁶

Heparin Cofactor II (Leuserpin 2)

Heparin cofactor II, also called leuserpin 2, is a member of the serpin family.¹⁴¹⁷ Like antithrombin, heparin cofactor II inhibits thrombin in a reaction that is accelerated more than 1,000-fold by heparin.¹⁴¹⁸ However, heparin cofactor II is unique in that it is also stimulated by the proteoglycan dermatan sulfate. The plasma concentration of heparin cofactor II is 0.5 to 1.4 $\mu\text{mol/L}$ ^{1419,1420} (Table 18.4). Its plasma $t_{1/2}$ is approximately 2.5 days. The physiologic role of heparin cofactor II is uncertain at the present time. Low levels of thrombin-heparin cofactor II complexes are detected in normal plasma samples; elevated levels were detected in patients with DIC.¹⁴²¹ Although inherited deficiency of heparin cofactor II has been associated with thrombosis, this is not always the case.^{1422,1423} and ¹⁴²⁴ The incidence of heparin cofactor II deficiency in patients with thromboembolytic disorders appears to be similar to that in the normal population.¹⁴²⁵

Gene Structure and Expression

The gene encoding human heparin cofactor II, consisting of five exons and four introns, spans approximately 14 kb on chromosome 22 in the q11 region proximal to the breakpoint cluster region.^{1426,1427} The human heparin cofactor II gene is expressed exclusively in the liver and by a hepatoma-derived cell line.^{1428,1429}

Biochemistry

Human heparin cofactor II ($M_r = 66,000$) circulates as a singlechain protein of 480 amino acid residues that contains 10% carbohydrate.^{1419,1427,1428} It is glycosylated at Asn³⁰, Asn¹⁶⁹, and Asn³⁶⁸ and is sulfated at Tyr⁶⁰ and Tyr⁷³. It has three cysteines with no identified disulfide bonds. A cationic region of the molecule encompassing residues 163 to 194 constitutes the GAG binding site; dermatan sulfate and heparin bind to heparin cofactor II at nonidentical but overlapping

sites in this region.^{1430,1431} Residues Lys¹⁷³, Arg¹⁸⁴, Lys¹⁸⁵, Arg¹⁸⁹, Arg¹⁹², and Arg¹⁹³ have been specifically implicated in heparin binding.¹⁴³² The NH₂-terminal region of heparin cofactor II contains a cluster of acidic residues that are thought to interact with the positively charged GAG binding site.^{1433,1434} This "acidic" tail of heparin cofactor II contains two so-called hirudin domains—Glu⁵⁶AspAspAspTyrLeuAsp⁶² and Glu⁶⁹AspAspAspTyrIleAsp⁷⁵; in each, the Tyr residue is sulfated. It has been proposed that the NH₂-terminal "acidic" tail is constrained in the native structure through association with the highly cationic heparin-binding region. In the presence of GAG, the acidic region is displaced from the heparin-binding site, thus making it available for binding to the anion-binding exosite I of thrombin.¹⁴³⁵ However, crystallographic studies of heparin cofactor II indicate that the acidic tail of heparin cofactor II is flexible in the crystal and not associated with the heparin-binding site.¹³⁶⁷ Other functionally important regions of heparin cofactor II include a chemotactic peptide harbored between residues Asp⁴⁹ and Tyr⁶⁰ that is released by leukocyte proteases.¹⁴³⁶ Residues Phe⁴⁵⁶ to Ile⁴⁶⁰ constitute a pentapeptide recognition motif for the hepatic serpin-enzyme complex receptor that may be involved in clearance of heparin cofactor II-enzyme complexes.¹⁴³⁷

The domain of heparin cofactor II with homology to other serpins is at the COOH-terminus of the protein. It exhibits approximately 30% homology to antithrombin and other serpins. The reactive site peptide bond is Leu⁴⁴⁴-Ser⁴⁴⁵.¹⁴³⁸ This reactive center loop sequence is consistent for an inhibitor with specificity for proteases with a preference for nonpolar residues with relatively bulky side chains in the P1 position. Two such proteases, chymotrypsin and cathepsin G, do react with heparin cofactor II. Thrombin reactivity with heparin cofactor II is unusual because thrombin generally prefers substrates with arginine in the P1 position. Exosite binding interactions, such as that between the hirudin-like sequences of heparin cofactor II and exosite I of thrombin, compensate for the less than ideal structure of the P1 residue and allow thrombin to form a productive Michaelis complex with heparin cofactor II.^{1367,1439}

Function

The only coagulation enzyme inhibited by heparin cofactor II appears to be thrombin.¹⁴⁴⁰ However, the rate of thrombin inhibition by heparin cofactor II in the absence or presence of GAGs is significantly slower than by antithrombin under similar conditions. Considering that the plasma concentration of heparin

P.472

cofactor II is 25% to 50% that of antithrombin and that low levels of heparin cofactor II are not strongly associated with thrombosis,¹⁴⁴¹ the physiologic role of heparin cofactor II as a systemic thrombin inhibitor has been questioned. In vitro, heparin cofactor II inhibition of thrombin is stimulated by dermatan sulfate proteoglycans synthesized by fibroblasts and vascular smooth muscle cells.¹⁴⁴² Thus, heparin cofactor II may be uniquely suited to regulate extravascular thrombin in areas of vascular endothelium disruption, in which heparin cofactor II would be exclusively stimulated by dermatan sulfate in the subendothelial layers.¹⁴⁴³ In addition, heparin cofactor II may participate in regulation of acute inflammation and wound healing by harboring a peptide chemotactic for neutrophils and monocytes that is released by leukocyte proteolysis.¹⁴³⁶

Heparin cofactor II may also have a role in protection from thrombosis during pregnancy. Increased levels of dermatan sulfate in the maternal and fetal circulation¹⁴⁴⁴ along with increased levels of heparin cofactor II in pregnant women have been reported.^{1445,1446} Heparin cofactor II has also been reported to potentiate the activation of endothelial cells and promote angiogenesis.¹⁴⁴⁷

α_1 -Proteinase Inhibitor (α_1 -Antitrypsin)

α_1 -Proteinase inhibitor is the most abundant circulating inhibitor of the serpin family. It is a single-chain glycoprotein that circulates in blood at a concentration of 1.5 to 3.5 mg/ml with a relative molecular weight of 53,000^{1272,1448} (Table 18.4). It is synthesized predominantly in the liver and has a $t_{1/2}$ of 6 days.¹⁴⁴⁹ α_1 -Proteinase inhibitor is considered an acute-phase reactant.¹⁴⁵⁰

Deficiency in α_1 -proteinase inhibitor is a common autosomal recessive disorder (1:1,600 to 1:1,800) that can potentially be lethal.^{1451,1452} It is found associated with emphysema,¹³⁵⁵ liver cirrhosis,¹³⁵⁷ and hepatocellular carcinoma.¹³⁵⁷ Treatment for α_1 -proteinase inhibitor deficiency relies on infusions of human plasma-derived α_1 -proteinase inhibitor.¹⁴⁵³ Progress is under way to develop a therapy based on gene repair^{1454,1455} and¹⁴⁵⁶ or strategies to block aberrant conformational transitions.^{1452,1453,1457}

Gene Structure and Expression

The gene for α_1 -proteinase inhibitor is located on chromosome 14 band q32.1, is approximately 5 kb long,¹⁴⁵⁸ and contains seven exons and six introns^{1458,1459,1460} and¹⁴⁶¹ (Table 18.6). Uniquely, α_1 -antichymotrypsin, corticosteroid-binding

globulin, kallistatin, and protein C inhibitor also map to the same region on chromosome 14.^{1460,1462,1463} These genes are actively transcribed in the liver and cultured hepatoma cells. However, a few other cell types (macrophages and intestinal epithelial cells) express some of these serpin genes.¹⁴⁶⁴ Hepatocyte nuclear factor-1 α and hepatocyte nuclear factor-4 play important roles in expression of the α_1 -proteinase inhibitor gene in hepatic, intestinal, and pulmonary epithelial cells.¹⁴⁶⁵

Biochemistry

α_1 -Proteinase inhibitor is the most studied of the serpins, with high-resolution crystal structures achieved for the inhibitor by itself and in complex with a target protease.¹³⁷³ The 452-amino acid sequence for human α_1 -proteinase inhibitor shows two disulfide bridges and four glucosamine-based carbohydrate chains.^{1466,1467} The reactive site bond that is targeted by serine proteinases is between Met³⁵⁸ and Ser³⁵⁹.¹⁴⁶⁸ Studies using ¹³C nuclear magnetic resonance spectroscopy of the complex between human¹³C methionine-labeled α_1 -proteinase inhibitor and porcine pancreatic elastase have shown that a tetrahedral intermediate complex is formed during the serpin-proteinase interactions.¹⁴⁶⁹ The three-dimensional x-ray crystal structure of cleaved α_1 -proteinase inhibitor identified that for activity, α_1 -proteinase inhibitor requires the insertion of a single residue, Thr³⁴⁵, into β sheet A.¹⁴⁷⁰ This was supported by the x-ray crystal structures of α_1 -proteinase inhibitor complexed with synthetic peptides that correspond to the unprimed NH₂-terminal side of the active site loop.¹⁴⁷¹ The five-stranded β sheet A of α_1 -proteinase inhibitor undergoes conformational changes that facilitate and stabilize the insertion into sheet A of the reactive center loop after cleavage by its target serine proteases. The solution structure of α_1 -proteinase inhibitor has also been characterized by high-flux neutron scattering and by synchrotron x-ray scattering.¹⁴⁷²

Function

α_1 -Proteinase inhibitor can inhibit a wide range of serine proteases. Its primary physiologic target is the inhibition of neutrophil elastase to protect the elastin fibers of the lung. The role of α_1 -proteinase inhibitor in blood coagulation is minimal. It has been shown to inhibit factor XIa in vivo^{1473,1474} to be an important inhibitor of factor Xa in purified and plasma systems.⁶³⁰ APC complexes with α_1 -proteinase inhibitor have also been detected by enzyme-linked immunosorbent assay in patients with DIC.¹⁴⁷⁵ Inhibition by α_1 -proteinase inhibitor is heparin independent.

C1 Esterase Inhibitor

C1 esterase inhibitor is a member of the serpin proteinase inhibitor family that is present at 170 μ g/ml in blood¹⁴⁷⁶ (Table 18.4). It is predominantly synthesized in the liver. When complexed with a protease (e.g., factor XIa), it has a $t_{1/2}$ of 95 to 104 minutes.¹⁴⁷⁴ Targets for C1 esterase inhibitor are found in the complement cascade and the coagulation cascade.

Deficiency in C1 esterase inhibitor can result in hereditary angioedema¹⁴⁷⁷ and has been identified in a patient with lupus erythematosus.¹³⁵⁶ Cases of acquired C1 esterase inhibitor deficiency have been reported associated with splenic lymphoma.^{1478,1479} C1 esterase inhibitor-deficient mice show no obvious phenotypic abnormality,¹⁴⁸⁰ although, in conjunction with a bradykinin type 2 receptor knockout, diminished vascular permeability was observed.¹⁴⁸⁰ The C1 esterase inhibitor is used in the treatment of hereditary angioedema^{1481,1482} and sepsis.¹⁴⁸³ Its potential use in reducing ischemia reperfusion injury is being investigated.¹⁴⁸⁴

Gene Structure and Expression

The primary structure of human C1 esterase inhibitor was initially determined by peptide and DNA sequencing.¹⁴⁸⁵ The only proteolytic processing that occurs is that a 22-residue signal peptide required for secretion is cleaved. The C1 esterase inhibitor gene is located on chromosome 11, bands p11.2-q13¹⁴⁸⁵ (Table 18.6). The C1 esterase inhibitor gene consists of eight exons and seven introns and is approximately 17 kb in length.¹⁴⁸⁶ In vivo, androgens enhance expression of C1 esterase inhibitor. In vitro studies show that C1 esterase inhibitor mRNA and protein levels increase after stimulation with γ - and α -interferon, TNF- α , IL-6, and monocyte colony-stimulating factor.¹⁴⁸⁶

The molecular defects found associated with C1 esterase inhibitor deficiency include Alu repeat-mediated deletions, missense mutations, frame-shifts, stop codon mutations, promoter variants, splice site mutations, or deletions of a few amino acids.^{1487,1488} The clinical manifestation of this deficiency is predominantly angioedema.

Biochemistry

C1 esterase inhibitor is a single-chain glycoprotein containing 478 amino acid residues that circulates with an apparent molecular

P.473

mass of 104,000 when analyzed by SDS-PAGE. The amino acids account for only 51% of the apparent molecular mass of the circulating protein, with 35% of the remaining mass accounted for by carbohydrate moieties.¹⁴⁷⁶ Neutron scattering, x-

ray crystal structure determinations, ¹H nuclear magnetic resonance spectroscopy, and Fourier transform infrared spectroscopy have been used to study the structure of C1 esterase inhibitor, revealing a two-domain structure.^{1489,1490} and ¹⁴⁹¹ The NH₂-terminus, containing 113 amino acids, is heavily glycosylated with three N-linked and seven O-linked oligosaccharides. The COOH-terminus contains 365 amino acids with three N-linked oligosaccharides. When C1 esterase reacts with target proteases, the serpin undergoes changes in its whole secondary structure—not only the reactive site loop.

Function

C1 esterase inhibitor is a member of the serpin inhibitor family. It plays an important role in the regulation of the classic complement pathway, specifically as the sole regulator of the activities of C1r and C1s.¹⁴⁹² C1 esterase inhibitor's role in coagulation is mainly targeted to the contact activation pathway through the regulation of kallikrein,^{179,1493} factor XII,¹³⁴ factor XIIa,¹³⁶, and factor XIa.^{286,293,1426,1427,1494} Unlike other serpin inhibitors, such as antithrombin, protein C inhibitor, or PAI-1, the activity of C1 esterase inhibitor is not affected by heparin.¹⁴⁹⁵

Protein C Inhibitor (Plasminogen Activator Inhibitor-3)

Protein C inhibitor is a member of the serine proteinase inhibitor family. It is also known as PAI-3. Protein C inhibitor is considered nonspecific in that its targets range from procoagulant, anticoagulant, and fibrinolytic enzymes to plasma and tissue kallikreins, the sperm protease acrosin, and prostate-specific antigen.^{1496,1497} It circulates in blood at a concentration of 5 µg/ml^{1498,1499} (Table 18.4), and is cleared from the circulation with a t_{1/2} of 1 day. When in complex with a target (e.g., APC), it is cleared from circulation with a t_{1/2} of 20 minutes.¹⁵⁰⁰ Hereditary or acquired protein C inhibitor deficiency has not been documented to date.¹⁵⁰¹ A case control study of thrombophilia showed that high levels of protein C inhibitor might constitute a mild risk factor for venous thrombosis. Protein C inhibitor-deficient mice (-/-) show impaired spermatogenesis and male infertility.¹⁵⁰²

Gene Structure and Expression

The gene for protein C inhibitor has been mapped to chromosome 14 band q32.1 (Table 18.6). It is 11.5 kb in length and consists of five exons separated by four introns.^{1503,1504} The organization and location of this gene are similar to those of the genes for α₁-antitrypsin and α₁-antichymotrypsin, suggesting a common ancestor for these genes.^{1503,1505,1506} Human protein C inhibitor is mainly synthesized in the liver,¹⁴⁹⁹ but has also been identified in platelets and megakaryocytes,^{1507,1508} the kidney,¹⁵⁰⁹ and the testes, seminal vesicle, and prostate.¹⁵⁰⁹

Biochemistry

Human protein C inhibitor in blood has a relative molecular weight of 57,000.^{1498,1505} The mature protein contains 387 amino acids; a 19-amino acid signal peptide is present before secretion. Five potential N-linked glycosylation sites were found in the mature protein,¹⁵⁰⁵ and their roles in protein C inhibitor activity have been studied by mutational analysis.¹⁵¹⁰ The reactive site bond is located at Arg³⁵⁴-Ser³⁵⁵, and a stable 1:1 molar complex is formed between protein C inhibitor and its target proteinases. Protein C inhibitor binds heparin, and its activity is accelerated when in complex with heparin¹⁵¹¹; unlike other related heparin-binding serpins such as antithrombin, heparin cofactor II, and protease nexin, the primary heparin-binding site of protein C inhibitor is in the H helix, not the D helix.¹⁵¹² A recent crystal structure of this inhibitor provides a structural basis for understanding its multiple functions.¹⁵¹³

Function

Protein C inhibitor is a nonspecific inhibitor of serine proteinases and inhibits APC, thrombin, thrombin-thrombomodulin, factor Xa, u-PA,^{1514,1515} and ¹⁵¹⁶ and t-PA.^{1517,1518} The major target of protein C inhibitor, as its name suggests, is APC,^{1500,1519,1520} although from a kinetic point of view, the reaction with thrombin-thrombomodulin is the most favorable.¹⁵¹⁸ This is the physiologically most important inhibitor of APC. Protein C inhibitor has been shown to regulate TAFI activation by inhibiting the thrombin-thrombomodulin complex.¹⁵¹⁴ Its importance as a dual regulator of coagulation and fibrinolysis remains unresolved.¹⁵²¹ The importance of the regulation of APC by protein C inhibitor is evident by the use of this complex as a marker for detection of deep vein thrombosis.¹⁵²² Other targets for protein C inhibitor include human kallikrein,¹⁸³ factor XIa,¹⁸³ factor Xa, and thrombin. Because there are no documented patients with a deficiency to date, the actual function of protein C inhibitor in vivo is yet to be elucidated.

PROTEINS OF CLOT FORMATION

Early efforts to understand how blood clots form were directed at dissecting the vertebrate coagulation system and determining its components. This work revealed the central event in blood coagulation to be the conversion of soluble fibrinogen (factor I) to insoluble fibrin. Basically, this is accomplished when the coagulation enzyme thrombin (factor IIa)

removes small polar peptides (termed fibrinopeptides) from each fibrinogen molecule, forming fibrin. These fibrin molecules noncovalently interact with each other, forming a fibrin web. Fibrin stabilization is accomplished by the action of a second coagulation enzyme (factor XIIIa) that introduces numerous covalent cross-links between these fibrin molecules. The resulting fibrin web is able to capture platelets and red blood cells, effectively sealing the wound and stemming plasma loss.

Factor XIII (Fibrin Stabilizing Factor)

The first apparent suggestion of cross-linked fibrin by factor XIII came in 1923 from Barkan and Gaspar, who reported that fibrinogen preparations, when clotted in the presence of Ca^{2+} , generated clots that were insoluble in weak bases.^{1523,1524} Later, in the 1940s, work by Robbins,¹⁵²⁵ Laki and Lorand,¹⁵²⁶ and Lorand¹⁵²⁷ confirmed the presence of a serum factor that caused the transition to an insoluble clot and termed it fibrin stabilizing factor. It was not until 1963 that the International Committee on Blood Clotting Factors acknowledged fibrin stabilizing factor as a clotting factor and termed it factor XIII.¹⁵²⁸ Recommended terms and abbreviations for factor XIII have been established.¹⁵²⁴

Factor XIII functions as a transglutaminase that can form cross-linked amide bonds between specific glutamine and lysine residues on polypeptide chains. It plays an important role in hemostasis and thrombosis as well as participating in physiologic processes of cell proliferation and cell migration. Factor XIIIa has multiple substrates including fibrin(ogen), fibronectin, α_2 -plasmin inhibitor, collagen, vitronectin, vWF, actin, myosin, factor V, and thrombospondin.^{1529,1530,1531,1532,1533,1534,1535,1536} and ¹⁵³⁷ Recent reviews discuss the role of factor XIII in blood clotting,¹⁵³⁸ angiogenesis,¹⁵³⁹ cellular function,¹⁵⁴⁰ inflammation,¹⁵⁴¹ and cardiac and vascular diseases.¹⁵⁴²

Gene Structure and Expression

Plasma factor XIII circulates as a heterotetramer composed of two A-chains and two B-chains. The genes are located on different

P.474

chromosomes. The gene for the factor XIII A subunit is located on chromosome 6, bands p24-25,^{1543,1544} and spans approximately 160 kb¹⁵⁴⁵ (Table 18.2). The gene has 15 exons specifying a mature protein of 730 amino acids. The circulating product of the B subunit gene is a protein of 641 amino acids. The gene is located on chromosome 1, bands q31-32.1,¹⁵⁴⁶ spans approximately 28 kb, and has 12 exons¹⁵⁴⁷ (Table 18.2). Ten short homologous units, termed sushi or glycoprotein-1 domains, are coded for by exons 2 to 11 in the B subunit gene.^{1548,1549} Proteins associated with regulation of the complement system also contain sushi domains.^{1550,1551}

Factor XIII deficiency is autosomal recessive and is a rare bleeding disorder. It has a frequency in the general population of 1 in 2 million.^{1552,1553} The phenotype displays varying degrees of bleeding and is typically associated with the absence of cross-linking of fibrin monomers and impaired cross-linking of α_2 -antiplasmin inhibitor to fibrin.¹⁵⁵⁴ Mutations have been identified in both the A and B subunits,¹⁵⁵⁵ with the latter being the least common. Reviews by Loewy et al.¹⁵⁵⁴ and Ariens et al.¹⁵⁵⁶ describe the deficiency mutations and polymorphisms for both gene products that have been identified to date.

Five common polymorphisms in the A subunit have been identified. Three of these (Val34Leu, Pro564Leu, and Glu651Gln) have allele frequencies > 0.2. Adverse effects have not been associated with the Glu651Gln variation; however, young women with the Leu564/Leu⁵⁶⁴ genotype may be at increased risk of hemorrhagic stroke.¹⁵⁵⁷ The (Val34→Leu) polymorphism in the A subunit is found in approximately 25% of the population.¹⁵⁵⁸ This Val to Leu replacement takes place three amino acids away from the thrombin cleavage site at Arg³⁷-Gly³⁸.¹⁵⁵⁸ Due to its close proximity to the thrombin cleavage site, it has been postulated that this mutation might modulate factor XIII activation. Studies suggest that this polymorphism is a determining factor in arterial and venous thrombosis.^{1559,1560,1561,1562,1563} and ¹⁵⁶⁴ This polymorphism has been suggested to be associated with a protective effect against myocardial infarction.^{1559,1565} The Leu encoding allele occurs at a lower frequency in patients exhibiting myocardial infarction, deep vein thrombosis, and cerebral infarction. Studies also showed that the Leu³⁴ mutation accelerates factor XIII activation by thrombin and affects fibrin cross-linking.^{1566,1567,1568} and ¹⁵⁶⁹ This acceleration has been proposed to account for the wide reference range reported for factor XIII activity. A study by Undas et al.¹⁵⁷⁰ demonstrated in a bleeding time blood model that aspirin has a more pronounced effect on factor XIII activation when individuals are carriers of the Leu³⁴ allele. The mechanism underlying the lower risk for myocardial infarction observed in the Leu³⁴ carriers, despite faster factor XIII activation, is still unclear.

Biochemistry

There are two pools of factor XIII—a plasma pool and an intracellular platelet pool. Plasma factor XIII circulates as a 320-kDa A₂B₂ heterotetramer composed of two identical A-chains (M_r = 83.2 kDa) and two B-chains (M_r = 79.7 kDa)¹⁵⁷¹ (Table

18.1). The A- and B-chains associate noncovalently with an apparent binding constant of 0.4 $\mu\text{mol/L}$.¹⁵⁷² Plasma concentration of factor XIII is approximately 30 $\mu\text{g/ml}$ (94 nmol/L),¹⁵⁷³ with a reference interval in the population of 66% to 134%.¹⁵⁷⁴ The A subunit contains 730 residues, is not glycosylated, and contains three important functional sites: the catalytic site (Cys³¹⁴-His³⁷³-Asp³⁹⁶), a calcium-binding site, and the activation peptide.^{1575,1576} The A subunit is arranged into five distinct structural domains: The activation peptide (residues 1 to 37); the β sandwich (residues 38 to 184); the catalytic core (residues 185 to 515); barrel 1 (residues 516 to 628); and barrel 2 (629 to 730). The activation peptide of one A subunit limits access to the active site cysteine of the other A subunit of the dimer. The B subunit contains 641 residues, is glycosylated, and contains 10 sushi domain repeats.¹⁵⁴⁸ Each sushi domain repeat contains approximately 60 amino acids and is stabilized by two disulfide bonds. By electron microscopy, the B domain appears as strands that are thin, flexible, and kinked.¹⁵⁷⁷ The B-chain has no enzymatic activity and has been thought to function as a carrier of the A subunit.^{967,1578,1579}

Several x-ray crystal structures of the zymogen factor XIII A₂ subunit have been solved up to 2.0 Å.^{968,1580} These studies revealed a catalytic triad of Cys³¹⁴-His³⁷³-Asp³⁹⁶ similar in structure to that observed in cysteine proteases. Crystal structures of thrombin-activated factor XIII have been solved with¹⁵⁸¹ and without Ca²⁺.^{1582,1583} and¹⁵⁸⁴

The bone marrow is the primary site of synthesis for the plasma factor XIII A-chain.^{1585,1586} and¹⁵⁸⁷ Intracellular factor XIII is present in platelets, megakaryocytes, and monocytes as the 160-kDa A₂ homodimer.^{1588,1589,1590} and¹⁵⁹¹ The intracellular A₂ dimer, located in the cell cytosol, does not contain a leader sequence or carbohydrate, and its amino terminus is acetylated. How the A₂ dimer is transferred out of the cell and which cell type is the primary source of plasma A₂ are not clearly understood.¹⁵⁹² Secretion may be accomplished by the same pathway used by other nonclassically secreted proteins in blood, including fibroblast growth factor¹⁵⁹³ and the interleukins.¹⁵⁹⁴ Approximately 50% of the total potential factor XIII A-chain activity in human blood is found in platelets.¹⁵⁸⁸

During fibrin formation, platelet A₂ can be expressed on the platelet surface and plays an important role in fibrin cross-linking. Plasma factor XIII A-chains can also bind to thrombin-activated platelets.^{1595,1596} This binding is enhanced by thrombin cleavage of the A-chains as well as the thrombin-independent activation of the platelet. The association of the factor XIIIa molecule with the activated platelet surface allows it to participate at the platelet-fibrin interface, thereby stabilizing hemostatic plugs. The factor XIIIa binding site on platelets can be degraded by plasmin.¹⁵⁹⁵ The B subunit is solely synthesized in the hepatocyte^{1586,1597} and is secreted as a monomer.¹⁵⁹⁷ After being secreted, the A and B subunits associate, becoming an A₂B₂ tetrameric molecule in the blood.

Activation

Activation of the zymogen by thrombin occurs in the NH₂-terminus of the A-chains at Arg³⁷-Gly³⁸ and releases a 36-amino acid activation peptide from each of the A-chains¹⁵⁹⁸ (Fig. 18.13). Whether immediate dissociation of the activation peptide from the rest of the molecule is part of the activation process is not clear, because crystals of thrombin-activated FXIII showed no change in the location and conformation of the activation peptides.¹⁵⁸¹ This was also seen in the ion-bound structures,^{1582,1583} and¹⁵⁸⁴ in which the active site residues remained inaccessible to solvent and substrate. These combined results suggest that exposure of the catalytic residues is likely to occur on substrate binding.¹⁵⁵⁴ Calcium is required for factor XIIIa to expose its active site cysteine.^{1599,1600} and¹⁶⁰¹ Catalytic activity is expressed only after the A-chain dimer is dissociated from the B-chain through a Ca²⁺-dependent process after thrombin proteolysis.^{1578,1579} Fibrin and fibrinogen play important roles as cofactors in the dissociation of the B-chains from thrombin-cleaved factor XIII.^{1587,1593} The intracellular form of factor XIII only contains the A-chain; therefore, it does not require the dissociation of the B-chain, but it still requires a calcium-dependent thrombin proteolysis.

The process of factor XIII activation in whole blood has been correlated with fibrin formation,¹⁰¹³ while in hemophilia this coordination is disrupted.¹⁶⁰² This creates a carefully regulated system that has cross-linked polymers occurring as soon as fibrin is being formed. The rate of thrombin cleavage of plasma factor XIII has been shown to be greatly accelerated by the presence of fibrin polymers.^{1603,1604} This positive feedback network between thrombin, fibrin(ogen), and factor XIIIa ensures that a stable clot can form rapidly to maintain hemostasis.

FIGURE 18.13. Activation of plasma factor XIII. The thrombin-catalyzed activation of plasma factor XIII (A_2B_2 ; 320,000 Da) occurs in two steps. In the first step, thrombin cleaves the ($R^{37}-G^{38}$) bond. This releases the activation peptides (residues 1 to 37) from the A-chains, producing the inactive intermediate a'_2B_2 . Fibrinogen interactions promote this event. In the second Ca^{2+} -dependent step, the B-chains dissociate from the a'_2B_2 intermediate, exposing the active site cysteine, Cys^{314} , of the a' subunits. These chains can re-associate in the presence of divalent cation chelators like ethylenediaminetetraacetic acid (EDTA). The enzyme a'_2 is now capable of catalyzing the formation of isopeptide bonds between glutamine residues and lysine residues of adjoining polypeptide chains. In this model, the a' -chains are oriented in such a way as to promote cross-linking of fibrin polymers in an antiparallel configuration.

Function

Activated factor XIII is essential for normal hemostasis and performs numerous functions in pathologic processes.^{1529,1554} Being a transglutaminase, activated factor XIII forms isopeptide bonds between the γ -carboxylamide and -amino groups of glutamyl and lysyl residues, respectively. Factor XIIIa is the only enzyme in the blood coagulation cascade that uses a cysteine for catalysis. To date, no known endogenous inhibitor has been described to regulate this important enzyme. Substrates for factor XIII include fibrin(ogen), fibronectin, α_2 -plasmin inhibitor, collagen, vitronectin, vWF, actin, myosin, factor V, and thrombospondin.^{1529,1530,1531,1532,1533,1534,1535,1536} and ¹⁵³⁷

Fibrin is the main physiologic substrate for factor XIIIa. The basic mechanism involves γ -chain dimerization and α -chain polymerization by creating isopeptide cross-links. The structural specificity for this reaction remains poorly defined. It

appears to reside within the primary amino acid sequence surrounding the surface-exposed glutamine residues.^{1605,1606} How clot stabilization occurs in fibrin formation is covered in the section on Polymerization (Fibrin Formation).

Fibrinogen (Factor I) and Fibrin

This section focuses on the gene structure, structure/function relationships, and regulation of fibrinogen and its insoluble counterpart fibrin. These topics, although extensively discussed within this section, have also been the subject of several comprehensive reviews,^{1607,1608,1609,1610} and¹⁶¹¹ as well as a 2000 New York Academy of Sciences symposium.¹⁶¹²

Fibrinogen is composed of six polypeptide chains (two A α -chains, two B β -chains, and two γ -chains); after posttranslational modification, the mature protein circulates in the blood with an average molecular weight of 340,000 Da (Table 18.1). The polypeptide chains are distributed into two symmetric halfmolecules, each containing one A α -, one B β -, and one γ -chain with the NH₂- and COOH-termini oriented in the same direction. The half-molecules are linked by noncovalent and disulfide bonds at their amino termini, yielding a linear arrangement of three nodular structures. The outside two domains, formed by the carboxyl-terminal regions of the B β - and γ -chains of fibrinogen, are designated D, whereas the central domain that contains the amino termini of all the chains is designated E. Between 1.7 and 5.0 g of fibrinogen is synthesized per day by the liver,^{1613,1614} with approximately 75% of this fibrinogen secreted into the plasma and the remainder distributed between the lymph and interstitial fluids.¹⁶¹⁴ This translates into a mean plasma level of 2.5 mg/ml with a normal t_{1/2} of 3 to 5 days.^{1615,1616} Fibrinogen is considered to be an acute-phase reactant, and as such, it is upregulated two to 10-fold in response to a variety of physiologic stresses including trauma, pregnancy, and tissue inflammation.¹⁶¹⁷

Fibrinogen has been found in the blood plasma of all vertebrates, including the most primitive vertebrate, the lamprey. Early phylogenetic work on fibrinogen began with protein sequences obtained for various fibrinopeptides.^{1618,1619} It was immediately obvious that although these peptides were exceptionally variable, certain features were conserved; without exception, they all contained an arginyl-glycine bond required for thrombin cleavage.¹⁶²⁰ Determination of the protein sequences for all three chains revealed that they were homologous and were evolved from a common ancestor.¹⁶²¹ The β - and γ -chains share the most identity (42%) in their COOH-terminal domains, although they share no homology with the C-terminal α -chain.^{1622,1623,1624} and¹⁶²⁵ In fact, the C-terminal α -chain varies greatly between species (molecular weight ranges from 60 to 120 kDa).

Sequence data, especially the detailed work determining intron/exon junctures, support the hypothesis that all three fibrinogen genes evolved from a common ancestor through a series of duplications that began approximately 1 billion years ago.^{1626,1627,1628,1629} and¹⁶³⁰ At this point, the ancestral gene duplicated to form both the A α -chain and a β/γ -chain precursor gene. Then, sometime before the last time lampreys and mammals shared a common ancestor (450 million years ago), the β/γ gene duplicated, forming today's β - and γ -chains. There is now a growing collection of proteins that share more than 30% sequence identity with both the β - and γ -chains, including α _c domains,^{1631,1632} and¹⁶³³ chicken cytotactin,¹⁶³⁴ mouse T-cell protein,¹⁶³⁴ sea cucumber,¹⁶³⁵ and scabrous gene product from the fruit fly.¹⁶³⁶

Gene Structure and Expression

The fibrinogen locus is composed of three closely linked genes (specifying the polypeptides A α , B β , and γ) found as single copies in a region of approximately 50 kb (bands q23 to q32) of chromosome 4.^{1637,1638,1639,1640,1641} and¹⁶⁴² (Table 18.2). Both the A α - and γ -chains are transcribed from the same DNA strand, whereas the B β -chain is transcribed from the opposing strand.¹⁶²⁶ The A α gene contains six exons, whereas the B β has eight and the γ -chain has 10.^{1643,1644} and¹⁶⁴⁵ The expression of all three genes appears to share a common regulatory mechanism, potentially via their 5'-flanking regions.^{1646,1647} and¹⁶⁴⁸ Therefore, expression for the three chains is coordinately controlled and, at least for the hepatocyte, results in almost equal levels of mRNA for each chain in the cell.^{1629,1641,1644,1649}

A single transcription initiation event at the promoter of each chain produces multiple mRNAs due to alternative polyadenylation site selection in all three chains, as well as alternative splicing for both A α - and γ -chains.^{1631,1650,1651} and¹⁶⁵² In the case of the γ -chain, normal processing results in a polypeptide chain ending at Val⁴¹¹ (human numbering); however, approximately 10% of the time during splicing, the last intron is retained as an exon, resulting in a new chain, γ' , which ends at Leu⁴²⁷.^{1641,1653} Sometimes the α -chain also fails to remove the last intron, producing a translated protein product that is 27-kDa larger.^{1631,1632} and^{1633,1654} The resulting larger form of fibrinogen is called fibrinogen-420 (1% to 2% of circulating human molecules), and the α -chain extension is called

$\alpha_E C$.¹⁶⁵⁵ Interestingly, this new domain shares as much sequence identity (~40%) with the COOH-terminal domain of the β - and γ -chains as the two share with each other.¹⁶⁵⁴

Common polymorphisms of the fibrinogen genes are associated with plasma fibrinogen concentrations as well as susceptibility to, or severity of, atherothrombotic disease.¹⁶⁵⁶ Epidemiologic studies have shown a strong association between two polymorphisms of the fibrinogen β -chain gene and fibrinogen plasma concentration.^{1657,1658} However, the majority of the studies did not find any relation with fibrinogen polymorphisms and cardiovascular disease.^{1657,1658} The effect of these polymorphisms and vascular disease still remains in question because environmental or intermediate conditions of the phenotype can influence the outcome. This supports the notion of individualized susceptibility to disease, which is determined by the genotype and environmental risk factors.

Afibrinogenemia

Inherited or congenital afibrinogenemia is an autosomal recessive disorder characterized by a total lack of fibrinogen in the plasma. This disorder, originally described in 1920, now affects more than 150 families, putting the estimated prevalence in the general population at approximately 1 in 1 million.^{1641,1659,1660} It is usually detected at birth with uncontrollable bleeding from the umbilical cord. The phenotype varies from mild to severe with some patients experiencing spontaneous intracranial hemorrhage and splenic rupture throughout life, as well as bleeding after minor trauma.^{1661,1662} It has been suggested that the presence of functional vWF, which allows platelet thrombus formation in the absence of fibrin, may be responsible for the phenotypic variation observed.^{1663,1664} Most patients respond well to replacement therapy.¹⁶⁶⁵ To date, 86% of all afibrinogenemia results from a truncation mutation in the fibrinogen A α gene.¹⁶⁵⁹

Investigation of the roles that both fibrinogen and fibrin play in vivo has been greatly enhanced by the creation of transgenic mice either lacking fibrinogen¹⁶⁶⁶ or expressing a modified form of fibrinogen.¹⁶⁶⁷ The fibrinogen-deficient mice (Fib A α ^{-/-}) were often able to survive to sexual maturity even though they had no immunologically detectable levels of any chain (A α , B β , γ) in circulation.¹⁶⁶⁶ As expected, plasma from these deficient mice was unable to clot in vitro even when combined with exogenous thrombin. In addition, the plasma did not support platelet aggregation in vitro. This is consistent with the view that fibrinogen bridges platelets via activated receptors (e.g., $\alpha_{IIb}\beta_3$).¹⁶⁶⁸ However, in vivo, these mice are able to form platelet thrombi and are often able to withstand spontaneous bleeding episodes.¹⁶⁶⁴ The resilience of the Fib A α ^{-/-} mice is probably due to the fact that all factors required for thrombin generation and platelet activation are present and that platelets have alternative ligands for their activated receptors that are capable of supporting adhesion and thrombus formation.¹⁶⁶⁰

Breeding experiments crossing fibrinogen-deficient mice with other mice deficient in a hemostatic factor are providing insights into the roles fibrinogen and fibrin play in vivo. For example, mice with combined deficiency in both fibrinogen and vWF were found to form stable thrombi, although platelet deposition was found to be delayed and unstable.¹⁶⁶⁴ However, crossbreeding plasminogen-deficient mice (Plg^{-/-}) with A α ^{-/-} mice eliminated many of the spontaneous pathologies^{1669,1670} (conjunctivitis, pulmonary lesions, terminal vessel thrombosis, ulceration, or prolapse of the rectum and wasting) normally associated with the Plg^{-/-} genotype, including death at 6 months. In addition, the delayed tissue repair observed in Plg^{-/-} mice after arterial challenge,¹⁶⁷¹ corneal damage,^{1672,1673} or skin incision were all corrected by the removal of fibrinogen. These data, in combination with other data not discussed here, support the concept that the physiologic role for the plasminogen activation system is fibrin lysis.¹⁶⁷⁴

Hereditary Dysfibrinogenemias

Like many of the other coagulation disorders, classic dysfibrinogenemias were frequently recognized by the mother when her child bled abnormally. These disorders are associated with prolonged thrombin times usually caused by a point mutation in one of the chains, but clinically, the patient presents with normal plasma fibrinogen concentrations. Hypofibrinogenemias, on the other hand, are associated with low plasma fibrinogen concentrations (< 1.5 mg/ml) due to a mutation(s) that can affect transcription, mRNA processing, translation, chain processing, and assembly, excretion, or stability of the mature protein.¹⁶⁷⁵ Hypofibrinogenemias can be classified into four groups according to the effect of the mutation: (a) mutations that affect intracellular processing, (b) retention in the endoplasmic reticulum, (c) intracellular assembly, and (d) A α -chain truncations.^{1661,1662,1675}

Dysfibrinogenemias can be divided into five groups based on their specific action: (a) mutations that impair or impede thrombin, (b) defects in the construction of protofibrils, (c) impaired lateral association of protofibrils, (d) defects in interactions with other substances, and (e) other unknown mechanisms.¹⁶⁷⁵ Thus, most common mutations are those that impede conversion of fibrinogen to fibrin by thrombin, which catalyzes the hydrolysis of the bonds between Arg α^{16} -Gly α^{17}

and Arg¹⁴-Gly¹⁵, releasing FPA and FPB, respectively. The active site of thrombin is highly specific for an Arg in the P1 position as observed by the human variant replacement of Arg¹⁶ by His, which leads to delayed release of FPA¹⁶⁷⁶ or Cys, resulting in no release of FPA.^{1677,1678} In the case of Arg¹⁴, only a Cys variant (fibrinogen Christchurch¹⁶⁷⁹) has been observed.

The identification of these mutations, originally through protein chemistry methods and now using DNA technology, has provided unique insights into the structural/function relationships of fibrinogen and fibrin. These mutants were originally gathered and published in the Index of Variant Human Fibrinogen,¹⁶⁸⁰ but with the advent of the Web, the material has been converted to a dynamic database (<http://www.geht.org>).¹⁶⁸¹ As of January 2012 (Release 37), 617 molecular abnormalities were present in the database, with 356 found in the A α -chain (99 were Arg¹⁶ mutations), 82 in the B β -chain, and 176 in the γ -chain.

Biosynthesis

Pulse chase experiments in a human hepatic carcinoma line have shown that there is a large intercellular pool of both A α - and γ -chains, but it is the B β -chain synthesis that limits assembly in the rough endoplasmic reticulum.^{1682,1683} However, in both chicken and rat hepatocytes, it seems to be the A α -chain that limits fibrinogen assembly.^{1683,1684} Additionally, several extrahepatic sites of fibrinogen synthesis have been identified, including human cervical epithelial cells¹⁶⁸⁵ and lung alveolar epithelial cells.¹⁶⁸⁶ γ -Chain-only synthesis has been observed in vivo in the brain, lung, and bone marrow.^{1687,1688} A physiologic role remains to be determined.

A number of posttranslational modifications (Table 18.8) must occur after synthesis but before secretion. These include removal of the signal peptides from all three chains during or after passage across the membrane¹⁶⁸⁹; a biantennary carbohydrate (M_r ~ 2,500 Da) being added to Asn⁵² on the γ -chain much earlier than the Asn³⁶⁴ on the B β -chain^{1687,1690,1691,1692} and ¹⁶⁹³; and when synthesized, fibrinogen being fully phosphorylated (Ser³ and Ser³⁶⁴)—but in its circulating form, only 20% to 30% of these sites remain phosphorylated.¹⁶⁹⁴ Additionally, the first residue on the B β -chain is also posttranslationally modified to form pyroglutamic acid, thus removing its free amino terminus.

Biochemistry and Activation

The fibrinogen molecule contains two copies of three separate polypeptide chains designated A α , B β , and γ (Table 18.8). These

P.477

are arranged into two identical half-molecules in an elongated structure composed of three globules. In the central globule all six NH₂-termini of the polypeptides reside, and thus it has been referred to as the N-disulfide knot.^{1618,1695} There are 11 disulfide bonds in this region, three of which link the two half-molecules. Experiments in which one or more of the 29 intra- and interchain disulfides were removed or small deletions made have shown that for dimer formation both disulfide bonds and the noncovalent interactions of the amino termini are important.^{1696,1697,1698,1699} and ¹⁷⁰⁰ The common form of the A α -chain contains 610 amino acid residues with an M_r of 66,500 D and two phosphorylation sites (Ser³ and Ser³⁶⁴), and thrombin cleavage of the Arg¹⁶-Gly¹⁷ bond releases FPA. The A α -chain of fibrinogen has sites appropriate for factor XIIIa-catalyzed formation of cross-links,¹⁷⁰¹ t-PA enhancement site (residues 148 to 160) found in fibrin,¹⁷⁰² as well as consensus integrin recognition sites (residues 95 to 98 and 572 to 575). The B β -chain is composed of 461 amino acids, displays an M_r of 52,000 Da and has a single glycosylation site (Asn³⁶⁴) and a Ca²⁺-binding site (residues 381 to 385). Thrombin cleavage of the Arg¹⁴-Gly¹⁵ bond releases FPB. The γ -chain of fibrinogen is made up of 411 amino acids with an M_r of 46,500 D, is glycosylated at Asn⁵², and has a Ca²⁺-binding site (residues 318 to 324), a t-PA enhancement site (residues 320 to 324) in fibrin, and both donor (Gln³⁹⁸) and acceptor (Lys⁴⁰⁶) sites for cross-link formation.

TABLE 18.8 KEY FEATURES OF HUMAN FIBRINOGEN CHAINS

	Aα	αECBβ	γ	γ'
Total number of residues	610	236 461	411	427
Expression level (%)	98	2 100	90	10
Fibrinopeptide length	16	14		
Thrombin cleavage site	Arg ¹⁶ -Gly ¹⁷	Arg ¹⁴ -Gly ¹⁵		
Newly exposed N-termini	Gly ¹⁷ -Pro-Arg-Val	Gly ¹⁵ -His-Arg-Pro		

Cross-linking sites

Acceptor (Gln)	328, 366	398
Donor (Lys)	508-584	406
Number of calcium-binding sites?	1 2	1 1
Carbohydrate linkage site	667 364	52 52
Phosphorylation site	3, 346	

A comprehensive history of early fibrinogen and fibrin structure/function relationships can be found in an excellent review by Blomback.¹⁶¹² In the first recorded structural experiment, Bailey et al.¹⁷⁰³ placed both a concentrated solution of fibrinogen (which forms a viscous strand) and a fibrin thread in an x-ray beam. The resulting patterns were indistinguishable not only from each other, but also from the patterns of keratin and myosin. They all showed a characteristic 5.1 Å-repeat spacing that was later determined to be due to supercoiled α helices.¹⁷⁰⁴ Around this same time, a different physiochemical “picture” of fibrinogen was emerging. Techniques including electrophoresis, ultracentrifugation, viscosity measurements, and light scattering were coming into vogue and determined that fibrinogen was a prolate ellipsoid with a length between 500 and 700 Å, an axial ratio between 5 and 20 Å, and a molecular weight near 340 kDa.^{407,1705,1706} and ¹⁷⁰⁷

Hall and Slayter¹⁷⁰⁸ produced shadow-cast photographs of fibrinogen and observed three unconnected globules in a line. The center globule was the smallest, with a diameter of approximately 50 Å; the terminal globules were found to be of equivalent size, approximately 60 Å. The total molecule length was estimated to be 475 Å; thus, the connections between the globules were approximated to 150 Å, and Cohen¹⁷⁰⁹ suggested that these globules could be linked by α helices, which would explain the characteristic α -helix 5.1 Å-repeat spacing observed in the fiber diffraction. This trinodular structure has become known as the Hall and Slayter model of fibrinogen.

The reconstruction of fibrinogen from both enzymatic and chemical fragmentation products has allowed an exact picture of the structure and function of fibrinogen to emerge. Many fragments were subjected to protein sequencing, and the sequences reassembled until the whole structure was determined. These fragments also gave insights into the polymerization process as well as the shape of fibrinogen. Because plasmin is the natural protease for fibrin removal, it was the obvious choice for initial fragmentation. Nussenzweig et al.¹⁷¹⁰ characterized such a fibrinogen lysate that was chromatographed using a diethylaminoethyl cellulose column. The resulting peaks were denoted A through E, and it was determined that the pools D and E contained the bulk of the material, with an approximate mass ratio of 2:1. This coordinated well with the Hall and Slayter model in which pool E would represent the center globule and be called fragment E, and the terminal globules would be found in pool D and called fragment D.¹⁷¹¹ Thus, fibrinogen is a symmetric molecule, with a dyad axis drawn through fragment E.

Much effort has been expended in trying to crystallize fibrinogen. The first view was an 18-Å structure of a modified bovine fibrinogen,¹⁷¹² later refined to approximately 4 Å.¹⁷¹³ The modification was a partial proteolysis that predominantly removed the C-terminal α -chains. However, the density for the central domain was “poorly defined.” The first look at an unmodified fibrinogen was the 5.5-Å followed by 2.7-Å structures of chicken fibrinogen.^{1714,1715} Chicken fibrinogen was chosen as a target because it has the shortest α -chains that lack a series of repeated sequences found in most other species^{1633,1716,1717} (Fig. 18.14). This structure provided the first atomic resolution view of the central domain of fibrinogen, although the α domains were too disordered to allow the chain to be traced. A 35-kDa digestion product of fragment E (FE₅) was solved at 1.4 Å,¹⁷¹⁹ which correlates well with the observed fragment E region in the 2.7-Å chicken fibrinogen structure.

The first atomic resolution structure in the fibrinogen field was for a human recombinant γ -chain.¹⁷²⁰ As predicted, the fold of the γ -chain was unique and not represented in any of the structural databases.¹⁶²⁵ The next advance came with the 2.9-Å structure of human fragment D,¹⁷²¹ displaying the two globular β and γ domains forming the furrow. As expected, the β and γ COOH-terminal domains share the same fold^{1720,1722} and are

P.478

oriented approximately 130° apart. These observations have been confirmed in a structure of lamprey fragment D¹⁷²³ and a recombinant human fragment D.^{1724,1725} To date, a crystal structure of intact human fibrinogen has not been solved.

FIGURE 18.14. A schematic and crystal structure of human fibrinogen (PDB-ID: 3GHG). All six NH₂-termini are gathered together in the central or E domain.¹⁷¹⁸ Three chains [α -, β -, and γ -] extend out from this domain through coiled-coils in either direction forming the terminal or D domains. Thrombin (IIa) cleavage sites at the N-termini of the α A and β B are indicated, with the new N-termini that associate with “holes” in the D domains to form fibrin depicted in the boxes. Pink spheres indicate the four Ca²⁺ sites. Note that the carboxy termini of the α -chains are not visible in this structure.

Polymerization (Fibrin Formation)

The goal of a polymerization is to build a scaffold of sufficient mechanical strength to serve as a hemostatic plug. Interestingly, only 20% of a “clot” is actually protein—the remainder is solvent.¹⁷²⁶ In 1952, Ferry¹⁷²⁷ proposed a half-staggered overlap model to explain the polymerization process. This model can be expressed succinctly in terms of “knobs” and “holes”.¹⁶²¹ When thrombin removes the fibrinopeptides, it creates new amino termini on the α - and β -chains called knobs. Because the knobs are located in the central globule (fragment E) of the Hall and Slayter model, the holes for them to fit into must be present on the terminal domains (fragment D). To accommodate the half-staggered overlap model, the knobs on one molecule interact with holes in two different molecules. Reciprocally, a knob from each of these molecules fits into the holes on the first molecule’s fragment D. The binding sites of the α and β knobs were localized to the γ - and β -chains, respectively, using fragment D digested to different extents.¹⁷²⁸ To identify the polymerization hole in the γ -chain, recombinant γ -chain crystals were soaked in a solution containing a peptide mimic of the knob.¹⁷²² As was expected, the hole was preformed and contained a strong electronegative potential that was neutralized on the binding of the doubly positively charged peptide. The binding interaction was noncovalent and composed of only ionic and hydrogen bonds. Using laser tweezers, the strength of this interaction has been measured between 125 and 130 pN, which is the majority of the force holding fibrin polymer together at this early stage.¹⁷²⁹

The existence of a β -chain hole and that this hole binds the β -chain knob were confirmed with a double-D x-ray crystal structure in which peptide knobs for the α - and β -chains were present.¹⁷³⁰ As would be expected, the β -chain knob also binds with a combination of ionic and hydrogen bonds to the β -chain hole, though it contributes only 15 to 20 pN to the interaction.¹⁷²⁹ In another study using combinations of peptide knobs, it was determined that the β hole is not fully formed until the knob is present¹⁷³¹ and is much less discriminating in peptide acceptance.¹⁷³² This conformational change may be the basis for the acceleration of fibrin formation observed in the presence of the peptide ligand GHRP.^{1611,1728} No evidence has been found for an analogous mechanism with the γ hole; rather, the γ hole seems always ready to accept an α knob, though in the absence of an α knob, the β knob readily binds to both holes.¹⁷³¹ A single example of an α knob peptide (GPRVVE) has been observed occupying a β hole,¹⁷³³ but recent experiments using laser tweezers have demonstrated that this interaction is not physiologically relevant.¹⁷²⁹

The conversion of fibrinogen to fibrin can be separated into three congruent processes: (a) removal of the fibrinopeptides, (b) assembly, and (c) covalent stabilization. We examine each in depth in the following sections.

Fibrinopeptide Release

Many early investigators tried to determine the differences between fibrinogen and fibrin. Their molecular weights were identical, and fibrinogen was the more electronegative of the two.¹⁷³⁴ In the conversion of fibrinogen to fibrin, thrombin catalyzes the hydrolysis of Arg-Gly bonds, removing small, polar amino terminal pieces (fibrinopeptides) from the α - and β -chains.^{1735,1736} Cleavage of Arg α ¹⁶ by thrombin releases FPA and forms fibrin I. The release of two FPA peptides exposes a site in fragment E that aligns with a complementary site in fragment

P.479

D to form overlapping fibrils. Subsequent cleavage by thrombin at Arg β ¹⁴ releases FPB and leads to the formation of fibrin II, presumably increasing lateral aggregation of the protofibrils. FPA and FPB vary in length (between 13 and 21 amino acids in various mammals) and constitute < 2% of the total mass.¹⁷³⁷

Early studies in citrated plasmas or purified fibrinogen found that FPA and FPB are released at very different rates, with FPA being released first.^{1735,1738,1739} and ¹⁷⁴⁰ A sequential model for release has been postulated in which thrombin binds equally to both chains, but the presence of FPA hinders the release of FPB because thrombin is unable to undergo a required conformation change.^{1741,1742,1743} and ¹⁷⁴⁴ As the polymerization process proceeds, the FPB release rate continues to increase, suggesting that a polymerization-induced structure change facilitates its release.^{1741,1742,1745} When the fibrinogen to fibrin conversion is studied in a nonanticoagulated whole blood system, the pattern of fibrin formation based on fibrinopeptide release is different from that seen in citrated plasma or purified fibrinogen.¹⁰¹³

Bettelheim and Bailey¹⁷⁴⁶ first hypothesized that on FPA and FPB release these newly exposed amino termini (knobs) must be the principal contact sites during polymerization. In human fibrinogen, the α -chain knob, after FPA release, begins with the sequence GPRVV; whereas the β -chain, after FPB release, starts with GHRPL. Synthetic peptide GPR derivatives based on the β knob were found to bind to both fibrinogen and fragment D and inhibit fibrin monomer polymerization.¹⁷²⁸ Peptides based on the β knob also bound to both fibrinogen and fragment D but were unable to inhibit fibrin monomer polymerization. In analogous studies, venoms can be used to selectively remove only FPA without activating factor XIII, and fibrin will still form.^{1747,1748} Although it appears morphologically the same, this type of fibrin lacks the normal strength of fibrin.^{1749,1750} and ¹⁷⁵¹ Removal of only FPB (without FPA release) results in fibrin formation in lampreys,¹⁶²⁰ but human fibrinogen clots only if the temperature is maintained below 15°C.¹⁷⁵¹

FIGURE 18.15. Schematic representation of whole blood fibrin formation. Thrombin at the beginning of clot formation simultaneously acts on fibrinogen (D-E-D) and factor XIII (fXIII). A portion (~40%) of fibrinopeptide A (FPA) is released from fibrinogen, and an initial clot is formed from the complementary overlap of the exposed sites between the E and D domains of adjacent molecules. Activated factor XIII (fXIIIa) simultaneously cross-links adjacent D domains (D=D). Thus, the initial soluble fibrin clot is composed of fibrinogen, fibrin, and γ - γ dimers (double yellow lines) with fibrinopeptide B (FPB) still attached. The initial clot is continuously acted on by thrombin, releasing the remaining FPA and some of the FPB to yield a final clot with the majority of FPB still attached. The released FPB is selectively acted on by a carboxypeptidase B-like enzyme (CPB) cleaving the carboxyl terminal arginine to produce des-Arg FPB. The significance of this cleavage is still unclear. (From Brummel KE, Butenas S, Mann KG. An integrated study of fibrinogen during blood coagulation. *J Biol Chem* 1999;274:22862-22870, with permission.)

Fibrin Assembly

The release of the FPAs from fibrinogen results in the formation of an intermediate termed fibrin monomer, which is all but indistinguishable from fibrinogen, and leads to the formation of the fibrin dimer through the noncovalent charge-charge (salt links) and hydrogen bonds between the knobs and the holes.¹⁷⁵² As fibrin monomers continue to be generated, the dimer elongates from both ends as a two-stranded molecule until it reaches approximately 30 monomers, when it becomes a protofibril.^{1738,1753,1754}

The second step in fibrin assembly is the lateral association of protofibrils into thicker fibrin fibers.^{1753,1754} These fibers are formed from the association of between 14 and 22 protofibrils.¹⁷⁵⁵ Because protofibrils, not dimers, are required for this step, it is believed that the forces involved in lateral association are weak and, therefore, only become "strong" in large numbers. Fragment D, specifically the β -chain, is likely responsible for this aspect of fiber growth.^{966,1756,1757} Clots are known to branch, although how this is accomplished is not clear. For example, perhaps a protofibril can attach and form a

link between two growing fibers,^{966,1608,1758} or perhaps this is the role for the C-terminal region of the α -chains.^{1759,1760} The presence or absence of carbohydrates also seems to affect branching.¹⁶⁹³

The description of fibrinogen activation and fibrin assembly has been based on studies using citrated plasmas, purified proteins, or both. To understand the *in vivo* process of fibrin formation, a system with nonanticoagulated blood has been used; in this experimental model, the pattern of fibrin formation based on fibrinopeptide release is different from systems using citrated plasma or purified fibrinogen¹⁰¹³ (Fig. 18.15). In this study, cleavage of FPA and subsequent clot formation occur just before the propagation phase of thrombin generation. At the point of visual clot formation, virtually all fibrinogen (and some product already cross-linked) disappears from the fluid phase of the reaction. Thus, the "clot" appears to be a mixture composed of fibrin I and fibrinogen. The insoluble material present in the fibrin clot is

P.480

virtually all cross-linked by factor XIIIa, whose activation is nearly simultaneous with FPA removal. Therefore, the transglutaminase factor XIIIa is available to cross-link the γ -chains of the initial fibrinogen/fibrin I clot. In purified systems, it has been observed that FPB removal precedes the cross-linking reaction. However, in the whole blood clotting model, the FPB antigen epitope is found associated with the β -chain after clot formation has occurred. FPB release proceeds at a slower rate than FPA release, occurs after γ - γ dimer formation, and only reaches approximately 38% of its theoretical maximum value. Doolittle and Pandi¹⁷⁶¹ have recently proposed that interaction of the β -knob with the β -hole generates a conformational change and exposes t-PA binding sites, which ultimately hasten a clot's removal.

Fibrin Cross-linking

To strengthen the "weak" (noncovalent) interactions holding the dimers and protofibrils together, factor XIII (a transglutaminase found circulating in the plasma) is activated to factor XIIIa by thrombin in the presence of Ca^{2+} to link the side chains of lysyl and glutamyl residues by isopeptide bonds. Thrombin activation of factor XIII activation has been shown to coincide with FPA release during the initiation phase of thrombin generation.^{569, 1013} The concentrations of thrombin (based on thrombin-antithrombin complex) needed for factor XIII activation, FPA release, and FPB release have been calculated to be 0.8 ± 0.3 nmol/L, 1.3 ± 0.4 nmol/L, and 1.7 ± 0.5 nmol/L, respectively.⁵⁶⁹

It has been proposed that as many as six cross-links can form between a fibrin monomer and its neighbors^{1762,1763} and that the presence of these cross-links increases the strength, chemical resistance to urea, and lysis by plasmin.^{1525,1526,1764,1765,1766,1767} and ¹⁷⁶⁸ Early in fibrin assembly, factor XIIIa has been shown to link Gln³⁹⁸ and Lys⁴⁰⁶ in reciprocal cross-links between adjacent C-terminal γ -chains.^{1532,1769} Once the majority of γ -chain crosslinks are inserted, then a much slower process begins to insert multiple cross-links between neighboring α -chains.¹⁷⁷⁰ Because each α -chain has two glutamyl acceptor sites and five potential lysine donor sites, a complex cross-linked network can result.¹⁷⁷¹ The result is cross-linked fibrin, which is more resistant to clot lysis.^{1768,1772} Factor XIIIa also covalently attaches α_2 -plasmin inhibitor (the principal fibrinolytic inhibitor) to α -chains in the clot, thereby increasing resistance to degradation.^{1773,1774}

Function

Fibrinogen functions in hemostasis to stem blood loss. It serves as a molecular bridge to support interplatelet aggregation, and it is the precursor of fibrin, which is the main component of the protein scaffolding of the forming hemostatic plug. Platelet aggregation critically depends on fibrinogen binding to activated platelets via the platelet fibrinogen receptor gpIIb-IIIa as well as fibrin adhesion. Fibrinogen/fibrin also regulates thrombin activity by interactions that include the proteolytic cleavage by thrombin of fibrinopeptides to form a fibrin clot and thrombin exosite binding to fibrin, which potentially limits the diffusion of thrombin and thereby regulates clot propagation. The structure, stability, and duration of the insoluble counterpart fibrin are controlled by an interplay between fibrin formation and fibrinolysis, which includes other molecular and cellular components. An important enzyme for the structure and stability of the fibrin clot is the transglutaminase factor XIIIa. Its function is to cross-link fibrin and other adhesive proteins including integrin receptors, providing a stable network. Once activated, the fibrinolysis inhibitor called TAFI functions to attenuate fibrinolysis by removing C-terminal lysines from fibrin. This appears to be critical in the stabilization of the fibrin clot by reducing the number of sites available for plasminogen binding, thus reducing the rate of plasmin generation with consequent prolongation of fibrin dissolution.^{1011,1775} TAFI has also been shown to play a role in the premature lysis of clots from hemophilic plasma.¹⁷⁷⁶

Fibrinogen is primarily recognized for its role in hemostasis but is also required for competent inflammatory reactions. Fibrinogen is an acute-phase reactant, with levels increasing during inflammation. During these situations, fibrinogen functions as a bridging molecule in cell-cell interactions. Fibrin and fibrinogen constitute a matrix that can allow for the modulation of cellular responses through a variety of different cell types, including endothelial cells, epithelial cells,

leukocytes, platelets, and fibroblasts. Cellular receptors that can bind fibrinogen and fibrin include the integrins $\alpha_{IIb}\beta_3$, $\alpha_v\beta_3$, and $\alpha_5\beta_1$, and the cellular adhesion molecules intercellular adhesion molecule-1 and vascular endothelial cadherin.

Although the function of fibrinogen and fibrin as a barrier to stemming blood loss through the dense fibrin network appears central to hemostasis, the findings from fibrinogen-deficient mice suggest that compensating mechanisms exist. Homozygous A α -chain-deficient mice are born with normal appearance and without elevated fetal mortality.¹⁶⁶⁶ These mice have no detectable levels of the A α -, B β -, and γ -chains in their blood.¹⁶⁶⁶ Therefore, the maintenance of hemostasis in these animals is most likely derived from normal thrombin generation and the support of platelet aggregation and adhesion by vWF.

Most clinical assays use fibrin formation as a means to assess hemostasis (PT and activated partial thromboplastin time). The formation of a visible fibrin clot occurs during the initiation phase of coagulation at very low levels of thrombin, approximately 3% to 5% of the total amount of thrombin produced.^{569,616} The majority of thrombin (~95%) is generated after clot formation during the propagation phase, which is overlooked when a fibrin endpoint assay is used.⁵⁶⁹ In congenital hemophilia A and B, only a slight prolongation of clot time is observed; the major impairment is in thrombin generation during the propagation phase of the reaction (Fig. 18.7).⁸⁸² Thus, most catalyst and thrombin formation is ignored using the current technology for evaluating clinical hemorrhagic risk or thrombosis. The survivability of the afibrinogenemic genotype in mice and male patients also supports this concept that critically important events are taking place beyond the endpoint of fibrin formation.

Regulation of Fibrin Lysis

The coagulation system prevents blood loss at the site of injury, filling one role in hemostasis. However, there must also exist mechanisms to limit the coagulation system and processes to remove a clot once it is no longer needed. This role is filled by the fibrinolytic system that uses elements from plasma, platelets, tissue, and other blood cells to regulate the degradation of fibrin. The main player is the zymogen plasminogen that on activation becomes plasmin, a serine protease, whose primary physiologic role is the degradation of the fibrin clot and extracellular matrix molecules. Even though the plasmin cleavage sites are similar for both fibrinogen and fibrin, we consider them separately for clarity.

Fibrinogenolysis

Marder^{1777,1778} proposed a scheme for fragmentation of fibrinogen based on his own detailed studies and the work of others.^{1779,1780} In the first step, fibrinogen is converted to fragment X ($M_r \sim 247,000$) by the removal of the C-terminal α -chain as well as the first 42 amino acids of the β -chain^{1781,1782} (Fig. 18.16). Fragment X remains clottable before it is split asymmetrically, forming fragment Y ($M_r \sim 150,000$), fragment D ($M_r \sim 88,000$), and some small detritus relating to the coiled-coil region. Finally, fragment Y is further split into fragment D and fragment E ($M_r \sim 50,000$), and some more detritus is released.

P.481

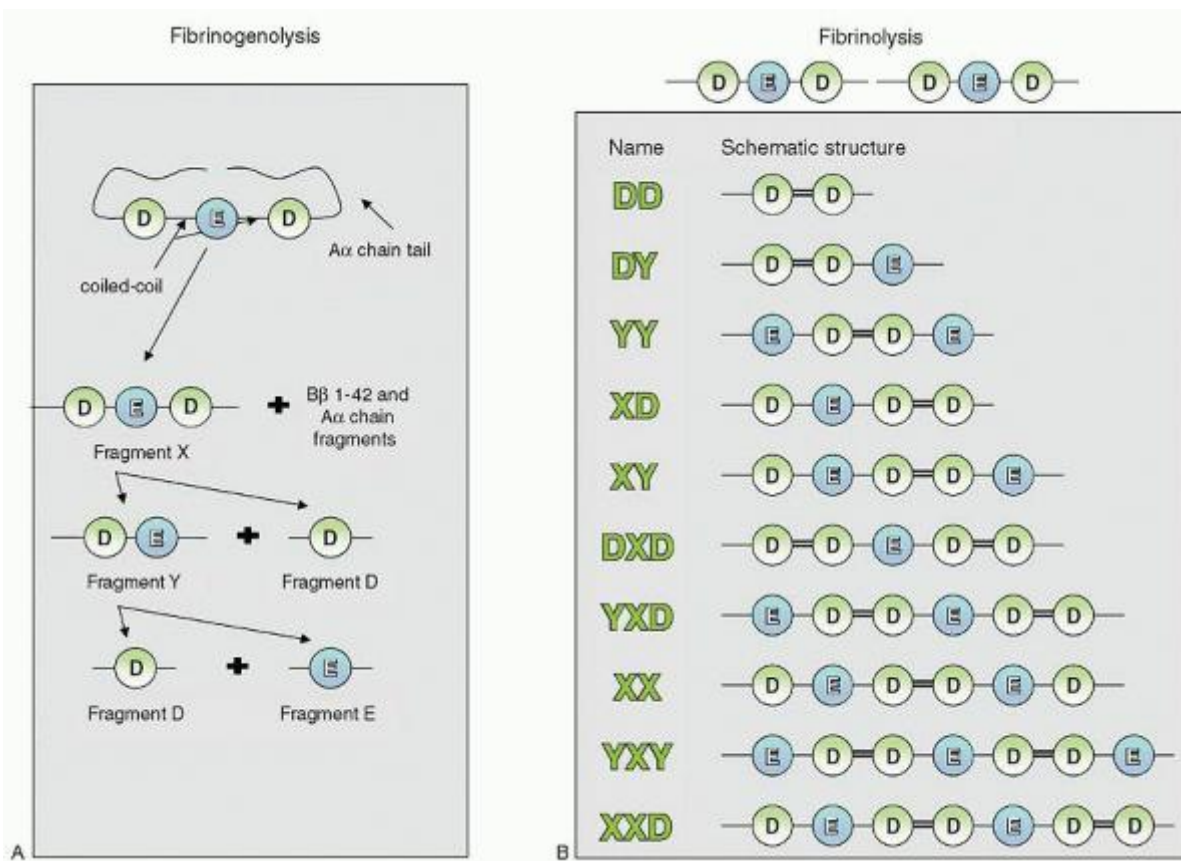

FIGURE 18.16. Fibrinogenolysis and fibrinolysis. A: Fibrinogen is represented as a trinodular structure (D-E-D domains). Each E domain and D domain is separated by a coiled-coil domain. The α -chain tail is shown as a line. Plasmin digests fibrinogen, yielding various fragments, the largest of which is fragment X. Fragment X contains the two D domains, the E domain, and the α -helical coiled-coils, but lacks the C-termini of the α -chains and the peptide $\beta\beta$ -chains. Fragment Y consists of the central E domain connected by the coiled-coil to one of the terminal D domains. Fragment Y can be further degraded by cleavage of the coiled-coil domain to release a second D domain and fragment E. B: The domain composition of the monomer units of degraded fibrin is indicated by the circles containing a D or an E. Intermolecular cross-links between the γ -chains are shown as thicker lines connecting the D regions. The structures of the various-sized fragments of cross-linked fibrin monomers resulting from plasmin proteolysis of fibrin are presented.

Fibrinolysis

Differences observed in the degradation products between fibrinogen and fibrin are due to the presence of the cross-links, not a change in the specificity of plasmin, which predominantly attacks the coiled-coil region between fragment E and fragment D. Degradation of cross-linked fibrin is much slower than fibrinogen, in large part because of the inaccessibility of the plasmin cleavage sites.^{1781,1783,1784} The first step in degrading cross-linked fibrin is the removal of the α -chains so that the coiled-coils are exposed. As the coiled-coils are cleaved, different-sized fragments are released.¹⁷⁸⁵ The smallest of these degradation products are double-D ($M_r \sim 180,000$), also known as D-dimer, a soluble fragment in which the two D fragments are linked by two isopeptide linkages, and a fragment with the stoichiometry D_2E (termed DY; $M_r \sim 235,000$), a double-D and a fragment E held in place by strong, noncovalent bonding.^{1786,1787} A large number of intermediate-sized fibrin degradation products arising from cleavages between the fragment D and fragment E regions are also generated (Fig. 18.16). The largest of these fragments is the XXD (two fragment Xs and a fragment D) with a mass in the range of 595 kDa. Some of these complexes (e.g., D-dimer) have been identified in the blood of patients with various thrombotic or thrombolytic disorders.

PROTEINS OF THE FIBRINOLYTIC SYSTEM

Clot formation is integrated with clot dissolution to maintain hemostasis. The biochemical mechanisms of clot dissolution center on fibrin-specific activation of plasminogen to plasmin. The key proteins involved are plasminogen, plasminogen activators (t-PA and u-PA), PAI-1, α_2 -antiplasmin, and TAFI (Fig. 18.17).

Plasminogen

Plasminogen is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation. Hereditary plasminogen deficiency has been described as either a deficiency of plasminogen antigen and activity (type I), or as a normal antigen level but reduced activity (type II, dysplasminogenemia).¹⁷⁸⁸ Thrombophilia and ligneous conjunctivitis are clinical manifestations associated with homozygous deficiency; the impact of heterozygous deficiency remains in dispute. Homozygous plasminogen-deficient mice are viable but exhibit severe thrombosis with systemic fibrin deposition, and die prematurely.^{1789,1790}

P.482

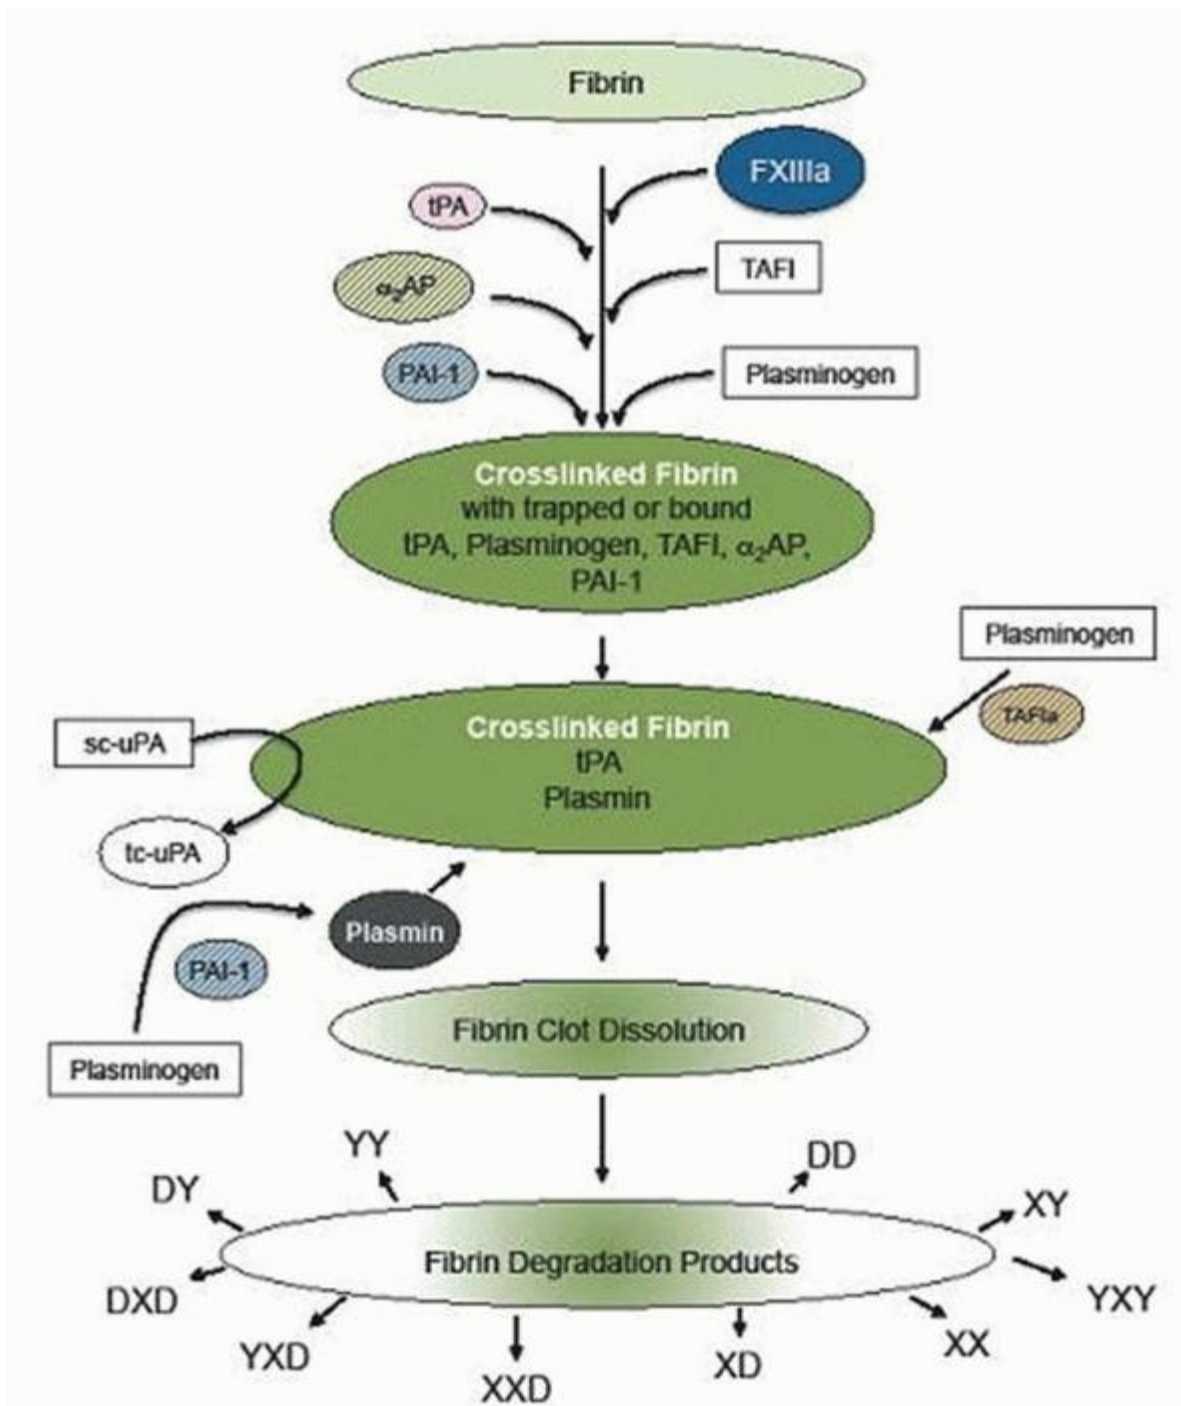

FIGURE 18.17. Schematic of the dynamic interaction between the proteins and inhibitors of fibrinolysis. Cross-linked fibrin formation is integrated with fibrin clot dissolution and degradation of its products. The enzymes (open circles), inhibitors (hatched circles), zymogens (open boxes), and complexes (large open ovals) are illustrated in a simplified form to show this multicomponent process. The key proteins involved are plasminogen, plasminogen activators (tissue-type plasminogen activator [t-PA], single-chain urokinase-type plasminogen activator [scu-PA], and two-chain urokinase-type plasminogen activator [tcu-PA]), plasminogen activator inhibitor-1 (PAI-1), α_2 -antiplasmin (α_2 -AP), and thrombin-activatable fibrinolysis inhibitor (TAFI). t-PA and plasminogen both bind to the fibrin surface, where t-PA is an effective catalyst of plasminogen activation. Initially, plasmin proteolysis of fibrin generates new, higher affinity binding sites for plasminogen, setting up an amplifying loop of plasminogen activation. Reinforcing this process, generated plasmin can convert the single-chain form of urokinase, an ineffective catalyst, to its active form, thus increasing the concentration of available plasminogen activation. Opposing these events are antifibrinolytic mechanisms. α_2 -AP, both soluble and cross-linked to fibrin, forms complexes with plasmin, rendering it inactive. PAI-1 rapidly reacts with both t-PA and two-chain urokinase, reducing the concentration of plasminogen activators. Formation of activated TAFI (TAFIa) results in removal plasmin-generated COOH-terminal lysine residues, thus suppressing the rate of fibrin lysis. Fibrin degradation occurs by cleavage at the D-E-D domains of fibrin polymers by plasmin to yield a variety of polymers as illustrated (see Fig. 18.16).

Gene Structure and Expression

The plasminogen gene is located on the long arm of chromosome 6 at band q26-q27^{1791,1792} (Table 18.9). It spans 52.5 kb of DNA with 19 exons. It is in close proximity to two genes for apolipoprotein A and for the plasminogen-related genes A and B.^{1793,1794} and ¹⁷⁹⁵ The first exon codes for the signal sequence; each of the five kringle domains is encoded by two exons, as is the activation peptide. Plasminogen expression is normally stable, with the regulation of the activity of the fibrinolytic system occurring mainly via the regulation of the plasminogen activators and their inhibitors. However, plasminogen is an acute-phase reactant protein.^{1701,1792} Two sequence elements common to acute-phase reactant genes have been located at positions 76 to 81 and -553 to -558.¹⁷⁹² Other potential regulatory transcriptional elements have been identified, including HNF-1, AP-1, CREB, and GATA.¹⁷⁹⁵

Biochemistry

Plasminogen is synthesized in the liver and is present in a wide variety of tissues and body fluids, including saliva, lacrimal gland secretions, seminal vesicle fluid, and prostate secretions.¹⁷⁹⁶ Plasminogen circulates in plasma at an approximate concentration of 200 mg/L (2 μ mol/L; Table 18.10). It has a circulating $t_{1/2}$ of 2.2 days.¹⁷⁹⁷ The $t_{1/2}$ in disease states, in which the fibrinolytic system is activated, can be shortened dramatically.

Human plasminogen is a single-chain glycoprotein of a relative molecular weight of 88,000 containing 2% carbohydrate (Table 10 and Fig. 18.18). Two major carbohydrate variants of plasminogen are found in roughly equal amounts in human plasma: plasminogen variant 1 is glycosylated at two sites, Asn²⁸⁹ and Thr³⁴⁶, whereas plasminogen variant 2 is glycosylated only at Thr³⁴⁶. Isoelectric focusing of either of these major carbohydrate variants, even when the proteins are isolated from a single plasma donor, reveals additional heterogeneity derived from variable sialic acid content.^{1798,1799,1800} and ¹⁸⁰¹ Heterogeneity in the primary sequence of plasminogen has also been observed, reflecting the presence of two high-incidence polymorphisms and a number of low-incidence polymorphisms in the human population. Functional differences between the two major carbohydrate forms have been reported.^{1802,1803,1804,1805} and ¹⁸⁰⁶ An additional glycosylation site at Ser²⁴⁹ containing a trisaccharide has been identified.¹⁸⁰⁷

The primary structure of plasminogen contains 791 amino acids segregated into an NH₂-terminal activation peptide domain (residues Glu¹-Lys⁷⁷), a region containing five kringles (K1-K5; residues Lys⁷⁸-Arg⁵⁴¹), and a catalytic domain (residues Val⁵⁶²-Asn⁷⁹¹)^{1791,1808,1809} (Fig. 18.18). As secreted into the blood, plasminogen has a glutamic acid at its NH₂-terminus, referred to as Glu-plasminogen. Proteolysis by plasmin at one of several potential sites in the NH₂-terminal region results in a degraded form of plasminogen; the most common product is Lys⁷⁸-plasminogen. Removal of the NH₂-terminal peptide region results in a major structural change in the plasminogen molecule, yielding a species of plasminogen that has a higher affinity than Glu-plasminogen for fibrin and is a better substrate for plasminogen activators.¹⁸¹⁰ The primary site for Lys-plasminogen formation is at the fibrin clot; the $t_{1/2}$ of Lys-plasminogen is shorter than the full-length molecule ($t_{1/2}$ = 0.8 days). Each kringle domain contains 78 to 80 amino acids. The K1 and K4 kringle domains have been identified as containing sites that are responsible for regulating the binding of plasminogen to fibrin,^{1811,1812} α_2 -antiplasmin,¹⁸¹³ histidine-rich glycoprotein,¹⁸¹⁴ the kininogens,¹⁸¹⁵ thrombospondin,¹⁸¹⁶ and cell surface receptors. These sites on the plasminogen kringles (called lysine-binding sites) bind lysyl residues in the target molecules; COOH-terminal lysyl residues are bound more avidly. Lysine analogs (i.e., ϵ -aminocaproic acid and tranexamic acid) can compete with lysyl residues in proteins for binding to plasminogen and, hence, are useful inhibitors of fibrinolysis.^{1817,1818} The conformational change associated with the removal of the NH₂-terminal activation peptide also occurs on binding of

lysine or its analogs to the appropriate kringles in Glu-plasminogen.^{1818,1819} and ¹⁸²⁰ The shape of the Glu-plasminogen molecule changes from a prolate ellipsoid of axial ratio 2.6 to a more random coil-type structure of axial ratio > 5, similar in dimension to Lys-plasminogen.^{1821,1822} A fragment of plasminogen comprising K1-K4, also known as angiostatin, has been shown to inhibit angiogenesis.¹⁸²³ The catalytic domain of plasminogen (Val⁵⁶²-Asn⁷⁹¹) shows considerable homology to trypsin and other serine proteases and includes the catalytic triad (His⁶⁰³, Asp⁶⁴⁶, and Ser⁷⁴¹) typical of these proteases.¹⁸²⁴

Function

Plasminogen is a zymogen devoid of enzymatic activity until converted to the serine protease plasmin by cleavage of the Arg⁵⁶¹-Val⁵⁶² peptide bond by plasminogen activators such as u-PA and t-PA (Fig. 18.19). In plasma or bound to fibrin in a blood clot, cleavage of this peptide bond by either t-PA or u-PA converts Glu-plasminogen into Glu-plasmin, a two-chain enzyme that can degrade fibrin, fibrinogen, and a number of other molecules.

P.483

Plasmin is composed of a heavy chain (kringle domains) and a light chain (catalytic domain) that are attached by two disulfide bonds. Glu-plasmin can autodigest by cleaving itself—most commonly at Lys⁷⁷ to generate Lys-plasmin.^{1825,1826} Inhibition of plasmin by α_2 -antiplasmin is the primary route for regulation of plasmin's hemostatic function; suppression of plasmin activity beyond the locale of fibrin deposition is imperative if systemic fibrinogenolysis is to be prevented. Plasmin bound through its lysine-binding sites to fibrin reacts more slowly with α_2 -antiplasmin than when free in solution. This differential reactivity effectively localizes plasmin activity to the fibrin surface.

TABLE 18.9 MOLECULAR GENETICS OF PROTEINS AND INHIBITORS OF THE FIBRINOLYTIC SYSTEM

Protein	Molecular Weight (Da)	Gene Location: Chromosome	Gene Size (kb)	Gene Organization: No. of Exons	Messenger RNA Size (kb)	UNIPROT Accession Number^a

Plasminogen Activators

The process of plasminogen activation can occur through three distinct pathways: (a) the intrinsic activator system (analogous to the contact system of blood coagulation), (b) the extrinsic activators (t-PA and u-PA), and (c) an exogenous

activator system involving pharmacologic agents (thrombolytic drugs). The pathway used in vivo appears to be the extrinsic pathway. However, both the intrinsic and exogenous activator systems could play an important role in human disease.

TABLE 18.10 BIOCHEMICAL PROPERTIES OF PROTEINS AND INHIBITORS OF THE FIBRINOLYTIC SYSTEM

Protein	Molecular Weight (Da) ^a	Amino Acid Number	Plasma Concentration		t _{1/2}	Carbohydrate (%)
			nmol/L	µg/ml		
Plasminogen	88,000	791	200	2,000	2.2 days	2

Intrinsic Activators

The body has evolved a mechanism to recognize invasion by foreign substances. Many of these foreign substances contain negatively charged surfaces that allow for the activation of the intrinsic (contact) pathway (factor XII, prekallikrein, HMWK, and factor XI). Plasminogen can interact with this intrinsic pathway of blood coagulation to generate plasmin. There is continued debate as to the extent to which the intrinsic pathway functions in regulating normal fibrinolysis. It has been estimated that this pathway contributes only approximately 15% of the total fibrinolytic activity in human plasma.¹⁸²⁷ Several studies have established that kallikrein and factors IXa and XIIa can directly activate plasminogen to plasmin.^{1828,1829,1830} and¹⁸³¹ At this time, it is best to conclude that the physiologic significance and relevance of the contact system

P.484

in fibrinolysis are not entirely clear. It has been suggested that individuals with factor XII deficiency as well as deficiencies in some of the other intrinsic coagulation factors may have a subtle, but potentially significant, defect in fibrinolysis under certain clinical conditions. Additional studies are needed to address this controversial subject.

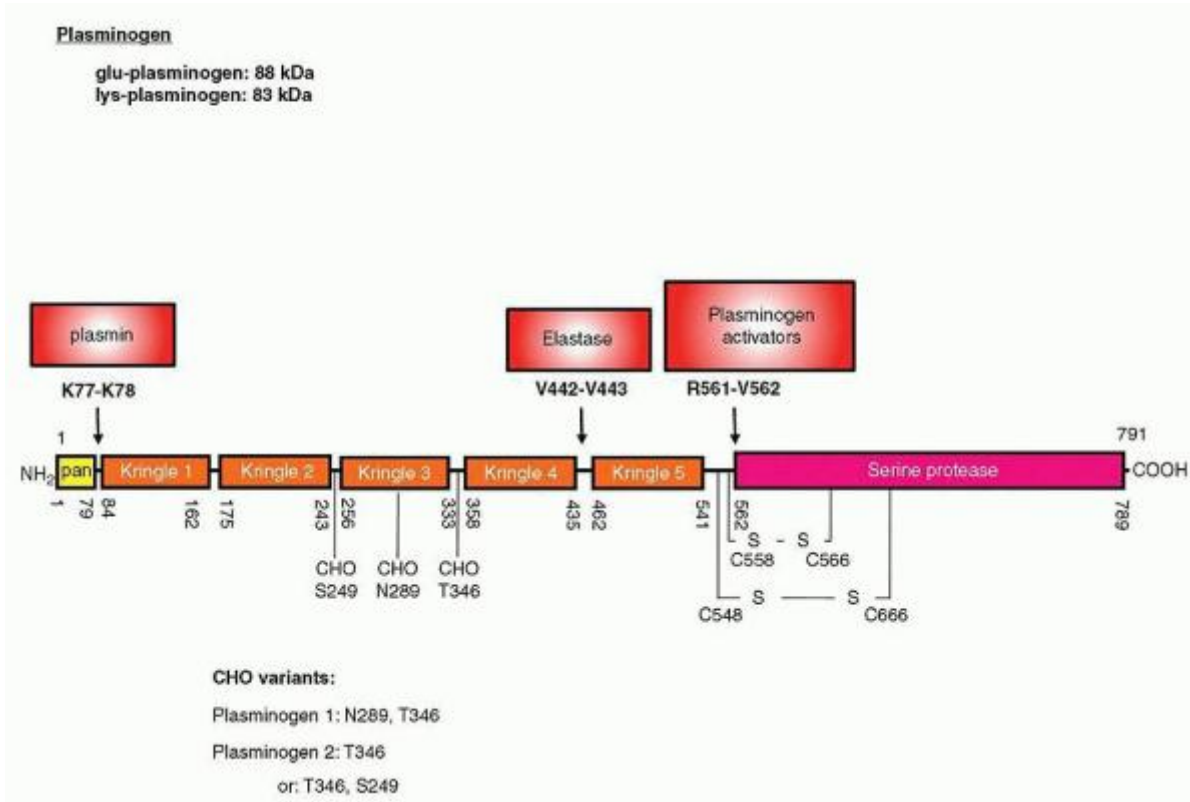

FIGURE 18.18. Schematic of plasminogen. Plasminogen is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation. Human plasminogen is a single-chain glycoprotein containing 2% carbohydrate (CHO). CHO variants are shown for plasminogens 1 and 2. The primary structure of plasminogen contains 791 amino acids segregated into an NH₂-terminal activation peptide domain (pan), a region containing five kringles, and a catalytic domain. Proteolysis by plasmin at one of several potential sites in this NH₂-terminal region results in a degraded form of plasminogen; the most common product is K⁷⁸-plasminogen. Cleavage by plasminogen activators at R⁵⁶¹-V⁵⁶² results in plasmin.

Extrinsic Activator: Tissue Plasminogen Activator

There are two dominant extrinsic activator systems in the body: t-PA and u-PA. These activators have unique structures and properties that affect the specificity and rate of plasmin generation.

The t-PA molecule is predominantly a product of endothelial cells^{1832,1833,1834,1835,1836}; it is also produced by vascular smooth muscle cells,¹⁸³⁷ neuronal cells,¹⁸³⁸ megakaryocytes,^{1839,1840} mast cells,^{1841,1842} monocytes,¹⁸⁴³ and fibroblasts.¹⁸⁴⁴ Factors that regulate its secretion and release from the endothelium are important mediators of blood clotting or inflammation. These include thrombin, histamine, acetylcholine, bradykinin, epinephrine, ILs, shear stress, and vaso-occlusion.^{1845,1846} t-PA antigen is present in normal plasma at approximately 5 µg/L (70 pmol/L; Table 18.10).^{1847,1848,1849,1850} and ¹⁸⁵¹ Functional concentrations have been reported to be < 20 pmol/L with the remainder of the t-PA antigen found in complex with PAI-1.^{1848,1852,1853} The t_{1/2} in plasma is quite short, with pharmacokinetic modeling indicating a t_{1/2} of 2.4 minutes for active t-PA and 5 minutes for the t-PA/PAI-1 complex.^{1854,1855} The t-PA molecule and the t-PA/PAI-1 complex are cleared from the plasma by two specific cell receptor systems in the liver as well as receptor-mediated clearance by endothelial cells¹⁸⁵⁶ (for review see^{1778,1857,1858}).

Gene Structure and Expression

The human gene for t-PA is found on chromosome 8, bands p12-q11.2, and spans 32.7 kb¹⁸⁵⁹ (Table 18.9). There are 14 exons with distinct structural motifs encoded by individual exons.^{1860,1861} and ¹⁸⁶² The processed transcript codes for a protein product of 562 amino acids: residues 1 to 23 comprise the signal peptide, whereas residues 24 to 32 function as a propeptide region. Further processing removes residues 32 to 35 to yield the circulating protein product. The 5'-flanking region of the t-PA gene extends more than 9,500 bp with a functional retinoic acid response element identified at -7,300 bp¹⁸⁶³ and a multihormone responsive enhancer localized to the region -7,145 to -9,758 bp.^{1864,1865} and ¹⁸⁶⁶ A number of cisacting elements have been identified in the proximal promoter region. A transcription initiation site 209 bp upstream of

the translation start site was initially identified. A consensus TATA sequence was identified 22 bp upstream from this transcription start site.^{1861,1862} Subsequently, a TATA-independent transcript initiation site 99 bp upstream from the translation start site was identified as the primary site of transcription initiation in fibroblasts¹⁸⁶⁷ and endothelial cells.¹⁸⁶⁸ The significance of t-PA transcripts with different-length 5'-untranslated regions is not established; deletion of the entire 5'-untranslated region of t-PA was observed to increase the stability of the t-PA transcript.¹⁸⁶⁹

P.485

Translational control of t-PA gene expression has been observed in some cell types, implicating a regulatory role for the 3'-untranslated region of the t-PA transcript.^{1870,1871}

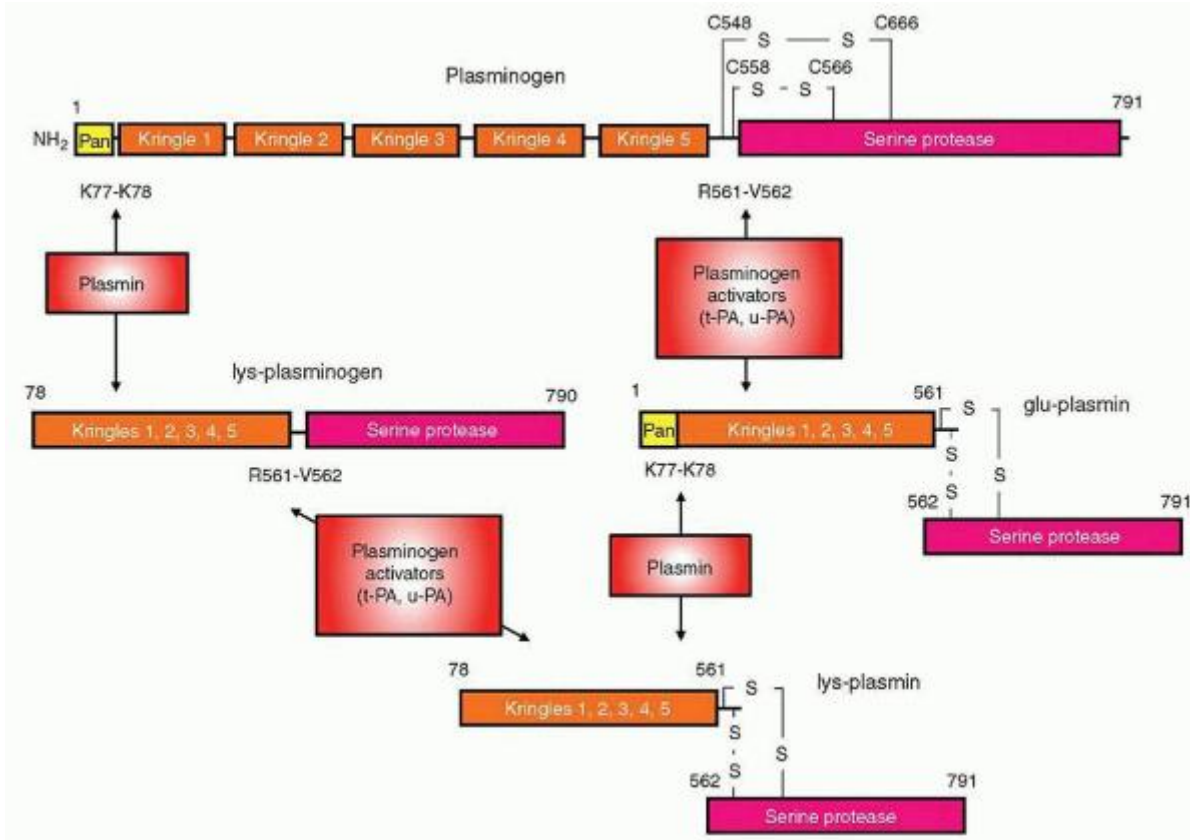

FIGURE 18.19. Molecular forms of plasmin(ogen). Plasminogen in its native form has a glutamic acid at residue 1 and is referred to as glu-plasminogen. Glu-plasminogen has a molecular weight of 88,000 Da and contains 791 amino acids. Cleavage at R⁵⁶¹-V⁵⁶² in glu-plasminogen by plasminogen activators (tissue-type plasminogen activator [t-PA] and urokinase-type plasminogen activator [u-PA]) yields glu-plasmin. Glu-plasmin consists of an NH₂-terminal heavy chain linked by two disulfide bonds to a catalytic domain. At the localized clot level, plasmin that is formed can cleave glu-plasminogen at the NH₂-terminal bond K⁷⁷-K⁷⁸ to yield lys-plasminogen. Lys-plasminogen can be activated by plasminogen activators that hydrolyze the R⁵⁶¹-V⁵⁶² bond to yield lys-plasmin.

A number of polymorphisms of the t-PA gene have been identified. A 311-bp Alu insertion/deletion polymorphism within the eighth intron of the t-PA gene has been extensively studied.^{1872,1873,1874,1875,1876} and ¹⁸⁷⁷ A similar polymorphism in the angiotensin-converting enzyme gene has been linked to plasma levels of this enzyme.¹⁸⁷⁸ In contrast, no correlation of plasma t-PA levels with its Alu polymorphism has been observed.^{1874,1875} and ¹⁸⁷⁶ With one exception,¹⁸⁷² clinical studies have indicated no correlation between this polymorphism and the incidence of stroke or myocardial infarction.^{1874,1875} and ¹⁸⁷⁶ A single nucleotide polymorphism (-7351 C/T) in an Sp1-binding site in the far upstream enhancer element of the t-PA gene has been linked to the vascular release rate of t-PA in vivo¹⁸⁷⁹ and to the frequency of occurrence of first myocardial infarction.¹⁸⁸⁰

No cases of congenital deficiency of t-PA have been reported. Transgenic mice lacking a functional t-PA gene developed normally and displayed a normal basal hemostatic phenotype.¹⁸⁸¹ Mice in which both the t-PA and u-PA genes were disabled had shortened lifespans and experienced severe, spontaneous thrombotic episodes.^{1881,1882}

Biochemistry

The t-PA molecule is a serine proteinase with a molecular weight of 70 kDa¹⁸⁸³ (Table 18.10 and Fig. 18.20). It was originally isolated as a single polypeptide chain of 527 amino acids¹⁸⁸⁴ with an NH₂-terminal serine residue; full-length t-PA has an NH₂-terminal extension of three amino acids (Gly-Ala-Arg).^{1885,1886} and ¹⁸⁸⁷ Numbering in this chapter is based on Ser¹-t-PA, the most extensively studied form because of its availability as a recombinant product.

The single-chain t-PA molecule is an efficient plasminogen activator in the presence of fibrin^{1888,1889,1890} and ¹⁸⁹¹ and is converted into a somewhat more active two-chain molecule by cleavage of the peptide bond between Arg²⁷⁵ and Ile²⁷⁶.^{1799,1889,1890,1891} and ¹⁸⁹² This cleavage is performed primarily by the action of plasmin during fibrinolysis; factor Xa and kallikrein can also catalyze this conversion. The t-PA molecule divides structurally and functionally into two major regions with the Arg²⁷⁵-Ile²⁷⁶ bond as the boundary: the 38-kDa NH₂-terminal portion (Ser¹-Arg²⁷⁵), called the heavy or A-chain in the two-chain molecule, contains structures involved in fibrin binding, fibrin-specific plasminogen activation, and plasma clearance mechanisms; and the 28-kDa catalytic region (Ile²⁷⁶-Pro⁵²⁷), called the light or B-chain, is homologous to the proteolytic domain of other serine proteases. Specifically, the A-chain contains a fibronectin fingerlike domain,¹⁸⁹³ an EGF-like domain,¹⁸⁹⁴ and two kringle domains.^{369,1895} The finger domain extends from residues 4 to 50 and is involved in the binding of t-PA to fibrin.^{1896,1897} The binding of the finger region to fibrin is not blocked by ε-aminocaproic acid.¹⁸⁹⁸ The finger domain of t-PA has sequence homology and structural homology¹⁸⁹⁹ to similar structures found in fibronectin. Selected mutations in the finger or

P.486

the EGF domain have been shown to result in prolonged half-lives in vivo for the modified t-PA molecules, indicating a role for these regions in uptake mechanisms.^{1900,1901} The kringle domains of t-PA span residues 87 to 176 (kringle 1) and residues 176 to 262 (kringle 2). The biologic role of kringle 1 remains undiscovered.^{1896,1897} and ¹⁸⁹⁸ The kringle 2 domain is involved in the binding of t-PA to fibrin.^{1896,1897} This binding interaction is blocked by lysine and its analogs such as ε-aminocaproic acid,¹⁸⁹⁶ indicating the presence of a plasminogen-like lysine-binding pocket. The overall crystal structure of t-PA kringle 2¹⁹⁰² resembles that of kringle 4 of plasminogen, although differences are observed in the arrangement of residues forming the lysine-binding sites.^{1902,1903,1904} and ¹⁹⁰⁵ The light or B-chain of t-PA contains the active site catalytic triad of this serine protease (His³²², Asp³⁷¹, and Ser⁴⁷⁸).^{663,1884,1906} Both the single- and two-chain forms of t-PA cleave plasminogen at Arg⁵⁶¹-Val⁵⁶² to yield the enzyme plasmin. The catalytic efficiency of single-chain t-PA toward plasminogen in solution and toward tripeptide paranitroanilide substrates is lower than the two-chain form.^{1889,1891,1907} Both forms have been crystallized^{1908,1909} and exhibit enhanced and roughly equivalent rates of proteolysis of plasminogen when fibrin is present.¹⁸⁸⁹

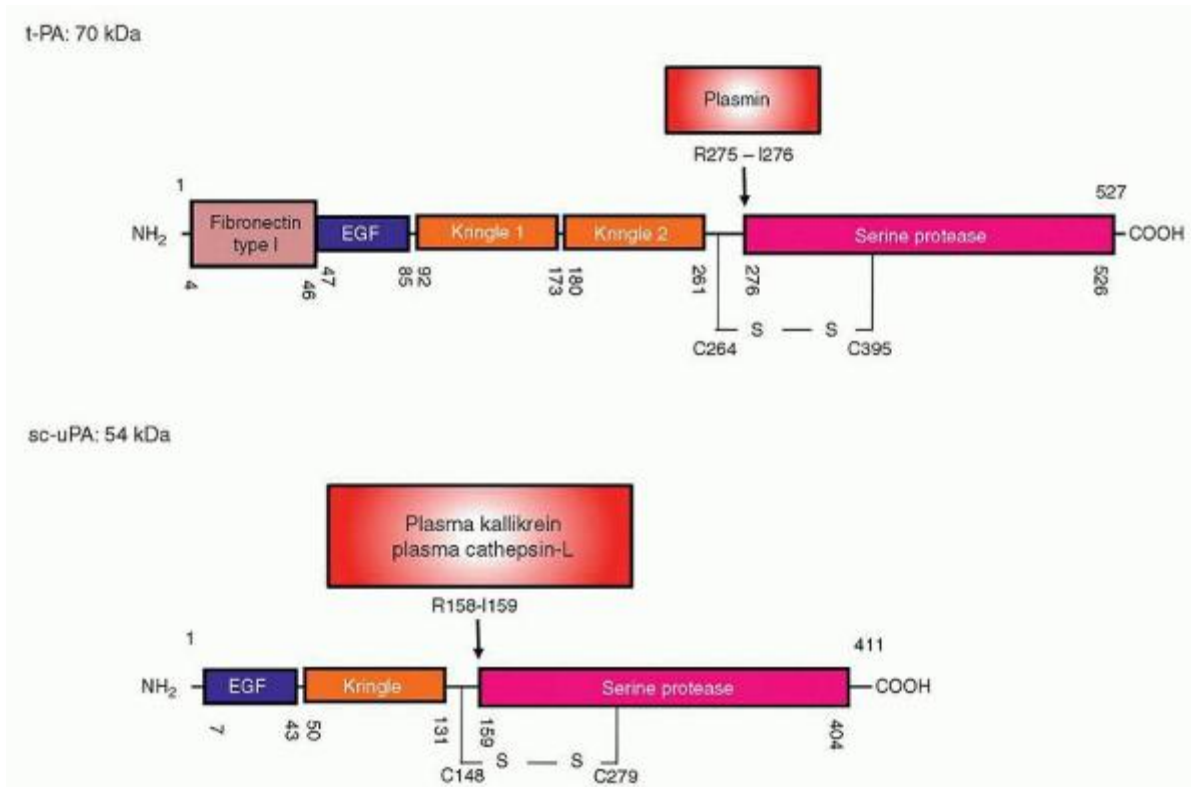

FIGURE 18.20. Fibrinolytic proteins tissue-type plasminogen activator (t-PA) and single-chain urokinase-type plasminogen activator (sc-uPA). The single-chain t-PA molecule is an efficient plasminogen activator in the presence of fibrin and is converted into a somewhat more active two-chain molecule by cleavage of the peptide bond between R²⁷⁵ and I²⁷⁶. This cleavage is performed primarily by the action of plasmin during fibrinolysis. Structurally t-PA contains a fibronectin type I domain, an epidermal growth factor (EGF)-like domain, and two kringle domains, as well as a serine protease-type catalytic domain. The kringle 2 domain and the fibronectin domain of t-PA are involved in the binding of t-PA to fibrin. sc-uPA is an ineffective catalyst. Plasmin or plasma kallikrein can hydrolyze the K¹⁵⁸-I¹⁵⁹ peptide bond, converting sc-uPA into the fully active two-chain form (two-chain urokinase-type plasminogen activator). u-PA is composed of an EGF domain (EGF), a single kringle domain, and the serine protease-type catalytic domain. One glycosylation site (CHO) is present in the serine protease domain.

The t-PA molecule has three potential N-linked glycosylation sites and one O-linked site. The O-linked site is found at Thr⁶¹ in the EGF domain.¹⁹¹⁰ The presence of a fucose at this site appears to facilitate the uptake of t-PA by hepatocytes.¹⁹¹¹ Two major carbohydrate variants of t-PA have been identified. Type I is glycosylated at Asn¹¹⁷ (kringle 1), Asn¹⁸⁴ (kringle 2), and Asn⁴⁴⁸ (catalytic domain), whereas type II is glycosylated only at Asn¹¹⁷ and Asn⁴⁴⁸.^{1912,1913} The presence of carbohydrate at Asn¹⁸⁴ appears to downregulate the fibrinolytic activity of type I t-PA by interfering with the association between the lysine-binding site of its kringle 2 domain and fibrin.

Regulation

Regulation of t-PA activity in blood is accomplished by three primary mechanisms: Control of its catalytic potential via the fibrin dependence of plasminogen activation; control of systemic levels of functional t-PA by the concerted processes of rapid t-PA removal by hepatic clearance and of inhibition by the circulating serpin PAI-1; and control of t-PA activity levels at the site of injury by the competing processes of increased t-PA secretion by traumatized and recruited cells versus PAI-1 release by activated platelets. t-PA manifests its full fibrinolytic potential only when bound to fibrin.^{1914,1915} and ¹⁹¹⁶ This binding interaction aligns t-PA and plasminogen on the fibrin surface so that the catalytic efficiency of t-PA is enhanced several hundredfold. This is vital to the localization of plasmin generation at the site of fibrin deposition. Systemic t-PA levels in blood are under highly dynamic control characterized by maintenance of relatively low levels of the protein (70 pmol/L) with a high clearance rate ($t_{1/2} = 2.4$ minutes) and by maintenance of an extremely effective inhibitor, PAI-1 (second-order rate constant for complex formation = 10^7 to 10^8 M⁻¹second⁻¹), at a

circulating concentration severalfold higher than t-PA. The release of t-PA from the vessel wall is another important regulator of fibrinolysis.^{1917,1918} The rate at which clots lyse is dependent on how rapidly t-PA is secreted by the relevant cells in the vicinity of an injury.^{1919,1920} For example, activated platelets secrete serotonin that can induce endothelial cells to release t-PA; they also release PAI-1 from their α -granules. Although only a fraction of this PAI-1 is in the active form, it functions to downregulate plasminogen activation.^{1921,1922} and ¹⁹²³

Extrinsic Activator: Urokinase Plasminogen Activator

The other major extrinsic activator in the blood is u-PA. This activator was first identified in the urine,^{1924,1925} and ¹⁹²⁶ where it is present at relatively high concentrations (40 to 80 $\mu\text{g/L}$).^{1926,1927} It was subsequently detected in the media of cultured human kidney cells, endothelial cells, malignant cell lines, and tumors; and in plasma.^{1928,1929,1930} and ¹⁹³¹ u-PA is a serine protease and is synthesized as a single-chain molecule called prourokinase or single-chain u-PA (scu-PA). The plasma concentration of scu-PA ranges from 2 to 4 ng/ml (37 to 74 pmol/L; Table 18.10)¹⁹³²; the $t_{1/2}$ of scu-PA is quite short, approximately 5 minutes, and metabolism occurs in both the liver and the kidney. scu-PA has a very low level of proteolytic activity.¹⁹³³ Plasmin can hydrolyze the Lys¹⁵⁸-Ile¹⁵⁹ peptide bond, converting scu-PA into the two-chain form (tcu-PA).^{1924,1934,1935} and ¹⁹³⁶ The mechanism in blood by which scu-PA is converted into tcu-PA still remains poorly defined. It has been postulated that, within a thrombus, t-PA initially activates plasminogen bound to fibrin to form plasmin, and that it is this fibrin-localized plasmin that then converts scu-PA into tcu-PA.^{1937,1938} and ¹⁹³⁹ This process results in an amplification of the rate of plasmin formation. The main site of urokinase-driven plasminogen activation appears to be extravascular, where it has an important role in promoting degradation of extracellular matrix by triggering the activation of plasminogen and, possibly, matrix metalloproteinases.¹⁹⁴⁰ Regulation of urokinase is important to normal and pathologic processes including embryogenesis, wound healing, tumor cell invasion, and metastasis.^{1941,1942} and ¹⁹⁴³ Inhibitors of urokinase have been shown to suppress the growth of primary tumors and to interfere with metastasis of tumor cells.^{1944,1945,1946,1947,1948,1949,1950} and ¹⁹⁵¹

Gene Structure and Expression

The human u-PA gene spans 6.4 kb with 11 exons¹⁹⁵² and is located on chromosome 10, band q24¹⁹⁵³ (Table 18.9). The overall intron-exon arrangement is similar to that of the t-PA gene. The primary amino acid sequence of the purified, intact two-chain molecule has been determined,^{1924,1925,1954} and the cDNA has been isolated and sequenced¹⁹⁵⁵: The gene specifies a protein of 431 amino acids, with the first 20 residues constituting a signal peptide.

The disruption of the urokinase gene (u-PA^{-/-}) in mice is not lethal.¹⁸⁸¹ These mice did not display spontaneous thrombi in their vasculature. The phenotype of u-PA^{-/-} mice included occasional minor fibrin deposits in the liver and intestine, excessive fibrin deposits in chronic nonhealing skin lesions, and increased susceptibility to bacterial infections.^{1881,1956,1957} and ¹⁹⁵⁸

Biochemistry

u-PA is a single-chain glycoprotein containing 411 amino acids ($M_r = 54,000$; Table 18.10; Fig. 18.20). It has 12 disulfide bonds with one (Cys¹⁴⁸-Cys²⁷⁹) serving to link the catalytic domain (B-chain) to the NH₂-terminal domain (A-chain). Posttranslational modifications include glycosylation at Asn³⁰², addition of a single fucose residue at Thr¹⁸,¹⁹⁵⁹ and regulatory phosphorylation at Ser¹³⁸/Ser³⁰³.¹⁹⁶⁰ u-PA is composed of an EGF domain (residues 7 to 43), a single kringle domain (residues 50 to 131), a connecting peptide region (residues 132 to 157), and the serine protease-type catalytic domain (residues 159 to 411). The EGF domain contains the residues essential for urokinase binding to the urokinase receptor¹⁹⁶¹ and appears to be the domain responsible for the ability of urokinase to induce cellular proliferation and differentiation.^{1962,1963} and ¹⁹⁶⁴ The function of the kringle domain of urokinase remains to be established. It displays no binding affinity for fibrin. Recent evidence indicates that the kringle domain may have a role in mediating the process by which urokinase stimulates smooth muscle migration.^{1965,1966} and ¹⁹⁶⁷ Residues His²⁰⁴, Asp²⁵⁵, and Ser³⁵⁶ form the catalytic triad of urokinase; unlike the single-chain form of t-PA, they are not properly positioned for efficient catalysis. scu-PA does not form complexes with PAI-1 or react with peptidyl chloromethylketones that inhibit the two-chain form; scu-PA-catalyzed hydrolysis of tripeptide paranitroanilide substrates proceeds with 0.1% to 0.4% the efficiency of tcu-PA,^{1968,1969} and plasminogen activation by scu-PA appears to be equally inefficient when compared to tcu-PA.^{1939,1970}

The urokinase molecule is asymmetric in shape with the growth factor, kringle, and catalytic domains arranged like differently configured beads on a string.^{1959,1971,1972} and ¹⁹⁷³ A crystal structure for the entire urokinase molecule has not been accomplished. However, a crystal structure at a resolution of 2.5 Å has been reported for the catalytic domain. The molecule used was a recombinant, nonglycosylated human u-PA (residues 159 to 411) with its active site histidine residue derivatized with a peptidyl chloromethylketone.¹⁹⁷⁴ The catalytic domain of u-PA has the expected overall topography and

S1 specificity pocket of a tryp-sinlike protease, an S2 pocket of hydrophobic character, and a solvent-accessible S3 pocket suitable for binding a wide range of amino acid side chains. The crystal structure of a mutant urokinase catalytic domain (residues 159 to 404: C122A and N302Q) at a resolution of 1.5 Å has also been reported.¹⁹⁷⁵

Activation

Conversion of single-chain urokinase to an active two-chain form occurs principally through hydrolysis of the Lys¹⁵⁸-Ile¹⁵⁹ bond. This molecular form, referred to as high-molecular-weight tcu-PA, is composed of NH₂-terminal heavy chain (residues 1 to 158) linked by one disulfide bond to the catalytic domain. In the blood, during fibrinolysis, plasmin is the primary catalyst of this conversion; in addition, both kallikrein and factor XIIa,¹⁹³⁴ products of the intrinsic pathway of coagulation, hydrolyze this bond. A number of other proteases that cleave the Lys¹⁵⁸-Ile¹⁵⁹ bond have also been identified, including several cathepsins,^{1976,1977,1978} and¹⁹⁷⁹ mast cell tryptase,¹⁹⁸⁰ nerve growth factor-γ,¹⁹⁸¹ human T-cell serine proteinase-1,¹⁹⁸² and FSAP.¹⁹⁸³ A second, catalytically active form of two-chain urokinase, known as low-molecular-weight tcu-PA, is found in plasma when fibrinolysis is stimulated. It is formed by an additional plasmin cleavage at Lys¹³⁵-Lys¹³⁶. This yields a truncated heavy chain containing most of the connecting peptide region (residues 136 to 158) linked to the catalytic domain by the Cys¹⁴⁸-Cys²⁷⁹ disulfide bond. This cleavage produces a more efficient enzyme, and this low-molecular-weight form is used clinically for thrombolytic therapy. Another low-molecular-weight form of scu-PA arises from cleavage of the Glu¹⁴³-Leu¹⁴⁴ bond by the matrix metalloproteinases Pump 1 and metalloproteinase 3.^{1984,1985} and¹⁹⁸⁶ This form appears to be a better clot-lysing agent than low-molecular-weight tcu-PA.¹⁹⁸⁷

Neutrophil cathepsin G and elastase from granulocytes cleave scu-PA at the Ile¹⁵⁹-Ile¹⁶⁰ bond, yielding a two-chain molecule that is inactive.^{1988,1989} Thrombin^{1934,1990,1991} and, more efficiently, the thrombin-thrombomodulin complex¹⁹⁹² cleave scu-PA at Arg¹⁵⁶-Phe¹⁵⁷, yielding an inactive two-chain urokinase species. The release of the dipeptide Phe¹⁵⁷-Lys¹⁵⁸ from the catalytic domain is catalyzed by cathepsin C¹⁹⁷⁷ or plasmin.¹⁹⁹³

Function

t-PA appears to be the primary plasminogen activator in the vasculature, with fibrin-localized scu-PA conversion to tcu-PA acting

P.488

as an amplifying rather than initiating mechanism for plasmin formation.^{1939,1994} Direct scu-PA activation of Glu-plasminogen bound to COOH-terminal lysine residues found in partially proteolyzed fibrin has been proposed as contributing to clot lysis.^{1995,1996} and¹⁹⁹⁷ This catalytic role of scu-PA, although direct, still depends temporally on t-PA-derived plasmin to create the circumstance (plasmin proteolyzed fibrin) under which it can contribute to overall fibrinolysis.

Extrinsic Activator: Factor VII-Activating Protease

Recently, a novel serine protease in human plasma has been described that can support coagulation by activating factor VII.^{477,1983,1998} It was originally described as plasma hyaluronan-binding protein and was isolated by adsorption to immobilized hyaluronic acid as a disulfide-linked heterodimer.¹⁹⁹⁸ Independently, a thrombin-like amidolytic activity was purified from commercial prothrombin complex concentrates.^{1999,2000} Sequencing data indicated that this protease and plasma hyaluronan-binding protein were the same proteins. Subsequently, the protease from prothrombin complex concentrates was shown to be a potent activator of factor VII and termed FSAP.⁴⁷⁷ The capacity of FSAP to activate factor VII has been challenged.²⁰⁰¹ This protease has also been shown to be an efficient activator of single-chain urokinase and appears to catalyze the inactivating proteolysis of TFPI.²⁰⁰² Its single-chain precursor has been purified from plasma.²⁰⁰³

Gene Structure and Expression

FSAP has been mapped to chromosome 10, bands q25-q26.²⁰⁰⁴ It spans 35 kb and is composed of 13 exons (Table 18.10). Its transcript specifies a protein of 560 amino acids; the first 23 amino acids comprise the signal peptide sequence. Two single nucleotide polymorphisms have been identified. One, called FSAP Marburg I (SNP-1), yields a Gly511Glu substitution near the COOH-terminus of the protease resulting in impairment of its scu-PA-activating properties.^{2005,2006} and²⁰⁰⁷ The second polymorphism, Marburg II, contains a Glu370Gln mutation that does not appear to have an effect on the catalytic properties of FSAP.

Biochemistry and Activation

FSAP is a single-chain glycoprotein containing 537 amino acids with an M_r of 64 kDa.¹⁹⁹⁸ It circulates at a concentration of approximately 12 μg/ml (190 nmol/L; Table 18.10). It is composed of 5% carbohydrate and is glycosylated at Asn³¹ (NH₂-

terminal strand) and Asn¹⁸⁴ (kringle domain).²⁰⁰³ The structure consists of an amino terminal strand (residues 1 to 52) that is followed by three EGF-like domains (residues 53 to 166), a kringle domain (residues 170 to 254) and a COOH-terminus serine protease domain (residues 290 to 537). FSAP has structural regions that are homologous to those found in hepatocyte growth factor activator.²⁰⁰⁸ It binds to GAGs such as heparin.

The conversion to the active two-chain form requires cleavage of the Arg²⁹⁰-Ile²⁹¹ bond. This generates a heavy chain (residues 1 to 290) and a light chain or catalytic domain (residues 291 to 537). The two chains are linked by a single disulfide bond (Cys²⁷⁸-Cys⁴¹²). The active site residues of this serine protease are Asp³⁸², His³³⁹, and Ser⁴⁸⁶. Preparations of single-chain FSAP rapidly convert to the two-chain form. Whether this is due to an intrinsic activity of the single-chain molecule or to trace amounts of the two-chain form in single-chain preparations has not been resolved.²⁰⁰⁹ Heparin promotes conversion of single-chain FSAP preparations to the two-chain form,²⁰¹⁰ as do natural RNA²⁰¹¹ and histones.²⁰¹² The high-molecular-weight form of two-chain urokinase has been shown to convert single-chain FSAP to the two-chain form and may represent a physiologic activator.²⁰⁰³ The rate of this reaction is affected by heparin. In addition to factor VII and single-chain urokinase, other substrates for FSAP, determined from in vitro assays, include factor V/factor Va, factor VIII/factor VIIIa, fibrinogen, single-chain t-PA, fibronectin, and vitronectin.²⁰¹³ Similar to plasmin, two-chain FSAP binds to aprotinin. In vitro assays indicate that it also complexes with serpins such as C1-inhibitor,²⁰¹⁴ α_2 -antiplasmin, and antithrombin-heparin.^{1983,2015} Stoichiometric inhibitors of FSAP include C1-esterase inhibitor, α_2 -antiplasmin, and TFPI.²⁰¹⁶

Function

The physiologic function of FSAP still is unclear. The ability of two-chain FSAP to convert factor VII to factor VIIa in the absence of tissue factor suggests that it could contribute to the maintenance of normal factor VIIa levels in blood or contribute to the localized production of factor VIIa at the site of vascular injury. In a system of synthetic hemophilia (factor VIII deficiency), two-chain FSAP has been shown to correct the hemostatic defect.⁴⁷⁸ Similar results have been found with the addition of exogenous factor VIIa to hemophilia blood.⁴⁴⁶ The two-chain form of FSAP appears to be an efficient activator of single-chain urokinase, comparing favorably with plasmin when heparin is present.¹⁹⁸³ It has been suggested²⁰¹³ that GAG-binding properties of FSAP may localize it to cell surfaces and extracellular matrix proteins, where it may play a role as an initiator of urokinase-dependent proteolytic cascades. The role of FSAP in inflammatory processes is under investigation.²⁰¹⁷

INHIBITORS OF THE FIBRINOLYTIC SYSTEM

A wide variety of natural inhibitors of fibrinolysis exist in plasma, blood cells, tissues, and extracellular matrices. These natural inhibitors can act either to inhibit plasmin directly or to block the conversion of plasminogen to plasmin (Fig. 18.17). In this section, TAFI, PAI-1, PAI-2, and α_2 -antiplasmin inhibitor are reviewed in terms of their gene structure and expression, biochemistry, and function.

Thrombin-activatable Fibrinolysis Inhibitor

TAFI (E.C.3.4.17.20) (for reviews, see^{2018,2019,2020,2021} and²⁰²²) is a plasma zymogen with homology to procarboxypeptidases A and B. Its plasma concentration is 75 nmol/L (4.5 μ g/ml; Table 18.10). TAFI is synthesized in the liver and is thought to circulate in blood in complex with plasminogen. A small pool of TAFI (< 1% of plasma concentration) is found in platelets and has been found to enhance the attenuation of fibrinolysis in vitro.^{2023,2024} Activation of TAFI yields an exopeptidase (TAFIa) with carboxypeptidase B-like substrate specificity. It catalyzes the removal of basic amino acids (arginines, lysines) from the COOH-termini of polypeptides. Its primary physiologic activator appears to be the thrombin-thrombomodulin complex, thus defining TAFIa as a coagulation-dependent activity.⁹⁶⁹ COOH-terminal lysines that appear in fibrin as it degrades have been identified as the primary substrates for TAFIa (Fig. 18.21). The initial phase of plasmin proteolysis yields products that amplify plasminogen activation by t-PA. These fibrin degradation products thus constitute a positive feedback process, thereby accelerating clot lysis. COOH-terminal lysines that appear in fibrin as it is degraded by plasmin function as additional binding sites where efficient plasminogen activation can occur. Removal of these terminal lysine residues by TAFIa reduces the number of plasminogen-binding sites, thus serving to downregulate the rate of plasmin generation and thereby the rate of clot lysis. Thus, TAFI/TAFIa functions as an antifibrinolytic factor by suppressing the positive feedback pathway of fibrinolysis. The importance in vivo of the TAFI/TAFIa-mediated regulation of fibrinolysis remains to be established. Several studies involving animal models of thrombosis^{1964,1965,1966} and^{1967,2025,2026} and²⁰²⁷ have provided in

P.489

vivo evidence consistent with the proposed role of the TAFI/TAFIa system in regulating fibrinolysis. However, TAFI knockout mice develop normally and prove no more sensitive to a wide range of hemostatic challenges than their wild-

type littermates.²⁰²⁸ In humans, TAFI antigen concentration has been correlated with an increase in risk for deep vein thrombosis.^{2029,2030}

FIGURE 18.21. Mechanism of thrombin-activatable fibrinolysis inhibitor (TAFI) regulation of fibrinolysis. Thrombin-thrombomodulin (IIa-TM) cleaves TAFI to its active carboxypeptidase form TAFIa. TAFIa interferes with fibrinolysis by cleaving COOH-terminal Arg (R) or Lys (K) residues made available as a consequence of partial plasmin digestion of the fibrin clot. Removing these residues attenuates the self-amplifying mechanism of fibrin-based plasmin formation wherein partial plasmin proteolysis of fibrin increases the number of binding sites (COOH-terminal lysines) available for efficient plasminogen activation. (From Mann KG. Coagulation explosion. Vermont Bus Graph 1997, with permission.)

The nomenclature associated with carboxypeptidase B-type activity in serum reflects the history of its isolation and characterization. The presence of a carboxypeptidase B-type activity in serum that differed from that of carboxypeptidase N, a previously characterized enzyme found in plasma, was first reported by two groups: Hendriks et al.^{18,2031,2032} named the enzyme carboxypeptidase unstable because of its short $t_{1/2}$ compared to carboxypeptidase N; Campbell and Okada²⁰³³ named their activity carboxypeptidase R because of its apparent preference for substrates with COOH-terminal arginine residues, again in contrast to carboxypeptidase N, which showed a selectivity for COOH-terminal lysines. Subsequently, Eaton et al.^{19,2034} purified a novel plasminogen-binding protein from human plasma, which, based on sequence homology and enzymatic properties, proved to be a procarboxypeptidase. They named this protein plasma procarboxypeptidase B. Independently, Bajzar et al.,³⁶ using an assay designed to detect the factor responsible for thrombin-dependent inhibition of fibrinolysis, purified a protein from human plasma. Initial characterization of this protein indicated that it was a procarboxypeptidase B-type protein, which converted to an active carboxypeptidase on treatment with thrombin. This group named the protein TAFI. Further characterization established that TAFI is identical to protein plasma procarboxypeptidase B.^{19,1010} Whether carboxypeptidase R and carboxypeptidase unstable are identical to TAFI has not been resolved because of differences in the reported molecular mass and subunit structure of these proteins.

Gene Structure and Expression

TAFI is a member of a multigene family that includes the pancreatic and mast cell carboxypeptidases but not other carboxypeptidases with a specificity for basic amino acids, such as carboxypeptidases N, M, H, and D.^{2035,2036} TAFI shares a

34% to 40% amino acid identity with its family members, including exact conservation of cysteine residues and residues critical for catalysis, zinc binding, and substrate binding.

The human gene for TAFI maps to chromosome 13²⁰³⁷ and is composed of 11 exons within 48 kb of DNA²⁰³⁵ (Table 18.9). When the TAFI gene is compared with the genes from rat pancreatic carboxypeptidases A1, A2, and B and human mast cell carboxypeptidase A, the positions of intron/exon boundaries are conserved, whereas the intron lengths diverge significantly. The TAFI promoter lacks a consensus TATA sequence but does have a 70-bp sequence in the 5'-flanking region of the gene that is required for liver-specific transcription.²⁰³⁵ Transcription is initiated at multiple sites. Primer extension analysis of human liver Poly (A)⁺ RNA identified nine major transcription start sites with similar frequencies of usage.²⁰³⁵ The TAFI transcript is polyadenylated at three different sites.
